The induction of long-term potentiation (LTP) at visual cortical inhibitory synapses requires the activation of G protein-coupled receptors in postsynaptic cells. In the present study, the induction mechanism was further examined in developing rat visual cortical slices. Inhibitory postsynaptic currents evoked by layer IV stimulation were recorded from layer V cells using the whole-cell recording method under a blockade of ionotropic glutamate receptors. High-frequency stimulation of layer IV failed to generate LTP when the patch pipette solution contained an inositol trisphosphate (IP₃) receptor antagonist heparin (2 mg/ml) or a Ca^{2+} chelator BAPTA (10 mM). To identify receptors which mediate IP3 formation and thereby contribute to the LTP induction, involvement of metabotropic glutamate receptors and amine receptors including α_1 adrenergic, histamine H_1 , muscarinic and scrotonin 5-HT $_2$ receptors, which are all known to be coupled to IP3 formation, was tested by intracellular recording. Only bath application of an α_1 adrenoceptor antagonist prazosin or a 5-HT2 receptor antagonist ketanserin prevented LTP induction in most, but not all, of cells These results suggest that the LTP induction requires IP_3 -induced Ca^{2+} release from internal stores in postsynaptic cells and that the IP_3 formation is at least partly mediated by the activation of monoamine receptors. POTENTIATION OF SPONTANEOUS EPSCs IN CULTURED CEREBELLAR PURKINJE NEURONS BY A cAMP ANALOG. A.R. Parent* and D.J. Linden. Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

It has recently been shown that cerebellar parallel fiber synapses express a form of LTP which is both induced and expressed presynaptically via activation of a calcium-sensitive adenylyl cyclase and consequent production of cAMP (Salin et al., Neuron 16:797, 1996), in a manner identical to that proposed for hippocampal mossy fiber synapses (Weisskopf and Nicoll, Nature 376:256, 1995). To further characterize this form of synaptic plasticity, whole-cell patch-clamp recordings were made from Purkinje neurons in dispersed cultures of embryonic mouse cerebellum. Isolation of sEPSCs was accomplished using Cs/QX-314-containing internal saline, and external saline supplemented with picrotoxin. With Vhs-70 mV, two forms of inward current were seen; large, broad paroxysmal currents (500-1000 pA peak amplitude, 0.5-3 sec duration) and small brief currents (15-50 pA, 5-15 msec). Both reversed at 0 mV. The large currents were strongly attenuated by a high divalent cation containing external saline, an NMDA-R antagonist, suggesting that the large currents result from NMDA-R dependent multisynaptic network activity, while the small currents are predominantly monosynaptic and AMPA-R mediated. Application of a cAMP analog (Sp-8-CPT-cAMPS, 10-50 uM, 10 min) produced a >5-fold increase in the frequency of both sEPSCs (recorded in APV) and mEPSCs (recorded in TTX) which persisted >30 min after drug washout. These results are consistent with a presynaptic cAMP-mediated form of LTP at the parallel fiber-Purkinje neuron synapse. LONG-TERM POTENTIATION AND DEPRESSION (LTP & LTD) IN TURTLE CEREBELLAR PURKINJE CELLS IN ACSF WITH OR WITHOUT PICROTOXIN. <u>C.Y.Chan*</u>, <u>J.Li</u>, <u>L.Cross</u>. Dept. of Physiology, CUNY Med. School, 138th & Convent AV., NY 10031.

Intradendritic recording of 30 Purkinje cells (PC) and simultaneous field potential recording were used to demonstrate and characterize coelicited LTP and LTD by relatively low-speed repetitive dorsal-cerebellar surface stimulation (referred to here as "training"). Amplitude of the parallel fiber volley was basically unaffected by the training. Picrotoxin (80 μ M) seemed to slightly enhance LTD but reduced LTP generation. In cases when LTD was elicited alone, it usually had a 2-phase time course with a fast-recovering phase lasting 20-30 min and a slower tail phase lasting up to 70 min from training. More often, LTD was co-elicited with LTP and appeared as an early transitory (duration 24 +/- 10 min) suppression of the LTP, which lasted 53 +/- 16 min. The disparate durations suggest modulation or other involvements of distinct sets of intracellular processes.

In either recording medium, the intensity of training strongly affected the outcome: E.g. trainings with a 1 min train of 1 Hz pulse triplets, or with weaker current strengths elicited mostly LTP; while training with 0.5 Hz or stronger currents elicited mostly LTD. Evocation of Ca²⁺ spikes during training was correlated to higher incidence and magnitudes of LTD, but activation of climbing fiber responses were not necessary for LTD. Its main effect was suppression of LTP.

MECHANISMS OF LONG-TERM POTENTIATION INDUCED BY ELEVATED EXTRACELLULAR CALCIUM

<u>David B. Wheeler*</u> and <u>Richard W. Tsien</u>, Dept. Molecular and Cellular Physiology. Beckman Center B103, Stanford School of Medicine, Stanford, CA 94305-5426

Long-term potentiation (LTP) of synaptic transmission induced by tetanic stimulation has been studied extensively in the hippocampal slice. However, since tetanus can only stimulate a small subset of synapses within the slice, this system is often difficult to use for cellular and molecular studies of the mechanisms underlying LTP. To potentiate a larger proportion of the synapses than can be achieved with tetanic stimulation, we have used the standard hippocampal slice preparation to study LTP induced by elevated [Ca²¹¹]₀ (Turner et al., 1982, Neuroscience, 237:1411-16). Field recordings showed that the synaptic strength was increased for several hours following a 10 min period during which (Ca²¹¹]₀ was raised from 2 to 10 mM and [Mg²¹¹]₀ was reduced from 1.3 mM to 0. The slope of the EPSP at 60 min was 145±4% of control levels (n=10). When [Mg²¹¹]₀ was held at 1.3 mM during the exposure to high [Ca²¹¹]₀. LTP was not observed (n=6), raising the possibility of a role for NMDA receptors. The importance of NMDA receptors (Bliss et al., 1987, In: Excitatory Amino Acid Transmission, pp. 337-40) was confirmed by showing that 25 μM D-AP5 halved the amount of potentiation seen after exposure to 10 mM [Ca²¹¹]₀ (n=8). To test the possibility that other Ca²¹ entry pathways could be important for the induction of LTP, we looked for effects of Ca²+ channel blockers. We found that 10 μM nimodipine reduced the potentiation caused by elevated [Ca²¹¹]₀, to roughly the same degree as D-AP5 (n=5). Our findings indicate that multiple Ca²+ entry pathways underlie the induction of LTP by elevated [Ca²¹¹]₀. Further studies are needed to determine the loci of induction and maintenance of Ca-LTP, and to establish the extent to which the mechanisms of Ca-LTP and tetanic LTP overlap.

MODELS OF CALMODULIN TRAPPING BY CAMKINASE IN A DENDRITIC SPINE. <u>W.R. Holmes* and K-W. Tsao</u>. Neurobiology Program, Dept. of Biological Sciences, Ohio University, Athens, OH 45701.

CaMkinase activation by calmodulin following calcium entry into the cell is thought to be important for learning and memory. CaMkinase activation is much prolonged if calmodulin becomes trapped on CaMkinase. Models of a dendritic spine including calcium influx and subsequent calmodulin trapping by CaMkinase were developed to estimate levels of calmodulin trapping in experimental conditions thought to induce LTP or LTD.

Calcium influx through NMDA receptors on a dendritic spine was computed following tetanic input in a dentate granule cell model. Calcium ions could bind to calmodulin, bind to another unspecified buffer, be pumped out of the cell or diffuse to neighboring compartments. Calmodulin that was fully bound with calcium could bind to CaMkinase or to another calmodulin binding protein that had binding kinetics similar to calcineurin. CaMkinase subunits could be in either the free, bound with calmodulin, calmodulin trapped, automonous or capped states as in the model of Michelson and Schulman (J. Theor. Biol. 171:281-290, 1994).

Michelson and Schulman (J. Theor. Biol. 171:281-290, 1994). With non-tetanic input, weak tetanic input, or strong low frequency input, almost no calmodulin was trapped by CaMkinase. One reason is that the small volume of the spine required calcium concentration to exceed 1.25 μM before a single calmodulin molecule would be fully bound with calcium. With strong tetanic inputs, large numbers of CaMkinase subunits entered the trapped state. The nonlinearity was particularly steep as the frequency of tetanic input was raised from 20 to 100 Hz.

The results suggest that significant calmodulin trapping by CaMkinase is highly correlated with experimental conditions thought to induce LTP. (Supported by NIMH grant MH-51081).

DIFFERENTIAL ACTIVATION OF CAMKII AND CALCINEURIN TO LARGE AND MODERATE RISE IN [Ca²⁺]: AN ANALYSIS BY MODELING AND SIMULATION K.lchikawa*, H.Okamoto and I.Yamaguchi, Foundation Research Lab. Fuji Xerox Co., Ltd., 430 Sakai Nakaimachi Ashigarakamigun Kanagawa, 259-01 Japan

It is suggested that the large and moderate rise in intracellular calcium concentration([Ca²¹]) result in long-term potentiation(LTP) and depression(LTD), respectively. A model for the differentiation of LTP and LTD was proposed in which the net phosphorylation or dephosphorylation of CaMKII was resulted depending on the rise in [Ca²¹]. (Lisman, Proc.Natl.Acad.Sci.USA86, 9574-9578, 1989). In the present study, we analyzed the activity of CaMKII and calcineurin(CaN) assuming a different scheme in which the rivalry of the activity of kinase and phosphatase depending on the rise in [Ca²¹] resulted in the differentiation of LTP and LTD.

The present scheme was composed of the rise in [Ca²²], and the activation of calmodulin(CaM), CaMKII and CaN. A model for the rise in [Ca²²], was the same as before(Ichikawa, et al., Soc.Neurosci.Abstr.21, 711.10, 1995). CaM was activated by the binding of four Ca²². CaMKII was activated by the binding of active CaM(CaM). CaN was assumed to be activated by the binding of CaM² and four Ca²². The 4-Ca² bound but no CaM′ bound CaN was assumed to have 10% activity as was reported(Stweart, et al., Eur.J.Biochem.132, 289-295, 1983). Simulations of the present scheme showed that the activity of CaMKII was lower than CaN for the moderate rise in [Ca²²], while it was higher than CaN for larger rise in [Ca²²]. The steady state analysis of a simplified scheme showed the same differential activation of CaMKII and CaN. The difference in the affinity of Ca²² in reactions of CaM-CaMKII complex and CaN was found to play a critical role for this differential activation.

CAI LONG TERM POTENTIATION (LTP) IS DIMINISHED BUT PRESENT IN HIPPOCAMPAL SLICES FROM YOUNG α-CAMKII MUTANT MICE. H.L. Hinds'^, S. Tonegawa' and R. Malinow'* °Cold Spring Harbor Laboratory, Cold Spring Harbor, NY 11724 and ^HHMI, Center for Learning and Memory and Center for Cancer Research, MIT, Cambridge, MA 02138.

We are interested in using recombinant vaccinia virus as a vector for delivering the wild-type and Thr286Ala point mutant form of the $\alpha\text{-Cam}KII$ gene back to the CA1 region of hippocampal slices from α-CamKII mutant mice, to determine whether such complementation is sufficient for the rescue of some or all of the physiological defecits observed in these mice. Such analysis would help to determine if the defecits observed are due to an immediate absence of the $\alpha\text{-}CamKII$ molecule or from developmental abnormalities in these mice, and could further define the role of CamKII in the post- or pre-synaptic cell in hippocampal CA1 LTP. In pursuit of this aim, we have further analyzed the physiological deficits previously reported in these mutant mice. Mice of a mixed B6/129/Balbc inbred background derived from brother/sister mating of the original mutant line through multiple generations (> 10) were produced using in vitro fertilization. Young mice (10-56 days) were analyzed, with the majority of animals being between the ages of 10-21 days, as these ages are optimal for vaccinia virus infection of acute hippocampal slices. Field recordings in the CA1 region were monitored for extensive baselines and LTP was induced using a 100Hz tetanus (5 trains, 20 pulses per train, 10 seconds between trains) in the presence of picrotoxin. While LTP at 60 minutes post-tetanus was clearly deficient in (-/-) mice (142±9%, n=14) compared with (+/+) control animals (202 \pm 24%, n=7), young α -CamKII mutant mice did show a significant level of LTP. This LTP appears to be APV dependent (n=3). This implies that a form of \alpha-CamKII independent LTP is present in young mice that could be dependent upon another kinase, such as the $\,\beta$ isoform of CamKII. Supported by NIH grants to R.M. and S.T.

EFFECT OF TETANUS ON THE DISTRIBUTION OF AUTOPHOSPHO-RYLATED CaM KINASE II IN THE CA1 REGION OF RAT HIPPOCAMPUS, Y. Ouyang*, E.M. Schuman, K.M. Harris#, and M.B.Kennedy. Div. of Biology 216-76, Caltech, Pasadena, CA 91125; #Dep. Of Neurol., Children's Hosp., 300 Longwood Ave., Boston, MA 02115.

CaM kinase II (CaMKII) plays a critical role in synaptic plasticity in the hippocampal CA1 region. CaMKII is autophosphorylated after activation, and remains in an active state that is independent of calcium until it is dephosphorylated by protein phosphatases. We raised antibodies specific for the autophosphorylated (PO4-CaMKII) or nonphosphorylated form of CaMKII. The Abs were used to visualize the distribution of PO4-CaMKII in hippocampal slices by double-label confocal fluorescence immunchistor. CaMKII. The Abs were used to visualize the distribution of PO₄-CaMKII in hippocampal slices by double-label confocal fluorescence immunohistochemistry. The effect of tetanic stimulation of the Schaffer collateral pathway on levels of PO₄-CaMKII was examined by a "two-pathway" paradigm in which control slices received no or only test stimulation at 2 electrodes and exp. slices received a tetanus at 1 of the electrodes. Slices were fixed and stained 30 min after tetanus. Tetani that caused LTP consistently increased PO₄-CaMKII in somas of CA1 pyramidal neurons. In 80% of experiments, the tetani also produced an increase in PO₄-CaMKII in Somas of CA1 pyramidal neurons. neuropii (s.radiatum). In 80% of these, the amount of non-PO₄-CaMKII also increased in s. radiatum. At high mag, the staining for PO₄-CaMKII appeared to be concentrated in spines and along short segments of dendrites. The changes in PO₄-CaMKII associated with tetanus were dendrites. The changes in PO₄-CaMKII associated with tetanus were blocked by APV. In summary, tetanic stimulation of the Schaffer collateral pathway increases the level of PO₄-CaMKII in neuronal somas. The tetani usually produce an increase in PO₄-CaMKII in synapses along dendrites. This increase is confined to a subset of synapses, suggesting at least some synapse specificity. Finally, under some circumstances, it appears that the tetanus may increase the amount of CaM KII in dendrites. The data support the idea that autophosphorylation of CaMKII could play a role in the induction or maintenance of LTP. NIH NS17660; MH49176; NSF GER-9023446

EXAMINATION OF ALTERED HIPPOCAMPAL SYNAPTIC PLASTICITY DURING AGING. <u>C.M. Norris*1, T.C. Foster12, and S. Halpain13</u>. 'Neuroscience Graduate Program, 'Dept. of Psychology, 'Dept. of Neuroscience and The Center for Cell Signaling, Univ. Virginia, Charlottesville, VA 22903

Hippocampal slices from adult (4-7 mos) and aged (20-24 mos) Fischer 344 rats were prepared for electrophysiological and biochemical assays Electrophysiological data demonstrated that low-frequency stimulation (LFS, 900 pulses/1 Hz) of Schaffer collaterals resulted in robust AP5-sensitive longterm depression (LTD) in area CA1 of slices from aged but not adult rats. LTD in aged slices was blocked by raising the bath [Mg²¹] to 4 mM and AP5sensitive LTD of adult slices was revealed only when LFS was delivered in high Ca²⁺ (4 mM) medium. The results suggest that differences in Ca² signaling underlie age differences in susceptibility to LTD.

Because Ser/Thr protein phosphatases have been implicated in LTD, we have begun to examine the possibility that expression or activity of protein phosphatases is altered during aging. Preliminary data were gathered from immunoblot assays of the level of catalytic subunits for various protein phosphatases. No age differences were observed for PP2A or the Ca2+ calmodulin-dependent phosphatase, PP2B. Previous reports indicate that the cytoskeletal protein MAP2 is a substrate of several Ser/Thr protein phosphatases in vitro and is a major target of NMDA receptor-stimulated, PP2B-mediated dephosphorylation in slices. However, preliminary experiments have revealed no age differences in the coupling of NMDA experiments have revealed in age dimerences in the coupling of minion receptors to MAP2 dephosphorylation. Aging-related differences in LTD induction may therefore be due to phosphatase properties not examined in our assays, or to differences in other Ca²⁺-dependent signaling events at synapses. STRAIN-DEPENDENT DIFFERENCES IN HIPPOCAMPAL LTP AND SPATIAL MEMORY. T. Abel*, P.V. Nguyen, R. Bourtchouladze, M.E. Bach, I. Gaprindashvili, P. Jain, and E.R. Kandel. HHMI, Ctr. Neurobiol. & Behav., Columbia Univ., NY, NY 10032

Long-term potentiation (LTP), an activity-dependent form of synaptic plasticity, is a leading cellular model for certain types of memory in the mammalian brain. Many studies have used "reverse" genetics, through the generation of knock-out and transgenic mice, to explore the role of various molecules in LTP and spatial memory. The existence of a variety of inbred strains of mice provides an additional way of exploring the genetic bases of learning and memory. We have used a number of protocols to examine LTP induction and expression in the Schaffer collateral pathway of four different strains of mice: C57BL/6J, CBA/J, DBA/2J, and 129/SvEms/J mice. We found that long-lasting potentiation (> 3 hr), induced by four 100 Hz trains or brief (3 sec) theta-burst stimulation, was robust in C57BL/6J and DBA/2J mice, but was deficient in CBA/J and 129/SvEms/J mice. LTP induced by two 100 Hz trains separated by 20 sec was reduced in 129/SvEms/J and CBA/J mice. By contrast, only the 129/SvEms/J mice showed a deficiency for shorter-lasting potentiation induced by one 100 Hz train. We have begun to assess the performance of these strains on spatial memory tasks, and we have observed strain-related deficits. These findings provide strong support for a genetic basis for some forms of synaptic plasticity that are linked to spatial memory. Furthermore, this work lays the foundation for the genetic identification of the molecular components critical for LTP, learning and memory. [This work has been supported by the Runyon-Winchell Foundation, the MRC of Canada, NIH, and HHMI.]

CALCINEURIN INHIBITORS SUPPRESS THE NMDA RECEPTOR-MEDIATED POTENTIALS AND LONG-TERM POTENTIATION IN CA1 AREA OF RAT HIPPOCAMPUS. Y.-F. Lu, A. Moriwaki, K. Tomizawa, H. Onuma, and H. Matsui*, The First Dept. of Physiol., Okayama Univ. Med. Sch., Okayama 700, Japan.

Okayama Univ. Med. Sch., Okayama 700, Japan.

To reveal the involvement of dephosphorylation in the induction of long-term potentiation (LTP), we investigated the effects of Ca²⁺/calmodulin-dependent phosphatase 2B (calcineurin) inhibitors, FK506 and cyclosporin A (CysA), on the LTP and the depotentiation in CA1 and cyclosporin A (CysA), on the L1P and the depotentiation in CA1 area of rat hippocampal slices. Extracellular recordings were made from the stratum radiatum under stimulation on the Schaffer commissural pathway and the chemicals were applied through a perfusate. FK506 (1-50 μ M) and CysA (20-100 μ M) decreased the excitatory postsynaptic potentials and prevented the induction of LTP. These effects were dose-dependent and reversible. Analyses of the fiber volley and paired-pulse facilitation revealed that FK506 and CysA influenced postsynaptic mechanisms. FK506 and CysA had no effects on the depotentiation. mechanisms. FK506 and CysA had no effects on the depotentiation. We further investigated the effects of FK506 and CysA on the NMDA receptor-mediated potentials. The NMDA receptor-mediated potentials were recorded under perfusion of low Mg²⁺ (50 μ M) medium in the presence of DNQX (10 μ M). FK506 and CysA showed a reversible inhibition on the NMDA receptor-mediated potentials. These results showed that FK506 and CysA prevented the induction of LTP through the inhibitory effects on the NMDA receptors. The results also suggest that calcium is the progress of LTP. The differential inferential inferential in the progress of LTP. The differential inferential i that calcineurin is involved in the processes of LTP. The differential effects of FK506 on the LTP and the depotentiation may attribute to the partial inhibition on the activity of NMDA receptors and the subsequent attenuation of intracellular Ca²⁺ increase.

598.8

The role of protein kinase C on different forms of long-term potentiation (LTP) in the rat hippocampus. G. Y.-P. Ko*, and T. J. Teyler. Dept Neurobiology, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272-0095, U.S.A.

Protein kinase C (PKC) is a protein phosphotransferase involved in the phosphorylation of receptors and ion channels (Vaccarino, 1988). It may strengthen the efficacy of synaptic transmission, thus providing a basis for learning and memory (Tanaka and Nishizuka, 1994). In hippocampal CA1 area, there are at least two forms of LTP: one is NMDA receptor-dependent LTP (NMDA LTP), and the other is NMDA receptor-independent LTP (non-NMDA LTP) (Grover and Teyler, 1990). NMDA LTP can be selectively induced with a 25 Hz tetanus and blocked by 50 μM APV. Non-NMDA LTP can be induced selectively by 200 Hz tetanic stimulation in the presence of APV and can be blocked by nifedipine, a voltage-dependent Ca++ channel (VDCC) blocker (Grover and Teyler, 1990), thus non-NMDA LTP is termed VDCC LTP (Teyler et al., 1994). The expression of NMDA LTP but not VDCC LTP, can be prevented by the NMDA receptor antagonist APV or the non-selective PKC inhibitor H-7 (Grover and Teyler, 1995). In this study, we used the selective PKC inhibitor chelerythrine to investigate the role of PKC on NMDA LTP and VDCC LTP. Chelerythrine (10 µM) abolished the expression of NMDA LTP in a manner similar to the effect of H-7 and decreased the expression of VDCC LTP unlike H-7 which has no effect on VDCC LTP. Chelerythrine had no effect on the induction of both NMDA LTP or VDCC LTP. This result suggests that the expression phases of NMDA LTP and VDCC LTP may share some common enzyme systems.

This work is supported by grant NS-28698 from NIH to Teyler.

BRIEF THETA-BURST STIMULATION INDUCES A CAMP- AND TRANSCRIPTION-DEPENDENT LATE PHASE OF HIPPOCAMPAL LTP IN C57BL/6J MICE. P.V. Nguyen*. Ctr. Neurobiol. & Behav., Columbia Univ., College of Physicians & Surgeons, New York, New York 10032.

Long-term potentiation (LTP) is a form of activity-dependent synaptic plasticity that is thought to be a cellular mechanism for some types of memory. An effective protocol for inducing LTP consists of repeated, brief bursts of stimulus pulses [4 pulses per 40-ms burst, 5 bursts/s (known as "theta-burst")]. This pattern mimics the natural activity profiles of hippocampal neurons recorded in vivo during exploratory behavior. In the present study, I have found that 3 s of theta-burst induced a late phase of LTP (L-LTP) in the Schaffer collateral pathway of hippocampal slices from C57BL/6J mice (a strain often used for generating This L-LTP was blocked by APV and by inhibitors of transcription and cAMP-dependent protein kinase (PKA). Sp-cAMPS, a PKA analog, induced L-LTP that was occluded by prior induction of theta-LTP. By contrast, applying an equal number of stimulus pulses in a compressed pattern (60 Hz, 1 s) induced short-lasting potentiation that was insensitive to inhibitors of PKA and transcription. I also found that theta-induced L-LTP was not equally robust across various inbred mouse strains: CBAJ and 129/5vEms/J mice showed deficient L-LTP when compared with C57BL/6J and DBA/2J mice [see also T. Abel et al., this meeting]. These results show that gene transcription, mediated by cAMP and PKA, is critical for expression of L-LTP induced by physiological patterns of impulse activity. My findings also suggest a strong genetic basis for the expression of L-LTP induced by theta bursts. [Supported by NIH and HHMI, and by a Fellowship from the MRC of Canada. I thank Eric Kandel for his encouragement throughout this study].

FYN AND FAK NON-RECEPTOR TYROSINE KINASE REGULATION OF NMDA RECEPTOR SIGNALLING. S. G. N. Grant and S. Nada, Centre for Genome Research and Centre for Neuroscience, University of Edinburgh, Edinburgh , United Kingdom EH9 3JQ.

The induction of long-term potentiation (LTP) in the CA1 region of the hippocampus requires signal transduction cascades involving tyrosine and serinethreonine phosphorylation in the post-synaptic neuron. Mice lacking Fyn, but not Src, Yes, or Abl tyrosine kinase reveal a specific deficit in the induction step of LTP. Synaptic transmission, post-tetanic potentiation and paired pulse facilitation were normal. The fyn mutants also showed abnormal hippocampal architecture and impairments in spatial learning.

To identify components of a Fyn-dependent pathway that may be involved with hippocampus function we have studied tyrosine phosphorylated proteins in the kinase mutant mice. Focal Adhesion tyrosine Kinase (FAK) is hypophosphorylated in fyn mutants and shows reduced activity in immunecomplex kinase assays. Fyn can bind directly to FAK and modulate the kinase activity and signalling to downstream effector molecules.

We have investigated the role of Fyn and FAK in the phosphorylation of the NMDA receptor. The NMDA receptor 2A and 2B subunits are tyrosine phosphorylated and the mutants reveal that Fyn is required for the phosphorylation of the NMDA receptor. The role of Fyn and FAK may be to regulate the assembly of the NMDA receptor with a post-synaptic signal transduction cascade

NEUROTROPHINS REGULATE DEVELOPMENT OF TETANUS-INDUCED LONG-TERM POTENTIATION (LTP) AND SYNAPTIC RESPONSES TO HIGH FREQUENCY STIMULATION IN THE HIPPOCAMPUS. A. Figurov*, L. D. Pozzo-Miller, P. Olafsson, T. Wang, and B. Lu. Roche Inst. of Mol. Biol., Nutley, NJ 07110 and Lab. of Devel. Neurobiol., NICHD, NIH, MD 20892-4480

Neurotrophins have traditionally been viewed as trophic factors for neuronal survival and differentiation; the fact that their expression is modified by neuronal activity, however, suggests that they may also play a role in regulating synapse development and plasticity. In developing hippocampus, the expression of BDNF and its receptor TrkB increases in parallel with the development of LTP. Here we report a mechanism by which BDNF regulate tetanus-induced LTP (LTPT). Exogenous BDNF (2 nM, minimal incubation 2.5 hr) promoted the induction of LTPT in young (postnatal day 12-13) hippocampal slices, which in the absence of BDNF show only short-term potentiation (STP). NT-4/5 but not NT-3 or NGF had similar effect. The BDNFpotentiation (STP). NT-4/5 but not NT-3 or NGF had similar effect. The BDNF-facilitated LTPT was NMDA-dependent, and was not due to a decreased GABAergic inhibition. BDNF did not affect synaptic responses to low frequency stimulation (1 per min) at any ages examined. In contrast, the ability of hippocampal synapses to follow high frequency stimulation was significantly enhanced by BDNF in p12-13 slices. In adult hippocampus, weak tetanus that normally induce only STP produced long lasting enhancement of synaptic efficacy after BDNF treatment. Moreover, TrkB-1gG fusion protein (2 ug/ml), which scavenges endogenous BDNF, reduced the synaptic responses to tetanus as well as the magnitude of LTPT. Neither BDNF nor TrkB-1gG altered LTP induced by pairing low frequency presynaptic stimulation with postsynaptic depolarization, suggesting that LTP triggering mechanism was not affected. Our results suggest that BDNF may regulate LTP in developing and adult hippocampus by enhancing an ability of synapses to follow high frequency stimulation rather than direct modulation of LTP-triggering mechanisms.

Ca**-dependent enhancement of gap junctional conductance. A. Pereda¹, *, T. Bell¹, A.J. Czernik², A.C. Nairn², and D.S. Faber¹. Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA, and Rockefeller University, New York, NY.

Discontinuous tetanic stimulation of the posterior eighth nerve produces short- and long-term homosynaptic potentiations (STP, LTP) of both the electrotonic and chemical components of the mixed excitatory postsynaptic potential (EPSP) recorded from the Mauthner(M-) cell lateral dendrite. The potentiations are dependent upon activation of postsynaptic NMDA receptors, and presumably, an increased postsynaptic Ca++ level, since posspiraphic NewDa receptors, and presumany, an increased posspiraphic call levels since they are blocked by intradendritic BAPTA injections. In contrast, stimulating paradigms that increase presynaptic Ca** (e.g. paired pulses) enhance chemical transmission but not electrotonic coupling. Thus, we postulated that gap junctional conductance can be potentiated as a consequence of postsynaptic, but not presynaptic, elevations in calcium. We potermixed as a consequence or possyriaphr, country presynaphr, elevations in calcium, we directly tested this hypothesis by injecting Ca** pre-and postsynaptically. For this purpose, CaCl, (2-4 mM) was added to the electrode recording solution (2-5M KCl, 10mM HEPES, PH 7.2). Presynaptic iontophoretic injections of Ca**, performed while recording either from a single afferent in the eighth nerve and the M-cell dendrite or from afferent terminals in the medula, did not induce any changes in the amplitudes of orthodromic or normaliterent terminals in the medula, did not induce any changes in the amplitudes of orthodromic or antidromic coupling. Presynaptic membrane hyperpolarizations of 5 to 10 mV provided indirect evidence of successful Ca** injections. In contrast, intradendritic injections of Ca** riggered long-term enhancements of both components of the mixed synaptic response, and Ca**-induced potentiation occluded the stimulus induced LTP. The responsible Ca**-dependent pathway most likely involves the activation of the enzyme Ca**-calmodulin kinase III. dependent pathway most likely involves the activation of the enzyme Ca*+-calmodulin kinase II (CamKII) since: i) the induction of LTP could be prevented by prior intradendritic injections of KN-93, an inhibitor of the Ca*-calmodulin-dependent kinases, and ii) immunohistochemical studies with antibodies (G-301) selective for the alpha subunit of CamKII revealed the presence of this enzyme in the M-cell lateral dendrite. This asymmetric effect of Ca* may reflect different properties among gap junction channels (heterologous gap junctions) or the existence of different regulatory mechanisms on either side of the junction. NMDA RECEPTOR-INDEPENDENT LTP AND DIFFERENTIAL EXPRESSION OF trkB RECEPTOR IN BASAL VS APICAL DENDRITES. I. Cavus* & T. Teyler, Dept. Neurobiology, NE Ohio College of Medicine, Rootstown, OH 44272 USA

Apical dendrites (str. radiatum) of rat hippocampal area CA1 display both NMDA receptor dependent and independent forms of LTP. The NMDA receptor-independent LTP results in increased expression of trkB receptor protein in the apical dendrites and is blocked by tyrosine kinase inhibitors (Çavuş et al. Soc. Neurosci. Abstr. 1993, 376.11; 1995, 245.3). Little is known about the nature of LTP in the basal dendrites (str. oriens) of CA1 pyramidal cells. Here we report that the tetanus parameters used in str. radiatum (200 Hz/200 msec x 10 every 5 sec in 50 μ M D,L-APV) also elicit NMDA receptor-independent LTP in str. oriens. Although initially str. oriens LTP was much larger than str.radiatum LTP (63.9 \pm 6.0 vs 35.1 \pm 7.2, n=6, 20 min post-tetanus), later their magnitudes were comparable (39.8 \pm 6.5 vs 34.9 ± 7.6, 80 min post-tetanus). Str.oriens NMDA receptorindependent LTP was also completely inhibited by the tyrosine kinase inhibitor genistein (20 μ M, 4.4 ± 10.0, 80min post-tet, n=6). However immunohistochemical analysis with trkB antibody (gp145^{trkB}, Santa Cruz) revealed that while this receptor tyrosine kinase is abundant in the somata and apical dendrites of the CA1 pyramidal cells, it is completely absent in the basal dendrites. We conclude that other tyrosine kinases than the trkB receptors are probably involved in the basal dendrite NMDA receptorindependent LTP. Supported by NS# 28698

AN ECTO-PROTEIN KINASE REQUIRED FOR THE MAINTENANCE OF LTP IS LOCALIZED ON THE SURFACE OF THE SYNAPTIC JUNCTION IN THE CLEFT. W. Chen, R.S.Lasher, A. Wieraszko and Y. H. Ehrlich*, CSI/IBR Center for Developmental Neuroscience, City Univ. of NY, Coll. Staten Island, NY 10314 and Dept. C.&S. Biol., Univ. Colorado Med. Sch., Denver, CO 80262.

During the induction of long-term potentiation (LTP) in hippocampal slices ATP is secreted into the synaptic cleft, and a 48K/50K protein duplex becomes phosphorylated by extracellular ATP. All the criteria required as evidence that these two proteins serve as principal substrates of ecto-protein kinase activity on the surface of hippocampal pyramidal neurons have been fulfilled. Addition to the extracellular medium of a monoclonal antibody termed M.Ab.1.9, directed to the catalytic domain of protein kinase C, inhibited selectively this surface protein phosphorylation activity and blocked the stabilization of LTP induced by high frequency stimulation (HFS) in hippocampal slices. This antibody did not interfere with routine synaptic transmission nor prevent the initial enhancement of synaptic responses observed during the 1-5 min period immediately after the application of HFS (the induction-phase of LTP). However, the initial increase in the slope of EPSP as well as the elevated amplitude of the population spike induced by HFS, both declined gradually and returned to pre-stimulus values within 40 mins after HFS was applied in the presence of M.Ab.1.9. Immunoperoxidase localization of the ecto-PK was carried-out with intact, unfixed synaptosomes. The externally-oriented epitope that is recognized by M.Ab.1.9 in this ecto-PK was localized on the surface of the synaptic junctional plasma membrane, within the synaptic cleft. These results provide the first direct evidence that a synaptic, surface ecto-PK localized at the site where ATP is secreted during tetanic stimulation, plays a causal role in the maintenance of stable LTP, an event implicated in the formation of memory in the brain. Supported by NIH grant HD28788 to YHE.

EXPRESSION OF MUTANT ENDOTHELIAL NITRIC OXIDE SYNTHASE (eNOS) BLOCKS LONG-TERM POTENTIATION (LTP). D.B. Kanter, S.J. Stary, W.B. Smith, B.M. Sultivan, N. Davidsen, E. M. Schurman* Callech, Division of Biology 216-76. Pasadena CA, 91125. Several studies have demonstrated the importance of intric oxide (NO) as an intercellular signal chring some forms of LTP. Evidence from wildtype and neuronal NOS (nNOS) knockout mice suggests that eNOS may catalyze the production of NO following LTP induction. The most notable difference between eNOS and nNOS is the co-translational N-myristoylation, and consequent membrane localization of eNOS. Using antibodies selective for the eNOS isoform, we have shown that eNOS is enriched in hippocampal siloes incubated in the N-myristoyltransferase inhibitor hydroxy-myristic acid (HMA) failed to exhibit LTP. In order to specifically address the role of eNOS in LTP, we have created an adenovirus vector containing a truncated eNOS (TeNOS) which lacks catalytic activity, yet retains the N-terminal sequence required for myristoylation. Control experiments with adenovirus containing the β-galactosidase (β-gal) gene show that infected slices express marker protein in 46 hrs, remain electrophysiologically viable for at least 34 hrs, and display normal synaptic transmission and plasticity. In blind experiments, slices infected with TeNOS virus and allowed to incubate 23-34 hrs (nean = 27.3 +/-2.2 hrs) failed to exhibit LTP, while control slices infected with β-gal virus display normal LTP [mean % baseline 1 hr after tetrans: TeNOS, 99.2 +/-3.0% (n=9); control, 216.2 +/-8.5% (n=8); Centrol, 216.2 self-88% (n=8); TeNOS interaction and impulsorupt curves. Recent work has shown that the heterodimerization of wildtype eNOS with runcation mutants similar to our TeNOS construct inhibits wildtype enzyme activity, raising the possibility that our construct is acting as a dominant negative. Alternatively, it is possible that TeNOS competitively inhibits myrisoylation of wildtype eNOS (or another myristo

Augmented LTP in mice lacking GluR2 subunit of AMPA receptor. N. Agopyan*, Z.P. Jia, J. Roder. Dept. of Molecular Neurobiology, SLRI, Mount Sinai Hospital, Toronto, Ontario, Canada.

GluR2 subunit of AMPA receptors is highly expressed in the mammalian central nervous system, and neurons expressing this subunit permate less calcium. In order to examine the extent of its involvement in synaptic plasticity, we created mutant mice lacking the GluR2 subunit (Taverna et al,

Dendritic field responses were elicited by focal stimulation of Schaeffer collaterals and recorded at 32 °C from the CA1 subfield of hippocampal slices. Input-output curves, constructed by plotting the slope of field EPSP versus presynaptic fiber volley amplitude revealed that the efficacy of excitatory synaptic transmission was indistinguishable between the control (+/+) and GluR2 mutant (-/-) mice. The magnitude of paired-pulse facilitation was also not changed over an interpulse interval range of 20 ms to I see between slices obtained from control and -/- mice. However tetanic (100Hz for 200 ms, 5x at 0.1 Hz) stimulation-induced LTP was 2-fold higher in the -/- mice; the normalized EPSP slope at 60 min after tetanus was 167 ± 15 % and 252 ± 17.8 % in +/+ and -/- respectively (n = 20). When the tetanic stimulation was delivered in the presence of 50-100 µM D-AP5, slices from control mice did not exhibit LTP while those from -/- mice displayed a residual LTP, which persisted even in the presence of nifedipine.

In conclusion, our data indicate that Ca2+ permeable AMPA receptors can both induce LTP and enhance it by modulating NMDA-dependent component. (Supported by MRC, N. Agopyan is a MRC Centennial Fellow)

AMPA RECEPTOR CHANNEL CONDUCTANCE IS INCREASED IN LTP IN CAI REGION OF RAT HIPPOCAMPUS. T. A. Benke, W. W. Anderson* and G.L. Collingridge, Dept. of Anatomy, University of Bristol,

In order to study the properties of glutamatergic ion channels responsible for synaptic transmission in the hippocampus, dendrites of CA1 pyramidal neurons of ~ 14 day-old rats were voltage-clamped with patch-electrodes (6-8 MΩ when filled with CsMeSO₄ based solution) in the whole-cell configuration (30-40 M Ω access resistance) under visual control. AMPA receptor mediated synaptic currents, elicited by focal stimulation of nearby presynaptic fibers with an insulated and sharpened tungsten monopolar electrode (tip \sim 5 µm), were recorded in the presence of picrotoxin (50 µM) at -70 mV in the presence of 1mM Mg²⁺ and were completely abolished by CNQX (10 μ M). Typical currents showed relatively fast rise times on the order of 1-2 msec and decay times of 5-9 msec. Pairing of minimal stimulation (0.5-1 Hz) with depolarization (+10-20 mV for 30 shocks, test intensity) resulted in long-lasting (30 minutes) potentiation of these currents with no apparent change in kinetics and an apparent reduction in synaptic failures. Non-stationary analysis of the variance of these currents revealed a basal single channel AMPA receptor conductance of 7-9 pS before pairing and 13-16 pS after pairing. This provides evidence for a post-synaptic mechanism of expression of long-term potentiation in the rat hippocampus. Supported by the U.S. NIH (NS09894 to T.A.B) and the Medical Research

Council (UK).

HYPOXIC INHIBITION OF LTP IN CA1 OF RAT HIPPOCAMPAL SLICES IS MEDIATED BY THE ACTIVATION OF NMDA RECEPTORS AND NO Y. Izumi*, A.M. Benz & C.F. Zorumski, Dept. of Psychiatry, Washington Univ., School of Med., St. Louis, MO 63110.

It is known that the cognitive impairment and learning disability that follow brain hypoxia or asphyxia may not be manifest for some time after the insult. To understand these delayed sequelae, we examined the effects of hypoxic conditions on hippocampal long-term potentiation (LTP), a leading candidate to be a mechanism underlying memory.

Although 20 min oxygen deprivation (replacement of oxygen with nitrogen)

completely suppressed excitatory postsynaptic potentials (EPSPs) in CA1 region of

rat hippocampal slices, EPSPs were fully restored following reoxygenation.

The maintenance of LTP was not blocked when the oxygen deprivation was introduced 30 min after tetanus (EPSP slope 60 min after reoxygenation; 136 ± 2 %, N=4). However, LTP could not be induced when a tetanus was delivered 100 min after reoxygenation (EPSP slope 60 min after tetanus; 105 ± 4%). Administration of 100 μM D,L-amino-phosphonovaleric acid (APV), a competitive antagonist of Nmethyl-D-aspartate (NMDA) receptors, during the oxygen deprivation, overcame the hypoxic inhibition of LTP (142 \pm 7 %, N=5). Similarly, 100 μ M L-monomethyl arginine (LMNA), a competitive inhibitor of nitric oxide synthase (NOS), administered during oxygen deprivation, but not during reoxygenation, allowed LTP induction by a tetanus delivered 100 min after reoxygenation (127 \pm 6%, N=5). The effects of LMNA were blocked by co-administration of 1 mM L-arginine, a substrate of NOS.

These results suggest that the activation of NMDA receptors during hypoxic conditions results in the failure of LTP induction through NO release

POSSIBLE INVOLVEMENT OF PLASMIN AND PLASMINOGEN IN LONG-TERM POTENTIATION OF RAT HIPPOCAMPUS. N. Matsuki*, A. Mizutani and H. Saito. Department of Chemical Pharmacology, Faculty of Pharmaceutical Sciences, The University of Tokyo, Tokyo

Effects of proteases and protease inhibitors on generation of long-term potentiation (LTP) were investigated in the CA1 and dentate regions of rat hippocampus in vitro. Plasmin, a serine protease, and its precursor plasminogen significantly enhanced short-term potentiation (STP) induced by a weak tetanic stimulation, without affecting basal responses. The STP-enhancing effect of plasmin disappeared by concomitant perfusion of $\alpha_2\text{-antiplasmin,}$ an endogenous plasmin inhibitor. Other proteases, such as thrombin, trypsin and cathepsin B, did not affect STP. On the other hand, α_2 antiplasmin and leupeptin significantly attenuated LTP induced by a strong tetanus though plasminogen or plasmin itself did not influence Furthermore, plasminogen and plasmin did not affect NMDA receptor-mediated synaptic responses in the absence of extracellular These results suggest that endogenous plasmin is involved in the mechanism of LTP in CA1 and dentate regions of rat hippocampus and that the STP-enhancing effect of plasmin is independent of NMDA receptors. LONG-TERM POTENTIATION: PHYSIOLOGY VII

599.1

LONG-TERM POTENTIATION OF DENTATE GYRUS MOSSY CELLS, S. Chattarji* 1.2 and H.E. Scharfman^{2,3}. ¹NNC, Yale University, New Haven, CT 06511, ²Neurol. Res. Ctr., Helen Hayes Hosp., NY State Dept. of Health, W. Haverstraw, NY 10993, and ³Depts. Pharmacology & Neurology, Columbia Univ., NY, NY 10032

Granule cells (GCs) and pyramidal cells are thought to play a role in learning and memory functions of the hippocampus. Since mossy cells (MCs) of the dentate hilus are synaptically connected with these cells, MCs may also have a role. In support of this hypothesis, loss of hilar cells has been noted in Alzheimer's disease, and animals with hilar lesions display memory deficits. We studied the potential role of MCs in hippocampal plasticity by determining whether MCs exhibit long-term potentiation (LTP), an increase in synaptic efficacy following high frequency stimulation, and a potential cellular substrate of learning and memory

Intracellular sharp microelectrode recordings were made from adult rat hippocampal slices (400 μ m). Buffer contained (in mM) 126 NaCl, 5 KCl, 26 NaHCO3, 2 MgSO4, 2 CaCl2, 1.25 NaH2PO4, and 10 d-glucose. Electrodes were filled with 4% Neurobiotin in 1M KCH3COOH so that MCs could be identified morphologically. The perforant path was stimulated tetanically (100 Hz 1 sec trains 1-4 times) in the molecular layer. Extracellular recordings monitored LTP of the GC population spike or population EPSP simultaneously

Under these conditions, LTP of MCs was rare (2 of 10 cells), as was LTP of GCs (4 of 10 slices), although short-term potentiation occurred. However, in the presence of the GABA, receptor antagonist bicuculline (5-10 µM), 3 mM CaCl₂, and 3 mM MgSO₄, LTP was robust (4 of 4 cells). MCs demonstrated LTP in several ways, such as a decrease in stimulus strength required to reach threshold, increased EPSP amplitude, or increased number of action potentials per suprathreshold stimulus. Spontaneous EPSPs increased after LTP. These data suggest that afferent inputs to mossy cells can exhibit LTP and that local inhibitory circuits may regulate this plasticity. OXYTOCIN INHIBITS HIPPOCAMPAL DENTATE GRANULE B.G. Smith, M.J. Wayner and D.L. Armstrong*. Division of Life Sciences, The University of Texas at San Antonio, San Antonio, TX 78249-0662, USA.

Oxytocin is a hypothalamic peptide produced in the paraventricular nucleus. It is synthesized by single large clusters of neurons that give off multibranched axons to several distant targets. Oxytocin decreases spontaneous motor activity and retention of a learned response. The purpose of this study was to determine the dose relationship effects of oxytocin on hippocampal granule cell long-term potentiation (LTP). Oxytocin in doses of 1, 5, 10, 30, 50, 100, and 200µg/kg was given to male Harlen Sprague-Dawley rats. To determine these effects of oxytocin, we examined LTP synaptic changes in vivo. We stimulated the medial perforant path and recorded from dentate granule cells. Urethane anesthetized rats were injected with the appropriate dose of oxytocin 2 hours and 15 minutes prior to tetanization. The results show that oxytocin can effectively block LTP in doses of 50 and $100\mu g$. Oxytocin did not significantly decrease or inhibit LTP when given in the lower concentrations. Oxytocin has an inhibitory effect on hippocampal dentate granule cell LTP that is probably related to the previously reported impairment of spontaneous motor activity and retention of learned responses

THE 2B SUBUNIT OF THE NMDA RECEPTOR IS ON DENTATE GYRUS INTERNEURONS AND ITS TYROSINE PHOSPHORYLATION MAY CONTRIBUTE TO LOCAL CIRCUIT PLASTICITY. G. Richter-Levin^{1*}, K. Rosenblum², S. Hazvi² and Y. Dudai². Haifa University¹ and the Weizmann Institute of Science². Israel.

We have recently reported that gustatory experience enhances tyrosine phosphorylation of a set of synaptic proteins in the rat insular cortex (PNAS 92: 1157), including the 2B subunit of the NMDA receptor (NR2B). A similar effect was found following the induction of LTP in the rat dentate gyrus (Soc. Neurosci. Abst. 21: 20.1 and submitted). Immunocytochemistry with antibodies to NR2B revealed that this subunit is preferentially located in dentate interneurons, at least part of which are CABAergic. The cellular localization of NR2B suggests a role in modulation of local circuit properties. To further investigate this hypothesis, we compared frequency-dependent inhibition (FDI) in role in modulation of local circuit properties. To further investigate this hypothesis, we compared frequency-dependent inhibition [FDI] in the dentate gyrus before and after LTP induction. FDI was assessed by increasing stimulus frequency from 0.1 to 1 Hz. Before induction of LTP the population spike (PS) was reduced to 33+/-13% of its size during stimulation at 0.1 Hz (n=7). At one hr after LTP induction FDI was reduced (PS size inhibited to only 52+/-13% of its size during stimulation at 0.1 Hz, p<0.01, n=8). The NMDA channel blocker MK801 (2 mg/kg i.p.) applied 10 min after LTP induction further reduced FDI (PS became 82+/-7% of its original size, n=7). It is suggested that in the dentate gyrus, NMDA receptors on inhibitory interneurons play a role in regulating circuit connectivity, and that tyrosine phosphorylation of NR2B, which in neuronal culture regulates NMDA receptor mediated currents (Wang & Salter, Nature 369: 233), may contribute to this mechanism of plasticity. (Supported by the US-Israel Binational Science Foundation, Jerusalem.)

RYANODINE GENERATES A LOW FREQUENCY INDUCED LTP WHICH IS NMDAR INDEPENDENT BUT mGLUR AND L-TYPE VOLTAGE-GATED CA CHANNEL DEPENDENT B. Anwyl. Wang, M.J. Rowan, and J. Gigg*. Dept Physiology, Trinity College Dublin 2, Ireland.

The induction of LTP was investigated in slices of the rat dentate gyrus in the presence of ryanodine, an agent which is known to selectively bind to the intracellular ryanodine receptor (RyR-receptor) Ca channels which regulate Ca release from intracellular Ca stores.

which regulate Ca felease from finaceurial Ca stoles.

In control media, high frequency stimulation (HFS) induced LTP, and prolonged low frequency stimulation (LFS), 5Hz, 900 pulses, induced long-term depression of field epsps and patch clamped epscs. In the presence of ryanodine, at a threshold concentration of 1µM, HFS-induced presence of fyanodine, at a threshold concentration of 1μM, HFS-induced LTP was inhibited, whereas LFS induced LTP. The N-methyl-D-aspartate receptor (NMDAR)-antagonist D-AP5, (200μM), did not prevent the induction of LTP by LFS in the presence of ryanodine. This demonstrates the NMDAR-independence of LTP induction in ryanodine. Furthermore, AP5 reversed the block of HFS-induced LTP by ryanodine, showing that activation of NMDAR inhibitis LTP induction in ryanodine. The induction of LTP by LFS in the presence of ryanodine was blocked by the L-type voltage-gated Ca channel blocker infedipine, and also by Ni. a commonly-used T-type voltage-gated Ca channel blocker. The LFS-induced LTP in ryanodine was inhibited by the metabotropic glutamate receptor antagonist MCPG. The LFS-induced LTP in ryanodine was also blocked by ruthenium red, an agent known to block RyR channel opening. The results of the red, an agent known to block RyR channel opening. The results of the present studies emphasize the importance of intracellular Ca stores in the induction of LTP.

599.7

INVOLVEMENT OF PROTEIN TYROSINE PHOSPHORYLATION IN SYNAPTIC TRANSMISSION AND LTP IN DENTATE GYRUS. H. Xiong, J. M. Wojtowicz and M. Salter¹ Dept. of Physiology, University of Toronto, Toronto, Ont., Canada M5S 1A8, and Div. of Neuroscience, Hospital for Sick Children¹, Toronto, Ont., Canada M5G 1X8.

Several lines of evidence indicate that pre- and post-synaptic kinases are involved in molecular mechanisms underlying long-term potentiation (LTP). Tyrosine kinases are abundant in the central nervous system and may possibly be involved in LTP. In this study we investigated the effects of tyrosine kinase inhibitors on synaptic transmission and synaptic plasticity in the dentate gyrus of rat hippocampal slices $(400\mu m \text{ in thickness})$ taken from 2-4 week old Wistar rats. Applied by bath at a concentration of 50 μ M, Genistein, a tyrosine kinase inhibitor, was found to block the induction of LTP evoked by tetanic stimulation of the medial perforant path. The amplitude of LTP was reduced from 162.2 \pm 22.8% of control to 82.8 \pm 35.2% of control by Genistein. Pre-incubation of slices with Lavendustin A, another tyrosine kinase inhibitor, had similar depressant effects on LTP. In addition to its effect on LTP, Genistein was also found to inhibit basal synaptic transmission and post-tetanic potentiation in dentate gyrus, possibly through a presynaptic mechanism. These results suggest that protein tyrosine phosphorylation is involved in regulation of synaptic transmission and synaptic plasticity in dentate gyrus

ARACHIDONIC ACID STIMULATES PROTEIN TYROSINE KINASE IN HIPPOCAMPUS: IMPLICATIONS FOR LTP IN DENTATE GYRUS M.A. Lynch" and B. McGahon Dept. Physiology, Trinity College, Dublin, Ireland

The mechanism by which arachidonic acid (AA) and the metabotropic glutamat The mechanism by which a ratinuous cate (AA) and the metabotropic glutamate receptor agonist, ACPD, interact to increase glutamate release in long-term potentiation (LTP) involves activation of phospholipase C (PLC)¹. The finding that AA and ACPD alone increase PLC activation, while coincident application of both agents is required to increase glutamate release, indicates that a threshold must be reached before activation of PLC is translated into increased glutamate release. We report here that this threshold relies on tyrosine phosphorylation, and subsequent

activation, of PLC γ by AA and activation of PLC β by ACPD. Synaptosomes were prepared from rat hippocampus and incubated in Krebs solution containing [3 H]-inositol to assess PLC activity or [$^{^3}$ P]- γ -ATP to assess phosphorylation of the substrate poly[Glu*Tyr1]. AA-induced PLC activity was phosphorylation of the substrate polyfolia fyr]. An-induced PLC activity was inhibited by the tyrosine kinase inhibitor genistein, while it did not affect ACPD-induced PLC activity. AA also increased phosphorylation of poly[GluTyr]. Immunoblotting of SDS gel separated proteins from synaptosomes incubated in the presence of AA or ACPD probed with anti-phosphotyrosine and anti-PLCγ antibodies revealed that AA, but not ACPD, increased tyrosine phosphorylation of antibodies revealed that AA, but not ACPD, increased tyrosine phosphorylation of PLCy. LTP was induced in dentate gyrus in urethane-anaesthetized rats. Synaptosomes prepared from potentiated tissue showed an increase in tyrosine phosphorylation of PLCy compared to controls.

These data provide evidence that AA increases tyrosine kinase activity in

hippocampus. The data also suggest that one role for AA in LTP is phosphorylation of PLC γ , which together with stimulation of PLC β by ACPD, allows a threshold activation of PLC to be reached which translates into increased glutamate release. SELECTIVE nNOS INHIBITOR, TRIM, BLOCKS BOTH LTP AND LTD IN RAT DENTATE GYRUS IN VITRO

J Wu, Y Wang, ¹ R Anwyl ¹ and MJ Rowan* Dept of Pharmacology and Therapeutics, ¹Dept of Physiology, Trinity College, Dublin 2, Ireland The possible role in the induction of synaptic plasticity of NO generated by the neuronal isoform of NO synthase (nNOS) was investigated in the rat hippocampus in vitro. Field population EPSPs investigated in the rat hippocampus *in vitro*. Field population EPSPs were recorded in the medial perforant pathway in the dentate gyrus of submerged slices maintained at 32°OC in standard media containing picrotoxin (100µM). Brief bursts of high-frequency stimulation (HFS, 200 Hz) induced a short-term potentiation (STP; 197±43% baseline, p<0.05) and long-term potentiation (LTP; 167±20%, p<0.05) in control slices. The selective nNOS inhibitor 1-(2-trifluoromethylphenyl) imidazole (TRIM, Handy *et al.*, Brit J Pharm 116, 2349), at a concentration (100µM) which had no effect on baseline transmission, significantly reduced STP (127±18%, p<0.05) and completely blocked. significantly reduced STP (127±18%, P<0.05) and completely blocked LTP (90±8%). This effect was prevented by co-administration of the substrate amino acid of NOS, L-arginine. Low-frequency stimulation (LFS, 900 pulses at 1 Hz) induced stable long-term depression (LTD; to 69±8%, p<0.05) in control slices. Pretreatment with TRIM (100µM) abolished LTD (92±13%). L-Arginine also opposed this effect.

NO generated by nNOS appears to play a critical role in the induction of both LTP and LTD in the dentate gyrus *in vitro*. This is consistent with our previous findings in the CAI region *in vivo* (Doyle *et al*, J Neurosci 16, 418).

PROLONGED MEMBRANE DEPOLARIZATION AND INCREASED NUMBER OF ACTION POTENTIALS DURING INDUCTION OF LONG-TERM POTENTIATION IN RAT DENTATE GYRUS. S. Wang* and J.M. Wojtowicz, Department of Physiology, University of Toronto, Toronto, Ontario, Canada M5S 1A8.

In dentate gyrus from immature rats (16-30 days), tetanic stimulation fails to produce long-term potentiation (LTP) in a large proportion (65%) of granule neurons. We have addressed possible mechanisms which can enhance the depolarization required for induction of LTP. Under the whole-cell current-clamp configuration, four 0.5 s, 100 Hz pulse trains, separated by 10 s intervals, were used to induce LTP in the medial perforant path-dentate granule cell synapses in the hippocampal slice preparation. It was observed that during the four trains, the number of action potentials increased in parallel with the duration of membrane depolarization in successive trains. This phenomenon was only seen in those cells in which LTP was successfully induced after the tetanic stimulation. Using extracellular field potential recordings to examine the changes during the tetanic pulse trains, it was noticed that in each train the evoked synaptic responses were initially increased then progressively depressed towards the end of the train. However, the first response of each train was larger in the successive trains. Activation of muscarinic receptors by carbachol is known to block the M current and the slow after-hyperpolarization potential in CA1. When we tested the carbachol effects in dentate gyrus, carbachol (10 $\mu M)$ enhanced the synaptic responses during high frequency trains. Average LTP induced synaptic responses during high nequency rains. Average ETF induced in the presence of carbachol was 132% larger than control. We conclude that cholinergic input may contribute to the induction of LTP by prolonging postsynaptic depolarizations during tetani. Supported by MRC of Canada.

HIPPOCAMPAL LONG-TERM POTENTIATION AND KINDLING-INDUCED POTENTIATION IN THE FREELY MOVING GUINEA-PIG. T. H. Gilbert*, L. P. Spongberg and G. C. Teskey. Behav. Neurosci. Res. Grp., Dept. of Psychology, Univ. of Calgary, Calgary, AB, Canada T2N IN4.

Compared to rats, guinea-pigs show a number of differences in kindling behaviour, seizure progression and the induction and decay parameters of piriform evoked responses following either high-frequency stimulation (HFS) or kindling. Understanding the nature of these differences may help to inform us about the underlying neuroplastic mechanisms. Thus, this study was undertaken to examine long-term potentiation (LTP) and kindling-induced potentiation (KIP) of the perforant path - dentate gyrus synapse, in awake behaving guinea-pigs.

Mixed-strain guinea-pigs were chronically implanted with bipolar stimulating electrodes in the perforant path (PP) and bipolar recording electrodes the dentate gyrus (DG). Following a two week recovery period, baseline input/output (I/O) responses were generated. These were based on the application of rectangular 200 usec pulses at 11 intensities through the PP electrodes. In the LTP protocol, I/O responses were taken for 3 days before HFS and immediately following HFS. Follow-up I/Os were then taken daily for 3 days and then once weekly for at least 3 weeks. In the KIP protocol, I/O responses were taken 3 days before kindling stimulation, immediately following the first afterdischarge (AD), and 24 hrs after the first AD. The animals were then stimulated once per day for 4 consecutive days. Follow-up I/O responses were then taken for 3 days following the last AD and once weekly for at least 3 weeks.

Preliminary results of the LTP data showed no change in the evoked response with the application of only one session of high frequency stimulation. Preliminary results of the KIP data showed an increase in the amplitude of the evoked response 24 hrs after the first AD and a further increase following the subsequent ADs. However, there appears to be a rapid decay of the evoked response within 2-3 days. Supported by NSERC.

LEVELS OF THE mRNA ENCODING SYNTAXIN 1B ARE DIFFERENTIALLY INCREASED IN THE CORTEX, ACCUMBENS AND HIPPOCAMPUS FOLLOWING ACQUISITION OF A SPATIAL REFERENCE OR WORKING MEMORY TASK. S. Davis*, J. Rodger, A. Hicks, J. Mallet and S. Laroche. NAM, CNRS URA1491, Université Paris-Sud, 91405 Orsay, France: LGN, CNRS UMR9923, Hôpital de la Pitié Salpétrier, 75013 Paris, France.

UMR9923, Hôpital de la Pitié Salpétrière, 75013 Paris, France.

It has been suggested that the presynaptic vesicle protein, syntaxin 1B is implicated in mediating a form of transsynaptic plasticity, as induction of LTP on the perforant path leads to an increase in the mRNA in the dentate granule cells and a subsequent increase in the protein at the mossy fibre terminal zone. We hypothesised that this may be a mechanism for the propagation of plasticity through interconnected neural networks. To test this hypothesis, the mRNA levels of syntaxin 1B were measured in several brain structures of rats which had been trained to criterion on either a spatial working or reference memory task on the radial arm maze (5-7 days). The data show that rats learning a spatial working memory task showed a significant increase (approx 30-40%) in syntaxin 1B mRNA in the dentate gyrus, CA3 and CA1 of the hippocampus compared with controls, whereas rats learning a spatial reference memory task showed an increase in the prelimbic region of the prefrontal cortex (80%) and the shell of the accumbens (80%). Naive and motor control groups showed no structure specific change and no group showed specific change in either the motor or parietal cortices. As syntaxin has been shown to be a marker of transsynaptic plasticity and as the hippocampus has monosynaptic connections to both the prelimbic region and the accumbens that support LTP induction, we believe the differential increase in syntaxin 1B mRNA may reflect one possible mechanism underlying the propagation of plasticity through hippocampal connections with other structures, such that continuous manipulation of information (as in a working memory task) occurs in the hippocampus but as information becomes consolidated across time (as in a reference memory task) it is represented in efferent connections of the hippocampus. Further studies are under investigation to test changes in the mRNA expressing syntaxin 1B at different stages of learning. Supported by a grant from the HFSP.

SYNAPTIC STRUCTURAL BASIS OF LTP: SPECIFIC MORPHOLOGICAL CHANGES 24 HOURS POST-LTP INDUCTION IN THE RAT DENTATE GYRUS. A. Weeks, T. Ivanco, J. LeBoutillier, R. J. Racine and T. L. Petit*. Dept. of Psychology and Prog. in Neuroscience, University of Toronto, 1265 Military Trail, Scarborough, Ontario, CANADA, M1C 1A4.

Long-term potentiation (LTP) involves a long-lasting enhancement of electrophysiological response following tetanic stimulation which is thought to arise from synaptic plasticity. The present study examined synapses in the stimulated middle molecular layer of the rat dentate gyrus following high frequency stimulation of the medial perforant path. Implanted non-stimulated animals and the non-stimulated inner molecular layer served as controls. The animals were sacrificed 24 hours after the final stimulation of the LTP group. The number of synapses in each of the molecular layers was estimated using an unbiased dissector technique. The shape of each synapse and the presence of perforations in the post synaptic density were recorded. The maximal lengths of the pre- and postsynaptic elements were also measured. The results did not indicate changes in all of the structural features that have been observed at shorter post-induction intervals. However, there was a significant increase in the number of concave and irregularly shaped synapses in the tissue stimulated during LTP. These synaptic types were also found to be significantly smaller in the LTP tissue It is possible that these synaptic shapes underlie increases in synaptic efficacy Their increase in number may, therefore, help support the potentiated electrophysiological response observed 24 hours after the induction of LTP. Research Supported by grants from the Natural Sciences and Engineering Research Council of Canada to T.L.P.

A NOVEL IMMEDIATE-EARLY GENE, Ti3, IS INDUCED DURING SEIZURE AND LTP. K. Inokuchi*, A. Kato, K. Hirai and F. Ozawa. Mitsubishi Kasei Institute of Life Sciences, Machida, Tokyo 194, Japan.

The prolonged maintenance of hippocampal LTP depends on de novo protein and RNA synthesis, indicating an involvement of altered gene expression in long-lasting changes in synaptic efficacy. We have employed PCR-based mRNA differential display to identify a set of genes that are induced by neural activity in the rat hippocampus. One of the cDNAs isolated, denoted Ti3, was rapidly induced in the hippocampus following the intraperitoneal injection of pentylenetetrazole (PTZ). The increase in Ti3 mRNA was mainly observed in granule cells of the dentate gyrus, while no or very weak induction in the CA1 and CA3 region. Ti3 represents one of the immediate-early genes since the transcripts were induced by PTZ even in the presence of protein synthesis inhibitor cycloheximide. Ti3 mRNA was approximately 7 kb in size. DNA sequence analysis of the cDNA clone and search of the EMBL and GenBank databases showed that Ti3 seems to be novel and not related to any known genes. Under the urethane-anesthesia, repeated high frequency stimulation given to the perforant pathway, which elicited a long-lasting (>10 h) LTP measured from the dentate gyrus, caused a drastic increase in Ti3 mRNA at granule cell layer of the hippocampus ipsilateral to the stimulating electrode 45 min after the delivery. The increase persisted at least for 3 h. Preinjection of a specific NMDA receptor antagonist, MK801, completely blocked the increase in the level of Ti3 mRNA as well as LTP induction, suggesting a correlation between the induction of Ti3 transcription and of LTP. SYNAPSIN I AND SYNTAXIN 1B: KEY ELEMENTS IN THE CONTROL OF NEUROTRANSMITTER RELEASE ARE REGULATED BY NEURONAL ACTIVATION AND LONG-TERM POTENTIATION IN VIVO. A. Hicks. S. Davis, J. Rodger, A. Helme-Guizon, S. Laroche* and J. Mallet, LGN, CNRS UMR9923, Hôpital de la Pitié Salpêtrière, 75013 Paris, France; NAM, CNRS URA1491, Université Paris-Sud, 91405 Orsay, France.

Little is known about the regulatory effects of synaptic plasticity on the proteins of the exocytotic machinery in vivo. At different times following the induction of long-term potentiation (LTP) or increasing neuronal activity in neurones within the dentate gyrus in vivo, in situ hybridisation revealed that from the many mRNAs that encode proteins involved in regulated exocytosis, only those encoding synapsin 1 and syntaxin 1B were specifically increased. Increased neuronal activity by high-intensity stimulation to evoke a response matching that seen in LTP, produced short-lasting unilateral changes visible two hours after tetanus (94±26% for synapsin J and 20±6% for synapsin J), whereas induction of LTP resulted in long-lasting postsynaptic changes visible at least five hours after tetanus (98±13% for synapsin 1 and 120±34% for syntaxin 1B). Furthermore, LTP induction produced contralateral changes visible also at five hours (52±15% for synapsin I and 95±41% for syntaxin 1B). These changes suggest an overall increase in neuronal excitation within a neuronal network can be differentiated from a change in synaptic strength at a specific subset of synapses, where only plastic changes lead to enduring modification. Thus we demonstrate that synaptic plasticity can lead to relatively long-term changes in selective members of the exocytotic machinery. Altered concentrations of key vesicle proteins may thus provide the means for modulation of neurotransmitter release over long time periods. The persistent postsynaptic increase, induced by LTP, in mRNAs encoding these presynaptic proteins has important implications for the propagation of signals downstream from the site of LTP induction in hippocampal neural networks, and highlights a candidate cellular mechanism for mediating the propagation of plastic changes in such networks, which may be important in the laying down of memories. THE Ca²⁺ CHANNEL BLOCKER Ni²⁺ REDUCES THE INDUCTION OF THE HEBBIAN FORM OF LTP AT HIPPOCAMPAL MOSSY FIBER SYNAPSES A. Kapur* and D. Johnston, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

roscience, Baylor College of Medicine, Houston, TX 77030

Long-term potentiation (LTP) at mossy fiber synapses does not require the activation of NMDA receptors, but may have two forms, called Hebbian and non-Hebbian, based on factors required for induction (Urban and Barrionuevo, J. Neurosci., 1996). The Hebbian form depends on postsynaptic membrane potential and intracellular Ca²⁺. In this study we tested the hypothesis that Ni²⁺-sensitive Ca²⁺ channels are one source for the rise in postsynaptic [Ca²⁺], that permits the induction of the Hebbian form of LTP. Perforated-patch recordings of mossy fiber EPSPs were obtained from CA3 neurons in hip-pocampal slices by stimulating with a glass pipette in stratum lucidum. Test pulses were delivered at 0.1 Hz, and LTP was induced with high frequency stimulation (HFS) of 15 bursts delivered at 5 sec intervals, with each burst consisting of 7 pulses at 100 Hz. Depolarizing pulses were injected into the recorded cell, in conjunction with the stimulus bursts, to evoke spikes during the bursts. In the presence of NMDA-receptor blockers (50 μM D,L-APV, or APV + 10-20 μM MK-801) and GABA_A blockers (10 μM bicuculline + 10 μM picrotoxin), LTP was induced in 6/7 cells. The EPSP slope 15 min after HFS was potentiated by 72±26% (mean± SEM). When NiCl₂ (25–100 μM) was added to the bathing medium, the same HFS induced LTP in only 7/14 cells. The EPSP slope 15 min after HFS was potentiated by only 29±7%. In 4 of the 7 cells that did not show LTP in the presence of NiCl₂, LTP could be induced after washing out the Ni²⁺. These results suggest that Ca²⁺ entry through Ni²⁺-sensitive channels plays a role in the induction of the Hebbian form of LTP at mossy fiber synapses. Further studies will be needed to determine whether the effects of Ni²⁺ are being mediated through a block of the low- or high-voltage activated Ca²⁺ channels that are known to be sensitive to Ni²⁺. (MH44754, MH48432, NS11535).

PROPERTIES OF LTP INDUCTION IN THE CA3 REGION OF THE PRIMATE HIPPOCAMPUS. G. Barrionuevo*, N.N. Urban, D.A. Henze, D. A. Lewis Departments of Neuroscience and Psychiatry and Center for the Neural Basis of Cognition University of Pittsburgh, Pittsburgh, PA 15260.

We performed experiments to compare LTP induction in primate CA3 to previous work in the rat. Transverse hippocampal slices ($400~\mu m$) were prepared from young cynomologous macaque monkeys. Field EPSPs were recorded in the CA3 region following stimulation of mossy fiber (MF) or collateral/associational (C/A) axons

Application of HFS to C/A fibers resulted in LTP of the field EPSP recorded in s. radiatum (132 ± 7% of control, N=5). LTP induction at this synapse was reversibly blocked by the addition of 25 μ M D-APV to the bathing medium (N=4).

Presumed MF field EPSPs were recorded in s. lucidum in response to granule cell stimulation. Unlike in guinea pig, but like in rat, MF responses were insensitive to L-AP4 (N=7). Thus, this drug could not be used to screen for pure MF responses. D-APV (25 μ M) and in some cases MK-801 (10 μ M) were added to the bathing medium to block NMDA-dependent LTP. MF LTP was induced using two patterns of HFS (Urban and Barrionuevo, J. Neurosci. In press). Long trains of HFS (L-HFS: 100 pulses at 100 Hz, repeated 3 times) induced LTP that included a large early component. L-HFS applied during blockade of synaptic transmission by 10 mM kynurenic acid (KYN) also induced LTP following the washout of the KYN (137 \pm 6% LTP at 35 minutes post HFS, N=6), suggesting that L-HFS can induce a presynaptic non-Hebbian form of LTP. L-HFS also induced LTP in 10-30 μ M naloxone (131 \pm 8% of control, N=12). Brief trains of HFS (B-HFS: 8 pulses at 100 Hz repeated 10 times) induced LTP of the MF field EPSP under control conditions, but not when administered in the presence of KYN (N=110 ± 12% of control, N=4), suggesting that LTP induction by B-HFS requires postsynaptic depolarization. Together, these data suggest that the induction of synaptic plasticity in the primate CA3 region is similar to what we have observed in the rat. INTENSITY-DEPENDENT BIDIRECTIONAL PLASTICITY AT THE MOSSY FIBER-CA3 SYNAPSE. J.A. Reyes, B.E. Derrick, and J.L. Martinez, Jr. Div. of Life Sciences, Univ. of Texas, San Antonio, TX 78249

Data supporting theories of bidirectional modification (LTD and LTP) of synaptic strength are observed in a number of neocortical and archicortical synapses, suggesting that NMDA receptor-dependent LTP and LTD display different induction thresholds dependent on the level of postsynaptic activity, and perhaps the degree of postsynaptic depolarization. The mossy fiber synapse also displays bidirectional modifications of synaptic strength However, both LTP and LTD at this synapse appear independent of NMDA receptor activation. We reported previously that both homosynaptic mossy fiber LTD and LTP are dependent on mossy fiber activity and the activation of opioid receptors (Derrick and Martinez, Nature, in press). However, the dependence of stimulation intensity (cooperativity) on the induction of homosynaptic LTD and LTP has not been investigated in this pathway. In anesthetized adult rats, we used a stimulation paradigm (two, 1 sec, 100 Hz trains) that reliably elicits mossy fiber LTP, and varied the intensity of mossy fiber stimulation. Current intensities eliciting mossy fiber field EPSPs 25% and 33% of the maximum response amplitude produced a homosynaptic LTD of the mossy fiber field EPSP slope. Stimulation at current intensities eliciting responses 40% and 50% of maximum response amplitude elicited LTP of mossy fiber responses. Importantly, in agreement with bidirectional rules suggesting a null effect at the cross-over point between LTD and LTP, an intermediate current intensity (37%) did not produce significant changes in mossy fiber responses. These data suggest that homosynaptic mossy fiber LTD and LTP display mechanisms of induction that display different thresholds of intensity. This data is consistent with the BCM model, for this cooperative effect likely is related to the level of postsynaptic activity, and possibly postsynaptic depolarization. GAP-43 IS EXPRESSED WITH THE INDUCTION OF MOSSY FIBER LTP. E.J. Barea-Rodríguez, S. Peña de Ortiz, M. Escobar, J. A. Reves and J.L. Martinez, Jr. Division of Life Sciences, University of Texas, San Antonio, TX 78249.

Growth Associated Protein (GAP-43) is associated with axonal growth and synaptic plasticity. In the present study we investigated the expression of GAP-43 after the induction of mossy fiber long-term potentiation, a form of plasticity which depends on the activation of opioid receptors. Animals were handled for 7 consecutive days to minimize stress. Rats were then anaesthetized and were implanted with stimulating electrodes in the mossy fibers and recording electrodes in the CA3 pyramidal cell region. Baseline evoked responses were collected for 20 min and this was followed by the delivery of high-frequency stimulation (2, 100Hz, 1 sec) which induced LTP. Animals were sacrificed at 18 and 24 hrs after LTP induction and the brains were sectioned and prepared for *in situ* hybridization. In sham animals, low frequency stimulation resulted in a moderate hybridization. In sham animals, low frequency stimulation resulted in a moderate bilateral increase in GAP-43 mRNA in all hippocampal subfields when compare to intact controls. LTP resulted in a pronounced decrease in GAP-43 mRNA levels in area CA3 at 18 hrs when compared to sham. In contrast, GAP-43 mRNA was robustly increased in the dentate gyrus 24 hrs after LTP induction. This increase was blocked by prior administration of the opioid receptor antagonist naloxone (10 mg/kg, i.p.). These results suggest that GAP-43 may be involved in the long-term changes in synaptic plasticity associated with mossy fiber long-term potentiation and its expression, under the conditions used in this study, is regulated by opioid receptors. MONOSYNAPTIC PERFORANT PATH-CA3 RESPONSES DISPLAY ASSOCIATIVE LTP In Vivo. Brian E. Derrick* and Joe L. Martinez, Jr. Division of Life Sciences, The University of Texas, San Antonio, TX 78249

Direct medial and lateral perforant path projections to the CA3 region of the hippocampus display LTP (Breindl et al., 1993). However, studies have not yet addressed associative interactions within medial and lateral perforant path-CA3 projections, or between the perforant path projections and other afferents to area CA3. Adult (>90 day) male Sprague Dawley rats were anesthetized with pentobarbital and maintained at 37° C. Using stereotaxic coordinates, perforant path-CA3 responses were evoked by stimulation of the extreme dorsomedial or lateroventral aspects of the angular bundle as described previously (Breindl, ibid). In addition, commissural-CA3 responses were evoked by stimulation of the contralateral CA3 region. In each experiment, responses from two of the pathways were evoked alternately at a rate of 0.33 Hz. In one pathway, responses were evoked at intensities that elicited responses 20-25% of the maximal field EPSP amplitude. The alternate pathway was stimulated at intensities producing a response that was 50% of the maximal EPSP amplitude. After a 20 min period of stable baseline responses, the 50% intensity pathway was stimulated (five 2 sec trains of 100 Hz, 50 msec bursts at intervals of 200 msec) to produce LTP in this pathway, and to verify independence of the two afferent systems by the lack of LTP in the 25% intensity pathway. Thirty min following this stimulation, the 25% pathway was stimulated alone to verify that this intensity was ineffective in inducing LTP. Thirty min later, both the 25% and 50% pathways were stimulated simultaneously. Using this paradigm, we observed that medial and lateral perforant path-CA3 afferents display associative LTP with each other or with commissural-CA3 afferents. Thus associative LTP can occur between

medial perforant path-, lateral perforant path-, and commissural-CA3 synapses.

PROPERTIES OF LONG TERM POTENTIATION BETWEEN PAIRS OF HIPPOCAMPAL NEURONS IN ORGANOTYPIC CULTURE P. Pavlidis* and D.V. Madison. Department of Molecular and Cellular Physiology, Stanford University School of Medicine. Stanford CA, 94305.

We are studying associative LTP between monosynaptically coupled pairs of pyramidal cells. We use 7-14 day old organotypic interface cultures of hippocampal slices taken from 7-10 day old rats. We first showed that LTP can be induced reliably by pairing postsynaptic depolarization with extracellular stimulation of afferent axons at 1 Hz for 1 minute. To determine whether LTP could be observed between pairs of neurons, we used dual whole-cell recordings from nearby pyramidal cells within area CA3 or between CA3 and CA1. Monosynaptic EPSCs could be reliably observed following the stimulation of an action potential in the presynaptic cell with a depolarizing current pulse. We found that LTP of the EPSC could be induced between pairs of cells by pairing depolarization of the postsynaptic cell with presynaptic spike delivery at 1 Hz for 1 min. The LTP is associative, as 1 Hz stimulation or depolarization alone do not result in LTP. The LTP is pathway specific, as potentiation of an extracellularly stimulated pathway did not result in potentiation of the pair synapse; likewise, inducing LTP in the pair did not result in LTP of the extracellularly evoked response. Thus this LTP has many of the properties of associative LTP in acute slices. These results set the stage for an exploration of the role of the presynaptic neuron in the potentiation. We plan studies in which the presynaptic cell will be pharmacologically manipulated specifically via the presynaptic recording electrode. Supported by the Conte Center for Neuroscience Research (MH48108).

HZF-3 IS AN IMMEDIATE-EARLY GENE IN MOSSY FIBER LTP AND

INDUCED BY TRAINING IN THE MORRIS WATER MAZE. J. Onton.
S. Peña de Ortiz', J. Reyes, C. Vallejos, E. J. Barea-Rodriguez, and, J.L. Martinez,
Jr. Division of Life Sciences, University of Texas, San Antonio, TX 78249.
Induction of mossy fiber LTP in anesthetized rats results in enhanced expression of HZF-3, an immediate-early orphan receptor related to NGF1-B.
HZF-3 mRNA levels increase ipsilaterally in the dentate gyrus one hour after mossy fiber LTP induction and remain elevated after 5 hours. The importance of this gene activation to the establishment of LTP is strongly suggested by the fact that the opioid receptor antagonist naloxone blocks both the induction of LTP and the upregulation of HZF-3 mRNA levels. To determine whether HZF-3 expression is also regulated during learning we studied the changes in HZF-3 mRNA which occur after training in the Morris water maze. Rats were subjected to two training sessions of 10 trials each in which they were allowed to search for the submerged platform for 60 seconds. Animals were sacrificed 5 hours after initial exposure to the maze and HZF-3 mRNA levels were studied using *in situ* hybridization. Training resulted in a pronounced increase in HZF-3 mRNA in the hippocampal formation, entorhinal cortex, subiculum, and several white matter areas, including the fimbria, and internal capsule. Naloxone (10 mg/kg), injected 15 minutes prior to the first training session resulted in a complete blockade of HZF-3 mRNA upregulation in all brain areas but the internal capsule. Together, these studies support the notion that HZF-3 is an important immediate-early gene associated with changes in synaptic plasticity which occur during spatial learning and provide evidence that opioidergic neuromodulation is involved in leaning as well as in LTP. This work was supported by NSF (J.L.M., grant IBN 9411-564) and a NSF postdoctoral fellowship (S.P.O.)

COMPARISON OF TWO INDEPENDENT FORMS OF LTP IN AN ANIMAL MODEL OF IN UTERO COCAINE EXPOSURE J.S. Martinez, J.Z. Little, W.J. R. Cruce* and T.J. Teyler Dept. Of Neurobiology, Northeastern Ohio Univ. Coll. Of Med., Rootstown, Ohio 44272

The effects of in utero cocaine exposure on two independent forms of LTP were studied in hippocampal area CA1. Using 400 μ m hippocampal slices from a rabbit model of gestational cocaine exposure we compared NMDA-receptor dependent and independent forms of LTP. Slices were maintained in an interface chamber at 33° C and extracellular electrodes were used to record field EPSPs. NMDA-receptor dependent LTP was induced by afferent fiber activation at 25Hz for 1 second. NMDA-receptor independent LTP was in the presence of 50 μ M APV by four tetanic bursts of 200 Hz each lasting .5 seconds. Differences in LTP kinetics and magnitude were analyzed. Possible mechanisms underlying observed differences will be discussed. This project was supported by NIDA Grant #DA06871

EFFECTS OF HYPERCAPNIA ON HIPPOCAMPAL LONG-TERM POTENTIATION IN ANESTHETIZED RATS. M. Yoshioka*, Y. Itoh, M. Matsumoto, H. Togashi, K. Mori and H. Saito Dept. of Pharmacol. Hokkaido Univ. Sch. of Med., Sapporo 060, Japan.

The effects of hypercapnia, which has been reported to impair consciousness, on the long-term potentiation of the population spike in the hippocampus were studied in vivo. Experimental conditions of hypercapnia were obtained by loading of 13 % CO_2 ($F_{ICO2} = 0.13$) with normal O_2 concentration ($F_{IO2} = 0.21$) for 80 min in halothan-anesthetized rats. Arterial CO2 and O2 tension was 104.09 ± 12.86 and 90.71 ± 18.89 mmHg (mean \pm S.D., n = 18), respectively. A stainless steel bipolar electrode with 0.5 mm tip separation (0.1 mm in each tip diameter) was lowered into Schaffer's collaterals to stimulate. A monopolar glass-coated recording electrode (approximately 20 mm in tip diameter) was placed in the CA1 region. Under these conditions the amplitude of the population spike was reduced. After delivery of tetanic stimulation (400 Hz, 10 burst of 8 pulses, inter-burst interval 1 s) population spike height was not enhance relative to the baselines. Unloading of inspired CO2 unmasked population spike amplitude enhancement to 150% of the basal levels. Following the second delivery of the same high frequency trains, population spike height was still enhanced to the levels of control rats. These results suggest that hypercapnia may suppress both hippocampal synaptic transmission and its long-term potentiation.

600.5

LTP AND LTD ARE INDUCED BY ACTIVATION OF DISTINCT NMDA RECEPTOR SUBTYPES. S. Hrabetova*, T. C. Sacktor. Depts. of Pharmacology and Neurology, State University of New York at Brooklyn, Brooklyn, NY 11203. In the hippocampal CA1 region, a common trigger for the induction of

In the hippocampal CAT region, a common trigger for the induction of homosynaptic LTD and LTP is the increase in postsynaptic calcium through the activation of NMDA receptors. The mechanism by which the activation of the NMDA receptor leads to these opposing forms of synaptic plasticity is not known. Here we report evidence indicating that LTP and LTD are induced through the activation of pharmacologically distinct subpopulations of NMDA receptors. Hippocampal slices were prepared from Sprague-Dawley rats (16-21 days). Field

Hippocampal slices were prepared from Sprague-Dawley rats (16-21 days). Field excitatory postsynaptic potentials (EPSPs) were recorded from stratum radiatum using standard extracellular technique. For LTP induction, 100Hz tetanization of Schaffer collaterals was given for 1 sec, producing enhancement of synaptic transmission (149.3 \pm 2.4% of the baseline 30 min after tetanization, p < 0.001, n = 8). LTD was induced by 3Hz stimulation for 5 min (73.0 \pm 3.2%, p < 0.005, n = 8). We examined the effect of two different competitive antagonists of the NMDA receptor. p-2-amino-5-phosphonovaleric acid (D-AP5) and 3-((RS)-2-carboxypiperazin-4-ylpropyl-1-phosphonic acid (CPP). CPP, in contrast to D-AP5, binds with high affinity to conventional NMDA-receptor subtypes, but not to atypical subtypes that are relatively independent of Mg 2 +-mediated voltage-dependent blockade. As previously reported (Dudek and Bear, PNAS 89: 4363, 1992; Mulkey and Malenka, Neuron 9: 967, 1992), applications of D-AP5 (50 μ M) blocked both LTP and LTD (102.1 \pm 0.9%, 99.5 \pm 1.7%, respectively, n = 8). In contrast, CPP (10 μ M) prevented LTP (101.7 \pm 1.7%, n = 8) but not LTD (76.5 \pm 4.8, p < 0.005, n = 8).

4-8. p. 0.003, ii = 8).

We conclude that the induction of LTD and LTP requires the activation of different NMDA-receptor subpopulations. Since the only atypical NMDA subunit expressed in the hippocampus is NR2D, we propose that LTD is specifically induced through activation of NMDA receptors containing the NR2D subunit. Sponsored by grants from the NIH and the Epilepsy Foundation of America.

CHARACTERIZATION OF LIPOSOME MEDIATED TRANSFECTION OF MOUSE ORGANOTYPIC HIPPOCAMPAL CULTURE SYSTEM. Christine L. Olssonff, Loan B. Nguyen', Alfred T. Malouf', and Bruce L. Tempel#. VM Bloedel Hearing Res. Ctr., Dept. of Otolaryngology# and Neurosurgery', U.W., Seattle, WA 98195, Dept. of Pediatrics' 6003, Case Western Reserve Univ., Cleveland, OH 44106.

In order to study focal alterations in the expression of mouse K channel genes we have developed a mouse organotypic hippocampal slice culture system. Our culture conditions allow hippocampi from 3-5 postnatal day C3HeB/FeJ mice to be maintained in vitro for up to 2 months. To characterize the system, cultures were fixed at day 11 in vitro, a time corresponding to 14 days postnatal, and processed for Timms staining, cresyl violet staining, or immunocytochemistry using antibodies against mKv1.1 or mKv1.2 protein. Staining patterns were similar to control 14 day postnatal hippocampus. Adult hippocampus showed different staining patterns, most obviously with Timm's staining and ICC. Since the culture system appears to model hippocampal development in vivo, we attempted to develop a focal transfection system using plasmid-liposome complexes delivered by pressure injection. Plasmid constructs contained the CMV early gene promoter and mye epitope tagged K channel genes. At 11 days in vitro, cultures were injected near the pyramidal cell layer with plasmid-liposome complex, liposome alone or plasmid DNA alone. The cultures were fixed and stained with myc antibody from 1 to 7 days after injection to assess introduced gene expression. Cultures injected with DNA alone showed no transfection. Approximately 30% of the cultures injected with plasmid-liposome complexes expressed myc tagged K channel protein. Cresyl violet staining of injected slices indicated no obvious cell mortality. These results suggest that the mouse organotypic hippocampal culture models normal hippocampal development and that pyramidal cells in these cultures can be focally transfected with plasmid-liposome complexes. Supported by NIH grant NS27206.

SYNAPSES IN MATURE HIPPOCAMPAL SLICES (CA1) WITH AND WITHOUT LONG-TERM POTENTIATION (LTP) <u>K.E. Sorra* and K.M. Harris</u>, Division & Program in Neuroscience, Children's Hospital and Harvard Medical School, Boston, MA 02115.

Hippocampal slices are a model system in which to study the cellular mechanisms of synaptic transmission and plasticity (LTP). To establish whether changes in synapse number underlie the enduring expression of LTP in area CA1, hippocampal slices were evaluated electrophysiologically and the number and structure of synapses were analyzed. Experiments involved: (1) an across slice comparison, and (2) a within-slice experimental design. The unbiased series sample analysis, and 3-D reconstructions of dendritic segments were used to evaluate synapse number in s. radiatum at 2 hours posttetanus. In the across slice comparisons, slices were tetanized either in the presence or absence of 50 μM APV, and untetanized slices also served as controls. Results from 7 young adult rats revealed synapse number was not significantly different between the LTP, untetanized control and APV conditions. For the within slice experiments, a "coulombic" control (5 Hz) and LTP pathway (100 Hz) were monitored independently. Quantitative anatomical analysis of these slices also revealed no significant difference in synapse number between the LTP and control sites. Together, these results suggest that the increased synaptic efficacy characteristic of LTP in area CA1 does not involve synaptogenesis at 2 hours posttetanus. To address whether enduring LTP involves structural modification of existing synaptic elements. quantitative analysis of synapse dimensions is ongoing.

Long-term potentiation (LTP) in the hippocampus has been suggested to

Long-term potentiation (LTP) in the hippocampus has been suggested to model memory formation. Recently it was shown that LTP in the dentate gyrus of the hippocampus can be blocked without affecting spatial learning, and that mossy-fiber LTP in area CA3 is not required for spatial learning. Here we show that the presynaptic metabotropic glutamate receptor (mGulR) agonist (1S.3S)-1-aminocyclopentane-1.3-dicarboxylic acid (1S.3S-ACPD; 100 nmol icv) depressed baseline (55% of control) and totally blocked LTP induced by high-frequency stimulation (HFS; 600 pulses at 200 Hz; 180±20% LTP in control, 91±21% in ACPD group; p<0.0001) in the CA1 region in urethane anaesthetised rats. 50 nmol 1S.3S-ACPD also blocked LTP but did not affect baseline (101±9% of baseline after drug injection). The block of LTP was prevented by the presynaptic mGluR antagonist MCCG (151±9% LTP; MCCG 500nmol +ACPD 50nmol group).

In contrast, 1S,3S-ACPD (100 nmol icv) only marginally impaired learning a spatial task in a water maze or radial arm maze. No effect was seen in the acquisition phase of the water maze or the radial arm maze while a small effect was detected in the transfer tasks (distance swum in target quadrant $37\pm3\%$ for control; $29\pm3\%$ for drug group; p<0.05). Swim speed or behavior in the open field was not affected.

The results contradict the assumption that LTP in CA1 is a valid model for synaptic plastic events that might occur during learning. Supported by the Health Research Board of Ireland.

APICAL DENDRITIC LOCATION OF SLOW AHP CHANNELS IN HIPPOCAMPAL CA1 PYRAMIDAL NEURONS

P. Sah * and J. M. Bekkers The Neuroscience Group, Discipline of Human Physiology, Faculty of Medicine, University of Newcastle, Newcastle, NSW 2308 & Division of Neuroscience, John Curtin School of Medical Research, Australian National University, Canberra, ACT 2601, Australia

In CA1 pyramidal neurons trains of action potentials are followed by a slow afterhyperpolarization (AHP) which is due to activation of a calcium-activated potassium current (sI_{AHP}). The AHP is responsible for spike frequency potassium current (sl_{AHP}). The AHP is responsible for spike frequency adaptation and is modulated by a range of neurotransmitters including noradrenaline, acetylcholine and glutamate. In this study we have examined the cellular location of active sl_{AHP} channels. Hippocampal slices were prepared from 18-21 day-old rats and whole-cell recordings made using the "blind" approach. First we measured the "switchoft" of the AHP current and compared it with that of two GABAergic synaptic currents (IPSCs) with known somatic and dendritic locations. For the sl_{AHP} , the switchoff had a time constant of 7.4 ± 0.4 ms, compared with 3.5 ± 0.5 ms and 8.8 ± 0.3 ms for the somatic and dendritic GABAA IPSCs respectively. Analysis of the data using a passive cable model of the CA1 pyramidal cells indicated that active AHP channels are concentrated on the proximal dendrites within about 200 µm of the soma. Excitatory postsynaptic potentials (EPSPs) evoked in *Str. Radiatum* had their amplitudes shunted more during the AHP (0.81 ± 0.04) than did EPSPs evoked in *Str. Oriens* (0.98 ± 0.07) indicating that sIAHP channels are restricted to the apical dendritic tree. We then examined one possible consequence of this AHP-induced apical shunt for synaptic integration. A brief tetanic stimulus in *Str. Radiatum*, which in control conditions produced short-term potentiation (STP), produced long-term potentiation (LTP) when the AHP was blocked. These results suggest that, in addition to its role in spike frequency adaptation, the AHP works as an adjustable gain control, variably shunting synaptic potentials arising in the apical dendritic tree. ACTIVITY-DEPENDENT 8-ADRENERGIC MODULATION OF CALLTP M.J. Thomas*, T. Moody, M. Makhinson, T.J. O'Dell, Dept. of Physiology and the Interdepartmental Ph.D. Program for Neuroscience, UCLA School of Medicine, Los Angeles, CA 90024

 β -adrenergic receptor (β AR) activation has a central role in the memory enhancement that occurs during heightened states of emotional arousal. Although βAR activation may enhance memory formation by modulating long-term potentiation (LTP), the cellular basis of this modulation is not fully understood. We thus investigated the effects of the βAR agonist isoproterenol (ISO) on LTP in the CA1 region of mouse hippocampal slices. ISO alone (1.0 μM for 10 mins.) had no persistent effect on synaptic transmission (n \approx 8) but enabled the induction of LTP by 1 min. of 5 Hz synaptic stimulation (field EPSPs were $109.8 \pm 7.6\%$ of baseline 45 mins. after 5 Hz stimulation alone, mean \pm SEM, n = 6, and were 169 \pm 15.6% of baseline following 5 Hz stimulation in ISO, n = 5). In contrast, 15 seconds of 5 Hz stimulation induced an ISO-insensitive potentiation (EPSPs were 150.1 \pm 15.8% of baseline, n = 10 after 5 Hz/15 sec. stimulation in the absence of ISO and were 154.3 \pm 20.2% of baseline following 5 Hz/15 sec. stimulation in ISO, n = 5). Like ISO, the protein phosphatase inhibitor calyculin A (CA, 0.5 to 1.0 μ M) enabled the induction of LTP during 5 Hz/1 min. stimulation (EPSPs were $101.5 \pm 5.1\%$ of baseline in controls, n = 7 and were $171.8 \pm 15.2\%$ of baseline in CA treated slices. n=11) but had no effect on LTP induced by 5 Hz/15 sec. stimulation (EPSPs were 154.6 \pm 8.7 in controls, n=7 and were 145.5 \pm 10.9% of baseline in CA treated slices, n = 7). This suggests that 1 min, but not 15 sec, of 5 Hz stimulation activates protein phosphatases that oppose the induction of LTP. Thus, βAR activation selectively enables the induction of LTP by patterns of synaptic activity that activate protein phosphatases. THE LONG-TERM POTENTIATION IN THE HIPPOCAMPAL CAI AREA DEPENDED ON THE SPATIO-TEMPORAL INFORMATION

T. Aihara*, M. Mizuno', M. Tsukada', H.Saito', and H. Kato'
Dept. of Information-Communication Engineering, Tamagawa Univ., Machida, Tokyo, 194, and ²Dept. of Physiology, Yamagata Univ., School of Medichine, Yamagata, 999-23, Japan.

We investigated the amount of LTP induced by "spatio-temporal pattern" stimuli. The stimuli consisted of weak ("w") and strong "s") electric pulses which stimulated different areas of Schaffer region. Intensity of the stimulus "s" and that of "w" were adjusted to be a half and one tenth of that producing the maximum amplitude of the population spike. Spatio-temporal pattern stimuli consisted of the same number of component "s" (100 pulses) and "w" (100 pulses) and are identical in the spatial coincidence, but are different in the time correlations; for the stimulus with strong-positive correlation long trains of "s" or "w" are prevalent, while for the stimulus with strong-negative correlation "s" and "w" tend to

The results suggest that the LTP is sensitive both to the cooperation of input stimuli (the spatial coincidence) from ensembles of neurons impinging upon the target cell and to temporal correlation of stimuli.

By using the optical-imaging method, we also observed that the spatial distribution of LTP was different according to the difference in the spatio-temporal pattern of stimuli.

LTP EXPRESSED IN THE HIPPOCAMPAL CA1 REGION FOLLOWING 100 HZ OR THETA-PATTERNED STIMULATION IS ENHANCED BY GABA, RECEPTOR ANTAGONISM. C.A. Chapman*, Y. Perez, and J.-C. Lacaille, Centre de Recherche en Sciences Neurologiques et Département de Physiologie, Université de Montréal, Montréal, Canada, H3C 3J7.

Long-term potentiation of excitatory synaptic responses in hippocampal CA1 pyramidal neurons is also accompanied by increases in GABA inhibition generated by local interneurons. The impact of potentiated inhibitory inputs on the enhancement of postsynaptic responses in CA1 pyramidal cells was assessed here by monitoring the effects of tetanization on stratum radiatum field potentials evoked by stimulation of Schaffer collaterals in the presence and absence of inhibition. Conventional rat hippocampal slices (400µm, 32°C, n=8/group) were tested either in normal ACSF, or with the GABA receptor antagonist bicuculline (20 μ M; BIC) to block inhibition. LTP was induced using either a 1 sec 100 Hz train (HFS), or 3 episodes of theta-burst stimulation (TBS; 4 pulses at 100 Hz, repeated at 5 Hz for 1 sec). In both control and BIC-containing media, the initial cay of responses during the first 10 min post-tetanus was larger after HFS than TBS. In normal ACSF, both stimulation patterns resulted in a similar mean potentiation of the population EPSP slope and peak amplitude (*115%) 30 min after tetanization. In BIC, both TBS and HFS produced a larger LTP of the field EPSP slope (149±14.1 and 127±9.5%, respectively) and amplitude (136±9.9 and 113 \pm 8.0%, respectively). Bicuculline alone (10 μ M, n=10) enhanced the field EPSP slope (121 \pm 8.5%) and amplitude (128 \pm 6.2%). These results indicate that removal of inhibition results in an enhancement of excitatory responses of CA1 pyramidal cells and also facilitates LTP of these responses. The increased LTP of excitatory responses observed in BIC could be due to a block of long-lasting enhancement of inhibition in CA1 pyramidal neurons.

BRIEF TRAINS OF 5 HZ STIMULATION INDUCE NMDA RECEPTOR AND PROTEIN KINASE A-DEPENDENT LTP IN THE CAI REGION OF THE HIPPOCAMPUS. T. Moody, M.J.Thomas, M. Makhinson, T.J. O'Dell*, Dept. of Physiology and the Interdepartmental Ph.D. Program for Neuroscience, UCLA School of Medicine, Los Angeles, CA 90024

We have observed that brief trains of 5 Hz synaptic stimulation (duration = 30 sec., intensity = 50% of max.) induces NMDA receptor-dependent LTP in the CAI region of mouse hippocampal slices (EPSPs were 144.1 \pm 7.8% of baseline 45 min. after 5 Hz stimulation in control experiments, mean ± SEM, n = 18 and were 117.3 \pm 4.8% of baseline when 5 Hz stimulation was delivered in 100 μ M APV, n = 7). 5 Hz stimulation did not induce LTP at commissural/associational fiber synapses in the CA3 region of the hippocampus (EPSPs were $101.3 \pm 9.4\%$ of baseline, n = 9) suggesting that 5 Hz stimulation cannot induce LTP at all synapses capable of NMDA receptor-dependent, high-frequency stimulation-induced LTP. different mechanisms may be involved in high vs. low-frequency stimulationinduced LTP. Consistent with this notion the protein kinase A (PKA) inhibitor H89 blocked the induction of LTP by 5 Hz stimulation in the CA1 region (EPSPs were $162.1 \pm 8.7\%$ of baseline in vehicle (DMSO) controls, n = 8 and were $108.4 \pm 4.7\%$ of baseline in slices exposed to $10~\mu M$ H89, n=8) but had no effect on the induction of LTP by 2 trains of 100 Hz stimulation (control: 183.0 \pm 11.2% of baseline, n = 6, H89: 183.0 \pm 7.5, n = 8). The phosphatase inhibitor calyculin A (CA, 0.5 to 1.0 $\mu M)$ had no effect on LTP induced by 5 Hz stimulation (EPSPs were $158.2\pm10.9\%$ of baseline, n = 8), but restored the induction of LTP in H89 treated slices (EPSPs were $165.6 \pm 8.4\%$ of baseline, n = 6). These results suggest that PKA is particularly important for the induction of LTP during short trains of 5 Hz stimulation in the CA1 region of the hippocampus, perhaps by inhibiting protein phosphatases. Supported by grants from NIMH (MH52876) and the Esther A. and Joseph Klingenstein Fund to T.J.O. and an ARCS award to T.M.

PRIMING ACTIVATION OF GROUP I METABOTROPIC GLUTAMATE RECEPTORS FACILITATES LTP INDUCTION IN CA1. C.R. Raymond, A.S. Cohen, and W.C. Abraham. Department of Psychology, University of Otago. Dunedin, New Zealand

Previously we have shown that LTP induced in area CA1 of rat hippocampus can be facilitated by prior "priming" activation of metabotropic glutamate receptors (mGluRs; Cohen & Abraham, in press). We have now investigated the receptor specificity of this effect and whether it can be observed throughout the LTP induction function. Several durations of theta-burst stimulation (TBS) were used to induce varying LTP in CA1 slices from young adult male rats. In control slices, mild TBS (5 bursts) just above threshold for LTP induction generated a 15 ± 1% (n=5) increase in fEPSP slope measured 1 hour post-tetanus. A 10 min application of the specific Group I mGluR agonist 3,5-dihydroxyphenylglycine (DHPG, 20 μ M), 30 min prior to the mild TBS, transiently suppressed synaptic transmission but significantly enhanced subsequent LTP (43 \pm 10%, n=7, p<0.05). Maximal LTP induced by repeated TBS, however, was not facilitated by DHPG pre-treatment. Furthermore, LTP produced by a very weak tetanus (2 bursts) was the same in control (6 \pm 4%, n=7) and DHPG-treated slices (5 \pm 3%, n=5). Facilitation of LTP was not mediated by Group II mGluRs since slices primed with (2S,3S,4S)-α-(carboxycyclopropyl)glycine (L-CCG-I, 10 μM) yielded LTP $(13 \pm 8\%, n=5)$ that was not significantly different from control. Similarly, priming with the ionotropic receptor agonist NMDA (20 µM) did not enhance LTP. Finally, activation of muscarinic ACh receptors by carbachol (1-50 µM) did not prime LTP induced by a mild TBS. These findings indicate that prior selective activation of Group I mGluRs facilitates the induction of submaximal LTP, probably via biochemical sequelae to phospholipase C activation and subsequent hydrolysis of phosphoinositide.

EXCESSIVE HIGH-FREQUENCY STIMULATION REVERSES LTP BY NMDA- AND ADENOSINE-MEDIATED MECHANISMS. W.C. Abraham, C. Coussens' and A. Huggett. Department of Psychology, University of Otago, Dunedin, New Zealand.

Recent data from our lab has indicated that an inverted U-shaped function describes the relation between the number of high-frequency trains and the induction of LTP, in the dentate gyrus in vivo. We investigated this phenomenon further in CA1 slices from young adult male rats. The inverted U-shaped induction function was confirmed in CA1 Thus, peak LTP (56% increase in EPSP slope) occurred after 8 trains of 'theta-burst stimulation' (TBS), but little or no LTP resulted after 24 (10%) or 32 (8%) trains of TBS (i.e., "over-stimulation"). Overstimulation also inhibited the subsequent induction of LTP by additional TBS for 60-90 min. The lack of LTP after over-stimulation suggests a reversal of LTP as induced by the initial trains of TBS. Over-stimulation could not produce this reversal, however, if LTP were given 10 min to stabilize first. Both D-AP5 (100 µM) and DPCPX (50 nM, an A antagonist), applied to the perfusate after the initial few trains of TBS, prevented the reversal of LTP by the remaining trains. On the other hand, little LTP occurred when over-stimulation was given in the presence of 20 μM nimodipine (19%), or when extracellular Ca²⁺ was lowered from 2.5 mM to 2.0 mM (17%). These data indicate that over-stimulation causes a reversal of recently established LTP by NMDA- and adenosine-mediated mechanisms. (Supported by the New Zealand Health Research Council.)

ACTIVITY-INDUCED ENHANCEMENT OF HB-GAM EXPRESSION IN RAT HIPPOCAMPAL SLICES: IMPLICATIONS FOR LONG-TERM POTENTIATION? S.E. LAURI*T, TAIRA, K. KAILA AND H. RAUVALA Department of Biosciences, Division of Animal Physiology and Laboratory of Molecular Neurobiology, Institute of Biotechnology, P.O.Box 17, 00014 University of Helsinki, Finland. Email: slauri@helsinki.Fi

Heparin-binding growth-associated molecule (HB-GAM) is a developmentally regulated secretory protein with neurite outgrowth-promoting activity. The putative role of HB-GAM in synaptic plasticity was studied with conventional electrophysiological methods and in situhybridization in rat hippocampal slices. High-frequency stimulation (HFS, 100 Hz/1s) leading to induction of LTP increased the expression of HB-GAM mRNA in the CA1 pyramidal neurons. A combination of antagonists of NMDA receptors (80 μ M AP5 + 50 μ M ketamine) and postsynaptic voltage-gated calcium channels (50 μ M Ni²⁺ + 10 μ M nimodipine) inhibited the HFS-induced enhancement in HB-GAM expression, while a less complete inhibition was seen with an NMDA receptor block only. The effects of HB-GAM on synaptic transmission and plasticity were studied by injecting recombinant HB-GAM into the CA1 dendritic area. The presence of excess HB-GAM inhibited LTP specifically and dose-dependently, but had no effect on the initial induction of potentiation or on the slope or amplitude of fEPSPs evoked by low-frequency baseline stimulation. The results indicate that high-frequency stimulation inducing LTP leads to a calcium-dependent enhancement in HB-GAM expression, and imply a role for this extracellular protein in the regulation of synaptic function in hippocampus. Supported by the Academy of Finland.

SHORT-TERM POTENTIATION LOWERS THE INDUCTION THRESHOLD FOR LONG-TERM POTENTIATION J.C. Fitzgibbons* & P.E. Schulz, Dept. Neurol. & Div. Neurosci., Baylor College of Medicine, Houston, Tx 77030.

High frequency stimulation (HFS) induces potentiation of synaptic efficacy with at least three phases: a brief, APV-insensitive post-tetanic potentiation, a decremental short-term potentiation (STP), and a sustained long-term potentiation (LTP). It has been unclear whether LTP and STP are expressed via the same or different mechanisms. We have obtained two lines of evidence from extracellular recordings in rat hippocampal area CAI suggesting that STP may in fact be a separate form of potentiation. First, saturation of LTP does not decrease the magnitude of STP, and second, LTP expression is associated with a change in paired-pulse facilitation, while STP expression is not. While these data suggest differing mechanisms of expression, there is an interesting relationship between STP saturation and LTP induction. With progressive increases in the duration of HFS, the amount of STP increases. We find that as STP is saturated, LTP is first induced, which suggests that the two forms of potentiation may share similar induction mechanisms. If STP is a separate form of potentiation from LTP, what is its function? We have found that, while a subthreshold stimulation will induce only STP, two subthreshold stimuli separated by 1 minute can produce LTP, suggesting that STP may lower the LTP induction threshold for several minutes. This data supports the hypothesis that, while LTP and STP may have similar mechanisms for induction, they may utilize different expression mechanisms. In addition, the data suggests that one function of STP may be to lower the LTP induction threshold, so that two subthreshold stimuli may induce LTP (supported by NIH).

Facilitation of NMDA receptor-dependent homosynaptic LTD by the type II corticosteroid receptor agonist RU-28362. <u>C. Coussens, D.S. Kerr*, and W.C. Abraham.</u> Departments of Psychology and Pharmacology*, University of Otago, Dunedin, New Zealand.

Activation of the low-affinity type II corticosteroid receptor (CSR) has been associated with a decrease in the magnitude of LTP both in vivo and in vitro. However, the role of type II CSR activation in the induction of homosynaptic LTD has not been firmly established. As previously shown, two episodes of lowfrequency stimulation (LFS; 600 pulses at 1 Hz, each episode separated by 10 min), delivered to the Schaffer collaterals of area CA1 at 0.5 mV field EPSP strengths, did not significantly induce LTD of field EPSPs (-3 \pm 4%, n=6). The addition of the type II CSR agonist RU-28362 to the perfusate for 2 hours prior to recording facilitated the induction of LTD in a dose-dendent manner. RU-28362 $(1 \mu M)$ resulted in a non-significant depression (-10 + 3%, n=4), while perfusion with 10 μM RU-28362 resulted in a significant synaptic depression following LFS (-27 \pm 4%, n=9, p<0.01). The facilitation of LTD by RU-28362 was blocked by co-application of the type II CSR antagonist RU-38486 (30 μ M, n=3). The LTD observed in the presence of RU-28362 is dependent on NMDA receptor activation, since LTD was blocked by co-application of D-APV (50 μM; -9 \pm 3%, n=6) and was readily induced following APV washout (-22 \pm 3% n=4, p<0.01). One known effect of RU-28362 is to enhance voltage-sensitive calcium currents (Kerr et al., 1992, PNAS 89:8527-8531). However, bath application of nimodipine (an L-type calcium channel antagonist, 20 µM) did not prevent the facilitation of LTD by RU-28362 (-20 \pm 3%, n=7). The role of Ntype calcium channel activity in this phenomenon is currently under investigation (Supported by the New Zealand Health Research Council.)

HIPPOCAMPAL LTP IN SEGMENTAL TRISOMIC TS65DN MICE
F.E.N. LeBeau, N. Varma, J. Wagner, B.K. Krueger*, P.J. Yarowsky¹ and
B.E. Alger. Departments of Physiology and Pharmacology¹, University of
Maryland School of Medicine, Baltimore, MD, 21201.

Spatial learning and memory have been shown to be impaired in the segmental trisomic 16 mouse (Ts65Dn), a possible model for Down syndrome. We wished to determine whether abnormalities in hippocampal LTP could account for these deficits. Experiments were performed blind and data from 50 slices (26 from 12 Ts65Dn mice, 24 from 11 control mice of either sex) were analyzed. Synaptic field EPSPs were recorded extracellularly in CA1 stratum radiatum of hippocampal slices during stimulation (every 10 or 30 seconds) of the Schaffer collateral-commissural pathway. LTP was induced using 3 trains of stimuli (100 Hz for 1 sec) at 10 minute intervals. Changes in synaptic efficacy were determined as increases in EPSP slope measured 25-30 minutes (carly-LTP) or 50-60 minutes (late-LTP). following the last tetanic stimulus. Increases of >20% above control were considered significant. Early-LTP was seen in 19/24 Ts65Dn slices and 21/26 control slices, with a mean increase in significant difference between these two groups (p = 0.45). Late-LTP was observed in 8/12 Ts65Dn slices and 7/8 control slices with mean increases of 71% ±12 and 64% ±11 respectively. These differences were also not significant (n = 0.69)

These preliminary results suggest that LTP in the CA1 region of Ts65Dn mice is normal, and cannot account for the observed impairment in spatial learning.

FIRING OF POSTSYNAPTIC ACTION POTENTIALS DURING TETANIZATION IS REQUIRED FOR INDUCTION OF NMDA-RECEPTOR INDEPENDENT LTP IN AREA CA1 OF RAT HIPPOCAMPUS. L.M. Grover*. Dept. Physiology, Marshall Univ. Sch. Med., Huntington, WV 25755.

High frequency (200 Hz) tetanization can induce an NMDA-receptor independent LTP in hippocampal area CA1. This LTP is blocked by nifedipine, suggesting involvement of high threshold, voltage-dependent Ca²⁺ channels (VDCCs). Because postsynaptic action potentials activate high threshold dendritic VDCCs (Spruston et al., Science, 1995; Magee & Johnston, Science 1995), postsynaptic firing may be critical during induction of NMDA-receptor dependent LTP. To test this possibility, whole cell, current clamp recordings were made from CA1 pyramidal cell somata. Stimulating electrodes were placed in stratum radiatum to activate two independent afferent inputs. Under control conditions (50-100 μM APV, n=10 cells). 200 Hz tetanization of one input increased EPSP slopes by 38±10%, with no change in the nontetanized input (-5±7%). Loading cells (n=6) with QX-314 (5 mM) blocked postsynaptic action potentials and abolished NMDA-receptor independent LTP (change in EPSP slope for tetanized input = $-3\pm14\%$, for nontetanized input = $9\pm9\%$). Hyperpolarizing neurons (n=6) to -100 to -120 mV by constant current injection greatly reduced the number of action potentials during tetanization and also abolished NMDA-receptor independent LTP (EPSP change for tetanized input = -16±17% for nontetanized input = $-34\pm13\%$). These results indicate that firing of action potentials in postsynaptic neurons is necessary for induction of NMDA-receptor independent LTP, mostly likely as a stimulus for activating high threshold VDCCs. Postsynaptic spiking is probably not sufficient for induction of this LTP, however, since metabotropic glutamate receptors are also required (Little et al., Neurosci. Lett., 1995). (Supported in part by the NSF and Marshall Univ.)

OPTICAL RECORDING OF TRISYNAPTIC PATHWAY IN RAT HIPPOCAMPAL SLICES WITH A VOLTAGE-SENSITIVE DYE. Y. Nakagami*, H. Saito and N. Matsuki, Department of Chemical Pharmacology, Faculty of Pharmaceutical Sciences, The University of Tokyo, Tokyo 113, JAPAN

In the present study, voltage-sensitive dye and an optical recording system with a 128 × 128 photodiode array were utilized to investigate the spatial and temporal propagation of rat hippocampal trisynaptic pathway. Sequential propagation in the hippocampus was clearly detected in DG, CA3 and CA1 when the perforant pathway was stimulated. Duration of excitation in the stratum radiatum of CA3 was significantly longer than that in other hippocampal area. The long-lasting dendritic excitation is probably important to integrate synaptic transmission and may be related with epileptogenesis. When long-term potentiation (LTP) was induced by a tetanic stimulation (100 Hz for 1 sec), the excitatory region dramatically broadened out and the onset latency in the stratum radiatum of CA1 was reduced by as much as 60 %, indicating an increase of conduction velocity. The optical recording of excitation in the hippocampus is a powerful technique to analyze neural networks related to learning and memory process including LTP. INCREASED NEURONAL EXCITABILITY DURING DEPOLARIZATION-INDUCED SUPPRESSION OF INHIBITION. J.J. Wagner1* and B.E. Alger2. 1. Dept. Pharm. Sci., North Dakota State Univ., Fargo, ND 58105 and 2. Dept. Physiol., Univ. Maryland Sch. Med., Baltimore, MD 21201.

Brief (1sec) depolarization of CA1 pyramidal cells results in the Ca2+dependent induction of a retrograde signal which acts presynaptically to inhibit spontaneous and evoked GABAergic synaptic responses for approximately 1 min (see Pitler and Alger, 1995, TINS 18 (8): 333-340 for review). Inhibition plays a critical role in regulating the extent of excitatory transmission, and this depolarization-induced suppression of inhibition (DSI) is potentially an important mechanism by which the degree of GABAergic influence may be transiently modified.

Because of the temporal overlap of EPSPs and IPSPs following s. rad. stimulation in the rat hippocampal slice preparation, we predicted that the excitatory component would be enhanced during DSI due to the decrease of the inhibitory component. We tested the effects of DSI on synaptic transmission using whole-cell voltage-clamp recordings to monitor EPSC/IPSC responses from CA1 pyramidal cells. Following a 20/30 mV depolarization from a holding potential of -50/-60 mV, the peak amplitude (23±5%), initial slope (13±6%), and inward charge (42±9%) of the EPSC were all significantly enhanced during the DSI period (n=10). In current-clamp recordings, the probability of synaptically evoked action potential firing was increased from 13±4% to 46±9%, n=4. Thus the induction of DSI can indirectly lead to an increase in the efficacy of excitatory synaptic transmission in the hippocampus. Supported by NS30219 & NS22010 to B.E.A and DA09603 to J.J.W.

BICARBONATE-MEDIATED GABA DEPOLARIZING COMPONENT AND

BICARBONATE-MEDIATED GABA DEPOLARIZING COMPONENT AND SYNAPTIC PLASTICITY. C. Debray. D. Diabira. I. Chaudieu*. Y. Ben-Ari & H. Gozlan. INSERM U-29, 123, Bld de Port-Royal, 75014 -Paris (France). In the adult CNS, GABA exerts an inhibitory control over the activity of NMDA receptors but also generates a bicuculine-sensitive depolarizing response, following intense electrical stimulation. Several mechanisms are involved in this depolarizing response including a high permeability of bicarbonate ions through GABA, receptors (Staley et al., Science 1995). Since depolarizing responses have been observed in the hippocampus and aparticularly in depolarities where NMDA receptors are localized use have particularly in dendrites where NMDA receptors are localized, we have examined the role of the bicarbonate-mediated $GABA_A$ depolarization in the induction of NMDA receptor-dependent long-term potentiation (LTP) in CA1. Experiments were conducted in slices of adult rats in a bicarbonate buffer (CTRL), in the presence of acetazolamide or in a HEPES buffer to suppress the bicarbonate-mediated GABAA depolarization. In CTRL suppress the bicarbonate-mediated GABAA depolarization. In CIRL conditions LTP of AMPA receptors was similarly induced in the presence or in the absence of bicuculine and the inhibition of the bicarbonate-mediated GABAA depolarization has no significant effect on the induction of LTP. As the depolarization induced by GABAA receptors may be less efficient than that provided by AMPA receptors, these were transiently blocked during the train. Again, no modification of the induction of LTP was observed in either conditions. In contrast, when AMPA receptors were permanently blocked and when NMDA receptors were boosted by a low concentration of magnesium ions, the LTP of NMDA receptors is affected by the inhibition of bicarbonatemediated GABA_A depolarization. This suggests that in physiological conditions the contribution of this depolarizing component is not sufficient to relieve the high magnesium block of NMDA receptors but in conditions that enhance the level of excitability of NMDA receptors such as in certain pathological conditions, this component may play a role. Supported by INSERM and the Medical Research Foundation

AN INFLUENCE OF GABACTRIC FEEDBACK INHIBITION ON LTP AND LTD IN THE CA1 REGION OF THE HIPPOCAMPUS. P.M. Steele* & M.D. Mauk, Dept. of Neurobiology and Anatomy, Univ of Texas Medical School a Houston; Houston, Tx. 77225

Previous studies of the CA1 region in hippocampus have shown that prolonged low frequency stimulation induces long-term depression (LTD) and high frequency stimulation induces long-term potentiation (LTP). Between the stimulation frequencies that induce LTD and LTP is a threshold frequency, where on average no change in synaptic strength is observed. Here we demonstrate that the threshold frequency is influenced by inhibitory synaptic transmission. Standard techniques were used to prepare hippocampal slices from Spraque-Dawley rats (5-9 weeks old). The γ aminobutyric acid type A receptors GABAAR agonist muscimol (3nM) increased the threshold frequency, so LTD was induced at higher stimulation frequencies (> 10 Hz). The GABA_A antagonist picrotoxin (50µM) decreased the threshold frequency, so LTD was induced only at very low stimulation frequencies (.25-.5 Hz). These findings suggest that modulation of inhibitory interneuron activity may control the ability to induce LTD or LTP by sliding the threshold frequency (i.e. increased inhibitory interneuron activity will favor LTD induction and decreased activity will favor LTP induction). To investigate the effects of feedback inhibition on the threshold frequency, we paired antidromic stimulation of the alveus (4 pulses at 100 Hz given every 500 msec.) with afferent stimulation at 8 Hz. The induction frequency of 8 Hz is close to the threshold frequency where no net change in synaptic strength is induced (105 \pm 13.3%, n=5). We find that 8 Hz stimulation presented during antidromic activation of pyramidal cell spikes induced LTD (73 \pm 4%, n=4, p<05). Since this effect was blocked by picrotoxin (120 ± 9%, n=4), we propose that pyramidal cell driven recurrent inhibition via GABA_AR modulates the threshold frequency between LTD and LTP. Such inhibitory feedback modulation may play an important role in maintaining pyramidal cell activity in its effective dynamic range. Support: R29 MH46904 (MDM)

ARE AMPA RECEPTORS ESSENTIAL FOR THE INDUCTION OF LTP IN PHYSIOLOGICAL CONDITIONS? N. Chevassus au Louis*, D. Diabira, C. Debray, Y. Ben-Ari & H. Gozlan. INSERM U29, 123, Bld de Port-Royal,

There is a general argument that in the CA1 region of the hippocampus the induction of long term potentiation (LTP) is controlled by NMDA receptors, blockade of AMPA receptors during tetanization does not prevent the induction of LTP. However, this has been shown using non-physiological conditions i.e. high Ca2+ or low Mg2+ concentrations (see Kauer et al., Neuron 1988; Muller et al., Science 1988). Indeed, in keeping with these earlier studies, tetanic stimulation of Schaffer collaterals (2 x 100 Hz, 1s) induces a LTP in CA1, i) in presence of 4 mM Ca²⁺ and 4 mM Mg²⁺ (+ 87%, n= 3/4), or ii) in presence of a low concentration(0.02-0.1 mM) of Mg²⁺ (+ 54% n=

We repeated the above experiments in physiological conditions, in a bicarbonate buffer containing 2 mM Ca2+ and 1.3 mM Mg2+, and with no GABAA antagonists, expecting also a LTP of AMPA receptors upon washing out of CNQX. Surprizingly, no synaptic modification of these receptors was observed 30 min after tetanization (\pm 3% n= 0/6). The plasticity of the slice was carrefully checked using a different stimulation pathway in the same slice before the application of CNQX (+47% n=6/6). Similar results were obtained in a HEPES buffer (n=6/6). Thus, in physiological conditions LTP cannot be induced when AMPA receptors are blocked during the train. These results suggest that AMPA receptors are essential for the induction of LTP in physiological conditions

Activation of metabotropic glutamate receptors induces EPSP-spike potentiation in area CA1 of the submerged rat hippocampal slice. N.A. BREAKWELL* M.J. ROWAN and R.ANWYL. Depts of Physiology and Pharmacology and Therapeutics, Trinity College Dublin.

EPSP-spike (E-S) potentiation refers to a potentiation of the population spike (PS) which cannot be accounted for by a commensurate potentiation of the EPSP. E-S potentiation induced by high frequency stimulation (hfs) has been well documented as a shift to the left of the input/output (I/O) curve describing PS as a function of EPSP, but mechanisms involved in E-S potentiation remain unclear. We examined the role of mGluRs in E-S coupling, (1S.3R)-ACPD induced a long lasting potentiation of the population spike (PS) amplitude which was consistently larger than that of the EPSP measured in the cell body area. E-S potentiation was confirmed by a shift in the I/O curve following (1S.3R)-ACPD washout and by analysis of data interpolated from regression lines. This E-S potentiation was not observed in the presence of the gamma-aminobutyric acid A (GABA_A) receptor antagonist, picrotoxin (50μM), suggesting an mGluR mediation of GABAergic inhibitory transmission. E-S potentiation induced by hfs, which was of the same magnitude as that induced by (1S.3R)-ACPD, was blocked by the mGluR selective antagonist (+)-a-Methyl-4-carboxyphenylglycine (+MCPG; 250μM). These results suggest that uncoupling of the E-S relationship is mediated by mGluRs and provide further evidence that both synaptic and E-S potentiation induced by (1S,3R)-ACPD share common mechanisms of expression with hfs induced long-term potentiation.

ECTOPIC PACEMAKER GENERATOR IN AXON TERMINALS ASSOCIATED WITH EPILEPTIFORM ACTIVITY AND LTP. V.L.Ezrokhi, A.M.Kasyanov, Yu.I.Alexandrov*. Institute of Higher Nervous Activity and Neurophysiology and Institute of Psychology*, The Russian Academy of Sciences, 5a Butlerov St., Moscow, 11365.

Intracellular and extracellular recordings were used to study ectopic (i.e. nonsomatic) action potential (AP) generation occurring in three experimental environments. First, in callosal neurons during electographic seizures induced by various means (penicillin, strychnine, electroconvulsant) in rabbit cortex. Second, in CA3 pyramidal cells during LTP in the CA1 induced by theta-rhythm stimulation of Schaffer collaterals in rat hippocampal slices. Finally, we studied strychnine-treated inhibitory neurons situated on the slow- and fast-adapting mechanosensory neurons of the crayfish during molting. Antidromic AP bursts were recorded in the soma of callosal neurons simultaneously with as well as between the paroxysmal EEG waves, for up to 2 hrs after the cessation of the paroxysmal activity in the opposite hemisphere, and also as a consequence of kindling-like electrical stimulation. Occurrence of ectopic APs in CA3 pyramidal cells during LTP in CA1 was found to be dependent on the extracellular calcium concentration, and varied from single ectopic APs (2.2 mM) to ectopic AP bursts (1.3 mM). In the isolated crayfish stretch receptor, ectopic APs were observed in the axon terminals of the inhibitory neuron. AP bursts in an inhibitory terminal evoked IPSPs recorded from the postsynaptic membrane of one neuron and inhibited another neuron via the axon reflex. The AP bursts in the axon terminal arised either spontaneously or following orthodromic AP, as well as after a depolarization shift of the postsynaptic membrane or extracellular polarization. Our data reveal a long-term increase of axon terminal excitability, resulting in the generation of ectopic AP ranging from epileptiform activity to LTP. The work was support by grant RFBR 96-04-48842.

LONG-TERM POTENTIATION AT SINGLE FIBER INPUTS TO HIPPOCAMPAL CA1 PYRAMIDAL CELLS. J.T.R.Isaac*, G.O.Hjelmstad, R.A.Nicoll and R.C.Malenka, Depts.of Psychiatry, Physiology and Cellular and Molecular Pharmacology, University of California, San Francisco, CA 94143. Despite extensive investigation, it remains unclear whether presynaptic and/or

postsynaptic modifications are responsible for the expression of LTP. We attempted to address this using minimal stimulation and analysis of failures. In a first group of experiments we used whole-cell recordings and minimal stimulation at an intensity which elicited EPSCs on approximately 50% of trials. Following pairing LTP was associated with an increase in potency (194±22%), defined as the average size of the successes, and a shift in the amplitude histogram from small events to large in 8/8 cells. There was also a significant reduction in failure rate in 4/8 cells. In a second set of experiments (n=8) perforated patch-clamp recordings were used. The likelihood of reliable activation of a single axon and a presumptive single site was maximized by using stimulus intensity ramps in which EPSCs exhibited an abrupt threshold, and a plateau in amplitude and failure rate for at least 2 further increases in intensity. In 4 of these cells, paired pulses were also applied during the baseline which induced paired pulse facilitation, but a potency ratio (potency of 2nd response/potency of 1st) of ≤1. This indicated a single release site was likely being activated. In these experiments LTP caused an increase in potency (414±94%) and a shift from smaller to larger amplitude events in all 8 cells. There was a decrease in failure rate in 4/8 cells. In 2 of these cells paired pulse data was collected during LTP and an increase in the paired pulse potency ratio was observed consistent with an increase in n. In a final set of single axon experiments we attempted to induce LTP in the presence of 5 mM Ca²⁺ which raised baseline Pr to 0.84±0.05 (n=5). LTP was reliably induced in 5/5 cells (247±58%), and was associated with an increase in potency (238±57%). These data suggest that LTP is accompanied by an increase in q and is very difficult to explain by an increase in Pr alone. Supported by the Wellcome Trust, NSF and NIH.

IMAGING OF PROPAGATION OF PRE- AND POST-SYNAPTIC NEURAL ACTIVITIES IN CA1 REGION OF RAT HIPPOCAMPAL SLICES. T. Akaike*', Wang, J.¹, M. Sokabe¹, N. Kuno¹, A. Itoh² and T. Nabeshima² Dept. Physiol., ²Dept. Neuropsychopharmacol. and Hosp. Parm. Nagoya Univ. Sch. of Med., Nagoya 466 Japan. Our aim is to see how neural activities evoked in CA1 region of rat hippocampal slices spread to neighboring regions. We used an optical imaging method (Fujifilm Deltaron 1700: 0.6 ms/frame, 128x128 pixel) and a voltage sensitive dye (RH482). Neural activities were evoked by an electrical stimulation of either Schaeffer collaterals and/or commissural fibers in the radiatum and lacunosum moleculare (RLM) layers or those in oriens (Ors) layer. We used a technique of paired pulse facilitation to confirm correspondence between neural responses and optical signals. By applying CNQX in perfusing solution we could record optical signals of a primary component of neural activities, i.e., action potentials evoked in the passing fibers. By subtracting them from optical records obtained in normal solution we could calculate their secondary component which seem postsynaptically to be generated by primary activities. The fact that secondary neural activities propagate further than primary ones suggests that some feedford activities originating either from pyramidal cells or from interneurons propel the neural propagation. To see whether recurrent collaterals of pyramidal cells are necessary for the propagation we made incisions either across RLM layers leaving Ors layer intact or across Ors layer with intact RLM layers. A cut of RLM layers completely blocked the propagation, whereas neural activities could propagate after a cut of Ors layer. It suggests that interneurons may play more important role for propelling the propagation than recurrent collaterals of pyramidal cells.

601.8

LONG- AND SHORT-TERM PLASTICITY OF THE TEMPOROAMMONIC PATHWAY IN RAT HIPPOCAMPAL SLICE. H. Dvorak* and E. M. Schuman. Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

We are interested in activity-dependent modulation of the temporoammonic pathway, the direct projection from entorhinal cortex to area CA1 of the hippocampus. To isolate the temporoammonic pathway in a hippocampal slice, the dentate gyrus is removed and a cut is made through stratum radiatum in distal CA1. The temporoammonic pathway is stimulated in stratum lacunosum-moleculare distal to the cut through radiatum, and a field response is recorded in the same layer on the other side of the cut. Low frequency (1 Hz) stimulation applied to the temporoammonic pathway for 10 min resulted in a modest depression of the field response 20-30 min after cessation of low-frequency stimulation (mean±s.d. % of baseline of initial EPSP slope: 82.6±11.5) in nine out of ten slices. This depression is dependent upon NMDA receptor activation; in the presence of the NMDA receptor antagonist AP5 (50 μM), no significant depression was observed (mean % of baseline: 104±22, n=6). In five slices, the response recovered to baseline values (mean % of baseline: 104±9.2) after tetanic stimulation (4x100 Hz for 1 sec) of the We are also examining short-term plasticity by temporoammonic pathway. applying paired-pulse stimulation to the temporoammonic pathway. Unlike the Schaffer collateral response, in which facilitation is seen only at interstimulus intervals (ISIs) of less than 400 ms (at 22-25°C), the temporoammonic pathway shows a significant facilitation at ISIs as long as 800 ms. We are currently using intracellular recording to investigate the basis for this facilitation. Preliminary results suggest a differential effect of paired-pulse stimulation on excitatory and inhibitory postsynaptic potentials

LONG-TERM POTENTIATION IN CA1 OF THE NEONATAL RAT. J.A. Cummings**, J.T.R. Isaae³, R.A. Nicoll^{1‡}, and R.C. Malenka^{1‡}, Neuroscience Graduate Program*, Depts. of Cellular and Molecular Pharmacology[†], Physiology[‡], Psychiatry[§], and Center for Neurobiology and Psychiatry[§], University of California @ San Francisco, San Francisco, CA 94143.

It has often been reported that long-term potentiation of synaptic strength is difficult or impossible to obtain at the Schaffer collateral - CAI hippocampal synapse of neonatal rats (J. Physiol. 346, 27 [1984]; J. Neurosci. 13, 2910 [1993]). Most recently, it has been reported that LTP results from an increase in the probability of neurotransmitter release (p), and that p of neonatal CAI synapses is very high, thus precluding LTP (Science 269, 1730 [1995]). In contrast to these results, we have found that it is possible to induce LTP in hippocampal synapses of neonatal (P4-P8) rats. Tetanic stimulation of CAI fields (4X100 Hz, 1sec) resulted in a potentiation to 132% \pm 9% (S.E.M.) of the original baseline fEPSP slope (n=7), and pairing of neonatal CA1 cells (60 pulses at 2 Hz with cell held at 0 mV) resulted in an average $187\% \pm 32\%$ potentiation (n=10). The discrepancy between our own and previous results has many possible explanations, among them the possibility that p is not as high in our own preparations as it was in the previous studies. To gain insight into the differences between our own and previous results, we are currently examining LTP at presumptive single synaptic sites (Eur. J. Neurosci. 7, 1882 [1995]; Neuron 14, 795 [1995]) using perforated patch recordings. Supported by grants from the National Institutes of Health (R.A.N., R.C.M.), the Wellcome Trust (J.T.R.L.), and the Howard Hughes Medical Institute (J.A.C.).

LONG-TERM POTENTIATION AND FUNCTIONAL SYNAPSE INDUCTION DURING EARLY HIPPOCAMPAL DEVELOPMENT. G. M. Durand*, Y. Kovalchuk and A. Konnerth. I. Physiologisches Institut, Universität des Saarlandes, 66421 Homburg/Saar, Germany. In the adult mammalian central nervous system, excitatory synapic transmission is mediated mostly by co-localized AMPA and NMDA receptors. Our results indicate that, at their earliest stages of development, hippocampal glutamatergic synapses involve almost exclusively NMDA receptors, forming a "silent" neuronal network. By combining confocal calcium imaging with whole cell recordings in hippocampal slices, we found that these immature synaptic contacts are localized on dendritic shafts and not on spines as in the case of mature synapses. During the first week of development, the are localized on dendritic shafts and not on spines as in the case of mature synapses. During the first week of development, the hippocampal glutamatergic network becomes gradually functional due to the transformation of preformed NMDAergic synaptic contacts into conducting synapses, a process that we termed functional synapse induction. The early form of glutamatergic synaptic transmission was sensitive to CNQX and cyclothiazide indicating that it is mediated by AMPA receptors. Interestingly, synapse induction shared several properties with long-term potentiation (LTP). Thus, it was long-lasting, input-specific and easily triggered experimentally by pairing presynaptic stimulation with postsynaptic depolarization. We conclude that the induction of functional synapses is governed by Hebb's rule of association. Moreover, our data indicate that LTP or a closely related process may be involved in the activity-dependent formation of the glutamatergic network in early development. Supported by the Deutsche Forschungsgemeinschaft (SFB 246). G.M.D. is supported by the Alexander von Humboldt-Stiftung and the Human Frontier Science Program.

ACETYLCHOLINE RECEPTORS: NICOTINIC-PHARMACOLOGY II

α7/5HT3 CHIMERIC HOMOMERS: SIMILARITY TO PC12 α-BUNGAROTOXIN RECEPTORS. S.V. Rakhilin, P. Atluri, R.C. Drisdel* E. Ko, F. Rangwala, S. Salman, W.N. Green. Department of Pharmacological & Physiological Sciences, University of Chicago, Chicago, IL 60637.

The nicotinic acetylcholine receptor (AChR) α7 subunit forms homomeric α-bungarotoxin receptors (BuTxRs) in Xenopus oocytes. However, attempts to express α7 homomers in heterologous mammalian systems have met with little success. In contrast, a subunit chimera, which contains the N-terminal toxin binding domain of the α7 subunit and the C-terminal domain of the 5-hydroxytryptamine (5HT3) subunit, is expressed as a BuTxR homomer in mammalian cells (Corringer et al. 1995. IBC 270). In the present study, α7/5HT3 homomers were stably expressed (~500,000 surface sites/cell) in tsA201 cells and characterized in parallel with BuTxRs from PC12 cells (Drisdel et al., this meeting). α7/5HT3, BuTxRs bind BuTx with high affinity (Kp.~2x10⁻¹0 M, 4°C) and sediment as a single 10S peak on sucrose gradients. The cross-linked receptor-¹²³1-BuTx complex also migrates as a 10S peak and at ~250 kDa based on SDS-PAGE. Inhibition of cell surface ¹²³1-BuTx binding by agonists and antagonists is similar to that observed for PC12 cells. Hill coefficients for ACh, carbachol, cytisine, and nicotine were between 2 and 3. Based on the inhibition of cell surface ¹²³1-BuTx binding by bromoacetylcholine alkylation of cysteines at the ligand binding site, the chimeric receptor possesses high (~70%) and low (~30%) affinity sites, analogous to the PC12 receptor. Our data indicate that the α7/5HT3 BuTxRs, like the PC12 BuTxRs have at least three nonequivalent toxin binding sites per receptor and thus possess structural and pharmacological properties similar to BuTxRs described in PC12 cells. Supported by NSF IBN-9319656. Council for Tobacco Res. Scholar Award (W.N.G.), and Am. Heart Assoc. Sr. Res. Fellowship. (S.V.R.).

Differential discrimination between human and rat α7 nAChR by GTS-21 and its primary metabolite, 4-OH,2 Methoxybenzylidene anabaseine R.L. Papke* E. M. Meyer, and C.M. de Fiebre University of Florida, Department of Pharmacology.

GTS-21 (3-(2,4)-dimethoxybenzylidene anabaseine, DMXB) is a neuronal nicotinic partial agonist, highly selective for rat α7 receptors. The activation of α7 receptors has been proposed to provide a mechanism for cytoprotection of PC12 cells and cognitive enhancement in a rat model of cholinergic hypofunction. The ability of GTS-21 and other anabaseine derivatives to elicit maximal responses from α7 receptors expressed in Xenopus oocytes appears to be limited both by variable efficacy for receptor activation and by a secondary noncompetitive inhibitory activity. Therefore, we define the alpha7 activity factors (A7AF) as the product of the response at 20 μM (relative to 500 μM ACh) and the residual control response remaining after a 20 μM application. DMAC (3-(4)-dimethylamino-cinnamylidine anabaseine), a compound previously reported to have high α7 efficacy (9.93, relative to 500 μM ACh), has an A7AF of 10) (9.32, due to high residual inhibition. In contrast, while at 20 μM, GTS-21 stimulates responses of rat α7 receptors that are only 0.20 the 500 μM ACh control responses. GTS-21 has an A7AF of 0.20, because the application of a 20 μM solution produces no significant inhibition of subsequent ACh responses. 4-OH,2Methoxybenzylidene anabaseine (4-OH BA) is the primary metabolite of GTS-21 (B. Kem, personal communication), and 4-OH BA has a A7AF of n.35 for rat α7 receptors. When DMAC was applied to Xenopus oocytes expressing human α7 receptors, the calculated A7AF was 0.11, and the GTS-21 A7AF for human receptors was only 0.034. In contrast, the A7AF of 4-OH BA for human receptors was only 0.034. In contrast, the A7AF of 4-OH BA for human receptors was 0.31, greater than that of GTS-21 for the rat α7 receptors. These results suggest that for effects were said eliciting in vitro effects

These experiments were supported by Taiho Pharmaceuticals. Anabaseine compounds were generously provided by Dr. B. Kem and Taiho Pharmaceuticals. We thank Jon Lindstrom for the human α 7 clone.

THE PC12 α-BUNGAROTOXIN RECEPTOR HAS MORE THAN TWO TOXIN BINDING SITES. R.C. Drisdel, P. Atluri, A.P. Fox, A.B. Harkins*, E. Ko, E. Potter, S.V. Rakhilin, F. Rangwala, W.N. Green, Department of Pharmacological & Physiological Sciences, University of Chicago, Chicago, IL 60637.

We have characterized an α-bungarotoxin receptor (BuTxR) in PC12 cells (~40,000 surface sites per cell) that sediments as a single 10S peak on sucrose gradients. Cross-linked cell surface receptor-1251-BuTx complexes also migrate as a 10S peak on sucrose gradients and as a single band of 290-300 kDa based on SDS-PAGE, PC12 receptors bind BuTx with high affinity (K_D~1x10⁻¹⁰ M, 4°C) and are precipitated by α-specific antibodies. The nicotine-induced whole cell current in these cells is almost completely blocked (~90% inhibition) by BuTx (0.5 μM) or methyllycacontine (1 μM) and is similar to BuTxRs in other preparations. Inhibition of cell surface 125 -BuTx binding with a panel of nicotinic acetylcholine receptor (AchR) agonists and antagonists reveal a distinct nicotinic pharmacological profile. Hill coefficients for acetylcholine, carbachol, cytisine, and nicotine were between 2 and 3. Inhibition of cell surface BuTx binding by bromoacetylcholine (BrACh) alkylation of cysteine residues at the ligand binding site indicates two different classes of BrACh binding sites, high affinity sites (~70%, IC₅₀=3 μM) and low affinity sites (~30%, IC₅₀=2 mM). Our results are consistent with the presence of at least three nonequivalent toxin binding sites per receptor and indicate that the neuronal BuTxR is structurally different from other AChRs. Supported by NSF IBN-9319656, Council for Tobacco Research Scholar Award (W.N.G.), and Am. Heart Assoc. Sr. Research Fellowship (S.V.R.). Fellowship (S.V.R.).

602.4

The disposition of use-dependent binding sites in nAChR. M. M. Francis 1,2 , Kyung Choi 3 , Ben Horenstein 3 and R.L. Papke 1,2 Univ. of Florida, Departments of 1 Pharmacology, 2 Neuroscience and 3 Chemistry, Gainesville, Florida. Neuronal nicotinic acetylcholine receptors (nAChRs; e.g. $\alpha 3\beta 4$) are more sensitive

to a class of noncompetitive inhibitors known as ganglionic blockers than muscle-type nAChRs (e.g. $\alpha 1\beta 1\gamma\delta$). Bis-TMP-n compounds are potent use-dependent bi-functional inhibitors of nAChRs. These compounds are symmetrical conjugates of methylated piperidine rings connected by a flexible aliphatic linker chain consisting of "n" number of carbons, Bis-TMP-10 inhibits neuronal ((a3,64) and chimeric a [B16]44TM2)y8 nAChRs with prolonged kinetics of recovery as compared to inhibition of muscle-type nAChRs, localizing the site responsible for conferring prolonged kinetics of inhibition to eight amino acids in the pore-lining second transmembrane domain of the neuronal beta subunit (B4).

Since the slow reversibility of inhibition of neuronal nAChRs by bis-TMP-10 Since the slow reversibility of innibition of neuronal nAChRs by 0is-1MP-10 seems to arise from an ability of the compound to bind to multiple sites within the receptor complex, we have been able to estimate the separation distance between sites by examining the kinetics of inhibition after application of bis-TMP-n compounds. α1β1(β4TM2)γδ receptors showed complete recovery from inhibition five minutes after co-application of ACh with bis-TMP-8 while responses were inhibited by 93±01% five minutes after co-application of ACh with bis-TMP-10. This result demonstrated the maximal separation distance between use-dependent sites to be between 20Å and 23Å in chimeric $\alpha1\beta1(\beta4TM2)\gamma\delta$ receptors. However, additional between 20A and 23A in chimeric α1β1(β4TM2)γδ receptors. However, additional studies of compounds composed of identical piperidine rings connected by rigid linker groups showed the separation distance to be between 15.2Å and 18.3Å. While α1β1(β4TM2)γδ and α3β4 nAChRs showed comparable sensitivities to inhibition by bis-TMP-n compounds at the time of co-application, they differed in their kinetics of recovery suggesting that the potential for binding to adjacent beta subunits in the neuronal receptor complex alters the requirements for bi-functional inhibition. This result opens the possibility of using this class of compounds as probes for subunit arrangement and stoichiometry in nAChRs. This work was supported by NIH R01 NS3288-0A2 to RLP and NIMH NRSA 1 F31 MH11258-01 to MMF.

PACAP RECEPTOR ACTIVATION INHIBITS α7-CONTAINING NEURONAL ACETYLCHOLINE RECEPTORS. <u>D. Pardi* J. F. Margiotta</u> Dept of Physiology & Biophysics, Mount Sinai School of Med, NY, NY 10029, and Dept of Anatomy & Neurobiology Med. College of Ohio. Toledo, OH. 43699.

Physiology & Biophysics, Mount Sinai School of Med, NY, NY 10029, and Dept of Anatomy & Neurobiology, Med. College of Ohio, Toledo, OH, 43699. Two major classes of nicotinic AChRs are present on chick ciliary ganglion neurons. One contains the α7 AChR subunit, displays rapid desensitization, and is blocked by α-bungarotoxin (αBgt). The second class lacks α7 subunits, desensitizes much more slowly, and is unaffected by αBgt. We previously showed that peak ACh-evoked responses are enhanced ~50% after increasing cAMP levels in the neurons, either by injecting cAMP or by activating pituitary adenylate cyclase activating peptide (PACAP) type I receptors. Interestingly, after blocking adenylate cyclase with 2′,5′ eideoxyadenosine (ddA), PACAP treatment resulted in ~50% reduction in the ACh response (ddA alone was without effect) suggesting that a parallel, cAMP-independent, PACAP-activated signaling pathway inhibits some AChRs. In order to identify the AChRs targeted by such signals, ciliary ganglion neurons were pretreated with 200uM ddA and 10nM PACAP, and then challenged with 500uM ACh or 20uM Nicotine. In ddA/PACAP treated neurons, the rapidly desensitizing, initial component of the agonist induced response was reduced 36.21±12.3% (p<0.001, n=16 cell pairs), while the slowly desensitizing components were unaffected (p>0.25). In parallel experiments, αBgt abolished the rapidly desensitizing initial component, indicating that α7 containing AChRs are inhibited by PACAP-activated cell signals. In other systems, PACAP has been shown to increase both cAMP and IP3/Ca++. We find that PACAP elevates inositol phosphate (IP) levels in ciliary ganglion neurons with a 10nM dose causing an 85.06%±7.47 increase (p<0.05, n=16 separate platings). A possible link between IP production and selective inhibition of α7-containing AChRs or ciliary ganglion neurons (Vijayaraghavan et al., 1995). Supported by NIH NS24417.

METHYLLYCACONITINE A COMPETITIVE INHIBITOR OF THE α7 DESENSITIZED OPEN MUTANT L247T. S. Bertrand*, E. Palma, P.J. Corringer, S. Edelstein, J.P. Changeux and D. Bertrand University of Geneva, 1211 Geneva, Switzerland, Institut Pasteur, 75734 Paris Cedex France.

The natural insecticide methyllycaconitine (MLA) competitively inhibits the wild type homomeric α7 neuronal nicotinic acetylcholine receptor in the picomolar range. We have now examined the action of this compound on the desensitized open mutant L247T. We find that in contrast to other competitive inhibitors such as dihydro-β-erythroidine (DHβE) MLA applications induce no detectable current but reversibly block successive ACh-evoked currents. MLA IC50 of the L247T mutant (~30 pM) is comparable to that exhibited by the wild type receptor. Furthermore, recovery from MLA blockade follows a sigmoidal time course suggesting the existence of multiple binding sites for this compound. L247T inhibition by MLA resembles the effect of the snake toxin α-bungarotoxin which suggests that the binding sites for these two compounds might partly overlap.

INHIBITION OF THE HUMAN α7 NICOTINIC RECEPTOR BY PARTIAL AGONISTS. C.A. Briggs* and D.G. McKenna. Neuroscience Research, D-47W, Bldg. AP10, Abbott Labs, 100 Abbott Park Rd., Abbott Park, IL 60064.

Previous studies using human $\alpha 7$ nicotinic acetylcholine receptor (nAChR) expressed in Xenopus oocytes identified substances, such ABT-089 (see also Sullivan et al., this volume) that acted as inhibitors at low micromolar concentrations and as weak partial agonists (≤15%) at higher concentrations (0.1-1 mM). The mechanism of inhibition could include channel block, competitive antagonism or receptor desensitization. In evaluating the last possibility, we determined the relative potencies and efficacies of a variety of standard compounds to act as inhibitors as well as activators of the human $\alpha 7$ nAChR expressed in Xenopus oocytes. Responses were measured using two-electrode voltage clamp in the presence of 10 mM Ba 2* to prevent secondary activation of Ca 2* -dependent CI currents, and 2 μ M atropine to prevent activation of endogenous muscarinic receptors. Acetylcholine (ACh), (-)-nicotine, (+)nicotine and dimethylphenylpiperazinium (DMPP) each inhibited the response to ACh with IC50 values 60- to 130-fold more potent than their EC50 values to activate the α 7 nAChR. The stereoselectivity of nicotine as activator was maintained when it was applied as an inhibitor. At the IC50 concentrations, these agonists activated slow responses that were only 0.6% to 1.2% of the maximal response. (-)-Cotinine elicited a 1% response at 1 mM, and inhibited the response to ACh with an IC50 of 175 μ M. L-Lobeline, surprisingly, acted only as an antagonist, eliciting no agonist-like response up to a concentration of 1 mM while inhibiting the response to ACh with an IC50 of 8.5 µM. These results are consistent with the hypothesis that weak partial agonists can appear to be more potent and effective as inhibitors than as activators of the rapid nAChR response due to receptor desensitization

DIFFERENTIAL BLOCK BY MECAMYLAMINE OF NICOTINIC SYNAPSES ON SYMPATHETIC B AND C NEURONS W-X Shen* and JP Horn Department of Neurobiology, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261.

We have previously shown that the blocking effect of mecamylamine differs between sympathetic B and C neurons. The IC_{50} for block of nicotinic transmission is 25 μ M in the B system and 5 μ M in the C system (Shen & Horn, Soc. Neurosci. Abstr. 19, 1532, 1993). We have now analyzed the underlying mechanism for this differential effect by recording nicotinic synaptic currents under voltage-clamp.

recording nicotinic synaptic currents under voltage-clamp. In 6 B cells, mecamylamine (1-8 µM) reduced the amplitude and speeded the decay of EPSCs in a voltage- and concentration-dependent manner. The mechanism was further analyzed using a sequential reaction model. The blocking rate constant (k₊B*) for mecamylamine was 6.4 x 10⁷ M·1 s·1 at -100 mV. A potential change of -91 mV gave an e-fold shift in k₊B*. This corresponds to a binding site for mecamylamine that senses 28% of the membrane field. In 3 C cells mecamylamine showed similar effects. In one cell, we succeeded in recording EPSCs over a range of holding potentials and drug doses. The k₊B* for mecamylamine block was 1.2 x 10⁷ M·1 s·1 at -100 mV. A potential change of -144 mV gave an e-fold shift in k₊B*, which corresponds to a binding site 18% into the membrane field.

These results indicate that mecamylamine acts in a similar manner on B and C neurons. Its ability to distinguish between receptors on the 2 cell types probably arises from the difference in their mean open times. (Supported by a Grant-in-Aid from the AHA, PA Affiliate).

ATROPINE INHIBITS NEURONAL NICOTINIC RECEPTORS

R. Zwart* and H.P.M. Vijverberg. Research Institute of Toxicology, Utrecht University, P.O. Box 80.176, NL-3508 TD Utrecht, The Netherlands.

The neurotransmitter acetylcholine (ACh) acts on two distinct types of receptors: G-protein coupled muscarinic receptors (mAChRs) and ionotropic nicotinic receptors (nAChRs). Atropine is a selective antagonist of mAChRs as compared to endplate nAChRs. Little is known, however, about effects of atropine on neuronal nAChRs. The finding that the recently cloned α9 nAChR is sensitive to atropine (Cell 79,705-715) prompted us to investigate the effects of atropine on various nAChR subunit combinations expressed in *Xenopus* oocytes.

1 μ M atropine inhibited 1 mM ACh-induced ion currents of α 4 β 2 nAChR to 75% and of α 4 β 4 to 45% of control values. Possible contributions of endogenous mAChRs in oocytes to the effects of atropine have been excluded. The concentration dependence of the effect of atropine on 100 μ M ACh-induced ion current revealed an IC50 of 660 nM for α 4 β 4 nAChR-mediated ton currents by an apparent non-competitive mechanism. However, at very low ACh concentrations atropine potentiated α 4 β 4 nAChR-mediated ion currents. The EC50 of the concentration-effect curve for ACh was not significantly affected, but the Emax was reduced to 49% in the presence of 1 μ M atropine. The slope factor of the curve was slightly reduced in the presence of atropine, which is likely caused by the atropine-induced potentiation at low ACh concentrations. Atropine-induced inhibition of the α 4 β 4 nAChR was voltage-dependent, suggesting open nAChR channel block as the mode of action. Supported by the Netherlands Organization for Scientific Research (N.W.O. #903.42.011).

THE ENDOGENOUS CANNABINOID, ANANDAMIDE, POTENTLY INHIBITS THE FUNCTION OF NICOTINIC α_7 RECEPTORS EXPRESSED IN XENOPUS OOCYTES. M. Oz', E. Podrasky, A. Ravindran, S. Singhal, L. Zhang and F. F. Weight Laboratory of Molecular & Cellular Neurobiology, NIAAA, NIH, Bethesda, MD 20892-8205.

Anandamide is a recently isolated endogenous ligand for cannabinoid receptors that mimics effects of cannabinoids in the CNS. Currently, little is known about cellular mechanism of anandamide actions. Recently, several studies have suggested that the modulation of brain type nicotinic acethylcholine receptors (nAChR) may be involved in some of the behavioral effects of several drugs of abuse. In this study, the effect of anandamide on the function of recombinant, homomerically expressed a, receptors was investigated in Xenopus oocytes. In the concentration range 1 nM to 5 µM, anandamide reversibly inhibited the current activated by 10 µM nicotine. The inhibition was concentration and time dependent. The IC₅₀ value for the steady-state inhibition was 29 nM, and the apparent Hill coefficient was 1.2. The effect of anandamide was not dependent upon membrane potential. Maximum responses to nicotine were also inhibited, and increasing the concentration of nicotine did not affect the inhibitory effect of anandamide. By contrast, maximal current amplitudes mediated by mouse muscle nAChR were not altered by anandamide up to the concentration of 100 nM. The results provide evidence that the endogenous cannabinoid, anandamide, can selectively and potently inhibit the function of brain type nicotinic ACh receptors. This work was supported by the intramural research program of NIAAA/NIH.

CHARACTERIZATION OF SIB-1508Y, THE ACTIVE ENANTIOMER OF A NOVEL NICOTINIC ACETYLCHOLINE RECEPTOR (NAChR) AGONIST, SIB-1765F, F. Menzaghi*, A.J. Sacaan, R.T. Reid, E. Santori, L.D. Correa, P.B. Adams, K.T. Whelan, V.B. Risbrough, T.S. Rao, J.S. Schneider and G. K. Lloyd. SIBIA Neurosciences Inc., La Jolla, CA 92037, and Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA 19102.

SIB-1765F [(±)-5-ethynylnicotine fumarate] is a novel NAChR agonist (Soc Neurosci. Abs. 25, #11.10, 1995). In this investigation, we characterized SIB-1508Y and SIB-1680WD, the two isomers of SIB-1765F. SIB-1508Y and SIB-1680WD displaced the binding of $[^3H]$ -nicotine to rat cortical membranes with IC₅₀ values of 3 and >100 nM, respectively. The rank order of potency at releasing striatal dopamine (DA) in vitro was SIB-1508Y>SIB-1765F>>SIB-1680WD. In freely moving rats both nicotine and SIB-1508Y increased hippocampal ACh release. Dopamine DI receptor activation subsequent to NAChR-induced DA release appears to be important in SIB-1508Y-evoked hippocampal ACh release as evidenced by its sensitivity to SCH-23390. Nicotine and SIB-1508Y appear to release hippocampal ACh through distinct mechanisms as the response to the former is both Mec and DH β E sensitive while the response to the latter is sensitive only to DH β E. The locomotor stimulating actions of SIB-1765F appear to be due to its active isomer SIB-1508Y as SIB-1680WD did not act as a partial agonist. Similar to SIB-1765F, SIB-1508Y potentiated the action of L-DOPA in reserpine-induced hypolocomotion. Nicotine was inactive in this model. An inactive dose of SIB-1508Y potentiated the effects of an inactive dose of L-DOPA in improving the latency for object retrieval in MPTP-treated cynomolgus monkeys (J. Schneider et al., this meeting). In addition, SIB-1508Y showed antidepressant activity in the learned helplessness model in rat while nicotine was inactive (Studies performed with ITEM-Labo, Paris, France). These results taken together suggest potential utility of SIB-1508Y in treating motor, cognitive and affective deficits in Parkinson's disease

PHARMACOLOGICAL INVESTIGATION OF LOBELINE, A NICOTINIC RECEPTOR LIGAND. M.I. Damaj * and B.R. Martin. Department of Pharmacology and Toxicology, Medical College of Virginia/Virginia Commonwealth University, Richmond, VA 23298. Lobeline, a naturally-occurring alkaloid with a binding affinity comparable to that of nicotine, has a complex pharmacological profile. In this study we evaluated the pharmacological responses of lobeline in different behavioral assays and investigated the acute and chronic tolerance to this drug in mice. Male ICR mice were used to test the effects of s.c. lobeline on locomotor activity, motor coordination, body temperature and antinociception (tail-flick test). Lobeline-induced hypomotility, hypothermia and motor impairment was dose-dependent but lobeline was less potent than nicotine. However, lobeline's effects were not blocked by neither mecamylamine nor dihydro-β-erythroidine, two known nicotinic antagonists. On the other hand, lobeline elicited little antinociception by itself but significantly enhanced nicotine's antinociceptive effects. In another group of mice, lobeline injected intrathecally (i.t.) induced a dose-dependent antinociceptive effect. Acute tolerance to lobeline-induced hypothermia, motor impairment and antinociception (after i.t. injection) did not develop after one-dose or repeated injections. In contrast, tolerance developed to lobeline's effects after chronic treatment with lobeline (15 mg/kg twice a day for 10 days). Furthermore, cross-tolerance to nicotine-induced hypomotility and hypothermia was observed in mice rendered tolerant to lobeline and its interaction with nicotine. (Supported by NIDA grant #DA-05274).

EVIDENCE THAT PHOSPHORYLATION EVENTS AND PROTEIN SYNTHESIS ARE IMPORTANT IN NICOTINIC RECEPTOR TURNOVER IN BOVINE ADRENAL CHROMAFFIN CELLS. B.W. Wenger, R.T. Boyd*, and D.B. McKay. Division of Pharmacology, The Ohio State University College of Pharmacy, Columbus, OH 43210

In these studies, the ability of bromoacetylcholine (brACh) to induce nicotinic acetylcholine receptor (nAChR) turnover in cultured bovine adrenal chromaffin cells was investigated. Several protein kinase inhibitors and a protein synthesis inhibitor were also tested for their ability to affect turnover. Under reducing conditions, brACh treatment causes a rapid loss of nAChR-stimulated adrenal catecholamine release, but is without effect on catecholamine release stimulated with depolarizing concentrations of KCl (56mM). The effects of brACh are concentration-dependent (IC50, ~300 nM) and at concentrations > 10 µM, brACh eliminates > 90% of nAChR-stimulated release. Recovery of nAChR-stimulated secretory response following brACh treatment occurs slowly. After 100 µM brACh treatment, a functional recovery rate of ~2-3% per hr is observed, with full recovery achieved within 48 hrs. The protein synthesis inhibitor, cycloheximide (5 μ g/ml), prevents recovery of nAChR-stimulated secretion. When present during the recovery period (24 hr), the protein kinase inhibitors, chelerythrine chloride (10 µM), K252a (1 μ M) and H-7 (50 μ M), prevent full recovery of the functional response, while having no effects on control, non-brACh treated cells. H-8 (50 μ M), another protein kinase inhibitor, has little or no effect on recovery. These studies support the ability of brACh to induce nAChR turnover. These studies also provide evidence that nAChR functional recovery involves protein synthesis and that phosphorylation events contribute to the recovery process.

LOBELINE: AN ATYPICAL NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR (NACHR) AGONIST. A. I. Sacaan*, F. M. Menzaghi, R. T. Reid, E. M. Santori, L. D. Correa, K. T. Whelan, G. K. Lloyd, and T. S. Rao, SIBIA Neurosciences Inc., La Jolla, CA 92037.

Lobeline (LOB) and nicotine (NIC) are known to show differential pharmacological effects. These include a lack of effect of LOB on **Pkb-efflux from mouse fibroblasts stably transfected with cDNAs encoding the chick α4β2 subunits and on prepulse inhibition in an acoustic startle assay in rats. In this study, effects of LOB were compared to NIC and SIB-1765F (±)-5-ethynylnicotine fumnarate] in several assays. Unlike NIC and SIB-1765F, LOB-induced increases in striatal and olfactory tubercle DA release were relatively mecamylamine (Mec) and dihydro-β-erythroidine (DHβE)-insensitive and Ca**-independent. NIC-, but not LOB-induced hippocampal NE release was Mec-sensitive and Ca**-dependent. LOB attenuated basal striatal ACh release in a sulprirde-independent mechanism. In contrast to NIC, LOB attenuated N-methyl-D-aspartate (NMDA)-evoked striatal ACh release in a Mec or DHβE-insensitive manner with an IC₅₀ of 35 μM. LOB however, did not affect NMDA-evoked hippocampal NE release suggesting that LOB is not a general NMDA antagonist. Both NIC and LOB increased hippocampal ACh release in vivo. Unlike NIC and SIB-1765F which increased striatal and n. accumbens DA release in vivo. Unlike NIC and SIB-1765F which increased striatal and n. accumbens DA release and failed to induce turning behavior in 6-OHDA-lesioned rats, LOB decreased striatal DA in a Mec-sensitive manner, did not significantly alter n. accumbens DA release and failed to induce turning behavior. Consistent with this profile, NIC and SIB-1765F, but not LOB increased locomotor activity in rats that were acclimated to activity cages. In addition, LOB produced pronounced transient locomotor depressant effects in naive rats as compared to NIC and SIB-1765F. In contrast to NIC, the locomotor depressant effects of LOB were insensitive to blockade by NAChR antagonists Mec, hexamethonium (Hex) and DHβE. Repeated administration of LOB (2 mg/kg/sc twice a day for 4 days) resulted in a tolerance to locomotor depressant effects and did not alter locomotor simulant e

PRESYNAPTIC NICOTINIC RECEPTORS ENHANCE GLUTAMATE RELEASE IN THE HIPPOCAMPAL SLICE AND RAISE Ca IN SINGLE MOSSY FIBER TERMINALS. R. Gray* and J.A. Dani. Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

Nicotine applied locally onto the dendrites of a CA3 neuron increased the frequency of glutamatergic miniature excitatory postsynaptic currents (mEPSCs). Furthermore, when mossy fiber presynaptic terminals where loaded with fura-2, local application of nicotine induced a Ca influx that could be measured from single mossy fiber terminals.

Hippocampal slices (200-400 μm) were prepared from Sprague-Dawley rats. Na and Ca channels were inhibited by 1 μM TTX and 200 μM Cd. CA3 neuron were whole-cell voltage clamped and mEPSCs were collected before, during, and after a pressure puff of 20 μM nicotine directed toward the dendrites. The frequency but not the amplitudes of the mEPSCs increased, consistent with a presynaptic effect. We then loaded presynaptic mossy fiber terminals in the CA3 region with fura-2AM. Pressure puffs of 20 μM Nic produced changes in the fura-2 signals from individual mossy fiber terminals consistent with a presynaptic Ca influx. The results indicate that cholinergic innervation or applied nicotine is capable of altering glutamatergic synaptic transmission in the hippocampus. The results are consistent with presynaptic nicotinic receptors mediating a Ca influx that then enhances glutamate release. Supported by NIH, NINDS; Smokeless Tobacco Research Council.

ROLE OF NITRIC OXIDE IN NICOTINIC RECEPTOR INDUCED MYOPATHY. M.D. El-Dada* and M. Quik. Dept. Pharmacology, McGill Univ., Montreal, Quebec, Canada.

Previous studies have shown that nicotinic cholinergic agonists mediate a calcium-dependent muscle cell degeneration. Recently nitric oxide The present (NO) synthase was identified in skeletal muscle. experiments test whether this intracellular messenger is involved in agonist induced myopathy. Both the irreversible NO synthase inhibitor L-N-iminoethylornithine (NIO) and L-nitroarginine methyl ester, a reversible inhibitor, protected the muscle cells from the myopathic effects of nicotine. These results suggest that nicotinic receptor stimulation produces an increase in NO to result in muscle cell degeneration. In line with this interpretation, exposure of the muscle cultures to the NO donor sodium nitroprusside (SNP) resulted in a dose dependent decline in myotube branch points. Neither NIO nor SNP altered the binding of $^{125}I-\alpha$ -bungarotoxin to muscle cells in culture, indicating that the effect of these agents was not mediated through an interaction at the nicotinic receptor. In many systems, NO mediates its effects through cGMP. Exposure of the muscle cultures to cGMP analogs produced a muscle cell degeneration which was not additive with that of nicotine, while the guanylate cyclase inhibitor LY 83583 protected against the myopathic effects of nicotine. The present results suggest that nicotinic receptor activation results in skeletal muscle degeneration through the production of NO and a subsequent activation of guanylate cyclase. Supported by the MRC and Verum Foundation.

NICOTINIC RECEPTOR MEDIATED CALCIUM MOBILIZATION AND ENHANCED GROWTH IN CELLS STABLY EXPRESSING RAT α7 RECEPTORS. M. Quik* and B. Weinberger. Pharmacology, McGill Univ., Montreal, Quebec, Canada.

Our previous work had demonstrated stable expression of rat α 7 α bungarotoxin (α -BGT) binding sites by GH_4C_1 rat pituitary cells, a clonal line which does not endogenously express nicotinic receptors. The stably expressed α 7 sites were similar to rat brain α -BGT receptors in terms of binding affinities, pharmacological profiles, kinetic properties and molecular size, suggesting that they represent a good model system for studying the α 7 receptor. The present data show that nicotinic receptor agonists increase intracellular calcium mobilization (fura 2-AM) in α7/GH₄C₁ cells in a dose dependent manner with EC₅₀'s of 0.2, 2, 5 and 10 µM for epibatidine, nicotine, dimethylphenylpiperazinium and acetylcholine, respectively. The agonist evoked responses were completely inhibited by α -BGT, methyllycaconitine and d-tubocurarine. Interestingly, the α^7/GH_4C_1 cells exhibited differential growth related properties as compared to control cells. Nicotine at 10^5 M resulted in a long term increase in cell number, which was not observed in untransfected cells or transfected cells not expressing α -BGT receptors. In addition, the cells expressing receptors appeared more adherent than control cells. The present results suggest that activation of stably expressed $\alpha 7$ α -BGT receptors, which results in a mobilization of intracellular calcium, may lead to long term effects on cellular growth. Supported by the MRC and Verum Foundation.

INDUCTION OF C-FOS PROTEIN IN THE RAT BRAIN AFTER ACUTE AND REPEATED INJECTIONS OF NICOTINE. A.M. Mathieu, C. Pages, B. Zalc*, M.J. Besson, Lab. Neurochimie-Anatomie, IDN, UPMC, URA 1488, 9 Quai St Bernard, 75005 & Lab. Neurobiology Cell. Mol. Clin., INSERM U134, 75013 Paris

The detection of the immediate early gene c-fos acting as a third messenger, coupling cell surface events to gene expression, has been widely used as a functional marker. In order to identify brain regions potentially involved in psychostimulant properties of nicotine, we have analyzed the induction of c-Fos protein 90 min after a single (0.35 mg/kg, sc.) and a repeated (0.35 mg/kg, 3x day, 15 days, sc.) injection of nicotine. A high number of c-Fos positive nuclei was observed in the anterior part of the cerebral cortex (medial prefrontal, cingulate and orbital cortices) and posterior part whereas a moderate number of positive nuclei was observed in the sensorimotor cortex. The pyriform cortex exhibited a particular strong immunoreactivity. In subcortical structures, c-Fos positive nuclei were visualized in the dorsal striatum (only in the medial part) and in the nucleus accumbens (rostral pole and cone of the shell). More caudally, immunostained nuclei were localized in the ventral pallidum and the substantia innominata. An induction was also obvious in the superficial layers of the superior colliculus and in the pontine nucleus. A prior mecamylamine injection (1mg/kg, ip) antagonized the nicotine effects. Following repeated injections of nicotine, c-Fos was still expressed in these various structures but the number of c-Fos positive nuclei was less abundant, suggesting a desensibilisation of c-Fos expression. In all these responsive regions, a high to moderate density of nicotine binding sites and of mRNA encoding subunits of the nicotinic receptor has been described. Several regions (thalamus, cerebellum, mesencephalic DA neurons) with high levels of nicotinic receptors failed, however, to express c-Fos. The region specific effects suggests that the nicotine-induced c-Fos expression may involved a specific nicotinic receptor subunit combination Supported by MESR (contract 94 VO253)

NICOTINE STIMULATED RELEASE OF [3H]NOREPINEPHRINE FROM CULTURED LOCUS COERULEUS CELLS. K.A. Gallardo* F.M. Leslie. Department of Pharmacology, College of Medicine, University of California, Irvine,

The structure and function of neuronal nicotinic acetylcholine receptors (nAChR) are of primary importance in clucidating the effect of nicotine on the developing central nervous system (CNS). Morphological and molecular studies of developing central nervous system (CNS). Morphological and molecular studies of these pentameric ion channels suggest receptor subtype heterogeneity exhibited by differential subunit expression in rat brain. Upon stimulation of central nAChRs diverse cellular responses can be measured depending on the age and type of tissue being examined. We have chosen to assess the functional properties of a subpopulation of nAChRs by examining the release of norepinephrine (NE) from primary dissociated locus coeruleus cells in culture. Cells were harvested from rostral hombencephalon of E14 Sprague-Dawley rat embryos, cultured for 4 days, then preloaded with [3 H]NE. Following a washout period, the effect of various nicotinic agonists and antagonists on [3 H]NE release was examined. Nicotine was a full agonist with an E $_{\rm CS}$ 0 of 0.63 \pm 0.07 uM, DMPP was as a weak partial agonist, whereas cytisine, lobeline, and DH $_{\rm F}$ E were without agonist effect but antagonized nicotine's actions. Preliminary data indicate the presence of a functional $\alpha_{\rm AB}$ 2 receptor subtype when compared to existing pharmacological profiles of known receptor subtype when compared to existing pharmacological profiles of known receptor subunit combinations. An anatomical survey was also performed using *in situ* hybridization techniques to confirm the presence of α_i and β_2 mRNA, and to establish the presence of any other nAChR subunit mRNA. Embryonic, neonatal and adult time points were analyzed. These data suggest that the nicotinic receptors on LC cells during early embryogenesis are of the $\alpha_s\beta_s$ subtype, but does not exclude the presence of other combinations. Work in progress involves a more complete pharmacological characterization of the nAChRs in this system. *PHS grant* #19319 and 30109

ACRTYLCHOLING RECEPTORS: NICOTINIC-RECOMBINANT

Isolation and Localization of the Human Neuronal Nicotinic Acetylcholine Receptor Alpha 2 Subunit. L. Monteggia*, Weverst, J-M Roch, E. Touma, K. Idler, H. Schrodert, and J.P. Neuroscience Research, Abbott Laboratories, Abbott Park, IL 60064-3500 and †Department of Anatomy, University of Koln, Koln, Germany.

Neuronal nicotinc acetylcholine receptors (nAChRs) are members of the ligand gated ion channel gene superfamily. nAChRs are composed of two types of subunits, ligand-binding α subunits $(\alpha 2 - \alpha 9)$ and structural β subunits $(\beta 2 - \beta 4)$. The structural, biophysical, and pharmacological properties of a number of human nAChRs have been reported however, no information regarding the human $~\alpha 2$ subunit currently exists. In rat the $\alpha 2$ subunit is characterized by a very restricted localization and discrete pharmacological properties. In this present report, we describe the initial characteristics of the human $\alpha 2$ subunit. Human $\alpha 2$ was cloned from whole human brain and shown to contain an open reading frame of 1587bp. The proposed mature $\alpha 2$ protein is composed of 472 amino acids preceeded by a leader sequence of 57 residues. The $\alpha 2$ protein has three potential N-linked glycosylation sites at residues 79, 129 and 235. Additionally, potential protein kinase C phosphorylation sites exist at residues 132, 242 and 488 while a potential tyrosine kinase phosphorylation site exists at residue 468. The human $\alpha 2$ subunit has 84% amino acid identity with rat $\alpha 2$. In situ hybridization studies to assess the distribution of the $\alpha 2$ transcript in human brain are ongoing. (Supported by Abbott Laboratories)

The General Anesthetic Propofol inhibits ACh response in heterologously expressed a3b4 nAChRs and in Sympathetic neurons in culture. P. Flood, R. Girod*, J. Ramirez-Latorre and L. Role. Departments of Anesthesiology and Anatomy and Cell Biology in the Center for Neurobiology & Behavior, Columbia Univ., P&S, 722 W. 168th St. NY, NY 10032. General anesthetic agents are a diverse variety of particularly toxic compounds used in clinical medicine today. Many of these agents have been shown to act potently and specifically at ligand gated ion channels in the CNS. We have recently reported potent inhibition of the α4β2 type nAChR. Here we report inhibition of the α3β4 nAChR and inhibition of ACh mediated current in sympathetic ganglia cells in culture by the general anesthetic, propofol.

RNA for the chick α3 and β4 subunits were expressed in Xenopus laevis oocytes, and studied with standard two electrode voltage clamp methodology. The oocytes expressing α3β4 nAChRs were exposed to a pulse of 1 μM ACh in a continuous perfusion chamber with or without an escalating concentration of Propofol from 12nM to 2μM (Clinical EC.50 x 1/32-5). ACh mediated current from heterologously expressed α3β4 receptors was reduced by propofol application to a maximum inhibition of 60% in the presence of 2 μM propofol.

Sympathetic ganglia were dissected from E11 chick and cultured for 3-5 days. Whole cell currents were recorded from these sympathetic neurons. 5 second pulses of 5 μM ACh were pressure applied to the neurons and evoked whole cell currents were measured using standard patch clamp methodology. 400 nM Propofol was preapplied for ten seconds prior to ACh application as above. Ach mediated current is mympathetic neurons was reduced 90% by 0.4 μM propofol.

Propofol inhibits the ACh mediated currents in heterologously expressed α3β4 nAChRs and in sympathetic neurons was reduced 90% by 0.4 μM propofol, was preapplied for ten seconds prior to ACh application in the cultured neurons was more profound, perhaps because of the particip

NICOTINIC RECEPTOR SUBUNIT mRNAs IN DEVELOPING RAT HIPPOCAMPUS VIA RT-PCR. T. Moreira, E. F. R. Pereira, D. R. Burt*. Dept. of Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD

Nicotinic responses in hippocampal neurons increase during development. We studied the level of mRNAs for several neuronal type nicotinic subunits $(\alpha_3,\alpha_4,\alpha_5,\alpha_7,\beta_2,\beta_3,\beta_4)$ in postnatally developing neurons in the hippocampus (days P1, P7, P16 and P21). We extracted total RNA from rat hippocampi dissected at the different ages and reverse transcribed (RT) it into cDNA with random priming. We made a pair of primers spanning at least one intron for each subunit and performed polymerase chain reactions (PCR). The β_4 band was stronger at P7 and P16 than at other ages (P1 and P21). Similar results were seen with α_3 . The composition $\alpha_3 \beta_4$ is proposed to be one of the possible subunit combinations of native nicotinic receptors expressed in hippocampal neurons. The mRNA signals for both subunits appear to rise together. The α_s band was present at P1, P7 and P16 but hardly detected at P21. The α_s band was detected strongly in all ages but peaked in intensity at P16. The β_2 band was present throughout development, with a gradual increase with age. Thus, although α_4 β₂ is another proposed receptor combination in native hippocampal nicotinic receptors, the correlation of developmental patterns of the two subunits is not as clear as for $\alpha_3\beta_4$. The α, mRNA appeared to be by far the most abundant, with a slight increase during development and a possible peak at P16. The α_7 homopentamer is thought to give to rise to the most widespread type of response, type IA, in hippocampal cultures. These qualitative changes in mRNA levels in vivo appear to be consistent with existing functional data for changes in nicotinic response patterns in hippocampal neurons developing in vivo and in vitro. FORMATION OF THE DIFFERENT ACETYLCHOLINE (ACH) BINDING SITES DURING ACH RECEPTOR ASSEMBLY. C.P. Wanamaker, M.A. Gertz & W.N. Green*. Dept. Pharm. & Physiol. Sci., University of Chicago, Chicago IL 60637

The 2 ACh binding sites of the ACh receptor (AChR) are located on different α subunits at or near the interface with either the γ(αγ) or δ (αδ) subunits. To determine when each of the two ACh binding sites form during assembly, subunit complexes were precipitated using bromoACh affinity resin or α-Bungarotoxin (BuTx)-sepharose. The first ACh binding site forms at about the same time as the first BuTx site and the epitope for monoclonal antibody (mAb) 14, which indicates that this site forms on αβγ trimers just before the addition of the δ subunit. The second ACh site forms soon after the addition of the second α subunit to the αβγδ tetramers. Pharmacological and immunological probes were used to distinguish the two ACh sites. D-tubocurare (dTC) binds to the αγ ACh site with a higher affinity than to the αβ ACh site. Based on dTC competion of ¹²⁵I-BuTx binding, subunit complexes that assemble early (trimers and tetramers) have the high affinity dTC site. Using a mAb specific for the αγ site (mAb 247g from R. Fairclough, U.C. Davis), we immunoprecipitated αβγ trimers and αβγδ tetramers. We conclude that the αγ ACh site is the first site to form and does so on αβγ trimers just prior to the addition of the δ subunit. The αδ ACh site appears later soon after α2βγδ pentamers assemble. The order of ACh site formation provides evidence for the subunit arrangement of the trimers and tetramers and places the δ subunit recognition site at the γ-β subunit interface of the αβγ trimer. FUNCTIONAL ROLE OF THE α 5 SUBUNIT IN THE HUMAN RECOMBINANT α 3 ACHRS. F. Wang*, V. Gerzanich, and J. Lindstrom. Dept. of Neuroscience, Univ. of Pennsylvania Med. Sch., Philadelphia, PA, 19104-6074. cRNA's encoding α 3, β 2, and α 5 or α 3, β 4, and α 5 nicotinic acetylcholine receptor (AChR) subunits yielded functional AChRs containing α 5 subunits in *Xenopus* oocytes. The epitope for mAb 142 was inserted at the C-terminus of α 5 to immunotag this subunit. Efficient coassembly of the α 5 subunit with α 3 β 2 or α 3 β 4 AChRs combinations was proven by immunoisolating α 5-containing AChRs Efficient coassembly of the αS subunit with $\alpha \beta \beta Z$ or $\alpha \beta \beta A$ combinations was proven by immunoisolating αS -containing AChRs with mAb 142-coupled Actigel. Surface expression of the αS -containing AChRs was shown by surface labeling with mAb 142. No functional AChRs were detected after expression of αS alone or in pairwise combinations with αS , βZ , and βA subunits. The presence of αS subunits increased the rate of the desensitization of AChRs containing both αS and βZ or αS and βS or αS at αS to αS and αS or αS and αS or αS and αS or αS and αS or αS and αS or αS and αS or αS and αS or αS and αS or αS and αS or αS and αS or αS and αS or αS or αS or αS and αS or α as du not change voltage-dependence of α 3p2 of α 3p4 AChRs. α 5 caused only subtle changes in the activation potencies or equilibrium binding affinities of α 3 AChRs for ACh, nicotine, cytisine or DMPP. However, addition of α 5 to α 3 and β 2 subunits increased the efficacy for nicotine from 50% to 100%, and for DMPP from 107% to 183%. By contrast, addition of α 5 to α 3 and β 4 subunits decreased the efficacy for nicotine from 100% to 90%, and for DMPP from 100% to 13%. The pharmacological properties of α 3β2, α 3β2 α 5, α 3β4 and α 3β4 α 5. ACRB were compared to notive α 3. AChR from the burson α3β4α5 AChRs were compared to native α3 AChRs from the human neuroblastoma cell line IMR-32.

THE ROLE OF THE CYSTINE LOOP IN ACETYLCHO-LINE RECEPTOR ASSEMBLY. W. N. Green, S. V. Rakhilin* and C. P. Wanamaker. Department of Pharmacological & Physiological Sciences, University of Chicago, Chicago, IL 60637.

Nicotinic acetylcholine receptors (AChRs) contain α, β, γ and δ subunits assembled into α2βγδ pentamers. A highly conserved region of ionotropic neurotransmitter receptors is a 15 amino acid cystine loop. We have addressed whether the cystine loop is involved in AChR subunit assembly. AChR subunit assembly was assayed using an 35S-methionine pulse-chase protocol. With the addition of 5 mM DTT to reduce disulfide bonds on all 4 subunits, the subunits assemble into αβγ trimers, but all subsequent steps in assembly is blocked at the same step as with DTT. However, when homologous β subunit cysteines are mutated to serines, assembly proceeds further and is blocked at a later step, between the assembly of αβγδ tetramers and α2βγδ pentamers. Using a monoclonal antibody (mAb) that recognizes only the intact α subunit cystine loop (from J. Lindstrom, U. Penn.), we demonstrate that the α subunit mutation. The mAb precipitated αβγ trimers at early chase times, after which the epitope disappeared and the subunits could not be precipitated at later chase times. The disappearance of the epitope is a conformational change that buries the epitope since the epitope reemerges when the subunits are denatured. The cystine loop conformational change occurs at the same step in assembly as the block by DTT and the α subunit traction indicating that this step in assembly requires a conformational change of the cystine loop. The data suggest that the δ subunit recognition site forms after a series of folding events key to which is the cystine loop conformational change. THE C-TERMINAL REGION OF THE γ SUBUNIT IS NEEDED FOR FULL ASSEMBLY OF THE ACETYLCHOLINE RECEPTOR. A.L. Eertmoed* and W.N. Green. Committee on Neurobiology, University of Chicago, Chicago, IL 60637.

Fast excitatory transmission is mediated by a family of heterooligomeric neurotransmitter-gated ion channels, of which the nicotinic acetylcholine receptor (AChR) is the best characterized member. We are attempting to identify regions of the AchR subunits important for oligomerization by creating chimeric subunits and examining their ability to associate with wild-type subunits. A chimeric subunit (δγ) consisting of the extracellular N-terminus of the δ subunit fused to the region of the γ subunit from the first transmembrane domain (M1) to ability to associate which white-type subunits. A Chilherte Subunit (oy) consisting of the extracellular N-terminus of the δ subunit fused to the region of the γ subunit from the first transmembrane domain (M1) to the C-terminus is able to associate with the α , β , and γ subunits to form cell surface receptors which bind the AChR antagonist, α -bungarotoxin (BuTx). These results suggest that the N-terminus of δ is sufficient to direct assembly of this subunit. In contrast, the reverse chimera ($\gamma\delta$), which consists of the N-terminus of δ , does not associate with α , β , and δ subunits to form cell-surface complexes that bind BuTx. The $\gamma\delta$ chimera associates with the α and β subunits, but does not form BuTx binding sites, and in fact prevents the formation of these sites when cotransfected with all four wild-type subunits. Thus, the C-terminal region of γ is needed for the complete assembly of the AChR. Without this region assembly is blocked. The block occurs after α trimers assemble and before formation of the BuTx binding site and the addition of the δ subunit. These results suggest that the C-terminal half of the γ subunit is involved in the folding events occurring during the formation of the δ subunit recognition site. CAN FORM A ACETYLCHOLINE NICOTINIC AChR SUBUNIT HETEROMERIC FUNCTIONAL RECEPTOR V. Gerzanich, A. Kuryatov, R. Anand, and J. Lindstrom*. Departments of Neuroscience and Pharmacology, Univ. of

Pennsylvania Med. Sch., Philadelphia, PA, 19104-6074.

Previously, a rat brain cDNA was reported which was designated α6 because of its homology with nicotinic acetylcholine receptor (AChR) α subunits. α6 is especially homologous to α3, yet no ACh-gated cation channels were detected when it was expressed in Xenopus oocytes alone or in combination with other known rat AChR subunits. We cloned chicken $\alpha 6$ and human $\beta 4$ AChR subunits and subunits. We coned enclosed the data and infinite p4 ACIR subunits and occytes alone or in pairwise combination with chicken $\alpha3$, $\beta2$, $\beta4$ or human $\alpha3$, $\beta2$, $\beta4$ ACIR subunits. Chicken $\alpha6$ formed detectable functional ACIRs only when expressed together with the human $\beta4$ subunit. The $\alpha6\beta4$ ACIR mediated currents showing strong inward restification, and dependence on extraogulate Cott. rectification and dependence on extracellular Ca^{**} . It exhibited a distinct pharmacological profile with an EC_{50} for ACh of 28 μ M, for (+)-epibatidine of 24 nM, cytisine of 6.6 μ M and DMPP of 15 μ M. Both cytisine and DMPP behaved as partial (-30 %) agonists. Nicotine Both cytisine and DMPP behaved as partial (-30%) agonists. Nicotine (EC₅₀ = 22 μ M) was an even weaker partial agonist (\sim 18%) and had a relatively long lasting inhibitory effect. Coexpression of the previously cloned rat α 6 subunit with the human the β 4 subunit also resulted in functional α 6 β 4 AChRs with properties resembling those of the chicken/human α 6 β 4 AChRs. Thus, α 6 can function as part of AChRs with unusual pharmacological properties.

Subunit dependent desensitization of neuronal nicotinic receptors at low concentrations of nicotine. Robin A.J. Lester and Michael W. Quick. Neurobiology Research Center and the Department of Physiology & Biophysics, University of Alabama at Birmingham, Birmingham AL 35294.

Both activation and desensitization of CNS neuronal nicotinic acetylcholine receptors (nAChRs) have critical roles in nicotine addiction. Because these functional properties are determined by the subunit composition, and subtypes of nAChRs show differential expression in various brain regions, information regarding the subunit specific interactions between nicotine and the receptor will be important. We have compared the activation (EC₅₀) and desensitization (IC₅₀) dose-responses for purious combinations. for various combinations of nAChR subunits expressed in Xenopus oocytes. Desensitization properties were determined from the change in the amplitude of a test pulse (5-10 s) of acetylcholine (10-300 μ M). The data imply that the effective concentrations of nicotine for nAChR desensitization and the time course of its onset and recovery are highly dependent on the receptor composition.

subunit type	$\begin{array}{c} EC_{50} \\ (\mu M) \end{array}$			desensitization		
		IC ₅₀ (μM)	block at 1 μΜ	max. block	onset (min)	recovery (min)
α7	127	4.0	0.13	1.0	~3	~5
α3β2	60	0.2	0.63	0.75	~4	~12
α3β4	48	1.5*	0.45	1.0	~50	~40

LEUCINE MUTATIONS AT THE 9' POSITIONS OF THE M2 DOMAIN IN ACHR CHANGE THE CHANNEL GATING AND SIMULATED SYNAPTIC RESPONSE. H. Zhang*, C. Labarca, P. Deshpande, Y. Zhang and H. A. Lester. Division of Biology, 156-29, Caltech, Pasadena, CA 91125

Mutation of a highly conserved Leucine residue to Serine at the 9' position of the M2 transmembrane domain of mouse muscle nicotinic ACh receptors (nAChR) produces a ~10-fold leftward shift in the ACh doseresponse relation for each subunit mutated. We expressed nAChRs with varying numbers (m*s) of Leu9 Ser mutated subunits in Xenopus oocytes and studied single-channel properties in outside-out patches with symmetrical KCl solutions. ACh-induced openings at mutated AChRs have (1) longer openings and bursts, (2) briefer closed times, and (3) more frequent spontaneous openings. These effects increase with m*, For example, average channel open times for wild type $\alpha_2\beta\gamma\delta$ and for $\alpha^*_2\beta^*\gamma\delta^*$ $(m*_s = 4)$ receptors are 1.8 ± 0.3 ms and 40 ± 5 ms, respectively. spontaneous openings, however, have the average open time of 0.24 ± 0.02 ms for all m*_s > 0. Synthesized postsynaptic currents, produced with a piezoelectric micromanipulator that delivered ACh pulses, decayed as expected from channel burst durations: for $\alpha_2^*\beta^*\gamma\delta^*$ (m*_s = 4), the time constant is 2,200±500 ms, ≥100 fold higher than for wild type. Thus (1) both longer and more frequent openings contribute to the ≥10⁴ fold shift in EC₅₀ between wild type and $m*_s = 5$; and (2) the highly conserved 9' Leucine is crucial for appropriately brief synaptic events

STABLE FUNCTIONAL EXPRESSION OF THE NEURONAL NICOTINIC STABLE FUNCTIONAL EXPRESSION OF THE NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR α3β4 IN MEL (MURINE ERYTHROLEUKEMIA) CELLS: A NOVEL EXPRESSION SYSTEM FOR LIGAND GATED ION CHANNELS. M. Garcia-Alonso *1, SJ Dunbar¹, JD Windass¹, M. Needham², M. Criado³. ¹ ZENECA Agrochemicals, Jealotts Hill, Bracknell, Berkshire, RG42 6FT, United Kingdom. ² ZENECA Pharmaceuticals, Alderley Park, Macclesfield, Cheshire SK10 4TJ. ³ Universidad de Alicante, Dpto. de Neuroquimica, Campus de San Juan, Ap. correos 374, 03080, Alicante, Spain.

MEL cells are erythroid progenitor cells which have been infected with the Friend virus complex and thus arrested at the pro-erythroblast stage. In recent years a novel method for high level of expression of heterologous proteins has been developed at ZENECA using MEL cells (Needham et al. 1992 Nucleic Acid Research 20 997-1003). The overall expression levels were increased using the human $\beta\mbox{-globin}$ promoter, the $\beta\mbox{-globin gene}$ (which provides mRNA processing and maturation signals) and the locus control region (LCR) which confers position-independent expression of stably transfected genes linked in cis. Here we describe the use of this system for the expression of a neuronal nicotinic acetylcholine receptor $\alpha 3 (bovine)/\beta 4 (rat)$. MEL cells were transfected with equal amounts of both cDNAs, confirmed by Northern Blot analysis. Clones containing both sub-units were studied electrophysiologically using whole cell patch-clamp and pressure application of the agonist DMPP (100µM). Rapidly desensitising currents were detected, indicating that expression of the receptor was functional. The simplicity and speed of the MEL/LCR system affords advantages over many other expression systems, such as Xenopus oocytes, for the detection of functional activity of receptors and ion channels

Ca⁺² MODULATION OF α4β2 AND α4α5β2 COMBINATIONS OF NEURONAL NICOTINIC RÉCEPTORS.

C. Yu*, J.A. Ramirez-Latorre and L.Role. Center for Neurobiology & Behavior,

Columbia University. 722W 168th St. New York, NY 10032. We have studied the modulatory effects of Ca^{+2} on the α 4 β 2 and α 5 α 4 β 2 combinations. With increasing Ca^{+2} Ext to mM levels, we observe a decrease in single channel conductance and an increase in open probability. If Ca^{+2} Ext is maintained at µM levels, multiple transitions within opennings of individual channels i.e. The openings transit between the normal conducting state and two or more additional states. Increasing ${\rm Ca}^{+2}{\rm Ext}$ to mM concentration reduces the conductance states to one.

Ca⁺² produces a potentiation on the α4β2 combination of similar magnitude to that produced by MTSEA, a positively charged sulfyhdryl reagent. We have also observed that MTSEA interferes with the potentiating effects of ${\rm Ca}^{+2}$ in the α4β2 combinations. At the single channel level, Ca+2 and MTSEA increase the open time of the channel, decrease the single channel conductance and affect the optimited the channel, decrease the single channel conductance and arter the rate of desensitization at concentrations of ACh ranging from 1 to 100 μ M. In outside out patches, $\alpha 4\beta 2$ channels reacted with MTSEA have lower apparent permeability to Ca^{+2} . The presence of $\alpha 5$ in the complex affects the permeability and the kinetics caused by alteration of external Ca^{+2} concentrations. Mutational analysis of the $\alpha 4$ sequence implicates a Cys residue in the intracellular M2 domain as being part of a modulatory Ca^{+2} site. We are currently examining whether comparable Cys residues in either αS or in the β subunit are similarly implicated in Ca⁺² modulation. Supported by NS22061.

SUSTAINED NICOTINE EXPOSURE INCREASES PHOSPHORYLATION OF THE lpha4 SUBUNIT OF lpha4eta2 NEURONAL NICOTINIC RECEPTORS EXPRESSED IN XENOPUS OOCYTES BY BOTH CYCLIC AMP-DEPENDENT PROTEIN KINASE AND A TYROSINE KINASE. <u>Y-N. Hsu. S.C. Edwards, and L. Wecker*.</u>
Dept. Pharmacol., Univ. South Florida Coll. of Med., Tampa, FL 33612.
Studies have shown that the chronic administration of nicotine to rats

increases the density of nicotinic receptors, but decreases the ability of nicotine to release acetylcholine (ACh) from brain slices. In addition, we have demonstrated that nicotine-induced currents in *Xenopus* oocytes expressing α4β2 receptors are significantly reduced following 24 hour exposure to 1-50 nM nicotine. To determine whether this nicotineinduced loss of function involved alterations in the state of phosphorylation of the receptor, the cRNAs for $\alpha 4$ and $\beta 2$ subunits were coinjected into oocytes, and cells were incubated for 24 hours in media in the absence or presence of 50 nM nicotine. Receptors were isolated from a detergent-solubilized membrane fraction using an ACh-AffiGel affinity column and immunoprecipitated with a β2 monoclonal antibody (mAb270, J. Lindstrom) and protein G Sepharose. When receptors were either: a) treated with the catalytic subunit of PKA and 32 P-labeled ATP, separated by SDS PAGE, and visualized by autogradiography; or b) subject to western blot analysis with an antiphosphotyrosine antibody, results indicated that phosphorylation the α 4 subunit by both PKA and a phosphotyrosine kinase was increased significantly by sustained exposure to nicotine. Results support the idea that nicotine-induced receptor phosphorylation may mediate decreased receptor function. (Supported by grant 0411 from the STRC, Inc.)

HEK293 CELLS STABLY EXPRESSING RECOMBINANT HUMAN NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS $\alpha3\beta2$ AND $\alpha4\beta2$ DISPLAY DIFFERENTIAL SENSITIVITY TO EXTERNAL Ca^{2*}. L.S. Mahaffy, K.A. Stauderman*, L.E. Chavez-Noriega, J. Crona, and J. Corey-Naeve. SIBIA Neurosciences, Inc., La Jolla, CA 92037.

We examined the influence of external Ca²⁺ on agonist-induced responses in HEK293 cells stably transfected with cDNAs encoding full-length human neurona nicotinic acetylcholine receptor (nAChR) subunit combinations α3β2 (A3B2.1) and α4β2 (A4B2.1; see also Chavez-Noriega et al., this meeting). In whole-cell recordings, application of ACh, DMPP, or nicotine evoked inward currents in both A4B2.1 and A3B2.1 cells that were 2-3 fold larger when external [Ca2+] was raised from 2 to 20 mM. In comparison to the electrophysiology, single-cell imaging of nicotine-evoked increases of cytosolic $[Ca^{2+}]$ ($[Ca^{2+}]$), revealed that elevating external Ca2+ from 2 to 20 mM increased the percentage of A4B2.1 cells responding to nicotine from 68% to 96%, whereas the percentage of responding A3B2.1 cells increased from 5% to 97%. Furthermore, the magnitudes of nicotine-evoked [Ca²¹], signals were 3.6- and 23-fold larger in 20 mM external Ca²⁺ in the A4B2.1 and A3B2.1 cells, respectively. Consistent with the single-cell results, nicotine-stimulated increases of $[Ca^{2^*}]_i$ in a population of cells were enhanced 4-fold in A4B2.1 cells and 8- to 16-fold in A3B2.1 cells when external Ca^{2^*} was raised from 1.8 to 21.8 mM. In contrast, raising the external [Ca2+] from 1.8 to 21.8 mM caused only a 2-fold increase in nicotine-stimulated $[Ca^{2^{+}}]_i$ increases in cells expressing human $\alpha \beta \beta 4$ receptors (A3B4.1 cells). These data suggest that $Ca^{2^{+}}$ flux through human $\alpha \beta \beta 2$ receptors is more sensitive to changes in external $Ca^{2^{+}}$ than either $\alpha 4\beta 2$ or α3β4 receptors. Changes in external [Ca²⁺] may, therefore, differentially regulate the activity of nAChR subtypes in neurons.

CHARACTERIZATION OF HUMAN NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS (nAChrs) α 4 β 2 and α 3 β 2 STABLY EXPRESSED IN HEK293 CELLS. LE. Chavez-Noriega*, N. Zahl, L.S. Mahaffy, J. Crona, R. Reid, P. Adams, K.J. Elliott, K. Berckhan, K.A. Stauderman and J. Corey-Naeve. SIBIA Neurosciences, Inc., La Jolla, CA 92037

HEK293 cells have been stably transfected with cDNAs encoding full-length nAchR subunit combinations $\alpha4B2$ (A4B2.1) or $\alpha3\beta2$ (A3B2.1; see also Mahaffy et~al., this meeting). Northern blot analysis demonstrated mRNA encoding each subunit. 3H -epibatidine bound to A4B2.1 and A3B2.1 cells with a K_d value of 103 ± 14 pM (mean ± SD) and 7.5 ± 2.4 pM, respectively. Increases in cytosolic [Ca 24], measured with fluo-3, were elicited by nicotine (NIC), DMPP or cytisine with EC $_{50}$ values of 2.1 ± 1.3, 2.5 ± 0.6 and 1.6 ± 0.9 μM for A4B2.1 cells, and 8.3 ± 3.7, 3.2 ± 2.1 and 32.8 ± 25.0 μM for A3B2.1 cells, respectively. Responses are stable for at least 35 passages in A4B2.1 and 50 passages in A3B2.1 cells. Agonist-induced responses were blocked by DHβE, d-tubocurarine and mecamylamine with IC $_{50}$ values of 0.7 ± 0.4, 4.1 ± 3.8 and 0.3 ± 0.1 μM for A4B2.1 cells, and 14.3 ± 5.2, 0.2 ± 0.2 and 1.0 ± 1.4 μM for A3B2.1 cells (1,113 ± 2,643 pA, n=20) in response to ACh, NIC or DMPP (30-100 μM). A3B2.1 cells displayed faster desensitization kinetics than A4B2.1 cells. Agonist-induced currents from both cell lines exhibited strong inward rectification in the current-voltage (I-V) relation with an $E_{\rm rev}$ near 0 mV. Our results indicate that stably expressed nAChRs $\alpha4\beta2$ and $\alpha3\beta2$ are pharmacologically diverse and are valuable tools for the discovery of subtype-selective nAChR compounds with potential therapeutic utility.

603.17

PERMEABILITY OF DIVALENT CATIONS IN RAT α 7 NICOTINIC AChR ION CHANNEL. M. <u>Dabrowski¹, K. Eskesen²², P. Bennekou¹</u>. ¹August Krogh Institute, Universitetsparken 13, DK 2100 Ø, Denmark. ²Novo Nordisk A/S, Novo Nordisk Park, DK-2760 Måløv, Denmark.

In this study we examined the relative permeabilities of divalent cations on mature Xenopus laevis oocytes expressing the rat $\alpha 7$ homooligomeric incotinic AChR. Whole-cell current responses induced by 10 and 30 μM (-)-nicotine from oocytes voltage-clamped at -80 and -60 mV was obtained. The endogenous Ca²*- activated Cl²- channel was blocked by flufenamic or niflumic acid to less than 5% of the unblocked response. The potentiation and regulatory effects of Ca²* were minimized by using a constant background of 100 μM Ca²* solution when, obtaining concentration-current curves for the other divalent ions. We found the relative permeability sequence for the Group 2A ions: Ba²* > Sr²* > Ca²* > Mg²*. The sequence is monotonic in radius and the selectivity ratio is near 10 for Ba²*/Mg²*, which suggests a weak-site electrostatic effect in the permeation. We also examined some of the transition elements and found: $mn²* > Co²* > Ni²* \text{ and } Cd²*. Ni²* \text{ and } Cd²* \text{ both completely block the channel (at 1 mM), whereas the Co²* current is comparable to Mg²* and Mn²* even more permeable than Mg²* at low concentration (1 mM). This not a simple electrostatic effect: <math display="block">Co²* \text{ bas a radius comparable to } Ni²* \text{ and hence similar hydration-energies and water-substitution rates but } Co²* is somewhat permeable whereas <math>Ni²* \text{ carries no current. All ions except } Ca²* \text{ show decreasing currents with increasing concentrations (from 1 mM).}$ This could be explained by competition at receptor regulatory site(s), rather than a sudden block by a normally permeant ion.

603.19

UPREGULATION OF RECOMBINANT HUMAN NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS BY CHOLINERGIC CHANNEL LIGANDS: A ROLE FOR PROTEIN KINASES. E. Molinari, M. Gopalakrishnan and J. P. Sullivan* Neuroscience Research, Abbott Laboratories, Abbott Park, IL 60064-3500.

Alterations at the level of neuronal nicotinic acetylcholine receptors (nAChRs) have been implicated in a variety of homologous and heterologous influences including neuropathologic conditions. This study was designed to examine the regulation of the human $\alpha 4\beta 2$ nAChRs by cholinergic channel ligands and to address the underlying mechanisms. Significant increases in [3 H]cytisine binding sites were observed following treatment of cells stably expressing the human $\alpha 4\beta 2$ nAChRs for 24 - 162 h by activator ligands including ()-nicotine, (-)-cytisine, DMPP, ABT-418, ABT-089 and (\pm)-epibatidine, and by antagonists including dihydro- β -erythroidine (DH β E), d-tubocurarine and methyllycaconitine. A good correlation was observed between the K₁ values for binding inhibition and the EC50 values for receptor upregulation. (-)-Nicotine-evoked increase in [3 H]cytisine binding sites was maximal at 10 μ M [15-fold], steroselective, rapid (t_{0.5} = 4.0±0.5 h] and totally reversible [t_{0.5} = 11.7±0.1 h]. Mecamylamine failed to upregulate nAChRs and did not alter (-)-nicotine-evoked effects. Upregulation was blocked by cycloheximide suggesting a role for protein synthesis. Functional studies showed that chronic treatment with (-)-nicotine or DH β E resulted in a differential enhancement in the maximal functional efficacy of ACh to activate cation efflux. Upregulation was be mimicked by treatment of cells with phorbol myristate acetate (100 nM) or forskolin (10 μ M) increased 2 H]cytisine binding by 95±19% and 79±9% respectively and increased the functional efficacy of ACh to enhance cation efflux by 108±39 % and 54±9 % [n=4] respectively. These studies demonstrate that human α A β 2 nAChRs are rapidly upregulated by both activator and competitive antagonist ligands and that protein kinases may play a role in receptor upregulation. (Supported by Abbott Laboratories).

6-HYDROXYDOPAMINE LESION OF RAT NIGROSTRIATAL DOPAMINERGIC NEURONS DIFFERENTIALLY AFFECTS NICOTINIC ACETYLCHOLINE RECEPTOR SUBUNIT mRNA EXPRESSION. K.J. Elliott*. A.I. Sacaan, T.S. Rao, G.K. Lloyd and J. Corey-Naeve. SIBIA Neurosciences, Inc., La Jolla, CA 92037.

Parkinson's disease is characterized by degeneration of the donamine (DA) neurons originating in the substantia nigra (SN) and ventral tegmental area. Since neuronal nicotinic acetylcholine receptors (nAChRs) participate in the control of DA release in vitro and in vivo, the subunit composition of nAChRs in the DA-ergic neurons of the SN is of interest. We have initiated a study using RT-PCR to examine the effect of unilateral 6-hydroxydopamine (6-OHDA) lesioning of rat nigrostriatal DA-ergic neurons on nAChR subunit mRNA expression levels. 6-OHDA was injected into male SD rats according to the atlas of Paxinos and Watsons at (A/P = -4.8; D/V = -8; ML = +1.9) (Zivic Miller). After 6 months, tissues were collected bilaterally from various brain regions and total RNA was isolated. Semi-quantitative RT-PCR was performed with oligonucleotide primers specific for glyceraldehyde-6-phosphate dehydrogenase (GAPDH), glutamic acid decarboxylase (GAD) and nAChR α5, α6 and β2 subunit mRNAs over a linear amplification range as determined by template titration. RT-PCR products were separated on an ethidium bromide-stained agarose gel and signal intensities were normalized to GAPDH. The results indicate significantly reduced levels of α 5 and α 6 but not β 2 mRNAs in lesioned compared to unlesioned SN. GAD mRNA levels appeared to be unaffected by lesioning, confirming the integrity of the GABA-ergic neurons in the SN. The treatment did not affect α 5, α 6 or β 2 mRNA levels in hippocampus, prefrontal cortex or thalamus, which are known to express nAChR transcripts. The results suggest that nAChR α 5 and α 6 mRNAs are expressed in SN DA-ergic neurons, while \(\beta 2 mRNA \) is more heterogeneously expressed in the SN.

603.18

REGULATION OF RECOMBINANT HUMAN α7 NICOTINIC RECEPTORS BY ACTIVATOR AND ANTAGONIST LIGANDS. M. Gopalakrishnan 2, Delbono, E. J. Molinari, M. Renganathan, L. Messi, S.P. Arneric and J.P. Sullivan, Neuroscience Research (D-47W), Abbott Laboratories, Abbott Park, IL 60064-3500 and Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157-1083.

Although (-)-nicotine has been shown to regulate the neuronal α4β2

Although (-)-nicotine has been shown to regulate the neuronal α 4β2 AChRs following chronic treatment, very little is known about changes at the level of the α -bungarotoxin [BgT]-sensitive nAChRs. In this study, we examined changes in the expression and functional characteristics of the human α 7 nAChRs stably expressed in HEK-293 cells following treatment with nicotinic cholinergic ligands. Treatment of cells for 120 h with activator ligands such as (-)-nicotine, (±)-epibatidine and DMPP elicited significant upregulation of [125f] α -BgT binding sites although the concentrations required for upregulation were at least 100-fold higher than those required at the α 4β2 nAChRs [see Molinari et al., this meeting]. (-)-Nicotine [100 μ M] treatment increased the Bmax values of [125f] α -BgT binding 3-4 fold over untreated cells with no change in ligand affinities. A concentration-dependent upregulation of binding sites was also observed following treatment of transfected cells with the selective α 7 nAChR antagonist, methyllycaconitine. Functionally, the peak amplitude of the whole-cell currents recorded by fast application of (-)-nicotine after treatment of cells for 120 h with 100 μ M (-)-nicotine [495±17 pA] and 10 μ M methyllycaconitine [1450±150 pA] was significantly larger than those observed in untreated cells [298±35 pA; n = 5-6]. The single channel properties including unitary current amplitude [5 pA at -100 mV], conductance [65 pS] and dwell time distributions were unaltered under such conditions. These studies suggest that α 7 nAChRs are upregulated by activator and antagonist ligands and that regulation at the level of the human α 7 nAChR may be important in the long-term therapy with cholinergic channel modulators. MOLECULAR AND FUNCTIONAL EXPRESSION OF THE NICOTINIC α_{7} ACETYLCHOLINE RECEPTOR (nAChR) IN RAT SPINAL CORD MOTONEURON. M.L.Messi, M. Renganathan, E. S. Grigorenko and O. Delbono.'. Bowman Gray School of Medicine, Dept. of Physiology-Pharmacology and Internal Medicine (Gerontology), Winston-Salem, NC 27157.

Spinal cord motoneurons (MN) undergo early and late onset developmental and pathological modifications. As α_1 nAChR has been related with neuronal trophism due to the high Ca^{2+} permeability, we investigated the receptor expression on a purified embryonic (E15) spinal cord MN culture. The α_1 subtype was identified in single MN using antisense RNA amplification technique combined with PCR. Fast (-)-nicotine application elicited inward currents that were blocked by 2 nM α -bungarotoxin (α -BgT)- or 3 nM methyllycaconitine. (-)-Nicotine-induced currents were associated with a significant increase in Ca^{2-1} , (cell body .475 ±51 nM; neurites,780 ±65; n=5). Single channel activity induced by 100 μ M (-)-nicotine showed two mean open time distributions of 0.193 ms and 2.13 ms, corresponding to α_2 nAChR and $\alpha_4 \delta_3$, respectively. Brief and long single channel events were blocked by preincubation in 2 nM α -BgT or in 10 nM dihydro-5-erythroidine, respectively. (-)-Nicotine was applied chronically to MN cultures using basically two schemes. A pulsed protocol (50 μ M, 4 times/day for 1 min) significantly increased (3 fold) MN survival 3 days after plating. This effect was precluded by 2 nM α -BgT. A steady state (-)-nicotine application protocol (1-100 μ M, 6-12 hs/day) did not show significant increase in MN survival respect to control. These studies demonstrate that activation of the α_2 nAChR promotes a Ca^{2+} -mediated increase in spinal cord MN survival. (Supported by MDA and NIH).

THE MONGOOSE ACETYLCHOLINE RECEPTOR α-SUBUNIT IS INSENSITIVE TO α-BUNGAROTOXIN AND IS HIGHLY SENSITIVE TO ACETYLCHOLINE. O. Asher¹, M. Lupu-Meiri², B. S. Jensen¹, T. Paperna¹, Y. Oron² and S. Fuchs¹*. ¹Department of Immunology, Weizmann Institute of Science, Rehovot 76100, Israel. and ²Department of Physiology and Pharmacology, Sackler Faculty of Medicine, Tel Aviv University, Ramat Aviv 69978, Israel.

and ⁴Department of Physiology and Pharmacology, Sackler Faculty of Medicine, Tel Aviv University, Ramat Aviv 69978. Israel.

In studying the ligand binding site of the nicotinic acetylcholine receptor (AChR), we have cloned recently the mongoose AChR α-subunit. This subunit is highly homologous to the mouse and rat AChR α-subunit and has only six amino acid substitutions at positions that are conserved in animal species that bind α-bungarotoxin (α-BTX). Four of the six substitutions are present in the ligand binding region of AChR and one of these (Asn-187) is a putative N-glycosylation site. Indeed, the glycosylated form of the mongoose α-subunit has a higher molecular mass (46kD) than that of the glycosylated rat α-subunit (44kD). Expression of the mongoose α-subunit together with the rat β, γ & δ subunits in *Xenopus* oocytes. results in the assembly of functional AChR channels. The affinity of the expressed mongoose/rat hybrid AChR to α-BTX is three orders of magnitude lower than that of the rat AChR, whereas its affinity to ACh (EC50 10.1 ±0.31μM) is higher than that of the rat AChR (EC50 10.2 ± 2.13 μM). Thus, substitution of just a few amino acid residues in the mongoose AChR α-subunit appears to be sufficient for determining the resistance to α-BTX, and may also alter the sensitivity to ACh. STRUCTURAL DETERMINATES OF AGONIST/ANTAGONIST ACTIVITY AT THE AMPA RECEPTOR. D.M. Weinstein*, G. Shams, D.M. Miller, R.A. Hill, College of Pharmacy, The Ohio State N.J. Uretsky, and L.J. Wallace. University, Columbus, OH 43210

Glutamate, the most abundant excitatory neurotransmitter in the central nervous system, mediates excitatory activity in neurons through its activation of three families of receptors: N-methyl-D-aspartate, AMPA/kainate, and metabotropic. Our work is focused on agents that interact with the AMPA receptor, with the goal of finding potent agents that show selectivity for AMPA and for kainate mediated effects. From a variety of compounds examined using radioligand binding analysis and an in vitro bioassay, two series with interesting properties have been discovered. In one series, the addition of an N(1)-linked alanine residue to the parent quinoxaline-2,4-dione produced a potent, stereoselective AMPA receptor agonist (isomeric EC values = 3 uM vs. > 1000 uM). Placing a 6,7-di-methyl substitution on these molecules resulted in non-stereoselective AMPA antagonists (isomeric IC_{so} values = 144 uM vs 156 uM). This suggests differences in binding sites/orientation between agonists and antagonists. In the other series, (RS)-5-nitrowillardiine behaves as a potent agonist, while the compounds (RS)-3,5dinitro-m-tyrosine and (RS)-2,4-dinitro-o-tyrosine behave as weak antagonists. These results suggest that differences in substituent patterns and/or electronic properties in the heterocyclic ring systems have a profound effect on receptor interactions. (NIH grants DA06776 and DA7722)

GLUTAMATE RECEPTOR PROFILE OF THE AMPA/KAINATE RECEPTOR ANTAGONIST LY293558.

D. Bleakman*, ¹B. Ballyk, ¹K. Hoo, ²P. Ornstein, ¹R. Kamboj & ²D.D. Schoepp. Eli Lilly and Co., Lilly Research Centre, Windlesham, Surrey, U.K., ¹Allelix Biopharmaceuticals Inc., Mississauga, Ontario, Canada and ²Lilly Research Laboratories, Indianapolis, Indiana, U.S.A.

The activity of the competitive non-NMDA ionotropic glutamate receptor LY293558 ((3S,4aR,6R,8aR)-6-[2-(1(2)H-tetrazole-5yl)ethyl]decahydroisoguinoline-3-carboxylic acid), has been examined on HEK293 cells expressing cloned human homomeric and heteromeric AMPA and kainate (KA) receptors. Ligand binding studies using either ³H-AMPA or ³H-KA as ligands revealed that LY293558 was active at GluR1, GluR2, GluR4 and GluR 5 receptors, but did not compete for binding at GluR6 receptors (approximate Ki values: GluR2, 3.2μM; GluR5, 4.8μM; GluR1, 9.2μM; GluR4, 50.5μM and GluR6, >1mM). LY293558 also showed relatively weak activity at GluR7 and KA2 receptors. In support of the binding studies we have been able to demonstrate functional antagonism of agonist-induced currents for the cloned AMPA (GluR1,2 and 4) and KA receptor subtypes (GluR5) expressed in HEK293 cells using whole-cell voltage clamp electrophysiology. In addition, LY293558 showed no antagonism of agonist-induced currents for either homomeric GluR6 or heteromeric GluR6/KA2 KA receptors expressed in HEK293 cells. We have also compared the functional activity of LY293558 at human cloned AMPA/KA receptors to responses in native AMPA receptor and KA receptor-mediated responses in acutely isolated rat cerebellar Purkinje cells and rat dorsal root ganglion neurons, respectively. These studies illustrate the pharmacological profile of LY293558 at AMPA/KA receptor subtypes and the potential of LY293558 as a pharmacological tool for the discrimination of AMPA and KA receptors.

IN VITRO CHARACTERIZATION OF YM872: A SELECTIVE, POTENT AND HIGHLY WATER-SOLUBLE AMPA RECEPTOR ANTAGONIST.

A. Kohara, M. Okada, K. Ohno, S. Sakamoto, J. Shishikura, H. Inami, M. Shimizu-Sasamata†*and T. Yamaguchi. Neuroscience Neuroscience and Castrointestinal Res. Lab., Institute for Drug Discovery Res., Yamanouchi Pharmaceutical Co., Ltd., 21 Miyukigaoka, Tsukuba, Ibaraki 305, Japan †Stroke Res. Lab., M.G.H., Harvard Medical School, Boston, MA, USA.

AMPA receptor antagonists are potentially useful as novel therapeutic agents for the treatment of cerebral ischemia. We have discovered a competitive AMPA receptor antagonist, YM872 ([2,3dioxo-7-(1*H*-imidazol-1-yl)-6-nitro-1,2,3,4-tetrahydro-1-quinoxalinyl]acetic acid monohydrate), that is a highly water-soluble agent. have characterized the pharmacological properties of YM872 in vitro

YM872 has a potent inhibitory effect on [3H]-AMPA binding with the Ki value of 0.095 µM. In contrast, YM872 has very low affinity for other ionotropic glutamate receptors, using [3H]-CGS19755 (NMDA receptor glutamate binding site), [3H]-glycine (NMDA receptor glycine binding site) and [3H]-kainate (high affinity kainate binding site) as a ligand (Ki = 100 μM, >100 μM and 2.2 μM, respectively). YM872 has an inhibitory effect on 300 μM kainate-induced currents with an IC50 value of 0.24 μM in Xenopus Laevis Oocytes expressing AMPA receptors by injecting rat brain poly(A)+RNA. In rat hippocampal primary cultures, YM872 blocked 300 μM kainate-induced neurotoxicity with an IC₅₀ value of 1.1 μM

These data indicate that YM872 is a potent and selective AMPA receptor antagonist, and YM872 may be useful in the treatment of cerebral ischemia

NON-PEPTIDE CONUS VENOM COMPONENTS: EFFECTS ON KAINATE/AMPA RECEPTORS AND OTHER CONDUCTANCES IN SQUID GIANT FIBER LOBE NEURONS, D.J. Steel*1, D. Piper2, J.P. Danaceau2, S.S. Mitchell³, C.M. Ireland³, L.J. Cruz¹, B.M. Olivera¹, and M.T. Lucero.² Depts. of Biology¹, Physiology², and Medicinal Chemistry,³ University of Utah, Salt Lake City, UT 84112

Cone snails are members of a class of predatory marine snails which immobilize their prey by injection of a potent venom. Study of these venoms has lead to the discovery of highly selective peptides for targets including Ca channels, Na channels, nACh receptors, and NMDA receptors. We examined the venom of Conus marmoreus, a molluschunting cone snail, for novel substances which might affect neuronal activity in the nervous system of molluscs. RP-HPLC-purified fractions of 0.1% TFA-extracted venom were examined for effects on squid giant fiber lobe (GFL) neurons. Two separate activities were identified. Both elute under highly polar conditions, and subsequent analysis established that they were non-peptide, small organic molecules. We have identified one of these substances as betaine, a molecule known to be an osmoregulator in the molluscan nervous system. In squid GFL neurons, betaine activates a large conductance that washes out rapidly, suggesting that the response is second messenger-mediated. The second molecule has a distinctive UV absorbance maximum of 335 nm. Electrophysiological studies in squid GFL neurons indicate that this molecule activates an ionotropic kainate/AMPA receptor. Thus, *Conus* venoms contain a number of small molecules capable of selectively interacting with unique target sites. Supported by NIH NS09771 and DC02587.

IN-VITRO AND IN-VIVO PHARMACOLOGY OF SYM 2206 & SYM 2207: A NOVEL SELECTIVE NON-COMPETITIVE INHIBITOR OF THE AMPA RECEPTORS, <u>David P. Hesson</u>, <u>Jeffrey C. Pelletier</u>, <u>Kenneth A. Jones'</u>, <u>Ana-Maria Costa</u>. Symphony Pharmaceuticals, 76 Great Valley Parkway, Malvern, PA 19355

As part of our effort to find selective modulators of ionotropic glutamate receptors, we discovered a series of novel 1,2-dihydrophthalazines which selectively antagonize AMPA receptors. The lead compounds, SYM 2206 SYM 2207, are active in animal models which suggests it could be a useful antiepileptic and neuroprotectant. SYM 2206 and SYM 2207 antagonizes AMPA receptor mediated currents in recordings of rat cortical neurons (ICS0 = 2.3 μM & 1.8 μM) but do not antagonize Kainate receptors (GluR6) expressed in HEK293 cells. Neither compound inhibits binding of [3H]-CGS 19755, [3H]-glycine, [3H]-AMPA, or [3H]-kainic acid. Therefore, the inhibitory action on AMPA receptors occurs at a site separate from the glutamate binding site. SYM 2206 is protective in the MES seizure model when tested in mice (ED50 = 30 mg/kg ip). and rats (ED50 = 39 mg/kg po). SYM 2207 protects all of the animals at 30 mg/kg ip. The therapeutic index for SYM 2206, measured by comparison of rat MES and rat rotorod, is approximately 2 while the therapeutic index of SYM 2207 is significantly greater than 2. Neither compound is effective in inhibiting subcutaneously injected metrazol in mice but also did not increase seizure activity in the intravenous metrazol model. SYM 2206 is not active in a rat hippocampal kindled rat model. Both compounds at 30 μM show 100% protection of rat hippocampal neurons in an ivitro model of ischemia. In additional receptor when compared GYKI 52466. The anticonvulsant activity and safety profiles suggests that these compounds makes them candidates for further development.

PHARMACOLOGY OF NMDA RECEPTOR SUBTYPES. V.J. Andaloro¹, H.W. Tse², D.E. Jane², J.C. Watkins², and D.T. Monaghan⁴². ¹ Department of Pharmacology, University of Nebraska Medical Center, Omaha, NE 68198-6260 ² Department of Pharmacology, University of Bristol, Bristol BS8 1TD, UK

Previously, we have shown that at least four pharmacologically distinct NMDA receptor subtypes exist (agonist- and antagonist-preferring, cerebellar, and midline thalamic receptors), and presently identify several structural features of competitive NMDA receptor antagonists that lend to receptor subtype selectivity. Using quantitative receptor autoradiography, we have examined the ability of over 75 compounds to compete with [³H]-glutamate binding to NMDA receptors in horizontal rat brain sections. The compounds we have studied fall into six major structural classes; straight chain amino acid derivatives, piperidine carboxylates, piperazine carboxylates, decahydroisoquinolinates, quinolinates, and 5-phosphonehyl-1,1 biphenyl-3-alkylcarboxylates. We report here that compounds containing a straight-chain structure are the least subtype-selective inhibitors of [³H]-glutamate binding to NMDA receptors. Piperazines and piperidines all tend to be more potent in antagonist preferring regions, while sparing receptors in agonist-preferring regions and cerebellar receptors, but have a unique pharmacology of selective potency for midline-thalamus, a region known to be enriched in NMDAR-2D receptor subunit. Quimolinate derivatives spare both cerebellar and midline thalamic receptors. Extension of a 5 carbon bond-length compound to a 7 carbon homolog results in a significant and specific decrease in only cerebellar NMDA receptor affinity. Lastly, compounds containing a phosphonate or tetrazole moiety in the ω-acidic position are more selective for antagonist-preferring regions than the corresponding carboxylates. These data reveal several chemical structural features that confer selectivity between NMDA receptor subtypes. Supported by US-DOD contract DAMD 17-94-C-4050

SPECIES DIFFERENCES IN VACUOLIZATION OF CORTICAL NEURONS AFTER ADMINISTRATION OF THE NMDA RECEPTOR ANTAGONIST DIZOCILPINE. <u>Patrick Raboisson**</u> <u>Karin Flood*, Anders Lehmann* and Odd-Geir Berge**</u>. *Dept. Pharmacol. Astra Pain Control AB, S-151 85 Södertälje, Sweden, *Lab. Physiol. Oro-Faciale, Faculté de Chirurgie Dentaire, 63000 Clermont-Ferrand, France and *Gastrointestinal Pharmacol., Astra Hässle AB, S-431 83 Mölndal, Sweden.

In rats, NMDA receptor antagonists may cause transient vacuole formation in neurons of the posterior cingulate and retrosplenial (PC/RS) cortex and, after higher doses, necrosis in the same regions. We have now investigated whether vacuolization occurs in the guinea pig.

Dizocilpine ((+)-MK-801) or saline were given subcutaneously to adult female Dunkin-Hartley guinea pigs (age 15-18 weeks; 1, 4 and 12 mg/kg) and female Sprague-Dawley rats (age 16 weeks; 1 mg/kg). After four hours, the animals were anesthetized and transcardially perfused. Brains were embedded in plastic, thin-sectioned, stained with toluidine blue and examined by light microscopy.

In the guinea pig, only occasional vacuolated neurons were identified in the PC/RC cortex after dizocilpine but additional affected neurons, mainly large pyramidal cells of layer V, where found in neocortical areas lateral to the anterior cingulate cortex. This reaction was evident at 1 mg/kg and reached a maximum at 4 mg/kg. Rats injected with 1 mg/kg dizocilpine showed an intense vaculolar reaction in layers III and IV of the PC/RS cortex but no affected neurons were noted in the neocortical areas. Vacuoles were not seen in any of the saline injected animals.

We conclude that there is a significant species difference in intensity and location of vacuolization induced by NMDA receptor antagonists.

604 6

PHARMACOLOGY OF ZK200775 AND ZK202000, COMPETITIVE NON-NMDA GLUTAMATE RECEPTOR ANTAGONISTS. <u>L. Turski 1*, A. Huth 1, M.J. Sheardown 2, P. Jacobsen 2, and E. Ottow 1, 18 Research Laboratories of Schering AG, Müllerstr. 178, D-13342 Berlin, Germany and 2 Novo Nordisk AS, Novo Nordisk Park, DK-2760 Copenhagen, Denmark.</u>

AMPA receptor antagonists have been shown to have marked neuroprotective effects in a variety of animal models of cerebral ischemia and trauma which indicates that this class of compounds may have clinical potential for the treatment of stroke or head trauma in humans. The major drawback of currently available AMPA/KA receptor antagonists is their poor solubility in water. Therefore we investigated pharmacological and neuroprotective properties of ZK200775 and water-soluble quinoxaline-phosphonate derivatives in rodents. ZK200775 and ZK202000 specifically inhibit ³H-AMPA binding (IC50 0.15 μM and $0.44~\mu\text{M})$ and have no affinity to non-glutamate receptors. The biochemical profile of both compounds is reflected in vitro by selective antagonism of non-NMDA receptor mediated spreading depression in chicken retina and quisqualateinduced depolarisation in the rat cortical slice preparation. In vivo pharmacology shows selective elevation of seizure threshold for non-NMDA receptor agonists. In models of neurodegeneration, ZK200775 and ZK202000 protect against neuronal cell loss induced by global ischemia in rodents, reduce the infarct volume in mouse models of focal ischemia, and mitigate traumatic brain damage in rats. The neuroprotective action of ZK200775 is seen in focal ischemia models when the drug is administered up to 4 h post occlusion. These data indicate that ZK200775 is a potent and selective AMPA/KA receptor antagonist and neuroprotective drug with a wide therapeutic time-window in animal models of neurodegeneration. ZK200775 may therefore prove useful in the therapy of stroke and head trauma.

604.8

CHRONIC ANTIPSYCHOTIC TREATMENT AFFECTS NMDA RECEPTOR GENE EXPRESSION. F. Tascedda**, E. Lovari*, J.M.C. Blom*, G. Racagni*, and M.A. Riva**b. "Center of Neuropharmacology, Univ. of Milan, 20133 Milan, Italy; bDi.Bi.T., San Raffacle Hospital, Milan, Italy.

The neurochemical mechanisms underlying the effects of antipsychotic drugs (APD's) are not well understood. The majority of these drugs share one common pharmacological property, namely the blockade of dopamine D-2 receptors, although many ADP's interact with other neurotransmitter receptors as well. More recently, based on anatomical evidence and functional interactions between dopamine and glutamate, new hypothesis on their mechanisms of action have been put forward. In particular, the cloning of different glutamate receptors has given the opportunity to investigate in more detail the regulation of this system. The N-methyl-D-aspartate (NMDA) receptor is a glutamate-gated cation-specific ion channel which plays a key role in many forms of neuronal plasticity. Using a sensitive RNase protection assay, the gene expression of two families of NMDA receptors (RR-1 and NR-2) was evaluated in different brain areas following 21 day ip treatment of young adult male rats (Sprague-Dawley) with typical (haloperidol Img/kg/day) and atypical (clozapine 30 mg/kg/day) neuroleptics. Haloperidol produced a significant increase in mRNA levels of NR-1 and NR-2 in striatum, whereas clozapine, consistent with its relative weaker influence on nigro-striatal dopamine function, did not affect the expression of NR-2 subunit mRNA in the hypothalamus, but not in the hippocampus. The regulation of these neurotransmitter systems and of NMDA receptor subunits by ADP's in different brain structures may provide useful information to discriminate between therapeutical and side effects of these drugs, and may represent a novel and important mechanism through which ADP's affect the brain.

604.10

POTENTIAL NMDA RECEPTOR LIGANDS: TWO NEW SLEEP-INDUCING PEPTIDES FROM CONUS RADIATUS VENOM. E. Jimenez¹, F. Abogadie², B. M. Olivera², J. Rivier³ and L. J. Cruz.^{1,2}* Marine Science Inst.¹, Univ. of the Philippines, Diliman, Quezon City, 1011, PI; Dept. of Biology², Univ. of Utah, Salt Lake City, UT, 84112; Clayton Foundation Laboratories for Peptide Biology³, Salk Institute, La Jolla, CA, 92186.

Conantokin-G, the first peptide ligand known to inhibit NMDA receptors induced a sleep-like state in mice. To identify other potential NMDA receptor ligands, we examined the venom of Conus radiatus for fractions which induce sleep; two peptides were purified and characterized. The first, conantokin-R, is homologous to conantokin-G and contains the unusual amino acid \(\gamma\)-carboxyglutamate (Gla); however, conantokin-G) and has a disulfide bond. The other sleep-inducing peptide of C. radiatus venom exhibits no homology to the conantokins; this 33 AA peptide has 3 disulfide bonds and 4 Gla residues. Whereas conantokins induce sleep upon i.c. injection in young mice and hyperactivity in older mice, the novel C. radiatus peptide causes sleep in both age groups. The peptide is very potent in 9-day-old mice, causing sleep at 10-15 pmol/g body weight. (Supported by GM PO1 48677 and Philippine DOST-ESP Program (E. J.).)

FELBAMATE INHIBITION OF RECOMBINANT N-METHYL-D-ASPARTATE RECEPTORS EXPRESSED IN *XENOPUS* OOCYTES. J. C. Glazewski, C. C. Chen, T. D. Moscrip, and N. W. Kleckner*. Bates College, Lewiston, ME 04240.

The anticonvulsant effects of felbamate are thought to be mediated through an interaction with N-methyl-D-aspartate (NMDA) receptors. The site on NMDA receptors with which felbamate interacts is unknown, although both the glycine and channel sites have been suggested. The purpose of this study was to determine the site of action of felbamate, and its specificity of action against recombinant NMDA receptors comprised of different receptor subunits. NMDA receptors comprised of the NR1a subunit and either the NR2A or NR2C subunits were expressed in Xenopus laevis oocytes. The oocytes were voltage-clamped with two microelectrodes, and the currents measured in response to perfusion of NMDA and glycine in the absence and presence of felbamate. For both NR1a-NR2A and NR1a-NR2C receptors, the maximum current measured during glycine and NMDA dose-response curves in the presence of felbamate was reduced compared to the currents measured in the absence of felbamate. Furthermore, the EC₅₀ values for glycine and NMDA were unchanged by felbamate. These data suggest that felbamate is not a competitive inhibitor of either site. Felbamate dose-response analysis showed felbamate to be slightly more potent for NR1a-NR2C receptors (IC₅₀ ~2 mM) than for NR1a-NR2A receptors (IC₅ mM). In addition, NR2A-containing receptors required the pre-perfusion of felbamate for effective (but highly variable) inhibition, suggesting that the access to felbamate on NMDA receptors containing NR2A subunits is limited compared to NR2C-containing receptors, and that the open channel may not be required for inhibition. The lower potency of NR2A-containing receptors is surprising, in that they have been postulated to be the antagonist-preferring receptors (Buller, et al. 1994). These findings may be useful for the design of new anticonvulsants with fewer side-effects than felbamate. (Supported by Grants to N.K., T.M. & C.C. from the Howard Hughes Medical Institute through Bates College)

604.13

AN ANTAGONIST AT THE STRYCHNINE-INSENSITIVE GLYCINE SITE DIFFERENTIALLY AFFECTS HYPERACTIVITY AND THE DISRUPTION OF PREPULSE INHIBITION (PPI) INDUCED BY PHENCYCLIDINE. Y. Furuya, T. Kagaya, Y. Nishizawa* and H. Ogura. Tsukuba Research Lab. Eisai Co., Ltd. Tsukuba, Ibaraki 300-26 Japan The amplitude of the acoustic startle response is reduced by a preceding

The amplitude of the acoustic startle response is reduced by a preceding weak stimulation, which by itself does not elicit the startle response. This phenomenon has been named prepulse inhibition (PPI) and is thought to reflect the operation of the sensorimotor gating system, which is deficient in schizophrenic patients. It has been reported that (+)-HA-966, an antagonist at the strychnine-insensitive glycine site, antagonizes phencyclidine (PCP)-induced hyperactivity and has an atypical neuroleptic profile. We examined the effect of (+)-HA-966 on PCP-induced (3 mg/kg, s.c.) hyperactivity and disruption of prepulse inhibition in rats, and compared the effects with that of haloperidol, a typical neuroleptic. The antagonism of (+)-HA-966 on PCP-induced hyperactivity was ascertained. However, (+)-HA-966 did not antagonize the PCP-induced disruption of PPI, which is thought to be a model of refractory symptoms in schizophrenia. Haloperidol exhibited the same results as (+)-HA-966. Moreover, (+)-HA-966 slightly disrupted PPI at 30 mg/kg, s.c., and intracerebroventricularly administered 5,7-dichlorokynurenate, an antagonist at the strychnine-insensitive glycine site, disrupted PPI. These results indicate that (+)-HA-966 antagonizes only the dopamine-dependent effects (hyperactivity) but not dopamine-independent effects (disruption of PPI) of phencyclidine. Furthermore, it is apparent that an antagonist at the strychnine-insensitive glycine site disrupts PPI, although the disruptive effect is weaker than that of PCP.

604.15

SUBUNIT SPECIFIC EFFECTS OF D-CYCLOSERINE ON NMDA RECEPTORS EXPRESSED IN XENOPUS OOCYTES. A. J. O'Connor, G. Vlachogiannis, J. Moskal*, S. R. Kelso. Dept. of Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL 60607, and Chicago Inst. of Neurosurgery and Neuroresearch, Chic., IL 60614.

D-cycloserine (DCS) is a partial agonist at the glycine binding site of the NMDA receptor. Administration of DCS in both nonhuman and human subjects surgests it may act to enhance learning and

of the NMDA receptor. Administration of DCS in both nonhuman and human subjects suggests it may act to enhance learning and memory in certain cognitive tasks. However, this enhancement is lost when DCS is administered chronically or at high doses. To better understand how DCS interacts with the NMDA receptor, we studied the effects of DCS on several heteromeric receptors. Using in vitro transcription, RNA was made from clones for the zetal and epsilon 1-3 subtypes of murine NMDA receptors. The RNA was injected into Xenopus occytes and recordings were made using standard voltage clamp techniques. Dose response curves indicate that the efficacy of DCS is different for the different subtypes. It is a partial agonist for z1/e1 and z1/e2 heteromers (with 38% and 56% the efficacy of 10 uM glycine). By contrast, for z1/e3, DCS was more effective than glycine (130% compared to 10 uM glycine).

These results may explain why DCS is effective at enhancing only

These results may explain why DCS is effective at enhancing only certain cognitive tasks and may prove to be helpful in understanding the mechanism whereby chronic administration of DCS leads to impairment of cognition.

GLYCINE DOES NOT REVERSE ETHANOL-INDUCED INHIBITION OF NMDA RECEPTORS IN CEREBELLAR GRANULE CELLS. S. Liljequist*, G. Cebers, A. Cebere and A. Zharkovsky. Dept of Clinical Neuroscience, Div Drug Dependence Research, Karolinska Institute, S-17176 Stockholm, Sweden.

The effects of ethanol and/or glycine on NMDA-induced enhancement of cytoplasmic free Ca²⁺ [Ca²⁺], ⁴⁵Ca²⁺ uptake, 4-β-[³H]phorbol-12,13dibutyrate ([3H]PDBu) binding, and neuronal necrosis in cultured rat cortical and cerebellar granule neurons were examined. In microfluorimetric assays with rapid perfusion of single brain neurons, we found that ethanol (50 mM; in the presence of 10 µM glycine) inhibited the effects of NMDA in some, but not all, cortical and cerebellar granule neurons. In monolayers of cortical and cerebellar granule cells, glycine (10 µM) was a necessary prerequisite to unmask inhibitory actions of ethanol on ⁴⁵Ca²⁺ uptake induced by NMDA. Moreover, NMDA-induced stimulation of [3H]PDBu binding to monolayers of intact cerebellar granule cells was concentration-dependently inhibited by ethanol (20-100 mM). Finally, ethanol caused a concentration-dependent inhibition of NMDA-induced necrotic cell death, assessed by measuring the ability of cerebellar granule cells to transform MTT into formazan. In none of these assays, the ethanol-induced inhibition of NMDA receptors was reversed by glycine (up to 100 µM). In contrast to earlier reports, our data suggest that ethanol and glycine produce their effects by acting at different regulatory sites within the NMDA receptor system in brain neurons.

BLOCKADE OF PHENCYCLIDINE- AND MK801-INDUCED REGIONAL zif268 mRNA EXPRESSION WITH D-CYCLOSERINE AND NE-100. X.-M. Gao*, L.-W. Chen and C.A. Tamminga. Maryland Psychiatric Research Center University of Maryland School of Medicine. Baltimore MD 21228

Phencyclidine (PCP)-induced neurochemical changes in CNS may provide a useful paradigm for studying the neurochemistry of psychosis. We have already studied several pharmacologic features of PCP pharmacology in animals and reported time-dependent effects of PCP and MK801 on glucose utilization, NMDA-sensitive glutamate receptor density, its subunit mRNA and on the expression of zif268 and cfos mRNA in rat brain (Gao, et al., Neurosci. Abstr., 1995). In cortical areas, different doses of PCP and MK801 produced early induction (3h) and delayed suppression (24h) of the zif268 mRNA. The pharmacology of this immediate early gene could suggest neuronal mechanisms associated with PCP's other acute and delayed neuro-pharmacological effects. In the present study, we tested the ability of D-cycloserine, a partial agonist at the glycine site of the NMDA-sensitive glutamate receptor, and NE100, a sigma receptor antagonist, to block PCP-and MK801-induced zif268 mRNA expression at 3h and 24h in rat brain. We employed in situ hybridization and quantified the film densities autoradiographically. D-cycloserine (5 mg/kg) significantly attenuated the PCP (1 mg/kg) stimulated induction of zif268 mRNA at 3h in medial prefrontal (MPC) and dorsolateral frontal (DFC) cortices. In hippocampal areas (CA., CA., CA., and DG), D-cycloserine significantly increased the zif268 mRNA at 3h compared with either PCP or MK801 alone. NE100 (1 mg/kg) failed to block any of the PCP- or MK801-induced zif268 mRNA changes at 3 h. We will report the effects of D-cycloserine and NE100 on the actions of PCP/MK801 on zif268 mRNA at 24h. Research supported by NIMH (CRC MH40279).

NOVEL SYSTEMICALLY ACTIVE ANTAGONISTS OF THE GLYCINE SITE OF NMDA RECEPTOR - BEHAVIOURAL CHARACTERISATION W. Danysz¹, C.G. Parsons¹, M. Karcz-Kubicha¹, M. Gold¹, I. Kalvinch², L. Piskunova² and E. Rozhkov², Dept. Pharmacol., Merz + Co, 60318 Frankfurt / Main, Germany¹, Institute of Organic Synthesis, 1006 Riga, Latvia².

Although a number of uncompetitive and competitive NMDA receptor

Although a number of uncompetitive and competitive NMDA receptor antagonists are already used clinically or are at a late phase of development, less is known about the therapeutic potential of antagonists acting at the strychnine-insensitive glycine recognition site of the NMDA receptor (glycine_B). Suggested better therapeutic index of such compounds was mainly based on central administration of compounds and needs verification using systemically active agents.

Several glycine_B antagonists - pyridazine quinoline derivatives (see Parsons et al. and Chizh et al. - this meeting) - have been tested in behavioural tests. They inhibited PTZ-, NMDA- and MES-induced convulsions in mice with ED₃₀s ranging from 8 to 20 mg/kg i.p. The duration of anticonvulsive action was rather short (30-40 min.) but was prolonged by the organic acid transport inhibitor probenecid (100 mg/kg). At doses within the anticonvulsive range, myorelaxation (traction test) and ataxia (rotarod test) were observed. In rats in the open field test the same glycine_B antagonist produced sedation and attenuated the hyperlocomotion induced by both PCP and amphetamine. This antagonism was specific at moderate, non-ataxic doses as evidenced by a significant interaction factor in ANOVA. These data indicate a lack of psychotomimetic potential and possibly even antipsychotic activity of Merz glycine_B antagonists. Merz glycine_B antagonists also attenuated haloperidol-induced catalepsy but failed to produce reliable anxiolytic activity either in the elevated plus maze or the Vogel test. At higher doses all Merz glycine_B antagonists tested induced anterograde amnesia in the passive avoidance test.

Hence, the agents tested represent a novel class of systemically active glycine antagonists with potential antipsychotic and antiparkinsonian activity.

NOVEL ANTAGONISTS OF THE GLYCINE SITE OF THE NMDA RECEPTOR -ELECTROPHYSIOLOGICAL AND BIOCHEMICAL CHARACTERISATION C.G. Parsons*1. W. Danysz¹, S. Hartmann¹, A. Bartmann¹, M. Gold¹, J. Kalvinch², L. Piskunova² and E. Rozhkov², Dept. Pharmacol., Merz + Co, 60318 Frankfurt / Main, Germany¹, Institute of Organic Synthesis, 1006 Riga, Latvia².

A series of novel pyridazine quinoline derivatives was tested for antagonistic

effects at the strychnine-insensitive glycine modulatory site of the NMDA receptor complex (glycine_B). All compounds displaced [3H]-5,7-dichlorokynurenic acid (10nM) and [1 H]-glycine (20nM) binding to rat cortical membranes with IC $_{50}$ s of between 10nM and 1 μ M. Steady-state inward current responses of cultured superior colliculus neurones to NMDA (200µM with glycine 1µM) were antagonized by these same compounds with IC50s of 0.2-2.0µM. The antagonism observed was typical for glycine_n antagonists i.e. they induced desensitisation and their effects were not use-or voltage-dependent. Moreover, increasing concentrations of glycine were able to decrease their apparent potency e.g. Mrz 2/502 had IC₅₀s of 0.28, 1.06 and 3.08μM in the presence of glycine 1, 3 and 10µM respectively. Much higher concentrations (>100 µM) were required to antagonise steady-state inward current responses to AMPA (100µM) and, in this case, the antagonism observed was reminiscent of a competitive interaction i.e. peak responses were more affected than steady state responses. These glycine_B antagonists were also tested against NMDA (500µM) induced neurotoxicity in cultured cortical neurones and provided near complete protection at 5µM in the presence of 1µM glycine. These compounds are also NMDA receptor antagonists in the CNS following systemic administration and are active in a variety of in vivo behavioural models where glutamate is known to play a pivotal role (Chizh et al., and Danysz et al. this meeting). Hence, these pyridazine quinoline derivatives represent a novel class of systemically active glycine_B antagonists and should prove to be useful tools to elucidate the therapeutic potential of this class of NMDA receptor antagonist

IN VIVO SIGNIFICANCE OF THE DIFFERENT VOLTAGE DEPENDENCE OF UNCOMPETITIVE AND GLYCINE® NMDA ANTAGONISTS

M. McClean¹, B.A. Chizh¹, M.W. Jones¹, C.G. Parsons² and P.M. Headley¹
[SPON: Brain Research Association]. Dept. Physiology. University of Bristol. BS8
ITD, UK¹ and Dept. Pharmacology. Merz + Co, 60318 Frankfurt/Main, Germany²
In isolated tissues, uncompetitive NMDA antagonists show voltage dependence, whereas NMDA receptor associated glycine® antagoinsts do not. The extent to which this property affects their actions on synaptic responses under in vivo conditions is not established. We have now examined two uncompetitive channel-blocking NMDA antagonists and two glycine® NMDA antagonists (Chizh et al. Parsons et al., this meeting). In α-chloralose anaesthetized spinalized rats, cumulative doses were tested on spinal mixed NMDA/non-NMDA receptor mediated responses to calibrated noxious pinch stimuli to the hindfoot (on motoneurones), and to iontophoretic NMDA (on dorsal horn neurones). The log of antagonist doses reducing responses to 50% control (mg/kg i.v.) was plotted against antagonist does reducing responses to 50% control (mg/kg l.v.) was plotted against control response amplitude (mean spike discharge during pre-drug responses, taken as a measure of membrane depolarization) by linear regression. The rank order of these slopes (with Pearson product moment correlation values) was: memantine (r=0.73, n=12) > ketamine (r=0.58, n=20) > Mrz 2/502 (r=0.73, n=18) = Mrz (1-0.78, n-12) - ketantine (1-0.78, n=20) - MTZ 2/502 (T=0.73, n=18) = MTZ 2/576 (T=0.95, n=8). Equivalent data for responses to iontophoretic NMDA were memantine (T=0.86, n=12) = ketantine (T=0.68, n=17) >> MTZ 2/502 (T=0.28, n=8) = MTZ 2/576 (T=-0.21, n=9). This rank order matches the degree of voltage dependence determined in vitro. The results suggest that, as predicted, greater dependence determined in view. The testins suggest that, as pictuited, greater voltage dependence results in lower effectiveness on those synaptic responses generating higher levels of spike discharge. NMDA antagonists having greater voltage dependence are therefore less likely to affect strong synaptic signals than low level NMDA receptor mediated activity, and so should have less serious side effect profiles.

AN IN VIVO STUDY OF THE POTENCY AND SELECTIVITY OF NOVEL SYSTEMICALLY ACTIVE ANTAGONISTS AT THE GLYCINE SITE OF THE NMDA RECEPTOR. B.A. Chizh¹, M. McClean¹, C.G. Parsons² and P.M. Headley¹ [SPON: Brain Research Association*], Dept. Physiol., Univ. Bristol, Bristol BS8 ITD, U.K. and Dept. Pharmacol., Merz+Co., 60318 Frankfurt/Main, Germany

A new series of pyridazine quinoline derivatives has been tested for activity as antagonists of NMDA and of nociceptive responses in the rat spinal cord after i.v administration in α-chloralose-anaesthetized spinalized rats in vivo. They are selective antagonists at the NMDA receptor glycine (glycine_B) site and are active as anticonvulsants in mice (Parsons et al. and Danysz et al., this meeting) Compounds were tested on responses of dorsal horn (DH) neurones to iontophoretic NMDA and AMPA. The most potent and selective NMDA antagonists were Mrz 2/502, Mrz 2/576 and Mrz 2/570 (ID $_{50}$ \pm s.e.m. 1.6 \pm 0.3, 2.8 \pm 0.7 and 4.5 \pm 0.7 mg/kg i.v., n=6-7, cf 1.3 \pm 0.3 mg/kg i.v. for ketamine, n=9). At the maximal doses tested responses to NMDA were reduced by Mrz 2/502 (2-4, mean 3 mg/kg) to $17\pm6\%$ control (AMPA 76±8%); by Mrz 2/576 (2-8, mean 4 mg/kg) to 30±7% control (AMPA 88±6%); by Mrz 2/570 (4-16, mean 9 mg/kg) to 29±4% control (AMPA 100±9%). On the same cells, ketamine (1-4, mean 3 mg/kg, n=17) reduced NMDA to 15±3% control (AMPA 91±4%). MRZ 2/502 and MRZ 2/576 were also tested i.v. on responses of hindlimb flexor muscle single motor units to noxious pinch of one foot. These responses had a strong NMDA receptor mediated component (ketamine ID $_{50}$ for inhibiting nociceptive responses 0.9 ± 0.2 mg/kg, n=11). The potency rank order and ID $_{50}$ values were similar to those obtained on NMDA responses of DH neurones: Mrz 2/502 1.0 ± 0.3 mg/kg (n=10), Mrz 2/576 3.3 ± 0.4 mg/kg (n=5). In both kinds of tests the effects of all compounds were short-lived (t_{1/2} 8-12 min). These compounds are therefore selective, and systemically active, antagonists of NMDA receptor mediated events. Supported by Merz+Co

EXCITATORY AMINO ACIDS: PHARMACOLOGY II

PRETREATMENT WITH NMDA RECEPTOR ANTAGONIST MK801 IMPROVES NEUROPHYSIOLOGICAL OUTCOME AFTER AN ACUTE SPINAL CORD INJURY. S.S. Haghighi*, G.C. Johnson, C.F. de Vergel, and B.J. Vergel Rivas. Dept. of Neurosurgery, MCPHU, Phila., PA.

The posttraumatic release of excitatory amino acids (EAA) and their actions on N-methyl-D-aspartate (NMDA) receptors plays a major role in the spinal cord secondary injury process. The neuronal damage caused by the release of EAA may be reduced by NMDA-receptor channel blockers. To investigate the involvement of NMDA receptors in spinal cord injury (SCI), we pretreated animals with the non-competitive NMDA antagonist MK801 (1.0 mg/kg) before a compressive acute SCI. Pretreated animals with MK801 significantly (p=0.038) improved the recovery of function as measured by evoked potential activities. Morphologically specimens from rats treated with MK801 were characterized by milder and more localized hemorrhage in the gray matter. Immunohistochemical staining for glial fibrillary acidic protein (GFAP) and neurofilament (NF) histochemistry showed leakage of these antigens in traumatized cord while characteristic staining of astrocytes and neurons and their processes was observed in morphologically preserved tissue. The loss of NF immunoreactivity was reduced by MK801 treatment.

MK-801 CAUSES TERMINAL DEGENERATION IN WIDESPREAD AREAS OF RAT BRAIN. S. Sparenborg*, R.C. Switzer III, J. Forster and M.G. Filbert. FDA, Rockville, MD, 20857, NeuroScience Associates, Knoxville, TN, 37922, and U.S. Army Med. Res. Inst. of Chemical Defense, Aberdeen Proving Ground, MD, 21010

Single sc injections of the NMDA antagonist MK-801 (0.1, 0.3, or 0.5 mg/kg) were given to female rats 6, 14, 24 or 96 hrs before sacrifice. Neuronal degeneration was evaluated in one brain hemisphere with the cupric-silver method. A single 1-micron-thick methacrylate section from the other hemisphere, containing the retrosplenial cortex, was stained with toluidine blue for visualization of neuronal vacuoles.

Rats sacrificed after 6 hrs had vacuoles in the cytoplasm of retrosplenial neurons (0, 0, 10, and 30 neurons w/vacuoles, respectively, in the control, low, mid and high dose groups). Vacuoles were not found in rats with longer survival times. After 6 hrs. synaptic terminal degeneration (TD), induced by MK-801, appeared in the superficial (I-IV) layers of dysgranular retrosplenial cortex (Rsd) and in its efferent cortical targets, including granular retrosplenial cortex (Rsg), occipital and parietal areas processing vision and audition, and frontal (motor) association areas. In the hippocampus, TD was mild to severe in the molecular layer of the dentate gyrus and in stratum lacunosum moleculare of CA1. These effects were noted at all dose levels and generally increased in severity with longer survival times. Dead neurons were noted in the piriform cortex of some rats given the low dose of MK-801 and sacrificed 14 or 24 hrs later. However, silver staining was virtually absent from all brain areas of low-dose rats sacrificed after 96 hrs, indicating that degenerated terminals and soma had been cleared from the brain.

Many dead cell bodies were visible in Rsg and Rsd of mid- and high-dose rats sacrificed after 24 and 96 hrs, and were occasionally found in piriform and entorhinal cortices. TD represents the permanent loss of interneuronal communication through the affected synapses. Widespread TD and the loss of cells in the piriform cortex indicate that MK-801 produced a long-lasting toxic effect at a dose lower than that which produced vacuoles. Supported by USAMRICD

CGS-19755 FULLY GENERALIZES TO THE DISCRIMINATIVE STIMULUS PROPERTIES OF PHENCYCLIDINE WHEN ADMINISTERED INTRAVENOUSLY IN RATS. M.J. Piesla and K.L. Marquis*, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

wyeth-Ayers Research, CN 6000, Finiteding, NV 053-34. When studying glutamate antagonists, these drugs should be tested in animal models that predict a potential for psychotomimetic side effects. In the current study, phencyclidine (PCP) and CGS-19755 were compared following intraperitoneal or intravenous administration in male Sprague-Dawley rats trained to discriminate 1.25 mg/kg i.p. PCP from saline in a food-reinforced operant procedure. PCP fully generalized to the PCP discriminative stimulus when administered 15 minutes prior to the test session (ED50 = 0.79 mg/kg i.p. and 77% of the animals selected the drug appropriate lever at 0.54 mg/kg i.v.). CGS-19755 partially generalized when administered either 15 minutes (maximum effect = 45% of the animals selected the PCP lever; ED50 > 54 mg/kg i.p.) or 90 minutes (maximum effect = 64%; ED₅₀ = 7.0 mg/kg i.p.) prior to the test session in i.p. dose response studies. CGS-19755 fully generalized when administered i.v. 90 minutes prior to the test session (maximum effect = 83%; ED50 = 11.1 mg/kg i.v.). CGS-19755 (30 mg/kg i.p.) fully generalized (> 70%) 60 and 120 minutes following i.p. administration. CGS-19755 partially generalized at other time points tested ranging from 45 minutes to 6 hours (i.p. and i.v.). These data indicate that the competitive NMDA antagonist CGS-19755 has the potential to produce PCP-like stimulus properties in some subjects at high doses. When conditions are optimized in animals by altering pretreatment time or route of administration, full generalization to the PCP cue can be observed. As PCP discriminative stimulus properties predict psychotomimetic potential in humans, these data indicate a risk for these side effects in some individuals following administration of CGS-19755. These results are consistent with recent reports of psychotomimetic side effects induced by CGS-19755 in clinical trials (Grotta *et al.*, 1995).

AMPA MODULATES NITRIC OXIDE RELEASE IN THE STRIATUM AS MEASURED BY BRAIN MICRODIALYSIS. K. Sakai', K. Kashihara'*, T. Tsuji', K. Akiyama², and T. 1)Department of Neurology 2)Department of Neuropsychiatry, Okayama University Medical School, 2-5-1 Shikata-cho, Okayama 700

An effect of amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), a specific agonist of AMPA receptor, on the striatal nitric oxide release was investigated using in vivo microdialysis technique in the freely moving rat. Each dialysis probe was implanted into the left anterior dorsal striatum. The probe was perfused with artificial cerebrospinal fluid and perfusates were collected every 20 min.

The perfusion of the AMPA 1.0 mM increased concentration of extracellular nitric oxide oxidation products nitrite and nitrate. The perfusion of the AMPA 0.1 mM did not change the extracellular nitrite and nitrate levels.

The present results demonstrate that AMPA receptor modulates the release of nitric oxide in the striatum.

AMPA receptor may be involved in the release of nitric oxide in the central nervous system.

605.7

THE EFFECTS OF DIRECT INFUSION OF NMDA INTO THE PREFRONTAL CORTEX ON NUCLEUS ACCUMBENS AND VENTRAL TEGMENTAL AREA DOPAMINE: AN IN VIVO MICRODIALYSIS STUDY USING SIMULTANEOUS SAMPLING. J.J. Panos, K.J. Thompson, T.E. Egan, and R. E. Steinpreis*. Department of Psychology, The University of Wisconsin-Milwaukee, 53211.

NMDA was infused directly into the prefrontal cortex and the effects on extracellular dopamine in the nucleus accumbens and the ventral tegmental area were measured using simultaneous micro-

were measured using simultaneous micro-dialysis sampling. Male Sprague Dawley rats had indwelling unilateral cannula surgically implanted in the prefrontal cortex. Microdialysis probe guides were cortex. Microdialysis probe guides were implanted in the nucleus accumbens and the ventral tegmental area. Three days later microdialysis samples were collected simultaneously from the nucleus accumbens and the ventral tegmental area for two hours pre-NMDA infusion into the prefrontal cortex and for six hours post injection. Dialysis samples were analyzed using HPLC. Infusion of NMDA resulted in elevations of extracellular dopamine in the nucleus extracellular dopamine in the nucleus accumbens and the ventral tegmental area. These elevations corresponded to increases in locomotor activity.

ABSENCE OF [3H]MK-801 BINDING IN COS-7 CELLS TRANSIENTLY EXPRESSING THE NMDAR1 GLUTAMATE RECEPTOR SUBUNIT. J.E. Roth*, P.H. Franklin, T.F. Murray and M. Leid. College of Pharmacy,

J.E. Roth*. P.H. Franklin, T.F. Murray and M. Leid. College of Pharmacy, Oregon State University, Corvallis, OR 97331.

To increase our understanding of the functional significance of recombinant homomeric NMDAR1 receptors, COS cells transiently expressing NR1-1a were tested for their ability to bind the noncompetitive NMDA antagonist [3H]MK-801. Rat forebrain membranes and membranes derived from COS cells electroporated with either NR1 or pTL1 (empty vector) were incubated with increasing concentrations of [3H]MK-801 for this. at 22°C in the presence of glycine (10 µM) and glutamate (10 µM). A centrifugation assay was employed to separate bound from free radioligand. [3H]MK-801 bound saturably and with high affinity (K_D = 2 nM, B_{max} = 3 monthm protein) to ref. prophranes as detected using either 1 µM. [³H]MK-801 bound saturably and with high affinity ($K_D = 2$ nM, $B_{max} = 3$ pmol/mg protein) to rat forebrain membranes as detected using either 1 μM PCP or 10 μM MK-801 to define nonspecific binding. However, [³H]MK-801 binding as defined by 1 μM PCP was not detected in membranes derived from COS cells transfected with NR1 even though these membranes specifically bound the glycine site antagonist [³H]5,7-dichlorokynurenic acid and contained high levels of NR1 protein as determined by immunoblot and immunocytochemical analysis. Interestingly, the use of 10 μM unlabelled MK-801 to define nonspecific binding allowed detection of displaceable [³H]MK-801 binding in membranes derived from COS cells transfected with NR1. [³H]MK-801 labelled a population of binding sites with an apparent K_D of 54 nM and B_{max} of 11 pmol/mg protein. However, [³H]MK-801 labelled a similar population of binding sites in control membranes transfected with the of 34 nM and B_{max} of 11 pmormg protein. However, [YH]MN-801 labelled a similar population of binding sites in control membranes transfected with the expression vector pTL1, suggesting that this [³H]MK-801 binding is not dependent on NR1 expression and therefore not associated with occupancy of NMDAR1. These findings caution against the use of a self displacement strategy when using this radioligand.

N-METHYL-D-ASPARTATE ADMINISTRATION IN RAT HIPPOCAMPUS AND STRIATUM INCREASES NITRITE AND NITRATE LEVELS: A MEASURE OF NITRIC OXIDE RELEASE. Edward Spangler, Donald K. Ingram and Hideki Kametani. Gerontology Research Center, NIA, NIH, Baltimore, MD 21224, and Fukuoka Prefectural University, Fukuoka, JAPAN

Nitric oxide (NO) in the central nervous system has been linked to long-term potentiation, possibly the cellular basis for learning, and brain dysfunction including ischemia and aging. Stimulation of the N-methyl-D-asparate (NMDA) receptor results in release of NO, which serves as a retrograde messenger, that binds to cGMP to induce glutamate release. Wistar Kyoto rats 4-mo old were anesthetized, and a probe stereotaxically implanted unilaterally into striatum (STR:AP 0.7;ML 3.0;DV -4.5) and hippocampus (HC:AP-3.8;M/L2.0;D/V-2.2). Using an in vivo microdialysis procedure on the following two days, we first perfused HC and STR, counterbalancing side and day, with artificial cerebrospinal fluid (aCSF) for approximately 90 min and evaluated basal levels of oxidized byproducts of NO, nitrite (NO₂) and nitrate (NO₃), using an automated NO analyzer (Eicom; Kyoto, Japan). Then, 1 mM N-methyl-D-aspartic acid, a potent NMDA agonist, was added to aCSF and perfused for 20 min, and NO₂ and NO₃, evaluated in the same way followed by 1 hr of aCSF. This injection was followed by 5mM and 10mM NMDA using the same procedure. NO_2 and NO_3 levels were increased 20-50% above basal levels at each dose of NMDA in STR and HC. Increases above baseline levels were maintained for 20 min after NMDA administration at each dose. In each rat, we observed marked behavioral changes associated with NMDA stimulation including wet dog shakes, increased movement and grooming. In vivo levels of NO₂ and NO₃ thus appear to represent reliable measures of NO release in brain and may be determined using automated equipment, such as the NO analyzer.

605.8

NMDA-STIMULATED NOREPINEPHRINE (NE) RELEASE IN SPINAL CORD: EFFECTS OF SCIATIC NERVE INJURY. <u>D.W. Glasser and D.J. Jones*</u>, Depts Pharmacol. and Anesth., Univ. of TX HIth. Sci. Ctr., San Antonio, TX 78284.

The N-Methyl-D-Aspartate (NMDA) subtype of glutamate (GLU) receptor has previously been shown to be involved in transmission of sensory impulses to the spinal cord. Since NMOA also stimulates the release of norepinephrine (NE) from spinal cord slices, the purpose of the present studies was to determine if NMDA-stimulated NE release may play a role in the spinal integration of increased sensory input using a sciatic nerve cryoneurolysis (SNC) as a model of chronic pain.

Male Sprague-Dawley rats were anesthetized and the right sciatic nerve exposed and frozen with a nitrous oxide cryoprobe. Sham-operated animals served as controls. After appearance of pain-related behaviors (autotomy and tactile hyperalgesia), animals were sacrificed and spinal cords removed for [3H]NE release experiments or frozen for [3H]MK-801 binding assays. Fractional [3H]NE release was measured from perfused regional spinal cord slices preloaded with [³H]NE (0.05µM).

In the absence of Mg⁺⁺, NMDA increased NE release from spinal cord

slices in a concentration-dependent manner. NMDA released more NE from dorsal spinal cord slices than ventral, whereas non-NMDA stimulation showed no difference between dorsal and ventral regions. In SNC animals, NMDAstimulated release of NE from dorsal lumbar spinal cord was significantly reduced compared to sham animals, but was unchanged in other regions. K*or non-NMDA stimulated release of NE was likewise unchanged. [3H]MK-801 binding was decreased in SNC animals but not controls. These findings suggest that interactions between spinal GLU and NE are altered when afferent input to the spinal cord is changed, possibly due to changes in the number or open state of NMDA receptors. Supported by S/IUCRC - CEBBI.

ASPARTATE AND GLUTAMATE RELEASE IN THE VENTRAL TEGMENTAL AREA INCREASES BIPHASICALLY FOLLOWING N-METHYL-D-ASPARTATE PERFUSION IN RAT PREFRONTAL CORTEX. A DUAL MICRODIALYSIS PROBE STUDY IN THE AWAKE RAT. K. Frantz*, U. Ungerstedt and W.T. O'Connor¹. Department of Physiology and Pharmacology, Division of Pharmacology, Karolinska Institute, Stockholm S171-77, Sweden and ¹Department of Human Anatomy and Physiology, Neuroscience Division, University College, Dublin, Ireland.

The effect of local perfusion with the glutamate receptor agonist N-Methyl-D-Aspartate (NMDA) in the left medial prefrontal cortex (mPFC) on aspartate and glutamate release locally in the mPFC and in the ventral tegmental area (VTA) was investigated using the dual microdialysis probe approach in the awake freely moving rat. One probe was implanted in the mPFC and a second probe in the ipsilateral VTA. Perfusion with NMDA into the mPFC at 100, 300 and 600µM elicited concentration-related increases in local aspartate and glutamate release. There was a strong correlation in the NMDA-induced increases in aspartate and glutamate release. In the VTA, a biphasic change in aspartate and glutamate release occurred, such that the 300µM dose of NMDA was associated with the strongest increases. Following perfusion with the noncompetitive NMDA receptor antagonist, MK801 (10µM), the NMDA (300µM)induced increase in aspartate and glutamate release was abolished in the mPFC and attenuated in the VTA

The data suggest that NMDA receptors are located on aspartate- and glutamate-containing neurons in the mPFC. The results also demonstrate an excitatory mPFC projection to the VTA and indicate that this pathway displays a biphasic response to mPFC NMDA receptor stimulation i.e. maximal activation at the 300μM concentration of NMDA and reduced activation at lower and higher concentrations of NMDA. Thus, in vivo functional evidence is provided for a dynamic regulation of VTA transmission by cortical aspartate and glutamate

INHIBITION OF GLUTAMATE TRANSPORTER ACTIVITY BY

INHIBITION OF GLUTAMATE TRANSPORTER ACTIVITY BY SUBSTANCE P. R. Ganel and C. E. Crosson*1.2, Departments of Pharmacology and Ophthalmology and Visual Sciences2, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

The termination of synaptic glutamate transmission and the prevention of excitotoxic damage depends on the fast removal of the glutamate by high-affinity transport systems. This study examines the effects of the neuropeptide substance P (SP) on a human glutamate transporter (EAAT2) expressed by Y-79 retinoblastoma cells. Retinoblastoma cell cultures were maintained in RPMI-1640 media containing 10% fetal calf serum. On the experiment day, cells were washed and then incubated in a modified Ringer's solution containing 2 µM tritiated L-glutamate (5 µCi) for 2, 4, 6 and 8 minutes. The uptake of the labeled glutamate was measured in control (untreated) cells and in cells pre-incubated for 10 minutes with 0.1 nM to 100 nM SP. Control uptake of 2 µM glutamate by retinoblastoma cells was found to be 1.3 ± cells pre-incubated for 10 minutes with 0.1 nM to 100 nM SP. Control uptake of 2 μ M glutamate by retinoblastoma cells was found to be 1.3 \pm 0.16 pmoles/min/million cells (n = 10). Following a 10-minute pre-incubation with 10-7 M SP. a 61% reduction in glutamate uptake was measured. Analysis of the dose-response curves revealed an IC₅₀ of 22 nM for the SP-induced inhibition of glutamate uptake. Preincubation with the NK1 antagonist CP-96345 or the NK2 antagonist SR 48,968 did not alter the SP-induced inhibition of glutamate uptake. Analysis of glutamate uptake kinetics demonstrated that preincubation with 100 nM SP significantly reduced the Vmax for glutamate uptake from 2.5 \pm 0.19 to 0.6 \pm 0.13 pmoles/min/million cells. However, no significant change in Km was observed. This study demonstrates that the EAAT2 glutamate transporter expressed by human retinoblastoma cells is inhibited by the neuropeptide SP in a non-competitive manner. However, this response is not due to the activation of NK1 or NK2 receptors.

605.13

COMPARISON OF [3 H]-(S)-FLUOROWILLARDIINE AND [3 H]-(S)-AMPA BINDING IN RAT BRAIN MEMBRANES. Stephen A. Espitia. D. Scott Wieland* and Jon E. Hawkinson.
Technology Dr., Irvine, CA 92618 CoCensys, Inc., 213

[*H]-(S)-Fluorowillardiine binding in the presence and absence of the chaotopic agent KSCN was evaluated relative to [*H]-(S)-AMPA binding in the presence of KSCN in rat brain membranes. AMPA receptor assays were conducted with 10 nM radioligand in a 96-well receptor assays were conducted with 10 nM radioligand in a 95-Weil plate format and terminated by filtration. In contrast to [\$H]-(\$)-AMPA (specific binding 80-90%, ~0.7 pmol/mg protein), [\$H]-(\$)-fluoro-willardiine displays acceptable specific binding in the absence of KSCN (specific binding 85-90%; ~0.7 pmol/mg protein). KSCN (50 mM) increases [\$H]-(\$)-fluoro-willardiine specific binding to 90-95% with ~2 pmol/mg protein. The rank order potency for displacement of radioligand binding by selected agonists and antagonists was similar radioligand bindling by selected agonists and antagonists was similar with both ligands and conditions. However, quisqualate is less potent in the [*H]-(S)-fluorowillardiine assay in the absence of KSCN, possibly because KSCN increases the affinity of [*H]-(S)-fluorowillardiine to a greater extent than quisqualate. The antagonist ligands NBQX, DNQX and CNQX were consistently more potent in the absence than in the presence of KSCN in the [*H]-(S)-fluorowillardiine assay, possibly due to a decrease in affinity of [*H]-(S)-fluorowillardiine in the absence of KSCN. In conclusion, [*H]-(S)-fluorowillardiine displays a similar pharmacological profile to [*H]-(S)-AMPA, provides higher specific binding than [*H]-(S)-AMPA, can be used in filtration assays in the absence of KSCN, and provides a useful tool to evaluate the effects of KSCN on the potency of AMPA receptor agonists and antagonists. KSCN on the potency of AMPA receptor agonists and antagonists.

PENTOBARBITAL INHIBITS N-METHYL-D-ASPARTATE-EVOKED RELEASE OF DOPAMINE IN RAT STRIATUM. Megumi Sugahara, Shinji Shibanoki and Koichi Ishikawa*. Dept. of Pharmacol., Nihon Univ. Sch. of

The effect of pentobarbital on N-methyl-D-aspartate (NMDA)-evoked dopamine release in the rat striatum was investigated by in vivo microdialysis combined with high-performance liquid chromatography and electrochemical detection. The basal output of dopamine was slightly decreased when pentobarbital (50 mg/kg) was injected intraperitoneally. Under pentobarbital anesthesia, the effect of continuous NMDA (1 mM), which causes an increase in extracellular dopamine concentration accompanied by decreases in its metabolite (3,4-dihydroxyphenylacetic acid and homovanillic acid) concentrations, was significantly inhibited. However, the effect of NMDA on dopamine was not inhibited by other intravenous anesthetics such as urethane (400 mg/kg, i.p.). The inhibitory effect of pentobarbital on the NMDA-evoked dopamine release was reduced by increasing the perfusate concentration of Ca2+. On the other hand, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (non-NMDA agonist)-evoked release of dopamine was not inhibited by the treatment with pentobarbital. High K+ (50 mM KCl)-evoked release of dopamine also remained under pentobarbital anesthesia. These results suggest that pentobarbital selectively inhibits the extracellular release of dopamine by activation of NMDA receptors, but not non-NMDA receptors in the striatum, and the inhibition of neurotransmitter release may, in part, contribute to the protective effect of pentobarbital on brain damage induced by ischemic brain injury

DEVELOPMENTALLY REGULATED RNA EDITING OF GLUR5 AND GLUR6 TRANSCRIPTS IN CEREBELLAR GRANULE CELLS. S.M. Belcher and J.R. Howe*. Department of Pharmacology, Yale University School of Medicine, New Haven, CT 06520-8066.

RT-PCR analysis combined with patch-clamp techniques were used to compare the extent of RNA editing of the kainate receptor subunits GluR5 and GluR6 in developing rat cerebellar granule cells.

During the first two postnatal weeks the proportion of transcripts

edited at the Q/R site increased significantly for both GluR5 and GluR5. GluR5(R) transcripts increased from 9% at postnatal day 1 (P1) to 13% (P<0.01) at postnatal day 15 (P15); the corresponding values for GluR6(R) were 61% and 86% (P<0.01), respectively.

The extent of editing at the I/V and C/Y sites in TM1 of GluR6 was also determined for P1, P7 and P15. The extent of editing was least at the I/V site. As for the Q/R site, the proportion of edited transcripts increased for both TM1 sites during the first two postnatal weeks.

Single-cell RT-PCR analysis showed that individual cerebellar granule cells express both Q and R forms of GluR5 and GluR6, although GluR5(Q) and GluR6(R) transcripts are most abundant. Northern analysis of RNA from acutely isolated granule cells showed that GluR5 and GluR6 mRNAs are expressed at similar levels

The levels of each mRNA encoding the double-stranded RNA deaminases DRADA and RED1 were found to increase approximately two-fold between P1 and P15 indicating that either or both of these enzymes may contribute to the developmental increase in editing of GluR5 and GluR6. (Supported by NS 30996).

AGING AND GLUTAMATERGIC EFFECTS OF ANTIPSYCHOTIC DRUGS. E. Yablonsky-Alter*, T.I. Lidsky, S.P. Banerjee. Sophie Davis School of Biomedical Education, CUNY,

The present study investigated the basis of antipsychotic drug (AP) effects as a function of aging. Previous work from this laboratory indicated that APs have unique action on NMDA receptors. At low, clinically relevant concentrations, APs facilitate activity at NMDA receptors while at higher concentrations activity is suppressed. In the current study, a comparison was made of the characteristics of NMDA receptors in mature (13 month old) and aging (26 month old) adult mice. Specific binding of [3H]MK-801 in the presence of glutamate and glycine was significantly higher in older animals suggesting an increase in the functional activity of NMDA receptors. In contrast, affinity at the antagonist site was significantly decreased. This may suggest that a population of NMDA receptors with different characteristics emerges with aging In accord with this suggestion is the additional finding that the stimulatory effect of nanomolar concentrations of APs disappears with aging. The significance of these findings, particularly with respect to APs' increased risk of motor side effects in older patients, remains to be determined.

EFFECT OF ARGININE ADMINISTRATION ON PLASMA AND BRAIN LEVELS OF ARGININE AND VARIOUS AMINO COMPOUNDS IN RATS. I. Buchmann, L. Milakofsky, N. Harris, J. M. Hofford and W. H. Vogel Penn State Univ., Berks Campus, Reading, PA 19610 and Thomas Jefferson Univ., Dept. of Pharmacology, Phila., PA 19107.

Arginine (ARG) administration can cause many pharmacological effects in the periphery and CNS. Little information is available on the accumulation of ARG in rat brain and its effect on related amino compounds in this tissue after ARG administration. Thus, we studied the levels of ARG and related compounds via an HPLC-fluorometric method in rat plasma and 4 brain areas in the morning and aftermoon in control rats and in rats injected with ARG, 0.8 g/kg.jp. In control rats, brain values for ARG and some amino compounds are lower in the afternoon than in the morning. After ARG injection, ARG levels increase about 10 fold in plasma and 2 to 3 fold in the brain areas. Brain ARG levels follow plasma levels. Elevated ARG levels affect a number of related amino compounds both in the plasma and all brain areas (i.e. omithine, phosphoserine, glycine, GABA and ammonia). Increased citrulline after ARG injection suggests ARG stimulated nitric oxide formation in the midbrain. Thus, ARG shows a daily rhythm in the plasma and brain and its administration increases ARG brain levels. Also, ARG alters other amino compounds (GABA, glycine, ornithine and ammonia) indicating that some pharmacological effects seen after ARG injection might be caused by elevated levels of ARG and/or changes in other amino compounds. Supported by the Sanders Medical Research Foundation, Wilmington, DE.

EXCITATORY AMINO ACID RECEPTORS: PHYSIOLOGY, PHARMACOLOGY, AND MODULATION I

606.1

CHARACTERIZATION OF GLUTAMATE RECEPTOR AGONIST-INDUCED NITRIC OXIDE PRODUCTION IN THE RAT CEREBELLUM IN VIVO. K. Yamada* and T. Nabeshima. Dept. of Neuropsychopharmacology and Hospital Pharmacy, Nagoya Univ. Sch. of Medicine, Nagoya 466, Japan.

We examined the mechanisms of nitric oxide (NO) production in vivo by measuring levels of nitrite (NO₂⁻) and nitrate (NO₃⁻) in the dialysate of the cerebellum in awake rats, by using an in vivo brain microdialysis technique. The levels of both NO₂⁻ and NO₃⁻ were decreased by the i.p. injection of NG-nitro-L-arginine methyl ester (L-NAME), an inhibitor of nitric oxide synthase, whereas D-NAME had no effect. L-Arginine by itself increased NO₂⁻ and NO₃⁻ levels, and diminished the reduction of their levels caused by L-NAME. Direct infusion of L-glutamate (L-Glu), NMDA, AMPA or trans-(±)-ACPD into the cerebellum through a dialysis probe resulted in a dose-dependent increase in NO₂⁻ and NO₃⁻ levels. The stimulatory effects of both L-Glu and NMDA were inhibited by (±)-CPP, an NMDA receptor antagonist, while the effect of trans-(±)-ACPD was antagonized by L(+)-AP-3, a metabotropic glutamate receptor antagonist. NMDA failed to increase NO₂⁻ and NO₃⁻ levels in rats which had been previously treated with L-NAME. On the other hand, AMPA and trans-(±)-ACPD caused an increase in NO₂⁻ and NO₃⁻ levels in the L-NAME-pretreated rats. These results suggest that NO₂⁻ and NO₃ levels in the L-NAME-pretreated rats. These results suggest that NO₂⁻ and NO₃ levels in the L-NAME not production in vivo. Further it is suggested that although NMDA increases NO production through the activation of NO synthase, NO production caused by AMPA and trans-(±)-ACPD may be independent on NO synthase activity in the cerebellum in vivo. Supported by the grant from the Ichiro Kanehara Foundation.

GLUTAMATE MODULATES RELEASE OF SOMATOSTATIN FROM CULTURED HIPPOCAMPAL NEURONS THROUGH THE ACTIVATION OF NMDA AND AMPA RECEPTORS. G. Fontana, L. Valenti, A. Gemignani, M. Marchi* and M. Raiteri. Inst. of Pharmacology and Pharmacognosy, University of Genoa, Italy

L-Glutamate, NMDA, D,L- α -amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) and kainate (KA) increased the release of somatostatin-like immunoreactivity (SRIF-LI) from primary cultures of rat hippocampal neurons. In Mg 2 -containing medium, the maximal effects (reached at about 100 μ M) amounted to 737% (KA), 722% (glutamate), 488% (NMDA) and 374% (AMPA); the apparent affinities were 22 μ M (AMPA), 39 μ M (glutamate), 41 μ M (KA) and 70 μ M (MMDA). The metabotropic receptor agonist trans-1-aminocyclopentane-1,3-dicarboxylate did not affect SRIF-LI release. The release evoked by glutamate (100 μ M) was abolished by 10 μ M dizocilpine (MK-801) plus 30 μ M -1-aminophyl-4-methyl-7,8-methylenedioxy-5H-2,3-benzodiazepine (GYKI 52466). Moreover, the maximal effect of glutamate was mimicked by a mixture of NMDA + AMPA. The release elicited by NMDA was sensitive to MK-801 but insensitive to GYKI 52466. The AMPA- and KA-evoked releases were blocked by 6,7-dinitroquinoxaline-2,3-dione (DNQX) or by GYKI 52466 but were insensitive to MK-801. The release of SRIF-LI elicited by all four agonists was Ca dependent while only the NMDA-evoked release was prevented by tetrodotoxin. Removal of Mg caused increase of basal SRIF-LI release, an effect abolished by MK-801. Thus glutamate can stimulate somatostatin release through ionotropic NMDA and AMPA/KA receptors. Receptors of the kainate type (AMPA-insensitive) or metabotropic receptors seem not to be involved. Supported by grants from the Italian MURST and CNR.

REGIONAL EFFECTS OF CHRONIC LEAD EXPOSURE ON MK-801 AND AMPA BINDING IN RAT BRAIN. <u>Eric K. Richfield ** L. M. McCoy* and D.A. Cory-Slechta*</u>. Departments of Neurology*, Psychiatry*, and Neurobiology and Anatomy*, University of Rochester School of Medicine & Dentistry. Rochester. NY 14642

Prefrontal cortical glutamate modulates subcortical dopamine (DA) function in striatum, in part through the NMDA receptor/fon channel. Insults at any link in this prefrontal cortex-nucleus accumbens-thalamo-cortical circuit can result in effects on the entire circuit. Lead (Pb) exposure disrupts DA systems, decreasing DA binding preferentially in ventral striatum after as little as 2 weeks of postweaning Pb exposure. The present study sought to determine whether such changes might be an indirect consequence of changes in NMDA or non-NMDA receptor binding. ³H-MK-801 and ³H-AMPA binding in medial frontal cortex and dorsal and ventral striatum were measured autoradiographically. The ³H-MK-801 assay allowed the combined and individual assessment of glutamate, glycine and spermidine activation of the PCP site on the NMDA receptor/ion channel (McCoy and Richfield, 1995). Rats were treated with levels of 0, 50 or 150 ppm Pb acetate in drinking water for either 2 weeks or 8 mos. After 2 weeks of Pb exposure, AMPA binding in striatum, and glycine-activated MK-801 binding in ventral striatum were preferentially increased, particularly at 50 ppm, whereas decreases were seen in all regions at 150 ppm under condition of non- or maximally stimulated MK-801 binding. At 8 mos. notable Pb -related decreases in both AMPA and MK-801 sites were observed at both 50 and 150 ppm, with more pronounced decreases in situal regions than in cortex. These results demonstrate that chronic Pb exposure impacts both NMDA and non-NMDA receptors. Comparison of Pb effect levels on glutamate and DA systems raises the possibility that DA system dysfunction may arise indirectly from initial Pb alterations in glutamate systems since effects of 50 ppm Pb on DA were generally not evident. REGULATION OF ACETYLCHOLINE AND GABA RELEASE BY GLUTAMATERGIC AND DOPAMINERGIC AGONISTS IN RAT STRIATUM. T. Hanania and K. M. Johnson*. Dept. of Pharmacol. and Toxicol., Univ. of Texas Med Branch, Galveston, TX 77555-1031

Phencyclidine (PCP) is thought to act by blocking NMDA receptors and monoamine transporters. PCP-induced alterations in rat motor behavior is critically dependent on descending glutamatergic input as well as ascending dopaminergic input to the striatum. In this study, radioactivity released from striatal slices loaded with [14C]GABA and [3H]choline were used as markers of GABA and acetylcholine (ACh) release in order to understand how dopaminergic and glutamatergic receptors interact to regulate striatal function. NMDA increased ACh and GABA release in a dose-dependent and TTX sensitive manner. The duration of the release of ACh by NMDA was much greater than that of GABA, suggesting that different NMDA subunits mediate these responses as previously suggested by others. NMDA-induced GABA release is also PCP and nipecotic acid-sensitive. The D1 agonists SKF82958 and SKF38393 potentiated NMDA-induced GABA release. The D1 antagonist SCH23390 and the protein kinase A inhibitor, H-89, blocked this potentiation. Experiments with D1 agonists on ACh release gave inconclusive results. The D2 agonist quinpirole inhibited NMDA-stimulated GABA and ACh release, and this effect was reversed by the D2 antagonist sulpiride. The mGluR agonist 1S,3R-ACPD potentiated NMDA-stimulated GABA release, but had no effect on ACh release. The D1 agonist SKF82958 together with 1S,3R-ACPD, did not produce an additive effect on GABA release, suggesting the possibility that both agonists may act through G_s -mediated increases in cAMP. These data help to provide a better framework for understanding the mechanisms by which PCP alters striatal functions. Supported by DA 02073.

THE ACUTE SYSTEMIC ADMINISTRATION OF MK-801 INCREASES LOCOMOTOR ACTIVITY AND DOPAMINE METABOLISM IN RAT NUCLEUS ACCUMBENS. D. Jolly*, J. Brose and P. Vezina. Department of Psychiatry, University of Chicago, Chicago, IL 60637.

The present experiment assessed the effects of acute systemic injections of the noncompetitive N-methyl-D-aspartate receptor antagonist, MK-801, on locomotor activity and extracellular levels of dopamine (DA) and its metabolites, DOPAC and HVA, in the nucleus accumbens (NAcc). Each dose of MK-801 tested (0, 0.05, 0.10, 0.30 and 0.50 mg/kg, i.p.) was administered to rats in separate groups. Measurement of NAcc DA and its metabolites was accomplished with in vivo microdialysis in chambers designed to simultaneously measure locomotion. The DA, DOPAC and HVA recovered in dialysates during twelve 20 minute samples (three baseline and nine post-injection) were quantitated by HPLC-EC. MK-801 produced dosedependent increases in locomotor activity that were observed throughout the three hours of testing following injection. While consistent elevations in extracellular DA were not observed, levels of DOPAC and HVA showed dose-dependent increases, with the highest levels attained after the 0.30 and 0.50 mg/kg doses of MK-801. These locomotor and neurochemical results suggest that MK-801 activates DA neurons projecting to the NAcc and are consistent with electrophysiological data reported by others indicating increased firing of A10 DA cells after the systemic administration of this noncompetitive receptor antagonist

INTERACTIONS OF THE GLYCINE (NMDA) ANTAGONIST, MDL 103,371 WITH MONOAMINERGIC SYSTEMS: EVIDENCE FOR ANTIPSYCHOTIC-LIKE ACTIVITY. C.J. Schmidt, S. F. Chaney, G.M. Fadayel, T.C. McCloskey, Y. Senyah, V.L. Taylor, and J.H. Kehne* Hoechst Marion Roussel, Inc., 2110 E. Galbraith Rd., Cincinnati, OH 45215.

The clinical utility of antagonists of the NMDA-glutamate receptor for neurodegenerative states such as ischemic stroke or trauma has been severely limited by their psychotogenic activity. Results in models of psychotomimetic potential suggest that blockade of the NMDA-associated glycine site may offer a means of reducing NMDA receptor mediated damage without the side-effect liability observed for competitive and uncompetitive agents. MDL 103,371, *E*-3-[2-(3-aminophenyl)-2-carboxyethenyl]-4.6-dichloro-1*H*-indol-2-carboxylic acid. is a centrally active, highly selective glycine site antagonist with efficacy in several animal models of ischemic brain damage. Pharmacological studies of MDL 103,371 compared its effects on the dopaminergic (DA) system to those of other psychotomimetic agents such as MK-801 or the amphetamine analogue, MDMA. Unlike these agents, MDL 103,371 did not disrupt prepulse inhibition nor did it enhance *in vivo* DA synthesis in rats. Paradoxically, MDL 103,371 antagonized the stimulation of DA synthesis and release produced by MK-801. This functional anti-dopaminergic activity was also observed behaviorally in that MDL 103,371 significantly reduced amphetamine stimulated locomotion in mice. These results suggest that glycine site antagonists may provide a means of reducing NMDA receptor function without incurring significant psychotomimetic risk. In fact, the pharmacological profile of MDL 103,371 is in many ways predictive of antipsychotic activity.

COX-2 AND FOS PROTEINS IN BRAIN AFTER STIMULATION OR

COX-2 AND FOS PROTEINS IN BRAIN AFTER STIMULATION OR INHIBITION. D.J. Knapp*, G.E. Duncan, G.R. Breese, and F.T. Crews. Ctr for Alcohol Studies, Univ. North Carolina. Chapel Hill, NC 2759 reported in a regionally-specific manner in the rat brain following stress, acute or chronic drug reatments, or withdrawal from chronic ethanol treatment. Presented here are results of studies to investigate the brain regional distribution of FOS and cyclooxygenase-2 (COX-2) proteins following excitatory amino acid stimulation of blockade, ethanol administration, or during ethanol withdrawal from liquid diet. Kainic acid (15 mg/kg, i.p.) or NMDA (150 mg/kg, i.p.) injection increased COX-2 and FOS in the medial prefrontal cortex (MPC) and related limbic cortical areas but only FOS was robustly induced in the paraventricular nucleus of the hypothalamus (PVN) and central nucleus of the amygdala (CE). In the hippocampal CA1 area, kainic acid failed to induce COX-2, but intensely induced FOS, whereas both proteins were robustly induced in the dentate gyrus. Acute ethanol (2.5 g/kg, i.p.) induced FOS in the PVN, CE, and MPC, but inhibited NMDA-induced FOS in the MPC and CE. Withdrawal from chronic ethanol treatment induced a specific FOS response in brain regions thought to be important treatment induced a specific FOS response in brain regions thought to be important in mediating emotional responses, including the amygdala, limbic cortical regions, and PVN. Interestingly, the glutamate antagonist ketamine produced a dose-dependent FOS response in many cortical and subcortical regions of brain, even at anesthetic doses. These results indicate that 1) FOS and COX-2 are useful markers for isolating specific brain regions following drug treatments, 2) that measures of one immediate early gene may reveal regionally specific neuronal activation not revealed by another or that qualitatively different stimuli may specifically target a particular gene product in some brain regions. (Supported by NIAAA 00214, 10025, and 06069)

REGULATION OF DOPAMINE RELEASE BY N-METHYL-D-ASPARTATE IN THE STRIATUM OF RATS WITH PARTIAL DOPAMINE-NIGROSTRIATAL LESION. M.E. Andrés, K. Gysling and G. Bustos*. Lab. Biochemical-Pharmacology, Dept. of Cell and Molecular Biology, Faculty of Biological Sciences. Catholic University of Chile, Santiago, CHILE.

The role of N-methyl-D-aspartate (NMDA) in the regulation of striatal dopamine (DA) release, was studied with in vivo microdialysis, in rats with partial lesions of the DA-nigrostriatal system. Dopaminergic nigrostriatal input to the right striatum was partially lesioned with 6-hydroxydopamine (2-8 μg/ 4μl) injections. Seven days later a microdialysis probe was implanted in the right striatum and after a stabilization period, two stimuli period were performed, the first with 500 µM NMDA and the second with 40 mM K

In sham-treated rats, DA release induced by NMDA was higher than DA released by K. In rats with 20-80% of striatal DA depletion, DA release induced by NMDA was significantly diminished, whereas DA released by K was maintained. In rats with 80-95% of DA depletion, both stimuli induced a significant minor DA release, and the ratio between both stimuli was reverted. In contrast, rats with >95% of striatal DA depletion, exhibited a relatively high fractional DA release evoked by NMDA

These results suggest that partial destruction of nigrostriatal pathway in rats reduce the stimulatory regulation induced by NMDA on DA release. They also suggest that extreme lesions may produce a compensatory response that accounts for the fractional DA release induced by NMDA observed under this condition. CYCLOTHIAZIDE ENHANCEMENT OF NMDA- VS NON-NMDA-INDUCED RELEASE OF [³H]NE FROM SPINAL CORD SLICES: RECEPTOR DESENSITIZATION, <u>D. Jones, G. Woodlee, R. Suchdev, M. Albin, * D. Glasser, Dept. Anesth, Univ TX HIth Sci Ctr, San Antonio, TX 78284</u>

Previous studies have demonstrated rapid desensitization with activation of AMPA and kainic acid subtypes of the glutamate receptor. Cyclothiazide (CYCLO) and concanavalin A (CON A) have been demonstrated to modulate this desensitization in various regions of the CNS. Since desensitization plays a role in the overall efficacy of glutamate responses, the purpose of the present study was to determine the contribution of this process to [3H]NE release from spinal cord slices induced by agonists at subtypes of the ionotropic glutamate receptor.

Rat spinal cord slices (dorsal region; 0.3 µm) were preloaded with [*H]NE (0.05 µM). Slices were perfused (0.5 ml/min) and agonist-induced release expressed as % of total remaining [3H]. CYCLO and CON A were added to the perfusion 10 min before agonists were added.

4-AP, K*, NMDA, AMPA and kainic acid all produced concentration-

dependent release of [3H]NE from spinal cord slices. Only the NMDA response was Mg**-dependent. Both AMPA- and kainate-induced release of [3H]NE was enhanced by CYCLO in a concentration-dependent manner. Neither NMDAnor 4-AP-induced release was enhanced by CYCLO. In the presence of DNQX (10 μ M) which completely blocked kainate-induced release, CYCLO was still able to enhance release in a concentration-dependent manner. In contrast to the effects of CYCLO, the lectin CON A did not enhance either AMPA- or kainateinduced release

The results demonstrate that glutamate-receptor subtypes modulate [3H]NE release in spinal cord. Moreover desensitization of the receptor in the presence of agonists may play a role in modulating glutamate signal strength in this region. Supported by the S/IUCRC - CEBBI Fund.

PATCH CLAMP AND CSD ANALYSIS OF CHOLINERGIC THETA FREQUENCY OSCILLATIONS IN NEOCORTICAL SLICES

H. S. Lukatch* and M. B. MacIver. Dept. of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305.

Neocortical brain slices produce theta frequency micro-EEG oscillations when exposed to carbachol (100 μ M), a cholinergic agonist, and bicuculline (10 μ M), a GABA, antagonist. (Lukatch and MacIver Soc. Neurosci 1994). The present study examined phase, amplitude and current source density (CSD) profiles associated with these oscillations. Cellular mechanisms underlying oscillatory activity were further elucidated with laminar transection studies and whole cell patch clamp experiments. Peak oscillation amplitudes occurred in layer 2/3, and phase reversals were observed in layers 1 and 5. Current source density analysis revealed large amplitude current sinks and sources in layers 2/3 and 5, respectively. Laminar transections localized oscillation generating circuitry to superficial cortical layers. Whole cell recordings identified three distinct cell types based on their response properties during rhythmical micro-EEG activity: oscillation-on and oscillation-off neurons, and glial cells. Oscillation-on neurons displayed theta frequency membrane potential oscillations which increased in amplitude with hyperpolarization (from -30 to -90 mV). Sustained currents associated with oscillations reversed polarity near 0 mV under voltage clamp. These results, together with previous findings that glutamate antagonists depress oscillatory micro-EEG activity, suggest that excitatory synaptic transmission in superficial cortical layers underlies cholinergically-driven synchronized neocortical oscillations.

Supported in part by USAF OSR/SCEEE and NIH GM49811.

MUSCARINIC RECEPTOR ANTAGONISTS AFFECT MEMANTINE AND PHENCYCLIDINE INDUCTION OF HEAT SHOCK PROTEIN HSP72 IN THE POSTERIOR CINGULATE CORTEX OF RAT BRAIN. S.TOMITAKA*, K. Hashimoto, N. Narita, Y. Minabe and A. Tamura, Natl. Inst. Neurosci., NCNP, Tokyo and Dept. of Psychiatry, Tokyo Women's Medical College, Tokyo, Japan.

Non-competitive NMDA receptor antagonists such as memantine (1-amino-3,5-dimethyladamantane) and phencyclidine induce heat shock protein HSP-72, a useful marker of neuronal damage, in the posterior cingulate cortex. We studied the role of muscarinic receptors on the induction of HSP-72 by memantine and phencyclidine. Memantine (25-50mg/kg) and phencyclidine (40mg/kg) were injected into male SD rats. The immunohistochemistry of HSP-72 was studied 24 hr after the treatment. The administration of memantine and phencyclidine induced HSP-72 in the posterior cingulate and pnencyclidine induced HSP-72 in the posterior cingulate and retrosplenial cortex of rat brain. Pretreatment with the muscarinic receptor antagonists, scopolamie (0.1-5mg/kg) and atropine (1-5mg/kg), blocked induction of HSP-72 in the layer III of the posterior cingulate cortex. However, induction of HSP-72 in the layer V was not blocked by the muscarinic receptor antagonists. rayer v was not blocked by the muscarinic receptor antagonists. These results suggest a regional difference in the mechanism of HSP72 induction by NMDA receptor antagonists in the posterir cingulate cortex. This research was supported by the research grant from the Ministry of Health and Welfare, Japan.

PROLONGED RESIDENCE TIME OF GLUTAMATE IN THE SYNAPTIC CLEFT DETERMINES EXCITATORY SYNAPTIC TRANSMISSION AT A CENTRAL SYNAPSE

S.W. Schwarzacher# and B.U. Keller*. Physiologie, Humboldtallee 23 und #Zentrum Anatomie, Kreuzbergring, Universität Göttingen, 37073 Göttingen, Germany

Interneurones in the nucleus tractus solitarii (NTS) in Interneurones in the nucleus tractus solitarii (NIS) in the orain stem of rats were investigated with the patch clamp technique by using the thin (150um) slice preparation. Neurones were identified histologically as local interneurones by intracellular labelling with neurobiotin. Glutamate (AMPA/KA) receptor mediated synaptic transmission was investigated during stimulation of single presynaptic afferents. Unitary EPSCs displayed fast rise times and slow decay time constants (3.6±1.1ms) that did not result from dendritic filtering. Bath application of 1mM D - aspartate did not affect EPSCs, application of 1mM D - aspartate did not affect EPSCs, indicating that local glutamate uptake did not significantly shape their time course. Also, slow EPSC decays did not result from slow deactivation of postsynaptic AMPA receptors (0.7±0.1ms) which were investigated by rapid (<0.2ms) application of agonist to outside - out patches. Recordings in high and low extracellular calcium concentrations suggested that slow EPSC decays resulted from a prolonged residence time of glutamate in the synaptic cleft. Supported by DFG and SFB 406.

CHRONIC ANDROGEN TREATMENT EFFECTS ON EVOKED POTENTIALS IN THE CA1 REGION OF THE HIPPOCAMPUS. W. A. Pouliot*, R. J. Handa, S. G. Beck. Departments of Cell Biology, Neurobiology & Anatomy and Pharmacology, Loyola University Medical Center, Maywood, IL 60153

Stimulation of afferent input to CA1 neurons of the hippocampus results in the synaptic activation of the glutamate receptor subtypes, N-methyl-D-aspartate (NMDA) and non-NMDA. Area CA1 also contains a high density of androgen receptor. We examined the effects of chronic androgen treatment on synaptically evoked field potentials in the CA1 region. The treatment groups included gonadectomized (GDX) male Sprague-Dawley rats and GDX rats implanted with the non-aromatizable androgen, 5-α-dihydrotestosterone-propionate (GDX+DHTP). Hippocampal slices were prepared for electrophysiology after 3 weeks. Extracellular field potentials were recorded in the stratum pyramidale following stimulation of the Schaffer collateral pathway. Stimulus- response (S-R) curves were generated. Initial studies indicate that chronic androgen treatment shifted the S-R curve to the right and decreased the maximum amplitude of the population spike. The NMDA receptor-mediated field potential was pharmacologically isolated. Superfusion with Mg²⁺-free buffer containing 10μM CNQX led to the development of multiple population spikes which were abolished by $40\mu M$ AP-5, an NMDA receptor antagonist. The NMDA isolated population spike amplitude recorded from GDX treated animals was decreased when compared to population spikes generated in normal buffer. In GDX+DHTP treated animals the S-R curve for the NMDA isolated population spike was shifted to the right while the maximal spike amplitude was the same magnitude as the spikes generated in normal buffer. These preliminary data indicate that androgen treatment altered normal synaptic transmission from the Schaffer collateral pathway to CA1 neurons and NMDA receptor-mediated evoked potentials. MODULATION OF SENSORY AND EXCITATORY AMINO ACID (EAA) RESPONSES BY NITRIC OXIDE (NO) DONORS AND GLUTATHIONE IN THE

RESPONSES BY NITRIC ONLIE (NO) DONORS AND GLUTATHIONE IN THE RAT VENTROBASAL (VB) THALAMUS. <u>P.J. Shaw and T.E. Salt</u>. Institute of Ophthalmology, University College London, Bath Street, London. EC1V 9EL. U.K. The precursor of NO, L-arginine, potentiates somatosensory responses are responses to EAAs in rat VB. To further study the effects of the NO system in VB, somatosensory responses and responses to iontophoretically applied agonists were recorded extracellularly from single VB neurones in urethane anaesthetised rats. Reproducible controls were tested during iontophoretic coapplication of the NO-donors S-nitrosoglutathione (GSNO) and 3-morpholinosydnonimine (SIN1).

GSNO significantly (p<0.05, Wilcoxon Signed Rank; n=12) potentiated mean responses (+SEM) to air-jet stimulation of a vibrissa (10ms duration) to 124±7% of control. The response to a 1sec stimulus was increased to 126±8%; responses to NMDA and AMPA were increased to 123±12% and 123±10%. GSNO had no effect on the response to carbachol. SIN1 applied to a different sample of 6 VB neurones also potentiated responses (p<0.05): 10ms air-jet to 203±26% of control; 1sec to 138±15%; NMDA to 166±26%; AMPA to 176±33%. Reduced glutathione (GSH) significantly (p<0.05; n=6) inhibited responses to

a 10ms stimulus to $77\pm5\%$ of control and responses to NMDA and AMPA to $51\pm7\%$ and $48\pm11\%$ respectively. Oxidised glutathione (GSSG) inhibited NMDA responses to $70\pm9\%$ of control (p<0.05; n=10).

The results support the suggestion that NO can positively modulate sensory transmission through VB via a postsynaptic action on relay neurones, and that Larginine acts as a precursor for this system. Furthermore, the NO system is not fully activated under normal conditions in vivo but could be activated under conditions of prolonged stimulation. In contrast, the effects of glutathione suggest a modulatory role distinct from that of NO.

REGULATION OF POSTSYNAPTIC PROPERTIES OF AVIAN AUDITORY NEURONS IN VITRO J.J. Lawrence* and L.O. Trussell. Neuroscience Training Program & Dept. of Neurophysiology, U. Wisconsin, Madison 53706.

Nucleus magnocellularis (NM) consists of largely adendritic neurons which respond to long depolarizing current stimuli with a single action potential and express fast kinetic AMPA receptors. We explored the role of innervation and cellular environment by culturing E17-18 NM neurons on flat astrocytes at low density. Most NM neurons became multipolar within a few days, developing neurites which strikingly distorted the morphology of the cell body. This neuronal morphology showed similarities to that of E10-11 NM neurons, suggesting that the cells may dedifferentiate in vitro. In current clamp experiments, the neurons developed the capacity to fire multiple action potentials with long depolarizing current steps. Noise analysis of whole-cell current evoked by 30 μ M glutamate in the presence of 200 μ M APV allowed us to to determine mean channel burst time (τ) of AMPA receptors. Noise spectra generally fit best with sums of two Lorenztian functions; our results are therefore summarized as a weighted mean time constant from the fitted curves. Acutely dissociated NM neurons from E17-18 embryos showed a mean τ of $405\pm212~\mu sec$ ($\pm SD$, After two weeks in vitro, the mean τ was $1905 \pm 1025~\mu sec$ (N=7). These data suggest that voltage-dependent channels and transmitter receptors that are critical to auditory function in vivo may be dynamically regulated by the cellular environment, possibly through innervation, soluble factors, and/or glial cell contacts. PAIRED-PULSE FACILITATION (PPF) IN AN INTERNAL CAPSULSE-LATERAL AMYGDALA PATHWAY. M.G. McKernan¹ and P. Shinnick-Gallagher, Dept. of Pharmacology and Toxicology, Univ. of Texas Med. Branch, Galveston, TX 77555-1031

The amygdala is widely believed to play a role in the attachment of emotional significance to experience and memory. The medial geniculate nucleus of the thalamus projects directly to the lateral amygdala nucleus (LA) via fibers traveling through the internal capsule; this connection is crucial for fear conditioning to an auditory stimulus, a model of emotional learning. In the present study, the patch clamp technique is utilized for whole-cell recordings of neurons in the LA. Excitatory post-synaptic currents (EPSC's) evoked by stimulation of fibers arising from the internal capsule are predominantly glutamatergic, with an N-methyl-D-aspartate (NMDA) component and αν-amino-3-hydroxy-5-methyl-isoxazole propionic acid (AMPA) component in a subset of cells.

The goal of this study is to investigate alterations in this pathway induced by fear conditioning. One means of measuring potentiation at this synapse is to evaluate paired-pulse facilitation (PPF); changes in the degree of PPF are believed to reflect presynaptically-mediated synaptic alterations. EPSCs elicited with internal capsule stimulation showed both paired-pulse facilitation and depression. At an interstimulus interval (i.s.i.) of 35 ms, facilitation is 36.4 ± 18.8% (n=5); at an i.s.i. of 250 ms, depression is 15.9 ± 8.8% (n=5). In the presence of 50 μM D-APV, which blocks the NMDA component of the EPSC, control neurons fall into two groups with respect to PPF. In group i neurons, both facilitation and depression can be recorded, with 37.5 ± 5.5% facilitation (n=9) at 35 ms i.s.i. and 9.0 ± 3.4% depression (n=7) at 250 ms i.s.i. In group II neurons, primarily depression can be recorded, with 37.5 ± 5.5% facilitation and sepression can be recorded, with 37.5 ± 5.5% facilitation and sepression can be recorded, with 37.5 ± 5.5% facilitation

MEMANTINE, A CLINICALLY-TOLERATED NMDA OPEN-CHANNEL BLOCKER, DISPLAYS RELATIVE SPARING OF EPSCs. Posina V. Rayudu, H.-S. Vincent Chen*, and Stuart A. Lipton. Dept. of Neurology, Children's Hospital and Program in Neuroscience, Harvard Medical School, Boston, MA 02115.

Memantine, a drug used clinically in Europe for spasticity and Parkinsonism, is an uncompetitive NMDA antagonist (Bormann, 1989; Chen et al. 1002) and ampliturete focal inchange and other forces of

Chen et al., 1992) and ameliorates focal ischemia and other forms of NMDA receptor-mediated neurotoxicity in vitro and in animal models (Seif el Nasr, et al. 1990; Erdö and Schäfer, 1991; Chen et al., 1992). Recently, the basis for the clinical safety of memantine has in part been attributed to its sparing of LTP (Stieg et al., 1993; Frankiewicz et al., 1996). Here we show that in addition to the fact that memantine inhibition is relieved to some extent by depolarization during tetanic inhibition is relieved to some extent by depolarization during tetanic induction of LTP, evoked excitatory postsynaptic currents (EPSCs) are relatively spared in the presence of memantine (6 μM, a clinically-achievable concentration). EPSCs were evoked at 0.2 Hz during whole-cell recording with patch electrodes from autapses of solitary hippocampal neurons grown in "micro-culture" (Segal, 1991). In this preparation, memantine has excellent access to synaptic sites. Even at -60 mV which, compared to more depolarized holding potentials, should maximize compared to more depolarized holding potentials, should maximize voltage-dependent blockade by memantine of NMDA channels (Chen et al., 1992), only about 40% of the late (NMDA receptor-mediated) component of the EPSC was blocked. The relative sparing of EPSCs is probably due to their transient nature, producing a high concentration of glutamate in the synaptic cleft for a short time, which is functionally Funded by NIH grants R01 EY05477 and P01 HD29587 (to S.A.L.).

METABOTROPIC RECEPTOR AGONIST MODIFIES AMPA/KAINATE AND NMDA MEDIATED POTENTIALS IN NEOCORTEX. Bandrowski*, V.B. Aramakis, and J.H. Ashe. Departments of Neuroscience and Psychology, University of California, Riverside, CA 92521.

The purpose of this study was to examine a possible role of metabotropic glutamate receptors in cortical auditory processing. We examined the effect of (±)-1-aminocyclopentane-trans-1,3-dicarboxylic acid (ACPD), a glutamate metabotropic receptor agonist, on AMPA/Kainate (A/K) mediated early EPSP (e-EPSP), NMDA mediated late EPSP (I-EPSP), and NMDA mediated membrane depolarizations (NMDA-DPs). Responses were obtained from layer II/III pyramidal neurons in the in vitro rat auditory cortex using whole cell recording techniques. ACPD decreased the amplitude of both the e- and 1-EPSPs. The e-EPSP was decreased (44/46 cells) in a concentration dependent manner ($10-75~\mu M; 7\pm 1\%$ to $63\pm 3\%$). The I-EPSP was studied in the absence of the e-EPSP following the addition of an A/K antagonist, CNQX 10-20 µM. The I-EPSP was also decreased by ACPD (8/8 cells) in a concentration dependent manner (25-50 µM; 30±12% to 49±18%), and both effects were reversible (e-EPSP n=39; I-EPSP n=5). Effects of ACPD on the synaptic potentials may involve mechanisms located pre-, post-synaptically, or both, therefore we examined the effect of ACPD on NMDA-DPs. Subthreshold, NMDA-DPs were obtained by iontophoretic application of NMDA (50 mM; 1-37 nA; 5sec). These responses were increased in amplitude by ACPD (98±5%; 7/7 cells), and maintained for over 15 min. These results suggest that metabotropic receptors may have a function in auditory neocortex, both the e-EPSP and I-EPSP can be modified by a metabotropic receptor agonist, and the mechanisms of the effects may be differentially distributed in local cortical networks. EFFECTS OF IONTOPHORETICALLY APPLIED AMINO ACIDS ON SPONTANEOUS AND EVOKED ACTIVITY OF PRIMARY AUDITORY CORTEX
NEURONS IN THE CAT: AN IN VIVO STUDY. P.L. Herrling*. C.L. Meier and
TKrucker. SANDOZ Research Institute, CH-3001 Bern, SWITZERLAND.
The present study was performed to elucidate the possible role of excitatory
(EAA) and inhibitory (e.g. GABA) amino acids in neurotransmission within the
primary auditory cortex (AI). The main afferent to the AI, the ipsilateral medial
geniculate body (MGB). was electrically stimulated and evoked responses were
recorded intra- and extracellularly in the AI region in 104 halothane-anesthetized
cats. A seven-barelled iontophoresis pipette glued alongside the recording electrode
allowed localized application of compounds onto the recorded neuron. Iontophoretically applied NMDA (63 of 65 cells) and AMPA (43 of 54 cells) depolarized AI
neurons and evoked marked increase; in firing rate, NMDA evoked depolarizations retically applied NMDA (63 of 65 cells) and AMPA (43 of 54 cells) depolarized AI neurons and evoked marked increases in firing rate. NMDA evoked depolarizations were accompanied by increases in action potential frequency and the occurrence of depolarizing shifts carrying bursts of action potentials. AMPA evoked a regular firing pattern and transformed a spontaneous bursty firing pattern into regular firing (3 cells). Coapplication of the GABA_A antagonists SR95531 or bicuculline usually potentiated the effect of iontophoretically applied NMDA and AMPA (31 cells). Sustained GABA application decreased spontaneous activity in five neurons. Competitive EAA antagonists AP7 (30 cells) and CNQX (4 cells) or DNQX (2 cells) areas favule to substainly reduce as a bolich the reproperse in instance in the content of the content of the property is instanced. pentive EAA antagonists AP (30 cents) and CNQA (4 cents) or DNQA (2 cents) were found to substantially reduce or abolish the responses to iontophoretically applied NMDA and AMPA pulses, respectively. AP7 decreased spontaneous firing frequency significantly at ejection currents which had little or no effect on AMPA responses. The early excitatory responses to MGB stimulation were not affected by AP7 (13 of 13 cells) but inhibited by CNQX (6 of 6 cells, 50-85% inhibition) in AP7 (13 of 15 cents) dut illinoited by CAPA (6 of 6 cents, 30-53) milliotion) absence of any additional experimental manipulation. The GABA_A antagonist SR95531 strongly potentiated MGB-EPSPs and the augmented part was entirely abolished by AP7 (27 of 31 cells). We conclude that both NMDA and AMPA receptors can be involved with the MGB to AI synaptic transmission and that NMDA receptors also contribute to the spontaneous activity of the cortical region. NEURONAL CELL LINES FROM MOUSE HIPPOPCAMPUS EXPRESSING NEUROTRANSMITTER RECEPTORS AND NEURONAL-TYPE ION CHANNELS, M.Jung¹*, E.Krämer¹, T.Müller², C.Flocke², H.Antonicek², and J.Trotter¹, Dept. of Neurobiology, University of Heidelberg, INF 364, D-69120 Heidelberg, F.R.G. ² Bayer AG, ZF-F, Biotechnologie, Bayerwerk, Leverkusen,

In many neurological disorders neurotransmitter receptors may be involved in the final pathways leading to neuronal cell death. For the development of and initial screening of agents interfering with these destructive pathways, the availability of immortalised neural cell lines expressing receptors and channels of interest would be very advantageous. Cell lines were established from primary embryonic mouse hippocampus cultures using retroviral vectors expressing the v-myc oncogene or a hybrid protein between the EGF receptor and neu tyrosine kinase (egfr-neu). In the absence of EGF the kinase activity is down regulated permitting differentiation. Stable cell lines were generated consisting of either flat and/or bipolar cells. All cell lines expressed vimentin and nestin while some of the lines contained some cells positive for A2B5, LB1, 04, GFAP, MAP-2 and neurofilament. EGF-deprived egfrneu-expressing cell lines developed highly elaborate branched processes and many cells expressed the neuronal markers MAP-2 and neurofilament. Using Ca⁺⁺ imaging procedures, intracellular Ca⁺⁺ concentrations were measured after application of several agonists and antagonists for ionotropic and metabotropic glutamate receptors. Most cell lines express metabotropic glutamate receptors as shown by application of glutamate, quisqualate, t-APCD and L-CCG. Using the patch-clamp technique, AMPA, NMDA, glutamate agonists and GABA evoked inward currents mainly in the differentiated egfr-neu-expressing cells. Many cells showed a delayed and an inward rectifier. Differentiated egfr-neu-expressing cells often displayed a sodium current, enabling the generation of action potentials under current clamp conditions These lines are thus useful tools for investigating neuronal properties Financed by Bayer AG.

EXCITATORY AMINO ACID RECEPTORS: PHYSIOLOGY. PHARMACOLOGY, AND MODULATION II

D1 RECEPTOR MODULATION OF AMPA/KAINATE CURRENTS IN RAT STRIATAL NEURONS. C.J. Price and L.A. Raymond. Division of Neurosciences, Department of Psychiatry, University of British Columbia, Vancouver, B.C., Canada V6T 1Z3.

Dopamine receptor activation regulates intracellular cAMP levels and is critically involved in modulating neurotransmission in the striatum. Previous studies have shown that ion channel function of α-amino-3hydroxy-5-methyl-4-isoxazolepropionate (AMPA)- and kainate-type glutamate receptors is potentiated by activation of cAMP-dependent protein kinase. Therefore, we investigated whether D1 receptor activation had any effect on AMPA/kainate receptor currents in cultured rat striatal neurons. Perforated patch clamp recordings from medium spiny neurons showed that the D1 receptor agonist SKF 38393 (5 µM) potentiated currents evoked by rapid application of 1 mM kainate by approximately 24%. Moreover, this action could be mimicked by direct stimulation of adenylate cyclase using forskolin (50 The results of this study indicate that D1 receptor-mediated enhancement of AMPA/kainate-type glutamate receptors may, in part, contribute to dopamine's modulatory effects on striatal neuronal

NITRIC OXIDE AND cGMP MODULATE RETINAL AMPA-TYPE GLUTAMATE RECEPTORS. L.V.Ponomareva and D.G.McMahon* of Physiology, University of Kentucky, Lexington KY 40356-0084

Recent studies have shown that ionotropic glutamate receptors are targets for nodulatory second messenger signals affecting their function (Hollman and Heinemann,1994). We have investigated the nitric oxide (NO)/cGMP pathway for modulation of retinal horizontal cell (HC) AMPA-type glutamate receptors. HCs from the hybrid bass were dissociated in cell culture using standard techniques and whole cell patch-clamp recordings were made while glutamate($200\mu M$) or its agonist kainate-KA(10 or $50\mu M$) were applied by pressure ejection. Modulatory agents were applied by adding to the bath. Responses to glutamate and KA were reduced by approximately 50% in the presence of NO donors ImM sodium nitroprusside(SNP) (N=9) and 100µM S-nitroso-N-acetylpenicillamine(SNAP) (N=7). The effect of SNP was blocked by the NO scavenger hemoglobin and it could be mimicked by the application of a membrane permeable cGMP analog, 8-Br-cGMP(-63%,N=4). The NO effect was also blocked by application of the guanylate cyclase inhibitor LY-83583(N=7), and by a protein kinase G inhibitor peptide RKRARKE(N=6). In addition we found that the nitric oxide synthase stimulator L-arginine reduced KA responses in H1 type cells, while application of D-arginine had no effect. The NO receptor modulation mechanism may act in concert with other pre and post synaptic mechanisms to modify HC synaptic function according to the adaptational state of the retina and may also protect HCs from glutamate excitotoxicity. Molecular cloning of a GluR1 homolog from the bass retina performed in our laboratory indicates the presence of serine-kinase consensus sites on the C-terminal and high homology in the logy in the predicted membrane-spanning regions. The bass GluR1 predicts a 964 ami sequence with molecular weight of 107kDa and shows 77.8% identity to the rat GluR1. Supported by NEI EY 09256 and NS 01734.

EFFECTS OF TYPICAL AND ATYPICL ANTIPSYCHOTICS ON NON-NMDA SITE BINDING AND GENE EXPRESSION. <u>L.McCoy*, E.K. Richfield.</u> Depts of Psychiatry and Neurology, University of Rochester, Rochester, NY 14642-8409.

Results from human postmortem studies have suggested that binding to non-NMDA receptors is not affected by chronic treatment with antipsychotic drugs (APDs). However, more detailed animal studies on the effects of APDs are needed, since binding to non-NMDA receptors may be altered in some patients with schizophrenia. The heterogeneous anatomical distribution of 3H-CNQX binding sites correlate with 3H-AMPA binding to non-NMDA receptors, but binding to high and low affinity states differ between the two ligands. To determine if chronic APDs alter non-NMDA receptror site binding and receptor gene expression, we measured 3H-AMPA, 3H-CNQX and GluR1 and 2 (flip/flop) following chronic (21 day, i.p.) treatment with two atypical APDs, clozapine (CLZ) and risperidone (RSP) and two typical APDs, haloperidol (HAL) and pimozide (PMZ). Binding and mRNA expression densities were measured in six cortical and subcortical brain regions. With ³H-AMPA, APDs as a group were different from saline treated animals and both typical APDs and atypical APDs were different from saline. The typical agents HAL and PMZ resulted in the largest increases in binding (58 and 65%, respectively) compared to the atypical agents CLZ and RSP (10 and 25%, respectively). The overall ANOVA for 3H-CNQX binding showed no difference between drug treated and saline treated groups. These findings demonstrate an APD effect on the high affinity state of the AMPA receptor and that AMPA site binding may be a useful biochemical marker differentiating typical and atypical agents. The effect on AMPA receptor subunit expression and a synthesis of the data will be presented. Supported by MH18911; MH40381 and the Tourette Syndrome Association, Inc.

AMPA/KAINATE RECEPTORS INVOLVEMENT IN CONVULSANT AND PROCONVULSANT PROPERTIES OF MITOCHONDRIAL TOXIN, 3-MITROPROPIONIC ACID IN MICE. P. Blaszczak¹, T. Saran¹, W.A. Turski^{1,2}, E.M. Urbanska^{1,2}, ¹Dept. Pharmacology and Toxicology, Medical University School, Lublin, ²Dept. Clinical Toxicology, Institute of Agricultural Medicine, Lublin, Poland.

3-Nitropropionic acid (3-NPA) is a naturally occuring enzyme inhibitor. It inactivates succinate dehydrogenase of the complex II of mitochondrial electron transport chain. The clinical course of acute intoxication with 3-NPA in humans includes convulsions, sometimes leading to status epilepticus. Chronic poisoning with 3-NPA may produce neurodegenerative changes in the brain. This study investigates convulsant and proconvulsant activity of 3-NPA in mice. Albino-Swiss mice (20-25 g) were injected s.c. with 3-NPA. 3-NPA produced clonic convulsions and death of animals with an ED50 of 158 mg/kg and a LD50 of 189 mg/kg, respectively. The competitive AMPA/kainate antagonist NBQX (s.c.) blocked convulsions induced by 3-NPA (220 mg/kg) with an ED50 of 14.1 mg/kg. The competitive NMDA antagonist, D-CPPene (i.p.) and non-competitive NMDA antagonist, MK-801 were not effective at doses up to 20 and 0.4 mg/kg, respectively. 3-NPA (100 mg/kg) potentiated the convulsant properties of AMPA and KA (i.c.v.), which was reflected by lowering the ED50 doses of AMPA from 0.98 to 0.55 nmol and KA from 0.73 to 0.58 nmol, but not those of NMDA. These results may indicate that non-NMDA receptors could contribute to convulsant and proconvulsant properties of 3-NPA in mice.

EFFECTS OF A MEMORY ENHANCING DRUG ON AMPA RECEPTOR CURRENTS AND SYNAPTIC TRANSMISSION IN HIPPOCAMPUS.
A. Arai*, M. Kessler, G. Rogers and G. Lynch. Center for the Neurobiology of Learning and Memory (CNLM), University of California, Irvine, CA 92717.

The benzoylpiperidine drug BDP-12 enhances the encoding of transient and stable forms of memory by rats. Results reported here show that the drug increases fast, excitatory (glutamatergic) synaptic responses in hippocampal slices by about 50% with an EC $_{50}$ 0 fl 70 μ M. Analyses using polysynaptic responses indicated that the drug has a facilitatory action at concentrations a low as 12.5 μ M. BDP-12 at 1 mM did not change the resting membrane potential, input resistance or spiking threshold and it did not alter monosynaptic potentials mediated by GABA receptors; it did, however, enhance disynaptic inhibitory responses. In membrane patches excised from hippocampal neurons, BDP-12 at moderate concentrations (50 μ M) increased the steady-state currents mediated by AMPA receptors and slowed the rate at which the receptors desensitize, with a much larger effect on the former; the drug delayed the closing of the AMPA receptor channel after one-millisecond agonist pulses. BDP-12 had no detectable effect on [3 H]AMPA binding affinity. A related and more potent analogue produced a different pattern of results in that it had about equal effects on steady-state currents and desensitization rates and significantly increased binding to AMPA receptors. These results indicate that the benzoylpiperidine family of modulators has functionally distinct subclasses. The findings also establish that BDP-12 ij enhances synaptic responses in the same concentration range at which it alters AMPA receptors han on monosynaptic transmission, iii) does not directly influence inhibitory responses, and iv) is likely to modulate AMPA receptors on intermeurons as well as on pyramidal neurons. PROTON MODULATION OF AMPA-PREFERRING GLUTAMATE RECEPTORS. E. C. Ihle* and D. K. Patneau. Committee on Neurobiology, University of Chicago, Chicago, IL 60637.

Although NMDA receptors are more sensitive to changes in extracellular pH than AMPA receptors, the potential neuroprotective effects of acidification that occurs during ischemia may involve inhibition of both glutamate receptor subtypes (Giffard et al., 1990). We have examined proton modulation of AMPA-preferring glutamate receptors, to determine both the mechanism whereby protons exert their effects and the extent to which this modulation may affect neurotoxicity.

the extent to which this modulation may affect neurotoxicity. Proton modulation of native AMPA receptors was studied using fast perfusion techniques during whole-cell voltage-clamp recording of hippocampal neurons dissociated from newborn rats and maintained in primary culture. Steady-state AMPA receptor currents were unaffected by alkalinization (change from pH 7.3 to 7.8), but were significantly reduced at acidic pHs typically associated with ischemia (pH 6.5 - 6.8). This effect was dependent on agonist. At pH 6.5 currents evoked by the weakly-desensitizing agonist kainate were reduced by 15%, while those evoked by glutamate were 30% smaller than at physiological pH (7.3), suggesting that protons have a greater effect on more strongly desensitizing responses. Similarly, the effect of pH 6.5 on glutamate-evoked responses in the presence of cyclothiazide and other modulators that block desensitization were reduced by \leq 5% relative to control.

Receptor subunit composition also appears to influence sensitivity to proton modulation. Attenuation of kainate-evoked responses in Type I neurons was voltage-independent, whereas inhibition of kainate-evoked currents in Type II neurons was stronger at hyperpolarized potentials.

AUTORADIOGRAPHIC LOCALIZATION AND CHARACTERIZATION OF NON-NMDA BINDING SITES IN ADULT QUAIL BRAIN.

M. Martinez de la Torre, A. Misacos*, J. Balthazart, K. Zavitsanou and E.D. Kouvelas. Dept. Physiology, Med. Sch., Univ. Patras, Greece, Dept. Morphological Sci., Univ. Murcia, Murcia, Spain, and Lab. Biochemistry, Univ. Liege, Belgium.

Univ. Liege, Beigum.

The distribution of non-NMDA binding sites was studied in coronal and sagittal sections in the brain of adult Japanese quail by quantitative autoradiography, using tritiated 6-cyano-7-nitroquinoxaline-2.3-dione (CNQX), as a radioligand. Saturation binding experiments were, in addition, performed in areas showing high levels of binding and demonstrated that the binding of [PH]CNQX is saturable and of high affinity. Competition studies with AMPA and kainic acid indicated that kainic acid strongly inhibits [PH]CNQX binding in all brain areas, whereas AMPA is only a weak inhibitor. The highest [PH]CNQX binding levels were observed in the molecular layer of cerebellum. Very high levels of binding were detected in various preoptic/hypothalamic sites, including nucleus preopticus paraventricularis, nucleus suprachiasmaticus pars medialis, nucleus infudibularis and nucleus suprachiasmaticus pars medialis, nucleus infudibularis and nucleus commissurae pallii. In the preoptic area/hypothalamus, high levels of binding were clearly present in all areas that contain GnRH (LHRH) cells or fibers. Moderate binding was also present in nucleus fractus solitarius and nucleus motorius dorsalis, as well as, in dorsal thalamus, substantia grisea centralis and nucleus intercollicularis. Moderate levels of binding were associated with catecholaminergic areas, such as substantia nigra, area ventralis of Tsai and locus coeruleus. These anatomical data suggest a possible implication of [PH]CNQX binding sites in the synthesis and/or release of both GnRH and catecholaminergic neurotransmitters that should be tested by pharmacological experiments. Supported by EU grant HCM/CHRX-CT94-0472.

CHARACTERIZATION OF MICE LACKING THE GLUR2 AMPA RECEPTOR SUBUNIT. F. A. Tavernal* Z. Jia¹. W. Abramow-Newerly¹. J. Henderson¹, R. Gerlai¹, Z. Xiong² J. MacDonald² and J. Roder¹, Samuel Lunenfeld Research Institute, Mount Sinai Hospital¹, and Dept. of Physiology, University of Toronto, Toronto Ontario, Canada.

Glutamate receptors constitute the major excitatory neurotransmitter receptor system in the mammalian central nervous system. The GluR2 subunit is the most widely expressed member to the AMPA receptor family and controls the calcium permeability of the receptor. We generated mice lacking the GluR2 subunit by gene targeting. Mutant mice exhibited increased mortality, without spontaneous seizures, and reduced exploration and motor coordination. Mutant mice showed grossly normal development and organization of brain nuclei, fibre tracts and dendritic arbors. The time structure of the hippocampus appeared normal. The AMPA receptor mediated ion channel activity in the GluR2-deficient mice exhibited a 9-fold increase in calcium permeability. Western blot analysis revealed that the level of expression of other AMPA receptors, as well as representative members of kainate and NMDA receptors was similar in wild type and mutant mice. Preliminary experiments on cultured cortical neurons derived from perinatal mice suggest that there is no increase in basal excitotoxicity in the mutants. Experiments are now underway to determine if AMPA receptor-dependent excitotoxicity will be enhanced in mutant mice. In addition, we are examining the biochemical consequences of the enhanced calcium influx on second messenger mediated signal transduction pathways. Supported by the Medical Research Council of Canada.

Characterization of glutamate receptors in GluR2 null mutant mice. P. Miu*, Z.P. Jia, J. Roder, P.L. Carlen. Playfair Neuroscience unit, Toronto Western Hospital, Toronto, Ontario, Canada.

Seeburg et al (1995) reported that editing deficient GluR2 mice express AMPA receptors with increasing calcium permeability, and that these mice developed lethal seizures by 3 weeks of age (Science, 270:1677). In contrast, GluR2 null mutant mice (Traverna et al, this meeting) showed neither seizure-like activities nor high mortality rate. We, therefore, examined evoked synaptic responses of CA1 pyramidal neurons obtained from hippocampal slices (400 µM) of GluR2 null mutant and their sibling wild type mice using whole-cell mode of patch clamp technique.

Excitatory postsynaptic currents (EPSCs) were recorded in the presence of GABA antagonists. GABA, and GABA, were blocked by bicuculline (10 µM) and internal Cs⁺ (150 mM) respectively. Under these conditions, the dual component EPSCs did not show any obvious difference among cells obtained from control and GluR2 null mutant slices. In addition, we did not observe any spontaneous seizure-like activities, despite the absence of GABAergic inputs. The current-voltage relation of the NMDA PSCs was similar in cells obtained from control and GluR2 null mutant mice; while the AMPA PSCs of the GluR2 null mutant mice showed a significant rectification at the positive holding potentials.

These results provide some evidence that in the absence of GluR2 subunit, the remaining AMPA receptor subunits are capable of forming functional channels for fast synaptic transmission. (Supported by MRC Canada, and P. Miu is a fellow of Epilepsy Canada)

AMPA RECEPTOR CALCIUM FLUX AND CALCIUM PERMEABILITY IN CULTURED RAT CEREBELLAR GRANULE CELLS A.L. Utz* and T.A. Verdoorn, Dept. of Pharmacology, Vanderbilt Univ., Nashville, TN 37232 The contribution of AMPA receptor activation to calcium signaling in cerebellar granule cells was examined using both the fluorescent [Ca²+], indicator, fura-2, and whole cell patch clamp measurement of Ca²+ permeability. Ratiometric analysis and cobalt quench of fura-2 fluorescence were used to measure responses to glutamate receptor agonists. In 11 DIV granule cells (n=258), 30µM AMPA increased [Ca²+], 12.4±1.7mA above baseline. The addition of 50µM cyclothiazide augmented this response to 1013±84nM. Similarly, 100µM glutamate produced a [Ca²+], ise of 26.8±2.8nM that was increased to 702±65nM by 50µM cyclothiazide. Exposure to 100µM kainate increased [Ca²-1], by 768±60nM. Two approaches were used to distinguish direct AMPA receptor calcium flux from indirect flux through depolarization-activated channels. Decreasing AMPA-mediated depolarization by replacing extracellular sodium chloride with N-methyl-D-glucamine decreased the AMPA/cyclothiazide response by only 55% to 460±52nM. The magnitude of cobalt flux through activated ion channels was determined by measuring the fura-2 fluorescence quench rate (from 80% to 20% of maximum fluorescence). 50mM K+ and 30µM AMPA produced similar low rates of quench, 52.2±0.6sec (n=108) and 50.6±1.3sec (n=46), respectively. However, 30µM AMPA + 50µM cyclothiazide and 100µM kainate induced rapid cobalt quench, 31.7±1.9sec (n=47) and 33.2±1.2sec (n=115), respectively. Therefore, significant calcium flux in conditions of limited depolarization, and the selectivity of divalent-permeable AMPA receptors for cobalt suggest that sustained activation produces direct AMPA receptor calcium flux Whole cell patch clamp of cerebellar granule cells at 11 DIV, exposed to 100µM AMPA + 30µM cyclothiazide, showed a low average PCa/PNa ratio of 0.033±0.027 (n=7). These results suggest that low AMPA receptor calcium

ANTISENSE OLIGONUCLEOTIDES TARGETED TO GLUR2 INCREASE HIPPOCAMPAL NEURONAL CELL DEATH RAPIDLY AFTER KAINATE-INDUCED STATUS EPILEPTICUS IN ADULT RATS. <u>L. K. Friedman*</u>, J. Velísková, S.L. Moshé, D.C. Spray, X. Zheng, T. Opitz, R.S. Zukin. Depts Neurosci ence and Neurology, Albert Einstein Coll Med, Bronx, NY 10461

Kainic acid (KA) induces status epilepticus and a marked reduction in GluR2 (the AMPA subunit that limits Ca²⁺ permeability) expression that precedes the selective and delayed neuronal cell death of hippocampal CA3 neurons. To investigate whether reduced GluR2 subunit expression enhances CA3 vulnerability, we administered GluR2 antisense oligodeoxynucleotides by unilateral microinfusion into the dorsal hippocampus before inducing KA status epilepticus. CA3 cell loss was accelerated and enhanced following antisense pretreatment and KA status epilepticus; rats exhibited extensive or complete loss of CA3 neurons in the ipsilateral hippocampus at 24 hrs, a time when significant cell loss is not typically observed. Immunohistochemical and Western analyses confirmed that GluR2 receptor protein was reduced ipsilaterally after the GluR2 antisense infusions in the presence and absence of eizures. Injection into a different site (thalamus) did not enhance CA3 damage suggesting that a reduction in GluR2 expression within the hippocampus is important to alter the timing and pattern of the KA seizure-induced damage. In cultured hippocampal neurons, application of GluR2 antisense oligodeoxynucleotides increased Ca²⁺ permeability through AMPA receptors as determined by ratiometric imaging with Indo 1. Hence, the expression of GluR2 receptor subunits appears necessary for the survival of CA3 neurons following status epilepticus. The "GluR2 hypothesis", that increased formation of AMPA permeable $\mathrm{Ca^{2+}}$ channels enhances glutamate pathogenicity is further supported by these studies. INTRACELLULAR POLYAMINES MAY DETERMINE RECTIFICATION IN THE AMPA SUBTYPE OF GLUTAMATE RECEPTORS , C. B. McCullum , R.I. Hume, Univ. of Michigan, Ann Arbor, MI

We have studied the mechanism of rectification in the AMPA class glutamate receptor expressed in Xenopus oocytes. When the GluR1, 3, or 4 subunits are expressed alone, the whole cell I-V curves inwardly rectify and the permeability to divalent cations such as calcium is high compared to that of monovalent cations. When the GluR1, 3, or 4 subunits are co-expressed with GluR2 subunits, the whole-cell current-voltage relationship becomes linear and the relative permeability to divalent cations is low. We previously demonstrated that the inward rectification of receptors composed of the GluR1, 3 or 4 subunits is not caused by a voltage-dependent gate, by an external negatively charged blocker, by unequal concentrations of permeant ions, or by an intrinsic property of the channel in the membrane. At the same time, we also found that when outside-out patches were pulled from oocytes expressing homomeric GluR1, 3, or 4, the inward rectification was lost within 3-5 minutes following patch excision. Subsequently, we and others found that addition of micromolar quantities of polyamines to the intracellular solution of the patch pipette was sufficient to maintain inward rectification in outside-out patches. Because oocytes as well as many neuronal types contain 100-500 µm polyamines cytoplasmically, polyamines may mediate rectification physiologically. We tested whether polyamines are necessary for inward rectification in the whole occyte by manipulating the levels of polyamines with inhibitors of polyamine synthesis. Changes in polyamine levels were confirmed using HPLC analysis Our results strongly support the idea that polyamines endogenously regulate ion permeation through the AMPA class of glutamate receptor. TNFα TREATMENT INCREASES THE NUMBER OF CORTICAL NEURONS EXPRESSING Ca²⁺ -PERMEABLE AMPA/KAINATE RECEPTORS. D.M. <u>Turetsky*, L.L. Dugan and D.W. Choi.</u> Center for the Study of Nervous System Injury and Dept. of Neurology, Washington Univ. School of Medicine, St. Louis, MO 63110.

Recent studies have identified subpopulations of neurons in hippocampus, cerebellum, spinal cord and cortex which express Ca²⁺ -permeable AMPA or kainate receptors, and exhibit selective vulnerability to death induced by kainate exposure. These neurons can be identified by a histochemical stain for kainatestimulated cobalt uptake. We previously reported that oxidative stress specifically, a brief sublethal exposure to H₂O₂ (60 μM, 30 min) - produced a 25% increase in the number of neurons exhibiting kainate-stimulated cobalt uptake in murine cortical cultures, as assessed 24 hr after the treatment (Dugan et al., Soc. Neurosci. Abstr. 21:353). This increase in cobalt positive neuronal number was accompanied by a two-fold increase in kainate-stimulated 45Ca2+ influx, and a selective decrease in the amount of GluR B protein.

TNFα, a cytokine known to increase oxidative processes in a variety of cell types, is increased in brain after focal ischemia (Liu et al., Stroke 25:1481, 1994) or inflammation, as well as in AIDS-related dementia (Perrella et al., J Neurol 239:387, 1992). Because of our hypothesis linking oxidative stress and Ca² permeable AMPA/kainate receptor expression, we tested the effect of TNF α on cobalt positive neuronal number in our culture system. Twenty-four hour treatment with 100 ng/ml TNFa caused a 27% increase in the number of cobaltpositive cortical neurons at the end of the treatment period. Present observations raise the possibility that TNF α may alter AMPA/kainate receptor properties in certain disease states, favoring Ca²⁺ permeable forms and perhaps increasing neuronal vulnerability to excitotoxic injury. GENERATION OF ANTIBODIES SPECIFIC FOR THE PHOSPHORYLATED AMPA RECEPTOR GLURI SUBUNIT. K. Kameyama, A. L. Mammen, K. W. Roche and R. L. Huganir*, Dept. of Neuroscience, Howard Hughes Med. Inst., Johns Hopkins Univ. School of Med., Baltimore, MD 21205

Protein phosphorylation has been shown to be an important mechanism for modulating ionotropic glutamate important mechanism for modulating ionotropic glutamate receptors. We have shown previously that protein kinase A and C directly phosphorylate the AMPA receptor GluR1 subunit on serine residues 845 and 831 respectively, in a heterologous expression system. To study the phosphorylation state of this receptor *in vivo* and *in vitro*, we have generated antiphosphopeptide antibodies recognizing the GluR1 protein only when it is phosphorylated on either serine residues 831 or 845. when it is phosphorylated on either settle festides 831 of 843. These antibodies are very specific and recognize GluR1 only when it is phosphorylated on the appropriate serine residue. Immunoblot experiments with these antibodies indicate that GluR1 is basally phosphorylated on these sites in hippocampal slice preparations. Interestingly, the basal phosphorylation of slice preparations. Interestingly, the basal phosphorylation of these sites is much less in primary cultures of cortical neurons than in the hippocampal slice. The phosphorylation at serine 831 or 845 is increased by preincubation of slices or primary culture neurons with phorbol dibutyrate to activate PKC or forskolin to activate PKA, respectively. These antibodies should prove useful for monitoring the phosphorylation states of GluR1 during a variety of neuronal processes, such as LTP or LTD.

ACTIVATION OF GLIAL GLUTAMATE RECEPTORS MEDIATES THE TRANSFER OF THE NITRIC OXIDE PRECURSOR ARGININE FROM GLIA TO NEURON

G.Grima*, B.Benz and K.Q. DO; Brain Research Institute, University of Zurich,

8029 Zurich, Switzerland
Arginine (Arg), the nitric oxide (NO) precursor, has been reported to be predominantly localized in glial cells, whereas NO synthase, the NO producing enzyme, is mainly found in neurons. Therefore, a transfer of Arg from glial cells to neurons is necessary to replenish the neuronal precursor pool. This is further supported by the finding that Arg is released upon selective pathway stimulation both in vitro (Hansel et al., 1992) and in vivo (Do et al., 1994). We investigated the mechanism underlying this glial-neuronal interaction by analyzing the effect of glutamate (GIu) agonists on the extracellular [3-H]-Arg level in cerebellar slices and in cultures of cortical astrocytes and neurons. In cerebellar slices, Glu, in a TTX-insensitive manner, AMPA, kainate and NMDA increased significantly the extracellular level of labeled Arg. This effect was blocked by the selective antagonists, CNQX and CPP respectively. Moreover, tACPD induced a delayed rise of the Arg release, whereas L-AP4 and L-CCG1 were ineffective. In astrocytes, Glu, AMPA, kainate (effect blocked by CNQX) and the Ca²⁺-ionophore A23187 caused an increase in the extracellular Arg level. NMDA was ineffective in this system. Glu showed no effect in neurons. These results together with the glial localization of Arg support the hypothesis of an Arg transfer from glia to neurons in order to supply NO synthase with its substrate. The activation of ionotropic non-NMDA receptors present on astrocytes mediates this Arg transfer probably through a rise in intracellular [Ca²+]. Thus, NO synthesis and NO transmission may be based on the glial-neuronal transfer of Arg which is dependent on activation of excitatory amino acid receptors on glial cells. This interaction represents a novel glial-neuronal signaling which could play a role in the synaptic transmission. (Swiss National Foundation (NF31-39681.93) and Human Frontier Science Program)

LONG-TERM EXPOSURE TO GLUTAMATE RECEPTOR LIGANDS ALTERS THE SUSCEPTIBILITY TO EXCITOTOXIC DAMAGE AND GLUTAMATE RECEPTOR SUBUNIT EXPRES-SION IN HIPPOCAMPAL SLICE CULTURES, J. Zimmer*, B. Jakobsen, N. H. Diemer. PharmaBiotec, Dept. of Anat. & Cell Biol., Odense Univ. and Dept. of Neuropathol., Copenhagen Univ., Denmark.

Long-term treatment of developing rat hippocampal slice cultures by glutamate receptor agonists was used to explore inducible changes in glutamate receptor mediated neurotoxicity and receptor subunit

expression.

Slices of 5 day old rat hippcampi were cultured by the roller-drum method with preservation of the normal, basic cellular and connections. method with preservation of the normal, basic cellular and connective organisation. When 4 week old slice cultures were acutely exposed to a high dose of KA (10 µM), there was a selective loss of CA3 pyramidal cells. Similar cultures exposed to a low dose of KA (2 µM) from day 4 and onwards appeared normal, but had become resistant to the acute high dose of KA (10 µM). The long-term treatment with KA also resulted in downregulation of GluR6 mRNA in CA3ab and KA2 mRNA in CA3c, as revealed by quantitative in

Preliminary studies of cultures long-term treated with NS102, a AMPA/KA antagonist developed by NeuroSearch, DK, showed loss of CA3 pyramidal cells by an acute, otherwise sublethal dose of KA.

We conclude that the susceptibility of hippocampal slice cultures to KA is modifiable by long-term exposure to NS102 and KA, and that the KA exposure is parallelled by a decrease in glutamate receptor subunit mRNA expression.

ACTIVATION AND DESENSITIZATION OF KAINATE RECEPTORS IN CULTURED HIPPOCAMPAL NEURONS. T.J. Wilding and J.E. Huettner Dept of Cell Biology & Physiology, Washington Univ, St Louis, MO 63110 We have used whole-cell recording and rapid agonist applications in the

presence of MK-801 (2 μ M) and GYKI 53655 (100 μ M) to characterize the physiological properties of kainate receptors expressed by rat hippocampal neurons in dissociated cell culture. GYKI 53655 is a potent, non-competitive inhibitor of AMPA-preferring receptors (ICS0 \sim 1 μ M), with greater than 200 fold selectivity for the AMPA versus kainate subtype. In the presence of GYKI, both kainate (EC50 \sim 35 μ M) and glutamate (EC50

400 μM) evoked desensitizing currents. Maximal responses were roughly 10% as large as the current elicited without GYKI. In contrast to current mediated by AMPA receptors, kainate currents recorded in GYKI were blocked potently by lanthanum (IC50 \sim 3 μ M) and were desensitized strongly by 1 μ M 2S, 4R-4-methylglutamate. Coapplication of either 5 μM AMPA or 500 μM aspartate had little or no effect on responses to kainate, although 1 mM AMPA elicited a small current in some cells. Glutamate currents desensifized nearly to baseline with a τ of approximately 50 msec, while in most cells, kainate to baseline with a τ of approximately 50 misec, while in most cens, kalinate currents decayed along two exponentials ($\tau \sim 30$ and 460 msec) to a steady state level roughly 20 to 60% of the peak. Recovery from desensitization to kainate and glutamate followed 2 exponentials with τs of 4-6 and 30-40 sec. Collectively, these results confirm that kainate-preferring receptors underlie

the currents evoked by kainate or glutamate in the presence of GYKI 53655; they are not mediated by electrogenic transport or by AMPA-preferring receptors that are simply insensitive to GYKI. In contrast to previous work on native and recombinant kainate receptors, however, exposure of hippocampal neurons to Con A reduced the peak current amplitude but had little effect on

the amplitude at steady-state.

INTEGRINS INHIBIT THE KAINATE-INDUCED CALCIUM WAVE IN HIPPOCAMPAL ASTROCYTE CULTURES, A.H. Cornell-Bell^{1*}, W. Kim², M.G. Rioult², R.M. Villalba¹ and V.Trinkaus-Randall³. ¹Viatech Imaging, Ivoryton, CT 06442; ²Yale School of Medicine, New Haven CT 06510, ³BU School of Medicine, Boston, MA 02118.

Kainate superfusion (100uM) overwhelms the Na⁺-buffering capacity of astrocytes within 100 sec resulting in reversal of the Na*/Ca2* exchanger. Ca2* entering the cytoplasm contributes to long-distance regenerative waves which travels at 20 um/sec without decrement. Na*_{in} is regulated by the Na*/Ca^{2*} exchanger; TTX has no effect on the Kainate wave. Ca²⁺ enters through reversal of the exchanger; voltage-gated Ca²⁺ channels are not involved since Nimodipine has no effect on the Kainate wave. Ca²⁺ release from stores does not contribute to the kainate wave; MCPG the metabotropic (IP3) receptor inhibitor has no effect on the kainate wave. Removal of Na* or Ca2* inhibitor has no effect on the kainate wave. Kemoval of Na or Ca* from outside and the specific Na*/Ca²* exchange inhibitor benzamil (10 uM) inhibit the kainate wave. We speculated that the only requirement for the regenerative kainate wave was closely aligned cell membranes containing the Na*/Ca²* exchanger. This would imply that Ca²* or IP3 need not pass through the gap junction, but reversal of the exchanger would propel the Ca²* wave at the cell surface. Uncoupling gap junctions with octanol (Finkbeiner, 1993; Kim et al, 1995; Lee et al., 1995) inhibits the kainate wave which may result from membrane-membrane changes. Alpha6 Integrin antibodies immuno fluorescently stain astrocyte edges reflecting their role in cell-cell communication. Time-lapse confocal imaging was used to show that a functiona antibody to alpha6-Integrin inhibits the spread of the kainate wave in a dose and time-dependent manner. FRAP analysis shows gap junctions remain open in the presence of anti-alpha6. Viatech Imaging and NIHEY06000.

607.18

THE PROBABILITY OF OPENING OF HOMOMERIC GLUR6

THE PROBABILITY OF OPENING OF HOMOMERIC GLUR6 RECEPTORS. Philip Wahl*, David Mott, and Stephen F. Traynelis. Dept Pharmacology, Emory University, Atlanta, GA 30322 and NovoNordisk A/S, DK-2880 Bagsværd, Denmark GluR6 glutamate receptor subunits have been suggested to be involved in the development of the central nervous system. We have used rapid agonist application and nonstationary variance analysis to examine the single channel conductance and the probability of channel opening for rat GluR6 homomeric channels expressed in HEK293 cells and activated by the endogenous neurotransmitter, glutamate. Glutamate (0.15-10 mM) was applied to excised membrane patches (Vhold=80 mV) at 15 s intervals, and 35-240 current responses recorded at 50 kHz. The mean risetime (10-90%) for responses to 10 mM glutamate was 0.5 ms; desensitization was well described by a single exponential function with tau of 3.6 ms (n=10 patches), and recovered with a time constant of 2 s (n=11). The weighted mean slope conductance of single channel openings was 15 pS (n=6) for receptors unedited in the M2 region but fully edited in TM1; unitary current determined at -80 mV was independent of agonist concentration (0.15-10 mM; n=27). RNA editing in the M2 region (Q621R) reduced unitary conductance by more than 25-fold (n=3). Popen (0.6; n=15) was independent of voltage and RNA editing in M2 region, but varied with agonist concentration. The EC50 value (0.2 mM) for maximal Popen was similar to that obtained for the macroscopic current (0.5 mM). The Hill slope was 1.0. Inclusion of the catalytic subunit of PKA in the intracellular solution caused a 33% increase in Popen (p<0.5; n=24). We conclude that binding of a single molecule of glutamate to homomeric GluR6 receptors is associated with a high probability of channel opening, and this probability of receptor opening can be modified by intracellular kinases.

THE KAINATE BINDING PROTEIN FROM RANA PIPIENS HAS A FUNCTIONAL ION CHANNEL DOMAIN. <u>C. Villmann* and M. Hollmann.</u> Glutamate Receptor Laboratory, Max-Planck-Institute for Glutamate Receptor Laboratory, Max-Planck-Experimental Medicine, D-37075 Göttingen, Germany.

Kainate binding proteins (KBPs) have been cloned from several species (frog, chick, duck, and goldfish). They share significant sequence homology with ionotropic glutamate receptors, particularly kainate and AMPA receptors. Also, their transmembrane topology is believed to be identical to that of glutamate receptors. However, none of the KBPs forms functional ion channels upon heterologous expression in Xenopus occytes or mammalian cells. The observed lack of ion channel function could be due to lack of protein expression, lack of ligand binding, a non-functional ion pore domain, or a defect in the mechanism translating ligand binding into opening of the pore. Since ligand binding can readily be measured in heterologous systems, lack of ion channel function can neither be attributed to lack of protein expression nor failure of the agonist to bind.

Therefore, we set out to investigate whether the hypothetical ion pore domain of the KBPs in principle is capable of conducting ionic currents. We excised the ion pore domain of *Rana pipiens* KBP (kindly provided by Drs. Keiji Wada and Bob Wenthold) and inserted it into the kainate receptor GluR6 and the AMPA receptor GluR1. In both cases the chimeric receptors upon expression in Xenopus oocytes formed functional ion channels activated by kainate and glutamate. We conclude that the KBPs have an ion pore domain capable of conducting current. Lack of function in homomerically expressed KBPs may thus be due to a failure to communicate agonist binding to the ion pore. Supported by the Deutsche Forschungsgemeinschaft, and SFB 406.

POTENTIATION OF THE KAINATE RECEPTOR GIUR6 BY LECTINS APPARENTLY INVOLVES MULTIPLE CARBOHYDRATE SIDE CHAINS. I. Becker and M. Hollmann*. Glutamate Receptor Laboratory, Max-Planck-Institute for Experimental Medicine, D-37075 Göttingen, Germany.

Lectins such as Concanavalin A (ConA) have long been known to potentiate currents at certain glutamate receptors. This effect is thought to be due to inhibition of desensitization, and is most prominent with kainate receptors (up to 4000-fold increase in currents at GluR6). However, the molecular mechanisms underlying this effect are entirely unknown. Since ConA acts by binding to carbohydrates, we investigated whether the ability of ConA to potentiate GluR6 responses is mediated by the carbohydrate side chains present on the protein. Expression of GluR6 in Xenopus oocytes injected with tunicamycin to block all N-glycosylation totally abolished the ConA effect while receptor function was retained. We next analyzed whether any particular carbohydrate side chain attached to one of the 10 consensus N-glycosylation sites present on GluR6 might be responsible for the ConA effect. Only 9 of these sites are extracellular, and each of them was eliminated by site-directed mutagenesis. All mutants were still functional, although in some cases current amplitudes were significantly smaller than in wildtype GluR6. Importantly, though, all mutants still showed ConApotentiation. Thus, there is no single carbohydrate side chain which mediates the effect of ConA. Presumably. ConA interacts simultaneously with several such side chains. Combinations of sidechain mutations are currently under investigation Supported by the Deutsche Forschungsgemeinschaft, and SFB 406.

EXCITATORY AMINO ACID RECEPTORS: PHYSIOLOGY, PHARMACOLOGY, AND MODULATION III

608.1

IN VIVO RELEASE OF HOMOCYSTEATE FROM RAT THALAMUS FOLLOWING STIMULATION OF SOMATOSENSORY AFFERENTS T.E. Salt¹, B. Benz, K.E. Binns¹, S. A. Eaton¹ and K.Q.Do⁴. Brain Research Institute, Zurich University, CH-8029 Zurich, Switzerland; ¹Institute of Ophthalmology, University College London, London EC1V 9EL, UK. The sulphur-containing amino acid homocysteic acid (HCA) is present in and released from nervous tissue and is a potent neuronal excitant, predominantly activating NMDA receptors. However, HCA is localized not in neurons but in glial cells (Grandes et al., 1991), and activation of a nervous pathway in vitro leads to delayed efflux of HCA (Do et al., 1992). We now report the in vivo release of HCA from ventrobasal (VB) thalamus following natural stimulation of somatosensory afferents arising from the mustachial vibrissae of the rat. Simultaneously with electrophysiological recording, [3°-S]-methionine, a HCA precursor, was perfused (15 μ/min) through a push-pull cannula in VB thalamus of anaesthetized rats. One minute effluent perfusates were collected before, during and after 4 minute stimulation of the vibrissal afferents with an air jet. A marked release of radiolabeled HCA was observed during and after the stimulation. In separate experiments, the excitatory actions of inotophoretically applied L-HCA on VB neurons were inhibited by the NMDA receptor antagonist CPP, but not by the non-NMDA antagonist CNQX. These results, combined with the HCA release induced by noradrenaline from glial cells (Do et al., 1994) suggest a gliotransmitter role for HCA in VB thalamus. The release of HCA from glia might exert a direct postsynaptic response or modulate responses to other neurotransmitters, thus enhancing excitatory processes. These studies also indicate that the communication between glia and neurone is indeed part of their physiological activity and is induced by physiological conditions.

608.3

CLONING AND EXPRESSION STUDIES OF KYNURENINE/α-AMINO-ADIPATE AMINOTRANSFERASE FROM WHOLE HUMAN BRAIN. <u>S. Gatti</u>, <u>L. Cozzi</u>, <u>B. Valsasina</u>, <u>M. Mauriello</u>, J. Breton, N. Avanzi, <u>E. Okuno*</u>, <u>C. Speciale*** and S. Toma</u>. Pharmacia & Upjohn, Bioscience Center and **CNS Research, Nerviano (Mi), Italy, *Wakayama Medical College, Wakayama 640, Japan.

(Work supported by the Human Frontier Science Program).

In the brain, kynurenic acid (KYNA), an endogenous antagonist at the excitatory amino acid receptors, is produced from L-kynurenine by two different kynurenine aminotransferases (E.C.2.6.1.7.), KAT1 and KAT2. These enzymes, by regulating brain KYNA content, may play a role in neurobiology. Recently, KAT2 has been described as kynurenine/α-aminoadipate aminotransferase and its clone has been obtained from rat brain (Buchli et al., JBC, 270:29330, 1995). We have now partially purified hKAT2 from whole brain and sequenced 11 peptides fragments obtained by tryptic digestion of the SDS-PAGE band (44KDa). The hKAT2 cDNA sequence was obtained by RT-PCR using polyA+ from human hippocampus, and by screening of a $\lambda ZapII$ human striatum cDNA library. The analysis of the nucleotidic sequence showed the presence of a single open reading frame coding for a 425AA long protein. The deduced primary amino acid sequence of human KAT2 was found to have 78% homology to the rat kynurenine/ α -aminoadipate aminotransferase protein sequence. Northern blot analysis showed the constitutive presence of a 2000bp long mature KAT2 transcript in human liver and kidney. In the brain, the constitutive expression of hKAT2 mRNA was detectable in hippocampus, nucleus caudatus, hypothalamus, thalamus, subthalamic nucleus, substantia nigra, amigdala, and corpus callosum. The enzymatic activity of the recombinant protein expressed in COS1 cells tested as kynurenine aminotransferase and a-aminoadipate aminotransferase is currently ongoing. Molecular studies related to KYNA synthesising enzymes in the human brain will provide insightful information on the role of this endogenous compound in physiology and pathology in the central nervous system

PREFERENTIAL INHIBITION BY BARBITURATES OF CALCIUM-DEPENDENT SYNAPTOSOMAL RESPONSES INDUCED BY NMDA RECEPTOR ACTIVATION. K. Fink', W. Meder and M. Göthert, Inst. Pharmacol. Univ. Bonn, Reuterstrasse 2b, 53113 Bonn, Germany Barbiturates inhibit neuronal function by increasing CI conductance of the

Barbiturates inhibit neuronal function by increasing Cl conductance of the GABA, receptor channel. In addition, they may inhibit other ligand- and voltage-gated ion channels, thus decreasing Ca²+-dependent neurotransmitter (NT) release from axon terminals. To test this hypothesis, rat brain cortex synaptosomes were used to examine the influence of methohexital (1) on NT release induced by activation of NMDA receptors, voltage-gated Na* channels (by veratridine) or voltage-gated Ca²+ channels (by high K^) and (2) on depolarization-induced increase in intrasynaptosomal Ca²+ concentration. Synaptosomes preloaded with [¹H]noradrenaline ([¹H]NA) or [¹H]5-hydroxytryptamine([¹H]5-HT) were superfused with Krebs' buffer. [¹H]NT release was induced by addition of veratridine (1 μ M), NMDA (0.3 or 1 mM) or 15 mM K*. FURA 2-loaded synaptosomes (in Hepes buffer) were transferred into a fluorometer; the increase in [Ca²+], induced by K* (30 mM) or veratridine (1 μ M) was evaluated on the basis of 340/380 nm fluorescence ratios. The NT release induced by NMDA or overatridine was almost completely Ca²+-dependent. The increase in [Ca²+], induced by high K* or veratridine depended mainly on extracellular Ca²+ and was inhibited by 0.1 μ M ω -contoxin GVIA (by 33% and 24%, respectively), but not by 1 μ M nifedipine. Methohexital inhibited the veratridine-induced release of [¹H]NA or [¹H]5-HT (plCs_0 = 3.40 or 3.67, respectively), the increase in [Ca²+], induced by veratridine (plCs_0 = 3.30), the Ca²+-induced [¹H]NA release (plCs_0 = 3.47) and the increase in [Ca²+], induced by high K* (plCs_0 = 3.65) at similar potencies. However, the NMDA-evoked [³H]NA release was more potently inhibited (plCs_0 = 4.01). It is concluded in the nerve terminals methohexital inhibits both the depolarization-induced increase in [Ca²+], and the depolarization-induced NT release and (2) that methohexital inhibits the NMDA receptor channels at higher potency than voltage-gated Na* and Ca²+ channels. (Supported by a grant of the DFG)

EXPRESSION CLONING OF RAT KIDNEY KYNURENINE-3-HYDROXYLASE. S.Magagnin*, R.Bormetti, C.Speciale, M.Cini and L. Benatti. Pharmacia & Upjohn, CNS Research, Nerviano (MI), Italy. Several lines of evidence suggest that an enhancement of kynurenic acid

formation and a reduction of quinolinic acid production by pharmacological means may offer new opportunities to develop novel neuroprotective molecules. Following this strategy, kynurenine-3-hydroxylase (KYN 3-OHase), catalysing the conversion of kynurenine to 3-hydroxykynurenine has been proposed as the major target for the pharmacological manipulation of the kynurenine pathway (Speciale et al., this meeting) Since attempts for its purification have been so far unsuccessful, an expression cloning strategy was designed. Xenopus laevis oocytes were first injected with poly (A) RNA isolated from rat kidney, a tissue in which the activity of the enzyme was reported to be particularly high. KYN 3-OHase activity was present neither in water-injected oocytes nor in oocytes injected with $poly(A)^{+}RNA$ isolated from rat heart (a tissue in which the activity of the enzyme is very low). On the other hand, the oocytes injected with rat kidney mRNA showed an activity 6 folds over background. A directional cDNA library was therefore constructed from rat kidney poly(A)[†] RNA. The unamplified library (about 50,000 independent clones) was initially subdivided in 25 pools of about 2,000 colonies each. cRNA from each pool was injected in X. oocytes and positive clones selected on the basis of KYN 3-OHase expressed activity. Following the same criterion, in the last round of screening we had a single positive clone that showed an activity about 400 folds higher than that induced by injection of total rat kidney poly(A)+ RNA. Identity of the isolated clone was further verified comparing the kinetic parameters of the expressed activity with those of the native kidney enzyme. Isolation and characterization of KYN 3-OHase cDNA will help to understand its role in physiology and pathology and to design more specific inhibitors possibly bearing

INHIBITION OF KYNURENIC ACID SYNTHESIS BY AMMONIA IN RAT BRAIN SLICES. W.A. Turski^{1,2*}, J. Albrecht³, T. Kocki¹, T. Saran¹, E.M. Urbanska^{1,2}. ¹Department of Pharmacology and Toxicology, Medical University School, Lublin, Poland, ²Department of Clinical Toxicology, Institute of Agricultural Medicine, Lublin, Poland, ³Department of Neurotoxicology, Medical Research Centre, Polish Academy of Science, Warsaw, Poland.

Kynurenic acid (KYNA) is an endogenous neuroprotectant which acts on all three ionotropic excitatory amino acid receptors. Its synthesis from L-kynurenine is catalyzed by aminotransferase located preferentially in astrocytes. Astrocytes are the primary metabolic target of ammonia in the brain. This prompted us to investigate the effect of ammonia on KYNA synthesis. Rat cortical slices were incubated in the presence of L-kynurenine (10 µM) and different concentrations of ammonium acetate. KYNA was quantified by HPLC. Ammonia at the subtoxic to toxic concentration range from 1 mM to 10 mM produced a dose-dependent inhibition of KYNA synthesis by 21% and 76%. respectively. Subthreshold concentration of ammonia (0.5 mM) influenced neither KYNA synthesis under standard conditions nor the inhibition of KYNA synthesis evoked by L-glutamate. The results point to impaired neuroprotection by KYNA as a potential astroglia-mediated aspect of ammonia neurotoxicity observed in hyperammonemia. Supported by KBN Research Grant No. 4.PO5A.027.09

FACILITATED BRAIN UPTAKE OF HALOGENATED KYNURENINES VIA THE LARGE NEUTRAL AMINO ACID TRANSPORTER IN RATS. 1. L. Eastman*, M. Hokari, 1. H.-Q. Wu, 1. R. Schwarcz and Q.R. Smith. Lab. Neurosci., Nat. Inst. Aging, NIH, Bethesda, MD 20892 and 1 Maryland Psych. Res. Ctr., Baltimore, MD 21228.

7-Chlorokynurenic acid (7-Cl-KYNA) is of therapeutic interest as a potent NMDA receptor antagonist and neuroprotective agent. However, 7-Cl-KYNA crosses the blood-brain barrier only poorly following systemic administration. We therefore examined the brain uptake and metabolic conversion of L-4-chlorokynurenine (4-Cl-KYN), the immediate precursor of 7-Cl-KYNA (J. Med. Chem. 37: 334, 1994), using an in situ rat brain perfusion method (Am. J. Physiol. 247: H484, 1984) and 100, 200 or 500 μ M of the prodrug. 4-Cl-KYN was shown to be taken up readily into brain by the large neutral amino acid transporter of the blood-brain barrier (K_m = 101 \pm 12 μ M, $v_{\rm max} = 18.4 \pm$ 1.6 nmol/min/g tissue) and to reach concentrations comparable to that of endogenous KYN after 20 s. During the same period, some 4-Cl-KYN was also converted to 7-Cl-KYNA which was recovered in concentrations similar to those of endogenous cerebral KYNA (i.e. 15-25 pmoles/g tissue). Essentially identical tissue contents of 4-Cl-KYN and 7-Cl-KYNA, respectively, were measured in cortex, striatum and hippocampus. Parallel experiments using the precursor of 5,7-dichlorokynurenic acid, L-4,6-dichlorokynurenic acid, L-4,6-dichlorokynurenic arginity of the di-halogenated compound for the neutral amino acid transporter (K_m = 410 \pm 18 μ M; n=6). These results suggest that 4-Cl-KYN may be a useful prodrug for brain delivery of 7-Cl-KYNA. Supported in part by USPHS grants NS 16102 and NS 28236.

FCE 28833A, A POTENT INHIBITOR OF KYNURENINE 3-HYDROXYLASE, ENHANCES BRAIN KYNURENIC ACID AND IS NEUROPROTECTIVE IN THE GERBIL ISCHEMIA MODEL C.Speciale, P.Salvati, M.Cini, L.Benatti, M.Tamburin, A Molinari, B.Rosa, C.Allievi¹, C.Caccia, M.Varasi and C.Post*

Pharmacia, & Uniohn, CNS Passager, and ¹Pharm. & Matsh, Nangiano (M.) Italy.

Pharmacia & Upjohn, CNS Research and ¹Pharm. & Metab., Nerviano (MI), Italy. The presence of the neuroprotectant kynurenic acid (KYNA) in the mammals brain offers opportunities for pharmacological intervention in neurodegeneration. Inhibitors of kynurenine 3-hydroxylase (KYN 3-OHase), the first enzyme involved in kynurenine degradation, are able to enhance brain KYNA content. FCE 28833A. (R,S)-3,4-dichlorobenzoylalanine (Molinari et al., Soc. Neurosci., 1995), is the most potent and selective inhibitor (K_i=130 nM) described so far, and upon oral administration in gerbils (400 mg/kg) increases KYNA in brain tissue over 60-fold. In order to examine the possibility that the KYNA rise results in neuroprotection we tested FCE 28833A in the gerbil model of global ischemia. FCE 28833A (400 mg/kg) was given orally 3 hours before 5 min ischemic insult. 7 days later neuronal loss per mm CA1 was evaluated by image analysis. FCE 28833A-treated gerbils showed a significantly larger number of living neurons (95.8 \pm 13.2, n=31, p<0.01), in comparison with the vehicle-treated group (41.3 \pm 10.1, n=41). Excitatory amino acid (EAA) receptor antagonists can prevent the induction of immediate early genes (IEG) mRNA expression evoked by excitotoxic events. To investigate the link between increased KYNA in the brain and EAA receptor activation, the effect of FCE 28833A on ischemia-induced c-fos and c-jun mRNA was studied in gerbils by in situ hybridization in the dentate gyrus. Having ruled out any direct effect of FCE 28833A on the ionotropic EAA receptors, the significant attenuation of the ischemia-induced mRNA expression observed in the drug-treated group in comparison to controls, was consistent with the hypothesis that endogenous KYNA may cause EAA receptor blockade. Our results strongly support the notion that modulation of endogenous kynurenines constitutes a viable strategy for the development of neuroprotective therapies.

GLUCOSE DEPRIVATION RESULTS IN DECREASED KYNURENIC ACID PRODUCTION IN RAT BRAIN SLICES: EFFECTS OF LACTATE SUBSTITUTION. P.S. Hodgkins*, A. Rassoulpour and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228.

Kynurenic acid (KYNA) is an endogenous metabolite of tryptophan which is produced in the brain and is an established neuroprotective compound. As demonstrated previously using brain tissue slices, synthesis of KYNA from its immediate precursor L-kynurenine (KYN) is glucose-dependent (J. Neurochem. 52: 1629, 1989). This effect of glucose deprivation is not due to an impaired transport of KYN into the cell (J. Neurochem. 54: 156, 1990). Follow-up studies were now performed using tissue slices from male rats (routinely 200-220 g) and a physiological concentration of KYN (2 µM). Under standard incubation conditions [cortical slices, Krebs-Ringer buffer (KRB); 5 mM glucose], approx. 4 pmol KYNA/mg protein/h were produced and recovered extracellularly. Removal of glucose from the KRB decreased KYNA production to 32.7 ± 2.6% (SEM) of control levels (N=6; P < 0.001). No effect of glucose removal was observed in liver slices incubated under identical conditions. Similarly, KYNA production was glucose-independent in striatal slices from animals which had been lesioned 7 days previously with 300 nmoles quinolinic acid.

previously with 300 nmoles quinolinic acid. Lactate substitution partially reversed the effect of glucose deprivation, with 10 mM lactate restoring KYNA production in cortical slices from adult rats to 68.3 \pm 3.7% of controls (N=7; P < 0.001) (ED $_{50}$ 0.5 mM). In cortical slices from 14 day-old rats pups, glucose deprivation caused KYNA synthesis to decrease only to 61.7 \pm 2.5%, and addition of 10 mM lactate returned KYNA production to normal levels (N=3; P < 0.05 vs. no glucose). These data suggest a role of cellular energy metabolism in the production of KYNA and may be of relevance for hypoglycemia-induced excitotoxic damage. Supported by USPHS grants NS 16102 and NS 28236.

EXTRACELLULAR CONTENT OF KYNURENIC ACID IN THE RODENT HIPPOCAMPUS: EFFECTS OF SYSTEMICALLY ADMINISTERED KYNURENINE 3-HYDROXYLASE INHIBITORS. N. Carfagna, H.-Q. Wu¹, C. Speciale, C. Post, M. Varasi and R. Schwarcz¹. Pharmacia & Upjohn, CNS Research, Nerviano (MI), Italy and ¹Maryland Psychiatric Research Center, Baltimore, MD 21228, USA.

Kynurenic acid (KYNA) is a brain metabolite and broad spectrum

antagonist of ionotropic glutamate receptors. We have studied by microdialysis the effects of the p.o. or i.p. administration of two potent and selective kynurenine 3-hydroxylase inhibitors. (R.S)-3.4 dichlorobenzoylalanine (FCE 28833A) and m-nitrobenzoylalanine (mNBA), on KYNA levels in the hippocampus of unanesthetized rats and mice. These compounds divert kynurenine pathway metabolism to increase the formation of endogenous KYNA in the brain. The basal concentrations of extracellular KYNA were 13.0 nM and 5.3 nM, respectively, for rats and mice. P.o. administration of FCE 28833A (400 mg/kg) to rats or mice resulted in a substantial increase in KYNA, reaching a peak of 10-12 times control levels by 6 hrs and reverting to baseline by 12-18 hrs. P.o. treatment with the same dose of mNBA caused a maximal KYNA increase of 4-fold, peaking at 4 hrs and returning to baseline by 11 hrs. After i.p. injection in rats (400 mg/kg each), mNBA caused a peak increase of 10 times basal levels at 4-5 hrs, whereas FCE 28833A treatment resulted in a peak 80-fold increase above control levels after 9 to 11 hrs. In mice, repeated p.o. administration (400 mg/kg every 12 hrs for 3 days) failed to indicate tolerance to FCE 28833A-induced KYNA enhancement. These data confirm that FCE 28833A is the most potent KYNA-enhancing agent described so far. FCE 28833A-induced elevations of brain KYNA levels may be related to the compound's neuroprotective properties (cf. Speciale et al., this meeting). Supported by USPHS grant NS 16102.

FCE 28833A, A NOVEL KYNURENINE 3-HYDROXYLASE INHIBITOR. IN ITITIO AND IN ITITO CHARACTERIZATION OF THE TWO ENANTIOMERS M.Varasi*, C.Speciale, M.Cini, M.Marconi, M.Breda¹, A.Giordani, R.Bormetti and C.Post, Pharmacia & Upjohn, CNS Research and ¹Pharmacokinetic & Metabolism, Nerviano, (MI), Italy.

Modulation of the synthesis of endogenous neuroactive kynurenines has been proposed as a viable strategy for neuroprotection. In particular, inhibition of kynurenine 3-hydroxylase (KYN 3-OHase) has been shown to enhance the levels of endogenous kynurenic acid (KYNA) in the brain, and may thus increase the physiological defensive mechanisms of the brain. Indeed, FCE 28833A [(R,S)-3,4-dichlorobenzoylalanine], the most potent KYN 3-OHase inhibitor described so far (K₁=0.13 μM), provides neuroprotection in the gerbil model of global ischemia (Speciale et al., this meeting). When administered orally to gerbils or rats at 400 mg/kg, brain tissue levels of KYNA showed peak increases of 60- and 14-fold, respectively, by 8 hrs after the treatment. The competitive mechanism of enzyme inhibition was demonstrated by kinetic analysis. The enantiomeric (R)- and (S)-forms of FCE 28833A, termed FCE 29196A and FCE 29191A, respectively, inhibited KYN 3-OHase activity in vitro with K₁ values of 1.8 and 0.068 μM subsequently, the two enantiomers were separately administered orally to gerbils at a dose of 400 mg/kg, and the time curve of increases in brain KYNA levels was examined. Whereas the effect of FCE 29196A paralled the one obtained with the racemate, the increase evoked by the S-enantiomer was shorter-lasting Consistently, drug distribution studies in plasma and brain, performed by assessing the amount of the R- and the S-form after treatment with FCE 28833A, revealed a prolonged presence of the R-enantiomer in blood and brain. Full understanding of the *in vivo* effects of currently available KYN 3-OHase inhibitors provide insightful information for the design of future molecules.

FURTHER CHARACTERIZATION OF KYNURENIC ACID-SYN-THESIZING ENZYMES IN THE RAT BRAIN. P. Guidetti* and R. Schwarcz. Maryland Psych. Res. Ctr., Baltimore, Maryland 21228.

The endogenous neuroprotectant kynurenic acid (KYNA) is produced by

irreversible transamination of L-kynurenine (KYN). In the brain, two distinct kynurenine aminotransferases (KAT I and KAT II) appear to be responsible for the neosynthesis of KYNA. The present experiments were designed to examine the respective roles of the two KATs in KYNA production in the normal rat brain. To this end, the two enzymes were partially purified, and their characteristics were examined. KAT I (identical with glutamine transminase K) had an optimal pH of 9.5, preferred pyruvate as a co-substrate and was potently inhibited by glutamine. KAT II (identical with α -aminoadipate transaminase) had a neutral optimal pH, showed no preference for pyruvate and was essentially insensitive to inhibition by glutamine. Notably, KAT II was selectively inhibited by quisqualic acid (IC 50=450 μ M). The endogenous substrate 3-hydroxykynurenine had an approximately ten-fold preference for KAT II. These enzyme properties enabled us to measure brain KAT I and KAT II in parallel using dialyzed tissue homogenate (to remove interfering endogenous amino acids). Under these conditions, both enzymes presented the same apparent K_m values as the partially purified enzymes. Using dialyzed tissue and employing the selective inhibitors glutamine and quisqualate as tools, the respective roles of the two enzymes were examined at different pH values. The data indicated that under physiological conditions the majority of brain KYNA derives from KAT II. However, at more alkaline pH KAT I might play an increasingly important role in cerebral biosynthesis of KYNA.

ACTIONS ON TWO FORMS OF GABA-MEDIATED INHIBITION IN HIPPOCAMPAL CA1 NEURONS

S. Pittson and M. B. MacIver*. Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305.

Anesthetics have been shown to enhance GABA-mediated synaptic inhibition, but it is not known whether both feedforward and feedback inhibition contribute to the depressant effects. The GABA receptor antagonist, bicuculline, was used to probe involvement of enhanced inhibition in the depressant effects produced by halothane and propofol. Anesthetic effects on excitatory postsynaptic potential (EPSP) and paired pulse population spike (PS) responses were studied to determine effects on feedforward or feedback inhibition, respectively. Both anesthetics depressed PS responses to ~ 100% at clinical concentrations of 250 µM (1.0 rat MAC) and 30 µM for halothane and propofol, respectively. EPSP responses were depressed by $\sim 30~\%$ at these concentrations. Bicuculline (10 $\mu M)$ reversed the halothane-induced PS depression by > 20~%, but did not reverse EPSP effects. In contrast, the propofol-induced depression of PS responses was reversed by > 70 % and EPSP responses by > 80 % in the presence of bicuculline. These results suggest that halothane preferentially enhances feedback inhibition while propofol enhances both forms of GABA-mediated inhibition equally

EFFECTS OF HALOPERIDOL ON RAT EXCITATORY AMINO ACID RECEPTORS: COMPARING THE XENOPUS OOCYTE EXPRESSION SYSTEM WITH THE CORTICAL WEDGE PREPARATION. H.L. Sudan, K.S.J. Thompson, I. Phillips, P.L. Needham, K.F. Martin*, and D.J. Heal. Knoll Pharmaceuticals Research and Development, Nottingham NG2 3AA, U.K.

Glutamatergic systems have been implicated in schizophrenia and are potential targets for neuroleptics. We have compared the effects of haloperidol (HAL) on glutamate receptors expressed in Xenopus oocytes injected with rat brain RNA with those found occuring naturally in the rat brain cortex.

In voltage-clamped Xenopus oocytes, NMDA responses were potentiated by HAL in some oocytes (n=7), but concentration-dependently inhibited (10°9-10° ³M HAL) in others (n=14; IC₅₀=1.8 "0.9: M); however, complete inhibition was not achieved. Antagonism by HAL was voltage-dependent (7/8 oocytes) and only partially reversible by washing, suggesting that HAL does not readily dissociate from the NMDA receptor. Kainate responses were weakly inhibited by HAL and failed to achieve 50% inhibition (IC₅₀>10⁻³M); the inhibition was concentration-dependent, non-competitive and readily reversed by washing. In the cortical wedge preparation, HAL (1-100:M) had no effect on NMDA responses. However, kainate responses were reduced by HAL (1-100:M) in a concentration-dependent manner although complete inhibition was not observed.

The concentration of HAL effective in the oocyte experiments compares well with its affinity for the NMDA receptor-ion channel F site (IC₅₀=1.9:M), suggesting the oocyte is a valid model for assessing functional receptor interactions. However HAL's lack of effect in the rat cortical wedge raises important questions of the pharmacological relevance of these interactions.

Financial support provided by Knoll Pharmaceuticals.

KYNURENIC ACID PRODUCTION IN THE RAT STRIATUM: ACUTE AND CHRONIC EFFECTS OF QUINOLINATE LESIONS. G. Ceresoli*, P. Guidetti and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, Maryland 21228.

Intrastriatal injection of quinolinic acid (QUIN) in rats provides an animal model for Huntington's disease (HD). We have used this model to study the short- and long-term effects of the QUIN-induced lesion on the production of the endogenous neuroprotectant kynurenic acid (KYNA). Tissue levels of KYNA and its bioprecursor L-kynurenine (KYN), and the activities of kynurenine aminotransferases (KAT) I and II, were measured in the striatum after the focal injection of 300 nmoles QUIN. 2 hrs after the QUIN injection, KYNA levels were increased by 53%, whereas KYN, KAT l and KAT II remained unchanged. Two days later, both KYNA and KYN levels were elevated (to 630% and 173% of controls, respectively), KAT I activity was unchanged and KAT II activity was decreased by 33%. By 7 days after the QUIN injection, there were no changes in KYN levels and KAT II activity, a two-fold increase in KYNA levels and a 29% reduction in KAT I activity. At 1, 2, and 5 months after the lesion, 2 - 2.5-fold increases were observed in both KYNA levels and KAT II activity. KAT I activity was decreased by 24% and KYN levels were unchanged. These data show that multiple mechanisms are in place at different stages of the degenerative process to effect an elevation in the concentration of brain KYNA. The results also indicate that both KAT I and KAT II are present in neuronal and non-neuronal cells, and that KAT II is primarily responsible for the observed KYNA increases in the chronically lesioned striatum. Since this contrasts with the decreases in KYNA and KAT II activity seen in the HD striatum (J. Neurol. Sci. 130: 39, 1995), KAT II may play a role in the pathogenesis of HD.

STEROIDS MODULATE KAINATE-INDUCED ELECTRICAL RESPONSES IN OXYTOCINERGIC SUPRAOPTIC NEURONS THROUGHOUT LACTATION IN RATS. J.M. Israel, H. Breton, D. Theodosis* and D. Poulain. INSERM 378, Université Bordeaux 2, 33076 Bordeaux, France.

To study the role of glutamatergic inputs on the electrical properties of oxytocinergic (OT) neurons, intracellular recordings were performed on immunocytochemically identified neurons in rat hypothalamic slices (450 μm), obtained from rats at an early (5 days, EL) or late stage of lactation (20 days, LL). During long recording periods (4-6 h) most basal electrical properties were similar at the 2 stages of lactation. At both stages, OT neurons spontaneously displayed slow (or silent), continuous and bursting patterns of electrical activity; some cells switched from one pattern to the other spontaneously. All cells exhibited after-hyperpolarizations (AHP) and/or depolarizing after potentials (DAP). However, in LL cells, an additional outward rectification was observed However, in LL cells, an additional outward rectification was observed when depolarizing from hyperpolarized potentials. In EL cells, a spike frequency adaptation was noted during depolarizing current pulses. All neurons responded to the glutamate agonist, kainate, with a depolarization, which triggered or accelerated firing. Nevertheless, EL cells appeared more sensitive to kainate since they responded at concentrations of 10⁻⁵ M, versus 10⁻⁴ M for LL cells. 17-β-estradiol (10 ⁻⁷ M, 20 min) did not modify the membrane potential, despite a weak increase in membrane resistance. However, it potentiated kainate-induced responses in LL, but not in EL, neurons, an effect which was reversible after washing. These results show that responses to glutamate in OT cells changes in the course of lactation, and that these changes may be partly modulated by estradiol.

HALOTHANE ENHANCES SPONTANEOUS GABA RELEASE

V. A. Doze*, H. S. Lukatch, F. A. Monroe and M. B. MacIver. Dept. of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305.

This study investigated the effects of the volatile anesthetic, halothane, on This study investigated the effects of the volatile anesthetic, halothane, on spontaneous GABA release. Hippocampal brain slices (500 μm thick) were prepared from male Sprague-Dawley rats (80 to 120 gm) using an experimental protocol approved by the institutional animal use committee. Whole cell voltage-clamp recordings from CAI pyramidal cells were used to measure the frequency of spontaneous inhibitory postsynaptic currents (IPSCs) arising from local circuit GABAergic interneurons. Hippocampal interneuron and pyramidal cell discharge activity were also studied with whole-cell and cell-attached patch recordings, respectively. The volatile anesthetic, halothane, at clinically relevant concentrations (1.2 vol. %, 1 rat MAC) caused a >100% increase in IPSC frequency (5 \pm 3 Hz, control; 12 \pm 5 Hz, halothane; n = 5, p < 0.01). The effect of halothane persisted in the presence of glutamate receptor antagonists (8.5 μ M CNQX and 50 μ M APV, n = 5), suggesting a direct action on GABAergic interneurons. In a wholepresence of glutamate receptor antagonists (8.5 µM CNQX and 50 µM APV; n = 5), suggesting a direct action on GABAergic interneurons. In a whole-cell recording from a hippocampal interneuron, halothane at 1.2 vol. % caused a membrane depolarization (>15 mV) which increased spontaneous action potential discharge frequency from ~1 Hz in control to ~4 Hz in the presence of halothane. In contrast, in cell-attached patch recordings from pyramidal cells (n = 3), administration of halothane was associated with an cessation of all spontaneous discharge activity. All effects of halothane were fully reversible upon washout. These results suggest that halothane may act directly on hippocampal interneurons to increase their discharge frequency, leading to enhanced GABA release. This excitatory action of halothane on surrounding inhibitory interneurons may contribute to the halothane-induced decrease in the spontaneous activity of excitatory pyramidal neurons and the potent anesthetic actions of halothane observed *in vivo*.

DIFFERENTIAL EFFECTS OF A NOVEL GSH ADDUCT ON GSH AND NMDA RECEPTORS IN CORTEX. C.A. shaw^{1,2,3*}, B.A.Pasqualotto³, K. Curry⁵, S.U. Kim⁴, and M. Langmuir⁶. Depts.: Ophthalmology¹, Neuroscience², Physiology³, Medicine and Neurology⁴, Univ. of British Columbia, BC, Canada; Precision Biochemicals⁵, Vancouver; Covalent Associates⁶, Woburn, Mass.

We have used a variety of methods to examine the characteristics and distribution of a fluorescent adduct to GSH (GSHR-1) in an *in vitro* cortical slice preparation and in cortical neurons and astrocytes grown in culture. Field potential recordings from adult rat cortical slices showed typical responses to EAA agonists NMDA and AMPA and large depolar-izing potentials to GSH and cysteine (Shaw et al., NeuroReport, 1996; Pasqualotto et al., this meeting). NMDA and cysteine responses were reversibly blocked by AP5 and the GSHR-1 while the GSH response was unaffected, suggesting that GSHR-1 was exerting its effects on the cysteine modulatory site of the NMDA receptor. In human fetal cortical astrocytes and neurons in culture, GSHR-1 preferentially labelled GSH binding sites but had a low affinity for NMDA or other EAA receptors. The present data suggest similarities between NMDA and GSH binding sites which may have an agedependent component. GSHR-1 is also likely to prove a useful tool for localizing the cysteine binding site of NMDA receptors in various cell preparations. Supported by NSERC Canada (CAS) and NIH (ML).

RECEPTORS RESPONSIBLE FOR DEPOLARIZATIONS INDUCED BY BRIEF PULSES OF KAINIC ACID IN SLICES OF GUINEA PIG HIPPOCAMPUS. C. Yamamoto, S. Sawada, T. Ohno-Shosaku, N. Kobayashi and Y. Fukuda*. Dept. of Physiology, Fac. of Med. Kanazawa Univ., Kanazawa 920, Japan.

A brief pulse of kainic acid (KA) administered to proximal portions of apical dendrites of CA3 pyramidal neurons induces a fast depolarization and a following slow depolarization in these neurons. The purpose of this study was to determine subtypes of excitatory amino acid receptors responsible for these depolarizations. Transverse slices of the hippocampus were prepared from guinea pigs anesthetized with ether. Membrane potentials were recorded intracellularly from pyramidal neurons in the subfield CA3, and brief pulses (100-150 ms duration) of L-glutamate (Glu) or KA were ejected in the stratum lucidum at the spots where Glu pulses induced large depolarizing potentials in impaled neurons. 6-Cyano-7nitroquinoxaline-2,3-dione (CNQX) suppressed both the fast and slow depolarizations induced by KA. The action of CNQX was more potent on the fast response than on the slow one. While aniracetam augmented Glu-induced depolarizations, it had no effects on the fast and the slow depolarizations induced by KA. These findings suggest that the fast and slow KA-responses result from activation of AMPAspecific and KA-specific receptors, respectively. This work was supported by a grant from the Ministry of Education, Science and Culture of Japan.

EXCITATORY ACTIONS OF GSH IN NEOCORTEX. B. A. Pasqualotto*2, K. Curry⁴, and C. A. Shaw¹, 2, 3, Depts. of Ophthalmology¹, Physiology² and Neuroscience Program³, University of British Columbia and Precision Biochemicals

Inc.4, Vancouver, BC, Canada.
The reduced form of the tripeptide qlutathione (GSH) serves as a free radical scavenger and antioxidant defense mechanism and is involved in the detoxification of xenobiotics. In addition to these functions GSH may also act as an excitatory neuropeptide. Application of GSH to cortical slices produces a large, rapid depolarizing membrane potential shift in the cortical wedge recording preparation. This depolarization is concentration dependent and is not blocked by antagonists of the excitatory amino acid glutamate. GSH-induced depolarization is not attenuated by calcium or potassium removal from the extracellular medium but is blocked by sodium removal. GSH-induced depolarization does not appear to be mediated indirectly by breakdown into its constituent amino acids since neither glutamate, cysteine, nor glycine produce qualitatively or quantitatively similar effects. In contrast to GSH, the oxidized form of glutathione (GSSG) had no effect on membrane potential. These results demonstrate a novel role for GSH as an excitatory neuropeptide and indicate the existence of a novel GSH-gated, Na+-permeable ionotropic receptor. NEW PHOTOLABILE CAGED PRECURSORS OF KAINATE AND NMDA, INERT PRIOR TO FLASH PHOTOLYSIS <u>K.R. Gee, L. Niu, ² K. Schaper, ² C. Grewer, ² and G.P. Hess. ²

'Molecular Probes, Inc., Eugene, OR 97402</u> and ²Section of Biochemistry, Molecular and Cell Biology, Cornell University, Ithaca, NY 14853.

Photolabile ("caged") precursors of neurotransmitters have proven useful in the study of receptor activation mechanisms, receptor localization, and mapping of synaptic connections. Pulsed photolysis rapidly generates free neurotransmitter with better temporal and spatial resolution than is possible using simple diffusion of neurotransmitter solutions. We report here synthesis and photochemical characterization of a new caged version of kainic acid, in which the y-carboxylate is protected as a photolabile ester of 2-methoxy-5-nitrophenol. The caged compound does not induce any response on cultured rat hippocampal neurons before photolysis, nor does UV photolysis it potentiate or inhibit the response to free kainate. generates free kainate in the nanosecond time region, with a photolysis quantum yield of 0.21. A new caged version of NMDA has also been prepared, in which the β -carboxylate is protected as a photolabile ester of 2.2'-dinitrobenzhydrol. Again, the caged compound does not induce any response on cells before photolysis, nor does it potentiate or inhibit the response to free NMDA. These results represent the first caged NMDA that is inert before photolysis. UV photolysis generates free NMDA with a time constant of 6 μ s and a quantum yield of 0.18. CRF RECEPTORS: STRUCTURE AND FUNCTION

EFFECT OF CRH, α-hCRH AND CRH₁ ANTAGONISTS ON SOCIAL INTERACTION IN RATS. <u>K. W. Rohrbach*</u>, A.J. Cocuzza, R. Bakthavatchalam, W. J. Keim, J.F. Cawley, C. W. Johnson. Central Nervous System Diseases Research, The DuPont Merck Pharmaceutical Company, Wilmington DE 19880-0400. CRH has been implicated in the pathophysiology of anxiety.

CRH levels are increased in anxious conditions in humans and CRH produces effects in experimental animals consistent with increased anxiety and known anxiolytic agents decrease these effects. The social interaction test in rats has been used as an experimental animal test of anxiety, and less in rats has been used as an experimental animal test of anxiety, and has been shown to be sensitive to a range of anxiolytic treatments. CRH has been shown to produce an anxiogenic action in the social interaction test (Dunn and File, 1987). The following experiments were carried out to further characterize the effect of CRH in the social interaction test and to examine the effect of α -hCRH and selective CRH₁ antagonists on CRH and bright light-induced effects on social interaction. CRH, when administered i.c.v., produced a dose related decrease in social interaction. Light produced an intensity related decrease in social interaction. Both of these effects were reversed by chlordiazepoxide and α -hCRF. The previously reported selective CRH₁ receptor antagonist YY941 antagonized both CRH and light-induced decreases in social interaction as did the newly reported selective CRH₁ receptor antagonist SC241. The data are consistent with the interpretation that CRH induces a state of anxiety in rats, that the decrease in social interaction induced by bright light is mediated by CRH and that a selective CRH1 receptor antagonist may have utility as an anti-anxiety agent in humans

COMPARISON OF A CRH RECEPTOR ANTAGONIST AND KNOWN ANXIOLYTIC AGENTS ON DEFENSIVE WITHDRAWAL AND LOCOMOTOR ACTIVITY BEHAVIOR IN RATS. K.A. Weidemann, K.L. Zeller*, A.L. Fetterman and J.F. McElroy CNS Diseases Research, The DuPont Merck Pharmaceutical Co., Experimental Station, P.O. Box 80400, Wilmington, DE 19880-0400.

Rats placed in a small darkened chamber located in an unfamiliar open field spend most of their time within the small chamber (i.e., defensive withdrawal), an action consistent with a state of heightened anxiety. Rats pretreated systemically (1p) with the anxiolytic agent chlordiazepoxide (CDP) readily emerge from the chamber and explore the open field. This effect is dose-dependent, and the 50% effective dose (ED5₀) is 7.3 mg/kg. Direct intracerebroventricular (icv) administration of CDP (5 ug/rat) similarly reduced the latency to exit the chamber. This ~ 400-fold increase in potency (versus ip dosing) is consistent with a central site of CDP action. Two additional anxiolytic agents, pentobarbital (ED5₀ = 15mg/kg) and meprobamate (ED5₀ = 41 mg/kg), also reduced exit latencies in a dose-dependent manner. The agents, pentobarbital (ED $_{50}$ = 15mg/kg) and meprobamate (ED $_{50}$ = 41 mg/kg). also reduced exit latencies in a dose-dependent manner. The anxiolytic-like action of each of these agents occurred at doses 2- to 8-fold lower than doses required to reduce open-field locomotor activity, a behavioral effect employed as an index of non-specific drug action. The anxiolytic agent buspirone was inactive in the defensive withdrawal paradigm at all doses tested (0.1-30 mg/kg), including doses that markedly decreased locomotor activity (3-30 mg/kg). Corticotropin Releasing Hormone (CRH), a 41 amino acid peptide widely distributed throughout the CNS, has been implicated in anxiety and stress related disorders. Similar to CDP, pentobarbital, and meprobamate, the CRH antagonist α -helical CRH9-41 (20 ug/rat, icv) reduces exit latencies in defensive withdrawal. Results suggest that α -

reduces exit latencies in defensive withdrawal. Results suggest that α -helical CRH9-41, or preferably a non-peptide CRH antagonist, might represent a useful anxiolytic agent. Funding source: commercial.

CORTICOTROPIN RELEASING FACTOR (CRF) MEDIATES ACTH RELEASE AND HYPOTENSION BY TWO PHARMACOLOGICALLY DISTINCT CRF RECEPTOR SUBTYPES. D.R. Luthin, K.L. Youngblood, A.Rabinovich, M.R.Brown* and J.M. May, Alanex Corporation, San Diego, CA 92121.

Multiple CRF receptor subtypes with distinct brain and peripheral localization have recently been cloned and characterized. Using several peptide and non-peptide antagonists, we have compared the pharmacological profile of the CRF receptor subtypes mediating ACTH release and hypotension with the ability of compounds to displace ¹⁵⁵I-CRF binding to rat brain membranes and to recombinant CRF1 and CRF2β receptors.

Compound	CRFI IC ₅₀ (nM)	CRF2β IC _{so} (nM)	Rat Brain IC ₅₀ (nM)	Block of CRF 1 ACTH	Block of CRF BP
oCRF	2.2 ± 0.5	3.1 ± 0.2	3.6 ± 0.5	NA	NA
αH-CRF (9-41)	42 ± 3.3	3.5 ± 0.6	23.6 ± 8.1	-	+++
Tyr12-Astressin1	3.6 ± 0.4	2.4 ± 0.4	1.4 ± 0.2	+++	+++
Compound A ²	34 ± 2	>10000	28 ± 5.3	+	-
Compound B ³	124 ± 44	>10000	145 ± 49	+	-
Compound C4	121 ± 11	5300 ± 1800	413 ± 35	++	-

Gulvas et al., PNAS 92:10575-10579, 1995.

*Anti-parallel homodimeric peptide: Pmp-Arg-Lys-Cys-Cha-Asp-lle-Ala-NH₃;Pmp=3-Mercapto-3,3-cyclopentamethylene proprionic acid: Cha = Cyclohexylalanine.

These results suggest that the CRF receptor subtypes mediating ACTH release and hypotensive responses are the CRF₁ and CRF₂₀ receptors, respectively.

CRF RECEPTOR DESENSITIZATION AND RECOVERY IN HUMAN RETINOBLASTOMA Y-79 CELLS. R.L. Hauger^{1,2}, F.M. Dautzenberg¹ L.L. Judd*2, and J. Spiess1.2. Dept. Molec. Neuroendo., Max Planck Inst. Exp. Med¹., 37075 Goettingen & Dept. Psychiatry, UCSD², La Jolla, CA

Many G-protein receptors become rapidly desensitized by their ligand concentrations in the μM range, and rapid recovery typically occurs upon agonist removal. Since the stimulatory action of CRF during stress may require rapid counterregulation, we determined the time course for CRF receptor desensitization (CRFR des) in human retinoblastoma (Y-79) cells. CRFR des was characterized by an EC $_{50}$ of 6.34 ± 0.78 nM ovine CRF, a rapid onset at 10 min, and a $t_{1/2}$ of 38 min. Since the ability of VIP, isoproterenol, and forskolin to increase cAMP accumulation was not diminished in Y-79 cells desensitized to CRF, the observed CRFR des is considered to be a specific homologous action of CRF. Its specificity was also confirmed by CRFR des being markedly attenuated in the presence of a CRFR antagonist which by itself was not found to desensitize CRFR. The homologous CRFR des was associated with a >60% loss of CRFR from the Y-79 cell surface after 1 h exposure to 10 nM CRF. Since CRFR, type 1 (CRFR1), was identified on the basis of cDNA data to be the predominant receptor form in Y-79 cells, it was concluded that CRFR1 was responsible for the observed CRFR des. CRFR1 mRNA levels were not altered over 24 h of CRFR des in contrast to the rapid decrease in CRFR1 mRNA reported for CRFR des in anterior pituitary cells. The t_{1/2} for the recovery from CRFR des in Y-79 cells was ~13 h with a full reversal by 24 h. In conclusion, we propose that differential mechanisms mediate the homologous receptor desensitization and recovery in cells of different origin [Supported by the Max Planck Society and the UCSD Dept. of Psychiatry.]

MOLECULAR CLONING AND EXPRESSION ANALYSIS OF HUMAN CRH RECEPTOR TYPE 2 α AND β ISOFORMS.
W. Kostich, A. Chen, K. Sperle, R. A. Horlick^, J. Patterson, and
B. L. Largent*; DuPont Merck Research Labs, CNS Diseases Research and ^Applied Biotechnology, Wilmington, DE 19880.

The neuropeptide Corticotropin Beleasing Hormone (CRH) is an integral player in the HPA axis and is known to be present in a number of brain regions. CRH is bound by at least two G-protein linked receptor families termed type 1 and type 2 (R1 and R2). The R2 receptor was recently cloned in rat and mouse and exists in two isoforms, termed α and β , which have alternative exons at the amino terminus. We have cloned the human have alternative exorts at the attent terminis. We have content the further homologues of the R2 α and β isoforms from a human amygdala cDNA library and have characterized their expression in human tissues with quantitative RT-PCR. The human α isoform is approx. 94% identical at the amino acid level to rat α , corroborating the human CRIH2 α sequence reported by Liaw et al. (Endocrinology, (1996) 132-72-77). The human β isoform is approx. 89% identical at amino acid level to rat β . The β isoform specific exon at the amino terminus is only approx. 63% conserved between human and mouse at the nucleotide level and 55% at the amino acid level. The α isoform specific exon is much better conserved between rat and human with 92% identity at the amino acid level. Quantitative RT-PCR analysis of R2 α expression in human CNS tissues shows that R2 α is PCH analysis of H2 α expression in numan CNs itssues shows that H2 α is present in many of the same tissues as in rat. Rat septum has been noted for higher levels of R2 α expression, however, in human septum we do not find high R2 α expression. Also interestingly, in human heart RNA we find significant R2 α expression without strong R2 β expression, which is in direct opposition to what we observe for rat. Heterologous expression of human CRHR2 α in HEK293EBNA cells reveals a similar pharmacological agonist profile to rat CRHR2α for stimulation of adenylate cyclase, with EC50 for sauvagine < urotensin < r/>
r/h CRH.

CRF, RECEPTOR BINDING. mRN.\(\alpha\) EXPRESSION AND SUNAL TRANSDUCTION AFTER CHRONIC ANTIDEPRESSANT TREAT/4ENT IN RATS. S.C. Stout*, M.J. Owens, C.B.Nemeroff; L.\(\alpha\). of Neuropsychopharmacology. Dept. of Psychiatry and Behavioral Situnces. Emory Univ. Sch. Med., Atlanta. GA 30-322

Corticotropin-releasing factor (CRF) is the major regulator of the

hypothalamic-pituitary -adrenal (HPA) axis, and also plays a role in non-endocrine stress responses. Patients with major depression exhibit HrA axis hyperactivity including increases in hypothalamic CRF mRNA synthesis, and increases in CSF CRF concentration. Successful psychopharma ologic treatment reverses most of these alterations. Brady et al. reported that chronic antidepressant treatment redcues CRF mRNA synthesis in the paraventricular nucleus of the rat hyporhalamus under basal, non-sibessed conditions. We wished to examine whether antidepressants also produce CRF receptor changes in the CNS and pituitary gland. Desipramine (12 mg/kg/day), paroxetine (6 mg/kg/day) or vehicle were infused by osmotic minipump into adult, male Sprague-Dawley rats. Brains from several treatment batches were frozen, dissected, and processed for ¹²⁵I-oCRF binding, rCRF-stimulated adenylyl cyclase activity, and ribonuclease protection assays (n = 5 to 12 per group per assay). Although preliminary work suggested an upregulation of cortical and pituitary CRF receptors by desipramine, further investigation failed to demonstrate oCRF binding changes with either drug. 1 mM rCRF stimulation of adenylyl cyclase was unchanged in pituitary and frontal cortex. Expression of CRF, receptor mRNA was unchanged in pituitary, cortex, and several other brain regions, but was increased in the hypothalamus of drug-treated rats. These studies suggest that widespread alterations of CNS CRF, receptor binding and expression by antidepressants do not occur in non-stressed rats. Supported by NIH MH-42088 and NIH MH-51761

DIFFERENTIAL REGULATION OF TYPF-1 AND TYPE-2α DIFFERENTIAL REGULATION OF THE AND THE CONTICOTROPIN-RELEASING HORMONE RECEPTOR MRNA IN THE PARAVENTRICULAR NUCLEUS BY INTRAPERITONEAL LIPOPOLY-SACCHARIDE INJECTION AND ADRENALECTOMY. T. Takemura, S. Makino*, T. Takao and K. Hashimoto. 2nd Dept of Internal Medicine, Kochi Medical School, Okoh-cho, Nankoku, Kochi 783, Japan.

Novel corticotropin-releasing hormone receptor (CRHR), designated type- 2α CRHR (CRHR- 2α), was recently cloned and functionally characterized. In situ hybridization study revealed that CRHR-2α mRNA had a distinct distribution from type-1 CRHR (CRHR-1) mRNA in the rat brain. Interestingly, CRHR-2 α mRNA showed a relatively high expression in the hypothalamic paraventricular nucleus (PVN) even under unstressful condition. This may reflect the important role of CRHR-2 α in the autoregulation of CRH secretion in the PVN. To determine the regulation of CRHR-2 α mRNA expression in the PVN, we examined the alteration of CRHR-2a mRNA levels in the PVN in rats with lipopolysaccharide (LPS) injection or adrenalectomy, and compared with that of CRHR-1 mRNA, using in situ hybridization histochemistry. Intraperitoneal LPS injection (50 μ g) induced a significant increase in PVN CRHR-1 mRNA at 3 and 6 hours, whereas CRHR-1 mRNA levels in the PVN in adrenalectomized rats were significantly lower than that in sham-operated rats when sacrificed 7 days after surgery. This alteration in PVN CRHR-1 mRNA is consistent with previous reports. In contrast, $\text{CRHR-2}\alpha$ mRNA levels in the PVN were not altered by LPS injection or adrenal ectomy. These results indicate that CRHR-1 and CRHR-2 α mRNA are differentially regulated in the PVN. Further study will be necessary to elucidate the CRHR-2 α function in the PVN.

HUMAN CRF RECEPTOR CHIMERAS: MAPPING OF LIGAND BINDING DETERMINANTS R.L. Martone, J.M. Cook, A.W. Schmidt. ** Y.C. Clancy, C.L. James, D.W. Schulz* & J.R. de Wet Depts. of Molecular Sciences and *Neuroscience, Pfizer Central Research, Groton, CT 06340

Multiple physiological and behavioral effects of corticotropin releasing factor (CRF) are mediated by the G protein-coupled receptor, CRF1. CRF1 shares approx 70% amino acid sequence identity with the CRF2 receptor, but these receptors have significantly different pharmacological profiles in response to CRF, the related peptides sauvagine (SV) and urotensin I (UI), and to the non-peptide CRF1-specific antagonist CP-154,526. In order to elucidate the physical basis for these differences in pharmacological behavior, we generated several CRF₁/CRF₂ and CRF₂/CRF₁ chimeras by exchange of specific receptor cDNA restriction fragments, and by using the technique of random chimeragenesis. In the latter technique, a RecA+ Escherichia coli strain was transformed with linearized plasmids containing tandemly arranged single copies of each receptor cDNA. Homologous recombination between the receptor subtype cDNAs resulted in the generation of circular plasmids containing single chimeric receptor cDNAs. Several receptor chimeras were transiently expressed in COS-7 cells, and binding studies were performed using the radioligand [125I-Tyr⁰]-Sauvagine. Subtype-specific affinities for UI and ovine CRF appear to depend primarily upon the amino acid sequence of the first extracellular loop. The presence of the first extracellular loop of CRF₁ is necessary but not sufficient for binding the antagonist CP-154,526. The contribution of adjacent receptor sequences to the CRF₁-specific antagonist binding is suggested by the lack of CP-154,526 binding in both CRF2/CRF1 and CRF1/CRF2 chimeric receptors with crossovers in TM 3. These studies should contribute to the understanding of structure-function relationships in neuropeptide receptors

THE N-TERMINAL DOMAIN OF THE CORTICOTROPIN RELEASING FACTOR (CRF) RECEPTOR IS A MAJOR BINDING DETERMINANT FOR THE CRF ANTAGONIST, ASTRESSIN.

M.H. Perrin, S.W. Sutton, W.T. Berggren and W.W. Vale* Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Lable, CA 0.0027 Jolla, CA 92037

CRF receptors belong to a family of 7 transmembrane G-protein coupled receptors, which are characterized by relatively large N-terminal domains and which include the growth hormone releasing factor recentor (GRF-R). It has been shown that the N-terminal domain of the GRF-R contains major ligand binding determinants. In order to explore the binding determinants for the rat CRF-R1, we have constructed chimeric receptors in which domains of the rat CRF-R1 and the rat GRF-R (kindly provided by K.Mayo) have been exchanged. A chimera in which amino acids 1-127 of the rCRF-R are replaced by amino acids 1-135 of the rGRF-R and transiently expressed in COSM6 cells shows no binding to tracers related to CRF including the potent CRF antagonist, astressin (125I-[D-Tyr¹²]-astressin). The complementary chimera, in which amino acids 1-127 of the rCRF-R replace amino acids 1-135 of the rGRF-R (rCRF-RN/rGRF-R) binds labeled astressin with high affinity; the KD for astressin bound to this chimera is 16(6.2-42)nM, compared to 2.2(1.2-4.1)nM for the rCRF-R1 expressed in COSM6 cells. Both rCRF and the related novel mammalian peptide, urocortin, stimulate cAMP production in COSM6 cells expressing the $rCRF-R_N/rGRF-R$, but the maximal level of stimulation is reduced compared to that resulting from GRF stimulation of the rGRF-R or CRF stimulation of the rCRF-R1. Thus, determinants for binding and activation of the CRF-R reside in its N-terminal domain. Supported by NIH DK-26741

REGIONAL DISTRIBUTION OF PUTATIVE CRH₂ RECEPTORS IN RAT BRAIN AS DETERMINED BY [1²⁵1]SAUVAGINE RECEPTOR AUTORADIOGRAPHY. C. M. Rominger*, W. Zhang, S. Ho, R. Zaczek, and L.W. Fitzgerald, CNS Diseases Research, The DuPont Merck Research Laboratories, Wilmington, DE 19880.

Corticotropin-releasing hormone (CRH) is a crucial mediator of the hypothalamic-pituitary-adrenal stress axis, and likely serves a central neurotransmitter role throughout the brain. CRH mediates these functions via at least two G-protein-coupled receptor subtypes (CRH₁ and CRH₂). We here describe a novel subtractive binding strateey for

functions via at least two G-protein-coupled receptor subtypes (CRH₁) and CRH₂). We here describe a novel subtractive binding strategy for revealing high affinity CRH₁ and putative CRH₂ sites utilizing [1251]sauvagine, which at 150 pM, labels both receptor subtypes but neglibly the CRH binding protein (reported K₁ > 15 nM). Adjacent brain sections were incubated with [1251]sauvagine in the presence or absence of a potent triazolopyrimidine non-peptide CRH₁ antagonist which is inactive at CRH₂ receptors. Nonspecific binding of [1251]sauvagine was defined in the presence of 0.5 μM α-helical CRH. [1251]sauvagine, in the absence of CRH₁ blockade, produced a broad labeling pattern of cortical and subcortical regions that was concordant with previous reports using and subcortical regions that was concordant with previous reports using [125] oCRH. Interestingly, in the presence of CRH₁ blockade, specific l¹²³JoCRH. Interestingly, in the presence of CRH₁ blockade, specific labeling of the neocortex was virtually eliminated, whereas significant labeling of various subcortical regions remained. High density of residual, putative CRH₂ sites was observed in the choroid plexus and blood vessels, with moderate densities in the ventral medial hypothalamus, lateral septum, bed nucleus of the stria terminalis, and posterior cortical amygdala. These observations are very consistent with the reported distribution of CRH₂ mRNA. This strategy may be useful for attribute the fuerticant and equalities representation of CRH₂ mRNA. for studying the functional and regulatory properties of CRH2-specific neuronal circuits in brain.

CRH plays an important integrative role in regulating the endocrine, autonomic, immunological, and behavioral responses to stress. Moreover, CRH has been implicated in the pathophysiology of anxiety and other neuropsychiatric disorders. We describe the identification of novel triazolopyrimidine and anilinotriazine CRH₁ antagonists that potently inhibit (Ki's=4-50 nM) the binding of [$^{125}\Pi$]oCRH to hCRH $_1$ receptors stably expressed in HEK 293 cells and native receptors in rat cortex. These compounds as well as α -helical CRH inhibited CRH-stimulated adenylyl cyclase activity in HEK 293 cells and rat brain, and CRH-stimulated ACTH release in AtT20 cells, with rank-ordered potencies predicted by their binding affinities. Additionally, these compounds displayed selectivity for the CRH_1 receptor subtype as they did not inhibit [125] sauvagine binding to expressed CRH_{2α} receptors, or [125]]r/hCRH binding to the CRH binding protein (35-40 kDa) derived from human plasma as determined by SDS-PAGE. Novel non-peptide antagonists for CRH receptors may have unique utility in the treatment of anxiety, depression, and other disorders in humans.

STRUCTURAL AND MOLECULAR CHARACTERIZATION OF MAMMALIAN AND AMPHIBIAN CRF RECEPTORS

F. M. Dautzenberg, S. Sydow, A. Rühmann and J. Spiess*.

Dept. Molecular Neuroendocrinology, Max Planck Institute Exp. Med., Hermann-Rein-Str. 3, D-37075 Göttingen, Germany.

Corticotropin releasing factor (CRF) is the most important regulator of the secretion of hypophyseal ACTH and is involved in various endocrine, behavioral and autonomic responses to stress. In contrast to mammalian species, the CRF receptor (CRFR) from amphibian pituitaries does not respond to sauvagine. Thus, it was concluded that the involved receptor

species, the CRF receptor (CRFR) from amphibian pituitaries does not respond to sauvagine. Thus, it was concluded that the involved receptor proteins differ structurally.

For the investigation of the molecular differences between the amphibian and the mammalian CRF receptor(s), a degenerate PCR with cDNA from various tissues of *Xenopus laevis* was performed. By subcloning of the resulting PCR products, two different partial cDNAs were identified. One cDNA encoded a protein with approximately 65% identity to human CRFR1, whereas the second cDNA encoded a polypeptide that was more than 80% identical to human CRFR2. Meanwhile, we have cloned both receptor cDNAs by a PCR-based approach. The sequence and tissue distribution of both CRF receptors will be provided receptors will be provided.

To obtain further structural information on the receptor molecules, the

N-terminus of the rat CRFRI was overexpressed in *E. coli* and in mammalian cell lines. The N-terminal fragment which bound CRF specifically but with low affinity, is being used to characterize the binding site of the CRFR fragment cross-linked to a photoactivable CRF analog. Successively truncated forms of rat CRFR were expressed in mammalian cells to analyze the structural requirements for the formation of a CRF

binding site with high affinity. (F.M.D. and S.S. should be considered co-first authors; the work was supported by the Max Planck Society.)

[125I-TYR°]-SAUVAGINE AS A RADIOLIGAND FOR CRH-R20

RECEPTORS.
D.H. Rominger*, D.H. Rominger*, C.M. Rominger, A. Chen, K. Sperle, B. Largent,
R. Wilk, R. Zaczek Central Nervous System Diseases Research,
The Du Pont Merck Research Laboratories, Wilmington, DE 19880-0400

The in vitro binding properties of [125]-labeled tyro-sauvagine, were examined in HEK 293 cells expressing the CRH-r2 alpha receptor. Non-specific [125I-tyro]-sauvagine binding is defined using 500 nM α -helical-CRH₉₋₄₁. Specific binding at 23°C is linear up to 100 μg protein. Specific binding is saturable and reversible with addition of excess α -helical-CRH₉₋₄₁. The cell line exhibits two populations of sites. A high-affinity site posseses an apparent K₄ of 157 pM and a B_{max} of 67.4 fmol/mg protein. A low-affinity site posseses an apparent K_d of 5 nM and a B_{max} of 790 fmol/mg protein. [125I-tyr°]-sauvagine binding to CRH-r2a receptors is completely inhibited by sauvagine, urotensin, α-helical-CRH₉₋₄₁, r/h-CRH and o-CRH. In contrast, novel non-peptide compounds, which are potent and specific antagonists for the CRH-r1 receptor subtype, do not inhibit [125I-tyro]-sauvagine CRHr2α binding up to 10 μM. We also describe the use of [125I-tyr°]sauvagine, in the presence of these CRH-r1 antagonists, to specifically label CRH-r2 α receptors in rat brain homogenates. These data demonstrate the utility of [125 I-tyr $^{\circ}$]-sauvagine to specifically label and examine CRH-r2a binding in transfected cell lines and to distinguish between CRH-r1 and CRH-r2 selective antagonists.

NON-PEPTIDE CORTICOTROPIN-RELEASING HORMONE (CRH) RECEPTOR ANTAGONIST: CHARACTERIZATION OF BINDING, E. L. Webster*, D. Lewis, D. Torpy, K. Zachman, K. Rice, G. Chrousos, Pediatric Endo. Sect., NICHD and Med. Chem. Br., NIDDK, NIH, Bethesda, MD 20892.

CRH is a major regulator of the hypothalamic-pituitary-adrenal (HPA) axis and principal coordinator of the stress response, including its neuroendocrine, autonomic, immune, and behavioral components. Specific membrane receptors bind to and mediate the actions of CRH throughout the central nervous system and periphery. Recently, subtypes of the CRH receptor have been cloned, and characterized in terms of their pharmacological specificity and regional localization. characterized in terms of their pharmacological specificity and regional localization. Existing peptide antagonists for the CRH receptors cannot be given parenterally, are rapidly degraded, have limited bioavailability and, therefore, limited research and therapeutic usefulness. Recently, we prepared a nonpeptide CRH receptor antagonist compound, trimethyl-7-(2,4,6-trimethyl-phenyl-7H-pyrrolo[2,3-d]N-butyl-N-ethyl[2,5,6-pyrimidin 4-yl] amine, for use as a research tool to further characterize ethyl[2.5.6-pyrimidin 4-yl] amine, for use as a research tool to further characterize specific membrane receptor proteins, which interact with CRH to produce biological actions associated with stress. The affinity and potency of the antagonist compound were analyzed in competitive displacement studies in tissue homogenates from rat frontal cortex, pituitary, cerebellum, and heart. The trimethylpyrrolamine compound was potent in displacing ¹²⁵I-oCRH binding and exhibited Ki values of 4.2 ± 0.8, 4.6 ± 1.7, and 7.1 ± 1.9 nM (mean ± SEM) in pituitary, cerebellum, and frontal cortex homogenates, respectively. Approximately 87% of the specific binding of ¹²⁵I-oCRH observed with IµM rat/human CRH, was displaced in binding of ¹²⁵1-oCRH observed with 1µM rat/human CRH, was displaced in pituitary, cerbellum, and frontal cortex homogenates. Interestingly, this compound was not effective in displacing ¹²⁵I-oCRH binding from rat heart homogenates, a tissue expressing subtype 2 but not subtype 1 CRH receptors. Administration of the compound to intact rats for over 2 weeks revealed no apparent toxicity. We conclude that the nonpeptide CRH antagonist tested here is specific for type 1 CRH receptors and promises to enhance our understanding of the actions of CRH in normal and pathological states and in potentially providing a therapeutic tool. Source of funding: NICHD Intramural

THE MURINE NPY-Y1 GENE PROMOTER DIRECTS EXPRESSION OF E.COLI LACZ TO BLOOD VESSELS IN THE NERVOUS SYSTEM OF TRANSGENIC MICE. Alessandra Oberto, Rossella Brusa, Emanuela Tolosano", Fiorella Altruda", Nicoletta Aste and Carola Eva. Dept. Anatomy. Pharmacology and Forensic Medicine, Pharmacology Section, University of Torino and a Dept. Genetics. Biology and Medical Chemistry, University of Torino, Torino, Italy.

The Y1 receptor subtype plays important roles in mediating NPY-induced control of several functions, including cardiovascular system activity, neuroendocrine secretion, food intake and nociception.

1.3 kb of 5' flanking of the murine Y1 receptor gene has been ligated upstream the bacterial lacZ gene and used to generate transgenic mice. Expression of the transgene has been detected in two independent transgenic lines that show overlapping pattern of B-gal activity. In the embryo, at day 13 and 16 after fertilization, the transgene is expressed specifically in the posterior and lateral choroid plexi, in the otic vesicles and in the hypophysis in blood vessel structures. In the posterior region of the embryo body ß-gal staining is detectable at the level of the spinal cord.

Further analysis to define the transgenic expression during development and adult mice is in progress

IDENTIFICATION AND REGULATION OF A NOVEL G - PROTEIN COUPLED RECEPTOR EXPRESSED IN GLIAL CELLS M.E. CHARLTON' and R.S. DUMAN. Laboratory of Molecular Psychiatry. Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508

Previously we described the identification of several PCR products

which encoded fragments of novel putative G-protein coupled receptors.

One of these fragments, VTR 15-20, isolated from the rat ventral tegmental area was used for hybridization screening of several cDNA libraries. A one of flesse flagiliterits. Viri 15-20, isolated informer lat Verification area was used for hybridization screening of several cDNA libraries. A partial fragment isolated from a spleen library was ligated to a 3' RACE PCR product to form a full length VTR 15-20 clone. Sequence analysis revealed the highest overall amino acid homology with an orphan clone and lower homology to the PAF receptor. The 1.8 Kb VTR 15-20 transcript was detected in peripheral regions with highest levels of expression in the spleen as determined by northern blot. Lower levels were apparent throughout the CNS. In addition, RNA encoding VTR 15-20 was detected in several cells of glial (microglia and astrocytes) and hematopoietic (HL-60, murine B-cell line, and human monocytes) origin. The detection of VTR 15-20 expression in glial and blood elements suggests that this receptor may contribute to the function of the neuronimmune axis. Using several paradigms we have shown the differential regulation of VTR 15-20 expression. Chronic stress results in a 30% reduction of spleen mRNA levels as shown by northern blot. However, in a model of reactive gliosis, the expression of mRNA encoding VTR 15-20 increased approximately 5 fold in astrocyte and microglial cultures. We are currently investigating the regulation of VTR 15-20 by additional *in vitro* and *in vivo* models of neuronal insult. These studies suggest that VTR 15-20 may play a role in mediating the CNS response to injury / insult. 20 may play a role in mediating the CNS response to injury / insult. (Supported by DA 08227 Program Project Grant)

CLONING OF NEUROPEPTIDE Y RECEPTORS FROM THE ZEBRAFISH. I. Lundell*, M. Ringvall, P. Starbäck, E. Salaneck, M. Berglund, A. G. Blomqvist, D. Larhammar. Department of Medical Pharmacology, Uppsala Univ., Box 593, S-75124 Uppsala, Sweden. Neuropeptide Y (NPY), peptide YY (PYY) and pancreatic polypeptide (PP) form a family of structurally related peptides. As we have previously islolated clones for NPY and PYY from zebrafish (C.Söderberg et al. unpublished), we wished to isolate NPY receptor clones from this species to allow correlation of ligand and receptor expression in studies of tissue distribution and development. The Y1 receptor concensus sequence from several species was

expression in studies of tissue distribution and development. The Y1 receptor concensus sequence from several species was used to design degenerate primers for PCR. This approach gave two different subtypes of receptors with homology to the NPY family of receptors. A third subtype was obtained with degenerate primers based on the new sequences. The zebrafish receptors, tentatively designated zYa, zYb and zYc display equally high identity to the Y1 receptor as to the recently cloned PP1 receptor with an amino acid sequence identity of approximately 55% in the transmembrane regions. Like the PP1 receptor, they lack the intron after TM5 that is found in Y1. The a and b subtypes are also about 55% identical to one another, while the c receptor is more closely related to the b subtype. In agreement with the structural similarities, zYb and zYc display a binding profile that is more reminiscent of Y1 binding than Y2. Affinities for NPY and PYY are in the picomolar range and the affinity for PP is considerably lower. These observations show that the zebrafish receptors are related to Y1 but most probably represent distinct subtypes that are likely to be present also in mammals. These receptors will help elucidate the evolution of the NPY receptor family. Work is in progress to map the tissue localization in the zebrafish and Work is in progress to map the tissue localization in the zebrafish and to clone the corresponding mammalian receptors.

Supported by the Swedish Natural Science Research Council.

ISOLATION AND CHROMOSOMAL LOCALIZATION OF NOVEL HUMAN MEMBERS OF THE GPROTEIN-COUPLED RECEPTOR GENE (GPCR) FAMILY. B. O'Dowd*, T. Nguyen, B. Jung, A. Marchese, R. Cheng, H. Heng, L.F. Kolakowski, K. Lynch and S.R. George, Add. Res. Fdn., Dept. of Pharm., Univ. of Toronto; Hosp. for Sick Children, Toronto, ONT, Canada; Dept. of Pharm., Univ. of Texas, TX 78284, Dept. of Pharm., Univ. of Virginia, VA 22908.

The characterization of novel receptor systems in the brain continues in parallel with the discovery of endogenous peptides, however the ligands for many of these receptors, remain to be identified. Our research plan has been to identify GPCR genes involved in drug addiction, in particular opioid-like receptors which may bind opioid and related peptides. Our search for novel GPCRs has revealed 13 genes (at least 6 are expressed in the CNS) that presently have not been identified by pharmacological means: APJ, GPR1, GPR2, GPR3, GPR4, GPR5, GPR6, GPR7, GPR8, GPR9, GPR10, GPR14, GPR15. We now report the cloning of additional four genes named GPR16, GPR17, GPR18 and GPR19, each of which contain an intronless open reading frame encoding GPCRs. GPR16 was isolated by amplifying DNA with primers based on the opioid, opioid-like and somatostatin receptor genes. Searching of a human EST data option, option-like and solinatostatili receptor genes. Searching of a numan LST data base revealed cDNA sequences that partially encoded two novel GPCRs, and a third EST cDNA, encoding a novel GPCR, was identified by searching the GenBank data base. Each of these DNA clones were used as probes for screening a genomic library in order to isolate the full-length coding regions. A search of the GenBank data base with amino acid sequences of the receptors encoded by GPR16, 17, 18 and 19 revealed that the receptors were most closely related to the proteinase-activated receptor-2, the \$1-adrenergic receptor, the cholecystokinin-B receptor, and the purinergic P2Y5 receptor, respectively. Northern blot analysis revealed expression of GPR16 and GPR18 in human brain regions and GPR16 in liver. Fluorescence in-situ hybridization was used to map GPR16 to chromosome 8, GPR17 to chromosome 9, GPR18 to chromosome 17, and GPR19 mapped to chromosome X. (Supported by MRC)

NEUROPEPTIDE Y-FAMILY RECEPTOR CLONES FOR Y1, Y2, AND PP1/Y4 IN THE GUINEA PIG. D. Larhammar*. H. Eriksson, S. Holmberg, and M. Berglund. Department of Medical Pharmacology, Uppsala University, Box 593, S-751 24 Uppsala, Sweden. Neuropeptide Y (NPY) forms a family of structurally related peptides together with peptide YY (PYY) and pancreatic polypeptide (PP). Three receptors for these peptides have been cloned, namely Y1, Y2 and PP1/Y4, all of which couple to G proteins. Surprisingly, the Y2 sequence was found to differ dramatically from Y1 and PP1. Whereas the Y1 and Y2 sequences are highly conserved between species, the PP1 sequence is the most divergent heptahelix receptor sequence so far observed between man and rat. In addition, the PP1 receptor differs in pharmacological properties as well as tissue

sequence so far observed between man and rat. In addition, the PP1 receptor differs in pharmacological properties as well as tissue distribution between these species. To study these intriguing evolutionary differences, we decided to isolate receptor clones from various species including the guinea pig.

Clones were isolated from a genomic library by homology screening. The guinea pig PP1 sequence has approximately 82% overall identity to the human sequence but only 75% identity to the rat sequence. The latter displays 75% identity also to human PP1. Thus, although rat and human are evolutionarily more closely related to one another than either is to the guinea pig, the rat PP1 receptor is the most divergent. This agrees with the rat having the most divergent sequence for the receptor's ligand, PP, and suggests that receptor and ligand coevolve at a rapid rate. Further studies will show whether guinea pig PP1 is more similar to the human receptor also in pharmacology and tissue distribution.

Supported by the Swedish Natural Science Research Council.

610.6

CLONING OF A NOVEL MEMBER OF THE NPY/PYY/PP RECEPTOR FAMILY. M. Matsumoto, T. Nomura, Y. Ikeda, S. Kawabata* and T. Yamaguchi. Institute for Drug Discovery Research, Yamanouchi. Pharmaceutical Co., Ltd., 21 Miyukigaoka, Tsukuba, Ibaraki, 305, Japan Neuropeptide Y (NPY), peptide YY (PYY), and pancreatic peptide (PP) belong to a family of structurally related 36-amino acid peptides.

These peptide functions in both neural and endocrine signaling are mediated through specific membrane receptors. Although recent molecular cloning studies revealed the structure of Y1, Y2, and Y4/PP1 receptors, previous pharmacological study indicated the existence of additional type of receptors for this NPY/PYY/PP family, e.g. Y3, PYYpreferring and feeding receptor

Using low stringency hybridization method, we cloned a cDNA encoding novel receptor which shares significant homology with the receptors for this peptide family. The cloned cDNA from rabbit encodes a heptahelix receptor of 371 amino acids sharing the greatest identity with Y1 (50%) followed by Y4/PP1 (40%) and Y2 (25%) receptors. The mRNA was detected in brain, skeletal muscle and small intestine by RT-PCR. We also cloned a cDNA of human homologue, which shares 87% identity in nucleotide sequence with rabbit's. In human tissues the mRNA was detected at 3 kb, abundantly in heart and skeletal muscle. Lower level of mRNA was also detected in the small intestine, prostate, spleen, kidney, testis and colon. The pharmacological study is currently in progress to compare the profile of this novel receptor with that of proposed NPY/PYY/PP receptors

Expression of Neuropeptide Y/Peptide YY Receptor Subtypes in the Human Cerebral Cortex and Hypothalamus. M.A. Statnick*, D.A. Schober, J.P. Burnett, N.G. Mayne, and D.R. Gehlert. Lilly Research Labs, Lilly Corporate Center, Eli Lilly and Company, Indianapolis, IN 46285.

Neuropeptide Y (NPY) is a 36 amino acid C-terminally amidated peptide that is synthesized by peripheral and central nervous system neurons. NPY modulates neuronal activity through an interaction with at least three different receptor subtypes (Y1, Y2 and Y3 receptors). Recently, species related differences in the distribution of NPY receptors were described in the rat and human brain. From these studies it appears that the rat brain expresses a mixture of Y1 and Y2 receptors while the human brain is predominantly Y2. Because species differences in the distribution of NPY receptors could have functional consequences in man, we examined the expression of Y1 and Y2 receptors in the human cerebral cortex and hypothalamus by radioligand binding and competitive PCR (PATTY). Using saturation analysis with [1251][Leu³],Pro³4]-PYY (Y1 selective) and [1251]-PYY_{3,36} (Y2 selective), similar densities of Y1 and Y2 binding sites were found in the cerebral cortex, with estimated B_{max} values of 313 and 458 fmol/mg protein, respectively. In preliminary experiments using hypothalamus homogenates, [125I]-PYY₃₋₃₆ binding to Y2 receptors was twice that of [125]][Leu³¹,Pro³⁴]-PYY (Y1) binding. Using PATTY, we estimated the relative ratio of Y1 to Y2 mRNA levels to be ~200:1 in the human cerebral cortex. Conversely, the relative amount of Y2 mRNA was 5-10 times higher than Y1 mRNA levels in the human hypothalamus. Collectively, these data support our hypothesis that the human brain contains a mixture of Y1 and Y2 receptors. We attribute previous underestimation's of Y1 binding sites in the human brain to preferential labeling of Y2 receptors with low concentrations of [125I]-PYY. Therefore, to avoid underestimation's in receptor density, when studying tissues with a mixed or unknown receptor population, it is critical to use subtype selective ligands.

610.9

PHARMACOLOGY OF RAT VS. HUMAN Y-TYPE RECEPTORS FOR NEUROPEPTIDE Y, PEPTIDE YY AND PANCREATIC POLYPEPTIDE, INCLUDING A NOVEL RECEPTOR CLONE. P.J.-J. Vaysse*, M.W. Walker, C. Gerald, K.E. Smith, T.L. Laz, J.A. Bard, Z. Shaposhnik, N. Rogacki, R.L. Weinshank and T.A. Branchek. Synaptic Pharmaceutical Corporation, Paramus, NJ 072652

The pancreatic polypeptide family includes neuropeptide Y (NPY), peptide YY (PYY) and pancreatic polypeptide (PP). These peptides bind to and activate membrane bound receptors. Amino acid identity between cloned human and rat receptors is 93.7 % for Y1, 94.5% for Y2 and 74.7% for Y4. We evaluated the binding affinity of a series of compounds for the cloned human and rat homologs of binding affinity of a series of compounds for the cloned human and rat homologs of Y1, Y2, Y4 and a novel Y-type receptor, transiently expressed in COS-7 cells. Membrane preparations were incubated with ¹²⁵-PYY for competitive displacement assays. Some species-dependent differences in binding were observed. Consider as an example the Y1 antagonist BIBP 3226. This compound was described as having Y1 selectivity based on its ability to preferentially bind SK-N-MC neuroblastoma cells (a human Y1 model) vs. SMS-KAN neuroblastoma cells (a human Y2 model). The pK, values that we measured for BIBP 3226 binding to human Y1 and Y2 clones (8.07 and 4.51, respectively) are consistent with those reported previously for the neuroblastoma cells, while the pK, value for the human Y4 (5.20) provides new information not previously available in the absence of a Y4 model cell line. The pK, values that we measured for BIBP 3226 binding to rat Y1, Y2 and Y4 clones (7.70, values that we measured for BIBF 3226 binding to fat Y1, Y2 and Y4 Gibles Y1, A18 and 6.38, respectively) indicate a narrower window of selectivity for rat Y1 vs. Y4 receptors than for human Y1 vs. Y4. These data emphasize the need to characterize compounds not only with human receptor subtypes but also with receptor homologs appropriate for the animal model of choice. A comparative pharmacological analysis of the novel Y-type receptor homologs will be presented.

as outlined for the Y1, Y2 and Y4 receptors.

BINDING OF PANCREATIC POLYPEPTIDES AT A CONSERVED HYDROPHOBIC POCKET IN THE Y1, Y2 AND Y4 RECEPTOR SUBTYPES. J.A. Salon*, J.A. Tamm, P. Du, N. Adham, M.W. Walker, W. Cui, P.J.-J. Vaysse, B. Dowling, N. Boyle, T.A. Branchek, R.L. Weinshank, D.L. Linemeyer and C. Gluchowski. Synaptic Pharmaceutical Corporation, 215 College Road, Paramus, NJ 07652.

The pancreatic polypeptide family consists of NPY, PYY and PP. These peptides, together with their respective receptors Y1, Y2 and Y4, comprise one of the most important neurohormone signaling systems in the body. The PP family of peptides are structurally homologous and the possibility of similar modes of interaction between these peptide ligands and their receptors seems plausible. Accordingly, we have explored the binding interactions of NPY, PYY and PP to a conserved hydrophobic pocket formed by tyrosine residues in TMs I and II of the Y1, Y2 and Y4 receptors. The receptor residues were modified by site-directed mutagenesis and the ability of the mutated receptors to bind the peptides was assessed by measuring IC₅ values in competitive displacement assays using 125I-PYY as the displaceable radioligand. Results of these binding studies do not support a common mode of interaction between the conserved bioactive portions of NPY, PYY and PP with this conserved aromatic pocket found in the Y receptor family. Exploration of alternate scenarios for docking each peptide with its respective receptor is suggested.

DIFFERENCES IN CATION SENSITIVITY OF LIGAND BINDING TO Y₁ AND Y₂ SUBTYPE OF NEUROPEPTIDE Y (NPY) RECEPTOR OF RAT BRAIN, M.S. Parker^{2/*}, W.R. Crowley^{1/*} and S.L. Parker^{*1/*}, Dept. of Pharmacology, University of Tennessee College of Medicine^{1/*}, and Dept. of Biology^{2/*}, The University of Memphis, Memphis, TN 38163.

The high-affinity ligand binding to the Y₁ subtype of NPY receptor in rat brain particulates is increased three- to four-fold by Ca^{2**}, and also stimulated by Sr^{2**}, but reversibly reduced by Ba^{2*}, Mg^{2**}, Mn^{2**}, by the organic polycations neomycin and spermidine, and by chelators EGTA and EDTA. The alkali metal monovalent cations inhibit the Ca^{2**}-cnabled Y₁ subtype binding with some selectivity (Cs** >= NH4*> Li** > Na**, K**), with IC₅₀ values between 70-120 mM at 1.67 mM Ca^{2**}. Inhibition of the calcium-promoted Y₁ binding by alkali cations is essentially allosteric, since the half-maximal effect of Ca^{2**} remains in the range of 0.3 - 0.6 mM between 0-140 mM of Na* or K**. The specific Y₂ subtype binding is enhanced about threefold by all alkaline earth divalent cations, Mn^{2**}, neomycin or spermidine in the range of 0.1 - 10 mM, and also stimulated by Na₃EGTA and Na₃EDTA at 3-20 mM. The Y₂ binding is biphassically stimulated by glabali cations at up to 100 in the range of 0.7 - 10 mM, and also stimulated by Maghet IA and Naghet IA and Saghet receptor. The strong influence of monovalent cations on Y₁ binding could relate to the LSFSD motif in the second transmembrane segment of the receptor (similar to motifs known to allosterically modulate agonist binding to other monovalent cation-sensitive G-protein linked receptors). The low cation sensitivity and selectivity of the Y₂ binding could reflect use of the entire NPY(24-36) C-terminal stretch, LRHYINLITRQRY amide (invariant in all known NPY molecules, and largely conserved in all peptide YY variants) as a 'super-epitope' of the Y_2 site. Supported by HD-13703.

610.10

DELINEATION OF AGONIST BINDING DOMAINS IN THE HUMAN NPY1 AND NPY4 RECEPTOR SUBTYPES. J.A. Tamm, Y. Shifman, N. Adham, C. Hou, M.W. Walker, J.A. Bard, P.J.-J. Vaysse, R.L. Weinshank, T.A. Branchek, C. Gluchowski, W.E. Heydorn* and J.A. Salon. Synaptic Pharmaceutical Corporation, Paramus, NJ 07652

The isolation of pharmacologically distinct members of the neuropeptide Y (NPY) receptor family has facilitated the analysis of receptor chimeras to identify the domains responsible for subtype-specific agonist binding. The human Y1 subtype binds NPY with 15 times greater affinity than does the human Y4 subtype. Conversely, the binding of pancreatic polypeptide (PP) is almost 1000-fold higher at the Y4 subtype than at the Y1 subtype. By systematically exchanging sequences between the Y1 and Y4 genes, we have shown that any chimera containing extracellular loop 2 and/or TM5 from the Y1 subtype binds NPY with high affinity. The remaining regions of the Y1 receptor appear to have little direct impact on the selective binding of NPY. Similarly, our data suggest that discontinuous regions of the Y4 receptor specify high affinity binding of PP. Constructions that carry TM6 from the Y4 subtype generally bind PP with the highest affinity. In addition, the extracellular loops of the Y4 subtype, especially loops 2 and 3, promote improved binding of PP when exchanged with the corresponding loops in the Y1 receptor. Our results show that these two closely related receptors use different domains to selectively bind similar agonists

AUTORADIOGRAPHIC DISTRIBUTION OF NEUROPEPTIDE Y RECEPTOR SUBTYPES IN THE MONKEY BRAIN. J.A. St-Pierre*, Y. Dunnont and R. Quirion. Douglas Hospital Res Ctr. Depts. Psychiatry, and Neurological Sciences, McGill Univ, Montréal, Qc, Canada, H4H 1R3.

The distribution and pharmacological characteristics of neuropeptide Y (NPY) Y1 and Y2 receptor subtypes are well established in the rat brain (for example, Dumont et al., Synapse, 22: 139, 1996). In contrast, the postmortem human brain contained only low to very low levels of [125][Leu31,Pro34]PYY/Y1-like labeling in all brain structures except in the dentate gyrus (Widdowson, Brain Res., 631: 27, 1993). It is thus clear that major species differences exist in the discrete localization of brain NPY receptors. In orther to investigate further this issue, we studied here the respective distribution of the Y₁ and Y₂ receptor subtypes in the brain of two strains of primates using [¹²⁵][[Leu³].Pro³4]PYY and [¹²⁵][PYY₃₋₃₆ as radioligands. Adjacent coronal brain sections were incubated with 25-35 pM of either of the radiolabeled probes in the presence and absence of 1 µM pNPY to determine specific binding levels. The marmoset (Callithrix jacchus) brain contained significant levels of both Y₁- and Y₂-like binding sites in various cortical areas. Very high amounts of [125]PYY₃₋₃₆/Y₂like labeling were detected in superficial cortical laminae while moderate levels of [125][[Leu³¹,Pro³⁴]PYY/Y₁-like sites were observed in superficial and deep layers of the cortex. Moreover, the marmoset brain is highly enriched with specific Y₁- and Y₂-like binding sites in the cerebellum and various brainstem nuclei, respectively. Additionally, [127][[Leu³1,Pro³4]PYY binding is highly sensitive to the antagonist, BIBP3226, demonstrating further its belonging to the Y₁ subtype. In contrast, in the vervet monkey (Cercopithecus pygerythrus) brain, Y₁ and Y₂ binding sites are distributed as in the human brain with only low levels of Y₁ sites seen in most brain areas. Preliminary data also suggest that only low to very low levels of [125T]hPP/Y₄-like binding sites are present in the marmoset brain. Taken together, these results suggest that the respective distribution of the Y1 and Y2 receptor subtypes is rather similar in the vervet monkey and human brain while being different in the marmoset. Supported by the MRC of Canada

ULTRASTRUCTURAL LOCALIZATION OF NEUROPEPTIDE Y AND THE Y1 RECEPTOR IN RAT NUCLEUS ACCUMBENS. J. Chan'. A. Beck-Sickinger, H.A. Wieland, and V.M. Pickel. Dept. of Neurology and Neuroscience, Cornell University Medical College, New York, Dept. of Pharmacy, ETH, Zurich, Switzerland, and Dept. of Biological Research

Cardiovascular Pharmacology I, Dr. Karl Thomae GmbH, Germany.
The mRNA and ligands for neuropeptide Y (Y1) receptors are known to be present in the nucleus accumbens septi (NAS) where many large aspiny neurons also contain neuropeptide Y (NPY). To further assess the functional sites for the Y1 and its relation to NPY, we examined the electron microscopic immunocytochemical dual labeling of antipeptide antisera against sequences within the Y1-receptor and NPY in single sections through the rat brain NAS. The Y1-like immunoreactivity (Y1-LI) was seen mainly in dendrites and dendritic spines, but was also detetected in axon terminals and astrocytic processes many of which were near blood vessels. Within both neuronal and glial processes, Y1-LI was most often seen near the plasma membrane or associated with cytoplasmic organelles, especially smooth endoplasmic reticulum and vesicles. In dendrites, Y1-LI was also prominently localized within and near asymmetric, excitatory-type synapses on spines, and in larger aspiny dendrites some of which also contained NPY. Terminals containing Y1-LI were both with and without NPY and many formed asymmetric synapses with spines. This distribution implicates the Y1 receptor in the NAS in (1) modulation of the post- and pre-synaptic effects of excitatory transmitters, (2) autoregulation of NPY-containing neurons, and (3) shape or metabolic changes in astrocytes. (Supported by grants MH00078; MH40342; and HL18974).

EVALUATION OF VARIOUS SUBSTITUTIONS IN THE C-TERMINAL PORTION OF NEUROPEPTIDE Y IN Y,- AND Y,-LIKE BINDING ASSAYS: POSITION 29 IS CRITICAL FOR Y, VS Y, RECEPTOR RECOGNITION. T. Trnh Y Dumont', A. Fournier', S. St-Pierre' and R. Quirnon'. Douglas Hosp. Res. Ctr. and Depts. Psychiatry, and Pharmacology and Therapeutics. McGill University Montréal, Oc. Canada, H4H 1R3. 21NRS-Santé, Université du Québec. Pointe-Claire. Qc. Canada. H9R 1G6.

The existence of at least four, and possibly more, neuropeptide Y (NPY) receptor subtypes has clearly been demonstrated, at least three (Y, Y, and YyPP) having recently been cloned. Accordingly, the development of highly selective agonists and antagonists for each of these receptor subtypes is critical in order to properly assess their respective functional relevance. Highly selective non-peptide Y, receptor antagonist such as BIBP 3226 (Rudolf et al., Eur. J. Pharmacol., 271 R11, 1994) have recently been developed; such tools not being available for the other receptor classes. Regarding agonists, while early studies suggested that [Leu³]. Pro *1PYP behaved as highly selective Y, receptor agonists, more recent data revealed their affinities for the Y, and YyPP, receptor subtype. respectively (Dumont et al., Mol. Brain Res., 26:3220-3324, 1994. Gehlert et al., Eur. J. Pharmacol., in press). Accordingly, we are pursuing extensive structure-activity studies aimed at developing highly selective agonists for each receptor subtype and have recently focused on the C-terminal portion of the NPY molecule. Monosubstitution of residues in position 27 (Tyr), 29 (Asn), 34 (Gln) and 36 (Tyr) were studied here. Analogues were tested for their affinities in Y,-like/[125][PYY, 29 (Asn), 34 (Gln) and 36 (Tyr) were studied here. Analogues were tested for their affinities in Y,-like/[125][PYZ, 29 (Asn), 34 (Gln) and 36 (Tyr) were studied here. Analogues were tested for their affinities in Y,-like/[126]. Pro*1PYY and Y,-like/[126]. Pro*1PYZ, 36 binding assays (Dumont et al., PPET, 272:673-680, 1995)

DISTRIBUTION AND mRNA EXPRESSION OF NEUROPEPTIDE Y (NPY) RECEPTORS IN HUMAN BRAIN VESSELS, ASTROCYTES AND VASCULAR CELLS IN CULTURE. R. Abounader *D. Jacques* Y. Tong*. R. Ouring* & E. Hamel. Mont. Neurol. Inst., Dept. Neurol. & Neurosurg. and Douglas. Hosp. Res. Ctr., Dept. Psychiat. *Dept. Neurol. & Neurosurg. and Douglas. Hosp. Res. Ctr., Dept. Psychiat. *Dept. Neurol. & Neurosurg. and Douglas. Hosp. Res. Ctr., Dept. Psychiat. *Dept. Neurol. & Neurosurg. and Douglas. Hosp. Res. Ctr., Dept. Psychiat. *Dept. Neurol. & Neurosurg. Ind. NPY is a potent constrictor of extra- and intracerebral blood vessels where it may act through Y1 receptors (Br. J. Pharmacol. 116, 2245-2250, 1995). However, four receptors (Y1, Y2, Y3 and Y4) for NPY have been pharmacologically identified and three (Y1, Y2 and Y4) have recently been cloned in man. Here, we report the distribution and mRNA expression of various NPY receptors in human brain vessels, astrocytes and vascular cells in culture using quantitative binding radioautography, in situ hybridization (ISH) and/or reverse transcriptase-polymerase chain reaction (RT-PCR). Sections of human pial vessels were incubated with [129]—[1201]—PY 197 or [1291]—PY 3-13]—PY 3-13. respective radioligands for Y1 and Y2 receptors, and competition studies were performed with (10°-10° M) NPY, PYY, [Leu³]. Pro³¹]—NPY, NPY, 13-3 to the Y1 specific antagonist BIBP 3226. The cellular distribution of Y1, Y2 and Y4 receptor mRNAs in human brain vessels was studied by ISH with *S labelled cRNA probes, and Y1 mRNA expression was further analyzed in intracerebral microvessels, and cultures of astrocytes, smooth muscle and endothelial cells by RT-PCR. [1231]—[Leu³]. Pro³¹]—PYY binding was potently competed by NPY, PYY and the selective Y1 receptor antagonist BIBP 3226, indicating the presence of Y1 receptors on human brain vessels. In contrast, [1231]—PYY, abinding could not be competed by Y1 (NPY and Leu³]. Pro³³]—PYY binding sites in brain vessels. By ISH, a strong signal for Y1 mRNA was present in the

We recently reported on the apparent paucity of the Y₁ receptor subtype in the human brain, including in cortical areas known to be highly enriched with this receptor class in the rodent brain (Dumont et al., J. Neurosci. 13:73, 1993). Interestingly, the Y₁ receptor mRNA is expressed at a somewhat higher level than the translated protein as revealed using in situ hybridization and quantitative receptor autoradiography (Jacques et al., Neuroreport, in press) In the present study, we investigated the comparative, discrete localization of the Y₁ and Y₂ receptors in the normal and Alzheimer's (AD) human brain. post-mortem. This is particularly relevant since earlier studies reported decreases in NPY-like immunoreactivity (Chan-Palay et al., J. Comp. Neurol. 238:390, 1985; ibid, 248: 376, 1986) and [3H]NPY binding sites (Martel et al., Brain Res. 519:228, 1990) in the AD brain. As expected, the normal human brain is enriched with [125]PYY₃₋₃₆/Y₂-like receptors while [125] [[Leu31, Pro34] PYY/Y1-like receptors are rare and mostly concentrated in the dentate gyrus. In the AD brain, the level of Y2 binding sites is significantly decreased in temporal and frontal cortices, and in basal forebrain nuclei Specific Y1-like binding in the granular layer of the dentate gyrus is also apparently decreased in the AD brain. It thus appears that the amount of both Y₁-like and Y₂-like binding sites may be decreased in the Alzheimer's brain albeit in different areas. Supported by MRCC and FRSQ.

NEUROPEPTIDE Y Y₈/PP₁ RECEPTOR IN THE RAT BRAIN: A COMBINED IN SITU HYBRIDIZATION AND RECEPTOR AUTORADIOGRAPHY STUDY Y Dumont', Y. Tong', S.H. Shen', I. Lundell', D. Larhammar' and R. Quirion' (I) Douglas Hosp Res Cir and Dept Psychiatry. McGill Univ. Montréal, Qc. Canada (2) Biotech Res Inst. Montréal, Qc., Canada (3) Dept Pharmacol Uppsala Univ. Uppsala, Sweden.

Neuropeptide (NPY) Y₁ Y₂ and Y₂/PP₁ receptor subtypes have been cloned. The respective distribution and pharmacological characteristics of the Y₁-like and Y₂-like respective distribution and pharmacological characteristics of the Y₁-like and Y₂-like respective distribution and pharmacological characteristics of the Y₁-like and Y₂-like respective distribution and pharmacological characteristics of the Y₁-like and Y₂-like respective with the respective formalian CNS. To target this unique receptor, human PP (hPP) and rat PP (rtPP) were iodinated using the chloramine T method as previously described (Dumont et al., IPET, 272.673, 1995). Autoradiographic studies were performed on adjacent coronal rat brain sections using 35 pM of either 1 hlpPP or rPP in the incubation medium and represented less than 10 % of total binding. Very high to high levels of specific 1 hlpPP binding sites were detected in various brainstem nuclei including the interpenduncular nucleus, vestibular nuclei nucleus tractus soliratius, area postrema and dorsal vagal nucleus. Moderate amounts of 1 hlpPP labeling were found in the medial preoptic area and the paraventricular nucleus of the hypothalamus. Few other areas such as the external plexiform layer of the olfactory bulb, the anterior olfactory nucleus and the lateral septum contained significant levels of 1 "2"IIhPP binding sites while very low amounts of labeling were detected in cortical areas and the hippocampal formation. Specific 1 "3 IIrPP binding was similarly distributed. Competition binding studies confirmed that hPP is at least 10 times more potent than rPP to compete for specific 1 "3 IIrP

SUBSTANCE PINTHE TWO MAJOR SUBPOPULATIONS OF PROJECTION NEURONS WITHIN THE NUCLEUS ACCUMBENS. X.-Y. Lu*, M.B. Ghasemzadeh, L. Churchill and P. W. Kalivas. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164-6520.

Substance P, an endogenous tachykinin, was previously found to be primarily expressed in the striatal efferent projection to the substantia nigra rather than in the striatal efferent projection to the globus pallidus. The nucleus accumbens has projections analogous to those of the striatum with outputs to the ventral tegmental area and the ventral pallidum. To determine whether a similar substance P expression pattern holds for the nucleus accumbens in situ hybridization for mRNA of the substance P prohormone, β-preprotachykinin, was combined with Fluoro-Gold retrograde labeling. Substance P-containing neurons were found in the nucleus accumbens projecting to both the ventral tegmental area and the ventral pallidum. Following iontophoretic deposit of Fluoro-Gold in the ventral tegmental area, up to 67% of retrogradely labeled neurons in the shell of the nucleus accumbens expressed substance P prohormone mRNA. Following Fluoro-Gold deposit in the ventral pallidum, up to 41% of the retrogradely labeled neurons in the shell and up to 29% in the core of the nucleus accumbens also contained substance P. This study demonstrates the contained substance P. This study demonstrates the contained substance P. strated that substance P-containing neurons within the nucleus accumbens project to both the ventral mesencephalon and pallidum which differs from those neurons in the striatum. These data suggest that the projection from the nucleus accumbens to the ventral tegmental area may be similar to the striatonigral projection, whereas the projection from the nucleus accumbens to the ventral pallidum may be more complex than the striatopallidal projection. NEUROPEPTIDE-MEDIATED MODULATION OF SPINAL REFLEXES IN THE LAMPREY. M. Ullström, D. Parker, N. Bussières, and S. Grillner, Nobel Institute for Neurophysiology, Dept. of Neuroscience, Karolinska Institute, S-171 77 Stockholm, Sweden.

Neuromodulators change the output of the essential 'hard-wired' neural circuits by modifying cellular and synaptic properties. We have investigated the effects of the tachykinin substance P and NPY, both which are contained in terminals making close appositions on sensory axonal processes.

close appositions on sensory axonal processes.

Reflex activation of trunk motoneurons can be elicited by stimulating the tail fin electrically. These reflexes are analysed *in vitro* by using an isolated cord preparation with the tail fin left attached. The cord is split into three baths. Peptides are added to the caudal bath, which includes the tail fin and afferent synapses. Reflex activity is recorded (ventral roots) in the rostral bath, the middle bath centains Ringer with high concentration of Mg²⁺ and Ca²⁺ to block synaptic transmission. Thus, activity in the rostral bath is due to activity in the ascending axons of the sensory neurons and interneurons from the caudal bath. The cellular and synaptic basis of the modulation was studied by making intracellular recordings from sensory neurons and interneurons. Substance P potentiated synaptic input to sensory interneurons, depolarised and increased the excitability of the sensory neurons. NPY presynaptically inhibits synaptic transmission to the sensory interneurons (Parker et al., Eur. J. Neurosci., in press). Neuropeptides thus have opnosity modulatory effects on reflex responses in lammers.

have opposite modulatory effects on reflex responses in lampres.

Application of substance P to the caudal bath potentiates reflex responses, shown by enhanced ventral root response following tail stimulation. Preliminary results suggest that NPY reduces ventral root responses following tail stimulation.

NK, RECEPTOR EXPRESSION IN DEVELOPING RAT SPINAL CORD AND IN CULTURE. C.J. Lee, T.B., Allen, M.J.S. Heath, A.B. MacDermott*. Depts of Physio. and Cell. Biophys., Anesthesiology, and the Center for Neurobiology & Behavior, Columbia University, New York, NY 10032.

In spinal cord dorsal horn, substance P is released from small diameter primary afferents and acts as a neurotransmitter/neuromodulator by activating neurokinin(NK) receptor. Using a polyclonal antibody raised against the C-terminal peptide of NK₁ receptor (Vigna et. al. 1994), we studied the time course and localization of NK₁ receptor expression in rat cervical spinal cord from ages E16 to P25. Expression in the dorsal horn started at around birth (Po-P2) in laminae I. III and IV and continued through P25. Staining was absent from lamina II as previously reported (Bleazard et al. 1994) throughout the ages tested. Staining of the floor plate, which has been shown to start to express NK₁ receptor at E10-E11 (Heath et. al. 1995), persisted until P10. In ventral horn, NK₁ receptor was strongly expressed before birth (E16-E20) then the level of expression decreased subsequently. NK₁ receptor immunoreactivity appeared in the region of the autonomic preganglionic nuclei at E17, and was present on fibers that projected between the nuclei and the region of central canal.

NK₁ receptor expression in the dorsal horn was confirmed by fura-2 Ca²⁺ imaging of dissociated dorsal horn neurons growing in co-culture with dorsal root ganglion neurons. When applied in the presence of CNQX, APV, bicuculline, and strychnine, 100 nM substance P elicited a Ca²⁺ response (n=9). This response was mimicked by the synthetic NK₁ agonist, Sar²-Met(O₂)¹¹-substance P (n=2). On these neurons, Ca²⁺ responses to substance P were blocked by tetrodotoxin (n=3) and 30 μM lanthanum (n=1), suggesting that NK₁ receptor activation causes firing of action potentials and subsequent entry of Ca²⁺ through voltage-gated Ca²⁺ channels. These data indicate that NK₁ receptors show a specific developmental pattern of expression in the spinal cord and that their presence in lamina I after P0 is consistent with the well established role of substance P in pain transmission and modulation. MODULATION OF SYNAPTIC TRANSMISSION AND EXCITABILITY OF MOUSE HIPPOCAMPAL NEURONES BY SUBSTANCE P. M. Kouznetsova, A. Nistri*, Biophys. Lab., Int. Sch. Adv. Studies (SISSA), 34013, Trieste, Italy.

In order to investigate the effects of substance P (SP), a peptide physiologically present in the hippocampus, intracellular recordings with K-acetate microelectrodes were performed on pyramidal neurones of the CA1 region of the mouse hippocampal slice preparation. Synaptic responses were elicited by focal electrical stimulation of stratum lacunosum moleculare. In 12 cells (resting potential -68 \pm 1 mV, input resistance 131 \pm 13 M Ω , mean \pm s.e.m.) 7 min application of SP methylester (SPMeO; 1.2 - 5 μM), a selective NK1 agonist, elicited almost no change in membrane potential and input resistance; evoked potentials were however suppressed: EPSPs by $32 \pm 9\%$ (55% cells), IPSPs by 39 ± 9% (82% cells). Intracellularly applied depolarising steps (500 ms) were used to monitor spike current rheobase which in 7/8 neurones was decreased by $24 \pm 6\%$. The latency for the first spike was diminished in 50% cells. In 67% cells there was also a reduction in AHP amplitude. In addition to the increase in membrane excitability a large enhancement in frequency of spontaneous postsynaptic potentials was obvious in all neurones. This phenomenon had slow onset (>10 min) and a very slow recovery. These findings demonstrated that SPMeO has a complex effect on hippocampal CA1 neurones. Although SPMeO produced no changes in resting membrane properties, it modulated synaptic responses and some voltagedependent conductances. It remains to be established whether it was a direct effect by the neuropeptide or an indirect one via modulation of other transmitter pathways. Supported by CNR and INFM.

TACHYKININ-MEDIATED MODULATION OF MECHANO-SENSORY AFFERENTS IN LAMPREY. E. Svensson, D. Parker and S. Grillner*, Dept. of Neuroscience, Division for Neurophysiology, Karolinska institute, S-17177 Stockholm, Sweden.

Bath application of the tachykinin substance P modulates mechanosensory afferents (dorsal cells) in lamprey, by increasing the excitability and spike duration and reducing the afterhyperpolarisation. The effects are due to the reduction of a 4-aminopyridine-sensitive potassium channel. The endogenous source of tachykinins was investigated by Lucifer yellow filling of dorsal cells combined with immunohistochemistry against substance P. Tachykinin immunoreactive fibers were found in close apposition to the dorsal cell axons and occasionally close to their somata. Tachykinin immunoreactive fibers were also found in the dorsal root and dorsal root ganglion. Tachykinin immunoreactive cell bodies that project towards the dorsal region of the spinal cord were found in the grey matter, and also peripheral to the dorsal root ganglion.

The intracellular pathway responsible for the tachykinin-mediated spike broadening was analysed using G-protein and protein kinase activators and inhibitors. The tachykinin-induced spike broadening was blocked by injection of 10 mM GDPBs but not by preincubation with pertussis toxin (300 ng/ml, 36h). Preincubation with 10 μM H7, a protein kinase C (PKC) and protein kinase A (PKA) antagonist and with chelerythine, a specific PKC antagonist blocked the effects of substance P. Bath application of the PKC-activating phorbol ester PDBu (10 μM) mimicked the effect of substance P. The PKA and protein kinase G antagonist H8 (20 μM) did not block the effect of substance P. These results suggest that substance P modulates the action potential via a pertussis toxin-insensitive G-protein and through activation of PKC. The endogenous release of tachykinins onto dorsal cell axons will thus modulate mechanosensory input in the lamprey. (Swedish MRC 3026)

CHARACTERIZATION OF AN NK3-RECEPTOR MEDIATED NONSPECIFIC CATION CONDUCTANCE IN GUINEA PIG CARDIAC NEURONS.

J.C. Hardwick', G.M. Mawe. and R.L. Parsons. Department of Anatomy & Neurobiology, University of Vermont, Burlington, VT 05405.

The parasympathetic postganglionic neurons of the guinea pig cardiac ganglia appear to receive inputs from substance P (SP)-immunoreactive afferent fibers. Previous studies demonstrated that application of exogenous SP produced a slow. long-lasting depolarization in these neurons. The present studies demonstrate that this depolarization is mediated by NK3 receptor activation. Whole mounts of guinea pig atria were dissected and continuously superfused with Krebs solution at 35-37°C and gassed with 95%O₂/5%CO₂. Individual neurons within a ganglia were impaled with 2 M KCl filled microelectrodes for current clamp recording. Dose response curves were generated by determining the amplitude of depolarization in response to 15 sec (\sim 2 mL) superfusions of either SP, neurokinin A (NKA), or senktide (an NK3 agonist) at concentrations ranging from $10^{.10}$ to $10^{.3}$ M. The rank order of potency (senktide > NKA > SP) is consistent with an NK3 receptor. Superfusion with the specific NK3 antagonist SR142801 (30 nM) produced a 67% inhibition in the response to 10*M senktide. To determine the potential ionic currents underlying the NK3induced depolarization, we examined the amplitude of the depolarization induced with a brief (1 sec, 10psi) pressure ejection application of senktide (104M) with and without specific inhibitors added to the Krebs solution. The senktide-induced without specific immotions added to the Klen's solution. The Setikute-Induced depolarization was unaffected by C1-current inhibitors (100 μ M millumic acid or mefenamic acid), C1-substitution, 1-2 mM Ba++, 1 mM Cs+, 0.3 μ M TTX, or 5 mM TEA. However, replacement of 50% of the external Na+ with NMG resulted in an approximate 50% reduction in the amplitude of the senktide-induced depolarization. We conclude that the tachykinin-induced depolarization of cardiac neurons is mediated by NK3 receptors which lead to activation of a nonspecific cation conductance. Supported by NS 23978 (RLP), NS 26995, and DK 45410 (GMM).

THE MECHANISM OF TACHYKININ NK-3 RECEPTOR-INDUCED RELAXATION IN RAT MESENTERIC ARTERY. H. Kamiya, A. Mizuta, S. Tanaka, K. Honda, R. Saito, and Y. Takano*. Dept. of Pharmacol., Fac. of Pharmaceut. Sci., Fukuoka Univ., Fukuoka 814-80, Japan.

Dept. of Pharmacol., Fac. of Pharmaceut. Sci., Fukuoka Univ., Fukuoka 814-80, Japan.

Tachykinin peptides show a variety of pharmacological effects via three tachykinin receptors, NK-1, NK-2 and NK-3. Substance P (SP) has been shown to cause endothelium-dependent relaxation of precontracted arteries and coronary arteries in some mammalian species. In addition, binding studies have demonstrated that the endothelial cells of porcine aorta have NK-1 receptors which are coupled to G-protein (Saito et al., 1990). Although there is much evidence for vasodilation mediated by NK-1 receptors, little is known about NK-3 receptor-mediated relaxation of arteries. In this study, we examined the mechanism of vasodilation mediated by tachykinin peptides in isolated mesenteric arteries of rats, and obtained the results as follows: (1) Neurokinin B and senktide, a selective NK-3 agonist, clicited potent endothelium-dependent relaxation of rat mesenteric arteries precontracted with phenylephrine (10-5 M), but an NK-1 agonist did not. (2) A non-peptide NK-3 antagonist, SR 142801, inhibited senktide-induced relaxation. (3) N^{oo}-nitro-L-arginine (L-NA), a nitric oxide synthesis inhibitor, markedly attenuated the relaxant response to esnktide. (4) Electrical field stimulation (EFS) of the precontracted-artery produced a vasodilation in the presence of guanethidine. This EFS-evoked vasodilation was attenuated by tetrodotoxin and SR 142801. These results suggest that neurokinin B may play a role in the neurogenic vasodilation in the rat mesenteric artery, whose endothelium possesses tachykinin NK-3 receptors, and that the vasodilation is mediated by release of nitric oxide (NO) from the endothelium.

ENDOTHELIN MEDIATES Ca²⁺ SIGNALING IN ENTERIC GLIA VIA ACTIVATION OF ENDOTHELIN B RECEPTOR COUPLED TO PHOSPHOLIPASE C. WZ Zhang*, DC Barnhart, GA Sarosi, MW Mulholland. Dept. of Surgery, University of Michigan Medical Center, Ann Arbor, MI 48109

Dept. of Surgery, University of Michigan Medical Center, Ann Arbor, MI 48109
The ability of enteric glia to respond to endothelins (ET) was examined using fura2-based digital microscopy in glial cells derived from guinea pig taenia coli. Each
isoform of ET (ET1,ET2,ET3) evoked dose-dependent and equipotent increases in
intracellular Ca2+ ([Ca2+]₁) and in percentage of cells responding. ET3 (100nM)
caused a biphasic [Ca2+]₁ response, characterized by an initial peak (541±16nM)
followed by secondary, sustained elevation in [Ca2+]₁ in 100% of cells (n=117).
4alaET1, a specific ETB receptor (ETB) agonist, elicited similar [Ca2+]₁ increments
(540±17 nM, 100% response at |μM, n=84). BQ788 (100nM), an ETB antagonist,
abolished [Ca2+]₁ responses to low doses of ET3 (0.01-1nM), and inhibited [Ca2+]₁
increments to high doses ET3 (10 and 100nM) by 79% and 71%, respectively (n=542
). BQ610 (μM), an ETA antagonist, did not demonstrate significant inhibition (4%
±3%.n=159). Preincubation of glia with U-73122 (10μM), a PLC inhibitor,
abolished the initial [Ca2+]₁ response to ET3 exposure (100nM). Thapsigargin
(1μM), an inhibitor of endoplasmic reticulum Ca2+ ATPase, also eliminated initial
ET3-evoked Ca2+ signaling. The IP3 receptor antagonist, heparin, introduced into
glial cells by radiofrequency electroporation, decreased peak [Ca2+]₁; response to ET3
(100 nM) by 63% (n=49). The effect of extracellular Ca2+ on the secondary response
was studied by superfusion of glia with Ca2+-free buffer or Ni2+. The secondary
elevation in [Ca2+]₁ caused by ET3 was abolished by removal of Ca2+ from the
buffer, and inhibited 80% by Ni2+ (1mM, n=108). Preincubation of glia with
100nM PMA (16 hr) also inhibited the secondary response by 82% (n=87). The
presence of IP3 receptors in enteric glia was confirmed by immunofluorescent
confocal microscopy. This study demonstrates that (1) enteric glia possess ETB
receptors which mediate (Ca2+]₁ signaling; (2) ET3 acts via PLC to release IP3sensitive (Ca2+]₁ stores with, (3

VASOTOCINERGIC INNERVATION IN A MALE PASSERINE BIRD (Junco hyemalis): EFFECT OF PHOTOPERIODIC CONDITION. P. Deviche¹*, E. Garcia-Ojeda², L. Plumari², and G.C. Panzica². ¹Inst. Arctic Biology, Univ. Alaska Fairbanks, Fairbanks, AK 99775; ²Dept. Anatomy, Pharmacol. For Med., Univ. Torino, Italy.

In domesticated birds, vasotocinergic (VT) fibers innervate brain regions that play an important role in the control of reproduction, and there is evidence that VT innervation is modulated by testosterone (T). The present investigation compared the distribution of immunoreactive VT innervation in brains of intact adult male dark-eyed juncos that were photosensitive and either exposed to short photoperiods (nonphotostimulated; low plasma T concentrations; LO-T) or naturally stimulated by long vernal photoperiods (high plasma T concentrations; HI-T). VT-containing cells were observed in regions where this peptide was previously found in another passerine bird (canary: paraventricular and supraoptic n., n. stria terminalis [nST]). Also similar to canaries, VT-containing fibers were widespread across many brain regions, being particularly abundant in the medial preoptic area (POM), the basal region of the septum, and the hypothalamic-neurohypophysial tract. Brain region-specific differences in the distribution of VT immunoreactivity between LO-T and HI-T males were observed. Specifically, LO-T males had markedly less VT-containing nST cells and less VT-containing POM and lateral septum fibers than HI-T males. Thus, VT expression in brain regions that are presumably involved in controlling reproduction was photoperiodic condition-dependent. Based on other studies, it appears that this dependency may be gonadal steroid-mediated. Work supported by E.U. (CT94-0472), C.N.R. (94.02462), and M.U.R.S.T. Awards.

peptide(HCNP) precursor protein and cellular distribution of HCNP mRNA in the mouse brain by non-isotopic in situ hybridization N,Matsukawa1.2 K,Ojika1*H,Okada3 N,Tohdoh4 T,Yamamoto2 and R,Ueda1 ; 1: 2nd Department of Int. Med. 3: Department of Molecular Biology, Nagoya City Univ., Nagoya, 467; 2: Choju Medical Institute, Noyori-Fukushimura Hospital, Toyohashi, 441 : 4: Discovery Research Laboratories. Sumitomo Pharmaceutical Research Center, Osaka, 554, Japan. We have previously reported that rat Hippocampal Cholinergic Neurostimulating Peptide, an undecapeptide purified from the hippocampus of 10-12 day old rats, specially enhances acetylcholine synthesis in medial septal nuclei in vitro by inducing the production of choline acetyltransferase activity (K,Ojika et, al, 1992, Brain Res., 572, 164-171). In this study, we have cloned a cDNA which encoded for mouse HCNP precursor protein. A mouse brain cDNA library Uni-ZAP™ XR Vector (Stratagene, CA) was screened by the rat HCNP precursor protein cDNA as a probe. The deduced amino acid sequence is composed of the same 186 amino acid residues as rat and human HCNP precursor protein (N, Tohdoh. 1995, Mol Brain Res., 30, 381-384). Mouse HCNP proper aligned at the N-terminal domain of precursor protein is the same structure as that of rat HCNP. Subsequently, we studied HCNP precursor protein mRNA concentration and cellular distribution by Northern blot analysis and non sotopic in situ hybridization method in the adult mouse brain. The expression was significantly increased in the neuronal cells in the cerebral cortex, entorhinal cortex, hippocampus and Purkinie cells in the cerebellum

ENDOTHELIN RECEPTOR SUBTYPES MAP DIFFERENTIALLY IN THE RAT BRAIN. Nashat Latib 1, Bo Yoo 1, Emilio C. Tayag* 1, Arco Y. Jeng 2, John C. Lehmann 1, 1. Dept. Neurosurgery MS 407, Medical College of Pennsylvania and Hahnemann University, Philadelphia PA 19102-1192; 2. Research Dept., Ciba-Geigy Corp., Summit NJ 07901-1398.

Two clearly defined receptor subtypes for endothelin (ET), the ETA- and ETB -subtypes, were found to have a differential regional distribution in the brain. Cryostat sections were incubated with [125]ET-1 with or without ETA antagonist BQ123 (1 uM), ETB antagonist BQ788 (1 uM), or both ligands. In general, the ETA receptor was particularly concentrated in white matter, but the ETB receptor was by far predominant in the gray matter. ETB receptors were much more enriched compared to ETA receptors in the striatum, the nucleus of the diagonal band, the medial septum, the superior colliculus, the CA1 and dentate gyrus of the hippocampus, the fimbria, and the dorsal tegmental decussation. The choroid plexus contained both receptors. Some ventricular ependymal surfaces were labeled, e.g., the lateral surface of the lateral ventricles, but not the superior or medial surfaces, or, for instance, the periaqueductal gray. The pineal gland contained one of the highest densities of ETB receptors and also contained a substantial density of ETA receptors.

Ciba-Geigy Corp.

ABUNDANT NEUROPEPTIDE Y (NPY) Y1 mRNA EXPRESSION IN THE HUMAN FOREBRAIN. <u>L. Caberlotto, K. Fuxe, I.M. Rimland*, G. Sedvall, and Y.L. Hurd.</u> Karolinska Institute, Depts. of Neuroscience and Clinical Neuroscience, Stockholm, Sweden. Dept. Pharmacology, GlaxoWellcome

Spa, Medicine Research Centre, Verona, Italy.

Though many neurobiological functions have been ascribed to the NPY Y1 receptor subtype, autoradiographic analysis has failed to detect Y1 binding sites in most areas of the human brain in contrast to the rat. In the present study, we have analyzed the regional distribution of NPY Y1 mRNA-containing cells in the human brain to clarify if there exists a major discrepancy between the rat and the human brain in terms of the existence and distribution of NPY Y1 receptors in the telencephalon, in particular the striatum and cortex. *In situ* hybridization experiments revealed a widespread distribution of the Y1 mRNA signal in all layers of most limbic and neocortical regions with the predominant labeling localized to layer IV (most cortical regions) and layer VI. The striatum showed moderate levels of Y1 receptor mRNA expression with intensely expressing cells localized to the nucleus accumbens. Overall, the highest expression of the Y1 receptor mRNA was within the dentate gyrus, with the lowest in the subiculum, parahippocampal gyrus, cerebellum, and thalamus. Moderate levels were also evident in the amygdala. *In vitro* autoradiography using [125I]PYY with NPY (13-36) or Leu³¹Pro³⁴-NPY, to mask Y2 or Y1 receptors, respectively, confirmed the low presence of Y1 binding in the human brain despite abundant Y1 mRNA expression. However, using a rat model of the human autopsy process, we found that the inability to reveal high Y1 vs Y2 receptors in the human brain is related in part to significant reductions of the Y1 receptor even within a 4 hr postmortem delay in comparison to Y2.

REGULATION OF G-PROTEIN LINKED K AND CA CHANNELS BY A FAMILY OF NEUROPEPTIDE Y RECEPTORS, L. Sun*. L.H. Philipson¹ and R.J. Miller. Dept. Pharmacol. and Physiol. Sci. and ¹Medicine, University of Chicago, Chicago, IL 60637.

Neuropeptide Y (NPY) is a 36 amino acid peptide neurotransmitter member of the pancreatic polypeptide (PP) family that is widely distributed in both the central and peripheral nervous systems. NPY has frequently been shown to produce presynaptic inhibition, an effect which may involve its ability to regulate neuronal Ca and K channels. Here we show that 3 different NPY receptors can all regulate inwardly rectifying K channels and N type Ca channels. We expressed rat Y1, 2 and 4 receptors (Synaptic Pharmaceutical Corn). in Xenapus goocytes together with the proteins rectifying K channels and N type Ca channels. We expressed rat Y1. 2 and 4 receptors (Synaptic Pharmaceutical Corp.) in Xenopus oocytes together with the proteins GIRK1 and CIR. Addition of NPY and structural analogues produced large inwardly rectifying K currents in these oocytes. The rank order of potency was NPY> Leu³1Pro³NPY=PYY>PP=NPY13-36>D-Trp³2NPY for Y1; NPY>PYY>NPY13-36>Leu³1Pro³NPY=PP=D-Trp³2NPY for Y2 and PP>PYY>Leu³1Pro³NPY>NPY>NPY13-36>D-Trp³3NPY for Y2 and PP>PYY>Leu³1Pro³NPY>NPY>NPY13-36>D-Trp³3NPY for Y2 and PP>PYY>Leu³1Pro³NPY>NPY>NPY13-36>D-Trp³3NPY for Y4 receptors. The effects of NPY on the Y1 receptors were antagonized by the compound BIBP 3226 in a competitive fashion. However, the effects of agonists on Y2 receptors were not antagonized. The effects of agonists at all 3 types of receptors were absent if the oocytes were treated with pertussis toxin. We also expressed Y1, 2 and 4 receptors in HEK 293 cells that stably expressed N type Ca channels. Following expression these cells bound 1251 NPY with high affinity. Activation of Y1, 2 and 4 receptors in these cells produced robust inhibition of N type. Ca currents evoked by denolarization. The effects of all of these agonists. ammin. Activation of 11, 2 and 4 receptors in these cells produce robust minoritor of N type Ca currents evoked by depolarization. The effects of all of these agonists were absent in cells treated with pertussis toxin. These results show that all of the known NPY receptors are capable of increasing G-protein linked K channels and decreasing N type Ca channels and that these effects may underlie their synaptic modulatory effects. (This work was supported by PHS grants DA-02575, DA-02121, MH-40165 and NS-33502 to R.J.M.).

HYPOTHALAMIC NPY mRNA LEVELS IN OB/OB MICE DURING BODY WEIGHT LOSS NDUCED BY DOPAMINERGIC AGONIST TREATMENT. M. Jakubowski*, M. Lubkin E. Tozzo and A.H. Cincotta. Ergo Science Development Corp., Charlestown, MA 02129

We have previously shown that dopamine agonists can produce dramatic anti-diabetic and anti-obesity effects in man and animals. For the genetically obese ob/ob mouse, we have used a mixture of D1/D2 dopamine agonists that markedly decreases insulin resistance, blood glucose levels, food intake and body fat stores. Here, we examined whether those changes are associated with decreased hypothalamic levels of the mRNA encoding neuropeptide Y (NPY) which is known to promote insulin resistance and food intake. Female ob/ob mice (39-52 g) and lean C57BL/6J counterparts (19-23 g) were housed under a 12:12 h light:dark schedule. Obese mice were treated daily at 1 h after the onset of light with i.p. injections of 10 mg/kg SKF 38393 (a D1 agonist) and arter the diset of high with physicians of the highs are receiving corresponding injections of vehicles alone, as well as non-treated lean counterparts served as controls. Mice were sacrificed either 6 h before or 4 h after light onset, yielding no significant night-daytime differences for any of the parameters measured. After 14 days of treatment, obese mice lost 15% of their body weight (p < 0.001) compared to obese controls. Cumulative food intake in the treated obese mice plunged 43% (p < 0.001) and 21% (p < 0.05) compared to obese and lean controls, respectively. Blood glucose levels were elevated 3-fold in obese controls (p < 0.001) and normalized in the treated obese mice, compared to lean controls. NPY mRNA levels in the arcuate nucleus, measured by in situ hybridization, were 3-fold higher in obese controls than in lean counterparts (p < 0.001). NPY mRNA levels decreased 31% in the treated obese mice compared to obese controls (p < 0.05), but remained twice as high as in lean controls (p < 0.05). We conclude that the improvement of metabolic function in the ob/ob mouse using D1/D2 agonist treatment may be mediated in part by reduced hypothalamic NPY activity. Notwithstanding, our treatment induced hypophagia and euglycemia in the ob/ob mouse in the face of sustained heightened level of NPY gene expression. Ergo Science Development Corp.

MODULATION OF SYNAPTIC TRANSMISSION BY MULTIPLE NEURO-PEPTIDE Y (NPY) RECEPTORS IN THE ARCUATE NUCLEUS OF THE RAT. H. Rhim* and R.J. Miller. Dept. of Pharmacological and Physiological Sciences. University of Chicago, Chicago, IL 60637.

University of Chicago, Chicago, Lb 60637.

NPY is a 36 amino acid peptide that it is widely distributed in the central and peripheral nervous systems. Recently, NPY has been the focus of attention due to its dramatic effects on feeding behavior. It is highly concentrated in key regulatory feeding centers in the hypothalamus. Among these, the arcuate nucleus contains not only large numbers of NPY fibers but also high concentrations of NPY-immunoreactive cell bodies. We therefore examined the effects of NPY and its analogs in the arcuate nucleus using whole-cell patch clamp recordings in hypothalamic slices. Under voltage clamp conditions, the Y1 receptor agonist Leu³¹-Pro³⁴ NPY (100 nM) produced a outward current at Vh = -60 mV and this postsynaptic effect recovered within 10-15 min after washout. This effect was blocked by the selective Y1 antagonist BIBP 3226 (1 µM). Leu³¹-Pro³⁴ NPY also inhibited evoked glutamate-mediated excitatory postsynaptic currents (EPSCs, 54.0±8.5% inhibition of control, mediated excitatory postsynaptic currents (EPSCs, 54.0±8.5% inhibition of control, n=7) as well as spontaneous EPSCs. This presynaptic effect was not blocked by BIBP 3226 and reversed only slowly. Leu³¹-Pro³⁴ NPY was very potent, inhibiting the EPSCs at 1 nM. The post- and presynaptic effects of Leu³¹-Pro³⁴ NPY were mimicked by NPY itself. Pancreatic polypeptide only produced weak effects. The Y2 receptor agonist NPY13-36 (100 nM) inhibitied evoked EPSCs (75.8±8.8%, n=4) without changing the holding current. Interestingly, another NPY analog, D-Trp³²-NPY (100 nM) also produced inhibition of the evoked EPSCs (53.8±7.8%, n=7) with no change in holding current. However, D-Trp³²-NPY had little effect on GIRK1 channels in *Xenopus* oocytes in which rat Y1, 2 or 4 receptors were expressed (See L. Sun et al. this meeting). These data suggest that NPY receptors of different types regulate synaptic transmission in the arcuate nucleus. These include Y1 and 2 receptors and possibly another receptor with novel pharmacological properties (Y1-like). (PHS grants DA-02575, DA-02121, MH-40165 and NS-33502 to R.J.M.).

ACTIONS OF NEUROPEPTIDE Y RECEPTORS IN PARAVENTRICULAR NUCLEUS OF RAT HYPOTHALAMUS

N. Fronchuk & W.F. Colmers*. Dept. Pharmacol., Univ. Alberta, Edmonton, AB Injection of Neuropeptide Y (NPY) into hypothalamic nuclei causes a profound increase in carbohydrate-selective food intake. The receptor and neuronal mechanisms underlying this response are the subject of this report.

increase in carbohydrate-selective food intake. The receptor and neuronal mechanisms underlying this response are the subject of this report. Slices containing the paraventricular nucleus ($400~\mu m$) were prepared with a vibratome from brains of male Sprague-Dawley rats (5.7~ weeks old) according to an approved protocol. Slices from approximately 1.30~ and 2.12~ mm posterior to bregma were used (based on Paxinos and Watson, 1986). Slices were kept bubbled with 95% O₂/5% CO₂ at 30 °C for at least 1h, then maintained in a 500 μ L recording chamber submerged in a continuous flow (2.5~ ml/min) of ACSF at 34 \pm 0.5 °C. Whole-cell patch clamp recordings were made with pipettes containing (in mM): K* gluconate 120; KCl 2; HEPES 5; MgATP 5; BAPTA 1.1, Cacl₂ 0.1; 290 mOsm, Ph 7.25, while perforated patch recording were made with K*-gluconate 135, BAPTA 0.1, HEPES 10, MgCl₂ 5, with $450~\mu$ g/ml nystatin (286~ mOsm, pH 7.35). Stimulating electrodes were placed slightly ventral to PVN. Postsynaptic: Recordings were made from > 40 neurons in the perforated patch configuration. Neurons exhibited spontaneous activity. Application of a centrallytruncated 7, receptor agonist (300~nM- $1~\mu$ M) caused a reduction in firing rate in 9/14 cells, which reversed in 5, while 5 cells showed no response. There was no change in conductance associated with the change in activity. Synaptic: Whole-cell recordings made from > 20 neurons. Stimulation elicited short-latency synaptic responses that were sensitive to either NBQX/APV (EPSC) or picrotoxin (IPSC). Application of 7, agonists reversibly reduced EPSC amplitudes in 6/8 neurons and IPSC's in 5/10~cells. No changes in postsynaptic conductances were associated with the observed effects on synaptic activity. In PVN, both 7, and 7, receptors mediate effects on synaptic inputs to neurons, in addition to affecting their spontaneous activity. The presence of two receptors, if their actions are synergistic, may explain the "astypical 7" response in feeding.

LOCALIZATION OF THE NEUROPEPTIDE Y (Y4) / PANCREATIC POLYPEPTIDE-RECEPTOR IN RAT PARAVENTRICULAR NUCLEUS (PVN) AND EFFECT OF INTRA-PVN INJECTION OF PP IN FED RATS. P. Kristensen^{1*}, J. S. Rasmussen² and P. J. Larsen³. ¹Histology and ²Molecular Biology, Health Care Discovery, Novo Nordisk A/S Bagsværd and ³Department of Medical Anatomy, University of Copenhagen, Denmark

The recent isolation of the Y4 Neuropeptide Y (NPY) receptor subtype has prompted our interest into the potential role of this receptor during initiation of feeding behaviour. Within the hypothalamus, Y4 mRNA expression was exclusively found in the paraventricular nucleus. The highest level of expression was found in the lateral parvocellular subdivision and the ventral part of the the lateral parvocellular subdivision and the Ventral part of the medial parvocellular subdivision. The Y4 receptor binds PP-fold peptides with a rank order of PP > PYY >= NPY. Autoradiographic analysis of rat 125-I labelled PP binding (50 pM) showed specific binding (complete displacement by 1 μ M cold rat PP) to the medial and lateral parvocellular subdivision of the PVN. Finally, local application in the PVN demonstrated that at low and moderate doses (2.5 - 250 pmol) PP and NPY equipotent at inducing food intake in fed rats. At higher dose, however, NPY more potently stimulated the feeding response. These findings point to a potential role for the Y4/PPreceptor subtype in the induction of feeding behaviour

EFFECTS OF NEUROPEPTIDE Y₁ RECEPTOR ACTIVATION ON THE RESPONSES OF CELLS IN THE RAT'S VENTRAL POSTEROMEDIAL THALAMIC NUCLEUS. Y. Zhang*, N.L. Chiaia, R.D. Mooney and R.W. Rhoades. Dept. Of Anatomy and Neurobiology, Medical College of Ohio, Toledo, OH 43699

Neuropeptide Y (NPY) is contained along with norepinephrine in many axons that project from the locus ceruleus to the ventral posteromedial thalamic nucleus (VPM) and both NPY Y_1 and Y_2 receptors are present in this region. We previously reported that application of NPY altered the responses of vibrissaesensitive neurons in VPM and this study was undertaken to determine the contribution of Y1 receptor activation to these changes. The effects of the selective Y₁ receptor agonist, [Leu³¹][Pro³⁴], were tested on 35 vibrissae-sensitive VPM cells. It reduced the responses to principal whisker stimulation for 11 of these cells (31%) by \ge 30% and increased the responses of only one of these neurons (3%) by at least this amount. Similar effects were observed for responses to surround whisker stimulation; 18% of cells had their responses decreased by ≥ 30% and only 6% had their responses increased by at least this amount during [Leu³¹][Pro³⁴] administration. Application of the Y₁ receptor agonist also reduced responses to electrical stimulation of trigeminal nucleus principalis by ≥30% in 54% of cells. No PrV-evoked responses were increased by application of [Leu³¹][Pro³⁴]. Similarly, delivery of [Leu³¹][Pro³⁴] decreased the responses of 38% of VPM cells to electrical stimulation of trigeminal subnucleus interpolaris (SpI) by ≥30%. Here again, no SpI-evoked responses were increased by this amount during [Leu³¹][Pro³⁴] application. These results indicate that activation of the Y₁ receptor suppresses responses of vibrissae-sensitive VPM neurons to excitatory trigeminal brainstem input. Supported by DE 08971and DE 07734.

612.9

EFFECTS OF ACTIVATION OF NEUROPEPTIDE Y, AND Y, RECEPTOR ACTIVATION ON THE RESPONSES OF VENTRAL POSTEROMEDIAL THALAMIC NEURONS *IN VITRO*. M. Chen*, N.L. Chiaia, R.D. Mooney, and R.W. Rhoades. Dept. Of Anatomy and Neurobiology, Medical College of Ohio, Toledo, OH 43699

Radioligand binding and in vivo electrophysiological experiments have shown that neuropeptide Y₁ and Y₂ receptors are present in the rat's ventral posteromedial thalamic nucleus (VPM) and that selective activation of either of these receptors influences the sensory responses of VPM neurons. The present in vitro study was undertaken to assess the effects of the selective Y1 and Y2 agonists, [Leu31][Pro34] NPY and NPY 13-36, on the membrane potentials and responses to medial lemniscus stimulation of VPM neurons. Both agonists had mixed effects on both the membrane potentials and epsps. Administration of the Y, agonist resulted in hyperpolarization of 65% of 20 cells tested (mean change -5.23 \pm 3.29 mV) and depolarization of 30% (mean change 2.33 ± 1.11 mV). Application of [Leu³¹][Pro³⁴] reduced the epsps of 45% of cells tested by ≥20% (average reduction -3.0 ± 1.58 mV) and increased the epsps of 20% by at least this amount (average increase 2.88 \pm 1.08 mV). Administration of the Y₂ agonist resulted in hyperpolarization of 80% of 10 cells tested (mean change -3.88 \pm 2.57 mV) and depolarization of 10% (mean change 10 ± 0 mV). Application of NPY₁₃₋₃₆ reduced the epsps of 30% of cells tested by ${\scriptstyle \geq}20\%$ (average reduction -2.33 \pm 0.62 mV) and increased the epsps of 20% of cells by at least this amount (average increase 2.5 ± 1.0 mV). heterogeneity of the effects of selective Y1 and Y2 receptor activation in VPM is surprising given previous observations in several structures that activation of the former receptor results in postsynaptic excitation and stimulation of the latter is associated with presynaptic inhibition. Supported by DE 08971 and DE 07734.

612.11

NEUROPEPTIDE-Y DIFFERENCES BETWEEN FEMALE AND MALE RAT BRAIN: LOWER BASELINE AND DECREASED RESPONSE TO ELECTROCONVULSIVE TREATMENT IN FEMALES. BIOLOGICAL AND CLINICAL IMPLICATIONS. P.A. Jiménez, D.H. Overstreet and Neuroscience, Karolinska Institute, 112 81 Stockholm. Sweden and Dept. of Psychiatry, Univ. of North Carolina, Chapel Hill, NC.

Accumulated data indicate that neuropeptides, in particular neuropeptide-Y (NPY) may be involved in depression. The present study examined the concentrations of NPY-like immunoreactivity in several brain regions in three strains of rats (the Flinders Sensitive Line (FSL), Flinders Resistant Line (FRL), and outbred Sprague-Dawley (SD) rats) after a series of 8 ECT or sham ECT given every other day. Following sacrifice with focused high energy microwave irradiation, the brains were dissected, and the peptides extracted and measured with radioimmunoassays. Marked "baseline" (sham ECT treated) differences in NPY-LI concentrations in frontal cortex, occipital cortex, and hippocampus between the female and male rats of all three strains were observed. In addition, within the gender, the sham ECT treated SD males had higher values than FRL males in the frontal and occipital cortices and SD females had higher values than both FRL and FSL females in the frontal cortex. The results of ECT varied with strain, gender and brain region. ECT increased NPY-LI in the striatum of only the male SD rats. In contrast, there was an increase in the frontal cortex in all groups except the FSL female rats. The FSL rats (both genders) also were resistant to the increases induced by ECT in the occipital cortex. The largest increases in NPY-LI were seen in the hippocampus, with all genders and strains exhibiting significant changes. However, as with the other brain regions, the changes in NPY-LI were smaller in the FSL rats. In conclusion, significant NPY regional gender differences may have implications for gender biology and, together with the different response to ECT, suggest that NPY may be involved in affective disorders.

612 8

EFFECTS OF NEUROPEPTIDE Y₂ RECEPTOR ACTIVATION ON THE RESPONSES OF VIBRISSAE-SENSITIVE NEURONS IN THE RAT'S VENTRAL POSTEROMEDIAL THALAMIC NUCLEUS. <u>R.D. Mooney*, Y. Zhang, N.L. Chiaia, and R.W. Rhoades</u>. Dept. Of Anatomy and Neurobiology, Medical College of Ohio, Toledo, OH 43699

The ventral posteromedial thalamic nucleus (VPM) in the rat contains high concentrations of neuropeptide Y (NPY) receptors and the responses of vibrissaesensitive thalamic neurons are strongly influenced by both NPY and the Y1 receptor agonist, [Leu31][Pro34]. The present study was undertaken to determine the effects of selective activation of the Y2 receptor with NPY 13-36 on the responses of VPM neurons evoked by vibrissae deflection and electrical stimulation of either trigeminal nucleus principalis (PrV) or trigeminal subnucleus interpolaris (SpI). The effects of the selective Y₂ receptor agonist, NPY₁₃₋₃₆, were tested on 18 vibrissae-sensitive VPM cells. It reduced the responses to principal whisker stimulation for 4 of these cells (22%) by ≥30% and increased the responses of 3 neurons (17%) by at least this amount. Responses to surround whisker stimulation were decreased by ≥30% in 29% of cells tested and increased by at least this amount in 14%. Administration of NPY₁₃₋₃₆ reduced responses to electrical stimulation of PrV by ≥30% in 20% of cells tested and increased responses by at least this amount for 30%. Delivery of NPY₁₃₋₃₆ decreased the responses of 63% of VPM cells to electrical stimulation of SpI by 230% and increased the responses of only 13% of cells tested by this amount. These results indicate that activation of the Y₂ receptor has generally suppressive effects upon the responses of vibrissae-sensitive VPM cells. However, it also appears that activation of this receptor has differential effects on responses to stimulation of PrV and SpI. Supported by DE 08971 and DE 07734.

NPY INHIBITS GABA NEUROTRANSMISSION AND WHOLE-CELL CALCIUM CURRENTS THROUGH BOTH Y1 AND Y2 RECEPTORS IN SCN NEURONS. G. Chen* and A. N. van den Pol. Sect. Neurosurg., Yale Univ. Sch. Med., New Haven, CT 06520.

The suprachiasmatic nucleus (SCN) plays a critical role in the entrainment of circadian rhythms, GABAergic neurons dominate in SCN. Microinjection of NPY in SCN phase shifts the circadian rhythm, suggesting a modulatory role of NPY in SCN function. Whole-cell voltage clamp and current clamp methods were employed to study the modulation of NPY on synaptic release and barium currents in SCN cultures. NPY (80 nM) reduced the frequency of miniature spontaneous IPSPs to half of the control while having little effect on the postsynaptic GABA response, suggesting a presynaptic mechanism of NPY inhibition. Similar to NPY, [Leu³¹, Pro³⁴]-NPY (80 nM), a preferential Y1 agonist, and NPY 13-36 (80 nM), a preferential Y2 agonist, presynaptically inhibited the spontaneous GABA activity. To further characterize the NPY action, single-neuron microcultures in which a single neuron forms synapses with itself was used. The single autaptic neuron allowed us to record a presynaptic release induced response and a GABA application evoked response in the same sweep. Application of NPY inhibited the autaptic release while leaving the postsynaptic response unaltered, confirming the presynaptic mechanism of NPY action. In addition, application of Y1- and Y2-selective agonists to the same autaptic neuron also significantly inhibited the autaptic GABA release, suggesting the coexistence of Y1 and Y2 receptors in the presynaptic nerve terminals of SCN neurons. NPY, as well as [Leu³¹, Pro³⁴]-NPY and NPY 13-36, also inhibited whole-cell barium currents, indicating an expression of both Y1 and Y2 receptors in neuronal soma. The inhibition of presynaptic GABA release paralleled the inhibition of formum currents in the same autaptic neuron, suggesting an inhibition of calcium channels may underlie the NPY inhibition of GABA release. These results demonstrate that NPY Y1 and Y2 receptors coexist in both the cell body and axon terminals of a single neuron and mediate the inhibition of calcium channels and synaptic GABA release in SCN neuro

DIRECT EVIDENCE FOR THE INVOLVEMENT OF NEUROPEPTIDE Y (NPY) IN SYMPATHETIC NERVE-MEDIATED VASOCONSTRICTION S.P. Han*, C.L. Yang, X.L. Chen, L. Naes and T.C. Westfall Dept. Pharmacol. and Physiol. Sci., St. Louis Univ. Sch. Med., St. Louis, MO 63104.

NPY is a vasoconstrictor peptide and a cotransmitter with norepinephrine (NE) and epinephrine in sympathetic nerve terminals and the adrenal medulla, respectively. Several lines of evidence suggest that, in addition to NE, NPY may also mediate sympathetic nerve activation-induced vasoconstriction. Using BIBP3226, a newly synthesized Y1 receptor selective antagonist, we examined this hypothesis in the isolated and perfused mesenteric vascular bed of the rat. Our results indicate that NPY plays an important role in mediating sympathetic nerve activation-induced vasoconstriction. Periarterial nerve stimulation produced a frequencydependent increase in perfusion pressure in the isolated and perfused rat mesenteric vascular bed indicative of vasoconstriction. There were concomitant increases in NE and NPY immunoreactivity (NPYir) overflow in the perfusate determined by HPLC-electrochemical detection and radioimmunoassay, respectively. Vasoconstriction induced by NE or nerve stimulation was potentiated by [Leu31, Pro34] NPY, a selective Y1 receptor agonist. The potentiation was prevented by pretreating the vascular bed with BIBP3226. In addition, nerve stimulation-induced vasoconstriction was significantly attenuated by BIBP3226. These results strongly suggest that NPY is released and is involved in mediating sympathetic nerve stimulationinduced vasoconstriction in resistance vessels. Supported by NIH HL-26319 and HL-35202.

VASCULAR EXPRESSION OF NEUROPEPTIDE Y (NPY) AND NPY

VASCULAR EXPRESSION OF NEUROPEPTIDE Y (NPY) AND NPY RECEPTORS: MECHANISMS OF ANGIOGENESIS. E. Karwatowska-Prokopczuk¹, W. Rose², D.S. Grant², E. K. Dayao¹, G. J. Hauser¹. H. Ignatowska-Switalska³, and Z. Zukowska-Grojec¹*. ¹Dept. Physiology, Georgetown Univ, Washington DC, ²Cardeza Found Hematol. Res., Jefferson U., Philadelphia, PA, and ³Dept. Hypertension, Med. Acad., Warsaw, Poland.

Previously, we reported that NPY, a sympathetic neurotransmitter and a vasoconstrictor, is angiogenic in vivo and in vitro. All components of the NPY system - the peptide, its receptors, and dipeptidyl peptidase IV (DPPIV), an enzyme which converts NPY to NPY 3.36 (a Y2 selective agonist) - appear to be present in endothelial cells (ECs). We now attempted to determine 1) whether ECs synthesize and release NPY; 2) what is the angiogenic receptor subtype and its signaling; and 3) whether cell growth and/or differentiation alters the expression of NPY or Y1 receptors. Quiescent human umbillical vein endothelial cells (HUVECs) possess sub-pM NPY-immunoreactivity (-ir, ELISA) and undetectable NPY mRNA (Northern blot) levels. During growth on plastic and differentiation on Matrigel, HUVECs up-regulate NPY mRNA and Y1 receptor mRNA (6-fold) by 6-20 hrs, and release NPY-ir into the media by 24 hrs. NPY and NPY3-36 increased up to 2-fold the capillary tube formation by HUVECs on Matrigel by 18 hrs, whereas Leu³Pro³¬NPY (Y1 agonist) was less active. NPY antiserum blocked these effects. Y1 receptor antagonist, (R)-N2-(diphenacyl)-N-[(4-hydroxyphenyl)methyl]-D-arginineamide, BiBP3226 (1 µM), potentiated tube formation in control and NPY-treade cells by up to 2-fold. The Y2 antagonist, T4-(NPY)3.3-6 (1µM), abolished the NPY-induced tube formation and inhibited the NPY-induced tube formation and inhibited the NPY-induced tube formation and salpha-benzoyl-L-arginine ethyl ester reversed this action. Thus, during EC growth, NPY and Y1 receptor expression increase, NPY is released and stimulates angiogenesis. The NPY-mediated angiogenesis is mai

ELECTROPHYSIOLOGICAL EFFECTS OF CRF AND CRF ANTAGONISTS ON SELECTED BRAIN REGIONS AND PITUITARY OF THE RAT IN VITRO. M.D. Davis* and C.E. Curtis. Psychiatric Disorders Therapeutics, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., 2800 Plymouth Rd., Ann Arbor, MI 48105.

Corticotropin releasing factor (CRF) is a peptide which plays a key regulatory role in the hypothalamic-pituitaryadrenal stress axis, a system which is perturbed in human depression. Since intracerebral administration of CRF evokes anxiogenic and depressive types of behavior in animals, it may also participate in the extra-hypothalamic central response to stress. Here, we examined the effects of CRF on the activity of several brain and pituitary sites known to have high levels of CRF binding or receptor mRNA.

Tissue slices were obtained from Sprague-Dawley rats (14-21 days old) and superfused in vitro. Standard extracellular unit recordings were made while either vehicle, CRF1-41, a-helical-CRF9-41 and/or D-Phe-CRF12-41 were bath applied (≤1uM). CRF produced an elevated firing rate in the parabrachial, pontine, solitary, inferior colliculus, ventromedial hypothalamic and lateral septal nuclei and the pituitary intermediate lobe. These effects were blocked by the CRF antagonists, a-helical-CRF9-41 or D-Phe-CRF12-41 Partial tachyphylaxis was seen on repeated testing with CRF in some regions. The excitatory effects of CRF were not seen in the locus coeruleus, substantia nigra or raphe nuclei. These results demonstrate a wide distribution of CRF-sensitive neurons in the brain and contrast, in some cases, with previous reports using in vivo methods. (Supported by Warner-Lambert)

612.17

BLOCKADE OF CRF-INDUCED EXCITATION OF LOCUS COERULEUS CELL FIRING BY CP-154,526, A NON-PEPTIDE ANTAGONIST OF CENTRAL CRF RECEPTORS. J. Braselton*, Y. Chen and J. Sprouse. Pfizer Central Research, Groton, CT 06340 USA

Various clinical findings suggest that CRF (corticotropin releasing factor) is hypersecreted in certain psychopathological states. While a CRF antagonist might be useful in treatment of these disorders, the agents currently available are peptides (e.g. α -helical CRF₉₋₄₁) and as such are not ideal candidates due to their inherent poor bioavailability and difficulty in penetrating the blood-brain barrier. Here we describe the effects of CP-154,526, a potent and selective non-peptide CRF antagonist, on one measure of central CRF activity, excitation of locus coeruleus cell firing.

Extracellular single unit recordings of locus coeruleus neurons were made in male Sprague-Dawley rats anesthetized with chloral hydrate. r/h Table 1 made by agules-bawley tas an estimated with chloral hydrate. With CRF (3 μ g / 6 μ l) injected i.c.v. produced an increase in locus coeruleus cell firing (mean \pm SEM = 102 \pm 19%, n = 15), similar in magnitude to that previously reported (Valentino et al., Brain Res. 270, 363-367, 1983). CP-154,526 given i.v. 5 - 10 minutes prior to the CRF challenge blocked the excitation in a dose-dependent manner. The ID50 calculated from regression analysis of the dose response curve was 2 mg/kg i.v. Selectivity of the blockade by CP-154,526 was probed with substance P -induced excitation of cell firing. Substance P given alone (1.0 µg / 6.0 µl i.c.v.) increased firing rate by 102 ± 28 % (n = 4). When given as pretreatment, CP-154,526 at 5.6 mg/kg i.v., the highest dose tested against the CRF challenge, was ineffective at blocking the response to substance P (net excitation = $101 \pm 11\%$). Taken together these data suggest that CP-154,526 is a selective CRF antagonist, active against central CRF receptors when given systemically in a well characterized model of CRF activation.

ORGANIZATION AND LESION-INDUCED CHANGES IN GALANIN RECEPTORS IN THE RAT'S TRIGEMINAL SYSTEM. R.W. Rhoades*, D. Bodie, C.A. Bennett-Clarke, and N.L. Chiaia. Dept. Of Anatomy and Neurobiology, Medical College of Ohio, Toledo, OH 43699

Previous immunocytochemical experiments have shown that the neuropeptide, galanin, is dramatically upregulated in a vibrissae-related pattern in the brainstem after perinatal damage to either the infraorbital nerve or individual vibrissae follicles. The present study was undertaken to determine changes in the density of receptors for this peptide following such damage. Galanin receptors were labelled with 125I-galanin in rats that sustained unilateral transection of the ION either at birth (P-0) or in adulthood. Rats that sustained lesions on P-0 were killed either 7 or > 60 days after nerve transection while rats that sustained nerve damage as adults were killed 7 days after the ION transections. Autoradiograms of tissue sections through trigeminal nucleus principalis (PrV), subnucleus interpolaris (SpI), and subnucleus caudalis (SpC) were evaluated using quantitative densitometric methods. Transection of the ION in adulthood resulted in significant (P<0.05) reductions in binding density in PrV (-27 \pm 7%), SpI (-40 in significant (1 \times 0.5) reduced in 0 of SpC (-68 ± 15%). Transection of the ION on P-0 produced markedly different results. Animals killed on P-7 had slight (-18 ± 6% for PrV, -21 ± 9% for SpI, and -12 ± 2% for SpC) but significant (p<0.05) reductions in binding density, while those killed in adulthood exhibited significant (p<0.05) increases ($69 \pm 12\%$ for PrV, $44 \pm 10\%$ for SpI, and $13 \pm 1\%$ for SpC) in the density of galanin binding sites. Supported by NS 28888 and DE 07734.

CENTRAL CRF ADMINISTRATION PREFERENTIALLY ACTIVATES NEURONS EXPRESSING TYPE I CRF RECEPTORS. J. C. Bittencourt*, R. A.

Rissman and P. E. Sawchenko. The Salk Institute, La Jolla, CA 92037.

In an effort to explain frequently encountered "mismatches" between the central in an error to explain irequently encountered mismatches between the central distributions of synaptically active molecules and their cognate receptors, proponents of parasynaptic or volume transmission have frequently pointed to the ventricular system as an avenue for the delivery of ligands to receptors of the appropriate chemical specificity. The recent cloning of cDNAs encoding two distinct CRF receptors permits analysis of the specificity with which central CRF targets neurons bearing CRF receptors. We followed the time course and distribution (relative to that of CRF receptors. We followed the time course and distribution (relative to that of CRF receptors) of Fos-ir induction seen in response to CRF (1) ge in 10 µl salinie; icv) given to awake, freely moving rats. CRF provoked widespread Fos induction that was detected within 30 min after injection, peaked at 2 hr, and abated thereafter. The pattern of induced Fos expression closely mimicked the distribution of CRF-R1 mRNA expression, including widespread induction throughout the cortical mantle, in cell groups involved in the processing of visual, auditory, vestibular and somatic sensory information, and in the cerebellar cortex and several of its major afferents and targets. Dual labeling experiments revealed extensive correspondence of CRF-stimulated Fosi-and CRF-R1 mRNA at these and other loci. Major sites of CRF-R2 expression were lacking or impoverished in Fosi-in ucclei. CRF-induced cellular activation was observed in several cell groups that express neither CRF receptor subtype, including the central nucleus of the amygdala, the locus coeruleus and the paraventricular nucleus of the hypothalamus. Co-injection of a CRF receptor antagonist (1, 10 or 100 µg [DPhe¹²]. Nle21,38] rCRF₁₂₋₄₁) blocked CRF-induced Fos-expression in a dose-related manner. Injection of an inactive synthetic fragment of CRF (1 µg oCRF9-33) evoked Fos induction only in periventricular regions. It remains to be determined whether the highly preferential targeting of CRF-R1 expressing neurons by icv CRF may be explained by an initial activation of periventricular structures with subsequent recruitment of receptor bearing neurons by complex neuronal pathways, or by an ability of CRF to traverse the brain-CSF barrier and access receptor-expressing cells directly. (Supported by DK-26741 and the Brazilian CNPq)

CORTICOTROPIN-RELEASING FACTOR MICROINFUSION INTO THE LOCUS COERULEUS: EFFECTS ON DISCHARGE RATE, CORTICAL NOREPINEPHRINE LEVELS AND CORTICAL ELECTROENCEPHALOGRAPHIC ACTIVITY. AL. Curtis'. S.M. Florin-Lechner, L.A. Pavcovich and R.J. Valentino, Dept. Psychiatry, Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA 19102. Corticotropin-releasing factor (CRF) administered intracerebroventricularly (i.c.v.) activates rat noradrenergic locus coeruleus (LC) neurons. The present study used a technique for microinfusing CRF into the LC from calibrated micropipettes to characterize and quantify the effects of locally administered CRF on LC discharge in halothane-anesthetized rats. CRF (3-100 ng) microinfusion into the LC increased discharge rate in a dose-dependent manner from 28 ± 8%

into the LC increased discharge rate in a dose-dependent manner from $28 \pm 8\%$ to $103 \pm 22\%$ above pre-infusion discharge rates. In contrast, microinfusion of to 103 ± 22% above pre-infusion discharge rates. In contrast, microinfusion of vehicle had no effect. The CRF dose-response curve generated by local microinfusion was parallel to, and shifted 100-fold to the left, of that generated by i.c.v. administration with an ED50 of 5 ng vs. 700 ng, respectively. Microinfusion of the CRF antagonist, DPheCRF12-41 (10 ng in 30 nl) attenuated LC activation produced by both 3 and 10 µg CRF administered i.c.v., suggesting that effects produced by i.c.v. CRF administration are primarily due to actions within the LC. In addition to increasing LC discharge rate, intracoerulear CRF (60 ng) increased norepinephrine levels in prefrontal cortex measured by *in vivo* microdialysis. Finally, LC activation produced by CRF (60 ng) microinfusion into the LC was associated with cortical electroencephalographic activation, indicated by a decrease in the amplitude of low frequency activity. Taken together with previous anatomical and electrophysiological evidence for endogenous CRF interactions in the LC, the present results support the hypothesis that CRF serves as a excitatory neurotransmitter in the LC, and suggest that its actions on LC neurons are translated to enhanced norepinephrine release and an impact on cortical targets. Supported by USPHS Grants MH40008 and MH00840.

BEHAVIOURAL EFFECTS OF UROCORTIN IN RATS. <u>D.N.C. Jones*</u>, <u>P.D. Slade</u>, <u>R. Kortekaas and J.J. Hagan</u>. Psychiatry Res., SmithKline Beechams plc, Harlow, Essex, CM19 5AW, UK.

Urocortin, a novel member of the corticotropin releasing factor (CRF) family, has recently been reported. Compared with human/rat CRF (h/rCRF), urocortin has higher affinity for CRF_1 and $CRF_{2\beta}$ receptors and greater potency to increase cAMP in cell lines expressing these receptors. Further, intravenous urocortin is a more potent inducer of ACTH release in vivo. (Vaughan et al., Nature, 378: 287-292, 1995). The present study determined the effects of urocortin, injected into the cerebral ventricles (ICV), upon motor activation and feeding in the rat, behaviours which are sensitive to h/rCRF and CRF-related peptides (Jones et al., J. Psychopharmacol., BAP Summer Meeting, 1996). In rats previously habituated to motor activity chambers (at least 2 separate exposures and 60 min habituation on the test day), urocortin (0.03-1µg ICV) dose-dependently increased total beam breaks over a 70 min period (P<0.05), eg from 855 ± 167 [means \pm SEM, vehicle (VEH)] to 1304 \pm 172 (0.3 μ g, P<0.05). In a separate experiment, rats were food deprived for 23 h and then allowed access to food for 2 h. Urocortin (0.3-10µg ICV, 15-20 min prior to food access) dose-dependently decreased the amount of food eaten (P<0.001), eg from 15.4 \pm 1.4g (VEH) to 4.5 \pm 0.5g (10 μ g, P<0.05). Further, the increase in body weight during this period was reversed by urocortin (P<0.001), eg from 6.0 ± 1.4 g (VEH) to -4.8 ± 1.3 g (10µg, P<0.05). Therefore, centrally administered urocortin caused activation and hypophagia in the rat in a similar manner to that induced by h/rCRF and other CRF-related

ANGIOTENSIN II (AII), CHOLECYSTOKININ 1-8 (CCK) AND NEUROTENSIN 8-13 (NT) MODULATE CATIONIC CONDUCTANCE IN MAGNOCELLULAR NEUROSECRETORY CELLS (MNCs) ISOLATED FROM SUPRAOPTIC NUCLEUS OF THE ADULT RAT. Yassar Chakfe* and Charles W Bourque. Centre for research in Neuroscience, Montreal General Hospital and McGill University, Montreal, Canada H3G 1A4.

Whole cell recordings were obtained from 62 isolated MNCs using pipettes containing 6 mM [Ci], 8 mM [Na¹] and 120 mM [K¹] in order to examine the effects of various neuropeptides on membrane excitability. The perfusing solution comprised 147 mM [Ci], 140 mM [Na¹] and 3 mM [K¹]. Application of the peptides (0.1-10 μM; 1-30s) produced reversible depolarization and spike discharges lasting up to 10 minutes in 22 of 24 cells tested. In the presence of TTX (.5 μM) voltage ramps applied in the presence and absence of the peptides revealed increases in membrane conductance with reversal potentials (in mV) of -37±3 (AlI; n=8), -33±3 (NT; n=6) and -35±3 (CCK; n=3). Increasing [K¹]₀ to 6 mM caused these values to shift to -15±4 (AlI; n=7), -11±4 (NT; n=7) and -8±4 (CCK; n=3). Reducing [Ci]₀ to 10 mM failed to cause a depolarizing shift in reversal potential (n=4). These results indicate that postsynaptic receptors for NT, AlI and CCK are present on MNCs of the supraoptic nucleus. Activation of these receptors induces excitatory responses through the prolonged activation of a cation permeable conductance. Supported by the M.R.C. of Canada.

WATER DEPRIVATION REGULATES AT₁ ANGIOTENSIN II RECEPTOR GENE EXPRESSION IN THE RAT SUBFORNICAL ORGAN. G.L. Sanvitto, O. Jöhren, W. Häuser and J.M. Saavedra*. Section on Pharmacology, Lab. of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

In the rat brain two pharmacological distinct Ang II receptor subtypes, AT₁ and AT₂, have been described. AT₁ receptors are involved in the regulation of fluid homeostasis and hormone release. The regulation of AT₁ receptors by water deprivation has been shown previously using binding experiments. We used semiquantitative in situ hybridization to analyze the regulation of Ang II receptor subtype gene expression in the subfornical organ (SFO), the paraventricular nucleus of the hypothalamus (PVN), and the median eminence (ME) of male rats after 1, 3, and 5 days of water deprivation. We found a significant increase of [125] Sar1-Ang II binding to AT₁ receptors in the SFO after 5 days of water deprivation which was accompanied by an increase of AT1A receptor mRNA. No changes were observed in the PVN and the ME or after 1 and 3 days of water deprivation. In no case we were able to detect AT2 or AT1B receptor mRNA in the SFO, the PVN or the ME. The present results show that after 5 days of water deprivation AT1 receptors in the SFO are up regulated at the level of gene expression and that the receptor gene involved is that of the AT_{1A} but not the AT_{1B} receptor. Circulating Ang II might contribute to regulate drinking and fluid metabolism by stimulating AT_{1A} receptor synthesis at the level of the SFO.

613.2

ANGIOTENSIN ACTS AT AT₁ RECEPTORS TO DEPOLARIZE RAT MEDIAN PREOPTIC NUCLEUS (MnPO) NEURONS.

D. Bai* and L.P. Renaud. Neuroscience, Loeb Research Institute, Ottawa Civic Hospital and University of Ottawa, Ottawa, Ontario, CANADA KIY 4E9

The MnPO, an important area for angiotensin-induced drinking behaviour, contains a high density of angiotensin binding sites. The present study used whole cell patch clamp recordings from neurons in the ventral MnPO in adult rat sagittal brain slice preparations to characterize the effects of bath applied angiotensin II (AII). In 50% of cells, AII (10-2000nM for 40s) induced a tetrodotoxin-resistant and sustained (duration>6min) membrane depolarization associated with an increase in action potential frequency. Under voltage clamp, AII induced an inward current over a voltage range of -130 to -30mV. In neurons demonstrating spike frequency adaptation, AII appeared to reduced or abolish this property. AII responses were antagonized by the AT₁ receptor antagonist Losartan (2-10µM) but not the AT₂ receptor antagonist PD123,177 (20µM). These data support a direct neuromodulator role for AII on a population of MnPO cells. Supported by MRC and the Heart & Stroke Foundation of Canada.

613.4

EXPRESSION OF ANGIOTENSIN II RECEPTOR SUBTYPES IN THE OLIVOCEREBELLAR SYSTEM OF YOUNG RATS. O. Jöhren* and J.M. Saayedra. Section on Pharmacology, Lab. of Clinical Science, National Institute for Mental Health, Bethesda, MD 20892.

Both, AT₁ and AT₂ angiotensin II receptor subtypes have been shown in the molecular layer of the cerebellar cortex in 2-week-old rats by receptor autoradiography. Within the molecular layer Purkinje cells receive two major inputs, the climbing fibers which originate from the inferior olive and the parallel fibers from cerebellar granule cells. To clarify the cellular localization of angiotensin II receptor subtypes we analyzed their gene expression in the inferior olive and cerebellum of 2-week-old rats by in situ hybridization histochemistry. Therefore, we designed 35S-labeled riboprobes complementary to specific sequences of AT_{1A}, AT_{1B}, and AT₂ receptor mRNAs. Using emulsion autoradiography we found ATIA and AT_{1B} receptor mRNA expression in Purkinje cells, but not in granule cells or in the inferior olive. No AT, receptor mRNA was detected in any layer of the cerebellar cortex. However, we found AT2 receptor mRNA in the inferior olive and in the interposed nucleus of the cerebellum. Our results suggest that within the molecular layer of the cerebellar cortex AT₃ receptors are localized on climbing fiber terminals, whereas AT₁ receptors are localized on dendrites of Purkinje cells. A role for angiotensin receptors in the postnatal establishment of the olivocerebellar connectivity is supposed.

ANGIOTENSIN II RECEPTOR SUBTYPES IN MOUSE BRAIN. W. Häuser¹, O. Jöhren¹, G.L. Sanvitto¹, T. Inagami²* and J.M. Saavedra¹, ¹Section on Pharmacology, Lab. of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892; ²Department of Biochemistry, Vanderbilt University School of Medicine, Nashville, TN 37232.

Two pharmacological distinct Ang II receptor subtypes (AT₁ and AT₂) have been shown in rat brain. In addition, the existence of additional AT₂ receptor subtypes which could be the product of two different AT2 receptor genes was proposed. To further explore Ang II receptor heterogeneity we characterized Ang II receptors in brains of control and AT₂ receptor-deficient mice by [1251]Sar1-Ang II and [1251]CGP 42112 binding experiments in the presence of receptor subtype-selective displacers. In control animals AT1 receptors were found in areas involved in the regulation of fluid homeostasis and hormone release like the subfornical organ and the paraventricular nucleus. AT2 receptors were detected in sensory and motor related areas like the superior colliculus and the inferior olive. Interestingly, AT₁ receptors were found in the caudate nucleus where no receptors are present in rats. In AT₂ receptor-deficient mice no [125] CGP 42112 binding was found indicating the absence AT₂ receptors. In the locus coeruleus which shows AT2 receptor binding in rats [1251]Sar¹-Ang II binding was detected in both control and AT₃ receptor-deficient mice. However, here [1251]Sar¹-Ang II binding was sensitive to losartan. In summary, we revealed species-specific expression of Ang II receptors subtypes in selected brain areas. In addition, we clarified that in the mouse brain AT₂ receptors are the product of only one gene.

COLOCALIZATION OF ANGIOTENSIN TYPE 2 (AT₂) RECEPTOR AND VASOPRESSIN IMMUNOREACTIVITY IN MAGNOCELLULAR NEURONS OF THE RAT HYPOTHALAMUS. L.P. Reagan⁻¹, L.M. Flanagan-Cato² and S.J. Fluharty². ¹Laboratory of Neuroendocrinology, The Rockefeller University, New York, NY 10021 and ²Depts. of Animal Biology, Psychology and the Institute of Neurological Sciences, University of Pennsylvania, Phila., PA 19104

Angiotensin II (AngII) is an important mediator of body fluid and cardiovascular homeostasis. One of the mechanisms through which Angll mediates these effects is by regulating the release of arginine vasopressin (AVP) from the magnocellular neurons of the hypothalamus. We have recently developed antisera selective for the AT, receptor subtype and have utilized these antisera to localize AT, receptor populations in rat brain via immunohistochemical techniques. Among the brain regions immunodetected by these antisera were the magnocellular neurons of the paraventricular nucleus (PVN) and supraoptic nucleus (SON). In order to determine whether AT₂ receptor protein is colocalized with AVP, AT₂ receptor immunohistochemistry was performed concurrently with immunohistochemistry for AVP in rat hypothalamus. A subset of magnocellular neurons within the SON and PVN contained both AT2 and AVP immunoreactivity. In addition, AVP negative cells clearly exhibited AT2 staining, while some AVP containing neurons had undetectable expression of AT, receptors. These results, as well as the absence of double labelling in the presence of AT2 preimmune serum, confirm the specificity of the immunostaining. Collectively, these results demonstrate that \overline{AT}_2 immunoreactivity is colocalized with AVP containing neurons in the PVN and the SON. However, the precise role which AT2 receptors play in the regulation of AngII-induced vasopressin release from the magnocellular neurons of the hypothalamus remains to be elucidated. VASOPRESSIN PATHWAYS IN THE BRAIN OF COMMON MARMOSETS (CALLITHRIX JACCHUS): STUDIES WITH IMMUNOCYTOCHEMISTRY, IN SITU HYBRIDIZATION AND RECEPTOR AUTORADIOGRAPHY. Z.X. Wang¹*, D. Toloczko¹, L.J. Young¹, K. Moody², J.D. Newman², and T.R. Insel¹.¹ Dept of Psychiatry and Behav. Sci., Emory Univ. Sch of Med., Atlanta, GA, 30322, and ²Lab. of Comp. Ethology, NICHD, NIH, Poolesville, MD 20837

Vasopressin (AVP) pathways and receptors were examined in the forebrain in male and female marmosets (Callithrix jacchus). Matched AVP immunoreactive (ir) and AVP mRNA-labeled cells were found in the paraventricular, supraoptic, and suprachiasmatic nuclei, as well as in the lateral hypothalamus and the bed nucleus of the stria terminalis (BST). No AVP cells were detected in the amygdala with either technique. In the BST, males had more AVP-positive cells than females. This sexual dimorphism did not appear to be a direct result of androgen effects as AVP cells in the BST did not colocalize with androgen receptor immunoreactivity. Although AVP-ir was evident outside of the hypothalamic-neurohypophyseal tract, the sexually dimorphic plexus of fibers in the lateral septum and lateral habenula observed in the rat brain could not be detected in the marmoset. In addition, we mapped AVP receptors with ¹²⁵I-linear-AVP a high affinity antagonist selective for V_{1a} receptors. Specific binding was highest in the nucleus accumbens, diagonal band, lateral septum, BST, hypothalamus, and amygdala. Together these studies provide a comprehensive picture of AVP pathways in the marmoset brain. Supported by MH54368 & 54554 to ZXW and P51-RR00165 to TRI.

ORIGIN OF ANGIOTENSIN II (AII) IN THE RODENT CENTRAL EXTENDED AMYGDALA (CEA). Gong-yu Yang T.S. Gray, C.D. Sigmund and M.D. Cassell. Depts. Anatomy and Internal Medicine, U. of lowa, Iowa City, IA 52242 and Dept. Cell Biol. Neurobiol. Anat., Loyola UMC, Maywood, II. 60513.

We investigated the origin of the prominent AII innervation of the rodent CEA. Lesions of the rat pontine parabrachial complex (PB) and tractotomy anterior to the PB eliminated almost all AII immunoreactivity in the CEA suggesting the PB is the major source of AII in the forebrain. Injections of HRP into the CEA retrogradely labelled numerous neurons in the PB but none were immunoreactive for AII. We speculated therefore that AII might be produced locally in the CEA from angiotensinogen (ANG) transported anterogradely by PB neurons. Because of the low expression of endogenous ANG in the rodent PB we sought to determine the localization of ANG in transgenic mice which have appropriate cell and tissue specific expression of human ANG. In situ hybridization for human ANG mRNA revealed that the cells in the PB of these transgenic mice expressing human ANG are predominantly glia. To document more fully the distribution of ANG in transgenic mice we developed several transgenic lines with a B-galactosidase reporter gene linked to the 5' flanking region of the human ANG gene. Histochemical staining confirmed the expression of human ANG inglia in the PB but demonstrated that neurons in the medial locus ceruleus, a structure that projects to the CEA, also express human ANG. We are currently undertaking retrograde tracing studies to determine if the PB or locus ceruleus provide an angiotensinogen-containing pathway to the forebrain. Supported by NIH HL48058 & HL55006.

HYPOTHALAMIC VASOPRESSIN GENE EXPRESSION IN THE INBRED POLYDIPSIC MICE. Y.Ueta, H.Yamashita, R.Nishi, M.Nomura, N.Kabashima, I.Shibuya and ¹K.Koizumi*, Dept. of Physiol., Univ. of Occup. Environ. Health, Sch. of Med., Kitakyushu, 807, Japan, ¹Dept. of Physiol., SUNY Health Sci. Ctr. at Brooklyn, NY 11203, USA

The genetically inbred polydipsic mice, STR/N strain, are characterized by extreme polydipsia without a lack of vasopressin (AVP) and its receptors. Daily water intake in the STR/N is 5 to 8 times more than that in control mice (ICR). Northern blotting analysis revealed that hypothalamic AVP gene expression in the STR/N is twice to 3 times higher than that in the ICR. Furthermore, to reveal whether abnomality of the hypothalamic AVP gene expression in the inbred polydipsic mice exist or not, AVP gene expression was examined by *in situ* hybridization histochemistry with ³⁵S-labelled oligodeoxynucleotide probe for mouse AVP. In the STR/N mice AVP gene expression level in the hypothalamic paraventricular (PVN) and supraoptic nuclei (SON) was higher than that in ICR mice. In the anteroventral parts of the PVN AVP transcripts were observed in the STR/N. In ICR mice there were few AVP transcripts in the same area of the anteroventral parts of the PVN. These results suggest that abnormal expression of AVP gene in the hypothalamus may be involved in the mechanism of polydipsia in the genetically polydipsic mice.

EFFECTS OF VASOPRESSIN ON NEURONS FROM HORIZONTAL LIMB OF THE DIAGONAL BAND OF BROCA (hDBB) IN THE RAT: IONIC MECHANISMS AND RECEPTOR PHARMACOLOGY. J.H. Jhamandas, J.C. Easaw & B.S. Jassar. Dept. of Medicine (Neurology) and Div. of Neuroscience, Univ. of Alberta, Edmonton, Alberta, Canada.

The hDBB is an important basal forebrain region that subserves a wide variety of physiological functions. Vasopressin (VP), a putative peptidergic transmitter, is localized within fibres in the hDBB and modulates glutamate-evoked neurotransmission in this region. We have recently determined that applications of VP on hDBB neurons caused either a decrease or increase in outward postsynaptic potassium currents. In this study we further characterize the mechanisms of VP's dual actions. Whole-cell patch clamp recordings were obtained from acutely dissociated hDBB neurons. Under voltage clamp conditions, bath application of VP (300 nM) resulted in a reversible decrease in outward current between -30 to +30 mV that was blocked by the application of a V_1 receptor antagonist (n=26). In some cells (n=19), VP caused an increase in outward current that was blocked by V_2 receptor antagonist. Using the application of external medium containing 0 Ca⁺⁺ and 50 μ M Cd++ or charybdotoxin (25nM) we determined that the actions of VP were mediated through blockade of a voltage-dependent Ca⁺⁺-activated potassium conductance. We also observed that application of VP did not influence calcium currents, which we recorded in these neurons using the barium ion as the charge carrier. VP may influence the excitability of hDBB neurons in a dual manner using the activation of specific receptor subtypes that share a common ionic conductance.

NEW CENTRAL NEUROPEPTIDE FF (NPFF) PROJECTIONS IN THE RAT BRAIN. K.H. Harris and J.H. Jhamandas. Department of Medicine (Neurology) and Division of Neuroscience, University of Alberta, Edmonton, Alberta, Canada.

NPFF, a morphine modulatory peptide with opioid and anti-opioid profile, has been localized within discrete central autonomic regions. NPFF projections previously described include those originating from the medial hypothalamus to the brainstem nucleus tractus solitarius (NTS) and projections from the NTS to the pontine parabrachial nucleus (PBN) In this study, we further examined patterns of connectivity of NPFF cells within the hypothalamus and the brainstem. Under pentobarbital anesthesia, rats were injected with retrogradely transported rhodamine and FITC labelled microspheres. Target sites for injections were the caudal third of the lateral PBN and within the ventrolateral medulla (VLM) just lateral to the A1/C1 catecholaminergic cell group. These brainstem sites correspond to regions containing a high density of NPFF fibres. Immunocytochemical staining revealed the presence of NPFF neurons within the NTS that project to the PBN or VLM. We also observed cells with collateral branching projections to both the PBN or VLM. Within the hypothalamus, NPFF cells were also observed to project to the PBN and We did not observe any collateral projections from the hypothalamus to these two brainstem sites. Our data provide further evidence of connectivity of NPFF neurons between central autonomic These circuits may modulate autonomic- and pain-related information within the neuraxis

613.13

EXPRESSION OF NEUROPEPTIDE FF PRECURSOR IN RAT CNS. P. Panula, M. Nieminen, A.A. Aarnisalo, M. Lintunen, T. Karhunen*, F.S. Vilim, E. Ziff, K. Karlstedt. Dept. Biology, Abo Akademi Univ., Turku, Finland, Dept. Biomed. Sci.. Univ. Helsinki, Helsinki, Finland and Dept. Biochem. HHMI NYU Med.Ctr. NY, USA.

The known neuropeptide FF (NPFF) and neuropeptide AF (NPAF) precursor contains one copy of active peptides NPFF and NPAF involved in pain, autonomic and neuroendocrine functions and memory. Antibodies against the rat NPAF-related peptide SLAAPQRFamide were applied to compare peptide distribution to the expression pattern of the precursor mRNA using in situ hybridization with cRNA and oligonucleotide probes. Hybridization signals were strongest in the nucleus of the solitary tract (nts), spinal trigeminal nucleus and superficial laminae of the spinal cord. The paraventricular and supraoptic nuclei were also reactive. Of these sites, the spinal cord, spinal trigeminal nucleus and nts displayed very strong SLAAPQRFamide immunoreactivity, whereas immunoreactivity in the supraoptic and paraventricular nuclei was limited to a few cells. A central hypothalamic nucleus between the dorsomedial and ventromedial nuclei contained a population of immunoreactive neurons after treatment with colchicine, but no hybridization signal was detected in this area in normal brain. Thus, the results suggest that at least some NPFF-like peptides involved in pain autonomic and neuroendocrine regulation are derived from the known precursor, whereas the hypothalamic cell population with known connections to the limbic system and medulla may contain NPFF-like peptides derived from a hitherto unknown necursor.

Supported by the MRC of the Academy of Finland, Sigrid Juselius Foundation and Howard Hughes Medical Institute.

613.15

PFRF-AMIDE, A POSSIBLE AGONIST FOR NEUROPEPTIDE FF, BUT A POSSIBLE ANTAGONIST FOR FMRF-AMIDE. E. Y.-K. Huang, Á. Vehovszky, J. Bagust*, R. P. Sharma, and R. J. Walker. Dept. of Physiology and Pharmacology, University of Southampton. UK, SO16 7PX.

Using an isolated preparation of rat spinal cord we have previously shown that neuropeptide FF (NPFF; mammalian FMRFamide-like peptide) potentiated the amplitude of the monosynaptic reflex (MSR) whereas FMRFamide had no effect. In the present study we have examined the action of another peptide, PFRFamide, on the rat isolated spinal cord and the buccal retractor muscle of the snail Helix aspersa. Bath applied PFRFamide was tested on spinal cords isolated from two-week old rats at concentrations of 10°8M to 10°5M. A lumbar dorsal root was stimulated at 5 times threshold and the evoked reflex recorded from the corresponding ventral root using a suction electrode. In five experiments the MSR amplitude was significantly increased (t-test) above the control values at all doses. This effect is similar to that induced by NPFF.

Conc. PFRFamide	MSR %Control	±s.e.m	Significance
10 ⁻⁸ M	116.9	5.4	p<0.05
10 ⁻⁷ M	120.4	3.3	p<0.001
10-6M	125.6	3.4	p<0.001
10-5M	123.4	9.1	p<0.05

In contrast 10-5M PFRFamide decreased the amplitude of the contraction of the pharyngeal retractor muscle of *Helix aspersa*, whereas 10-6M FMRFamide potentiated this response. These results suggest that PFRFamide may be an agonist for NPFF in mammalian systems but act as an antagonist for FMRFamide in molluscs.

PEPTIDERGIC MODULATION OF CURRENTS THROUGH CALCIUM CHANNELS IN THE HORIZONTAL LIMB OF THE DIAGONAL BAND OF BROCA (hDBB). B.S. Jassar*, K. H. Harris, J.H. Jhamandas, Dept. of Medicine (Neurology), Univ. of Alberta, Edmonton, Alberta, Canada, T6G-2S2.

Voltage-activated calcium channels (VACC) are involved in several important physiological processes. The most commonly studied VACC include L, N and T-type. These are prime targets for modulation by various chemical transmitters, especially peptides, in different neuronal types. Anatomical studies have revealed the presence of several neuropeptides, including neurotensin (NT), vasopressin (VP), neuropeptide FF (NPFF, morphine modulatory peptide), metenkephalin (met-enk) and angiotensin II, in fibres innervating the hDBB. The hDBB, a basal forebrain region is involved in memory and learning mechanisms, generation of theta rhythm and central cardiovascular regulation.

Whole cell patch clamp recordings of currents through calcium channels, from acutely dissociated rat hDBB neurons, were performed using Ba⁺⁺ as the charge carrier (I_{Ba}). ω-conotoxin (100nM) irreversibly blocked >55% of whole-cell I_{Ba} An additional 30% was blocked by 10uM nimodipine. Thus N and L-type VACC carry the majority of the I_{Ba} in hDBB neurons. We tested the actions of six different peptides agonists on I_{Ba}. Maximum currents were evoked by a voltage command to -10mV or 0mV from a holding potential of -80mV. NT decreased the peak current by 30%. Application of DAGO (5μM; a μ-receptor opioid agonist), met-enkephalin (5μM; μ and δ opioid receptor agonist) and NPFF (5μM) reduced peak I_{Ba} by 35%, 25% and 20% respectively. In contrast, VP (300-500nM) and angiotensin II (1.5μM) were completely ineffective.

These results suggest that certain neuropeptides (NT, met-enk and NPFF) modulate excitability of hDBB neurons through VACC.

NEUROPEPTIDE FF AND PROLACTIN RELEASE; IN VITRO AND IN VIVO STUDIES. <u>A.A.Aarnisalo^{1*}, M.Nieminen², R. Tuominen¹, and P.Panula², ¹Institute of Biomedicine, POB 9, University of Helsinki, Helsinki, Finland. ²Dept. of Biology, Biocity, Åbo Akademi University, Turku, Finland.</u>

Neuropeptide FF (NPFF, FLFQPQRFamide) is an opioid analgesia modulating peptide, which is found in high concentrations in the pituitary and spinal dorsal horn of the rat. NPFF-immunoreactive nerve terminals and fibers are dense in the posterior pituitary, whereas no NPFF immunoreactive structures can be seen in the anterior lobe. Specific binding sites for NPFF have been localized both in the anterior and posterior lobes. We have measured the effect of NPFF on cultured male rat anterior pituitary (AP) cells in vitro and male rats in vivo on the release of prolactin (PRL), thyroid-stimulating hormone (TSH) and growth hormone (GH). NPFF, in small nanomolar concentrations, released PRL in vitro and in vivo after intraperitoneal injections. It was more effective than TRH in vitro in cultured AP cells. NPFF had no effect on the release of GH or TSH from AP cells in vitro. One of the functions of the hypothalamo-neurohypophyseal NPFF-containing system may be regulation of the anterior lobe and release of prolactin from the lactotrophes. Our results also support the importance of multiple factors in coordinated regulation of PRL release

Supported by the MRC of the Academy of Finland and Sigrid Juselius Foundation.

PROLACTIN RELEASE FOLLOWING LUTEINIZING HORMONE RELEASING HORMONE ADMINISTRATION TO RAT ANTERIOR PITUITARY GLANDS IN VITRO. W. Bryant, J. Janik and P. Callahan*, Miami Univ, Center for Neuroscience, Dept of Zoology, Oxford, OH 45056.

The purpose of these studies was to determine whether Luteinizing Hormone Releasing Hormone (LHRH) would stimulate secretion of prolactin from female rat anterior pituitary glands using a perfusion paradigm. Low doses of LHRH were administered to anterior pituitary glands collected from cycling female rats (3-5 months old). Pituitaries were minced and one half of a pituitary was placed in individual perfusion chambers. This preparation thus allows cellular interactions in the anterior pituitary gland to remain intact. Glands were allowed to equilibrate for at least 90 minutes prior to sample collection. After equilibration, samples were collected prior to any treatment and following 1, 10 or 1000 nM LHRH added in increasing concentrations. Each treatment was followed by 30 minutes recovery before the next dose of LHRH was administered. The flow rate was 0.25 ml per minute with samples collected over 5 minute intervals. Statistical analysis was accomplished utilizing area under the curve calculations.

Administration of LHRH increased total Prolactin secretion indicating that low levels of LHRH can stimulate Prolactin secretion from mature female rat anterior pituitary glands. The role of Angiotensin II in mediating this increase is currently being investigated by pretreating with Saralasin, an All antagonist. Supported by NIH DK48023-01 to PC.

PARATHYROID HORMONE-RELATED PROTEIN (PTHrP) BOTH ENHANCES AND DEPRESSES SYNAPTIC TRANSMISSION IN THE BASOLATERAL AMYGDALA (BLA). P. Shinnick-Gallagher*, C.W. Cooper and V. Neugebauer. Dept. of Pharmacology, The University of Texas Medical Branch, Galveston, TX 77555-1031.

Parathyroid hormone-related protein (PTHrP) shares sequence homology with parathyroid hormone (PTH) at the N-terminus but, unlike PTH, does function as a classical hormone. The fragment PTHrP(1-34) but not the receptor antagonist, PTHrP(7-34), activates the recently cloned PTH/PTHrP receptor that can couple via G-protein to cyclic AMP production, phosphoinositol hydrolysis, and cytosolic Ca²+ elevation. mRNA for the PTH/PTHrP receptor has been localized in the BLA. Although mRNA for PTHrP and the PTH/PTHrP receptor have been detected in brain, physiological effects on neuronal excitability and synaptic transmission have not been reported.

Using whole-cell voltage-clamp, the effects of PTHrP(1-34) and PTHrP(7-34) on BLA neurons were examined in rat brain slices. Monosynaptic EPSCs were evoked by stimulation in the lateral amygdala. Drugs were applied by superfusion.

PTHrP(1-34) had dual effects on monosynaptic EPSCs: lower concentrations (0.1 nM) potentiated EPSCs, higher concentrations (10 nM to 10 μ M) depressed EPSCs dose-dependently (EC $_{50}$ = 12 nM). The inhibitory action was accompanied by a small outward current (10 \pm 4 pA) and an increase in slope conductance (152 \pm 20 % of predrug). PTHrP(7-34) (0.1 μ M) antagonized the potentiation, the depression, and the membrane effects evoked by PTHrP(1-34). PTHrP(7-34) itself reduced EPSCs to 83 \pm 5 % of predrug without significant membrane effects.

The data suggest that both the excitatory and inhibitory effects of PTHrP reduced in the N-terminal region and that different mechanisms may account for the dual effects. Furthermore, the PTHrP receptor may be activated intrinsically. Supported by NIH (DK 35608, NS 29265) and the Deutsche Forschungsgemeinschaft.

CATECHOLAMINES: BIOSYNTHETIC ENZYMES

614.1

PURIFICATION AND CHARACTERIZATION OF A CATECHOLAMINE BINDING PROTEIN. V.D. Nair., M. Fu., E.S. Werstiuk*., and R.K. Mishra. Depts. of Psychiatry and Biomedical Sci., McMaster University, Hamilton, Ontario, Canada L8N 325.

Catecholamine binding proteins are capable of covalently coupling to dopamine, ADTN, and NPA and do not exhibit biochemical, pharmacological, or distributions characteristics with known dopamine receptors or transporters in the CNS. These proteins are identified by using a specific ligand, 6-hydroxy-¹²⁵iodo-(N[N-2',4'-dinitrophenyl]amino-propyl)-2-amino-1,2,3,4-tetrahydronaphthalene ([126]DATN). A 40 kDa catecholamine binding protein was purified from bovine striatal membrane and characterized. The striatal membrane was labelled with IDATN and separated on SDS-PAGE. The band corresponding to 40 kDa was excised out and the protein was collected after electro elution. The radioactivity associated with the band was measured and the homogeneity of the purified protein was confirmed by iso-electric focussing. Antibody was raised in rabbits against the purified protein and used to characterize the protein to elucidate the role in catecholaminergic neurotransmission. The 40 kDa protein is distributed throughout the CNS, but absent in various other tissues examined. Catecholamine depleting agent reserpine significantly decreased the concentration of the protein in rat brain, whereas, L-DOPA increased the concentration of the protein. These findings suggests that the 40 kDa protein may play an important role in the CNS function. Supported by Medical Research Council of Canada.

REGULATION OF TYROSINE HYDROXYLASE (TH) ACTIVITY IN ATT-20 CELLS EXPRESSING WT- OR S40L-TH BY TYROSINE AND COFACTOR BH4. A.Garcia-España, K. Harada, K.Y. Lee and M. Goldstein, Neurochemistry Research Laboratory, New York University Medical Center, New York, NY 10016

We have reported that replacement of serine 40 residue in TH with leucine by site-directed mutagenesis produces a mutated enzyme (S40L-TH) with high catalytic activity (Wu et al. J. Biol. Chem. 267: 25754, 1992). To study the mechanisms involved in the activation of S40L-TH, we have analyzed the changes in the catalytic activity of the enzyme by tyrosine and by sepiapterin, which is a precursor of natural cofactor, BH4. expressing wild type (WT-TH) or S40L were preincubated in tyrosine-free medium for 60 min and subsequently incubated with several concentrations of tyrosine with or without sepiapterin (0.6mM). TH activity in situ was assessed as dopa accumulation in the presence of an aromatic amino acid decarboxylase inhibitor, NSD-1015 (50 μM). Tyrosine (0-100 μM) inhibited dopa synthesis in a dose-dependent manner in cells expressing WT-TH, but not in cells expressing S40L-TH. Sepiapterin increased dopa synthesis slightly in cells expressing WT-TH and to a greater extent in cells expressing S40L-TH (up to +550 %). These results indicate that the mutated enzyme, S40L-TH is dysregulated and its high activity might be due to greater stimulation by BH4 and lack of inhibition by tyrosine. INHIBITORY EFFECTS OF ISOQUINOLINE ALKALOIDS ON CATECHOLAMINE BIOSYNTHESIS IN PC12 CELLS. M.K. Lee*, Y.H. Zhang, I.S. Shin, S.S. Lee, and H.S. Kim, Coll. of Pharmacy, Chungbuk Natl. Univ., Cheongju 361–763, Korea.

The rat pheochromocytoma PC12 cells have many properties of the adrenal medullary chromaffin cells, including the synthesis, storage and secretion of catecholamines. Inhibitory effects of 10 kinds of isoquinoline alkaloids on catecholamine biosynthesis in PC12 cells were investigated. Among them, protoberberine (berberine, palmatine), bisbenzylisoquinoline (tetrandrine, fangchinoline), phthalide isoquinoline (noscapine, hydrastine) and aporphine (bulbocapnine) alkaloids showed inhibitory effects on dopamine biosynthesis in intracellular PC12 cells. Tyrosine hydroxylase (TH) activity was also reduced by addition of isoquinoline alkaloids in PC12 cells.

It was thought that some isoquinoline alkaloids might be able to inhibit TH activity. Therefore, this hypothesis was investigated in bovine adrenal TH using a substrate L-tyrosine. Berberine, palmatine, hydrastine and bulbocapnine showed inhibitory effects on bovine adrenal TH (35-44% inhibition at concentration of 200 µM). Berberine, palmatine and hydrastine exhibited competitive inhibition, and bulbocapnine did uncompetitive inhibition on bovine adrenal TH.

These results suggest that the inhibition on TH activity by some isoquinoline alkaloids might be partially involved in the reduction of dopamine biosynthesis in PC12 cells. The intracellular mechanisms of isoquinoline alkaloids in PC12 cells need further investigation. Supported by KOSEF 951-0711-046-2.

DOPAMINE COVALENTLY MODIFIES AND INACTIVATES TYROSINE HYDROXYLASE. Y.M. Xu, A.H. Stokes, B.A. Vogt', R.Roskoski, Jr', and K. E. Vrana. Department of Physiology and Pharmacology, Bowman Gray Sch. of Med., Winston-Salem, NC 27157-1083 and 'Department of Biochemistry and Molecular Biology, LSU Medical Center, New Orleans, LA 70119.

It has been established that dopamine can autoxidize to form the reactive dopamine quinone. This oxidation can be enhanced through the enzymatic activities of tyrosinase or prostaglandin H synthase. The reactive dopamine quinone, in turn, can covalently modify nucleophilic groups in protein and DNA. We have shown in previous studies that 3H-dopamine covalently modifies DNA and that this modification was increased by the enzyme tyrosinase. The present studies established that dopamine quinone, formed through the activity of tyrosinase, inactivates tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine biosynthesis. Co-incubation of purified TH (10µg) or crude pheochromocytoma homogenates (100-200µg protein) with dopamine (100µM) in the presence of tyrosinase (10µg/ml, 4400units/mg) resulted in a decrease in TH activity of 70% for purified enzyme and 90% for activity in crude pheochromocytoma homogenates. Moreover, inactivation was associated with covalent incorporation of radiolabelled dopamine into the enzyme as assessed by immunoprecipitation, gel filtration chromatography, and/or denaturing SDS-PAGE. Antioxidant compounds (DTT, GSH, and NADH) blocked covalent modification and inactivation. These findings suggest that there exists a third mechanism by which dopamine can inhibit TH (in addition to kinetic feedback inhibition and the formation of an inhibitory dopamine Fe+3 complex) providing further complexity in the regulation of catecholamine biosynthesis. This work was supported by USPHS grant GM38931 (to K.E.V.)

PARALLEL UPREGULATION OF CATECHOLAMINE-SYNTHESIZING ENZYMES, PAM. AND NEUROPEPTIDE Y BY SYSTEMIC NICOTINE TREATMENT IN THE RAT ADRENAL MEDULLA. T.C. Wessel*, J.W. Jahng, T.A. Houpt, and T.H. Joh. Laboratory of Molecular Neurobiology, Cornell Univ.Med.Coll. at Burke Med. Res. Inst., White Plains, NY 10605.

The expression of catecholamine (CA)-synthesizing enzymes in the adrenal

medulla is upregulated in parallel by reserpine. In this study we examined whether a neuropeptide and its processing enzyme are also regulated in parallel with CA enzyme genes after drug treatment. Because the main effect of reserpine on the medulla is via splanchnic nerve stimulation of nicotinic receptors, we used nicotine to medula is via spianennic nerve stimulation of nicotinic receptors, we used nicotine it stimulate the medulla, and visualized expression of CA enzyme genes, the medullary peptide neuropeptide Y (NPY), and the neuropeptide-processing enzyme peptidylglycine alpha-amidating monoxygenase (PAM) by in situ hybridization. Ratis received a single injection of nicotine (0, 1, or 5 mg/kg s.c.). Six hours later, nicotine-treated rats and uninjected controls were transcardially perfused (n = 3-

6/group). Adrenal glands were cut into 40 μm sections, Free-floating sections from each group together in the same vial were hybridized with ³⁵S-labeled cDNA probes for tyrosine hydroxylase (TH), dopamine beta-hydroxylase (DBH), phenylethanolamine N-methyltransferase (PNMT), PAM, and NPY. Relative optical

density of digitized adreanl medulla images was quantified using NIH image.

Nicotine treatment upregulated expression of all genes in a dose-dependent fashion (5 mg/kg > 1 mg/kg > saline > uninjected). Quantitative differences were observed in the relative induction of the different genes, however. At 1 mg/kg, induction of NPY was greatest ($160 \pm 12\%$ of saline), followed by PAM ($146 \pm 13\%$) and TH ($132 \pm 11\%$). PNMT ($121 \pm 8\%$) and DBH ($112 \pm 5\%$) induction was lowest. These results suggest that common transcriptional activation mechanisms may differentially upregulate both CA synthesis and neuropeptide processing in the adrenal medulla. (Supported in part by NIH grant MH24285)

MOLECULAR MECHANISMS UNDERLYING THE SYNERGISTIC INDUCTION OF TYROSINE HYDROXYLASE GENE EXPRESSION BY ACIDIC FIBROBLAST GROWTH FACTOR AND COACTIVATORS. Z. Guo*, N.D. Stull and L. lacovitti Dept. of Neurobiology and Anatomy, Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA. 19102

Previous studies from this laboratory have demonstrated that the catecholamine (CA) biosynthetic enzyme tyrosine hydroxylase (TH) can be induced in non-CA neurons the striatum by the synergistic interaction of acidic fibroblast growth factor (aFGF) and a number of different co-activators (dopamine, TPA, IBMX/forskolin). In the present study, we sought to determine the underlying molecular mechanisms for this novel expression by identifying the relevant cis-acting DNA sequences and transcription factors. To do so, cultures of E14 rat striatum were grown one day in culture in defined medium prior to treatment with aFGF (100ng/ml) and/or dopamine (20μM), TPA (200nM), IBMX (0.25mM)/forskolin 50μM). Sixty minutes after stimulation, cultures were harvested, nuclear extracts were prepared and analyzed by gel shift assay. We found that protein binding to the AP-1 motif of the TH gene was significantly increased by aFGF and co-activator stimulation as compared to control (media only). To further investigate the components of the AP-1 protein complex, (media only). To further investigate the components of the AP-1 protein complex, supershift assays using antibodies to specific transcription factors were performed. We found that, in controls, the AP-1 protein complex contained c-Jun, Fos B, Jun-D, ATF2 and CREM. Stimulation of the cultures by aFGF and all of the co-activators resulted in the novel recruitment of c-Fos; the increased expression of Fos B and Jun D, and decreased expression of ATF2 in the AP-1 complex. c-Jun and CREM expression remained unchanged by stimulation. aFGF and individual co-activators each contributed in specific but dissimilar fashion to the stimulated complex. We conclude that the AP-1 motif of the TH gene and the AP-1 protein complex, in particular, specific members of the Fos/Jun and CREB families (ie. c-Fos, c-Jun, Fos B, Jun-D, ATF2 and CREM) play a critical role in TH gene activation by aFGF and co-activators. It is likely that other sites on the gene and other transcription factors are also involved in TH induction. (Supported by NIH NS 24204).

614.9

CHARACTERIZATION OF THE HYPOXIA-INDUCIBLE PROTEIN COMPLEX ASSOCIATED WITH THE PYRIMIDINE-RICH REGION IN THE 3' UNTRANSLATED REGION OF TYROSINE HYDROXYLASE mRNA, M.F. Czyzyk-Krzeska and J. Lipski* Department of Molecular and Cellular Physiology, University of Cincinnati, College of Medicine, Cincinnati, OH,

Stability of mRNA for tyrosine hydroxylase (TH), the rate limiting enzyme in catecholamine synthesis, is increased (30 h half life vs 10 h) in PC12 cells during hypoxia. This increase correlates with enhanced binding of cytosolic protein factors to the UCCCCU motif in the 3' untranslated region of TH mRNA. SDS-PAGE analysis of the UV-crosslinked binding reaction revealed two major specific RNA-protein complexes of 74 kD and 53 kD. The same complexes were formed with protein extracts from PC12 cells, carotid bodies (CB), superior cervical ganglia (SCG), adrenal glands (AG) and brain. The formation of the 53 kD complex was increased when extracts were obtained from PC12 cells, CB or SCG exposed to hypoxia Formation of both complexes was completely abolished by addition of poly(C) RNA. Therefore poly(C)-RNA agarose affinity chromatography was used to isolate TH mRNA binding proteins from PC12 cells S-100 protein fraction. Protein extracts were incubated with poly(C) agarose in the binding buffer at 4°C for 1 h. Four repeats of this procedure depleted PC12 extracts of the TH mRNA binding proteins and the depleted extract did not show any binding to the TH mRNA. Bound proteins were eluted with 4 M guanidine HCl for 2 h at room temperature The eluate was sufficient to restore formation of the binding with the TH mRNA. This binding was redox dependent and could be abolished by treatment with diamide. The work is in progress to further identify the TH mRNA binding proteins enriched by poly(C) agarose affinity purification

REMOVAL OF THE SUCKLING STIMULUS RAPIDLY INCREASES EXPRESSION OF TYROSINE HYDROXYLASE AND SYNTHESIS OF ITS PROTEIN K.A. Berghorn*, S.Y. Pharrams and G.E. Hoffman. Department of Neurobiology, University of Pittsburgh, Pittsburgh, PA, 15261.

Previous studies from our laboratory had described the suppression of tyrosine hydroxylase (TH) gene expression in neurons of the arcuate nucleus (Arc) in lactating animals and its upregulation following pup removal. Using biotin labeled riboprobes with in situ hybridization (ISH) immunocytochemistry (ICC), we demonstrated increases in both nuclear and cytoplasmic TH RNA as early as 6 h after pup removal, raising the question of when RNA levels first rise, and when TH protein expression increases. Lactating rats were perfused at 90 min - 48h following pup removal. The pattern of change in TH mRNA levels in lactating rats nursing 8 pups and following pup removal were detected using ISH with a biotin labeled TH riboprobe. After hybridization, biotin was detected with anti-biotin followed by ABC immunoperoxidase staining. To assess TH protein levels, separate groups of animals were decapitated and the median eminence was dissected; protein from tissue homogenates was assayed with Western blots. Arc TH mRNA levels in the lactating animals nursing their pups were at or below the limit of detection; within the first 3 h after pup removal. levels of TH mRNA in the arcuate nucleus were increased in both the nucleus and cytoplasm. These rose to a maximum 12-24 h after pun removal. Western blots revealed an increase in TH protein first detected at 90 min after pup removal that continued to rise over the next 24 h. These data indicate that the reestablishment of TH synthesis after the suckling stimulus ceases enables rapid re-establishment of dopamine's synthetic capacity.

EFFECTS OF CHRONIC PRENATAL HYPOXIA ON TH AND PNMT mRNA AND PROTEIN LEVELS IN MEDULLA OBLONGATA OF POSTNATAL RAT_L.D.White*,E.E.Lawson_ Dept. of Pediatrics, UNC-CH

Our laboratory has demonstrated that the first two weeks of postnatal life are important for development of the respiratory neurons of the medulla oblongata (Resp. Physiol. 98:123). A subset of these neurons is catecholaminergic as evidenced by expression of the enzymes tyrosine hydroxylase (TH) and phenylethanolamine N-methyltransferase (PNMT) Perinatal chronic hypoxia caused increased TH expression in respiratory neurons and decreased PNMT expression in dorsal respiratory regions (Soc. Neurosci. Abstr. 233.8). To characterize the effects of prenatal hypoxia on subsequent TH and PNMT gene and protein expression, pregnant rats were placed in moderate hypoxia (10% O₂) from gestational day 18 until birth. Northern and Western analyses of dorsal (C2/A2 cells) and ventral (C1/A1 cells) medullary tissue of P0, P3, P7, P10 and P14 pups then examined changes in TH and PNMT mRNA and protein compared to normoxia-reared controls. Prenatally hypoxic animals had lower levels of TH mRNA and protein at birth in dorsal medulla and higher levels of TH mRNA and protein the first postnatal week in ventral medulla compared to controls. Further, hypoxic animals had significantly lower levels of PNMT protein at P10 in dorsal medulla than controls. Altered levels of . catecholamine (CAT)-synthesizing enzymes in response to hypoxia may later be manifest by changes in function as these neurons continue to mature. Prenatally hypoxic animals may be less able to respond to an acute hypoxic challenge during early postnatal life because of altered levels of CATS. Hence, the subset of CAT neurons involved in respiratory control have the potential to be involved early postnatal respiratory dysfunction such as SIDS, congenital alveolar hypoventilation syndrome or infantile apnea. NIH Grant HL34919

CYTIDINE-RICH PROTEIN-BINDING SEQUENCE IN THE UNTRANSLATED REGION OF TYROSINE HYDROXYLASE mRNA AS A DETERMINANT OF THE TH mRNA STABILITY. J.E. Beresh & M.F. Czyzyk-Krzeska* Department of Molecular and Cellular Physiology, University of Cincinnati, College of Medicine, Cincinnati, OH, 45267-0576.

During exposure of PC12 cells to hypoxia the half-life of tyrosine hydroxylase (TH) mRNA increases from 10 to 30 h (JBC, 269, 760-4, 1994). This increase is associated with augmented binding of protein factors to the conserved 27 base long, pyrimidine-rich sequence located between bases 1552-1578 in the 3' untranslated region of the TH mRNA (JBC, 269, 9940-5, 1994). We further identified that the optimal hypoxia inducible protein binding site (HIPBS) is represented by the motif $(U/C)(C/U)\underline{CC}CU$, where the core binding site is indicated by underlined cytidines. Substitutions of either one of these cytidines with purine or uridine abolished protein binding (JBC, 271, 3293-9, 1996). In order to study whether the HIPBS regulates TH mRNA stability we have developed stably transfected PC12 cell lines that express wild type or mutated within the HIPBS TH mRNAs under control of the CMV promoter. This transfected TH mRNA is by 30 bases longer in the 5' untranslated end than the endogenously expressed TH mRNA. Thus both TH mRNAs can be detected using RNase protection assay with the riboprobe against the 5' region of mRNA. The stability of the transfected wild type TH mRNA is regulated during normoxia and hypoxia in the same manner as of the endogenous TH mRNA. However, mutations within the HIPBS that eliminate protein binding, destabilize the transfected TH mRNA and abolish regulation of its stability during hypoxia. These results indicate that the cytidinerich HIPBS is a determinant of TH mRNA stability in PC12 cells (Supported by: NIH grant HL 51078, AHA Grant-in Aid 94017440, NARSAD

Young Investigator Award; MFC-K is recipient of Parker B. Francis fellowship)

REGULATION OF TYROSINE HYDROXYLASE GENE EXPRESSION BY cAMP AND PHORBOL ESTER IS MEDIATED BY CREB. K.M. Piech* and A.W. Tank. Department of Pharmacology, University of Rochester, Rochester NY 14642.

Tyrosine hydroxylase (TH) gene expression is induced after activation of protein kinase A (PKA) or protein kinase C (PKC) signalling pathways. Previous data suggest that PKA or PKC mediated induction of TH gene expression is dependent on the cAMP-responsive element (CRE)(-45 to -38) in the TH gene promoter, but it is not known which transcription factors elicit these responses. To determine whether the cAMP response element binding protein (CREB) is involved in regulation of TH gene expression, clonal cultures of PC12 cells that were stably transfected with CREB antisense RNA were generated. CREB levels are decreased dramatically in these antisense CREB RNAexpressing PC12 cell lines.

Control PC12 cell cultures or those with diminished CREB were transiently transfected with a TH-CAT reporter gene construct and later incubated with a cAMP analog, phorbol ester or calcium ionophore. The cAMP inducibility of TH-CAT was dramatically decreased in cells expressing antisense CREB RNA Interestingly, the PKC mediated induction of TH promoter activity in these cells was also decreased. However, the calcium-mediated induction of TH promoter activity was not diminished. Presumably, the loss of PKA and PKC mediated inducibility of TH-CAT results from a decreased interaction of CREB with the TH-CRE or from the diminished expression of CREB-regulated transcription factors. Western blotting indicates that fos family members are still inducible in the CREB diminished cell lines. These data suggest that CREB is an essential factor in PKA and PKC-mediated activation of TH gene expression. (Supported by NIDA grants 05014 and 07232 and STRC grant 0481.)

ALTERNATIVE PROMOTER USAGE OF THE MOUSE AROMATIC L-AMINO ACID DECARBOXYLASE (AADC) GENE. Bruno Conti*, Jeong Won Jahng, Marco Belloni and Tong H. Joh, Laboratory of Molecular Neurobiology, Cornell University Medical College at the M. W. Burke Medical Research Institute, White Plains, NY 10605

Our previous studies of rat AADC gene structure showed that (1) rat AADC is encoded by a single gene; (2) both alternative promoter usage and differential splicing account for neuronal and non-neuronal specific expression of the gene; (3) there are two alternatively utilized splicing acceptor sites in exon 2; and (4) exon 1a is localized in non-neutonal cells and exon 1b in neuronal cells as shown by in situ hybridization. The present studies examined the presence of exons 1 and 2 in mouse

AADC gene and their pattern of differential transcription.
Using 5' primers specific for either rat exon 1a or 1b and a 3' primer specific for rat exon 2, we identified exon 1a and exon 1b of the mouse AADC gene by RT-PCR. Exon 1a was isolated from liver and exon 1b from substantia nigra RNAs. The mouse nucleotide sequence of exons 1 and 2 were nearly identical to the rat. However, the splicing acceptor site in exon 2 was the same in both mouse transcripts.

Thus, the present results indicate that, unlike the rat gene, no evidence exists for differential splicing in tissue specific expression of the mouse AADC gene. Alternative promoter usage alone likely accounts for mouse AADC mRNA processing in neuronal and non-neuronal cells. (Supported by NIH grant MH24285 to THJ)

614.15

INVESTIGATION OF TRANSCRIPTION FACTORS WHICH MAY BE INVOLVED IN REGULATION OF DOPAMINE β -HYDROXYLASE EXPRESSION IN PC12 CELLS AND ADRENAL MEDULLA. B. Nankova, B. Hiremagalur*, L. Serova and E.L. Sabban. Dept. Biochem. & Mol. Bio. New York Med. Coll., Valhalla, NY 10595.

Dopamine β -hydroxylase (DBH) mRNA levels are regulated by various stimuli in vivo in rat adrenal medulla (AM), such as repeated immobilization stress (IMO) and in PC12 cells by elevated cAMP. Binding to the DBH1 enhancer (-175 to -145) of nuclear extracts from PC12 cells with relatively high, or barely detectable levels of nuclear extracts from PC12 cents with relatively migh, or oralety detectable levels of DBH expression, at least 4 (as opposed to 2 in AM) specific complexes were identified. The pattern was unchanged by 8-bromo cAMP. One of these complexes. absent in AM, was identified as an ATF-1/α-jun heterodimer. Although DBH1 is reportedly essential in cAMP-induced DBH transcription in PC12 cells, it did not bind CREB in any of the extracts. Extending the oligonucleotide to include the distal CRE-like element (-184 to -145) did not yield additional complexes. These results suggest that increased expression of DBH in response to cAMP analogs is unlikely to be mediated by phosphorylation of CREB and probably involves other

transcription factors, perhaps ATF-1.

In AM, nuclear run-on assays revealed that IMO raised DBH transcription. Increased binding of AP1-like factors to DBH1 was observed with extracts from IMO animals. Our data revealed that proteins other than c-fos, fos B, Fra-1 or c-jun are involved in this complex. No CREB, ATF1 or YY1-immunoreactive proteins were found to be bound to DBH1. Taken together, our results suggest that CREB, ATF1 and YY1 are unlikely to be directly involved in the transcriptional activation of DBH by stress. Western blot analysis of the induction of immediate early genes by single and repeated IMO in AM suggest that jun-family members and other fos-related proteins may mediate increased expression of DBH elicited by IMO (Supported by NIH grants NS32166 and NS 28869).

TRANSGENIC EXPRESSION OF THE CRE RECOMBINASE IN THE MOUSE CNS. P.J. Cox, M. Hamon and B. Giros*. INSERM U-288, 91, Bd. de l'Hôpital, 75013 Paris, France.

INSERM U-288, 91, Bd. de l'Hôpital, 75013 Paris, France.

Transgenic 'knock-out' technology, i.e. the deletion of a specific gene of interest from the mouse genome, has revolutionized the study of gene/protein function. The technology although demanding has lead to many significant discoveries in a variety of disciplines including neurobiology. The major drawbacks of targeted gene deletion are:

1. the production of mice which are homozygote for the gene deletion whose survival rate precludes meaningful studies e.g. many knock-out animals do not survive beyond embryogenesis.

2. the original technology results in the deletion of a gene in all tissues which can give rise to the situation described in point one or to pleiotropic effects which complicate the interpretation of phenotype especially with regard to gene function in specific tissues.

A recent development in gene targeting technology is the use of the Crelox system which should allow the confinement of gene deletion to specific tissues, assuming tissue specific promoters are available to direct tissue specific expression of the Cre recombinase. The activity of the Cre-lox system within the CNS has not been determined. This poster describes the expression of the Cre recombinase under the control of a CNS specific expression of the Cre recombinase under the control of a CNS specific promoter and the assessment of the Cre-lox system as a method for deletion

of genes specifically within the CNS.

Concomitant with our research interests in dopaminergic systems and the Concomitant with our research interests in dopaminergic systems and time development of new animal models with perturbations in these systems, we have developed a line of transgenic mice expressing the Cre recombinase under the control of the Tyrosine Hydroxylase promoter. Breeding of these mice with mice containing a floxed \$\Gamma_GAl/CAT\$ transgene should allow the demonstration of Cre recombinase activity in the CNS.

NEONATAL LETHALITY OF PUPS BORN TO DBH-DEFICIENT MICE MAY BE DUE TO A DEFICIT IN MATERNAL BEHAVIOR. S. A. Thomas, N. M. Nathanson*, and R. D. Palmiter. Howard Hughes Med. Inst., Dept. of Biochemistry, Univ. of WA, Seattle, WA 98195

Using gene-targeting, we created mice deficient in the enzyme dopamine \(\beta\)-hydroxylase (DBH), which converts dopamine (DA) into norepinephrine (NE). The majority of pups (DBH +/-) born to females homozygous for the disruption (DBH -/-) die within several days after birth. Neonatal lethality is rare when the female is DBH +/-. In about 50% of the litters, pups are scattered within the bedding, suggesting that there may be a deficit in maternal behavior. However, this abandonment could be secondary to defects in the pups. To test whether the primary deficit resides in the DBH -/- females or their neonates, pups born to DBH -/and DBH +/- females were cross-fostered to the female with the other genotype within 24 hours of birth. To our surprise, 10 of 12 litters were successfully raised by the DBH +/- females, and 11 of 12 litters were successfully raised by the DBH -/- females. These results demonstrate that DBH -/- females can nurse, and suggest that an important interaction occurs between dam and neonate during the first 24 hours. To address who harbors the primary deficit, we are testing whether restoration of NE in DBH -/- females shortly after birth will enhance neonatal survival. In conclusion, maternal NE released during birth may promote maternal behaviors that enhance appropriate neonatal behaviors such as nursing

This work was supported by NIH grant HD 09172 and HHMI.

OVEREXPRESSION OF BCL-2 CAUSES WEIGHT GAIN AND ADRENAL HYPERTROPHY IN DBH-BCL-2 TRANSGENIC MICE. J.W. Jahng*, T.H. Joh, C.H. Peng, E.S. Corp, T.A. Houpt, and J.H. Son, Laboratory of Molecular Neurobiology and Bourne Behav. Res. Lab., Cornell Univ. Med. Coll. at the Burke Med. Res. Inst., White Plains, NY, 10605.

Noradrenergic (NA) and adrenergic (A) cells in the locus ceruleus, brainstem, and adrenal gland (identified by dopamine B-hydroxylase (DBH) expression) play key detering gaint (included by oppaning 5) and the proposition of a 4.2kb human DBH promoter. The cytoplasmic protein Bel-2 can partially rescue cells from proposition of a 4.2kb human DBH promoter. The cytoplasmic protein Bel-2 can partially rescue cells from developmental cell death, we made DBH-Bel-2 transgenic mice with human Bel-2 expression under the direction of a 4.2kb human DBH promoter. The cytoplasmic protein Bel-2 can partially rescue cells from respective death, in with a few first in this care and trall known as the proposition belongs to the proposition of the protein bel-2 can partially rescue cells from the proposition of the protein belongs and the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protein belongs and the protein belongs are the protei

apoptotic death in vitro, but its effects in vivo are not well-known.

Mice from 3 representative transgenic lines and wildtype littermates were transcardially perfused (n=5 pr/line). Overexpression of Bcl-2 was localized in the brain and adrenal gland by in situ hybridization. Body weight, body length, and

adrenal gland weight were measured. Fat pad size was qualitatively rated. Total volumes of adrenal glands were measured by $40\,\mu$ serial section reconstruction. Different levels of Bcl-2 mRNA were detected in the adrenal medulla, locus ceruleus, cortex, and hippocampus in all 3 transgenic lines, and at very low levels in the substantia nigra. No Bcl-2 expression was observed in wildtype controls. Body weight (but not length), fat pad size, and adrenal gland weight and volume varied weight (but not region), rat post soft and adrenal grand weight and votime varies with the level of Bcl-2 expression in the adrenal medulla within each line. Bcl-2 may have rescued adrenal gland cells from apoptotic cell death during development. Bcl-2 overexpression also appears to increase body weight and fat mass. These behavioral and physiological effects may be due to increased neuromodulatory and hormonal function of enlarged NA and A populations in both brain and periphery (Supported in part by NIH grant MH24285)

NOVEL CHARGE FORMS OF PNMT ASSOCIATED WITH DECREASED PNMT ACTIVITY. J.K. Stewart*, R.M. White, J.L. Andreassi, T.D. Gbadebo, and L.M. Kim. Dept. of Biology, Virginia Commonwealth Univ., Richmond, VA 23284-2012.

Recently we detected two closely migrating forms of rat PNMT on both Western blots and

blots of non-denaturing polyacrylamide gels. blots of non-denaturing polyacrylamide gels. In the present study we examined the electrophoretic pattern of adrenal PNMT extracted from male Sprague Dawley rats, weighing 210 - 270 g, maintained under constant conditions in our laboratory for 10 days. In 14 adrenal samples with unusually low PNMT activity (less than 50 pmol/ mg protein x 30 min), both forms of PNMT migrated more slowly on non-denaturing gels migrated more slowly on non-denaturing gels (a positive shift in charge) compared to the migration of PNMT in 26 adrenal samples with higher PNMT activity (100 - 500 pmol/mg protein x 30 min). Furthermore, in the high activity samples, 3 - 4 closely migrating charge forms of PNMT were observed, whereas only 2 charge forms were observed in low activity samples. These findings suggest that decreased PNMT activity is associated with modification of the PNMT protein. Supported by NIH Grant NS-26992.

GLUCORTICOID INDUCED-AP-2 CONTROL OF THE PHENYLETHANOL-AMINE N-METHYLTRANSFERASE GENE, D.L. Wong*, M.B. Ficklin and S.N. Ebert. Dept. Psych. and Beh. Sci., Stanford Univ. Sch. Med., Stanford, CA

The transcription factor AP-2 is important for differentiation of neural crestderived tissues. In RS1 cells, a cell line established from the rat adrenal medulla, a tissue of neural crest origin, AP-2 can induce phenylethanolamine N-methyltransferase (PNMT) gene expression, but only in the presence of glucocorticoids (GC) as demonstrated by transient transfection assays with a PNMT promoter-luciferase reporter gene construct (pRP863LUC) and AP-2 expression constructs. <u>In vitro</u> footprinting and consensus binding sequence identity suggest that within the proximal 863 bp of upstream PNMT promoterregulatory sequences are three potential AP-2 binding sites (-648, -576 and -100 bp upstream of the site of transcription initiation, +1). A glucocorticoid response element (GRE) is located at -513 bp. When the AP-2 binding sites and GRE are deleted, AP-2/GC activation does not occur. In addition, site-directed mutagenesis of the AP-2 sites and GRE causes a marked reduction in AP-2/GC-stimulated PNMT promoter activity. AP-2/GC induction of the PNMT promoter requires activation of a type I glucocorticoid receptor (GR) as demonstrated using the type I and type II GR agonists and antagonists, dexamethasone, corticosterone, RU28362, aldosterone and RU38486. AP-2 protein is present in RS1 cell nuclei under conditions of AP-2/GC-mediated PNMT promoter activiation. In addition, the combination of AP-2 and GCs stimulates endogenous PNMT mRNA expression. These results suggest that AP-2 may be important in PNMT gene regulation and adrenal chromaffin cell differentiation, but it requires interaction with an activated glucocorticoid receptor for transcriptional activation to occur. (Support: NIDDK 51025, Nancy Pritzker and Gray Endowments, Gerschel Charitable Trust)

HIGHLY SELECTIVE INHIBITORS OF PHENYLETHANOL-AMINE N-METHYLTRANSFERASE. G. L. Grunewald*, T. M. Caldwell, K. R. Criscione, V. H. Dahanukar, R. K. Jalluri, M. Slavica. Department of Medicinal Chemistry, University of Kansas, Lawrence, KS 66045.

Phenylethanolamine N-methyltransferase (PNMT) is the enzyme involved in the conversion of norepinephrine to epinephrine. In order to probe the role of epinephrine in the central nervous system, a potent and selective inhibitor of PNMT is desired. We will present data on a new compound which shows the highest PNMT selectivity thus far obtained. 3-Hydroxymethyl-7-aminosulfonyl-1,2,3,4tetrahydroisoquinoline shows good PNMT inhibitory activity (PNMT tetranydroisoquinoine snows good PiMT1 ininiotory activity (PiMT) $K_1 = 0.342 \, \mu\text{M}$), while being much less active at the α_2 -adrenoceptor ($\alpha_2 \, K_1 = 1400 \, \mu\text{M}$) giving a highly selective compound ($\alpha_2 / P\text{NMT} = 4100$). However, this compound is too hydrophilic to penetrate the blood-brain barrier (calculated log P = -1.01). New analogues—designed using molecular modeling methods—with enhanced likelihood of entering the CNS and retaining a high degree of selectivity ($\alpha_2 / P\text{NMT}$), along with preliminary data on blood-brain barrier restriction will be averaged a Scapend by NIM M 24103 barrier penetration will be presented. Sponsored by NIH HL34193.

OTHER NEUROTRANSMITTERS

CANNABINOIDS INHIBIT VOLTAGE-DEPENDENT CALCIUM CHANNELS IN CULTURED HIPPOCAMPAL NEURONS.

W. A. Twitchell* and K. P. Mackie. Departments of Anesthesiology and Physiology and Biophysics, Box 356540, University of Washington School of Medicine, Seattle WA 98195-6540.

INTRODUCTION: Cannabinoids and their analogs have been found to inhibit N and P/Q type Ca²+ currents in cell lines and sympathetic neurons. However, the effects of cannabinoids on Ca²- currents in the CNS are largely unexplored. In this study we have investigated if these compounds and sympathetic neurons inhibit Ca²+ currents in cultured rat hippocampal neurons. hippocampal neurons.

nippocampai neurons.

RESULTS: Using patch clamp electrophysiology we found that most pyramidally-shaped cells exhibited large Ba²⁺ currents (250-600 pA) that were inhibited by both 1 µM 2-chloroadenosine and 50 µM baclofen and were abolished by application of 100 µM Cd²⁺. 100 nM WIN 55,212-2 reversibly inhibited this current by 27±2% (n=10, mean±sem) in a voltagereversibly inhibited this current by 2/42% (n=10, meantsem) in a voltage-dependent, pertussis toxin-sensitive and concentration-dependent (Ki2 = -30 nM) fashion. The current was not significantly effected by WIN 55,212-3 (100 nM). Maximal inhibition by the non-classical cannabinoid agonist. CP 55,940, was similar to that seen with maximal concentrations of WIN 55,212-2. The Ba²⁺ current we measured was carried by several types of Ca²⁺ channels. Of these, P/Q-(mCTX-MVIIC sensitive) and N-type (mCTX-GVIA sensitive) channels appeared to be the ones chiefly modulated by WIN 55,212-2.

DISCUSSION: These results extend to central neurons previous results demonstrating cannabinoid receptor-mediated inhibition of distinct Ca²⁺ currents. As the channels which underlie these currents are chiefly located presynaptically, and are required for evoked neurotransmitter release, our results suggest a major role for cannabinoids (endogenous and exogenous) in the modulation of transmitter release at selected CNS synapses. ASSOCIATION BETWEEN THE CANNABINOID RECEPTOR GENE AND EEG AUDITORY EVOKED POTENTIALS IN SUBSTANCE ABUSERS. J. P. Johnson*, D. Muhleman, J. P. MacMurray, E. R. Verde, M. N. Ask, J. T. Kelly and D. E. Comings. Jerry L. Pettis Memorial VA Medical Center, Loma Linda, CA 92357

EEG activity is one of the most heritable characteristics in humans. Therefore, genetic markers for receptor systems implicated in the neural generation of brain evoked potentials are ideal candidates for study of the genetic basis of the EEG. Others have suggested that cannabinoid receptors in the hippocampus mediate working memory, and the recent identification of a tri-nucleotide repeat gene for the cannabinoid receptor gene (CNR1) allowed us to examine its association with brain evoked potentials in a study of 34 abstinent non-hispanic white substance abusers. The EEG was recorded on a QSI-9000 computerized EEG with an Electro-cap using the 10-20 system of electrode placement using an auditory "oddball" paradigm. Subjects homozygous for the high molecular weight alleles of the CNR1 gene had significantly reduced P300 amplitudes recorded at Fz, Cz, and Pz ($p \le 0.01$) and delayed P300 latency at Pz ($p \le 0.05$) compared to those individuals with low molecular weight alleles

FUNCTIONAL COUPLING OF RAT AND HUMAN CB1 CANNABINOID RECEPTORS. F. Petitet, B. Jeantaud, E. Heuillet, F. Perrot, M. Capet, P. Bertrand* and A. Doble. Rhône Poulenc Rorer, Neurochemistry Dept., CRVA, 13 quai Jules Guesde, Vitry sur Seine, France

The major psychoactive component of Cannabis sativa, Δ^9 -tetrahydrocannabinol (Δ^9 -THC), as well as the putative endogenous ligand for the cannabinoid receptor, anandamide, mediate their effects via specific G protein-coupled receptors. Two cannabinoid receptors have been cloned from rat and human tissues. The CB₁ receptor is expressed mainly in the brain while the CB₂ receptor is coalized exclusively in peripheral tissues. Using autoradiography, we have demonstrated that binding sites labelled by an agonist (${}^{1}^{1}$ HJWIN55212-2) and an antagonist (${}^{1}^{1}$ HJSR141716A) have the same localization in rat brain. ${}^{1}^{1}$ HJWIN55212-2 and ${}^{1}^{1}$ HJSR141716A binding sites, studied on rat cerebellar membranes, have similar pharmacological pattern. The affinities of the antagonist SR141716A and the agonist WIN55212-2 were shown to be the highest, while anandamide, Δ^9 -THC or 11-hydroxy- Δ^9 -THC had moderate affinities. WIN55212-2 (1 μ M) enhanced (+ 80 %) the binding of [35 S]GTP- γ -S on rat cerebellar membranes whilst SR141716A, devoid of activity by itself, antagonized the action of WIN55212-2. In two human preparations; the astrocytoma cell line U373MG and CHO-CB₁ transfected cells there was also a correlation between binding affinities and activities (determined by [35 S]GTP- γ -S binding and cAMP measurement) of natural and synthetic cannabinoids.

EFFECT OF 2-(2-BENZO-FURANYL)-2-IMIDAZOLINE ON LOCUS COERULEUS AND DORSAL RAPHE NEURONAL ACTIVITY IN RATS. L. Ugedo*, J.A. Ruiz-Ortega, R.Martín-Ruiz. Dept. of Pharmacology, Fac. of Medicine, Univ. of the Basque Country, E-48940 Leioa, Vizcaya, Spain.

Binding studies have shown that 2-(2-benzo-furanyl)-2-imidazoline (2-BFI) is a highly selective I₂-imidazoline receptor ligand (Nutt *et al.*, Ann. N.Y. Acad. Sci. 763: 125-139, 1995), and that a remarcable density of I₂-imidazoline receptors exists in locus coeruleus and dorsal raphe nuclei (MacKinnon *et al.*, Br. J. Pharmacol., 116: 1729-1736, 1995). In order to investigate a possible I₂-imidazoline receptor-mediated functional response, the effect of 2-BFI was assessed on locus coeruleus and dorsal raphe neurons using single-unit extracellular recordings in anesthetized rats. In locus coeruleus neurons local (36 pmoles) and systemic (1 mg/kg i.v.) administrations of 2-BFI increased the firing rate by 20% and 23% respectively; clonidine dose-response curve was not modified after 2-BFI indicating that this effect was not mediated by α_2 -adrenoceptors. In dorsal raphe neurons local (67 pmoles) and systemic (1 mg/kg i.v.) administration of 2-BFI decreased the firing rate by a 30% and a 27% respectively. These results suggest that 2-BFI has a neuromodulatory action in central nervous system which migh be mediated by 1_2 -imidazoline receptors.

SOLUBILIZATION AND CHARACTERIZATION OF A [³H]CORTICOSTERONE MEMBRANE RECEPTOR FROM AMPHIBIAN BRAIN. Simon J. Evans, Frank L. Moore and Thomas F. Murray. College of Pharmacy, Zoology Department and Molecular and Cellular Biology Program, Oregon State University, Corvallis OR, 97331.

Alternative to the classical action of steroid hormones acting as nuclear transcription factors a great deal of evidence exists for plasma membrane receptors for many members of the steroid hormone family. Evidence includes modulation of Ca^{2+} currents by estradiol and allopregnenalone in rat brain. Also suppression of K^+ currents by estrogen and Ca^{2+} currents by cortisol⁴ has been shown in guinea pig brain. Progesterone has been shown to bind with high affinity to Xenopus oocyte membranes⁵. In addition to these reports a membrane corticosterone receptor from newt (Taricha granulosa) brains has been pharmacologically characterized and correlated with inhibition of sexual behavior by Orchinik et al in 1992⁶. We have extended this research with solubilization of the membrane corticosterone receptor using non-ionic detergents and further characterized radioligand interactions with the soluble form. Using this system we obtain >50% yield of binding sites with 2 fold enrichment of the receptor relative to total protein concentrations. Solubilization of the [3H]corticosterone receptor will facilitate further characterization of the protein and perhaps enhance understanding of the membrane action of steroid hormones. CONCURRENT STIMULATION OF CANNABINOID CB1 AND DOPAMINE D2 RECEPTORS RESULTS IN AN AUGMENTATION OF FORSKOLIN STIMULATED CAMP ACCUMULATION IN STRIATAL NEURONS. M. Glass* and C.C. Felder. Laboratory of Cell Biology, National Institute of Mental Health. Bethesda 20892, MD, USA.

It is well established that cannabinoids act at the CB1 receptor to inhibit forskolin stimulated adenylate cyclase activity. This inhibition can be blocked by pertussis toxin, suggesting that it is mediated by a Git/Go type of GTP-binding protein. Previously we have demonstrated that treatment with pertussis toxin blocked the anandamide mediated inhibition of adenylate cyclase, and unmasked a stimulatory effect of anandamide on cAMP accumulation. The anandamide mediated accumulation of 6AMP could be blocked in a dose dependent manner by CB1 receptor antagonists LY320135 and SR141716A suggesting that the stimulatory response is regulated through the CB1 receptor. CB1 receptors have been demonstrated to be co-localized with dopamine D2 receptors within the striatum. In this study we have examined the interactions between these two receptors. In striatal neurons in primary culture both the CB1 agonist HU210 and the D2 agonist quinpirole inhibited forskolin stimulation of cAMP accumulation. In contrast, HU210 and quinpirole in combination resulted in an augmentation of cAMP accumulation. This augmentation was blocked by SR141716A. These results suggest that utilization of the Gi-mediated pathway by either pertussis toxin or agonist stimulation permits the unmasking of a stimulatory pathway coupled to the CB1 receptor.

LOCALIZATION OF MRNA AND PROTEIN OF GLUCOCORTICOID RECEPTOR IN RAT CENTRAL NERVOUS SYSTEM. H. Ozawa, M. Morimoto , N. Morita* and M. Kawata . Department of Anatomy and Neurobiology, Kyoto Prefectural University of Medicine. Kawaramachi-Hirokoji, Kamigyoku, Kyoto 602, JAPAN

It is recognized that the glucocorticoid plays an important role in the development, the differentiation and the functional activity of the nervous system. The effects of glucocorticoids are mediated by the glucocorticoid receptor (GR).

In this study, the cellular localization of GRmRNA and GR immunoreactivity in the adult rat brain was studied by in situ hybridization and immunocytochemistry.

The expression of GR mRNA was detected in the cytoplasm of

The expression of GR mRNA was detected in the cytoplasm of neurons and observed in the various regions of the rat brain, especially in the hippocampus, the thalamus, hypothalamus, the cerebral cortex. The distributional pattern of GR-immunoreactive cells was well-correlated with that of GR mRNA-containing cells, but in the hippocampus (CA3/CA4) discrepancy of the distribution of mRNAs and immunoreactivities.

Immunoelectron microscopy revealed that the immunoreactivity of GR was mainly localized in the nuclei of cells in the central nervous system. Small amount of GR immunoreactivity was also observed in the cytoplasm, particularly in the periphery of rough endoplasmic reticulum.

cytoplasm, particularly in the periphery of rough endoplasmic reticulum.

These results suggest that glucocorticod and its receptor are deeply related to the development and function of cells in the central nervous system.

IMMUNOCYTOCHEMICAL STUDY ON CALBINDIN D-28KA IN THE COCHLEAR NUCLEUS OF MIDBRAIN OF THE CHINCHILLA.

J.J. Kim*, Y.Y. Chung, I.Y. Chang, J.S. Moon and H.J. Kim.Dept. of Anat., Chosun Univ., Med. College 375 Suh-Seek Dong, Dong Ku Kwang Ju, Korea. 501-759.

This paper describes the distribution of structures stained with mono - and polyclonal antibo-

This paper describes the distribution of structures stained with mono - and polyclonal antibodies to the calcium-binding proteins calbindin D-28Ka in the cochlear nucleus of midbrain in the chinchilla.

Calbindin D-28Ka immunoreactivity was preferentially located in the dorsal cochlear nucleus with occational examples being present in the ventral cochlear nucleus, as well as in adjacent brain stem locations.

Calbindin D-28Ka immunoreactive neurons are of very varied morphology: bitufted, bipolar, double bouguet, multipolar and horizontal cells have been described in the cochlear nucleus.

been described in the cochlear nucleus.

Calbindin D-28Ka immunoreactive neurons were observed with a soma size of 15 - 17um and a few under 15um in the cochlear nucleus.

Calbindin D-28Ka immunoreactive dendrites are considerably more densely arrayed than those of other cochlear nucleus cells, including the cartwheel cells of the dorsal cochlear nucleus.

LIPID METABOLISM MODIFICATION AND PHOSPHOLIPASE ACTIVATION IN NEUROBLASTOMA SK-N-BE DIFFERENTIATED WITH RETINOIC ACID. A. Petroni*, N.Papini, P. LaSpada, M. Blasevich and C. Galli. Institute of Pharmacological Sciences, University of Milan, via Balzaretti 9, 20133, Milan, Italy.

The aim of our study was to investigate if retinoic acid-differentiation could affect lipid metabolism and phospholipase D activation in the human neuroblastoma SK-N-BE. At different stages of cell differentiation, we have evaluated the modification of cell growth and morphology (neurite emission, thymidine incorporation, etc.). We have evaluated endogenous lipid synthesis after 3 and 8 days of retinoic acid-cell differentiation. Undifferentiated and differentiated SK-N-BE were labeled with [14C]acetate (2.5µCi/dish), cells were extracted and radioactivity in major lipid classes were measured. After 8 day-differentiation, there was a reduction in the incorporation of radioactivity in phospholipids, associated with marked accumulation in TG, free fatty acid (FFA) and in diacylglycerol. Furthermore labeling cholesterol declined markedly compared to level after 3 days of retinoic acid differentiation. Moreover the conversion of 14 C]-linoleic acid was modified, major changes occured in Δ^5 desaturation step. To evaluate if retinoic acid modifies lipid homeostasis, we studied phospholipase D-activation in undifferentiated and 8 daysdifferentiated SK-N-BE. Cells were labeled with [14C]-palmitic acid (4μCi/dish for 6h), exposed to ethanol150mM and then stimulated with Platelet-Activating Factor (100nM for 5 min). Phosphatidilethanol (PEt) production was evaluated. In differentiated cells the incorporation of palmitic acid in TG was more elevated than in undifferentiated cells. After PAF stimulation there was three times increment of PEt compared with controls. These data indicate the involvment of lipid homeostasis during different stages of neuronal differentiation.

MEASUREMENT OF GLUTAMINE BY CAPILLARY ELECTROPHORESIS AND LASER INDUCED FLUORESCENCE DETECTION IN THE CEREBROSPINAL FLUID, S. Tucci*, P. Rada, L. Hemández, I. García and C. Pinto. Department of Physiology, P.O. Box 109, Mérida, 5101-A, VENEZUELA.

Glutamine is an amidated product of glutamic acid and the most abundant aminoacid in the brain. Glutamine measurements are an important diagnosis tool in certain diseases in which the metabolism of ammonia is compromised. It is helpful in differential diagnosis between bacterial and viral meningitis. Due to the medical relevance of glutamine, several assays for this aminoacid have been developed. Most of these techniques are based in the acidic or enzymatic breakdown of the glutamine molecule in glutamic acid and ammonia. The ammonia from this reaction is then measured by various methods. Recent observations have shown that glutamine concentrations in the brain inversely correlates with aging. In these experiment we developed a capillary zone electrophoresis with laser induced fluoresceenee detection (CZE-LIFD) method to measure glutamine prederivatized with fluorescein isothiocyanate (FITC). First, we conducted tests to optimize the derivatization procedure mixing standard solutions of glutamine with increasing concentrations of FITC. Then, we applied this method to the measurement of glutamine in normal cerebrospinal fluid of 79 children and 20 adults. Spinal taps in these children were performed when a CNS infection was suspected, however, cytochemical analysis later revealed normal CSF. Adult CSF samples were taken from patients undergoing subdural anesthesia. The analysis showed that the sensitivity limit was 10^9 M. Glutamine concentrations were 3.89 ± 0.05 mmol/lt in children and 1.60 ± 0.07 mmol/lt in adults. These results show that there is a significant difference of CSF glutamine concentrations between normal children and adults and that CZE-LIFD can be used as an alternative method for glutamine analysis. This research was supported by CDCHT-ULA

MELATONIN BLOCKS NICOTINIC CHANNELS IN THE GUINEA-PIG SUBMUCOUS PLEXUS. B. Prieto-Gómez*¹, A.L. Peres², R. Espinosa-Luna², C. Reyes-Vázquez¹ & C. Barajas-López². ¹Physiol. Depart., UNAM, México. ²Biomed. Sci. Depart., McMaster Univ., Hamilton, ON.

To investigate the possible role of melatonin (ME) as a modulator in the enteric nervous system. Intracellular and whole-cell recordings were made in submucosal neurons to measure ME effects on their electrophysiological properties. ME did not after the membrane potential, the membrane resistance, the noradrenergic inhibitory postsynaptic potentials and the slow resistance, the industriency minimizery possyriaphic potentians and the solution excitatory postsyriaphic potentials (EPSPs). However, ME (30-3000 µM) reversibly decreased the amplitude of nicotinic EPSPs in a concentration-dependent manner (IC₂₀=247 µM). Superfusion of ME also blocked the nicotinic depolarizations induced by locally applied ACh, indicating that at least part of its effects are postsynaptic. In whole-cell experiments, ME also inhibited the nicotinic inward currents induced by a maximal concentration of ACh (3 mM) in a concentration-dependent manner (IC₅₀=257 μM). ME (0.5 mM) decreased the maximal effects (3067 \pm 68 to 1173 \pm 80 pA) but did not affect the potency of ACh to induced the nicotinic inward current, indicating a noncompetitive antagonism. ME effects appear to be voltage-dependent because the blockage of the ACh-induced currents was larger for inward than for outward currents. These observations indicate that ME inhibits the fast EPSPs by directly blocking the cholinergic nicotinic channels. Our results also suggest that ME can be a local modulator of synaptic transmission in the enteric nervous system.

Supported by the grants MRC-MT-3491 (CBL), OMH-04500 (CBL), and DGAPA-UNAM IN205395 (BPG).

MODULATION OF RECOMBINANT GLYCINE AND GABAA RECEPTORS BY GENERAL ANAESTHETICS: A COMPARATIVE STUDY. M. Pistis*, D. Belelli, J.A. Peters and J.J. Lambert; Neurosciences Institute, Department of Pharmacology, Dundee University. Dundee, DD1 9SY, Scotland U.K.

Many general anaesthetics are known to act as positive allosteric modulators of the GABAA receptor and this may be their prime locus of action. Here, we have determined the effects of the structurally diverse anaesthetics propofol, pentobarbitone, etomidate and δ-hexachlorocyclohexane (δ-HCH) on human recombinant $\alpha_3\beta_1\gamma_2$ GABA_A receptors in comparison with their actions on the closely related glycine (GLY) receptors (human α_i , rat β) by utilizing the Xenopus laevis oocyte expression system and two point voltage-clamp techniques. All results reported below are the mean ± s.e.m. of 3-5 experiments. For cRNA (GABA_A) or cDNA (GLY) injected oocytes (-60mV) bath applied agonist evoked a concentration-dependent inward current with a EC $_{50}$ of $102\pm18\mu M$ and of $70+3\mu M$, respectively. Utilizing the appropriate EC $_{10}$ concentration of the agonist, propofol potentiated GABA and GLY evoked currents to 108±18% and 98±6% of maximum current (Imax), respectively, with an EC50 of $3.4\pm0.1\mu M$ and $28\pm2\mu M$, respectively . Pentobarbitone and etomidate potently enhanced GABA-evoked currents (110±17% and 75±8% of I_{max}, respectively; EC₅₀ of 44±5µM and 8.1±0.9µM, respectively), but were only partially effective on GLY induced currents (50±9% and 29±4% of I_{max}, respectively; EC₅₀: 757±39μM and 10±1μM, respectively). By comparison, δ-HCH enhanced GLY-evoked currents to $80\pm7\%$ of I_{max} (EC₅₀ $26\pm3\mu M$) with a reduced effect on GABA induced currents ($43\pm4\%$ of I_{max}) EC₅₀ $3.5\pm0.4\mu M$). Our results demonstrate that although some compounds are relatively selective for

GABA_A receptors (pentobarbitone and etomidate), a modulation of GLY receptor activity may contribute to the behavioural actions of propofol and δ-HCH.

We acknowledge the financial support of the MRC and MRC (ROPA) and thank

H. Betz for the glycine receptor cDNA

615.12

ENHANCEMENT OF HOMOMERIC GLYCINE RECEPTOR FUNCTION BY LONG CHAIN ALCOHOL AND ANESTHETICS. M.P. Mascia, T.K. Machu, and R.A.Harris. Pharmacology Dept., Univ. of Colorado HSC and VAMC Denver, Colorado, 80262; Pharmacology Dept., Texas Tech Univ. HSC Lubbock, TX 79430.

The effects of n-alcohols (ethanol-dodecanol) and anesthetics on strychnine-sensitive glycine receptors were studied in Xenopus oocytes expressing homomeric a1 or a2 glycine receptor subunits, using two electrode voltage-clamp recording. All the alcohols tested potentiated the function of homomeric α glycine receptors. Homomeric $\alpha 1$ and $\alpha 2$ receptors were potentiated to a similar extent by the n-alcohols, with the exception of the lower concentration of ethanol which showed a significantly greater effect on $\sigma 1$ than on a2 receptors (Mascia et al, Mol. Pharmacol. 1996). The potencies of these alcohols to enhance glycine-receptor function increased as the charbon chain lengh was increased up to decanol. Dodecanol was no more potent than decanol and weakly potentiated the glycine receptor function when compared to the other alcohols. Among the anesthetics tested, pharmacologically relevant concentrations of halothane and enflurane markedly potentiated the function of homomeric all glycine-receptor. A modest potentiation was obtained with the intravenous anesthetics propofol, alphaxalone and pentobarbital, but etomidate and ketamine were ineffective. Two novel cyclobutane compounds were also tested and the anesthetic compound, 1-chloro-1,2,2-trifluorocyclobutane, enhanced the action of glycine, while the non-anesthetic analog, 1,2-dichlorohexafluorocyclobutane, was ineffective. These results indicates a role for the strychnine-sensitive glycine receptor in the central depressant action of alcohols and anesthetics.

Supported by NIH grants GM 7818 and AA 06399.

ZINC (Zn^{++}) MODULATION OF VOLTAGE-ACTIVATED IONIC CURRENTS IN THE HORIZONTAL LIMB OF THE DIAGONAL BAND OF BROCA (hDBB) J.C. Easaw*, B.S. Jassar, J.H. Jhamandas, Dept. of Medicine (Neurology), Univ. of Alberta, Edmonton, Alberta, Canada, T6G-2S2.

The hDBB, a basal forebrain region which mediates memory and learning mechanisms, is affected in Alzheimer's disease (AD). Examination of the brains of patients with AD reveals that endogenous levels of the transition metal zinc are significantly reduced (Constantinidis, Alzheimer Disease and Associated

are significantly reduced (Constantinids, Alzheimer Disease and Associated Disorders, 5(1)31-15,1991). Zn⁺⁺, which is present in the basal forebrain, normally subserves important roles in enzyme function and also exerts neuromodulatory actions within the CNS. In this study, we characterized the actions of Zn⁺⁺ on voltage-dependent ionic currents in hDBB neurons. Whole cell patch clamp recordings were performed in acutely dissociated rat hDBB neurons. With respect to K* conductances, application of 50µM Zh* increased A-current by 20%. While activation of this current was unaffected, inactivation kinetics were shifted to the right in the presence of Zn⁺⁺. In contrast, 20* decreased delayed rediffer type K* currents by 20%. This metal was also Zn** decreased delayed rectifier-type K* currents by 20%. This metal was also observed to modulate other ionic currents. Zn** elicited a modest reduction of sodium currents (11%) and a significant blockade (85%) of Ca** currents recorded using Ba** as the charge carrier.

These results demonstrate that Zn** is a potent modulator of voltage-activated

ionic currents in the hDBB neurons. The effects of Zn** in the basal forebrain may be important in the context of the observed decrease in Zn** in AD.

AGMATINE IS RELEASED FROM SYNAPTOSOMES AND ADRENAL CHROMAFFIN CELLS BY DEPOLARIZATION. S. Regunathan*, M. Sastre and D.J. Reis. Div. of Neurobiol., Dept. of Neurol. & Neurosci., Cornell University Medical College, New York, NY 10021.

Agmatine (decarboxylated arginine) and its biosynthetic enzyme, arginine decarboxylase are present in rat brain (Li et al., Science, 1994). Moreover, the facts that admatine can be taken-up and stored in synaptosomes (Sastre et al. Soc. Neurosci. Abstr., 1996) and is contained in perikarya of specific brain areas (Wang et al., Soc. Neurosci. Abstr., 1995) suggests it has properties of a neurotransmitter/modulator. We investigated whether agmatine can also be released by depolarization from rat brain or adrenal chromaffin cells. Slices or synaptosomes were prepared from brains of rats killed by anesthetic overdose. Chromaffin cells were cultured from bovine adrenal medullae. Tissues were prelabeled by incubation with guanido ¹⁴C- or ³H-agmatine or ³H-putrescine and release of radioactivity into the medium measured for 10 min following exposure to 55 mM KCI (brain) or nicotine (100 μ M) (chromaffin cells) with or without Ca⁺⁺. Results were expressed as percent of total radioactivity released Depolarization with 55 mM KCl resulted in significant (p<0.05; n=6) release of labeled agmatine from synaptosomes (9.9 \pm 0.36 vs 12.6 \pm 0.37) or slices (9.1 ± 0.78 vs 15.3 ± 2.5). Removal of calcium from the incubation medium significantly (p<0.05) reduced release. Since no significant release of 3Hputrescine was observed, the released radioactivity cannot be attributed to metabolic conversion of agmatine to putrescine. In adrenal chromaffin cells, depolarization with KCl (55 mM) or nicotine (10 μ M) also resulted in significant release of 3H-agmatine. We conclude that agmatine can be released from presynaptic neurons and chromaffin cells in a calcium-dependent manner. The data provide further evidence that agmatine may be a novel neurotransmitter/ modulator

NITRIC OXIDE AND OTHER MODULATORS

616.1

ADRENERGIC INDUCED NITRIC OXIDE (NO) RELEASE FROM SENSORY NEURONS IS INHIBITED BY A SEROTONIN REUPTAKE INHIBITOR. M.S. Finkel, A.J. Kanai, K. Sugaya*, and L.A. Birder. Univ. of Pittsburgh. Depts. of Cardiology and Pharmacology, Pgh, PA 15261 and Univ. Of North Carolina Dept. Physiology, Chapel Hill, NC 27599.

Paroxetine, a selective serotonin reuptake inhibitor (SSRI) also reduces the activity of human cytochrome P_{450} . Neuronal nitric oxide synthase (nNOS) is structurally homologous to cytochrome P_{450} . The objective of this study was to examine the effects of paroxetine on nNOS activity. Lumbo-sacral dorsal root ganglia (DRG) were excised from deeply anesthetized adult rats (150-200 gms) and enzymatically dissociated. A nafion coated porphyrinic microsensor (tip dia. 0.5-1.5 μ m; NO detection limit, 5 nM was placed directly on the surface of individual neurons to measure NO release. Recordings were obtained from cells with a 30 μ m cell-free field to assure that the response was coming from a single cell. The calcium inophore, A23187 (10 μ M), elicited a transient release of NO, functionally demonstrating the presence of a constitutive NOS in DRG neurons. We have previously reported that the adrenergic agonist, norepinephrine (NE; range 0.1 to 0.5 nM) evoked transient NO release (range 87 \pm 11 to 310 \pm 41 nM) from medium diameter (15-30 μ m) DRG neurons. We note report that NE induced NO release is reversibly inhibited in a dose dependent manner by paroxetine (1-10 μ M; N=8), as well as by the nNOS specific inhibitor, 7 nitroindazole (7-NI, 100 μ M), in a population of medium diameter DRG cells (15-30 μ m). nNOS enzyme activity which was determined by measuring the conversion of [1°C] citrulline by a brain cytosol homogenate, was inhibited in a concentration dependent manner by known arginine analogue NOS inhibitors and paroxetine. This suggests that the SSRI, paroxetine, inhibits NE induced NO release from a subpopulation of sensory neurons by directly inhibiting neuronal NOS activity. This work was supported by NIH grant HL53372.

STRIATAL NITRIC OXIDE AND VOLUME TRANSMISSION. NITRIC OXIDE SYNTHASE INHIBITION MODULATES THE LOW MOLECULAR WEIGHT DEXTRAN DIFFUSION AND/OR CLEARANCE IN THE RAT NEOSTRIATUM, A. Jansson, L. Rosén, L.F. Agnati and K. Fuxe. Department of Neuroscience, Division of Cellular and Molecular Neurochemistry, Karolinska Institute, 171 77, Stockholm, Sweden, and Department of Human Physiology, University of Modena, Modena, Italy

Nitric oxide acts as an intercellular messenger in the brain via diffusion in the extracellular fluid and across membranes to act on intracellular targets. In this paper we have studied basic aspects of diffusion and/or clearance in the extracellular compartment of dextran and the possible modulation of these processes by nitric oxide.

Biotinylated-dextran (molecular weight 3000), in a volume of $0.1~\mu$ L was unilaterally microinjected into the neostriatum of halothane anaesthetized male rats. The total volume, maximal mean grey value and form factor of the dextran labelled area was estimated from serial sections of the neostriatum by means of computerized image analysis. A significant increase of the total volume of the biotinylated dextran labelling was observed with time after microinjection, without a change in the form factor. At the 30 min time-interval, nitric oxide synthase inhibition with two types of nitric oxide synthase inhibitors, L-nitro-arginine methyl ester (50mg/kg x 2, 4 days) and L-monomethyl-arginine (30mg/kg; 10 min) caused a significant reduction of total volume and maximal mean grey value of the biotinylated dextran labelling. These findings point to a possible role of nitric oxide in control of clearance and/or diffusion of chemical signals along extracellular paravascular pathways.

PROSTAGLANDINS (PGs) CONFER NEUROPROTECTION TO THE NEWBORN POSSIBLY BY INHIBITING NITRIC OXIDE SYNTHASE EXPRESSION. I. Dumont, A. Doke, P. Hardy, O. Dembinska, K.G. Peri, S. Molotchnikoff F. Lachapelle, S. Chemtob. Research Center Hönital Ste. Justine Montreal Canada.

Research Center, Hôpital Ste-Justine, Montreal, Canada.
PGs exert cytoprotection. PG levels in neural tissue (brain and retina) are high in the newborn (NB), but the role of these PG is not known. We postulated that high PG levels may confer neuroprotection. We used a model of NB asphyxia (Ax) to test the effects of prolonged (24 h) inhibition of PG G/H synthase (PGHS) using flurbiprofen (10 mg/kg/12 h iv, n=4), diclofenac (2.5 mg/kg/12 h iv [decreased PGs], n=10), or a combination of diclofenac and a stable analog of PGE2 (16,16 dimethyl PGE2, 6 g/kg/12 h iv; n=4), or saline (n=6), on the electroretinogram (ERG) of anesthetized (-chloralose) and paralyzed (pancuronium) ventilated newborn (NB) pigs (1 day old) before and 1 h after a 5 min period of asphyxia (interruption of ventilation). ERG was recorded before and 24 h after treatments, and repeated 1 h after Ax. The b-wave (generated by Müller and bipolar cells) amplitude decreased by 27-30% after Ax in saline-treated animals. In pigs treated with diclofenac and flurbiprofen the b-wave amplitude decreased to a much further extent by 52-66% 1 h after Ax. Addition of the PGE2 analog totally prevented the post-Ax ERG deterioration. Because PGs have recently been suggested to inhibit in cell lines expression of the inducible nitric oxide synthase (NOS), an important source of free radicals, we tested if the latter could explain the post-Ax neuro-deterioration observed after PGHS inhibition. Animals were treated with diclofenac and the relatively selective inducible NOS inhibitor, 2-amino-5,6-dihydro-6-methyl-4H-1,3-thiazine (AMT, 3g/kg/8 h iv) or with a neuronal/inducible NOS blocker, 7-nitroindazole (10 g/kg/8 h iv), and ERG was recorded as above. Treatment of piglets with diclofenac and AMT totally prevented the post-Ax neuroretinal damage; 7-nitroindazole exerted minimal attenuation of the reduction in b-wave amplitude. Data suggest that PGE2 confer neuroprotection to the NB apparently by inhibiting newly expressed inducible NOS activity. Supported by Medical Research Council of Canada

NITRIC OXIDE SYNTHASE IN THE GUINEA PIG PELVIC GANGLIA AND THE EFFECT OF SODIUM NITROPRUSSIDE STIMULATION ON GMP LEVELS. K. Holmberg*, Z.-O. Xu, H. Steinbusch, L.-G. Elfvin and T. Hökfelt. Department of Neuroscience, Karolinska Institute, S-171 77 Stockholm, Sweden.

Using the indirect immunofluorescence technique, the distribution of nitric oxide synthase (NOS)-like immunoreactivity (L1) was studied in pelvic ganglia of untreated guinea pigs and after lesion/crush of the hypogastric nerve. The results indicate that NOS-immunoreactive (IR) nerve fibers project in both directions of the hypogastric nerve. The NOS-positive neurons in the ganglia were choline acetyltransferase-positive and some contained vasoactive intestinal polypeptide, neuropeptide Y, somatostatin and calcitonin gene-related peptide. Nitric oxide (NO) stimulates soluble guanylyl cyclase and cGMP formation. In this study we have also examined the effect of the NO donor sodium nitroprusside (SNP) on cGMP in pelvic ganglia, and the effect of the guanylyl cyclase inhibitor 1H-(1,2,4)oxadiazolo(4,3-a) quioxaline-1-one (ODQ). The pelvic ganglia were exposed in vitro to SNP (10-4, 10-6M) or SNP+ODQ (100nM) for 10-15 min. Using immunohistochemistry and an antiserum to cGMP the stimulated ganglia showed a strong CGMP-LI in satellite cells and also in some neurons. Addition of ODQ abolished the cGMP staining. These findings suggest that both neurons and satellite cells may be targets for endogenously released NO in the guinea pig pelvic ganglia. (Supported by the Medical Research Council 2887 and 5189.)

Nitric oxide donors and cGMP analogs induce IPSCs in septohippocampal GABAergic neurons. W. Liu* and M. Alreja Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT.

The rat septohippocampal cholinergic but not GABAergic neurons of the medial septal/diagonal band complex (MSDB) contain the enzyme nitric oxide synthase. Both α_1 and β_1 subunits of guanylate cyclase are also present in the MSDB. Electrophysiological studies on the effects of nitric oxide (NO) and/or cGMP analogs on MSDB neurons are lacking. Therefore, we tested the effects of several NO donors and cGMP analogs on electrophysiologically characterized cholinergic and GABA-type MSDB neurons in an *in vitro* rat brain slice preparation using extracellular and whole-cell recordings.

brain slice preparation using extracellular and whole-cell recordings. In whole-cell voltage-clamp recordings with K gluconate-containing electrodes, bath-applied NO donors (sodium nitroprusside, sodium nitrocysteine, SIN-1 and DEA NONOate) increased the frequency of bicuculline and TTX-sensitive IPSCs in a subpopulation of GABA-type (15/29) but not in cholinergic-type (34/34) MSDB neurons. In extracellular recordings, NO donors increased the firing rate of a subpopulation of MSDB neurons (59/115) some of which were antidromically confirmed to be septohippocampal projection neurons (c.v.-1.71±0.12 m/s; n=20). cGMP analogs (8-Br-cGMP, dibutyryl cGMP, 8-pCPT-cGMP and PET-cGMP) mimicked the effects of NO donors and increased both the extracellular firing rate (20/21) and induced GABAergic IPSCs (n=4). Hemoglobin (100 µM) blocked the excitatory effect of NO donors (n=7) but not of cGMP analogs. In voltage-clamp recordings, NO donors had no effect on any of the cholinergic-type neurons tested. Thus, NO functions as an intercellular messenger in the MSDB as cholinergic neurons which synthesize NO are insensitive to NO donors. In contrast, NO donors, via the cGMP pathway, produce an excitatory effect on septohippocampal GABAergic neurons. Supported by NIH R 29 DA 09797.

EXPRESSION OF NO SYNTHASE (NOS) ISOFORMS AND GTP-CYCLO-HYDROLASE (GTP-CH) IN RAT C6 GLIOMA AFTER LPS AND IFN-Y TREATMENT. L. Bezin*, P.Z. Anastasiadis^{1,3}, M.C. Berent, M.D. Flam, J.A. Foster, L.J. Gordon^{1,3} and R.A. Levine^{1,2,3}. "Gossett Neurology Labs, Henry Ford Hospital; "Dpt of Psychiatry, Wayne State U.; "Detroit VAMC, Detroit, MI.

The synthesis of the radical, nitric oxide (NO), an important signaling and cytotoxic molecule, is dependent on variably regulated isoforms of NOS. Three isoforms have been identified, two of them clearly being Ca²⁺ All of them require tetrahydrobiopterin as a cofactor, the biosynthesis of which is regulated by the activity of GTP-CH. We investigated the regulation of activity of NOS isoforms (with respect to Ca²⁺-dependency) and GTP-CH 24h after treatment of C6 cells with lipopolysaccharide (LPS,1µg/mL) plus IFN-y (100 U/mL); total NO synthesis increased 24 fold (media nitrite accumulation), and total in vitro NOS activity (3H conversion assay) was increased by ~ +517%. Prior studies by others attributed the increase in NOS activity to the Ca²⁺-independent isoform (macrophage isoform). However, we demonstrate that Ca²⁺ chelation by 3 mM EGTA in the NOS assay reduced the magnitude of elevation of NOS activity to only \sim +223%. These results suggest that about half of the total induction of NOS activity involves a Ca²-dependent NOS (endothelial or neuronal isoform). GTP-CH activity remained stable after treatment, suggesting that increased NO synthesis in this case does not require the elevation of GTP-CH activity. We are now characterizing the Ca²⁺-dependent component of NOS activation following LPS+IFN-7 treatment, by the blockade of Ca²⁺-independent isoform expression using dexamethasone pre- and co-treatment. We are also examining the subcellular localization of the different isoforms of NOS by confocal microscopy and the analysis of the expression of mRNAs for macrophage and endothelial NOS isoforms by quantitative RT-PCR.

CHARACTERIZATION OF NITRIC OXIDE SYNTHASE (NOS) - CONTAINING NEURONS IN THE INSULAR CORTEX OF THE SYRIAN GOLDEN HAMSTER. Richard G. Wehby*, Center for Neurological Sciences, University of Connecticut Health Center, Farmington, CT 06030-3405.

We have previously documented two types of NADPH diaphorase (NADPHd)-positive neurons in the insular cortex of the Syrian golden hamster (Wehby and London, 1995, Soc. Neuroscience Abstracts, 21:1619.) We here further characterize these neurons. Animals were fixed with 4% paraformaldehyde for 45 min, and brains postfixed in the same solution for 2h. Antibodies to human NOS (rabbit polyclonal anti-nNOS and anti-iNOS; mouse monoclonal anti-eNOS; Transduction Laboratories) were incubated for 24h at 4 °C, then incubated with the appropriate biotinylated goat anti-IgG. Antibodies were visualized with an ABC reaction (Vector) using DAB histochemistry. In the insular cortex, (1) the "solid" labeled neurons seen with NADPHd histochemistry were immunoreactive for the nNOS (but not eNOS or iNOS) isozyme, and (2) the "punctate" cells labeled with NADPHd histochemistry were not labeled by antibodies to either nNOS, eNOS or iNOS isozymes. In agreement with these antibody results, when the NADPHd reaction was run with various inhibitors/chelators (e.g. EGTA, levamisole), the "solid" cells reacted with a NOS-like profile, but the "punctate" cells did not. In agreement with the NADPHd histochemistry results, nNOS-positive neurons were present primarily (>80%) in layers V and VI. Thus, the "solid" NADPHd-labeled cells contain nNOS, but the "punctate"-labeled cells do not. Supported by NIH grants T32DC00025 to R.G. Wehby and 2P50DC00168 to J.A. London.

EXPRESSION OF ALTERNATIVE FORMS OF NEURONAL NITRIC OXIDE SYNTHASE (nNOS) IN BRAIN. H.-Y. Yun*1, V. L. Dawson¹⁻³ and T. M. Dawson¹⁻². Departments of Neurology¹, Neuroscience² and Physiology³, Johns Hopkins University School of Medicine, Baltimore, MD 21287.

Physiology³ Johns Hopkins University School of Medicine, Baltimore, MD 21287.

Nitric oxide (NO) is a messenger molecule in central and peripheral nervous system and nNOS is thought to be a principal NO-generating enzyme in neurons. However, studies on nNOS null mutant mice showed grossly normal brain development and structure, normal hippocampal LTP and cerebellar LTD. Furthermore, we and others showed that nNOS null mice brain contains residual NOS activity (-8% of wild type level) and nNOS immunoreactive proteins (136 kDa and 125 kDa) in discrete brain areas such as striatum, hippocampus and cortex. The molecular identity of this NOS activity and proteins detected in nNOS null mice is not clear. We investigated nNOS expression in wild type and nNOS null mice with targeted deletion of exon 2 by in situ hybridization using an exon 3 riboprobe. nNOS transcripts were detected in cerebellum, hippocampus (dentate gyrus and CA1-CA3) and olfactory bulb in nNOS null mice, with a pattern generally similar to wild type except for relatively lower level in hypothalamic nuclei in mutant mice. However, the distribution of nNOS transcripts in nNOS mull mice brain did not parallel that of residual NOS activity and nNOS immunoreactive proteins reported previously in nNOS null mice brain. Reverse transcription-coupled PCR of nNOS null mice brain mRNA yielded many nNOS cDNA clones containing the exon 3 region. These results indicate the expression of alternative forms of nNOS transcripts in nNOS null mice brain and in situ hybridization using probes specific to each form of nNOS transcripts will provide the expression patterns of these transcripts in wild type mice. Supported by NIH.

NITRIC OXIDE SYNTHASE IN DIFFERENTIATING CULTURED CEREBELLAR GRANULE CELLS. R.W. Burryl and D. S. Bredt Dept. Cell Biol. Neurobiol. & Anat., The Ohio State Univ., Columbus, OH, 2Dept. Physiol., UCSF, San Francisco, CA

Neuronal nitric oxide synthase (nNOS) is expressed in adult cerebellum, and produces nitric oxide (NO), a modulator of signaling in neurons. In the careballing make plant layer improportoclemical labeling has shown the

Neuronal nitric oxide synthase (nNOS) is expressed in adult cerebellum, and produces nitric oxide (NO), a modulator of signaling in neurons. In the cerebellar molecular layer, immunocytochemical labeling has shown the expression of nNOS reaches adult levels by postnatal day 14 (P14). In the granule cell layer at P8, nNOS labeling was uniform, but after P14, nNOS-positive cells are found in alternating bands. This banding pattern indicates that after 14 days subpopulations of nNOS-positive granule cell bodies were separated by subpopulations of nNOS-negative granule cell bodies. We show here, in cultures from neonatal rats that nNOS is expressed only in a subpopulation of granule cells. With immunocytochemistry, nNOS was first seen in some granule cell bodies at 7 days of culture. At this and all subsequent times in culture, there was a range in levels of nNOS expressed in individual granule cells and their processes. Few of the early neurites at 7 days of culture were positive for nNOS, but at 21 days some of the growth cones and some axons were nNOS-positive. With scanning laser confocal microscopy, nNOS cytoplasmic labeling was distributed in fine, punctate regions around the nucleus and along axons. Some of these regions of label were associated with plasma membrane. Thus, in this neonatal culture system, only a subpopulation of granule cells ever some labeling. In early postnatal cerebellum most for old of the granule cells have been shown to express nNOS, and subpopulations are only seen later. Expression of nNOS in a subpopulation of cultured granule cells suggests that conditions within the developing cerebellum, prior to dissociation at postnatal day 2, determine the subpopulation of granule cells that will express nNOS. INHIBITION OF NADPH-DIAPHORASE ACTIVITY AND FORMATION OF AGGREGATES IN RODENT HIPPOCAMPAL AND CEREBELLAR CELL CULTURES BY CLORICROMENE.

M.O. López-Figueroa a* and L.C.B. Rønn b

^aDepartment for Medical Anatomy and ^bThe Protein Laboratory, Panum Institute, Blegdamsvej 3, 2200 Copenhagen N, Denmark.

Nitric oxide (NO) plays a very important role in the brain as an intercellular signaling molecule. Formation of neuronal aggregates and processes may be investigated *in vitro* in primary cultures of dissociated nerve cells grown in microwells. We have used histochemical NADPH-diaphorase (NADPH-d) staining to study expression of nitric oxide synthase (NOS) in primary cell cultures from rodent hippocampus and cerebellum. After 24h in vitro, neurons had assembled to form large cell aggregates connected by fasciculated processes. Development of aggregates was correlated with an increase in NADPH-d activity. The coumarin derivative cloricromene inhibited in a concentration-dependent manner the formation of aggregates as well as the increase in NADPH-d activity. Thus, we demonstrated that cloricromene interferes with neuronal cell adhesion and indicate a role for NO in the formation of neuronal connections in the developing brain.

IMPAIRED INTESTINAL RELAXATION IN MICE WITH TARGETED DELETIONS OF EITHER NEURONAL NITRIC OXIDE SYNTHASE OR HEME OXYGENASE-2: NO AND CO AS POTENTIAL CO-NEUROTRANSMITTERS

R. Zakhary, 1* K.D. Poss2, S. R. Jaffrey1, S. Tonegawa², S.H. Snyder¹

¹Department of Neuroscience, Johns Hopkins School of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205. ²Howard Hughes Medical Institute, Center for Learning and Memory, Massachusetts Institute of Technology, Cambridge, Massachusetts.

Neuronal nitric oxide synthase (nNOS) generates nitric oxide (NO) in neurons, while heme-oxygenase-2 (HO-2) synthesizes carbon monoxide (CO). Using mice with targeted deletions of nNOS or HO-2, we have evaluated the roles of NO and CO in intestinal neurotransmission. Nonadrenergic noncholinergic (NANC) relaxation and cyclic guanosine 3',5' monophosphate (cGMP) elevations evoked by neuronal depolarization are markedly diminished in both nNOS-7 and HO-2-7 mice. markedly diminished in both nNoS-/- and HO-2-/- mice. NOS inhibitors and HO inhibitors partially inhibit NANC relaxation in wild-type mice. In nNoS-/- animals, NOS inhibitors selectively lose their efficacy. Likewise, HO inhibitors have no effects in HO-2-/- animals. Immunohistochemical analysis demonstrates colocalization of nNOS and HO-2 in myenteric ganglia. These findings establish both NO and CO as physiologic modulators of intestinal relaxation. This research was supported by a grant from the National Institute of Drug Abuse.

ENDOGENOUS GENERATION OF CYANIDE IN NEURONAL TISSUE: INVOLVEMENT OF A PEROXIDASE SYSTEM. G.E. Isom*, P.G. Gunasekar, J.L. Borowitz. Dept. of Medicinal Chemistry and Molecular Pharmacology, Purdue University, W. Lafayette, IN 47907

We have shown that specific stimuli can initiate generation of cyanide in neuronal tissue. Further studies reveal that glycine, a substrate for cyanide production in lymphocytes, increased cyanide production in PC12 cells. Since myeloperoxidase generates cyanide in lymphocytes, peroxidase inhibitors (aminobenzoylhydrazide and azide) were tested and found to block cyanide production stimulated by carbachol. Furthermore H₂O₂ enhanced cyanide generation in the cells. Administration of aminobenzoylhydrazide to neonatal rats decreased endogenous cyanide after 30 min by 75% of control in cerebellum, with profound decreases also in hippocampus, medulla and hypothalamus (by 60-64% control). Cortical cyanide levels were decreased to a lesser extent by 33% of control. In adult rats, aminobenzoylhydrazide nearly abolished cyanide levels in all brain areas examined. Endogenous generation of cyanide in neural tissue appears to be related to activation of a peroxidase system linked to specific membrane bound receptors (muscarinic and mµ opiate) and glycine may serve as a substrate for the reaction. These results support the possibility that endogenous HCN generation may play a role in neuronal function. (Supported by NIH grant ES04140.)

616.15

ENDOGENOUS GENERATION OF CYANIDE IN NEURONAL HIGH LEVELS IN NEONATES DEMONSTRATION IN VIVO. P.G. Gunasekar*, J.L. Borowitz, R.S. Bitner and G.E. Isom. Dept. of Medicinal Chemistry and Molecular Pharmacology, Purdue Univ., West Lafayette, IN 47907

To examine the possible effect of age on cyanide generation in rat brain, newborn (8-15 days) animals were compared with adults. Cyanide levels in newborn were 2.7 to 3.3 fold higher in cortex, medulla, and hippocampus. Levels in hypothalamus and hippocampus however were only 1.1 and 1.5 times the adult. Dilaudid given ip increased cerebellar cyanide 4.7 times the endogenous level in the neonate after 15 min. Increases in the hippocampus (1.7 times) and hypothalamus (1.6 times) were more modest and no increase was evident in cortex or medulla. Patterns of drug-induced cyanide generation in brain areas appear to be different in adults vs neonates. A microdialysis probe spanning the cortical-hippocampal area of pentobarbital anesthetized adult rats revealed low levels of cyanide and a ten-fold increase was evident on ip injection of 10 mg/kg of dilaudid hydrochloride. Pretreatment with naloxone blocked the effect of dilaudid. These results further support the existence of a cyanide generating system in neuronal tissue and reveal an age-related difference in cyanide generation. (Supported by NIH grant ES04140.)

616.12

COLOCALIZATION OF CHOLINE ACETYLTRANSFERASE AND NITRIC OXIDE SYNTHASE IN CEREBRAL ARTERIES AND SPHENOPALATINE GANGLIA OF THE CAT AND PIG. T. KIMURA, J. G. YU, AND T. J. F. LEE*, Dept. of Pharmacology, Southern Illinois Univ Sch. of Med., Springfield, IL 62794

The transmitter mechanism involved in cerebral neurogenic vasodilation is not fully clarified. The presence of cholinergic innervation in pial vessels led to the suggestion that acetylcholine (ACh) was the transmitter for cerebral vasodilation. This was questioned, however, by the findings that ACh constricts exclusively the smooth muscle in major pial arteries from several species. Accordingly, it has been hypothesized that a second transmitter substance is co-released with has been hypothesized that a second transmitter substance is co-released with ACh to induce vasodilation. Recently, in pial vessels from different species the presence of dense nitric oxide synthase-immunoreactive (NOS-I) fibers originating in sphenopalatine ganglia (SPG) have been demonstrated. Results from pharmacological studies also have shown that endogenous NO mediates a major component of neurogenic vasodilator responses in isolated cerebral arteries. In this study, possible colocalization of choline acetyltransferase (ChAT) and NOS in SPG and cerebral pial arteries of the cat and pig was, therefore, examined immunohistochemically using antibody against ChAT and histochemically using nicotine adenine dinucleotide phosphate diaphorase (NADPH-d) staining. In SPG of both species, approximately half of the ganglionic cells were positive with ChAT-immunoreactivity and NADPH-d staining, while the other half of the ganglionic cells were positive with NADPH-d staining only. There were few cells showing ChAT immunoreactivity but not NADPH-d staining. In middle cerebral arteries most ChAT immunoreactivity but not staining only. There were rew cells showing ChAT immunoreactivity out not NADPH-d staining. In middle cerebral arteries most ChAT immunoreactive fibers and NADPH-d fibers were found to coincide with each other. These results provide a morphological evidence indicating that NOS and ChAT coexist in some SPG and cerebral perivascular neurons, and support the hypothesis that NO is co-released with ACh from "cholinergic" neurons to induce and/or regulate cerebral vasodilation. (Supported by NIH HL47574 and HL27763)

616 14

ENDOGENOUS GENERATION OF CYANIDE IN NEURONAL TISSUE: POSSIBLE NEW NEUROMODULATOR. J.L. Borowitz, P.G. Gunasekar, C. Davis, N. Patel, G.E. Isom and R.P. Maickel*. Dept. of Medicinal Chemistry and Molecular Pharmacology, Purdue Univ., W. Lafayette, IN 47907.

The possibility that hydrogen cyanide might be a gaseous neuromodulator, as proposed for nitric oxide and carbon monoxide, was examined in isolated neural cells and in rats. To determine whether nervous tissue actually generates cyanide, HCN produced by rat pheochromocytoma (PC12) cells in culture was collected and Small amounts of cyanide were detected (40 ng/106 quantitated. cells/10 min) using a sensitive, specific colorimetric method. carbachol and a mu opiate agonist, dilaudid, doubled cyanide generation and these effects were blocked by atropine and naloxone respectively. Calcium did not mediate the response since both high K⁺ and A-23187 were without effect on cyanide generation. Cyanide production was blocked by pertussis toxin showing involvement of G-protein. Injection of dilaudid ip into adult rats increased cyanide in the cortex (4 times), medulla (1.5 times), cerebellum (1.8 times), hippocampus (1.1 times) and hypothalamus (1.7 times) after 15 min. Endogenous levels were highest in hippocampus and hypothalamus (~0.5 μg/g wet wt.). The presence of a drug-responsive cyanide generating system in rat brain and in isolated neuronal cells suggests cyanide may function to regulate neuronal activity. (Supported by NIH grant ES04140.)

INCREASED LYSOPHOSPHATIDATE LEVELS IN CSF AFTER SUBARACHNOID HEMORRHAGE

M Baybek, GW Nietgen, C Bogaev, MB Fineman, R Polin, ZF Chen KS Lee, NF Kassell, ME Durieux Departments of Neurological Surgery and Anesthesiology University of Virginia, Charlottesville, VA 22908.

University of Virginia, CharlottesVille, VA 22908.

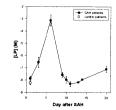

The mechanism of cerebrovascular spasm after subarachnoid hemorrhage (SAH) is still controversial, but probably multifactorial. We hypothesized that one potential mediator may be the phospholipid lysophosphatidate (LP). LP is released from activated platelets, endothelial cells, some cancer cells, and injured fibroblasts. The compound has been shown to have systemic vasoactive, smooth muscle contractile, and cerebrovalar effects at micromolar concentrations. We therefore determined LP concentrations in cerebrospinal fluid (CSF) of SAH patients.

With institutional approval, 39 CSF samples were collected from 32 SAH and 5 control patients treated at the University of Virginia. A blinded investigator determined the concentration of LP in the CSF using the Xenopus laevis oocyte bioassay. LP elicits oscillatory Ca²⁺-activated Cl'currents in these cells; the integrated amplitude of these currents is proportional to the LP concentration in the samples.

proportional to the LP concentration in unsamples.

LP concentrations in control CSF samples were below the limit of sensitivity of the assay (approximately 10³ M). In samples obtained after SAH LP concentrations increased over time, with a peak of approximately 10³ M on the 6th day after SAH, and a return to baseline on day eleven. This corresponds closely to the onset of vasospasm in patients with SAH.

Taken together with previous evidence indicating a vasoconstrictor effect of LP, the present findings suggest that LP can play a role in the development of vasospasm after SAH.

NADPH-DIAPHORASE DISTRIBUTION IN THE GOLDFISH MAUTHNER CELL. T. Bell, A. Pereda and D.S. Faber*. Dept. of Neurobiology and Anatomy, Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA. 19129.

Hahnemann University, Philadelphia, PA. 19129.

The compound nitric oxide (NO) has been implicated as a retrograde messenger in the maintenance of hippocampal long-term potentiation. Similar sustained enhancements in synaptic efficacy have been demonstrated at identifiable excitatory and inhibitory inputs to the goldfish Mauthner (M-) cells. In an attempt to determine whether NO is also involved in this system we assayed for the presence and subcellular distribution of the enzyme nitric oxide synthase (NOS), known to catalyze the generation of NO by the selective oxidation of L-Arginine residue. For this purpose NADPH-diaphorase histochemical staining was used to localize the enzyme. Widespread labeling was observed for specific cell types throughout the goldfish brain. The M-cells appeared to stain heavily, and the reaction product was uniformly distributed along their axon, soma, and ventral and lateral dendrites (n=9). Afferent fibers which synapse with the M-cell were also NADPH-diaphorase positive they include the i) inhibitory interneurons known as PHP (passively hyperpolarizing potential) cells which are typically identified by their unmyelinated axons in the periphery of the M-cell's axon cap and ii) large myelinated club endings of eighth nerve afferents, unequivocally identified by their diameter (5-15 µm) and typical segregation to the distal part of the M-cell lateral dendrite. Interestingly, this pattern of staining was also shared by other identifiable reticulospinal neurons, consistent with the notion that they could serve as functional analogs of the M-cell.

The presence of NADPH-diaphorase in the M-cell and its afferent suggests a possible role for NO in the previously described activity-dependent long term potentiation of both the excitatory and inhibitory synapses.

synapses.

TONIC RELEASE OF NITRIC OXIDE IN ELECTROTONICALLY-COUPLED SYNCHRONISED RAT SYMPATHETIC PREGANGLIONIC

David Spanswick, Victoria J. Clark and Stephen D. Logan*, Department of Biomedical Sciences, Marischal College, Aberdeen, U.K.

Spontaneous membrane potential oscillations in a population of sympathetic preganglionic neurones (SPN) have been described. The presence of these oscillations gives rise to bursting or beating patterns of spike discharge. We have used whole-cell recording techniques in spinal conduction properties are investigated with a presentation of the presentation o spike discharge. We have used whole-cell recording techniques in spinal cord slice preparations to investigate mechanisms underlying and regulating this activity in SPN. Simultaneous whole-cell recordings were obtained from 54 pairs of SPN. Of these, 9 pairs of SPN were observed to discharge action potentials and, or oscillations synchronously. The amplitude of the spikelets recorded in one neurone of a pair was larger in magnitude when the other recorded neurone discharged an action potential. In the spontaneously oscillating pairs of SPN, synchronous spikelets were detected in both neurones when recorded subthreshold for firing. Injection of hyperpolarising and depolarising current pulses into these SPN induced membrane hyperpolarising and depolarising responses respectively, in both neurones. Bath application of NO donors sodium nitroprusside (10-100µM) or DEA/NO, (10-100µM) induced concentration-dependent hyperpolarising responses in all SPN displaying nitroprusside (10-100µM) or DEA/NO, (10-100µM) induced concentration-dependent hyperpolarising responses in all SPN displaying spontaneous oscillations. In the presence of NO synthase inhibitors L-NAME (100-500µM), L-NOARG (50-250µM) or L-NMMA (50-200µM), the frequency of oscillations and firing in coupled SPN was increased, and in silent SPN, oscillations induced. We conclude that a subpopulation of SPN are electrotonically coupled and that spontaneous synchronised activity in these neurones is regulated by tonic release of NO. A P-450 METABOLITE OF ARACHIDONIC ACID MEDIATES THE DOPAMINE-INDUCED INHIBITION OF RAT ROD Na+,K+-ATPase VIA ACTIVATION OF A G PROTEIN COUPLED TO PLA₂. L.M. Shulman* and D.A. Fox. University of Houston, College of Optometry, Houston, TX 77204. Nanomolar concentrations of dopamine (DA), acting on D₂/D₄-like

receptors, inhibit ouabain-sensitive rod oxygen consumption in darkand light-adapted rat retinas and inhibit the $\alpha 3$, but not $\alpha 1$, isozyme of Na+,K+ (Na,K)-ATPase in rod outer-inner segments (ROS-RIS) via a second messenger (Shulman and Fox, PNAS 1996). To determine the mechanisms underlying this DA-induced inhibition, pharmacological and biochemical experiments were performed. ROS-RIS were incubated with or without DA in the absence or presence of: pertussis toxin (PTX); cholera toxin (CTX); forskolin (FSK); PLC inhibitor Utoxin (PTA); cholera toxin (CTA); forskolin (PSR); PLC inhibitor U-73122; PKC inhibitor Calphostin C (CalC); PLA2 inhibitors (p-bromophenacyl bromide: BPAB or Quinacrine: QUIN); BAPTA-AM; lipoxygenase inhibitor 5,8,11-eicosatetriynoic acid (ETI); or 7-ethoxyresorufin (7-ER), a P-450 inhibitor of arachidonic acid (AA). α1- and α3-isozyme activities were measured for each incubation condition. In the absence of DA, none of the drugs affected α1 and only FSK decreased α3 Na,K-ATPase activity. PTX, BPAB, QUIN, only FSK decreased α_5 Na,K-A Pa'se activity. F1X, BPAB, QUIN, 7-ER and BAPTA completely blocked the selective inhibitory effects of DA on the α_5 isozyme. In contrast, CTX, FSK, U-73122, CalC and ETI did not reduce the inhibitory effects of DA on α_5 . These results suggest that DA inhibits the α_5 -isozyme of Na,K-ATPase via: 1) a PTX-, but not CTX-, sensitive G protein: possibly Go, 2) activation of the Ca²⁺-sensitive PLA₂ and 3) the production of a P-450 metabolite of AA. Supported by NIH Grant ES03183.

ADENOSINE AND ATP AS NEUROTRANSMITTERS

ATP, SYNAPTICALLY RELEASED IN THE BRAIN, IS NOT A CO-TRANSMITTER WITH GLUTAMATE S.J. Robertson* & F.A.Edwards Dept. Physiology, University College London, Gower St, London U.K

In the peripheral nervous system ATP acts as a co-transmitter released with either noradrenaline or acetylcholine. We investigated, in slices of rat medial habenula nucleus, whether ATP is a co-transmitter with the dominant fast excitatory

transmitter, glutamate. Several lines of evidence suggest that this is not the case. Generally a much higher voltage of stimulation (>20V) was needed to find the sparse ATP inputs than was required to find the plentiful glutamate inputs which cover most of the slice. Consequently, in most cases, though it was clear that glutamate could be released without ATP, it was difficult to investigate directly whether ATP could be released without glutamate. In some cells however, (n=4), placement of the electrode was fortuitous and the stimulus which resulted in regular release of ATP did not result in any glutamatergic currents once CNQX was washed out, despite the presence of spontaneous glutamate currents. Thus it is clear that, in these cases, ATP is released from different axons to those which release glutamate.

Further evidence comes from the fact that various changes in stimulation parameters had different effects on failure rate of ATP- vs glutamate-mediated synaptic currents, implying that the two transmitters cannot be co-stored in the same vesicles. We then tested whether ATP and glutamate could be released from different vesicles but from a mixed population within the same bouton. If this were so, the build up of adenosine, shown in our other poster to occur at ATP-releasing synapses, should result in a progressive increase in glutamate failure rate as the stimulation frequency is increased. However glutamate release was observed to be affected by adenosine agonists and antagonists but, unlike ATP release, the sensitivity of glutamate release to adenosine antagonist, 8CPT was not frequency dependent but shifted the curve parallel throughout the frequency range (0.5-10Hz). FREQUENCY DEPENDENT INHIBITION OF SYNAPTIC ATP-RELEASE IN RAT BRAIN IS MEDIATED BY ADENOSINE RECEPTORS WITH NOVEL PHARMACOLOGY. <u>F.A.Edwards* & S.J. Robertson</u> Dept. Physiology, University College London, Gower St London U.K.

Synaptic ATP currents were recorded from slices of the medial habenula nucleus of 21-26 day old rats using the whole-cell patch clamp tecnique. The effect of stimulation frequency on ATP release was investigated by counting failures. Increasing the stimulation frequency from 0.5 Hz to 1, 2, 5, 10 and 100 Hz resulted in a progressive but readily reversible increase in failure rate. Thus increasing stimulus frequency results in little change in the number of quanta of ATP released

This effect of frequency was dose-dependently inhibited by the adenosine antagonist 8-cyclopentyltheophylline (8CPT) but only at concentrations of $\geq 5 \mu M$ (~500x the K1 for A1-receptor binding). We thus investigated whether the effect was mediated by adenosine receptors other than A1-receptors (which mediate most of the central inhibitory effects of adenosine in other brain areas). Surprisingly the frequency dependent effect could be mimicked by low concentrations of either the specific Al-receptor agonist 2-Cl-N⁶-cyclopentyl adenosine (CCPA 100nM) or equally the specific A2 receptor agonist DPMA (10, 100nM). These effects were also inhibited by 8CPT. The unusual pharmacology of the receptor(s) was further confirmed when the relatively non specific agonist 2-Cl-adenosine proved to be ineffective even at concentrations as high as 1µM.

Finally, in order to test whether the endogenous adenosine mediating the frequency dependent effects came from the breakdown of released ATP, we attempted to inhibit ectoATPases with ARL67156 (Astra). This approach was however unsuccessful as, in this system, the compound appeared to have additional effects consistent with a block of adenosine uptake or a long lasting increase in adenosine release. EXTRACELLULAR ATP AS A SOURCE OF ENDOGENOUS ADENOSINE IN BRAIN, T.V. Dunwiddie* and W. R. Proctor. Dept. of Pharmacology, University of Colorado Health Sciences Center, and Veterans Admin. Medical Res. Service, Denver, CO 80262.

The relative contributions of various sources to extracellular adenosine in brain are only partially understood. Adenosine is formed from the extracellular breakdown of ATP, but the rate at which this conversion can occur is unclear. To address this issue, we used infrared video-enhanced Nomarski optics to visualize CA neurons in hippocampal brain slices. Patch electrodes were used to make whole cell recordings from these cells, and adenosine and ATP were applied from double barrel drug application pipettes placed within 10 μm of the cell from which recordings were made Both ATP and adenosine elicited outward currents with a moderate ly fast onset and long duration, which were antagonized by the competitive adenosine receptor antagonist theophylline. The amplitude and duration of the responses to ATP and adenosine under these conditions were almost indistinguishable, except that there was a delay of approximately 500 msec in the onset of the ATP response. Much faster P2 (ATP receptor)-mediated responses were observed when larger amounts of ATP were applied. Because ATF cannot activate adenosine receptors directly, we conclude that the quantitative conversion of ATP to a purine that is active at adenosine receptors occurs very rapidly (<500 msec) in the extracellular space in brain, and that the rapid formation of adenosine via this mechanism might be an important source of extracellular adenosine Supported by NS 29173 and the Veterans Administration Medical Research Service

ADENOSINE KINASE INHIBITION ENHANCES KAINIC ACID-INDUCED INCREASES IN STRIATAL ADENOSINE. <u>D.R. Britton*, J. Mikusa, L. Lee, M. Williams and E. Kowaluk</u> Neuroscience Research, Pharmaceutical Discovery Division, Abbott Laboratories, Abbott Park, IL. 60064-3500.

Discovery Division, Abbott Laboratories, Abbott Park, IL 60064-3500. Adenosine (ADO) is released in response to nerve injury and in turn is proposed to be neuroprotective via its ability to inhibit further glutamate release. We have assessed the effects of the excitatory neurotoxin, kainic acid (KA), on extracellular ADO levels and the effects of the ADO kinase inhibitor, 5'-deoxy-5-iodotubercidin (5'd5IT) on basal and KA-stimulated ADO. Male S-D rats were anesthetized and bilateral microdialysis probes were placed in the striata. Probes were continuously perfused at a flow rate of 2.0 µl/min with artificial CSF with or without added KA. Following an immediate increase in ADO (to 20-80 µM) that accompanied insertion of the probes, levels fell over a period of 1 hr to a relatively stable baseline of approximately 1.0 µM. Pre-KA baseline samples were collected for an additional hour. Rats were then treated with saline or with 5'd5IT (2.5 then 5.0 µmO/kg) administered ip 2.0 min prior to and at the beginning of a unilateral 20 min exposure to 1.0 mM KA. At the end of the KA exposure the dialysis fluid was switched back to artificial CSF and the dialysis continued for an additional 60 min. ADO was assayed by HPLC using fluorometric detection of a derivatized product, ethenoadenosine. As indicated in the table below, KA caused a unilateral elevation in ADO levels. 5'd5IT significantly enhanced the ADO concentrations in the contralateral striatum.

Axonal Adenosine Receptors in the Corpus Callosum Are Physiologically Active. S.E. Krahl, Y.-Z. Liu, & T.H. Swanson. Departments of Neurology and Neuroscience, The Cleveland Clinic Foundation, Cleveland, Ohio.

We recently reported the presence of A_1 adenosine receptors on axons in the central nervous system. It was unclear, however, whether these receptors are functional or simply in transit from the cell body to the nerve terminal. We now present evidence that these receptors are physiologically active and are capable of modulating axonal conduction.

Coronal slices containing the corpus callosum were prepared from adult male Sprague Dawley rats for *in vitro* slice recording. Slices were placed in recording chamber and bathed in artificial cerebral spinal fluid (ACSF). The corpus callosum was stimulated once per minute and the resultant compound action potential (CAP) recorded. After collecting 30 minutes of baseline activity, the perfusion media was changed to ACSF containing one of a variety of adenosine agonists or antagonists.

The lipophilic specific A₁ receptor agonist, N⁶-cyclopentyladenosine (CPA), caused a dose-dependent decrease in the CAP. This effect was prevented by the specific A₁ receptor antagonist, 8-cyclopentyl-1,3-dipropylxanthine (DPCPX). Specific A₂ receptor agonists and antagonists did not produce significant effects on the CAP.

These data are the first to demonstrate that axonal conduction can be modified by adenosine agonists, and suggest a novel mechanism of adenosine action. Such a finding supports the notion that axons are not passive transmitters of action potentials, but may be modulated by neuroactive substances.

THE SOURCES OF EXTRACELLULAR ADENOSINE IN HIPPOCAMPUS AND NEOSTRIATUM OF THE RAT M. A. Pak* and H. L. Haas. Heinrich-Heine University, Department of Physiology, Moorenstr.5, D-40225 Düsseldorf, Germany

Endogenous adenosine can enter the extracellular space either by way of a bidirectional transporter or via formation from other purines. We have compared the effects of substances blocking the transporter (dipyridamole) or the ecto-5'-nuleotidase (α - β methylene adenosine 5'-diphosphate, AOPCP) on field potentials in the hippocampus and the striatum in vitro following stimulation of the stratum radiatum or the cortico-striatal pathway respectively. Population spikes in the CA1 region and field potentials in the neostriatum were registered. AOPCP, at 40 µM, enhanced the amplitude of field potentials by $34\pm17.5\%$ (mean \pm SEM, n=11) in the hippocampus and by 26.5 ±14% (n=5) in the striatum. The inhibitory response to exogenously applied ATP (10µM) which is quickly broken down to adenosine, was antagonized by AOPCP (80-100 µM). Dipyridamole (1-5µM) decreased the amplitude of evoked potentials in both structures by 51± 18% (n=8). Thus both, release of adenosine from the intracellular space and, to a lesser extent, extracellular dephosphorylation of ATP contribute to the electrophysiologically effective levels of adenosine in the extracellular space in hippocampus and neostriatum.

THE EFFECTS OF ADENOSINE KINASE (AK) INHIBITORS ON ACUTE THERMAL NOCICEPTION <u>E. A. Kowaluk</u>*, <u>A. Bannon</u>, <u>K. Gunther</u>, <u>K. Kohlhaas</u>, <u>J. Lynch</u>, and <u>M. F. Jarvis</u> Neuroscience Research, D-4PM, AP10, Abbott Laboratories, Abbott Park, IL 60064

Adenosine is an inhibitory neuromodulator that can increase the nociceptive threshold in animals exposed to a variety of noxious stimuli. Inhibition of the adenosine-catabolizing enzyme, AK, provides a means of locally enhancing extracellular adenosine concentrations. In the present study, the AK inhibitors 5'-amino,5'-deoxyadenosine (NH₂dADO), 5-iodotubercidin (5-IT), and 5'-deoxy,5-iodotubercidin (6'd-5IT) were examined for their analgesic efficacy in the hot-plate model of acute somatic nociception. Control and drug-treated adult male mice were placed on a 55°C hotplate and the latency to the tenth jump recorded via a computer driven infrared-beam photo-sensor. Mice that did not respond during the 180 sec test session were removed to prevent tissue damage. All three AK inhibitors were found to significantly increase jump latencies in a dose-dependent fashion. 5'd-5IT was the most potent AK inhibitor (approx. ED₅₀ value = 1 µmol/kg) followed by 5IT (ED₅₀ =10 µmol/kg), and 5'NH₂dADO (ED₅₀ = 100 µmol/kg). Pretreatment of mice with either theophylline (10 mg/kg) or cyclopentyltheophylline (10 mg/kg) which did not alter the jump latency of mice when administered alone, significantly attenuated the antinociceptive effects of 1 µmol/kg 5'd-5IT. The apparent efficacy of 2.5 µmol/kg of 5'd-5IT was not significantly altered following the repeated administration of this dose given twice daily for four days. The present data provide evidence for an antinociceptive action of AK inhibitors in the hotplate test, which, at least for 5'd5IT, is mediated by an enhancement of adenosine's actions at the A₁ receptor subtype and which does not exhibit tolerance following repeated administration.

RAPID DESENSITIZATION OF ATP RECEPTORS OF RAT PC12 CELLS. <u>L.</u> <u>Khiroug. R. Giniatullin. M. Talantova. G. J. Augustine* and A. Nistri.</u> Int. Sch. Adv. Studies (SISSA), 34013 Trieste, Italy and Duke Univ. Med. Ctr. Durham, NC 27710, U.S.A.

Whole-cell patch clamp recording was used to study the action of ATP on PC12 cells. Membrane potential was held at -70 mV and ATP (0.5 - 5 mM) was applied from micropipettes by brief (≤50 ms) pressure pulses. ATP induced inward currents with rapid onset and rapid decay, while ADP and α , β -methylene ATP were ineffective. Applying 5 mM ATP for more than 200 ms elicited a complex current response which had a rapid peak (smaller in amplitude than the one produced by shorter ATP applications) and then largely faded. Removal of ATP caused a strong rebound current that lasted several s. The amplitudes of both peak and rebound currents were depressed in parallel by bath application of a threshold dose of ATP (25 μM). The reversal potential of the peak and rebound currents was identical. When ATP was applied to a cell clamped at a depolarised potential, no current was observed but rapid return of the membrane potential to -70 mV at the end of ATP application caused a large rebound current. Brief (20 ms) application of ATP during the onset of the rebound current strongly and transiently suppressed this current. In contrast, similar applications during the gradual decay of the rebound wave elicited a small transient inward current. Application of 2 s ATP pulses at 20 s intervals reduced equally the peak and rebound currents, which both recovered at the same rate. These present data suggest two types of desensitization for ATP receptors. The first one is characterised by fast kinetics and low agonist affinity; rapid recovery from it causes receptor reactivation and yields the rebound current. The second desensitized state has slow kinetics and high affinity for the agonist and is seen during sustained application of a low dose of ATP. We propose that desensitization may contribute to the time course of responses mediated by purinergic receptors in situ. Supported by INFM.

ATP is a slow transmitter in neuro-neuronal synapse. V. A. Derkach*, Vollum Institute, Oregon Health Sciences University, Portland, OR 97201.

Extracellular ATP directly activates ligand-gated ion channels in a variety of neurons and muscle. At both peripheral and central synapses, ATP may act as a classical fast neurotransmitter. Here I report a slow excitatory postsynaptic current (e.p.s.c.) in cultured celiac ganglion neurons that can last a second, is selectively blocked by inhibitors of P2-purinergic receptors and is mimicked by millisecond applications of ATP to outside-out patches. Slow e.p.s.c.s alone or in combination with fast e.p.s.c.s could be evoked in the same neurons by stimulating of different inputs, indicating the presence of two populations of postsynaptic ATP receptors. Currents evoked in patches by ATP persisted in the absence of cytoplasmic GTP and were not occluded by GTP yS. Results imply that brief pulses of synaptically released ATP can have short and long lasting postsynaptic effects, both caused by activation of ligand-gated channels with different affinities to ATP. Supported by fund from Vollum Institute.

PHORBOL ESTER REGULATION OF A1 ADENOSINE RECEPTOR mRNA LEVELS IN SH-SY5Y CELLS. R.A. Peterfreund*. E.K. Gies. J.S. Fink. Depts. of Anesthesia and Neurology, Mass. General Hospital. Boston, MA 02114

The A1 adenosine receptor (A1R) is a member of the G protein-coupled receptor (GPCR) family widely distributed in the CNS. Phorbol esters, probably acting via protein kinase C (PKC), regulate the mRNA levels of many GPCR subtypes. We tested the hypothesis that the phorbol ester TPA can regulate A1R mRNA levels in the human SH-SY5Y neuroblastoma cell line. SH-SY5Y cells maintained in monolayer culture in serum supplemented medium were treated with TPA and total RNA was prepared by standard methods. A1R mRNA levels were measured by semiquantitative Northern blot analysis under high stringency conditions. The blots were hybridized to a 32P labeled riboprobe spanning 783 bp of the hA1R cDNA including 584 bp of 3' coding and 199 bp of 3'UT sequence. The blots were rehybridized to a cDNA probe for human flactin to control for loading. Hybridization of the A1R riboprobe to SH-SY5Y RNA resulted in a single band which comigrated with that of human cerebral cortex and cerebellum RNA. Treatment with TPA (100nM) decreased (to <50% of control) the levels of A1R mRNA in a time dependent fashion with the nadir at ~4h. There was no change in the hybridization signal after incubations with the ethanol vehicle control. The selective PKC inhibitor bisindolylmaleimide (1µM) prevented the TPA effects. Stability of A1R mRNA was determined by incubation with actinomycin D in the presence or absence of TPA. TPA did not accelerate the degradation of the A1R message. We conclude that SH-SY5Y human neuroblastoma cells express A1R mRNA. Phorbol esters reduce A1R mRNA levels via a mechanism likely mediated by PKC, but which does not appear to involve alterations in A1R mRNA stability. Supported by NSF # IBN-9319624

CHARACTERIZATION OF THE GENOMIC STRUCTURE OF MOUSE A2a ADENOSINE RECEPTOR GENE. J.F. Chen* and J.S. Fink. Molecular Neurobiology Lab. Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114

A2a adenosine receptors play an important role in the regulation of dopaminergic function in brain, and in cardiovascular

and immunological function in peripheral tissues. To analyze the A2a receptor at the level of gene expression, we characterized the genomic structure of mouse A2a receptor gene. We previously showed that a single gene encodes the mouse A2a receptors and that two exons encode the A2a receptor, with a single intron interrupting the coding sequences between transmembrane domain III and IV. In the present study, we further characterized the mouse A2a receptor gene by 5' rapid amplification of cDNA ends (RACE) and by direct sequencing of the genomic DNA upstream of the translation initiation codon of the A2a receptor gene. The study revealed an additional exon in the 5' region which encodes about 100 bp 5' untranslated sequences of A2a receptor mRNA. The identified transcription start site and promotor sequences indicate that the A2a gene promotor region are TATA-less, Sequences indicate that the Aza gene promotor region are TATA-less, GC-rich and contain several characteristic transcription factor binding sites, including AP1, AP2 and Sp1 sites. This result suggests that A2a receptor gene is characterized by a TATA-less and GC-rich promotor, a common feature of several G-protein coupled neurotransmitter receptors including D1 and D2 dopamine receptors.

PURINE MODULATION OF EPILEPTIFORM BURSTING IN RAT HIPPOCAMPAL SLICES. T. W. Stone*, M. J. Brodie and F. M. Ross. Division of Neuroscience and Biomedical Systems, University of Glasgow, Scotland, G12 8QQ.

Hippocampal slices (450µm) perfused with a medium containing no magnesium and 4-aminopyridine (4-AP) (50μM) generate spontaneous epileptiform activity which resembles interictal activity in vivo. It was of interest to determine if ATP could directly modulate this activity. Adenosine and ATP (2-100µM) caused a concentration-dependent decrease in epileptiform activity which was rapid and reversible. The A₁ receptor antagonist, 8-cyclopentyl-1,3-dimethylxanthine (CPT) (100nM) significantly increased the rate of activity suggesting the existence of a tonic purine inhibition. CPT (100nM) blocked the effects of both adenosine and ATP (50µM) Adenosine deaminase (0.2 U/ml) had a non-significant tendency to increase the frequency of epileptiform activity. At a concentration that neutralised adenosine's inhibition, adenosine deaminase failed to prevent the depression of activity caused by ATP. ATP analogues were used: α , β -methyleneATP (α , β -meATP) (10 μ M) produced a significant rise in activity which was not affected by adenosine deaminase. 2-methylthioATP (2-meSATP) (10µM) and UTP (50µM) were ineffective. P receptor antagonists suramin (10/50μM) and PPADS (5μM) had no effect on the basal rate of activity. Suramin at 10 and 50 µM and PPADS failed to antagonise the inhibition produced by ATP (50 μ M). The increase in activity by α , β -meATP was inhibited by suramin. Thus, ATP has a dual effect on spontaneous activity in the hippocampal CA3 region causing both inhibition and excitation. The excitatory effect is produced by the activation of a P2x -like receptor which is responsive to α , β meATP and inhibited by suramin. The inhibition is not affected by suramin or PPADS. It is unlikely that P2u receptors are involved due to the ineffectiveness of UTP. It is possible that another subtype of P2x receptor is involved in the inhibitory response or that a receptor which is activated by both nucleotides and nucleosides is responsible for the inhibitory effect.

CO-EXPRESSION OF RAT A₁-ADENOSINE RECEPTORS AND G-PROTEIN SUBUNITS IN Sf9 CELLS, <u>L, J. Blythe*</u>, <u>M. Dennis*</u> and <u>D. R. Hampson**</u>,

^a Faculty of Pharmacy, Univ. of Toronto, Toronto, Canada M5S 2S2. ^b Biosignal Inc., 1744 Rue William, Montreal, Quebec, Canada H3J 1R4

Adenosine, a purine nucleoside, modulates numerous effector systems including adenlyl cyclase, potassium channels and calcium channels. The effects of adenosine appear to be mediated by specific receptors that couple with guanosine adenosine appear to be ineduated by specific receptors that couple with guanosine nucleotide binding proteins (G-proteins). Of the four adenosine receptors that have been cloned, the A₁ receptor is particularly well characterized. These receptors may be involved in the pathogenesis of epilepsy and confer neuroprotective effects in cerebral ischemia. The primary objective of this project is to study and develop optimal conditions for the functional co-expression of adenosine A₁ with G-protein subunits in Spodoptera frugiperda (Sf9) cells using the baculovirus (BV) expression system.

In preliminary experiments A₁ receptors were expressed alone in Sf9 cells and characterized by radioligand binding analysis using the A₁ agonist [⁴H]CCPA. Agonist binding to the receptor was characterized by relatively low affinity binding. Co-expression of the receptor with Goi3 increased the affinity of the agonist for the receptor three fold. The effect of other G proteins on [3H]CCPA binding are currently being explored. Our results indicate that Sf9 cells and the BV system provide a good expression system for studying interactions between mammalian adenosine receptors and G proteins.

ADENOSINE A3 RECEPTOR SELECTIVE ANTAGONISTS: FLAVONOID AND DIHYDROPYRIDINE DERIVATIVES.

K.A. Jacobson^a*, A. M. van Rhee^a, J. L. Jiang^a, Y. Karton^a, X.d. Ji^a, D.K.J.E. von Lubitz^a, M.E. Olah^b, and G.L. Stiles^b ^aMol. Recognition, NIDDK/NIH, Bethesda, MD 20892; ^bDuke Univ. Med. Center, Durham, NC.

Adenosine A3 receptor antagonists are sought as cerebroprotective and anti-inflammatory agents. Xanthines, the classical antagonists, have failed to provide selectivity for A3 receptors. We have assembled and screened diverse chemical libraries and identified flavonoids (phenolics found in all vascular plants) and dihydropyridines (e.g. Ca2+ channel antagonists) as promising leads in displacing binding of [125I]AB-MECA $(N^6$ -(4-amino-3-iodobenzyl)adenosine-5'-N-methyluronamide) with μM affinity at cloned human and rat A3 receptors. The flavonol galangin had affinities of 13.6 and 3.2 μM at human A₁ and A₃ receptors, respectively. The dihydropyridines nicardipine and niguldipine had K_i values of 2-3 μM at human A₃ receptors (much weaker at A₁ and A₂ receptors). We have chemically modified these two chemical classes resulting in the more potent compounds MRS1067 (a flavone) and MRS1097 (a dihydropyridine). Both compounds displayed selectivity for A3 vs. A_1 receptors (>40-fold) and antagonized the A3-agonist elicited inhibition of adenylyl cyclase in membranes of CHO cells transfected with rat A3 receptors. It appears that flavonoids constitute a class of naturally occurring adenosine antagonists that are even more widespread in the diet than caffeine and other xanthines. MRS1097 did not bind to L-type Ca²⁺ channels nor to cholinergic, adrenergic, or other receptors.

PHOTOAFFINITY LABELING OF A P3 PURINOCEPTOR-PROTEIN PURIFIED FROM RAT BRAIN MEMBRANES. Y. Saitoh*, and H. Nakata, Dept. of Mol. & Cell. Neurobiol., Tokyo Metropolitan Inst. for Neurosci., Fuchu-shi, Tokyo

We have found a novel adenosine-binding protein in rat brain membranes. We partially purified this protein from rat brain membranes and characterized its properties. It can bind to both adenine nucleotides and adenosine. Based on the ligand binding specificities, the protein is likely to be classified into the P3 purinoceptor which was recently proposed (Shinozuka et al, 1988). In the present study, we characterized the P3 purinoceptor-like protein (P3LP) further by photoaffinity labeling. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of the labeled preparations with 8-azidoadenosine-5'-[32P]triphosphate revealed that the probe was incorporated specifically into a single band with an approximate molecular size of 54kDa. We compared the photoaffinity labeling pattern with the NECA-binding activity of several fractions obtained from the purification procedures. The patterns of the 54kDa band agreed well with those of the NECA-binding activity. These results suggest that the 54kDa band is the P3LP. This affinity labeling technique will be a useful method for the sensitive determination of P3LP.

CALCIUM REGULATED UPTAKE OF EXCITATORY AMINO ACIDS IN POSTSYNAPTIC NEURON. 1Y. Kataoka, 1H. Ohmori and 1K. Kataoka*. ¹Dept. of Neurosci., Osaka Bioscience Institute, Osaka. ²Dept. of Physiol., Kyoto Univ., Kyoto, ³Dept. of physiol., Ehime Univ. Sch. of Med., Ehime, Japan.

Excitatory amino acids released from the presynaptic terminal are known to be removed from the synaptic cleft or other extracellular space by their uptake systems or other extracellular space by their uptake systems existing in the presynaptic terminal and in surrounding glial cells. The ionic current mediated by the Nathependent uptake of excitatory amino acids was isolated in cultured rat cerebellar Purkinje cells voltage clamped at -65 mV with the whole cell patch clamp method. This uptake system was thought to work postsynaptically, since the uptake mediated current was induced in cell soma and in all over the dendrites. This postsynaptic uptake was accompanied by an increase in Cl. conductance, and was facilitated approximately 3 times by the postsynaptic Ca2+ influx brought by membrane depolarization. INHIBITION OF SYNTHESIS OF EAAC1 GLUTAMATE TRANSPORTER ALTERS y - AMINOBUTYRIC ACID LEVELS IN DISCRETE BRAIN REGIONS. C. U. Eccles*, M. Dykes-Hoberg, and

J. D. Rothstein. Dept. of Neurology, Johns Hopkins Univ., and Dept. of Pharmaceutical Sciences, Univ. of Maryland School of Pharmacy, Baltimore, MD.

Selective knockout of individual high-affinity glutamate transporter proteins using antisense oligonucleotides have demonstrated that the astroglial transporters GLAST and GLT-1 are of primary importance in maintaining low extracellular glutamate concentrations and in protecting against excitotoxicity. The neuronal transporter, EAAC1, appears to play a lesser role in clearing extracellular glutamate because selective knockout of EAAC1 produces minimal neurotoxicity or changes in extracellular glutamate (*Neuron*, 16,675). Loss of EAAC1 protein, however, produces behavioral abnormalities which include seizures and hyperresponsiveness suggesting that loss of EAAC1 function may alter synaptic function or neuronal metabolism. Because EAACI has been localized to GABAergic neurons and glutamate is a precursor for GABA synthesis, we hypothesized that EAAC1 may play a role in GABA synthesis and neurotransmission. In our initial studies, we determined GABA levels in several brain regions after 7 days of treatment with EAAC1 antisense (or sense) oligonucleotide delivered by infusion into the lateral ventricle of Sprague-Dawley male rats surgically prepared with subcutaneous miniosmotic pumps and intraventricular cannulae. After 7 days of treatment, brains were removed after decapitation, dissected into 6 regions, and prepared for HPLC analysis of GABA. Preliminary studies indicate that GABA concentrations are reduced by greater than 25% in thalamus and hippocampus. GABA concentrations in anterior cortex, posterior cortex and striatum are decreased from 10-20%. No changes were detected in cerebellum which is remote from the site of infusion. These results are consistent with the possibility that inhibition of glutamate uptake may lead to limited precursor availability and decreased GABA synthesis, i.e. that a portion of GABA synthesis depends on glutamate uptake by GABAergic neurons. The behavioral abnormalities observed may be manifestations of such a decrease in GABA function. (Supported by NIH)

GLUTAMATE CONTRACTS SCHISTOSOMA MANSONI (TREMATODA: DIGENEA) ISOLATED MUSCLE FIBERS: EVIDENCE FOR A GLUTAMATE **TRANSPORTER.** <u>C.L. Miller^{1*}, J.L. Bennett¹, and R.A. Pax²</u> Departments of Pharmacology & Toxicology¹ and Zoology², Michigan State University, East Lansing,

Schistosoma mansoni muscle fibers contract in response to L-glutamate in a dosedependent manner (10°-10°3M). D-Glutamate, L-aspartate and D-aspartate also cause contraction of the fibers. The glutamate receptor agonists NMDA, ibotenate, kainate, AMPA, quisqualate, ACPD, and L-AP4 produce little or no contraction a concentrations as high as 1 mM. The glutamate receptor antagonists, MK-801, CNQX, AP-5, and MCPG, did not block glutamate induced contraction of the muscle fibers. However, other amino acids such as, L-aspartate, L-cysteate, and cysteine sulfinate, known to be substrates of the high-affinity glutamate transporters were found to elicit contraction of the muscle fibers. Contractions induced by L-glutamate are dependent on extracellular Ca' and are blocked by the voltage-gated Ca' channel blocker nicardipine (10 and 1 μ M). [3H]-L-Glutamate, incubated with the muscle fiber preparation, is taken up in a dose-time- and temperature-dependent manner. Both L-glutamate induced contractions and [3H]-L-glutamate uptake are Na*-dependent, and are blocked by specific inhibitors of the high-affinity glutamate transporter, DL-threo-β hydroxyaspartate, and L-trans-pyrollidine-2,4-dicarboxylic acid (THA, PDC). These data suggest that there may be an electrogenic Na*-dependent high-affinity glutamate transporter on the schistosome muscle membrane. When glutamate is applied to schistosome muscle fibers it is possible that electrogenic transport of glutamate is causing the fiber membrane to depolarize, thereby opening nicardipine-sensitive voltage-gated Ca** channels, and raising intracellular Ca** concentrations leading to contraction. DIFFERENTIAL EXPRESSION OF THREE GLUTAMATE TRANSPORTER SUBTYPES IN THE RAT RETINA

1M.Wießner. 2J.D.Rothstein & 1T.Rauen*; 1Max-Planck-Institut für Hirmforschung, 60528 Frankfurt, Germany; 2Johns Hopkins Univ., Dept. of Neurology, Baltimore, MD 21287, USA

The major excitatory neurotransmitter in the mammalian retina is L-glutamate.

Reverse transcribed mRNA from rat retinae, amplified by polymerase chain reaction (RT-PCR) using gene-specific primers for GLAST-1, GLT-1 and EAAC-1, revealed the presence of message for all three transporter subtypes in the retina. Single cell RT-PCR of retinal dissociates demonstrated that GLAST-1 is the sole Lglutamate transporter expressed in Müller cells. Immunocytochemistry indicated that Müller glial cells and astrocytes are reactive for GLAST-1, whereas GLT-1 is preferentially expressed by different types of bipolar cells. EAAC-1 is found in horizontal cells, in amacrine cells and ganglion cells. Western blot analysis suggested the following rank order of glutamate transporter subtype expression in the retina: GLAST-1>EAAC-1>GLT-1. Additionally, accumulation of L-[3H]glutamate occurred predominately in Müller glial cells. This high capacity for glutamate uptake is compatible with our finding of relatively high amounts of GLAST-1 in Müller cell membranes surrounding synapses.

We have shown that GLAST-1, GLT-1 and EAAC-1 have specific distributions

in the retina and are expressed by different cell types and thus may have different functional roles in the retina. Uptake for metabolic reasons, reuptake of synaptically released glutamate and light dependent uptake might require different transporter characteristics. Thus glutamate transporters are not only found on presynaptic terminals of glutamatergic neurons, but also in postsynaptic elements of GABAergic neurons and in glial cells.

REGIONAL EXPRESSION OF THE GLUT4 GLUCOSE TRANSPORTER IN MOUSE BRAIN. L.A. Simpson*, K. Li, E. M. Koehler-Stee, E. M. Gibbs and S. J. Vannucci. NIDDK, Bethesda, MD 20892, Pfizer Inc., Groton, CT 06340 and Dept. of Pediatrics, Hershey Med Ctr. Penn State Univ, Hershey, PA 17033.

Glucose transport into brain is mediated by a family of facilitative glucose transporter proteins (GLUT1-7). The predominant glucose transporter isoforms in brain are: GLUT1, blood-brain barrier (55 kDa) and glia (45kDa); GLUT3, neurons; however, low levels of GLUT4, the insulin-sensitive glucose transporter, have been reported. GLUT4 is highly expressed in peripheral tissues (heart, skeletal muscle, adipose) in which insulin and contraction induce acute increases in glucose transport by a recruitment of intracellular GLUT4 transporters to the plasma membrane. The purpose of this study was to examine GLUT4 expression by in situ hybridization, laser confocal microscopy (LCM), and Western blot analysis in brains of normal, genetically diabetic (db/db) and GLUT4 transgenic diabetic (hGLUT4db/db) mice. In situ hybridization studies localized GLUT4 mRNA expression primarily to 3 brain regions: cerebellum (CB), dentate gyrus of the hippocampus (DG) and olfactory bulb (OB). Expression is most pronounced in cerebellum where it is localized to the granule cells. Granule cell-specific expression appears true of DG and OB as well. LCM studies confirmed this localization for GLUT4 protein and demonstrated intracellular GLUT4, as is seen in peripheral tissues. Both db/db and hGLUT4db/db mice demonstrate enhanced GLUT4 expression in CB. The results of this study indicate that a subset of neurons, the granule cells, express the insulin-sensitive glucose transporter, GLUT4, in addition to the usual neuronal transporter, GLUT3, which may be integral to patterns of granule cell migration and maturation. The enhanced expression of GLUT4 in these cells may be a locus for the effects of diabetes on the brain. Supported by JDFI Grant # 194182 (SJV), NIDDK, Pfizer.

DIFFERENTIAL POSTNATAL DEVELOPMENT OF EXCITATORY AMINO ACID TRANSPORTER SUBTYPES IN RAT BRAIN 12V.R. Roettger* and 12S.G. Amara. 14Doward Hughes Medical Institute and 2Vollum Institute. Oregon Health Sciences University, Portland, OR

Health Sciences University, Portland, OR
Maintenance of low extracellular glutamate (GLU), the major excitatory transmitter
in mammalian brain, is due primarily to re-uptake via Na⁺-dependent transporters.
Previous studies measured ³H-GLU uptake at 3 days post-birth (Blakely et al., <u>J. Neurochem.</u>, 56:860, 1991; Christensen & Fonnum, Neurochem. Res., 17:457,
1992) but did not differentiate between transporter subtypes. We used polyclonal
antibodies raised against excitatory amino acid transporter subtypes (EAAT1-4) and
Western blotting to determine the protein developmental pattern in three rat brain
regions: cerebellum. cortex, and hippocambus.

Western blotting to determine the protein developmental pattern in three rat brain regions: cerebellum, cortex, and hippocampus.

The developmental pattern of EAAT1 and EAAT2 protein expression was similar in all three regions; both proteins were present at very low levels beginning on postnatal (PN) day 1-4. Protein content continuously increased through the postnatal period leveling off at PN12 for EAAT1 and PN24 for EAAT2. In contrast, EAAT3 protein was present at adult concentrations beginning with PN1 in all three brain regions. Postnatal EAAT1-3 proteins showed no changes in molecular weight versus adult proteins. EAAT4 protein showed a different pattern. In cerebellum, a 68kD glycosylated protein species was observed beginning approximately PN14 and present through to adult. This species was not detectable at any timepoint in either cortex or hippocampus. In addition, a higher molecular weight species (app. 85kD) was present in all three regions on PN1; staining of this species was blocked when antibody was preincubated with GST-EAAT4 fusion protein but not with GST protein alone. The concentration of the second protein decreased during development becoming non-detectable after PN24. The identity of this second species has not been established; Northern blots and in vitual bridge to the protein submit of the protein concentration between the coming non-detectable after PN24. The identity of this second species has not been established;

Northern blots and in situ hybridization studies are currently being conducted.
This differential pattern of expression of EAAT proteins raises the possibility that the transporters may play a role in regulating brain development by altering the level of extracellular glutamate. Funding Source: Howard Hughes Medical Institute.

IMPAIRMENT OF DNA REPAIR LEADS TO LOSS OF GLUTAMATE TRANSPORT *IN VITRO*.

L. Jin*, G. C. Lin, C. Coccia, I. Nagano and J.D. Rothstein. Department of Neurology, Johns Hopkins University, Baltimore, MD 21287.

A loss of high-affinity glutamate transport was identified in certain brain regions and spinal cord of patients with amyotrophic lateral sclerosis (ALS). Our laboratory previously developed an in vitro model of defective glutamate transport by chronically blocking the glutamate carriers in cultured organotypic spinal cord slices. This resulted in the slow degeneration of motor neurons (over several weeks), a pathogenic marker for ALS. In this study we applied this paradigm to pursue the potential mechanisms which could cause a loss of glutamate transport. We hypothesized that reduced DNA repair capacity may lead to accumulation of damage on the glutamate transporter gene, which consequently would result in a loss of glutamate transport. 1-beta-Darabinofuranosylcytosine (araC), a DNA polymerase inhibitor, was used to inhibit DNA repair. Chronic inhibition of DNA repair synthesis with low concentrations of araC in spinal cord cultures initially produced a dose-dependent loss of glutamate transport, measured by [H3]-D-aspartate binding assay. A loss of the motor neuron marker choline acetyltransferase activity (ChAT) occurred approximately 7 days later. This motor neuron toxicity was prevented by NBQX, a non-NMDA antagonist, or by t-BPN, an anti-oxidant. In addition, the toxicity synergistically enhanced by concomitant treatment threohydroxyaspartate (THA), a glutamate transport blocker. These results suggest that impairment of DNA repair may be relevant to altered glutamate transport function and could potentiate glutamate toxicity (Supported by NIH and MDA)

REGIONAL AND ULTRASTRUCTURAL LOCALIZATION OF THE GLUTAMATE TRANSPORTER EAAT4 IN HUMAN AND RAT BRAIN. M Dykes-Hoberg*, A Furuta, LJ Martin‡, G Lin, JD

Rothstein. Johns Hopkins University, Dept. of Neurology and Pathology. Baltimore, MD 21287.

Glutamate transport is the primary mechanism for the synaptic inactivation of glutamate. EAAT4 is a novel glutamate transporter with properties of a ligandgated chloride channel, that was recently cloned from human brain. The present study is an investigation of the protein expression and cellular localization of EAAT4 in human tissue, and the cloning, expression, cellular and ultrastructural localization of EAAT4 in rat brain (rEAAT4). Regional immunoblot analysis of EAAT4, using a monospecific oligopeptide (carboxy-terminal) affinity-purified polyclonal antibody, revealed that the protein is restricted to the central nervous system. The EAAT4 protein was largely expressed in cerebellum, with a much lower expression in hippocampus, cerebral cortex, striatum, and thalamus. Immunocytochemical study showed intense EAAT4-immunoreactivity in the human and rat cerebellar Purkinje cells, in a somatodendritic pattern. Other brain regions including cerebral cortex, hippocampus, striatum show faint neuropil staining of EAAT4. Ultrastructurally, rEAAT4 protein was localized in Purkinje cell dendrites and spines. In the hippocampus and neocortex, rEAAT4immunoreactivity was found mainly in plasma membranes of distal dendrites, with enrichment at the post-synaptic density. Occasionally, rEAAT4 immunoreactivity was found in astrocytic cell processes. Thus, EAAT4 is primarily, although not exclusively, localized to cerebellar Purkinje cells, and to rarely in terminal dendrites and astrocytic processes of other brain regions. and MDA)

DIFFERENTIAL REGULATION OF GLUTAMATE TRANSPORTER SUBTYPES IN DEVELOPING RAT BRAIN.

<u>A Furuta*, LJ Martin*, JD Rothstein,</u> Johns Hopkins University, Dept. of Neurology and Pathology*, Baltimore, MD 21287.

Glutamatergic systems participate in dendritic and axonal arborization, synaptogenesis and activity-dependent synaptic plasticity during development. Extracellular glutamate concentrations are regulated by transporter proteins localized in neuronal (EAAC1) and glial cell membranes (GLAST and GLT-1). Recently a novel neuronal glutamate transporter, EAAT4 was cloned in human brain. We have generated a monospecific polyclonal antibody for EAAT4, and the rat homolog, rEAAT4. The present study examined the protein expression and cellular localization of glutamate transporter subtypes in embryonic (E12, 15, 18) and postnatal (P1, 5, 10, 16, 24, 26, adult) rat brain, using immunoblotting and immunocytochemistry with anti-peptide antibodies for all four glutamate transporter subtypes. By immunoblotting, GLAST expression increased with age to reach adult levels by P26. However, the glycosylation of GLAST was differentially regulated-glycosylated GLAST increased with maturation. GLT-1 expression increased progressively to adult levels, which were achieved at about P26 EAAC1 expression increased with maturation and reached maximum levels around P5 to P16, then decreased to adult levels by P26. Strong EAAC1-immunoreactivity was seen as early as E15, and by E18, it was throughout forebrain regions including neocortex, striatum and hippocampus. In contrast, GLT-1 was expressed in rhinencephalon, hypothalamus and hippocampus at E18; but little immunoreactivity was seen in neocortex and striatum embryonically, rEAAT4 increased with maturation and was mainly localized to cerebellar Purkinje cells, although a small amount of protein was seen in the adult striatum and neocortex. Thus, the expression and localization of glutamate transporter immunoreactivity was subtype-specific during the developmental period. These findings indicate that glutamate transporters could participate in neuronal and glial maturation. (Supported by NIH and MDA)

Modulation of astrocytic glutamate uptake by nitric oxide

Z-C. Ye* and H. Sontheimer. Neurobiology Research Center and Dept. of Physiology and Biophysics, Univ. of Alabama at Birmingham, Birmingham. AL 35294.

Glutamate is maintained at low micromolar concentrations in the extracellular space. This task, which in part serves to limit potential glutamate-mediated neurotoxicity, is believed to be primarily accomplished by the high affinity, Na*-dependent uptake into astrocytes. Astrocytes are also a primary target for neuronally released nitric oxide (NO). We have used measurements of $^3\text{H}\text{-}\text{glutamate/aspartate}$ uptake in a hippocampal culture system to evaluate the modulation of glial glutamate uptake by NO. Exposure of astrocytes to several nitric oxide donors consistently inhibited astrocytic glutamate uptake in a dose and time dependent manner. According to the degree and time-course of their effectiveness, NO donors could be divided into two groups: 1.) SIN-1 and SNAP, in the presence of SOD/CAT for 5-30 minutes, inhibited uptake rates by 20-40%. These effects were abolished by treatment with the NO scavenger hemoglobin. Effects could be mimicked by activating astrocytic iNOS by coculture (24h) with lipopolysaccharides (LPS) or several cytokines including TNF- α , IL-1 β , and IFN- γ . Their effects were abolished by the NOS inhibitors LNA, L-NMMA, and LNAME suggesting that inhibition was mediated by NO. 2.) Longer incubations (90 min) with SNP (0.1 mM) induced a dramatic release of glutamate by astrocytes with relatively little effect on uptake. These effects were not reversed by hemoglobin, but instead could be blocked by inhibition of guanylyl cyclase using methylene blue (20 μ M, 30 min). SNP-induced release of glutamate from astrocytes may provide a alternative explanation for the frequently observed neurotoxic effect of SNP. Taken together our data provided further evidence that astrocytic glutamate uptake is dynamically regulated and sensitive to numerous factors released by neurons or non-neuronal cells in the brain. These modulatory influences may be important for normal synaptic transmission and could account for some of the uncontrolled glutamate accumulations observed with some CNS diseases.

PHARMACOLOGICAL CHARACTERIZATION OF NOVEL GLUTAMATE TRANSPORT IN RAT CORTICAL NEURONS. G. J. Wang*, K. Pratt, J. Schnuer, P. A. Rosenberg, Dept. of Neurology, Children's Hospital and Harvard Medical School, Boston, MA 02115.

Glutamate transport in cortical synaptosomes is potently inhibited by dihydrokainate (DHK) but not L- α -aminoadipate (L- α -AA) [Robinson et al. (1993) J. Neurochem. <u>60</u> 167-179]. In order to pursue the possibility of a novel neuronal transporter, we sought to characterize glutamate transport in cultures of cortical neurons (astrocytes < 0.5%). Uptake studies using [3H]-L-glutamate showed Na*-dependent high affinity glutamate transport with a K_m of 9.6 \pm 2.3 μM (n=7). The V_{max} was 2.8 \pm 0.3 nmol/mg protein/min. DHK, at 1 mM, inhibited uptake of radioactivity by 88 \pm 3%, and had a K₁ of 65 \pm 12 μM . L- α -AA, at 1 mM, inhibited uptake by only 25 4%. Five other excitatory amino acid analogs were examined for their ability to inhibit ${l^1H}-L$ -glutamate uptake in these cultures. Of the analogs tested, L-trans-pyrrolidine-2,4-dicarboxylate, L-serine-O-sulfate, and kainate potently inhibited transport activity with K_i values of 5 ± 0 , 56 ± 6 and 102 \pm 9 μ M, respectively (n=3). α -Methyl-DL-glutamate and β -N-oxaly-L- α , β -diaminopropionic acid at 1 mM did not significantly inhibit transport. Autoradiography with [2 H]-D-aspartate labeled some but not all DHK at 500 neuronal cell bodies and processes as well as astrocytes. μM greatly reduced labeling on neuronal cell bodies and processes, but did not block labeling of astrocytes. In contrast, the labeling of both astrocytes and neurons was almost completely blocked by 1 mM PDC. Thus, the dominant glutamate transport activity in cortical neuronal cultures is similar to that of cortical synaptosomes.

This work was funded by grants from the NINDS (NS31353) and from the United Cerebral Palsy Foundation.

ENDOTHELINS INDUCE REVERSED UPTAKE OF GLUTAMATE FROM RAT CULTURED ASTROCYTES. Y. Sasaki*, M. Takimoto, K. Oda, T. Früh, M. Takai, T. Okada, and S. Hori. International Research Laboratories, Ciba-Geigy Japan Ltd.,

Takarazuka 665, Japan.

Release of glutamate (Glu) from glial cells via reversal transport is supposed to be one of the most critical events for the neurodegeneration resulting from cerebral ischemia. To investigate the reversal transport of Glu in glial cells, we measured Glu efflux from rat cultured astrocytes preloaded with [3H]Glu. Either 60 mM KCl or Na+-free medium, but not 10 µM ionomycin, induced Glu efflux. This result indicate that the efflux was due to reversed uptake of Glu via Na+/K+-dependent Glu transporter. We investigated the effect of various neuropeptides and neurotransmitters on this response in astrocytes and found that only endothelins (ETs) induced the reversed uptake. ET-1, ET-3 and an ET_B-specific agonist, IRL 1620 increased the reversed uptake of Glu with similar potencies (EC₅₀ = 0.6-2 nM). An ET_B-selective antagonist, IRL 2500, partially inhibited the reversed uptake induced by 1 nM ET-1 in a concentration-dependently manner, causing a maximum inhibition of 60% at 1 μ M. However, 1 μ M BQ-123, an ET_A-selective antagonist, did not cause significant inhibition. Combination of both antagonists completely inhibited the ET-1-induced reversed uptake. These results indicate that both receptor subtypes are involved in the reversed uptake with a major contribution of ET_B. Our findings suggest that ETs, which are known to be released in ischemia. exacerbate neuronal damage by stimulating the reversed uptake of Glu.

COS7 ENDOGENOUSLY EXPRESS THE GLAST SUBTYPE OF Na+-DEPENDENT GLUTAMATE TRANSPORTER. M.K. Perez I, P.A. Johansen* I, L.A. Dowd¹, J.R. Vondrasek¹, J.D. Rothstein², and M.B. Robinson¹. Children's Seashore House, Depts. of Pediatrics and Pharmacology, Univ. of Pennsylvania, Philadelphia, PA 19104 and ²Dept. of Neurology, Johns Hopkins Univ., Baltimore, MD 21287.

C6 glioma endogenously express the EAAC1 subtype of Glu transporter and are being used as a model system to study regulation (See Dowd et al., adjacent poster). In a search of cell lines, we found that COS7 cells endogenously express GLAST-like immunoreactivity but not EAAC1- or GLT1-like immunoreactivity. We characterized the properties of this endogenous Na+-dependent Glu transport in COS7 cells. Substitution of equimolar choline chloride for NaCl reduced the accumulation of both L-[³H]-Glu and D-[³H]-Asp to less than 15% of controls. Under conditions of initial velocity the Na+-dependent transport of both L-[³H]-Glu and D-[³H]-Asp were consistent with a single site with K_m values of 22 µM and 45 µM, respectively. The V_{max} values were 442 and 145 pmol/mg protein per min, respectively. The pharmacology of endogenous transport in COS7 cells was characterized using EAA analogs which have been shown to selectively inhibit subtypes of Glu transport in brain tissue. Na+-dependent L-[³H]-Glu transport was inhibited by L-trans-pyrrolidine-2,4-dicarboxylate, L-α-aminoadipate, DL-threo-β-hydroxyaspartate with IC₅₀ values of 60 µM and 18 µM, respectively. Na+-dependent L-[³H]-Glu Characteristic was initiated by L-trains-pytrointed-2,4-dicatosystack, E-α-aminoadipate, DL-threo-β-hydroxyaspartate with IC50 values of 60 μM, 500 μM, and 18 μM, respectively. Na⁺-dependent L-[3 H]-Glu transport was almost completely insensitive to dihydrokainate. This pharmacological profile is similar to that previously reported for primary astrocyte-enriched cultures. (NS29868)

NEUROTOXICITY OF DIHYDROKAINATE TO RAT CORTICAL NEURONS IN CULTURE. R.C. Blitzblau, G.J. Wang, M. Yonezawa*, E. Aizenman', and P.A. Rosenberg, Dept. of Neurol., Children's Hospital & Harvard. Med. Sch., Boston MA 02115 and Dept. of Neurobiol. Univ. Pittsburgh. Sch. Med., Pittsburgh, PA 15261.

Glutamate transport into cortical synaptosomes is potently inhibited by dihydrokainate (DHK), but not by $1-\alpha$ -amino-adipate. This pharmacological signature is replicated in nearly pure (less than 0.5% astrocytes) cultures of rat cortical neurons, but not in mixed cultures of astrocytes and neurons. If glutamate transport is important in protecting neurons against excitotoxicity, then in neuronal cultures (but not in mixed cultures) DHK would be expected to be neurotoxic. In mixed cortical cultures, a 20-24 hour exposure to 1 mM DHK had no significant effect on neuronal survival (94 \pm 17% of control; n = 4). In contrast, in neuronal cultures, survival in the presence of 1 mM DHK was 33 \pm 22% of control (p < 0.001; n = 3). This neurotoxicity of DHK was blocked by 10 μ M MK-801 plus 10 μ M GYKI 52466. In order to clarify the mechanism of toxicity of DHK, we investigated its effect on [1 H]-MK-801 binding to rat brain membranes, 45 Ca influx into cortical cultures, as well as on membrane currents in whole-cell recordings from cortical neurons. The results of these studies were consistent with a weak antagonist action of DHK at the NMDA receptor. In addition, a small current was observed with 1 mM DHK (10% of the current produced by 30 µM NMDA) that was blocked by 100 µM 7chlorokynurenate but not by 5 μM NBQX. It remains to be determined whether this current is due to a direct or an indirect action of DHK. Taken together, these data suggest that the toxicity of DHK that occurs in neuronal

cultures is due to its ability to block glutamate transport in these cultures.

This work was funded by grants from the NINDS (NS31353) and from the United Cerebral Palsy Foundation.

MECHANISMS INVOLVED IN RAPID STIMULATION OF THE EAAC1 GLUTAMATE TRANSPORTER BY PROTEIN KINASE C. L.A.Dowd*1, C.Lamothe¹, L.D.Rothstein², and M.B.Robinson¹.¹Children's Seashore House, Depts. of Pediatrics and Pharmacology, Univ. of Pennsylvania, Philadelphia, PA 19104 and ²Dept. of Neurology, Johns Hopkins Univ., Baltimore, MD 21287.
Four Na*-dependent glutamate (Glu) transporter cDNAs have been isolated (EAAC1, GLAST, GLT1, & EAAT4). We have recently demonstrated that C6 glioma endogenously express EAAC1 but not GLAST or GLT1 protein. We also showed that the PKC activator, PMA, rapidly increases the V_{max} for L-[³H]-Glu transport activity in C6 glioma (²- to 3-fold) but does not affect the K_m. This increase appears to be independent of protein synthesis. We are in the process of trying to define the mechanisms responsible for this regulation. To define which PKC isoform might be involved, we used the reported observation that, of the three isoforms expressed in C6 glioma (α, δ, and θ), the δ isoform is selectively down-regulated by 30 to 100 nM PMA (24h) (Chen & Wu, 1995). We found that a comparable pre-incubation blocked the effects of acute PMA treatment suggesting that the δ isoform of PKC is responsible for the stimulation of EAAC1 transport. To determine if the increase in activity is due to the movement of EAAC1 protein from intracellular vesicles to plasma membrane, as is observed with glucose transporters, C6 glioma cells were pretreated with PMA or vehicle, and subcellular fractionation was used to separate vesicular EAAC1 from plasma membrane EAAC1. Western analysis demonstrated that EAAC1 was present in both membrane fractions and PMA did not cause the movement of EAAC1 from vesicles to plasma membrane. We are in the process of determining whether direct phosphorylation of EAAC1 by PKC is occurring. (NS29868)

EXPRESSION OF Na⁺-DEPENDENT L-GLUTAMATE TRANSPORTER GLT1 IN PRIMARY CULTURES. J.R. Vondrasek ¹, L.A. Dowd ¹, J.D. Rothstein ², and M.B. Robinson ^{*1}.

¹Children's Seashore House, Depts. of Pediatrics and Pharmacology, Univ. of Pennsylvania, Philadelphia, PA 19104 and ²Dept. of Neurology, Johns Hopkins Univ., Baltimore, MD 21287.

Extracellular levels of the excitatory, amino acid glutamate (Glu) are

Neurology, Johns Hopkins Univ., Baltimore, MD 21287.

Extracellular levels of the excitatory amino acid glutamate (Glu) are primarily regulated by a family of Na⁺-dependent high affinity (SDHA) L-Glu transporters. The subtypes GLT1 and GLAST are expressed by glia in vivo. We previously characterized the pharmacology of SDHA transport in astrocyte-enriched cultures (14-17 days in vitro). This pharmacology differed from that observed for GLT1-mediated transport but was similar to that reported for GLAST-mediated transport. In the but was similar to that reported for GLAST-mediated transport. In the present study, the identification of transporter subtypes expressed by glial cultures and potential regulatory mechanisms were investigated. Unlike the cellular distribution of these subtypes *in vivo*, Western analyses indicated that astrocytes express GLAST but not GLT1. Two approaches were used to induce expression of GLT1. First, inclusion of L-Glu (1mM) or the mGluR agonist 1S, 3R ACPD (500 μ M) in the culture media did not induce GLT1. However, the addition of the cAMP analogs, dibutryl cAMP (250μM) or 8-bromo cAMP (250μM) to the culture media induced expression of GLT1. In addition, mixed cultures of neurons and glia also express GLT1. These data suggest that expression of the SDHA L-Glu transporter GLT1 is regulated through a cAMP response element (CRE) and potentially by the presence of neurons. (NS29868)

HYPOXIA RELEASES GLUTAMATE BY REVERSAL OF c-AMINOADIPATE-SELECTIVE TRANSPORTERS IN RAT HIPPOCAMPAL SLICES, J.E. Madl* and M.N. Hyden. Department of Anatomy & Neurobiology, CSU, Ft. Collins, CO 80523.

Hypoxia and other metabolic insults release toxic amounts of glutamate (Glu) and other excitatory amino acids. This release may be due to reversal

Hypoxia and other metabolic insults release toxic amounts of glutamate (Glu) and other excitatory amino acids. This release may be due to reversal of transporters. To identify the transporters primarily involved in pathologic release, we determined the effects of transportable Glu analogs on hypoxia-induced Glu release from rat hippocampal slices. Cloned members of the XAG* transporter family have much lower affinities for α-Aminoadipate (AAA) and quisqualate than D,L-threo-β-Hydroxyaspartate (TBH) or D-Aspartate. Differences in the ability of Glu analogs to inhibit the uptake of TBH and AAA suggest these analogs are taken up primarily via different transporters. The effects of low pH and ion substitution also suggests transport of TBH and AAA occurs by different systems. Hypoxia released more preloaded AAA than TBH, suggesting that AAA cotransporters may be more easily reversed than TBH transporters. Azide-induced release of endogenous Glu was inhibited by extracellular AAA and quisqualate, suggesting that pathologic Glu release occurs primarily via nonXAG* transporters. However, TBH and other analogs selective for XAG* transporters potentiated release, suggesting XAG* transporters continue to take up Glu during hypoxia. The apparent greater vulnerability of AAA transporters to reversal during metabolic insults and the ability of AAA to block ATP depletion-induced release of endogenous Glu strongly suggest that the initial pathologic release of Glu is primarily mediated by nonXAG* transporters. Funding was provided by PHS grant NS28824.

TWO ELECTROGENIC GLUTAMATE UPTAKE TRANSPORTERS WERE FOUND IN SECONDARY CULTURES OF RAT ASTROCYTES EXPOSED TO INJURY. Y.L. Lee, P.G. Lal, and D.L. Eng. VA Medical Center, Palo Alto CA and Stanford University, Stanford CA 94304.

Primary and secondary cortical astrocytes were tested for the expression of 3 different electrogenic glutamate uptake transporters. Astrocyte cultures were prepared from 1 day old rat pups and grown to confluence which is specified as time Day 0. The cultures were divided into 4 groups: Group A--untreated; Group B--astrocytes injured using a scratch wound model; Group C--astrocytes treated with dbcAMP, to induced morphological and cytoskeletal differentiation. Group D--astrocytes treated with dbcAMP and scratch wound injury. Astrocytes from each group were harvested, and total RNA was prepared from each group at the specified time points of Day 0, Day 1, Day 2, Day 4, and Day 7, after confluence. The total mRNA was reversed transcribed using AMV reverse transcriptase. Reverse transcriptase reaction was performed in duplicate for each Group A-D at each sample time point. cDNA samples were tested for 2 glial electrogenic glutamate uptake transporters GLT-1 and GLAST, and 1 neuronal form, EAAC-1, using PCR. PCR primers were designed so that they would specifically amplify GLT-1, GLAST, and EAAC-1. The 3 sequences were obtained from the Genbank and aligned using the program "Prime" to yield ~ 1.5kB products. The PCR reaction products were analysed using electrophoresis on 1.5% agarose gels. All samples from Groups A-D expressed mRNA for the 2 glial forms of the transporters, while none of the cultures expressed the neuronal glutamate uptake transporter. Of interest is the observation that all of these astrocyte cultures seemed to have expressed GLAST in greater proportion than GLT-1, whereas in vivo the GLT-1 is predominantly found in the astrocytes of the cortical hemispheres. By day 7, Group B and D, the scratch wound model, displayed an increase in the expression of glutamate transporter mRNA compared to untreated controls (Group A and C), however further quantitive analysis is being performed to confirm this finding. REDOX SENSING PROPERTIES OF A HUMAN NEURONAL GLUTAMATE TRANSPORTER. D. Trotti* and M.A. Hediger. Brigham and Women's Hospital, Harvard Medical School, 75 Francis St., Boston, MA 02115.

In the CNS, control of the extrasynaptic concentration of L-glutamate is critical because of its role in neurotransmission and excitotoxicity. Mechanisms that modulate glutamate transporters are therefore relevant to the regulation of synaptic transmission. Using the two-electrode voltage clamp technique and *Xenopus* oocytes expressing the human neuronal glutamate transporter EAAC1, we performed a molecular characterization of the redox sensing site of EAAC1 by studying the effect of the sulfhydryl specific reagents DTT (3mM) and DTNB (500 μ M) on the glutamate uptake current. Up and down changes in response to DTT (+35%) and DTNB (-20%) were observed in oocytes clamped at -60 mV. Blocking of free thiol groups with pCMPS (100 μ M) prevented the effect of DTNB. The redox interconversion of cysteines by DTT/DTNB influenced the V_{max} of glutamate transport but the apparent affinity for glutamate was not affected. Redox modulation occurred at any membrane potential tested (-150 to +50mV). Endogenous oxidants such as peroxynitrite (100 μ M) and H₂O₅ (5 mM) also affected the EAAC1 mediated uptake current (-35%, at -60mV) through a DTT reversible mechanism, suggesting that the redox site is targeted by oxidants. In addition to Na -coupled electrogenic glutamate transport, the current mediated by human EAAC1 is also affected by a glutamate gated anion influx. The net uptake current therefore reflects the inward current from electrogenic glutamate transport and the current arising from the glutamate-activated Cl conductance. Substitution of Cl with gluconate in the uptake medium did not abolish DTT-induced potentiation of uptake and had the same amplitude as observed in a Cl buffer, suggesting that redox modulation affects only the glutamate transport component of the current. Thus, our data provide new insights into the mechanism underlying the redox modulation displayed by the human glutamate transporter EAAC1. Supported by NIH NS32001 and the ALS Association.

GLUTAMATE TRANSPORTER EXPRESSION IN RAT CORTICAL CULTURES. B.S. Stein*, J.W. Miller, K. Farrell, M.C. Longuemare, J.D. Rothstein, and R.A. Swanson Dept. of Neurology, Univ. of California and VAMC, San Francisco, CA 94121.

GLT-1, GLAST, and EAAC are high affinity, Na*-dependent glutamate transporters identified in rat forebrain. This study characterizes the expression of these transporters in rat cortical cultures by immunostaining and Western blots. Three types of cultures were studied: astrocytes with or without dBcAMP-induced differentiation, and mixed astrocyte neuronal cultures. Results are summarized as follows:

	GLT-1	GLAST	EAAC
Astrocyte cultures (- dBcAMP)		+	
Astrocyte cultures (+ dBcAMP)	+++	++	
Mixed cultures, Astrocytes	++	++	
Mixed cultures, Neurons			++

Rare microglia were identified by OX42 immunostaining, and these cells were positive only for the GLT-1 transporter. Glutamate uptake in the astrocytes treated +/- dBcAMP differed only in $V_{\rm max}$; the apparent $K_{\rm M}$ was unchanged. These studies show that transporter expression in the mixed astrocyte-neuronal cortical cultures exhibits the same pattern as seen *in vivo*, and that GLT-1 expression can be induced in astrocyte cultures by dBcAMP or by co-culture with neurons. GLUTAMATE TRANSPORTERS II

619.1

SPECIFIC DOWN-REGULATION OF THE GLUTAMATE TRANSPORTER GIUT-1 IN PURKINJE CELL-ASSOCIATED ASTROCYTES OF THE REELER AND WEAVER MUTANT MICE. M. WATANABE*, T. SHIBATA, K. YAMADA, K. TANAKA¹, K. WADA¹, Y. INOUE. Dept. of Anat., Hokkaido Univ. Sch. of Med., Sapporo 060, and Dept. of Degenerative Neurological Diseases, National Institute of Neurosci., NCNP, Kodaira 187, Japan.

The GluT-1 (GLAST or EAAT1) is one of the four glutamate transporter subtypes, with its high expression in the Bergmann astrocytes. In the present investigation, we employed expression analyses in neurological mutant mice having impaired Purkinje cell synapse formation. By in situ hybridization with 33P-labeled antisense oligonucleotide probes, remarkable down-regulation of the GluT-1 mRNA was specifically detected in the reeler and weaver cerebella. In the reeler, the reduction was particularly remarkable in deep cerebellar regions, where most Purkinje cells lack synaptic contacts with the presence of numerous GluT-1 mRNA-positive cells in both mutant cerebella, but they were labeled at much lower levels than those in the wild-type cerebellum. The labeled cells were all small in size and GFAP-immunopositive. In addition, these labeled cells were located in the vicinity of cell bodies of the Purkinje cells. Furthermore, specific antibody raised against the C-terminal peptide demonstrated that GluT-1-immunopositive structures were closely associated with Purkinje cell dendrites and soma. Thus, the present study clarified that the GluT-1 is down-regulated in Purkinje cell synapse formation. This, together with our previous result on the striking upregulation in synaptogenesis, suggests that the gene expression of the GluT-1 may be controlled dynamically, in accordance with structural and functional state of synapses.

RECOMBINANT ADENOVIRUS MEDIATED TRANSDUCTION AND KNOCK-DOWN OF GLUTAMATE TRANSPORTER, J. Yang*, R. Sanga, and R. Roginski. Dept. Anesth. Pain Mgmt, UT Southwestern Med. Center., Dallas. TX and Dept. Anesth., UMDNJ Robert Wood Johnson Sch. Med., New Brunswick, NJ.

The Na-dependent glutamate transporter removes glutamate from the extracellular space. The ability to up or down-regulate the glutamate transporter will help elucidate the role of this transporter in a variety of CNS processes including synaptic transmission, excitotoxicity, and neurodegenerative diseases.

Replication deficient human adenovirus containing a RSV promoter driven expression cassette with the glutamate transporter cDNA inserted in the sense (ad(GluT1 β -S)) or antisense (ad(GluT1 β -AS)) orientations were constructed by homologous recombination in H293 cells. The GluT1 β transporter is a variant of the glia specific Glt-1 transporter with a truncated amino terminal (Nsci. Abstr. 20: 628, 94). Transduction of functional glutatmate transporter was examined by infecting the MRC-5 (lung epithelial cell line) with ad(GluT1 β -S), and the knock-down of constitutively present transporter activity by ad(GluT1 β -S) was evaluated by infecting the RCGU (rat glial cell line). Both the MRC-5 and the RCGU cells were infected by recombinant adenovirus at high efficiency. Control cultures exposed to add(lacZ) at a titre of 1 x 108 pfu/ml showed that > 90% of the RCGU and 60-70% of the MRC-5 cells were infected. The MRC-5 cells lack Na-dependent 3 [H]-glutamate uptake, however, upon infection with ad(GluT1 β -S) (2 x 10^8 pfu/ml, 48 hours incubation). Na- and [glutamate]-dependent uptake was demonstrated. Immunohistochemical staining with anti-GluT1 β antibody confirms successful transduction of the transporter protein. RCGU cells constitutively express dihydrokainate blockable Na-dependent transporter activity. This native transporter activity was reduced by ad(GluT1 β -AS) infection. We demonstrate the feasibility of adenovirus mediated transduction or knock-down of the glutamate transporter and should be useful for examining the role of this transporter in various CNS processes.

INHIBITION OF GLUTAMATE UPTAKE BY PEROXYNITRITE IN TRANSFORMED L CELLS EXPRESSING HUMAN GLUTAMATE TRANSPORTER SUBTYPES. I. Nagano*, G. C. Lin, L. A. Bristol and J. D. Rothstein. Department of Neurology, Johns Hopkins University, Baltimore, MD 21287.

Glutamate transport is essential to keep its extracellular levels below neurotoxic values. Altered transport function has been reported in CNS tissue of ALS patients. Recent studies have shown oxidative damage to proteins in ALS CNS tissue. In this study we demonstrate that a potent oxidant, peroxynitrite inhibits glutamate uptake mediated by two human glutamate transporter subtypes, excitatory amino acid transporter (EAAT) 2 (glial) and EAAT3 (neuronal). Stably transformed L cells expressing EAAT2 or EAAT3 were obtained by transfection with pcDNA3-EAAT constructs. After exposure to various concentrations of peroxynitrite, Na-dependent high-affinity glutamate uptake was measured in Krebs buffer containing [3Hglutamate. In EAAT2 expressing L cells, 300 µM peroxynitrite inhibited glutamate uptake by ~30%, while the same concentration of peroxynitrite induced ~60% reduction in EAAT3 expressing cells. Application of DTT, a disulfide-reducing agent, partially restored transport function, suggesting that oxidation of protein sulfhydryls may be partially related to glutamate uptake inhibition. In addition, chronic exposure to a peroxynitrite releasing agent, SIN-1, also induced glutamate uptake inhibition. These results suggest the possibility that peroxynitrite locally produced in the CNS could inhibit glutamate uptake and might be implicated in neuronal cell death through excitotoxicity. CONFORMATIONALLY CONSTRAINED INHIBITORS OF THE HUMAN GLUTAMATE TRANSPORTERS: DIFFERENTIATION OF SUBSTRATES AND NON-TRANSPORTABLE BLOCKERS R.J. Bridges*, M.P. Kavanaugh, N. Zerangue, H. Koch, S. Esslinger, J. Humphrey, S.G. Amara, and A.R. Chamberlin. Pharm. Sci., U.M., Missoula, MT 59812, Vollum Inst., OHSU, Portland, OR 97201 and 'Chem., UCL, Irvine, CA 92717. High affinity uptake is recognized for its role in regulating extracellular glutamate levels in the CNS. We have begun using conformationally constrained glutamate analogues to delineate the specificity of three transporter subtypes cloned from human motor cortex: EAAT1, EAAT2, EAAT3 and EAAT4. A series of pyrrolidine dicarboxylates (PDCs) were prepared using L-trans-2.4-PDC as a prototype. In the present work transport activity was determined by measuring analogue-induced currents in voltage clamped (-60mV) oocytes expressing individual subtypes. Nontransportable inhibitors were evaluated using Schild analysis. L-trans-2.4-PDC was found to be a substrate of all three subtypes: K, ≈10µM at EAAT2, ≈50µM at EAAT1 and EAAT3. Estimated I_{max} values were ≈30-80% that of L-glutamate. The bicyclic analogue, L-anti-endo-3,4-methano-PDC, was identified as a non-transportable inhibitor of EAAT2, K, ≈2µM. This inhibitor exhibited K, ≈30µM and 40µM at EAAT1 and EAAT3, respectively, and I_{max} values 20% and 35% that of L-glutamate. L-trans-2,3-PDC was identified as a non-transportable inhibitor of EAAT2 (K,=10µM) that exhibited negligible activity at EAAT1 or EAAT3. Another bicyclic analogue, meso-methano-PDC, was unusual in that it exhibited a K_m≈45 µM at EAAT2, but an I_{max} of 115% that of L-glutamate. The analogues were also tested as uptake inhibitors were differentiated from substrates by the inability of non-substrates to heteroexchange with ³H-D-aspartate pre-loaded into synaptosomes. Comparisons demonstrated the closest correspondence was found between the synaptosomal preparation and EAAT2. This work was supported by NIH NS30570, NS33270, NS27600 and

NOVEL COMPETITIVE INHIBITORS OF 3H-L-GLUTAMATE TRANSPORT INTO SYNAPTIC VESICLES. R.D. Bartlett*, B.E. Garnett. A.R. Chamberlin*, and R.J. Bridges, Pharm. Sci., Univ. of Montana, Missoula, MT 59812 and *Chemistry, Univ. of California, Irvine CA 92717.

A number of biochemical parameters distinguish the glutamate transporter present in synaptic vesicles from the cellular high-affinity, Na-dependent uptake systems found on neurons and astrocytes. The vesicular transporter is Na-independent, coupled to a Mg-ATPase-generated proton gradient, and selective for L-glutamate (Km ≈ 1-3 mM) but not D-aspartate. Unfortunately, the development of selective competitive inhibitors of the vesicular system has lagged behind progress on the Na-dependent transporters. The recent identification of kynurenate (KYN) and trans-ACPD as two EAA analogues that exhibit some cross reactivity with the vesicular transporter has, however, begun to provide some insight into the pharmacological specificity of this system. In the present work we have assayed a series of conformationally constrained EAA analogues with the expectation of identifying more selective blockers. The compounds were tested for their ability to inhibit the uptake of 3H-L-glutamate into synaptic vesicles prepared from the forebrains of male Sprague-Dawley rats. Two additional analogues of KYN were identified as potent competitive inhibitors: 7-Cl-KYN and xanthurenate. The latter compound is particularly interesting because previous reports suggest it exhibits little cross reactivity with EAA receptors. Among the pyrrolidine dicarboxylate (PDC) analogues tested, a previously identified inhibitor of Na-dependent synaptosomal uptake, L-anti-endo-3,4-methano-PDC, was found to also potently block vesicular transport. Surprisingly, this cross reactivity did not extend to the structurally similar analogue, L-trans-2,4-PDC. These newly identified inhibitors will be particularly valuable in modeling the binding site pharmacophore of the vesicular transporter. This work was supported in part by NIH NS30570 and NS27600.

DEVELOPMENT OF MONOCLONAL ANTIBODIES FOR HUMAN NEURON-SPECIFIC GLUTAMATE TRANSPORTER. P. Shashidharan 1*, G.W.Huntley², J. Murray¹, M. J. Walsh¹, T. Moran³, Dept. of Neurology, ²l'ish berg Research Center for Neurobiology and ³Dept. of Microbiology, Mount Sinai School of Medicine, One Gustave L. Levy Place, New York NY 10029.

Glutamate is a major excitatory amino acid neurotransmitter in the mammalian central nervous system. The synaptic action of glutmate is thought to be terminated by a high-affinity uptake system, which is dependent on Na † and K † . Here we report production and characterization of a monoclonal antibody for human neuron-specific glutamate transporter.

A monoclonal antibody was raised against a synthetic peptide (QYKTKREE-VKPPSDPEM) that corresponds to amino acid residues 161-177 of the human neuron-specific glutamate transporter cDNA cloned in our laboratory. The hybridomas were screened against the free peptide by ELISA initially and the clones were selected on the basis of their immunoreactivity. Western blotting of human and rat brain synaptosomal preparations from frontal cortex revealed a immunoreactive band at ~70 kD. The antibody was further characterized by immunoprecipitation and deglycosylation using N-glycosidase F. Deglycosylation of the immunoprecipitated material yielded a protein with a lower molecular weight (~65 kD) on western blots. These results are consistent with the molecular weight predicted by the cloned cDNA. Immunocytochemistry of cortex, hippocampus and substantia nigra of rat brain revealed strong immunoreactivity of neuronal cell bodies. In the cortical layers the large pyramidal neurons showed intense immunoreactivity, although there were other smaller neurons throughout the cortex showing lesser immunoreactivity. In the hippocampus neuronal somata and dendrities of the sub-fields CA1 to CA3 and the dentate gyrus were intensely immunoreactive. In substantia nigra in addition to neuronal somata with proximal dendritic labeling, the antibody stained fine caliber fibers and numerous puncta. Supported in part by Lowenstein Foundation for Parkinson's Disease Research.

619.6

A POTENT GLUTAMATE UPTAKE INHIBITOR: L-trans-PYRROLIDINE-4-SULFONO-2-CARBOXYATE (PSC) H.P. Koch*, C.S. Esslinger, A.R. Chamberlin', and R.J. Bridges, Dept. of Pharm. Sci., C. of Montana, Missoula, MT 59812, Dept. of Chemistry', U. of California, Irvine, CA 92717,

Pharm. Sci. U. of Montana, Missoula, MT 59812, Dept. of Chemistry! U. of California, Irvine, CA 92717,
High-affinity, sodium-dependent uptake of L-glutamate is postulated to participate in excitatory signal termination, transmitter recycling, and maintenance of sub-pathological levels of glutamate. In previous studies we identified L-trans-2,4-Pyrolidine dicarboxylate (L-trans-2,4-PDC) and L-anti-endo-3,4-methanopyrrolidine dicarboxylate (L-anti-endo-3,4-MPDC) as conformationally constrained analogues of glutamate that potently block the uptake of ³H-D-aspartate, a non-metabolized substrate, into rat forebrain synaptosomes. These two inhibitors can be further differentiated with respect to their ability to serve as substrates, i.e. be translocated into the synaptosome. In the present work we have prepared a novel series of analogues in which the +COOH group of L-2,4-PDC has been replaced with a sulfonate moiety. When tested for their ability to inhibit the uptake of "H-D-aspartate, only the trans isomer was identified as active. Kinetic analyses of the inhibition yielded a K, value of ≈ 9 µM for L-trans-2,4-PSC and ≈ 5 µM for L-glutamate. The activity of the sulfonate analogue as a substrate was evaluated by quantifying its ability to heteroexchange with "H-D-aspartate previously loaded into synaptosomes. The observed rank order of substrate activity was L-trans-2,4-PDC)-trans-2,4-PSC as a useful compound in delineating the binding site pharmacophore of the transport protein as well as an analogue with which to study the biochemistry of sulfonate-containing acdic amino acids. This work was supported in part by NIH NS30570 NS27600.

TRANSMEMBRANE TOPOLOGY OF THE GAT-1 GABA TRANSPORTER. J. A. Clark .* Laboratory of Cell Biology, NIMH, Bethesda, MD 20892-4090.

While the predicted two-dimensional model of the Na+/CI-dependent transporters derived by hydropathy analyses is commonly accepted, this transporter model has yet to be tested experimentally. The transmembrane topology of the GAT-1 GABA transporter has been studied as a representative member of this family. A FLAG epitope has been fused to GAT-1 at either the N- or C-terminus. When transiently expressed in mammalian cells, the membrane orientation of the FLAG epitope was determined using immunofluorescence under permeabilizing and non-permeabilizing conditions. To examine whether putative TM segments span the membrane, a series of C-terminal truncations were generated to which a prolactin epitope was fused. These truncated transporter constructs were expressed in *Xenopus laevis* oocytes and tested for protease sensitivity of the prolactin tag, as a determinant of transmembrane orientation. Results thus far support a model in which the N- and C-termini are intracellular, the large loop between TMs 3 and 4 is extracellular and glycosylated, and the first six hydrophobic segments span the membrane. Data from protease protection assays coupled with glycosidase treatment of these truncated transporters, reveal the presence of topogenic sequence(s) in TM5 responsible for correct orientation of the large extracellular loop. Study of the C-terminal six putative transmembrane segments is in progress. Knowledge of the transmembrane topology of these transporters is essential for interpretation of structure/function and chimeric analyses, and will contribute significantly to revealing their tertiary structure. Supported by an NIMH post doctoral IRT Award.

RESIDUES INVOLVED IN SUBSTRATE INTERACTIONS WITH A SODIUM-DEPENDENT GLUTAMATE TRANSPORTER IDENTIFIED USING CYSTEINE SCANNING MUTAGENESIS. 1,2R.P. Seal*, and 2,3S.G. Amara IProgram in Neuroscience, 2Vollum Institute and 3Howard Hughes Medical Institute, Oregon Health Sciences University, Portland OR 97201.

The Substituted Cysteine Accessibility Method (SCAM) was used to examine the contribution of residues in the Na⁺-dependent glutamate transporter subtype, EAAT1 to the binding of substrates and inhibitors and to the permeation of chloride ions. A highly functional cysteine-less EAAT1 carrier has been generated and characterized by measuring substrate-elicited currents in the Xenopus oocyte expression system. In the cysteine-less mutant, the transport affinities and current-voltage relationships observed for L-glutamate, L-aspartate and D-aspartate are nearly identical to the wild type carrier. Twenty-four consecutive residues (Pro392-Gln415) have been individually mutated to cysteine using the cysteine-less transporter as the template. We focused on this domain of the transporter because of its high sequence conservation among glutamate carriers and because previous studies of EAAT chimeras and mutants have suggested a role for the region in substrate and inhibitor binding. The effects of three sulfhydryl-reactive methanthiosulfonate derivatives, MTSEA, MTSES and MTSET on the uptake of tritiated substrate and substrate-elicited steady-state currents for each of the mutants was evaluated. None of these derivatives exhibited an affect on the cysteine-less transporter. Significant inhibition of L-glutamate transport was observed after application of 5mM MTSEA to oocytes expressing the E406C transporter mutant. In addition, co-incubation of MTSEA with a saturating dose of either glutamate or kainate and competitive inhibitor of the carrier, completely blocked the inhibition of uptake observed with MTSEA alone. These results suggest that Glu-406 resides within an aqueous environment that is accessible from the ex

MICRODIALYSIS STUDY OF BRAIN ADRENERGIC MODULATION OF GLUTAMATE REUPTAKE.

G.M. Alexander, J.R. Grothusen, S.W. Gordon and R.J. Schwartzman. Department of Neurology, Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA 19102.

The central nervous system has high affinity uptake systems for the clearance of amino acid transmitters. These systems are found in both neurons and astrocytes. Previous studies have shown that the uptake of amino acid transmitters by astrocytes in culture can be modulated by adrenergic agents. The objective of this study was to determine whether amino acid uptake in the intact CNS is under adrenergic regulation. Male Sprague-Dawley rats weighing 250-450 grams were used in this study. A guide cannula was placed under anesthesia in the anterior cortex. The following day the microdialysis probe was inserted and sampling started 3 hours later in the awake, behaving animal. The extraction fraction of ³H-L-glutamate using 14C-mannitol as a reference was performed by the method of Bruhn T, et al, (J Neurosci Meth, 59:169-174, 1995). The cortical extraction fraction of 3H-L-glutamate (an index of reuptake) was abolished by co-administration of the glutamate uptake blocker DL-threo- β -hydroxyaspartate. In agreement with tissue culture studies, the extraction fraction of $^3H\text{-L-glutamate}$ was increased by the α_1 adrenergic agonist phenylephrine and decreased by the α adrenergic antagonist phentolamine in a dose dependent manner. This study was supported by the Department of Neurology, MCPHU.

NEURONAL AND GLIAL GLUTAMATE TRANSPORTERS CONTAIN AN SH-BASED SITE RESPONSIBLE FOR REDOX MODULATION AND OXIDANT VULNERABILITY A. Volterra*, D.

Trotti, B. Lodi Rizzini, D. Rossi, P. Bezzi, N.C. Danbolt*, G. Racagni Ctr. Neuropharmacol., Institute Pharmacol. Sci., Univ. Milan, 20133 Italy & † Dept. Anatomy, Univ. Oslo, N-0317 Norway

Glutamate (Glu) uptake controls the extracellular Glu level in the brain and prevents excitotoxicity. Our group has found that Glu uptake is long-lastingly inhibited by a number of endogenous oxidants, including oxygen radicals, hydrogen peroxide (H₂O₂ Volterra et al, J. Neurosci. 14:2924 (1994) and peroxynitrite (ONOO, Trotti et al, J.Biol.Chem. 271:5976 (1996). All of these agents affect uptake by direct interaction with the Glu transporters at unidentified "oxidant-vulnerable" site(s). We report here that 3 recombinant rat transporter subtypes, i.e. GLT1 and GLAST (glial) and rEAAC1 (neuronal), expressed in HeLa cells and reconstituted in liposomes, respond to thiol-specific oxidants (DTNB, 500 μM) and disulfide-reductants (DTT, 3 mM) with loss and gain of function respectively. The 3 transporters show almost identical sensitivity to SH-redox reagents (±20-30%). Sequential applications of DTT and DTNB to whole-cell clamped rat cortical astrocytes, cause dynamic up- (+80%) and down-modulation (-40%) of the Glu uptake current. In the same paradigm, H₂O₂ (1 mM) and ONOO (nominally 250 μ M), like DTNB, antagonize DTT potentiation, bringing the current level below control; subsequently, DTT partially reverses oxidant inhibition ($\approx 70\%$ for H₂O₂). Therefore: (a) reversible interchange between free SH groups and disulfides regulates transport function; (b) GLT1, GLAST and rEAAC1 contain a similar SH-based redox site, probably formed by conserved cysteine residues; (c) this site most likely identifies with the "oxidant-vulnerable" site. Our findings may help to understand Glu uptake alterations in pathologies involving oxidative stress (e.g. ischemia and amyotrophic lateral sclerosis) Supported by Telethon-Italy (grant 754) & EC Biomed 2 (BMH4-CT95-571) to A.V.

The dopamine transporter (DAT) is a critical site for cocaine reward, and plays a central role in terminating dopamine neurotransmission. Transgenic mice regionally overexpressing a variant DAT, via the 4.8 kb tyrosine hydroxylase promoter, reveal modest overexpression in several catecholaminergic cell groups as assessed by Northern blots, immunohistochemistry, ligand binding and dopamine uptake. DAT transgenic animals demonstrate reduced striatal dopamine and serotonin levels, display altered responses to both cocaine and morphine conditioned place preferences, and variable alterations in microdialysis studies. Their dopamine neurons show enhanced sensitivity to MPTP. These animals provide a valuable model for the striking influences that modest alterations in expression of DAT can yield.

DOPAMINE DYNAMICS AND PSYCHOSTIMULANT EFFECTS IN DOPAMINE TRANSPORTER KNOCKOUT MICE S.R. Jones*, M. Jaber, B. Giros, R.M. Wightman and M.G. Caron. HHMI Labs, Dept. Cell Biol., DUMC, Durham and Dept. Chem., Curr. Neurobiol., UNC-CH, Chapel Hill, NC

The knockout of the dopamine (DA) transporter gene results in a strain of mice (DAT-ko) which exhibits spontaneous locomotor hyperactivity and no response to cocaine or amphetamine (AMPH). This phenotype is surprising given the marked biochemical adaptive changes such as decreases in dopamine receptor levels and in dopamine itself as measured by HPLC. In order to determine the physiological basis of this hyperdopaminergic phenotype, cyclic voltammetry was used to measure crimulated DA splaces and whether in strictly like in real time. Palence of DA in the stimulated DA release and uptake in striatal slices in real time. Release of DA in the DAT-ko mice is about one-fourth of control. The rate of clearance of released DA is 300-times slower in the DAT-ko mice than in wild-type controls (K = 0.05 vs. 16). There is no DA uptake in the DAT-ko mice, and inhibitors of other monoamine transporters or DA degradation enzymes have no effect on DA clearance. Cocaine and AMPH have a similar lack of effect. DA diffusion from the area is the only surviving mechanism for DA clearance. Thus, the hyperdopaminergic phenotype is best explained by the protracted period of time DA spends in the synapse. At the presynaptic level, D2 receptors are markedly down-regulated and their functional sensitivity is greatly diminished. AMPH has complex effects on DA neurons; it promotes DA release, inhibits uptake and disrupts vesicular stores. Whether these actions are strictly DA transporter dependent has remained controversial. We have used the DAT ko mice to further explore the mechaisms of AMPH action. In wild type mice, AMPH causes a 3-10 μ M efflux of DA over a 30 min period while it has to DA over a 30 min period while it has no DA releasing action in DAT-ko mice, even though AMPH enters terminals and destroys vesicular DA stores in both specimens. These results point to the DA transporter as a crucial determinant of DA tone and an obligatory mediator of the releasing action of AMPH. Supported in part by NIH grants #T32 AG00029 (SRJ) and NS19576 (MGC).

DRAMATIC REGULATION OF TYROSINE HYDROXYLASE IN THE BASAL GANGLIA OF MICE LACKING THE DOPAMINE TRANSPORTER, M. Jaber*, S. R. Jones, R. Bosse, B. Giros and M. G. Caron. HHMI labs, Dept of Cell Biology, Duke University Medical Center, Durham NC

Disruption of the mouse dopamine transporter gene results in spontaneous hyperlocomotion despite major adaptive changes, such as decreases in opposition receptor levels. This phenotype is a direct consequence of the extended length of time active collular space following release. We have that dopamine spends in the extracellular space following release. We have investigated the regulation of gene expression of tyrosine hydroxylase, the rate limiting enzyme of dopamine synthesis. While tyrosine hydroxylase mRNA levels were not modified, as evidenced by in situ hybridization, protein levels were dramatically decreased (>90%) in the ventral midbrain of homozygote mice, evidenced by western blotting. This decrease is correlated with a decrease in dopamine levels (>80%) in the striatum as measured by HPLC electrochemical detection. To determine whether this decrease is due to a down-regulation of the tyrosine hydroxylase protein expression levels or to the destruction of dopamine neurons, we have performed immunohistochemistry with a tyrosine hydroxylase polyclonal antibody and found no difference in the number of dopamine neurons of the ventral midbrain in homozygote compared to wild type mice. Moreover, we found that the decrease in tyrosine hydroxylase levels is less marked in the accumbens and olfactory tubercle than the striatum where dopamine transporter levels are normally higher. The dramatic extend of the down regulation documented here is only achieved in other animal models by destruction of dopamine neurons, which ultimately induce Parkinson-like syndromes. That mice lacking the dopamine transporter show a spontaneous increase in their locomotor activity despite the marked down regulation of tyrosine hydroxylase and dopamine levels strongly suggests that blockade of the dopamine transporter with highly selective antagonists could be beneficial in alleviating symptoms of Parkinson disease in humans.

METHANETHIOSULFONATE (MTS) INHIBITS DOPAMINE (DA) TRANSPORTER FUNCTION IN RAT STRIATUM. L.P. Dwoskin*, S.E. Moore, W. Shaw and D.A. Butterfield. College of Pharmacy, Department of Chemistry and Center of Membrane Sciences, University of Kentucky, Lexington, KY 40536.

The cloned DA transporter contains 13 cysteine moieties distributed across the protein in its intracellular N-terminal and C-terminal tails, in the 1st and 3rd intracellular and 1st, 2nd and 3rd extracellular loops, and in putative transmembrane (TM) domains 4, 6, 9 and 11. Primarily based on reports that treatment with the thio-selective reagent Nethylmaleimide (NEM) inhibits both DA transport and radioligand binding to the transporter and that DA transport inhibitors and substrates afford protection from effects of NEM, it appears that at least some of these cysteine moieties play an essential role for binding to and/or function of the DA transporter (Schweri, 1990; Johnson et al., 1992; Richfield, 1993; Saadouni et al., 1994). In the present study, DA transporter function was assessed following treatment with (1-oxyl-2,2,5,5,-tetramethyl-pyrroline-3-methyl)methanethiosulfonate (MTS), a thiol-specific spin labeling agent. MTS inhibited [PH]DA uptake into striatal synaptosomes with an IC50 of 15µM, indicative of sulfhydryl involvement in DA transport. Similarly, ascorbate-reduced MTS also inhibited [PH]DA uptake with an IC50 of $28\mu M$, indicating that the free radical moiety of MTS is not involved in the inhibition. Pretreatment with amphetamine $(1\mu M - 1mM)$, a DA releasing agent and substrate for transport, or with DA uptake blockers (cocaine, GBR 12935 or BTCP, 0.1 nM-100 µM) which are not transport substrates, were not able to protect against the MTS-induced inhibition of [³H]DA uptake. In contrast, dithiothreitol (10-100μM) provided complete protection from MTS-induced inhibition of [³H]DA uptake. Thus, MTS may interact with a specific sulfhydryl group essential for transport, but not involved in binding of ligands to the transporter. Thereby, MTS may differentiate the transport site from uptake inhibitor binding sites. Supported by DA07219, DA05312, AG10836 and AG05119

EXPRESSION OF NOREPINEPHRINE TRANSPORTER (NET) mRNA IS NOT REGULATED BY OVARIAN STEROIDS IN THE NON-HUMAN PRIMATE LOCUS CERULEUS (LC). W.E. Schutzer, S.R. Ojeda* and C.L. Bethea. Division of Reproductive Sciences & Neuroscience, Oregon Regional Primate Research Center,

Dysfunction of the noradrenergic neurons of the LC has been implicated in depressive illness. Many effective antidepressants block NET re-uptake of NE, thereby increasing the concentration of NE in the synapse. Depression is twice as frequent in women than men and has been correlated with physiological withdrawal of the ovarian steroids, estrogen (E) and progesterone (P), which occurs in pre-menstrual syndrome. post-partum, menopause and hysterectomy. To determine whether E or P alters function of LC neurons, the expression of NET mRNA was examined in ovariectomized-control (spay), E treated (28 d) and E+P treated (28 d E + last 14 d P) monkeys (n=4/group) using in situ hybridization. Serum steroid concentrations mimicked follicular phase for E treatment (205±61 pg/mL) and luteal phase for P mimicked follicular phase for E treatment (205±61 pg/mL) and lutcal phase for P treatment (6.2±0.9 ng/mL). Perfusion fixed hindbrain sections (10 µ or 20 µ) which contained LC neurons were hybridized with a 730 bp 355-antisense monkey specific NET probe at 50°C, then stringently washed in 0.1X SSC at 60°C. Sections were exposed to β-MAX film for 5 days and densitometry was performed on the autoradiographs. Analysis showed that NET mRNA was expressed along the entire extent of the dorsolateral pontine tegmentum area and confined to the noradrenergic cells of the LC. Mean optical density (OD) throughout the entire LC averaged 93.08 ± 16.84, 82.05 ± 13.4 and 87.54 ± 12.80 (arbitrary units) for spay. E and E+P groups respectively. There was no significant difference (p > 0.05) in mean OD between treatment groups at any level of the LC. These results suggest that ovarian steroids, at these concentrations, do not regulate NET mRNA expression in the non-human primate LC. Nonetheless, lack of regulation of mRNA does not exclude E and P as potential effectors of noradrenergic transmission. For example, ovarian steroids P as potential effectors of noradrenergic transmission. For example, ovarian steroids may act at different concentrations, post-transcriptionally, on enzymatic activity or on receptor expression. Supported by HD17269, HD18185, R00163.

KNOCK-OUT OF THE MOUSE DOPAMINE TRANSPORTER GENE LEADS TO PROFOUND MODIFICATIONS OF THE HYPOTHALAMO-PITUTARY AXIS. R.Bossé. F.Fumagalli. C.Missale, M.Jaber, B.Giros, and M.G. Caron*. HHMI Labs, Cell Biology, Duke University Medical Center, Durham, NC 27710
Despite the presence of both dopamine transporter (DAT) mRNA and protein in numerous nuclei of the hypothalamus, the physiological significance of dopamine uptake has remained enigmatic in this area of the brain. A strain of mice in which the dopamine transporter gene was disrupted by homologuous recombination (DAT-ko) has been generated. DAT-ko homozygous mice show significant deficit in weight gain compared to their littermates. DAT-ko mice mate and are fertile but females have an impaired maternal behavior and a markedly decreased ability to lactate their offspring. As these observations suggest significant hypothalamopituliary axis dysfunction, several parameters of this axis were investigated to gain insights into this phenotype. HPLC measurements show increased hypothalamus dopaminergic turnover as quantified by DOPAC/DA and HVA/DA ratios. Dopamine is known to inhibit prolactin secretion via its interaction with D2 receptors located on the lactotroph cells. It has also been shown to modulate the activity of the Pit-1 (GHF-1) gene in vitro. The Pit-1 gene modulates both somatotroph and lactotroph cell ontogeny and controls PRL and GH secretion by regulating the expression of their respective genes. Pituitaries of DAT-ko mice are about half the size of wild type glands. There is a marked reduction of both the anterior and intermediate lobes sizes while the posterior lobe remains unchanged. The D2 receptors density is significantly decreased in both the anterior and intermediate lobes sizes while the posterior lobe remains unchanged. The D2 receptors density is significantly decreased in both the anterior and intermediate lobes. We observed an 85% decrease of the prolactin (PRL) content of the female pituitaries while the pituitary growth hormone (GH) cont

ANTISENSE OLIGONUCLEOTIDES AGAINST THE DOPAMINE TRANSPORTER (DAT) GENE

C. Chatellard-Causse1*, M. Manier1, N. Cristina1, V. Leviel2 and C. Feuerstein1 1. LAPSEN-INSERM U318 - Université Joseph Fourier, CHU, BP217, 38043 Grenoble cedex 9; 2. UMR CNRS 105, 69372 Lyon, France.

To evaluate the influence of dopaminergic (DA) phenotype on the susceptibility of rat mesencephalic DA neurons to degenerescence (as observed in Parkinson's disease) and/or its participation in their development and maturation, antisense strategy has been developed to selectively decrease the expression of a target protein. In our study, we focused on DAT, which acts to terminate DA transmission by rapid uptake of dopamine into these neurons. To decrease the expression of DAT, we used antisense oligonucleotides, because of their specificity, thereby allowing selective blockade of the production and the action of only DAT, thus leaving other DA markers (TH for instance) unaltered.

On the basis of the sequence of DAT, we designed and synthezised phosphodiester oligonucleotides: a 18 mer (ASDAT13) antisense to a region surrounding the initiation codon (-11 to +7) and a 20 mer (ASDATSIM) antisense to a coding region (396 to 415). Sense oligonucleotides were used as controls.

Beside test experiments performed *in vitro*, antisense oligonucleotides were administered intracerebrally in rats. Continuous infusions were made using ALZET® osmotic minipumps connected to a cannula implanted unilaterally dorsally to the substantia nigra. Time of treatment and concentration of antisense were tested. The level of expression of DAT was studied on coronal sections by quantitative autoradiography using (H)GBR 12935 as a ligand. In light of the interesting preliminary results observed, the efficacy of this antisense strategy will

SIGMA RECEPTOR REGULATION OF AMPHETAMINE-STIMULATED (TRANSPORTER-MEDIATED) ['H]DOPAMINE (DA) RELEASE. S. Izenwasser, D. Thompson-Montgomery, J. Weatherspoon, W. Hong, and L.L. Werling*. Psychobiology Section, NIDA Division of Intramural Research, Baltimore, MD; Department of Pharmacology and Neuroscience Program, George Washington University School of Medicine, Washington, DC.

Some sigma ligands have been shown to bind with low affinity to the DA transporter and to inhibit ['H]DA uptake. However, it is difficult to be certain that the apparent inhibition of ['H]DA uptake is not in fact due to an increased release of ['H]DA via the transporter. To further examine the nature of the interaction between sigma ligands and the DA transporter, the effects of sigma ligands on amphetamine-stimulated ['H]DA release were examined in rat caudate putamen. In the absence of exogenous calcium, (+)pentazocine, rincazole, and ifenprodil each potentiated amphetamine-stimulated ['H]DA release at concentrations well below those necessary for binding to the DA transporter, but consistent with their affinities for sigma receptors. This potentiation was blocked by the sigma receptor antagonist BD 1008. Neither the sigma agonists nor the antagonist alone had any effect on basal ['H]DA release under these conditions. When amphetamine-stimulated DA release was measured in the presence of EGTA, to remove endogenous calcium, the potentiation by (+)pentazocine was absent. Thus, although the enhancement of amphetamine-stimulated ['H]DA release by (+)pentazocine does not appear to be exocytotic in nature, since it occurs in the absence of added calcium, it does appear to rely on an internal calcium pool. Further, these effects appear to be unrelated to the uptake of amphetamine into the cell, since rimcazole and ifenprodil, but not pentazocine, inhibit DA uptake. These data suggest the possibility that the sigma ligands potentiate the effects of amphetamine at the vesicular transporter via an intracellular pool of calcium. (Supported by NID

FOOD DEPRIVATION INDUCES UP-REGULATION OF NOREPINEHRINE UPTAKE IN THE NUCLEUS TRACTUS SOLITARIUS (NTS), BUT NOT IN THE LOCUS COERULEUS (LC) OF RATS. B. H. Hwang* and J. Guntz. Dept. of Anatomy, Indiana Univ., Sch. of Med., Indianapolis, IN 46202.

Food deprivation can sensitize animals to the reinforcing properties for food, self-stimulation and drugs of abuse. Many systems including the norepinephrine (NE) are associated with such a neuroadaptation. This study was designed to study how food deprivation may affect NE uptake capacity in the LC and NTS where NE-producing neurons are located. Adult male Sprague-Dawley rats (250-300 gm) were used for a 4-day food deprivation study for which water was ad libitum. The control rats had free access to both water and food. At the end of the experiment, the rats were decapitated. The brains were removed, frozen with dry ice powder and stored in a deep freezer. The NTS and LC were cut into 14-µm sections and processed for NE uptake study using 0.2 nM [H]-tomoxetine in 50 mM Tris-HCl buffer system. For the nonspecific control, 1 µM desipramine was added. After rinsing, tissue sections were processed for quantitative autoradiography. The quantitative analysis showed that (i) there was a similar high density (>290 x1000 cpm/mg protein) of NE uptake sites in the LC of both the control and deprived rats; (ii) however, in the NTS, the deprived rats (24.8 ± 2.4) had an up-regulation of NE uptake sites when compared with control rats (10.9 ± 0.7). Since food deprivation may induce stress, the present study suggests that norepinephrine uptake in the NTS could be an important parameter for studying stress related mechanisms. STRESS INCREASES DOPAMINE UPTAKE IN THE STRIATUM OF MICE. B.J. Copeland*, N.H. Neff and M. Hadjiconstantinou. Department of Psychiatry and Pharmacology and The Neuroscience Program, The Ohio State University College of Medicine, Columbus, Ohio, 43210.

Exposure of mice to restraint stress increased the uptake of dopamine into striatal synaptsomes in a biphasic manner. Uptake activity increased early during the stress, normalized, and rose again after the removal of the stressor. Similar changes were observed in olfactory tubercle. Kinetic analysis showed an increase in the apparent V_{max} without change in the apparent K_{m} for the substrate dopamine. Mazindol binding autoradiography revealed increased binding in accumbens, olfactory bulb, caudate/putamen and the region of A8, A9 and A10 dopaminergic nuclei. Other physiological stressors, also, enhanced the uptake of dopamine in the striatum and olfactory tubercle. Tolerance to the stressor, as well as cross-tolerance to novel stressors was observed.

DOPAMINE CLEARANCE RATE IN RAT STRIATUM: EFFECTS OF UPTAKE INHIBITORS AND DOPAMINE CONCENTRATION. N.R. Zahniser, G.A. Larson and G.A. Gerhardt Depts. of Pharmacol. and Psychiat. and Neurosci. Prog., Univ. Co. Hlth. Sci. Ctr., Denver, CO 80262.

Changes in the in vivo activity of the dopamine transporter (DAT) can be determined using electrochemical recording to analyze the disappearance of locally-applied DA. In general, DAT inhibitors have been reported to alter one or more of the following: maximal DA signal amplitude, clearance time (T₈₀) and clearance rate (slope of the initial signal decline). We observed that administration (doses i.p. in mg/kg) of d-amphetamine (1-10), cocaine (20-30) and CFT (3-10) produced minimal changes in amplitude, prolonged T₈₀ by as much as 250% and decreased clearance rate in medial dorsal striatum of urethane-anesthetized rats (N = 3-5). In contrast, nomifensine (10), benztropine (10), GBR 12909 (10) and mazindol (3) predominantly increased amplitude with minimal changes in T80 and thereby, paradoxically, increased clearance rate. These results suggest that DAT inhibitors with either high or low abuse potential alter DAT activity via somewhat different mechanisms. To investigate the relationship between extracellular DA concentrations and DA clearance, signals were measured in response to pressure-ejecting increasing amounts of DA (5-20 pmol; N = 4) at 5-min intervals at a single location. Amplitude increased nonlinearly from 0.37 to 10 μM, T₈₀ increased linearly from 32 to 42 sec and clearance rate increased from 0.02 to 0.32 µM/sec. These results suggest that in striatum DA clearance rate increases over this DA concentration range and may explain why DAT inhibitors that preferentially increase DA signal amplitude appear to increase DA clearance rate. REPEATED COCAINE AND STRESS INCREASE THE MAXIMAL VELOCITY OF DOPAMINE DISAPPEARANCE IN THE MEDIAL PREFRONTAL CORTEX, S. M. Meiergerd¹, J. O. Schenk¹ and B.A. Sorg*² Dept. Chemistry and ²Dept. VCAPP, Washington State University, Pullman, WA 99164.

The effect of repeated footshock stress or cocaine on the kinetics of dopamine (DA) disappearance in the medial prefrontal cortex (mPFC) was measured by rotating disk electrode voltammetry (RDEV). Five groups of male Sprague-Dawley rats were used: naive rats, animals administered once-daily injections of either saline or cocaine (15 mg/kg, ip), and those given five daily 20-min sessions of either sham shock or footshock (0.05 mA/200 msec/sec). Rats were sacrificed one week later, and the mPFC was dissected, homogenized and washed with physiological buffer seven times. Km and Vmax values were determined by Eadie-Hofstee analysis. No difference in Km values was present among the treatment groups, with the average Km value approximately 0.3 μ M for all groups. However, Vmax values were greater in daily sham shock, footshock and cocaine pretreated animals compared to daily saline and naive rats. Vmax values were approximately 40% higher in these three groups compared to naive and saline groups, which were not different from each other (Vmax, in pmol/s/g wet weight, = 28 ± 2 for pooled naive and saline groups). The increased ability to remove DA in the mPFC in daily sham shock, footshock and cocaine pretreated rats suggests that altered DA uptake may serve an adaptive mechanism in the mPFC, since a mild stressor such as daily handling (sham shock) produced changes in Vmax similar to animals treated with daily cocaine. Supported by USPHS Grants DA-07384 and DA-08212.

ALTERED DOPAMINE UPTAKE FOLLOWING 7-DAY WITHDRAWAL FROM CONTINUOUS VS. INTERMITTENT COCAINE TREATMENT. <u>I.H. Lee, K.R. Gee, E.H. Ellinwood and F.J. Seidler</u>. Dept. of Psychiatry and Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710 and Molecular Probes, Inc., Eugene, OR 97402.

Using fast scan cyclic voltammetry, we measured endogenous

Using fast scan cyclic voltammetry, we measured endogenous dopamine (DA) uptake and its inhibition by cocaine in the accumbens slices after 7-day withdrawal from chronic cocaine treatment. Rats were treated for 14 days with: (1) saline injections (1 ml/kg, s.c., qd); (2) cocaine injections (40 mg/kg, s.c., qd); or (3) continuous cocaine infusion (40 mg/kg/day, s.c., osmotic minipumps). Single-pulse, biphasic electrical stimulation was used to evoke endogenous DA release and extracellular DA concentrations measured in "real-time" (10 Hz) with nafion-coated carbon microelectrodes. Data were analyzed using an equation based on Michaelis-Menten kinetics (Jones et al., JPET 274, 396; d[DA]/dt = [DA]_o - V_{ms}/(K.,/DA]+1)).

While endogenous DA release and uptake kinetics were unaltered following either treatment regimen, the cocaine potency (1 - 10 µM) for inhibiting DA uptake was selectively enhanced in the injection group; no changes were observed in the infusion group. This enhanced cocaine potency on day 7 of withdrawal is consistent with the residual sensitization to cocaine-induced locomotion following daily injections. The differential effects of the two cocaine treatment regimens on the accumbens DA uptake kinetics following 7-day withdrawal will be further examined by measuring: (1) clearance of exogenous DA applied by photolysis of caged-DA (Lee et al., J. Neurosci. Meth., in press) and (2) uptake kinetics for [³H] DA

EFFECT OF DSP-4 TREATMENT ON DOPAMINE UPTAKE IN RAT FRONTAL CORTEX

Y. Takahashi*, I. Kusumi and T. Koyama, Dept. of Psychiatry, Hokkaido Univ. Sch. of Med., Sapporo 060, Japan

Recent microdialysis studies reported that noradrenaline (NA) uptake inhibitors such as desipramine (DMI) increased dopamine (DA) concentrations in the medial prefrontal cortex (mPFC) probably by inhibiting DA uptake through NA transporter (Carboni et al., 1990). We previously reported that most antidepressants excluding selective serotonin reuptake inhibitors (SSRI) increase extracellular DA in the mPFC in freely moving rats by using brain microdialysis (Koyama et al., 1994). The purpose of the present study was to confirm the mechanism for crossed DA uptake through NA transporter. DSP-4, a neurotoxin that selectively destroys noradrenergic neurons, was administered to male Wistar rats (250-280 g) i.p. at the dose of 50 mg/kg. Seven days later the rats were sacrificed by decapitation and the dissected frontal cortices and striata were used for [3H]NA or [3H]DA uptake studies. Uptake assays were performed as a modification of the methods of Richelson and Pfenning (1984). In the frontal cortex, [³H]NA uptake was reduced by DSP-4 treatment to approximately 30% of the control value. On the other hand, DSP-4 treatment significant decrease (p < 0.001) of [3H]DA uptake to approximately 68% of the control value in the frontal cortex, although it didn't affect [³H]DA uptake in the striatum. These findings suggested that DA was taken up by not only DA transporter but also NA transporter into NA terminals in the frontal cortex. The results support the postulated relationship between antidepressant effect and the preferential dopaminergic activation by antidepressant drugs in mPFC. This work was supported in part by Grant-in-Aid for Scientific Research (No. 05454308 T.K.) from the Ministry of Education, Science and Culture, Japan.

FASTING DECREASES THE INITIAL UPTAKE RATE OF DOPAMINE IN RAT STRIATUM, WHICH IS REVERSED BY 1 nM INSULIN IN VITRO. T.A. Patterson*1, A. Zavosh*, J.O. Schenk*, D. Figlewicz Lattemann*1.3, 'Dept. of Psychology, Univ. of Washington, Seattle, WA 98195, 'Dept. of Chemistry, Washington State Univ., Pullman, WA, 99164, 'V.A. Medical Center, Seattle WA, 98108

Previous behavioral and molecular data support the hypothesis that fasting - a condition of low endogenous insulin modulates CNS dopaminergic function. The timing of uptake occogenously applied dopamine (DA, 500 pmol) by individual striatum from male Wistar rats was determined using rotating disk electrode voltammetry (RDE). Rats were fasted for 24 hours or fed ad libitum. Striatum was dissected, minced and incubated with vehicle (170 nM HCl) or insulin (1 nM) for 30 min. at 37°C. The initial velocity (v) was determined from the DA uptake profile. In fasted animals, the observed v was significantly (p < 0.02) reduced vs. fed animals [91.6 \pm 5.4 (avg \pm SEM, n = 10) and 118.2 \pm 8.1 (n = 7) pmoles/sec/g, respectively]. Addition of insulin to striatum from fasted animals reversed this change (111.8 \pm 6.4 pmoles/sec/g, n = 5, p < 0.05 vs. fasted controls).

The observed decrease in v would result in DA being present in the synaptic cleft for a longer period of time in a fasted state, thereby resulting in increased synaptic action. The results also support the conclusion that the suppression of DA uptake rates observed in fasting animals is mediated via a lack of insulin action. Supported by NIH DK 40963 and VA Merit Review funds.

TRANSIENT UP-REGULATION OF THE DOPAMINE TRANSPORTER GENE EXPRESSION

M.P. Martres*, B. Demeneix+, M. Hamon and B. Giros, INSERM U288, Faculté de Médecine Pitié-Salpétrière, 75013 Paris; + CNRS URA90, Museum National d'Histoire Naturelle, 75005 Paris, FRANCE.

Museum National d'Histoire Naturelle, 75005 Paris, FRANCE.

In order to investigate the exact function of the brain dopamine transporter (DAT) in the central mechanisms of the development of dependence and tolerance to cocaine, methods are now available to selectively alter the gene expression of this membrane-bound protein and examine the induced changes in the dopamine transmission and the drug-associated behavior. As an alternative to the generation of a mouse line which does not express DAT ("knock-out" strategy, Giros et al., Nature 1996, 379,606), we have chosen to direct local expression through the intra-cerebral administration of cDNA plasmids. This transfer method should allow a long lasting and more efficient effect than that of an anti-sense oligonucleotide strategy (time and expression being a key feature related to delayed development of addiction). Thus, a plasmid construct containing the strong CMV promoter and the DAT sense cDNA was unilaterally injected in the rat together with the cationic polymer polyethylenimine (PEI, at a ratio of 3 charge equivalents) at the level of the ventral tegmental area and of the pars compacta of the substantia nigra, two cerebral structures rich in DA cell bodies. Three days after administration of 0.5 µg of the recombinant plasmid, the overexpression of the DAT protein was evidenced by a significant 20-40% increase of the immuno-reactive DAT like material as well as in the dopaminergic cell bodies than in the projection areas like the striatum, the nucleus accumbens and the olfactory tubercles, as compared with regions of rat administered with a non recombinant plasmid. This overexpression of the DAT is probably functional since the uptake of dopamine by striatal synaptosomes is increased by 35% and the mRNA of down-regulation and to other protein gene expression.

THE STRIATAL DOPAMINE RESPONSE TO REUPTAKE BLOCKERS AS MEASURED BY MICRODIALYSIS DECLINES OVER TIME POST-PROBE IMPLANTATION. B. Gough*, R.A. Gazzara, J.F. Bowyer, P. Clausing and R.R. Holson. National Center for Toxicological Research, Jefferson, AR 72079.

We have previously shown that amphetamine-stimulated dopamine (DA) release declines rapidly after microdialysis probe implantation. In this experiment 100 µM bupropion (BUP), a DA reuptake inhibitor, was infused for 10 min into rat striatum via the microdialysis probe three times at two hr intervals, with the first 10-min infusion beginning two hrs after probe implantation. The DA peak response to these three infusions declined rapidly (the response to the third infusion was only one third as great as that to the first infusion). This rapid decline in the striatal DA response to BUP was a function of time after probe implantation, since a separate set of rats given a single infusion at the same time as the third infusion in the above animals (i.e., six hours after probe implantation) showed identical peak DA levels. We conclude that neural tissue shows a time-dependent response to probe implantation which quickly reduces the response to both DA releasers and reuptake inhibitors. Supported by NCTR/FDA/DHHS.

EXPRESSION OF mRNA FOR SEROTONIN (5-HT) RECEPTORS IN HUMAN CORONARY ARTERIES. I. Bouchelet*. B. Case* and . E. Hamel. Montreal Neurological Institute and 'Royal Victoria Hospital, McGill University, Montréal, QC, Canada, H3A 2B4.

Treatment of acute migraine headache has improved considerably in recent years due to the availability of sumatriptan (Imitrex), a synthetic 5-HT1 receptor agonist. Sumatriptan exhibits high affinity at the $5\text{-HT1D}\alpha$, $5\text{-HT1D}\beta$ and 5-HT1Freceptor subtypes. Its efficacy in aborting migraine attack has been associated to its ability to interact with 5-HT1D receptors on cranial blood vessels and/or trigeminovascular afferents. Nevertheless, adverse side-effects such as coronary vasospasm have precluded its use in patients with a history of coronary artery disease. To better understand how sumatriptan can elicit such effects, we examined the expression of sumatriptan-sensitive 5-HT1 receptor messages in human coronary arteries using reverse transcriptase polymerase chain reaction (RT-PCR) and specific primers for the 5-HT1D α , 5-HT1D β and 5-HT1F receptors. Fragments of the expected size for the 5-HT1D β and 5-HT1F receptors were evidenced in coronary arteries. In contrast, the 5-HT1D α receptor message could not be detected in any coronary preparation. These results suggest that 5-HT receptors with high affinity for sumatriptan could exert vasocontractile actions on the cardiovascular system. Together with previous data in human brain vessels, they further point to the 5-HT1Dβ and 5-HT1F receptors being associated with cerebral and peripheral blood vessels. Moreover, they emphasize the importance of designing new drugs devoid of 5-HT1D β properties. Selective agonists at 5-HT1Dα receptors could be a primary choice to specifically target neural as opposed to vascular mechanisms involved in migraine manifestation. A vascular effect of 5-HT1F receptors needs to be investigated in order to clarify their possible contribution to the therapeutic and/or adverse effects of sumatriptan. Supported by the Heart and Stroke Foundation of Québec.

LATERAL (1-) VERSUS MEDIAL (m-) PREFRONTAL CORTEX (PFC): DIFFERENCE IN BASAL AND AMPHETAMINE (AMP)-INDUCED RELEASE OF DOPAMINE (DA) AND SEROTONIN (5-HT). T. Kuroki*, J. Ichikawa and H.Y. Meltzer. Dept. Psychiatry, Case Western Reserve Univ. Sch. Med., Cleveland, OH 44106.

Dopaminergic activity in the l-PFC has been suggested to play an important role in the pathophysiology of schizophrenia. However, less is known about the l-PFC DA neurons in animal studies. We examined the difference in basal and AMP-induced release of DA and 5-HT between the *l*-PFC (coordinates: A +3.2, L +3.0, V -5.0 mm) and the m-PFC (A +3.2, L +0.8, V -5.5 mm), using in vivo microdialysis in awake, free-moving rats. Basal extracellular levels (fmol/30 min) in the *l*-PFC were 0.71±0.04 for DA, obtained from six of 21 rats examined due to the lower DA levels in 15 rats than the detection limit (0.4 fmol/sample), and 0.63±0.07 (N=9) for 5-HT. Basal levels in the m-PFC were 1.49±0.20 (N=6) for DA and 0.67 ± 0.09 (N=5) for 5-HT. AMP (1.0 mg/kg, s.c.) produced an increase in extracellular DA levels in the *l*-PFC (15.58±1.89 fmol/180 min, N=4) to the similar extent to that in the m-PFC (14.79 \pm 2.00, N=5). AMP-induced increases in extracellular 5-HT levels were 2.20±0.19 (fmol/180 min, N=4) in the *l*-PFC and 2.76±0.87 (N=5) in the *m*-PFC. These results suggest that the lower basal levels and comparable AMPinduced increases in DA release in the *l*-PFC, compared to those in the m-PFC, may reflect upon facilitated DA transmission in the l-PFC under AMP-stimulated conditions. Supported by NARSAD.

IMMUNODECTION OF AN 85 kDa PROTEIN IN BRAIN REGIONS WITH AN IMIDAZOLINE RECEPTOR ANTIBODY T. R. Ivanov*, H. Zhu, and J. E. Piletz. Dept. of Psychiatry and Human Behavior, University of Mississippi Medical Center, Jackson, MS 39216.

The imidazoline receptor was first proposed to explain the nonadrenergic, hypotensive effects of clonidine following injection into cat brainston guida.

nonadrenergic, hypotensive effects of clonidine following injection into cat brainstem nuclei. At least two subtypes of this receptor have been identified based on their pharmacology and subcellular distribution. Recently, we have characterized an I_1 subtype on platelet plasma membranes based on competition affinities for ¹²⁵I-p-iodoclonidine binding. A polyclonal antibody has been raised to a bovine adrenal chromaffin cell, affinity-purified, imidazoline binding protein (receptor)(Wang et al. 1993, Mol. Pharmacol 43, 509). We have used this antibody to investigate the size and distribution of the inidazoline receptor, in at hrain regions. the size and distribution of the imidazoline receptor in rat brain regions. Western blot analysis of purified membranes revealed a predominant 85 kDa immunoreactive band across brain regions including hippocampus, brainstem, cortex, and cerebellum. This immuoreactive band is larger than MAOs (59-61 kDa) or α_2 -adrenoceptors (approx. 62-64 kDa). The detection of the 85 kDa band was dependent on the inclusion of at least 8 protease inhibitors during membrane preparation. Smaller sized bands (i.e., 45 kDa) were found with fewer protease inhibitors. The brain immunoreactivy was subcellularly enriched in a plasma membrane fraction characteristic of the I₁ receptor subtype. In platelets, the immunodensity of the major immunoreactive band was correlated (p=0.0036) with I₁ receptor density (Bmax values) suggesting that this antibody recognizes the $\rm I_1$ receptor subtype. EXPRESSION OF THE CENTRAL CANNABINOID RECEPTOR mRNA DURING THE EMBRYONIC DEVELOPMENT OF THE RAT. Nancy E. Buckley*, Stefan Hansson¹ and Eva Mezey. National Institute of Neurological Diseases and Stroke and ¹National

Institute of Mental Health, Bethesda, MD 20892

We mapped the distribution of the central cannabinoid receptor (CB1) mRNA in rat embryonic tissues to gain insight into how cannabinoids may affect development. In situ hybridization tainabilities may affect uverlopinent. In stra hybridization histochemistry studies were done using an antisense probe specific for the CB1 mRNA. We found that, at early embryological stages (i.e., at 11 days of gestation (E11)), CB1 mRNA is expressed within some cells of the neural tube and, in later embryological stages (from E15 to birth), it is found throughout the CNS (cortex, hippocampus, septum, subventricular zone, thalamus, hypothalamus, pons, medulla, in the differentiating cerebellum and in the spinal cord). In addition, high levels of CB1 mRNA were also found in the sympathetic ganglia, in the ganglionic cells within the retina and in the enteric ganglia of the gastrointestinal tract. High levels of CB1 mRNA were also present in two endocrine organs, the thyroid gland and the adrenal cortex. The high level of CB1 mRNA expression throughout the CNS and in endocrine organs may indicate that this gene has a very important regulatory role during embryonic development.

IMMUNOREACTIVITY FOR RETINOID X RECEPTOR ISOFORMS IN SPECIFIC BRAIN SITES OF THE RAT. M.C. Langub Jr.*, J.P. Herman, H.H. Malluche and N.J. Koszewski. Departments of Internal Medicine and Anatomy/Neurobiology, Univ. KY. Med. Ctr., Lexington, KY 40536-0084.

The retinoid X receptor isoforms (i.e., RXRα, RXRβ, and RXRγ), are members of the steroid/thyroid hormone receptor superfamily. These ligand-dependent transcription factors are known to mediate a wide variety of physiological processes as critical heterodimer partners with vitamin D, retinoic acid, thyroid hormone and several orphan receptors. Altogether, these factors may play important roles in the pathogenesis of age-related cell death and AD. Characterization of RXR mRNA isoforms in embryonic and adult brain indicated that all three are present at both developmental stages. However, precise neuroanatomical localization of the proteins has yet to be established. Therefore, immunocytochemistry and Western blot analysis were employed to detect RXR isoforms in specific brain cell populations. The results demonstrate distinct patterns of localization of positive cells in many regions implicated in aging and AD. The basal forebrain, basal ganglia, hippocampus, hypothalamic, thalamic and brainstem nuclei and neocortex contained labeled neurons Staining was localized in neuronal nuclei, cytoplasm and distal processes. Cytoplasmic staining may reflect either untranslocated receptors or receptors which evert primary physiological action outside the cell nucleus. Labeling in some astrocytes was also observed. Interestingly, of the three isoforms, the RXRα alone was observed in varioesities, suggesting its localization in synaptic terminals. Western blot results confirmed the presence of RXRα and RXRγ proteins in the neocortex, hippocampus and hypothalamus. Altogether, central nervous system localization of the RXRs suggests that these isoforms are integral factors and may play specific roles in age-related disease. Forthcoming studies examine the emerging importance of these steroid receptors in brain function. (Supported by DK 47883 (NJK) and MH49698 (JPH).

THE MU-OPIOID RECEPTOR IS DISTRIBUTED IN REGIONS OF THE RAT ROSTRAL VENTRAL MEDULLA CONTAINING LOCUS COERULEUS-PROJECTING NEURONS. E.J. Van Bockstaele*, M.E. Page#, and E.E.O. Colago, Dept. of Neurol. and Neurosci., Cornell Univ. Med. Coll., NY. NY. 10021; #Dept. Neurosci., Rutgers Univ., Newark, NJ, 07102.

The nucleus paragigantocellularis (PGi) in the rostral ventral medulla provides a strong opioid projection and potent excitatory amino acid input to the locus corrulary (I.C.) in the rostral dorsal nons. Soveral lines of evidence indicate that

coeruleus (LC) in the rostral dorsal pons. Several lines of evidence indicate that this pathway is critical for mediating certain physical signs observed in the opiate withdrawal syndrome. Specifically, the increase in discharge of LC neurons observed during opiate withdrawal has been reported to be caused by excitatory amino acid (EAA) release most likely deriving from the PGi. Activation of EAA-containing neurons in the PGi may depend on changes in the occupancy of opioid receptive sites located on LC-projecting neurons in the PGi which subsequently effect EAA release in the LC. To determine whether the morphine-like mu-opioid receptor (pOR) is localized to plasmalemmal sites of LC-projecting neurons in the PGi, we combined retrograde transport of either Fluoro-Gold or the proteingold tracer, wheat germ agglutinin-conjugated to inactive horseradish peroxidase, from the LC with immunocytochemical detection of µOR in the same section of from the LC with immunocytonemical detection of μ OR in the same section of the same section of the section which is the same section of the section which is the same section of the section which is the same section of the section which is the same section of the section which is the same section of the section which is the same section of the section which is the same section of the section which is the same section of the section which is the section of the section which is the section of the projecting perisarya and dendrites also contained immunotatening for µOK. These results indicate that µOR is distributed along plasmalemmal sites of neurons in the rostral ventral medulla which project to the LC. Elucidation of the anatomical substrates in the medullo-coerulear circuit may provide a model for our understanding of the neural circuits and neurochemicals associated with certain components of the opiate withdrawal syndrome. AND MEASUREMENT OF THE CANNABINOID RECEPTOR AGONIST, ANANDAMIDE, IN BRAIN AND PERIPHERAL TISSUE OF HUMAN AND RAT

C. C. Felder, M. Palkovits, †F. Karoum, ††J. M. Richardson, ††R. M. Riggin, J. Axelrod*, ††G. W. Becker

The Laboratory of Cell Biology, †Neurophychiatry Branch, National Institute of Mental Health, Bethesda, MD 20892, ††Lilly Research Labs, Eli Lilly and Co., Indianapolis, IN 46285

Anandamide (arachidonylethanolamide), first isolated from porcine brain, has been shown to be a functional agonist for the CB1 and CB2 cannabinoid receptors found predominantly in the CNS and immune system respectively. Studies were undertaken to measure anandamide by LC/MS/MS and GC/MS in the CNS and periphery of human and rat. In human brain, anandamide levels were highest in the hippocampus, striatum, parahippocampal cortex, thalamus and cerebellum, ranging from 25 to 148 pmol/gm wet weight of tissue. Levels of anandamide in rat brain where highest in striatum, cerebellum, and hypothalamus and ranged from 18 to 29 pmol/gm wet weight of tissue. inspondantials and tanged into 18 to 29 plinoigni wet weight of tissue.

Anandamide was also found in human and rat spleen which expresses high levels of the CB2 cannabinoid receptor. Small amounts of anandamide were also detected in human heart and rat skin. Only trace quantities were detected in pooled human serum, plasma, and CSF. The distribution of anandamide in human brain and spleen supports its potential role as an endogenous agonist in both of these tissues. The presence of anandamide in brain regions expressing little if any CB1 receptor suggests that additional physiologic functions may exist for this compound.

THE erbB4 RECEPTOR IS EXPRESSED IN CELLS WHICH EXPRESS THE NEUROTRANSMITTER GABA. <u>I. Weber, J. Ledesma, E</u> Battenberg, M. Morales, F.E. Bloom, G. Lemke+, and C. Lai*. The Scripps Research Institute and The Salk Institute+, La Jolla, CA 92037

The role of receptor protein-tyrosine kinases (PTKs) in the mature nervous system is not well understood. Here we report the observation that the receptor PTK, erbB4, is expressed in many of the cells that also express the neurotransmitter GABA. We have cloned the murine erbB4, the fourth member of the epidermal growth factor receptor subfamily of PTKs. The assembled cDNA encodes a protein having 97% identity with the human receptor. The predicted protein lacks 16 amino acids present in the human sequence suggesting that alternative splicing gives rise to at least 2 receptor forms. Both forms are detected in adult brain.

We provide evidence for the expression of erbB4 in GABA+ cells using a double-labeling approach where erbB4 mRNA is detected by hybridization and GABA is detected immunocytochemically. Coexpression is most readily scored in hippocampus and cortex where GABA+ cells are dispersed. Many hippocampal erbB4+ cells also express NGF. In rat embryos, we detect the presence of both erbB4 and GAD (glutamate decarboxylate) mRNA as of E12, the earliest time point sampled. This finding suggests a possible role for erbB4 in the differentiation of these cells. We are currently assessing if cells bearing the erbB4⁺/GABA⁺ phenotype correlate with identified subpopulations of interneurons. Supported by NIH R01 NS32367.

HISTOLOGICAL AND ULTRASTRUCTURAL STUDY OF FROG (Rana pipiens) GASTRIC MUSCULARIS EXTERNA. M. Rubio-Dávila, R. Lugo-López, C. Hernández, R.E. Blanco and G. Escalona de Motta*. Inst. of Neurobiology,

Univ. of Puerto Rico, Medical Sciences Campus, San Juan, P.R. 00901.

The frog gastric muscularis externa was used as a model preparation for pharmacological and toxicological studies showing two types of acetylcholine (ACh)-activated contractions: a tonic, sustained one that increased in amplitude with increasing ACh doses, and a spontaneous activity that increased in amplitude and frequency after ACh application. Four functional regions were observed along the vertical axis in response to ACh and muscarinc antagonists. In the upper, cardias region the distinct spontaneous activity was inhibited by ${
m M_3}$ blockers suggesting that this activity was initiated by endogenous ACh released from terminals in the myenteric plexus. We localized these terminals in histological and electron microscopic experiments. Staining with methylene-blue azure and fucshin red revealed the myenteric plexus between the two muscle layers. Sections of this area, stained with osmium tetroxide and observed under transmission electron microscope, showed nerve terminals with three types of vesicles: clear ones cholinergic vesicles, dense-core ones catecholaminergic vesicles, and a different and plentiful one that contained both clear and medium density core vesicles which were similar to granule vesicles found in neurosecretory neurons. Results of pharmacological experiments confirmed a sensitivity in the muscularis externa to the following potential neurotransmitters: muscarinic cholinergic, alpha and bela adrenergic, and delta, kappa and mu opiate suggesting a complex synaptic interaction in the myenteric plexus. (Supported by the NIH grants GM08102 and MH48190).

IMMUNOCYTOCHEMICAL LOCALIZATION OF THE D4 DOPAMINE RECEPTOR IN THE MOUSE BRAIN

. Mauger*, M. Brockhaust, B. Sivans, S. Fuchss, O. Civelli, F. Monsma. PRPN, PRPG F. Hoffmann-La Roche AG, Basel, Switzerland; §Weizmann Institute of Science, Rehovot, Israel.

In order to investigate the distribution and the properties of the dopamine D4 receptor, we have raised polyclonal antibodies (Ab) against the N-terminal part and the third intracellular loop of the mouse D4 receptor. Synthetic peptides D4-2 (composed of amino acid residues 2-11) and D4-266 (residues 266-278) were coupled to keyhole limpet hemocyanin and used to immunize rabbits. Ten weeks after immunization, the anti-peptide Abs were detectable by enzyme-linked immunosorbent assay at a dilution of at least 5×10^{-4} and were able to immunoprecipitate a 32 kDa mouse D4 receptor generated by in vitro translation. The antisera were affinity purified using peptide coupled to sulfolink gel. The purified Abs were successfully used in immunofluorescence (IF) experiments to detect the mouse D4 receptor in transiently transfected CHO cells, while no IF was detectable in untransfected or in cells transfected with rat D2 or human D4 receptors. Immunohistochemical studies with the anti D4-2 and anti D4-266 Abs demonstrated the presence of the D4 receptor immunoreactivity (D4-IR) in several regions of the mouse brain and showed the same immunoreactive pattern. D4-IR was abolished with peptide-blocked immune serum. D4-IR was present in the olfactory bulb, in the frontal, cingulate and entorhinal cortices, in the hippocampus and dentate gyrus, as well as in the lateral septal nucleus. Little or no D4-IR was seen in striatum. These anti-peptide Abs will help to further characterize the tissue distribution of the D4 dopamine receptor in the mouse brain and lead to new insights regarding the function of the D4 receptor.

ANALYSIS OF D, AND D, DOPAMINE RECEPTOR mRNA DISTRIBUTIONS AND RELATIVE LEVELS IN THE PREFRONTAL CORTEX. A. Y. Deutch 10, S. J. Watson, Jr.², and A. Mansour² Depts. of Pharmacol. and Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06508 and VA Medical Center, West Haven, CT 06516 and ²Dept. of Psychiatry and Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

The distribution of striatal dopamine (DA) receptors has been well

characterized, but little is known of the distribution and relative expression of the D₁ and D₂ mRNAs in the prefrontal cortex (PFC). We examined the distributions and relative levels of D, and D2 mRNAs in the PFC of rats by in situ hybridization. D₁ mRNA-containing cells were present in a distinct bilaminar pattern in the PFC, being present in layers II/III and in layer VI and adjacent deep V. In contrast, D_2 -expressing neurons were almost exclusively confined to layer V. The characteristic laminar patterns of expression of both transcripts were seen in the infralimbic and prelimbic parts of the medial PFC; somewhat fewer DA receptorexpressing neurons were present in the medial precentral cortex. The laminar patterns of expression of the DA receptor transcripts were seen in low density in an arc surrounding the external capsule, and many DA receptor mRNA-containing cells were observed in the suprarhinal portion of the frontal cortex. Examination of the relative expression of D2 receptor mRNA suggested the presence of two populations of PFC cells, including a smaller population with relatively high expression (as revealed by the percent area of the cell soma covered by silver grains). There was no significant difference between the infralimbic and prelimbic cortices in relative expression of the D2 transcript. Preliminary assessments do not suggest significant differences in D, mRNA levels between cells in the superficial and deep layers of the medial PFC, but suggest that the expression of the D₁ receptor gene is slightly higher in the infralimbic than prelimbic cortex Supported in part by MH-45124, the VA Center for Schizophrenia, and the NPF.

DISTRIBUTION OF DOPAMINE D. RECEPTOR IN THE RAT BRAINSTEM USING ANTI-PEPTIDE ANTIBODIES <u>H. van Dijken, J. Dijk.</u> <u>I.C. Holstege, and P. Voorn.</u>^{2*}. Dept. of Anatomy, Erasmus University Medical School, PO Box 1738, 3000 DR Rotterdam, 'Sylvius Laboratory, Leiden, and ²Dept. of Anatomy and Embryology, Free University, Amsterdam, The Netherlands.

We have investigated the distribution of the dopamine D2 receptor in rat brainstem using anti-peptide antibodies described in our previous study on the D₂ receptor in rat spinal cord (Eur. J. Neurosci., 8: 621-628, 1996).

Adult, male Wistar rats were perfused transcardially with 4% paraformaldehyde in phosphate buffer. Brain and spinal cords were cut in 40 μm frozen sections, incubated as free floating sections with partially purified D_2 receptor antibody (24-48 hours, 4 °C) and processed with the ABC technique, in some cases followed by tyramide signal amplification (NEN Dupont). As a negative control adjacent sections were incubated with pre-immune serum instead of antiserum.

In all positive-staining regions, the antibody was highly localized to neuronal cell bodies and their proximal dendrites, while the controls resulted in no contrast staining. Within the mesencephalon, at levels caudal from the substantia nigra, strongest labelling was found in neurons located in parts of the periaqueductal gray and the superior and inferior colliculi. In the pons the most prominent labelling was found in the locus coeruleus and parabrachial nuclei. In the medulla oblongata, labelled neurons were present in the nucleus of the solitary tract, dorsal motor nucleus of the vagus, and the area immediately above the inferior olive. Furthermore, all raphe nuclei contained labelled neurons. Weakly labelled neurons were observed in several other areas, but the labelling was sometimes difficult to distinguish from background staining. Therefore we are currently increasing the purity of the antiserum.

The results provide anatomical support for specific effects of dopamine via its D₂ receptor on several areas of the brainstem, including serotonergic and noradrenergic cell groups. (Funding: FGG-EUR-ANA-11-02-01)

mRNAs ENCODING D1, D2, D3, D4 AND D5 DOPAMINE RECEPTORS HAVE SIMILAR LAMINAR DISTRIBUTIONS IN THE PRIMATE PREFRONTAL CORTEX F. Wang*, Yang Cao, and M.S. Lidow Section of Neurobiology, Yale University, School of Medicine, New Haven, CT 06510 In situ hybridization histochemistry was used to compare striatal and cortical levels of D1, D2, D3, D4 and D5 dopamine receptor mRNAs and to determine the laminar distribution of these messages in the primate prefrontal cortex. All five subtypes of dopamine receptor mRNA were present in both the monkey striatum and the cerebral cortex. Analysis of the autoradiograms also showed a noticeably stronger labeling of D1 and present in Both the Monkey Striatum and the exterior Cortex. Analysis of the autoradiograms also showed a noticeably stronger labeling of D1 and D2 mRNAs in the striatum than in the cortex. In contrast, D4 and D5 expression was clearly higher in the cortex. The levels of D3 transcripts were nearly equivalent in the striatum and the cortex. A major finding in the prefrontal cortex is that mRNAs encoding all dopamine receptor subtypes have very similar laminar distributions with their highest level of expression in layer V. The Northern blot analysis of the prefrontal cortical tissue showed the D1 receptor mRNA to be the most abundant in this cortical region. The level of D5 transcript was nearly five times lower than that of D1, with the levels of D2, D3 and D4 receptor mRNAs being lower by factors of 7, 33 and 10, respectively. The relatively high levels of expression of several dopamine receptor subtypes, including D4 receptor, in the primate cerebral cortex underscores the importance of the cortical dopaminergic system for cognitive function and for the therapeutic actions of antipsychotic drugs. Further, the prominence of all dopamine receptor mRNAs in layer V of the prefrontal cortex, which contains the cortico-striatal and cortico-tectal projection neurons, provides a neural basis for pharmacologic regulation of motor control systems. systems.

DOPAMINE D4 RECEPTOR DISTRIBUTION IN NORMAL HUMAN OSTMORTEM BRAIN SECTIONS: AUTORADIOGRAPHIC STUDIES WITH [3H]-NGD-94-1 R.A.Lahti*, E.V. Cochrane*, R.J. Primus*, D.W. Gallager*, R.C. Roberts* and C.A. Tamminga*, "Maryland Psychiatric Research Center, Univ. of Maryland School of Medicine, Baltimore, MD 21228; *Neurogen Corporation, Branford, CN 06405

The dopamine D_2 -family receptors are the D_2 , D_3 and D_4 (Civelli, 1991). The D_2 receptor is primarily located in the caudate-putamen-accumbens. D₃ in the nuc. accumbens, and by indirect determination the D₄ receptors are located in the cortex and hippocampus (Lahti, 1995). Most neuroleptics are D₂ selective yet have high affinity for the D₄ receptor; clozapine, an atypical neuroleptic is selective for the D₄ receptor. Increases in D₄ receptor density were reported (Seeman, 1992; Murray, 1995) in caudate/putamen of schizophrenics vs normal postmortem tissue but others did not confirm these findings (Reynolds, 1994, 1995, Lahti, 1996)

In this study the distribution of the D4 receptor was determined using the D_4 selective ligand [3 H]-NGD-94-1, autoradiography, and sections from normal human (n=5) postmortem tissue. Numerous brain structures were analyzed for the density of the D4 receptor with the following findings: D4 receptors were most dense in the hippocampus, especially in CA1, dentate gyrus and subiculum; significant levels were observed in entorhinal, perirhinal, and cinqulate cortices, and parahippocampal gyrus. The receptor density was low in caudate, putamen and nuc. accum

DOPAMINE (DA) D3 AND D2 RECEPTOR mRNA EXPRESSING NEURONS IN THE HUMAN MEDIAL TEMPORAL LOBE. J.N.Joyce* and E.V.Gurevich. Sun Health Research Institute, Sun City, AZ 85372.

The DA D2 and D3 receptor proteins is compartmentally organized in the hippocmapus and parahippocampus of the human. To identify the mechanisms responsible for this the istribution of DA D3 and D2 receptor mRNA bearing neurons was studied with non-radioactive in situ hybridization histochemistry (ISHH). Granular cell in the dentate gyrus exhibit intense staining for D2 mRNA. Pyramidal cells of CA3 field, hilus (sometimes referred to as CA4 field), as well as CA1 and CA2 fields, exhibit intense staining for D2 mRNA. Pyramidal cells of CB3 field, hilus (sometimes referred to as CA4 field), as well as CA1 and CA2 fields, exhibit intense staining for D2 mRNA. Pyramidal cells of all fields of the subicular complex are stained for D2 mRNA. The D2 mRNA-axpressing cells form a distinct layer of islands in the presubiculum and continuous layer II of the stained cells in the parasubiculum. In the entorhinal cortex D2 mRNA is found in the layer II comprised of large modified pyramidal cells. Deep pyramidal layers III and IV of the entorhinal cortex also contain cells stained for D2 mRNA. This is ony the region with a mismatch for receptor protein. In the hippocampal formation the level of D3 mRNA expression is quite low. D3 mRNA is barely detectable in the granular layer of the dentate gyrus. It is rather visible, however, in the pyramidal cells of the CA3, especially in the hilus. Many relatively densely stained neurons can be observed in this area. Pyramidal cells of all hippocampal fields as well as that of subicular formation express D3 mRNA. It is also possible to detect D3 mRNA in the layer II of pre- and parasubiculum, though the staining is weak, and the cells are sparse. The modified pyramids of the layer II of the entorhinal cortex are densely stained for D3 mRNA. Double labeling experiments showed that these cells also express D2 mRNA. Pyramids of the layers III and IV also appear to express D3 mRNA, though the staining is less intense than in the layer II. Double labeling experiments showed that the pyramids i

DOPAMINE TRANSPORTER AND RECEPTOR DENSITY IN THE HUMAN CAUDATE-PUTAMEN AND PREFRONTAL CORTEX (B9). T. Hussain, S. Dimopoulos, G. Pavey, K. Opeskin, C. Hill F.A.O. Mendelsohn* B. Dean Rebecca L. Cooper Research Laboratories, The Mental Health Research Institute of Victoria, Vic. 3052, Australia. Department of Medicine, University of Melbourne, Austin and Repatriation Center, Austin Campus. Heidelberg 3064, Australia.

The importance of dopaminergic systems in human pathologies has led research to focus on the study of dopamine receptors and the transporters. quantitative autoradiography, this study compares the density of dopamine receptors in the human caudate-putamen and prefrontal cortex (Brodmman's Area 9(BA9)). Post-mortem brain tissue was obtained from 5 subjects (Age: 61.4 ±10 yrs mean±SEM; 3 males and 2 females). The density of D1-like and D2-like receptor binding was determined using [3H]SCH-23390 (3nM) displaced by 1µm cis-Flupentixol; and [3H]YM 09151-2 (4nM) displaced by 1µm (+) butaclamol The dopamine transporter was measured using [3H]mazindol (15nM) displaced with mazindol (1µm) all in the presence of desipramine $(0.3\mu m)$. The density of D1-like and D2-like receptors in BA9 was $68 \pm 11\%$ and $39 \pm 4\%$ of that in the caudate-putamen. The level of dopamine transporter in BA9 was much lower (7 ±3%) compared to the caudate- putamen. These findings most probably reflect the low numbers of dopaminergic neurons in the frontal cortex and provide basic information for further studies of the dopaminergic system within these two regions of the human brain. EXPRESSION OF DOPAMINE D₁ AND D₂ RECEPTOR mRNAs IN THE HUMAN PLACENTA Wan Sung Choi, Bong Hee Lee, Kyung Jae Cho, Myeong Ok Kim, Sook Kyeong Hwang, Jin Hyun Kim and Sang, Ho Baik, Dept. of Anatomy, College of Medicine, Gyeongsang Nat'l Univ, Chinju, 660–280, Korea and Dept. of Anatomy, College of Medicine, Seoul Nat'l Univ¹, Seoul, 131–742, Korea.

The presence of dopamine(DA) in the human placenta had already been described in the late 1970's. Recently, it was reported that the

major effect of DA in the human placenta was the regulation of human placental lactogens(hPLs) release from trophoblastic cells and this effect was mediated at least by cAMP through DA D_2 receptors. However, the role of DA in the control of PL release is still conflicting. The purpose of this study was to determine the distribution of dopamine receptor mRNAs and to search the correlation between the DA receptors and hPLs in the human placenta. Expression of DA D1 and D2 receptor mRNAs in the human placenta was studied by in situ hybridization histochemistry, using radiolabeled cRNA probes. DA D_1 and D2 receptor mRNAs were colocalized in the cytotrophoblastic cells and some stroma cells in the human placentas obtained at 7-38 weeks of gestation. Cytological localization of hPLs and prolactin like proteins(PLPs) in developing human placenta immunohista imistry. hPLs were syncytiotrophobiasts. However, PLPs detected mainly identified were in the cytotrophoblast, and some stroma cells in the placental villi. Expression sites of DA receptor were well coincided with the cells which expressed the PLPs, but not with the PL-secre and cells. Our results suggest that DA might have a role in the release of PLPs through DA D_1 and D_2 receptor in the human placenta

DISTRIBUTION OF DOPAMINE (DA) D3 RECEPTOR mRNA and D2 RECEPTOR mRNA IN THE HUMAN FOREBRAIN. <u>E.V.Gurevich* and J.N.Joyce</u>, Sun Health Research Institute, Sun City, AZ 85372.

Studies of the DA D3 receptor mRNA in rats demonstrated that it was much less abundant and its distribution in the brain was more restricted that of the D2 receptor. Here we report on the distribution of D3 receptor mRNA and D2 receptor mRNA in the subcortical areas of the human brain studied using non-radioactive in situ hybridization histochemistry (ISHH). D3 mRNA can be detected in the basal ganglia, thought it is expressed at a lower level and by fewer cells tanh for D2. D3 expressing cells are relatively abundant in the nucleus accumbens and ventral portion of the putamen. D3-expressing cells are detected in both external and internal segments of the globus pallidus. In nucleus of diagonal band and nucleus basalis a considerable proportion of D3 and D2 positive neurons are cholinergic, as shown by ISHH followed by ChAT immunohistochemistry. Unlike the rat, D3 mRNA is co-localized to many D2 mRNA neurons. In the thalamus the highest density of the D3 expressing neurons was observed in the anteroventral, parafascicular, and medial part of the mediodorsal nuclei. In the hypothalamus neurons that stain for D3 message can be found in all major neuronal groups. The most intensely stained cells were observed in the tuberomammillary and supramammilary nuclei, and mammilary body. Neurons expressing D2 mRNA were more abundant that the neurons expressing D3 mRNA in all areas. Neurons stained for D3 message also stained for D2 mRNA, but many D2 expressing neurons did not contain D3 mRNA. In the midbrain D2 positive neurons are found in all subdivisions of the substantia nigra, as well as in ventral tegmental and reprorubral areas. Majority of D2 mRNA containing neurons stain are dopaminergic. D3 mRNA and D3/D2 neurons from D2 mRNA only neurons is also observed at the level of protein expression. Thus, they are differentially expressed in neuronal circuits. Funded by MH 43852, MH55144

Differential Distribution of Dopamine D₂ Receptors in GABAergic Neurons in the Nucleus Accumbens Shell and Dorsolateral Caudate-Putamen. <u>K.T. DelleDonne⁻¹, S.R. Sesack² and V.M. Pickel¹. ¹Department of Neurology and Neuroscience, Cornell Univ. Med. Coll., New York, NY 10021 ²Departments of Neuroscience and Psychiatry, Univ. of Pittsburgh, PA 15260.</u>

Dopaminergic modulation of GABAergic neurons through D2 receptors has been implicated in motivational and motor functions processed through the nucleus accumbens shell (NAS) and caudate-putamen (CPn). To determine the cellular basis for this modulation, we examined the dual ultrastructural localization of the D2 receptor with respect to GABAergic neurons in these regions in the rat. In both the NAS and CPn, peroxidase reaction product and gold-silver deposits indicating immunoreactivity (IR) for the D_2 receptor and GABA, respectively, were co-localized within axon terminals and dendrites. and in perikarya having features of spiny and aspiny neurons. The degree of co-distribution in terminals and dendrites was found to differ regionally. D2-IR was detected most frequently in axons and terminals in the NAS, and a comparatively larger population of GABAergic terminals also contained D2-IR in this region. Conversely, D2-labeled dendrites and spines were more abundant in the CPn, where more GABAergic dendrites co-localized D2-IR compared with the NAS. Furthermore, dendrites containing only D2-IR more frequently received input from GABA-labeled terminals in the CPn. These results suggest a more prominent role for D2 receptors in the presynaptic modulation of both GABA and non-GABA transmitter release in the NAS. whereas D2 receptors may be relatively more important in mediating postsynaptic effects of dopamine on GABAergic neurons in the CPn. NEUROTENSIN RECEPTOR-IMMUNOREACTIVITY WITHIN DOPAMINERGIC NEURONS IN THE SUBSTANTIA NIGRA. Y. Delville*, J.C. Klick, C.F. Ferris, L. Lifshitz, S.P. Mitra and R.E. Carraway. Behavioral Neuroscience Program, Psychiatry Department, and Physiology Department, University of Massachusetts Medical Center, Worcester, MA 01655.

Synthetic peptides corresponding to portions of the rat sequence for neurotensin receptors (NTR) were used to raise polyclonal antibodies. Western blotting indicated staining of several bands (45-55 kDa) in cell lines producing NTR (amino acid content: 47 kDa). Two antisera towards the immediate C-terminus of NTR specifically labeled neuronal elements in rat brains. In the substantia nigra, NTR-immunoreactivity (NTR-IR) visualized by wide-field digital microscopy was partly associated with dopaminergic neurons labeled with a monoclonal antibody to tyrosine hydroxylase (TH). At a cellular level, NTR-IR was found within the soma and associated processes in the compact part of the substantia nigra. NTR-IR was limited to processes within the reticular part of the area. These results support the hypothesis that neurotensin can act directly on dopaminergic neurons in the substantia nigra.

ANTAGONISM OF THE RATE-DECREASING EFFECTS OF OPIOID PARTIAL AGONISTS. <u>E.A. Walker*, L.A. Dykstra, M.J.Picker</u>, Department of Psychology, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC 27599.

Opioid partial agonists may exert behavioral effects through a number of different opioid receptors. The hypothesis that the rate-decreasing effects of opioid partial agonists dezocine, l-α-acetymethadol (LAAM), and dpropoxyphene are mediated through the μ opioid receptor was tested using Sprague-Dawley rats were trained to naltrexone and β-funaltrexamine. respond under a fixed ratio 20 schedule of food presentation. Cumulative doses of dezocine (0.1-10 mg/kg, s.c.) and d-propoxyphene (1.0-100 mg/kg, s.c.) dose-dependently decreased response rates. Pretreatments of naltrexone $(0.01\text{-}1.0~\mathrm{mg/kg,\ s.c.})$ shifted the dose-response curves for dezocinc and dpropoxyphene to the right in a dose-dependent manner. Apparent pA2 analyses indicated that naltrexone was equi-potent as an antagonist of both agonists. Furthermore, naltrexone apparent pA2 values were similar to those obtained with other μ opioid agonists. Twenty-four hr pretreatments of $\beta\text{-}$ funaltrexamine (5 and 10 mg/kg, s.c.) also shifted the dezocine dose-response curve in a dose-dependent manner. These effects of B-funaltrexamine dissipated after 4 days. Cumulative doses of LAAM (0.032-10 mg/kg, s.c.) only produced a slight decrease in response rates. However, response rates for the following 2-3 days were depressed consistent with this compounds slow onset and long duration of action. No further antagonism tests were attempted with LAAM. These data support the hypothesis that the rate-decreasing effects of at least dezocine and d-propoxyphene are mediated through the μ opioid receptor. (Supported by DA07327, DA02749, DA00033)

NALOXONE AS A DISCRIMINATIVE STIMULUS: AN ASSESSMENT OF MU, KAPPA AND DELTA OPIOID MEDIATION. A. L. Riley* and W. Klymczak, Psychopharmacology Laboratory, The American University, Washington, D.C. 20016.

Previously, we have demonstrated that animals trained to discriminate naloxone from its vehicle within the taste aversion baseline of drug discrimination learning generalize naloxone control to naltrexone (see Smurthwaite et al., <u>Pharmacol. Biochem. Behav.</u> 41:43-47; 1992), suggesting that the mu antagonist properties of naloxone mediate its discriminative effects. Naloxone, however, binds to and has antagonist activity at a number of opioid receptor subtypes. It is not known if and to what extent activity at these other subtypes underlies naloxone's stimulus effects. Accordingly, the present experiment assessed whether naloxone's activity at kappa and delta receptor subtypes also establish discriminative control. Specifically, rats were trained to discriminate naloxone (1 mg/kg) from its vehicle and then given selective mu (naltrexone), delta (naltrindole) and kappa (norBNI) antagonists to assess their ability to substitute for naloxone. Under these training conditions, naloxone generalized only to naltrexone. Naloxone-trained subjects responded similar to control subjects when administered naltrindole or norBNI. From these data, we suggest that when naloxone is the training stimulus only its mu antagonist properties establish discriminative control. It remains unknown whether selective delta or kappa antagonists would serve such a function if used as the training stimulus.

INTRACEREBRAL MICROINJECTION OF THE ENDOGENOUS CANNABINOID ANANDAMIDE ALTERS RAT EXPLORATORY BEHAVIOR BUT DOES NOT AFFECT EITHER SPATIAL MEMORY OR LTP.

N. Meiri *1, C. Collin¹, D. Tomsic¹, H. Shah¹, J. Axelrod², D. L. Alkon¹.

¹LAS, NINDS/NIH, ²LCB, NIMH/NIH, Bethesda MD, 20892

Ananandamide, an endogenous ligand for the brain cannabinoid receptors has been implicated in behavioral and neuronal plasticity. Here we describe the effect of in vivo intracerebral administration of anandamide and synthetic cannabinoid agonists. Bilateral intraventricular microinjection of anandamide 20 min prior to behavioral testing significantly altered the exploratory behavior of rats in an open field (ANOVA P<0.01; n=20). This reduction of movement was probably not caused by a motor deficit since rats that were similarly treated swam the same distance in the water maze as vehicle-injected controls. The intracerebral administration of anandamide did not affect the latency time to find the island in the water maze (n=40). Anandamide is rapidly processed in the rat brain. In preliminary experiments we found similar results after injection of THC which is metabolized here slowly. In order to evaluate the effects of cannabinoid administration in vivo on synaptic physiology, the injected rats were sacrificed immediately after performing the water maze, and hippocampal slices (300µm thick) were prepared. In an interface chamber extracellular field responses (fEPSP) recorded from the CA1 stratum radiatum were elicited by Schaffer collateral stimulation (100 µsec every 1 min). Non-associative long term potentiation (LTP) was induced by a single tetanus (100Hz, 1 sec). Both the magnitudes of the fEPSP and LTP were not affected in the cannabinoid treated animals. In addition, in vitro perfusion of naive slices with Anandamide (10uM in BSA) also failed to produce changes in the fEPSP and LTP. Anadamide perfusion did, however, cause a complete elimination of associatively induced LTP elicited by paired stimulation of distal and proximal CA1 dendrites. Supported by NINDS/NIH

SENSITIVITY OF DIFFERENT RAT STRAINS TO THE DISCRIMINATIVE STIMULUS PROPERTIES OF NICOTINE, J.R. James*, H. Covington III, and J.A. Rosecrans. Dept. Of Pharmacology and Toxicology, Virginia Commonwealth Univ., Richmond, VA 23288

Toxicology, Virginia Commonwealth Univ., Richmond, VA 23298.

Male Sprague-Dawley (SD), Long-Evans (LE), and Fischer-344 (F-344) rats were trained in an operant procedure to discriminate between nicotine and saline. Rats (SD and LE) were trained at 400 ug/kg nicotine (free base, sc.) and F-344 at 900 ug/kg nicotine (free base, sc.). F-344 rats were unable to meet criteria at doses lower than 900 ug/kg. Dose response curves produced ED50 values of 140 ug/kg. Dose response curves produced ED50 values of 140 ug/kg. Dose response curves produced ED50 values of 140 ug/kg. To ug/kg LE, and 320 ug/kg F-344. Acute tolerance testing was performed using a cumulative dosing paradigm at time intervals of 0, 90, 180, and 270 min. Rats from all three strains exhibited unique acute tolerance (desensitization) 'fingerprints' similar to previously reported results by our laboratory using a drug discrimination paradigm. The variability of these 'fingerprints' suggests that each rat responds to the effects of nicotine in an individual manner. The underlying physiological mechanism determining the ability of a rat to either exhibit or fail to exhibit acute tolerance is possibly related to individual differences in distribution, sensitivity or quantities of specific nicotinic receptor subtypes. Cannulae were bilaterally implanted in the ventral tegmentum. Bolus injections of nicotine were used to determine the site specificity and sensitivity of this dopaminergic rich nucleus.

622.4

NALORPHINE'S OPIATE AGONIST/ANTAGONIST PROPERTIES WITHIN THE TASTE AVERSION BASELINE OF DRUG DISCRIMINATION LEARNING, <u>S.D. Ziervogel* and A.L. Riley</u>. Psychopharmacology Laboratory, Department of Psychology, The American University, Washington, DC 20016.

Recently, Melton and Riley (Pharmacol. Biochem. Behav. 46:237-242; 1993) reported that the stimulus properties of cholecystokinin (CCK) were blocked by the opioid agonist morphine and potentiated by the opioid antagonist naloxone. Given these opposite effects of agonists and antagonists on drug discrimination learning, this procedure may be useful in the general classification of the <u>relative</u> efficacy of partial opioid agonists, i.e., compounds with intermediate degrees of mu agonist effects. To that end, in the present experiment animals were trained within the taste aversion baseline of drug discrimination learning to discriminate between CCK and its vehicle. They were then given the partial mu agonist nalorphine either alone or in combination with CCK to assess its ability to block (agonist) or potentiate (antagonist) CCK's stimulus properties. The effects of nalorphine were like those of naloxone or morphine in individual subjects. In some subjects, nalorphine substituted for CCK and when given in combination with CCK potentiated its stimulus effects. In others, nalorphine did not substitute for CCK and when given in combination with CCK blocked its stimulus effects. Nalorphine appears to lie between naloxone and morphine in its relative efficacy at the opiate receptor, with the degree of similarity to naloxone and morphine dependent upon the specific subject examined

EFFECTS OF NICOTINE ON SEXUALLY DIMORPHIC PREFERENCES FOR DIFFERENT COGNITIVE STRATEGIES IN RATS DOES NOT INVOLVE DOPAMINE DA2 RECEPTORS. L. Kanit^{1,2}, D. Taskiran^{1,2}, R. McDonald³, B. Kulati¹, J.J. Füredy³ and S. Pogun^{1,2} * Ege Un. Center for Brain Research. Dept. of Physiology and ³TUBITAK Basic Neuroscience Research Unit, Turkey, ³Un. of Toronto. Dept. of Psychology, Canada

Nicotine exerts its central actions by impinging on neuronal nicotinic acethycholine receptors. These actions exhibit sexual dimorphism: in rats. males and females show differences in receptor densitites and regulation by chronic nicotine treatment (Pogun et al. 1995) and in the behavioral test of active avoidance(Yilmaz et al. 1995). Dimorphism in different strategies for problem solving have been shown only in humans (Kimurā. 1992). Nicotune regulates dopaminergic activity in the CNS and some of the observed effects may be via dopamine DA2 receptors (DA2R) since the dopaminergic system is also differentially regulated in males and females. A modified version of the Morris Water Maze (MWM) developed by McDonald and White (1994) using visual vs. spatial cues, could discriminate between independent memory systems in rats. The present study employed the MWM to screen cognitive strategies in rats that may show sex differences, which cannot be captured by learning and memory tests like active avoidance. Rats received 0.4 myRg nicotine, or saline, s.c., for 13 days prior to testing. The platform was in the same location for the first 12 days either visible or hidden. On the 13th day, the visible platform was moved to a new location, leaving the animals with a choice. At the termination of behavioral testing, brain DA2R binding was determined in the frontal cortex, c striatum, hippocampus, and amygdala. For the 12 days, nicotine improved performance, i.e. time to reach the platform, in both sexes On the 13th day however, female rats that received only saline went directly to the visible platform whereas males and the nicotine treated females used their spatial cues and searched for the platform in the quadrant it had been for the past 12 days. Even though there were regional variations and sex differences in DA2R binding, no interaction with nicotine treatment was observed. The results showed clearly that males tended to use spatial cues, whera females used visual cues to solve the problem. This difference, howev

QUANTITATIVE GENETIC STUDY OF COCAINE INDUCED STEREOTYPY. C.A. Ballas, G.T. Golden, T.N. Ferraro, G.S. Smith, G.C. Brainard*, W.H. Berrettini. Thomas Jefferson University, Phila., PA, DVAMC, Coatesville, PA.

Psychomotor (PM) stimulation is movement motivated by cognitive processes and is characteristic of many addictive substances, including occaine. Mice treated chronically with high doses of stimulants such as cocaine or amphetamine exhibit intense PM stimulation manifested as stereotypy, an increase in small, repetitive, purposeless movements.

Mature DBA/2J (D2) mice exhibit marked stereotypy to repeated cocaine injections while C57BL/6J (B6) mice do not. We hypothesize that stereotypy is the result of differential neuronal adaptation originating in various genetic loci have studied the induction of stereotypy in B6, D2, F1 and F2 intercross populations of mice. Mice (8-10 weeks old) were given a seven day regimen of cocaine injections (40mg/kg IP); after the last injection, mice were observed and rated for stereotypy every five minutes for fifty minutes using a scale adapted from Tolliver and Carney (Pharm Biochem Behav 48:169, 1994) (0-4, with 4 being extreme stereotypy). For the test period, cumulative scores ranged from 0 to 40. Means ± SD for the one hour test period were: B6 (n=24) 11.10 \pm 2.35; D2 (n=26) 28.33 \pm 4.05; F1 (n=22) 20.13 \pm 2.70; F2 (n=216) 17.76 \pm 4.91. Genetic variance can be calculated by subtracting the F1 variance from the F2 variance, revealing that approximately 70% of the F2 variance is mediated by genetic factors. Wright's formula (Lande R., Genetics 99:541, 1981) shows that the minimum number of genetic factors (QTLs) is 2.2. Screening of the murine genome will begin shortly to determine correlations between DNA markers and locomotor activity and cocaineinduced stereotypy. Defining the location of genetic loci underlying this quantitative behavior may lead to identification of genes important in influencing behavior related to cocaine addiction in humans

RESPONSE ALLOCATION IN A DRUG DISCRIMINATION TASK WHEN ONE RESPONSE OPTION IS REMOVED. J. R. Stadler*, W. F. Caul, R. J. Barrett. Department of Psychology and V. A. Medical Center, Vanderbilt University, Nashville, TN 37240

It is important to know how intermediate cue states are represented by responding in two- and three-choice discrimination tasks. Using animals trained on a three-choice task, response allocation was evaluated when all three or only two levers were present.

Rats were trained using a VI schedule to discriminate among 0.5 mg/kg amphetamine (AM), distilled water (DW), and 0.03 mg/kg haloperidol (HA). Two groups were tested after being injected with DW. For one group, all three levers were present, whereas for the other group, the DW lever was removed. Animals given a choice of all levers allocated responses predominantly on the DW lever, whereas animals given a choice between the AM and HA levers allocated responses about equally between the two levers.

In a second study, animals were injected with 1.0 mg/kg HAL 24 h prior to the test session. Animals given a choice of all levers responded predominantly on the DW lever, although increased AM lever responding was observed relative to pretreatment levels. Animals given the choice between AM and HA levers showed post-HA rebound responding by allocating their responses predominantly on the AM lever. Supported by NIDA grant DA 08202

STIMULUS EFFECTS OF COCAINE GIVEN CENTRALLY AND SYSTEMICALLY. W. B. West, S. Livreri, B. Simon, M. Goding, J. Buggy, and J. B. Appel*. Behav. Pharmacol. Lab., Dept. of Psych., Univ. S. Carolina, Columbia, SC 29208.

This study compared the discriminative stimulus effects of cocaine given systemically (i.p.) and directly into the nucleus accumbens (NAc), a probable site of action of many of the behavioral effects of CNS stimulants and related drugs. Spraque-Dawley rats were trained to discriminate i.p. injections of cocaine (10 mg/kg) from saline in a standard, water-reinforced, two-lever drug discrimination paradigm. Cannulae for intra-cranial (i.c.) injections were implanted bilaterally into the NAc (coordinates: 2.2 mm anterior to bregma, 1.5 mm lateral, and 6.0 mm ventral).

Centrally administered cocaine (l μl per side) substituted for i.p. cocaine in a dose-related manner with complete substitution at a dose of 20 μg . Systemic injections of the D1/D2 receptor antagonist cis-flupenthixol dose-dependently blocked the stimulus properties of i.e. cocaine, with complete antagonism occurring at 0.4 mg/kg. When given i.e., cis-flupenthixol blocked the i.p. cocaine cue only partially. Immunohistochemistry, using c-Fos antibodies (1:5000) demonstrated that i.e. administration of cocaine was confined to an area of 2000 μ surrounding the injection site.

Substitution of i.c. cocaine for i.p. cocaine supports the hypothesis that the NAc plays a role in the stimulus effects of cocaine. Antagonism by cis-flupenthixol suggests that DA receptors mediate the cocaine cue. However, the failure of i.c. cis-flupenthixol to antagonize i.p. cocaine completely indicates that sites other than the NAc may also be involved.

EFFECT OF INTRAPERITONEAL COCAINE PREEXPOSURE ON COCAINE-INDUCED TASTE AVERSIONS. <u>H.F. Diamond* and A.L. Riley</u>. Psychopharmacology Laboratory, Department of Psychology, The American University Washington DC 20016

American University, Washington, DC 20016.

In the present experiments, the effect of preexposure to cocaine on cocaine-induced aversions was assessed under conditions that typically sensitize animals to its rewarding effects, i.e., following massed (vs. spaced) IP injections. Specifically, rats were administered cocaine (32 mg/kg) or vehicle daily (i.e., massed) or every fourth day (i.e., spaced) for five exposures. They were then given saccharin to drink and injected with cocaine (32 mg/kg, SC) or vehicle. Animals preexposed to the vehicle and then injected with cocaine acquired a taste aversion to cocaine. Animals given spaced preexposure to cocaine and injected with cocaine during conditioning failed to acquire an aversion (similar to that reported following spaced and massed SC cocaine exposure; see Diamond & Riley Soc. Neurosci. Abs. 21:1953; 1995). Animals receiving massed preexposure to cocaine and then injected with cocaine did not display attenuated aversions, instead acquiring aversions comparable to nonpreexposed subjects. These results are consistent with the position that massed preexposure either prevents the development of tolerance to cocaine or results in sensitization to both its rewarding and aversive effects, functionally resulting in the normal acquisition of aversions.

EFFECT OF INTERDOSE INTERVAL ON AMPHETAMINE-INDUCED REBOUND RESPONDING. W. F. Caul*, R. J. Barrett, and J. R. Stadler. Department of Psychology and V. A. Medical Center, Vanderbilt University, Nashville, TN 37240

Our previous research, using a three-lever amphetamine-vehicle-haloperidol drug discrimination task, has shown that time-dependent, rebound changes in choice responding occur following administration of a single dose of drug. The present study evaluated rebound responding following 5 doses of amphetamine as a function of interdose interval.

Rats were trained using a VI schedule of food reinforcement to discriminate among 0.35 mg/kg amphetamine (AM), distilled water (DW), and 0.033 mg/kg haloperidol (HA). Orderly doseresponse functions were obtained for both AM and HA. Discrimination performance was used to form 3 matched groups. The group given DW on each of the 9 days of the treatment period responded predominantly on the DW lever when tested 24 h after the final injection. The group given AM (0.75 mg/kg) on days 5 through 9 responded predominantly on the HA lever while an intermediate level of rebound HA-like responding was observed for the group given the same dose of AM 5 times but on alternate days during the treatment period.

WITHDRAWAL FROM COCAINE "BINGES" in RATS: ULTRASOUNDS AS INDICES OF AFFECTIVE DISTRESS. Nicole H. Mutschler*, Jack Sutherland II, and Klaus A. Miczek. Dept. of Psychology, Psychiatry, and Pharmacology Tufts Univ., Medford MA 02155.

Human cocaine abusers report that they experience intense anxiety during withdrawal from chronic use or "bingeing". Because the symptoms of cocaine withdrawal are not easily observed, it has been difficult to develop an adequate animal model for cocaine withdrawal that detects anxiety-like behavior. The objective of the present study was to examine the effects of continuous access to intravenously self-administered cocaine on distress vocalizations induced by startling tactile stimuli as a possible animal model for cocaine withdrawal. Five days after implantation of a jugular catheter rats were placed into selfadministration chambers with access to cocaine (0.25mg/inf). Once the animal had a stable response rate over 3 days, on FR5, they were given free access to cocaine (0.25mg/inf) for 48 or 12 hours. Subsequently, animals were exposed to 18 air puffs (20 or 10psi) at 6, 24, 72 hours, 7 and 14 days after the "binge". Rats that "binged" on cocaine for 48 hours and were subsequently startled with 20psi stimuli increased the number of automatically recorded ultrasonic distress calls when compared to handled controls at 6 and 24 hours after the last cocaine infusion. After a 48 hour "binge", animals showed an increase in amplitude of the startle response up to 7 days after withdrawal in response to 20psi tactile stimuli but not to 10psi. Animals that "binged" for 12 hours also showed an increase in ultrasonic distress calls when compared to handled controls when the USVs were induced by 10psi tactile stimuli. Rats that experienced repeated 12 hour "binges" showed no evidence for habituation or sensitization due to multiple "bingeing". USVs during cocaine withdrawal may be interpreted to reflect affective distress during the first 72 hours after the last cocaine infusion of a 12 or 48 hour "binge". (PHS grant RO1 DA02632)

BRIEF SOCIAL STRESS SENSITIZES COCAINE EFFECTS ON MOTOR ACTIVATION AND OPERANT BEHAVIOR. J. Sutherland II*, G. J. Carter, N. H. Mutschler and K. A. Miczek. Dept. Psychology, Psychiatry and Pharmacology, Tufts Univ. Medford MA 02155.

Brief confrontations with an aggressive opponent comprise behavioral and physiological stress responses. This form of "social stress" interacts with psychomotor stimulants in a long-lasting sensitizing manner. The present study investigated how cocaine's effects on motor acts and positively reinforced responding behavior were sensitized by "social stress" episodes. Male Long-Evans rats lever pressed and male CFW mice nose poked, reinforced by milk presentation, according to joint FR5-FI180sec (rats) or joint FR5-FI300sec (mice) schedules. After response rates stabilized, subjects were exposed to social stress. For rats, social stress is defined as a threat of attack by an aggressive conspecific while protected in a cage for 15 or 60 minutes, and in mice, it is defined as attacks by an aggressive conspecific (20 bites) followed by 30 minutes inside a protective cage. Experimental subjects were randomly assigned to a dose of 3,6,10,17, or 30 mg/kg cocaine, receiving the same dose of cocaine 7,14, 21 and 28 days after social stress. Compared to pre-stress rates, cocaine (6.0 and 10.0 mg/kg) challenge increased response rates on days 7,14,21 and 28. Peak effects were observed on day 14 for rats and day 21 for mice. After a single social defeat by an aggressive resident, cocaine challenges increased locomotor and stereotyped behaviors. These data suggest that brief social stress produces sensitization to the stimulant effects of cocaine on conditioned and unconditioned motor acts at different times (Supported by PHS grant R01 DA 02632.)

CUMULATIVE LOCOMOTOR ACTIVITY CURVES FOR HABITUATION STUDIES WITH RODENTS. F.A. Barrios, M. Giordano and W. Freed*, Centro de Neurobiología, UNAM, México D.F. 04510 and NIMH, Neuroscience Center. Washington, D.C. 20032.

Locomotor behavior is commonly used in pharmacological and behavioral studies to assess the effects of pharmacological and experimental manipulations. Many of these studies rely on some means of automated measurement of locomotor behavior. We propose a novel approach for studying locomotor activity data Ordinarily, activity is monitored by measuring total amounts of activity for defined time intervals. Alternatively, cumulative locomotor activity data might be analyzed by fitting the data to a mathematical model. This approach could provide information not only about the quantity of locomotion, but also about the properties of locomotion over time. Locomotor activity data collected from several types of apparatus were fitted to mathematical models with the assumption that cumulative activity reaches a stable asymptote. By using the chi-square test for goodness of fit the best model was selected. The best model is based on the saturation function Ac(t) = At/(B+t), where Ac is the cumulative activity, t is time, and A and B are parameters. From the first derivative $dAc(t)/dt = AB/(B+t)^2$ at t=0, it can be seen that A/B represents the initial rate of activity. In addition the rate of activity will have diminished to A/4B at time t=B, and as t approaches infinity Ac(t) approaches A (which represents the asymptotic level of activity). Using this model we observed that stimulants (e.g. amphetamine) induced a ten-fold increase in the initial rate of activity. Analysis of locomotor activity by fitting the data to a mathematical model has several potential advantages. First, it may be possible to predict overall activity curves from a relatively short period of testing. Secondly, this information could provide hypotheses regarding a drug's mode of action by comparing its parameters those of drugs for which the mode of action is known. BEHAVIORAL PHARMACOLOGY: SEROTONIN

623.1

PSYCHOSOCIAL CONFLICT IN TREE SHREWS: NEURO-BEHAVIORAL EFFECTS OF CLOMIPRAMINE TREATMENT. E. Fuchs*, E. Nonn, M. Kramer, G. Flügge, C. Hiemke^{a)}. German Primate Center, D-37077 Göttingen and ^{a)}Department of Psychiatry, University of Mainz, D-55131 Mainz.

Male tree shrews (Tupaia belangen) provide a suitable model to study the neuro-behavioral effects of chronic psychosocial conflict. Since the overall pattern of the behavioral and physiological changes in subordinate male tree shrews resemble a depression-like symptomatology, we analyzed the effect of a chronic treatment with the antidepressant clomipramine in these individuals. The drug was administered orally (50mg/kg/day) for 28 days, while the psychosocial conflict continued during the whole treatment period. A clear and time-dependent improvement of locomotor activity, marking and grooming behavior, risk assessment, and the activity of both the HPA-axis and the sympathetic nervous system was observed. In 17 brain regions and the pituitary, numbers of binding sites for serotonin (5HT_{1A}), noradrenaline (alpha₂-adrenoceptors, beta2-adrenoceptors), and corticotropinbeta₁-adrenoceptors. releasing factor were quantified. The antidepressant treatment affected these receptor systems in a region and treatment specific pattern. Since the clomipramine treatment counteracts behavioral and endocrine effects of the chronic psychosocial conflict, the present data reflect distinct neurochemical processes that may underly the therapeutic actions of antidepressants. Supported by the DFG Fu 174/9-1 and Hi 399/3-1.

623.3

EFFECTS OF DULOXETINE, A DUAL SEROTONIN AND NORDEPINEPHRINE REUPTAKE INHIBITOR, ON THE STIMULUS PROPERTIES OF COCAINE AND LSD. B. Simon* and J. B. Appel, Beh. Pharm. Lab. Dept. of Psych., Univ. of S. Carolina, Columbia, SC, 29208.

Pharm. Lab., Dept. of Psych., Univ. of S. Carolina, Columbia, SC, 29208. Duloxetine, a newly developed antidepressant, inhibits the reuptake of both 5-HT and NE. Both of these neurotransmitters have been implicated in certain effects of cocaine and LSD. Although cocaine acts primarily by inhibiting the reuptake of DA, it also increases NE concentration in the amygdala and 5-HT throughout the brain. Studies of the stimulus properties of cocaine indicate that both NE and 5-HT uptake inhibitors substitute at least partially for this drug or potentiate the effects of relatively low doses. LSD acts primarily as an agonist at 5-HT, but some of its behavioral effects (e.g., neophobia, acoustic startle response) depend on NE projections from the locus coeruleus or involve NE activation in general. While there is considerable evidence that the stimulus properties of LSD are mediated by 5-HT receptors, drugs such as yohimbine, which acts at α₂ NE as well as 5-HT_{1α} and 5-HT_{1D} receptors, substitute for LSD. For these reasons, doloxetine was tested in rats trained to discriminate cocaine (10 mg/kg) or LSD (0.08 mg/kg) from saline.

Results indicate that duloxetine alone (2 - 16 mg/kg) does not substitute for either cocaine or LSD. However, two doses (8 and 16 mg/kg) enhanced the stimulus effects of a low dose of cocaine (2.5 mg/kg). Duloxetine (4 mg/kg) also potentiated the effects of a low dose of LSD (0.02 mg/kg).

These findings indicate that the stimulus properties of duloxetine do not resemble those of either cocaine or LSD. However, the fact that this drug enhanced the effects of both drugs suggests that 5-HT and NE reuptake plays some role in the actions of both cocaine and, to a lesser extent, LSD.

623.2

THE EFFECTS OF LESIONS OF BRAIN SEROTONIN AND NOREPINEPHRINE ON ANXIETY-LIKE BEHAVIOR. P.A. Ardayfio, A.J. Barron, G.U. Ikeri and R.L. Commissaris*. Pharmaceutical Sciences, College of Pharmacy & AHP, Wayne State University, Detroit, MI 48202

The present studies examined the hypothesis that the neurotransmitters serotonin (5-hydroxytryptamine; 5HT) and norepinephrine (NE) are redundant systems in the modulation of anxiety-like behavior. Anxiety-like (conflict) behavior in female rats was investigated before and after treatment with vehicle, the 5HT neurotoxin 5,7-DHT, the NE neurotoxin 6-OHDA, or the combination of the two neurotoxins. When the absolute number of shocks accepted in conflict sessions was used as the measure of "anxiety", there was no apparent effect of any neurotoxin treatment on conflict behavior. Treatment with vehicle, 5,7-DHT or 6-OHDA alone resulted in a very modest reduction in water intake (unpunished responding). In contrast, subjects receiving the combination lesion treatment exhibited a dramatic reduction in water intake, perhaps the result of a generalized behavioral disruption produced by the combination lesion. To normalize for the differences in water intake across the various treatments, conflict (anxiety like) behavior during the first week following lesion treatment also was evaluated in terms of a "suppression ratio" (i.e., shocks accepted/water consumed). This analysis again revealed that the vehicle and single lesion groups did not differ in their conflict behavior; in contrast, the subjects receiving the combination lesion exhibited a dramatic anticonflict effect (reduced "anxiety"). These findings with the suppression ratio measure are consistent with the hypothesis that 5HT and NE are redundant neurotransmitters in the modulation of anxiety-like conflict behavior. (Supported in part by GM08167).

623.4

AN ETHOGRAPHIC STUDY OF REVERSAL OF FIGHTING BEHAVIOR IN ISOLATED MICE BY SEROTOMERGIC AGENTS USING CORRESPONDENCE ANALYSIS <u>J. K. Chamberlain*</u>. Terre Haute Center for Medical Education, Indiana University School of Medicine, Terre Haute, IN 47809

Reversal of fighting behavior in mice is an animal model used for screening potential anxiolytic agents. Putative anxiolytic activity is inferred when an agent inhibits the aggressive response of an isolated mouse toward a group-housed intruder stimulus mouse. Ethological observation of resident-intruder encounters allows analysis of a broad spectrum of behaviors in assessing drug action. In the present study, correspondence analysis is used to evaluate ethological data. CD-1 mice weighing 18-22g were isolated for three weeks. Mice were then trained to a criteria of a biting attack on a stimulus mouse in 10 seconds or less on three consecutive training sessions. The mice were injected with various serotonergic agents at a previously determined ED50 dose for inhibition of fighting behavior. Isolated mice were scored on the frequency of several behaviors ranging from a biting attack to flight for a three minute period. A Fisher's exact test and a Monte Carlo simulation revealed a significant difference between drug treatments. Two-dimensional graphical representation reveals several associations. Between set comparisons of drug treatments with behaviors show 80H-DPAT associates with defensive posture, and the arylpiperazine axiolytics, buspirone and ipsapirone, group together and associate with high affinity for 5-HT1A receptors, group together and associate with high affinity for 5-HT1A receptors, group together and associate with alert posture. These data demonstrate that differently acting serotonergic agents with anti-aggressive activity, can be distinguished by ethological observation using multivariate correspondence analysis.

NOVEL MURINE AVOIDANCE ASSAY SELECTIVELY SENSITIVE TO ANXIOLYTICS. T.W. Seale*, Y. Zhang and K.M. Garrett, Depts. of Pediatrics and Physiology, Univ. Oklahoma Hith. Sci. Ctr., Oklahoma City, OK 73190

Well characterized behavioral assays responding selectively to anxiolytic agents are vital for drug discovery, for in vivo pharmacological studies and for pharmacogenetic analyses of anxiety-related behaviors. We have developed a new behavioral assay, the mirrored chamber aversion assay, which is based on innate approach-avoidance of mice and most other vertebrate species to mirrors placed in their environment. The assay has several attractive attributes: 1) selectivity of its pharmacological response profile; 2) its simplicity, rapidity and non-punishing nature; 3) its quantitative nature involving two endpoints, latency to enter and duration spent in the avoided environment; 4) the large magnitude of the observed behavioral changes; 5) the ability to respond to both anxiolytic and anxiogenic agents. Untreated or vehicle treated male and female mice (e.g. BALB/cByJ, C57BL/6J) exhibit high avoidance (mean latencies ≥ 280 sec, mean duration ≤ 3 sec) during a 300 sec test period. Mean latency is reduced to a nadir of 60 sec and duration increased to 60 sec in a dosage dependent manner following diazepam administration.+ Anxiolytic-like responses also are observed following several 5-HT_{1A} agonists, 5-HT₃ antagonists, the glucocorticoid dexamethasone, nicotine and ethanol. Progranolol, clonidine and volumbine, haloperidol, fluoxetine and tricyclic antidepressants, nisoxetine, caffeine, methylphenidate and phencyclidine had no effect up to motor depressant doses. Behavior of habituated mice resembles that of anxiolytic-treated mice but these respond to anxiogenic agents like DMCM and high dosage caffeine. Several situational variables have been identified which impact this behavioral assay: recent litter change, intra-cage aggression, diurnal rhythm, recurrent noise or vibration. Genotype has a major impact on both innate and drug-induced responsiveness in this assay. This new method may have value for the identification and characterization of novel anxiolytics. (Supported by NIMH grant MH49791).

DISCRIMINATION BETWEEN THE 5-HT, RECEPTOR AGONISTS FLESINOXAN AND ELTOPRAZINE. J. Gommans, T.H. Hijzen, J.C. Compaan and B. Olivier, Dept. of Psychopharmacology, Utrecht Univ., Sorbonnelaan 16, 3584 CA Utrecht, The Netherlands.

In previous drug discrimination studies flesinoxan (F) and eltoprazine (E), having cues mediated by 5-HT_{IA} and 5-HT_{IA/IB} receptors, resp., partially cross-generalized to each other. In a two lever FR10 operant procedure, rats learned to discriminate F (1.0 mg/kg, p.o.) from E (1.5 mg/kg, p.o.) readily. Saline administration resulted in approximately 50% of the responses being made on either lever. Different doses of the training drugs gave dose dependent increases in drug appropriate lever responding and in response rate, and a decrease in latency to the first response and lever selection. The training doses in the dose response curves, differed between the drugs, i.e. E was located more to the right than F. This might explain the following results: when the training doses of F and E were administered together this resulted in predominantly E lever responses. Lower doses of E together with F reduced E lever presses and, concomitantly, increased F lever responses. A second saline test resulted, again, in approximately 50% responses on either lever. We have no explanation why the point on the generalization curve representing the E training dose is located more to the right than that of F, while at the same time saline administration results in 50% responding on both levers. The full 5-HT_{1A} receptor agonist 8-OH-DPAT (0.01-0.1 mg/kg, p.o.) and the 5-HT_{1B} receptor agonist anpirtoline (0.063-0.25 mg/kg, p.o.) substituted completely for F and E, resp., showing that the discrimination is based on the effects of 5-HT_{1A} versus 5-HT_{1B} receptor activation. Mianserin (1.0-12.0 mg/kg, p.o.) did not substitute for either F or E. Buspirone (1.0-30.0 mg/kg, p.o.) partially substituted for F, probably due to its partial 5-HT_{IA} receptor

THE ANTIEMETIC EFFECT OF THE R- AND S-ENANTIOMERS OF ONDANSETRON AGAINST CISPLATIN AND MORPHINE-INDUCED EMESIS IN THE FERRET. R.H. Wong*, A. Carter, G. Haynes, P.D. Thut, R.L. Wynn, J.R. McCullough, and T.P. Jerussi. Department of Family Medicine, School of Medicine, and Department of Pharmacology, Dental School, University of Maryland, Baltimore, MD 21201, and Sepracor, Inc., Marlborough, MA 01752.

Ondansetron possesses an asymmetric carbon center which imparts chirality to the molecule. Previous studies with other antiemetics have shown differences in the pharmacological properties between the racemate and the constituent enantiomeric chemical pairs. This study examined the antiemetic effect of the R- and S-enantiomers of ondansetron against cisplatin and morphine-induced emesis. Ferrets were injected i.v. with cisplatin 10 mg/kg. After 30 min, the animals were injected i.v. with a test compound (racemic ondansetron or the R- or S-enantiomer; n=5/drug). For morphine-induced emesis, ferrets were injected i.v. with a test compound 5 min prior to 0.3 mg/kg morphine s.c. The results indicated that R-ondansetron was approximately 9-times more potent than the S-enantiomer against cisplatininduced emesis. Moreover, R-ondansetron was more potent and showed greater efficacy against morphine-induced emesis than the S-form which was lethal at higher doses. These results indicate that the enantiomers of ondansetron inhibit cisplatin and morphine-induced emesis in a graded dose response manner, with the R-isomer being the most potent and most effective antiemetic drug. Support provided by Sepracor, Incorporated.

MICROINJECTIONS OF 5-HT_{1A} AND 5-HT_{1B} AGONISTS INTO THE LS AND MPO OF MALE MICE: EFFECTS ON OFFENSIVE AGGRESSION. A. Cologer-Clifford, S. Smoluk, J. Nyby*, and N. Simon. Department of Biological Sciences, Lehigh University, Bethlehem, PA 18015.

Testosterone and its metabolites facilitate the expression of offensive intermale aggression, while serotonin inhibits this behavior. Previous findings demonstrated that androgens and estrogens differentially effected the ability of 5-HT receptor agonists to attenuate aggression. The present study examined whether steroidal modulation of agonist function occurred in the lateral septum (LS) or medial preoptic area (MPO), brain regions which have been linked to the expression of aggression and exhibit androgen, estrogen, $5\text{-}HT_{1A}$, and $5\text{-}HT_{1B}$ receptors. Castrated CF-1 male mice implanted with either the estrogen DES or the nonaromatizable androgen DHT were microinjected bilaterally into the LS or MPO with either 8-OH-DPAT (a 5-HT $_{1A}$ agonist), CGS12066B (a 5-HT $_{1B}$ agonist), or DPAT+CGS and tested for aggression and motor behavior. All procedures complied with Federal guidelines for animal care. In the LS, CGS decreased aggression in androgen-treated, but not estrogen-treated males. DPAT injections had no effect. In the MPO, agonist treatments reduced aggression in both androgen- and estrogen-treated animals. The only exception was DPAT+CGS in androgen-treated males where the effects were marginal (p<0.054). The findings demonstrate regional variation in endocrine modulation of 5-HT $_{1A}$ and 5-HT $_{1B}$ agonist effects on aggression. Supported by A.P.S. Dissertation Award (A.C.), a Howard Hughes Science

ACUTE EFFECTS OF DEXFENFLURAMINE ON RHESUS MONKEY PERFORMANCE IN AN OPERANT TEST BATTERY. M.G. Paule, M.P. Gillam, J. Gossett and D.L. Frederick. Division of Neurotoxicology, National Center for Toxicological Research/FDA, Jefferson, AR 72079.

The acute effects of dexfenfluramine (d-FEN), an anorectic drug believed to facilitate serotonergic neurotransmission, were assessed in rhesus macaques using behavior in several complex food-reinforced tasks designed to model aspects of time estimation, short-term memory, motivation, learning, and color and position discrimination. The endpoints monitored included measures of response rate and accuracy (or breakpoint for the motivation task). The acute effects of d-FEN (0.0-1.75 mg/kg; i.m.) manifest as dose-dependent disruptions in all tasks, but disruptions in the motivation and time estimation tasks occurred at a dose (1.0 mg/kg) below those affecting performance in all other tasks. Learning task performance appeared to be the least sensitive to d-fen, while the short-term memory and color and position discrimination tasks were intermediate in sensitivity. In both the learning and color and position discrimination tasks, d-FEN decreased response rate at a dose or doses that did not decrease accuracy, suggesting that these functions remained intact even at doses that affected the motoric components of task performance. These observations support the contention that d-FEN is an effective anorectic agent in the monkey (i.e., the task assessing motivation to work for food reinforcers is one of the most sensitive).

FLESINOXAN'S ANTIDEPRESSANT PROPERTIES IN VARIOUS FORCED SWIM TEST PARADIGMS. J.A.M. van der Heyden, J. Mos and B. Olivier. Solvay Duphar b.v., Dept of Pharmacology, P.O. Box 900, 1380 DA Weesp, The Netherlands

The 5-HT_L receptor has been found an important locus for the action of antidepressant treatment. In putative animal depression models 5-HT_{LA} agonists are highly active. Here we describe the effect of flesinoxan in the forced swim test, using several protocols.

Flesinoxan potently reduces the immobility in the forced swim test under standard conditions (i.e. swim period followed by two drug administrations and a final swim test session). The full agonists (flesinoxan., 8-OH-DPAT) reduced immobility over the entire 6 minute test period, whereas the partial agonists (buspirone, ipsapirone), like classic antidepressants, only reduced the immobility in the first three minute period. This reduction of immobility in the entire 6 minute period cannot be attributed to stimulation of motor activity. Flesinoxan has a good duration of action. The ED_g value (dose needed to reduce immobility by 8 seconds) calculated 4 hrs after the second drug administration only decreased a factor 3 over a four hour period. Tolerance for the effect of flesinoxan in the forced swim test did not occur, since a subchronic 1 week pretreatment with flesinoxan (1 mg/kg po once daily) did not affect the efficacy of the drug in the swim test after this period. Flesinoxan and imipramine were also tested in a deviant protocol of the forced swim test in which the compound was administered only once before the two consecutive swim sessions. Flesinoxan was active 24 hours after a single administration in contrast to the classic antidepressant imipramine. Similar effects were found using this deviant swim protocol if the animals were treated with the drugs for 4 consecutive days.

consecutive days.
 In conclusion, flesinoxan shows a clearcut dose-dependent and long-lasting
effect in the forced swim test in rats, on basis of which it is predicted to
possess antidepressant activity in man. Its profile is clearly different from the
classic tricyclic antidepressants.

VARYING THE TRAINING DOSE OF 8-OH-DPAT FACILITATES CHARACTERIZATION OF THE DISCRIMINATIVE STIMULUS PROPERTIES OF 5-HT_{1A} SELECTIVE COMPOUNDS WITH MIXED AGONIST/ANTAGONIST ACTIVITY. M. C. Wolff and J. D. Leander*. Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285.

Pigeons were trained to discriminate either 0.16 mg/kg (low dose) or 0.64 mg/kg of a selective 5-HT₁A agonist, 8-hydroxy-2-(di-N-propylamino)tertalin (8-OH-DPAT), from saline. In the low dose condition, the dose response curve for the training drug was shifted to the left (ED50 = 0.04 mg/kg) with respect to the high dose condition (ED50 = 0.14 mg/kg). A number of 5-HT agonists, partial agonists and putative antagonists were tested for stimulus generalization. Compounds, such as buspirone, which engendered only partial discrimination in the high dose condition, produced full discrimination in the low dose condition. Some compounds, such as (-)pindolol, which completely antagonized the 8-OH-DPAT cue in pigeons trained with the higher dose, produced full generalization in pigeons trained to recognize the lower training dose. Other compounds, such as WAY100635 and LY206130, completely antagonized the 8-OH-DPAT cue in both groups without producing 8-OH-DPAT-like responding in either group. Thus the training dose of 8-OH-DPAT determines whether some compounds will appear to discriminate as full agonists, partial agonists, or antagonists of 8-OH-DPAT. Using a relatively low training dose of 8-OH-DPAT may facilitate detection of the agonist properties of mixed 5-HT₁A agonists/antagonists.

EFFECTS OF 5-HT RECEPTOR ANTAGONISTS GR127935T (5-HT_{18/1D}) AND MDL 100,907(5-HT_{2A} ON LEARNING. A. Meneses* & E. Hong. Terapéutica Experimental, Depto. Farmacología y Toxicología, CINVESTAV-IPN. Ap. Postal 22026, México, D.F., 14000. MEXICO.

It has been previously reported that TFMPP, mCPP, 1-NP and mesulergine impaired the consolidation of learning, whereas, DOI or ketanserin improved it. In this work, we tested the effects of GR127935T (GR1) and MDL 100,907 (MDL) plus the afore-mentioned drugs in the autoshaping learning task. The results showed that the post-training injection of the 5-HT, AMBRID receptor agonist GR46611X (GR4) (1-10 mg/Kg) decreased learning, whereas GR1 (1-10 mg/Kg) increased it, the latter being reversed by PCA pretreatment. GR1 eliminated the decrement induced by GR4, TFMPP and mCPP. Moreover, MDL (0.1-3.0 mg/kg) had effect by itself and eliminated the effect of DOI, ketanserin, TFMPP, mCPP, 1-NP and mesulergine but did not modify the increase in learning induced by 8-OH-DPAT Therefore, it seems that presynaptic stimulation of 5-HT_{18HD} receptors impaired the consolidation of learning, whereas their blockade improved it. Additionally, 5-HT_{2A} receptors might be also involved in the consolidation of learning. Supported by CONACYT grant 4367-M9406.

623.13

5-HT, RECEPTOR AGONISTS AND SILENT ANTAGONISTS REVERSED THE DECREMENTS IN LEARNING INDUCED BY DIZOCILPINE AND SCOPOLAMINE E. Hong*., & A. Meneses Terapéutica Experimental, Depto. Farmacología y Toxicología, CINVESTAV-IPN. Ap. Postal 22026, México, D.F., 14000. MEXICO.

We have previously reported that the 5-HT_{1A} receptor agonist 8-OHDPAT (DPAT) enhanced consolidation of learning, whereas the silent 5-HT_{1A} receptor antagonists WAY 100635 (WAY) or S-UH-301(S-UH) had no effect by themselves. In this work, the effect of post-training injection of DPAT, WAY and S-UH plus dizolcipine (DIZ) or scopolamine (SCO) was determined in autoshaping learning task, which consisted of illumination of a retractable lever for 8 sec (conditioned stimulus, CS) followed by the delivery of a food pellet (US) every 60 sec. If the animal pressed the lever (conditioned response, CR) the trial was shortened and the lever was retracted, the light was turned off and the US was delivered. The results showed that both 5-HT $_{1A}$ stimulation (by DPAT) and blockade (by S-UH) reversed the learning deficit induced by DIZ and SCO, whereas WAY reversed only the effect of SCO, but not that of DIZ. These data confirm the role of 5-HT_{1A} receptors in learning and might further suggest a possible interaction of cholinergic systems with 5-HT_{1A} receptor function. Supported by CONACYT grant 4367-M9406

ESTROGEN EFFECTS ON GALANIN IMMUNOREACTIVITY IN THE GNRH NEURONS IN FEMALE MICE. G. V. Rajendren* and M. J. Gibson. Div. Endocrinology. The Mount Sinai Medical Center, New York, NY 10029.

Galanin is reported to be present in a significant proportion of GnRH neurons in the rat. Expression of galanin immunoreactivity in GnRH neuronal cell bodies reaches its peak in female rats when circulating levels of estrogen are high. The present experiments were undertaken to investigate the role of estrogen in the expression of galanin immunoreactivity in GnRH neurons in female mice. The females were ovariectomized (OVX) and either untreated, or given subcutaneous implants of 5 μg estradiol (E₂) to induce a strong feedback inhibition on LH secretion. A group of cycling females in proestrus were also included in the studies. Two representative coronal sections were selected from each mouse, one passing through the anterior septum and the other containing the organum vasculosum of lamina terminalis (OVLT), for analysis using a confocal laser scanning microscope. The GnRH cell bodies in these sections coexpressing galanin immunoreactivity, and those which were in close contact with galanin immunoreactive fibers were counted and compared. In the presence of strong steroid inhibition (OVX-E2) less than 7% of GnRH neurons colocalized galanin, while in the other groups 30-37% of the GnRH cells were also immunoreactive for galanin. In contrast, GnRH cells in all groups were closely associated with galanin immunoreactive structures, presumably synapses, with no apparent differences among the groups. GnRH neurons receiving synaptic contacts from galanin immunoreactive fibers were particularly abundant (74-92%) at the level of the OVLT. Thus, galanin immunoreactivity in GnRH neurons during E2 inhibition of LH release was suppressed, in contrast to facilitation of galanin immunoreactivity in GnRH neurons during a period of enhanced LH release (proestrus or OVX). This suggests that galanin may be involved in the steroid modulation of the GnRH system. Supported by HD 19077.

BASIC FGF IS A MAJOR NEUROTROPHIC SIGNALING AGENT DURING LHRH NEURON-ASTROGLIA INTERACTIONS:bFGF PRIMING SENSITIZES LHRH NEURONS TO GROWTH FACTOR NEUROTROPHIC EFFECTS. F. Gallo^{1*}, ²R. Avola, A. Beaudet¹, and B. Marchetti^{1,4}. Depts. of ¹Pharmacol. and ²Biochem, Catania Univ., ³Montreal Neurological Institute, Montreal, Quebec, Canada, and 4OASI Institute for Research and Care (IRCCS) Mental Retardation and Brain Aging Troina (EN), Italy Luteinizing hormone-releasing hormone (LHRH) neurons play a pivotal role in the

neuroendocrine control of mammalian reproduction. We have recently established an in vitro model system to study LHRH neuron-astroglial interactions and shown the presence of a bidirectional informative network between astroglial cells in primary culture and the immortalized hypothalamic LHRH neuronal cell line (GT₁₋₁ subclone), that displays highly differentiated properties of LHRH neurons (Endocrine 3: 863, 1995). In the present work we have characterized at a morphological and biochemical levels the neurotrophic effects exerted by different growth factors during neuronal differentiation, with the aim to elucidate a. whether certain growth factors are capable to directly exert neurotrophic and functional effect without glia intermediacy; b. whether there is a synergism/cooperation between growth factors in the induction of neuronal differentiation; and c. whether a specific growth factor participates in LHRH neuronastroglia crosstalk. Treatment of GT1-1 neurons for 24 hrs with bFGF exerted the most potent neurotrophic effects compared to epidermal growth factor (EGF), insulin (Ins), and insulin-like growth factor (IGF-I). Specificity of bFGF was underscored by a. the ability of a submaximal priming dose of bFGF to markedly potentiate EGF, IGF-I and Ins neurotrophic effects and b. the almost complete inhibition of astroglia neurotrophic effects after neutralization of endogenous bFGF action during GT_{1,1} neuron-astroglia interactions. EGF, Ins and IGF-I significantly affected LHRH release, bFGF was inactive alone, but induced a marked down-regulation of GFs-induced spontaneous LHRH release upon priming. All together these informations point to bFGF as a candidate intercellular signaling agent coordinating neuron-astroglia activity and suggest that bFGF in partnership with LHRH participates in the regulation LHRH release.

MODULATION OF LUTEINIZING HORMONE BY ANGIOTENSIN II AND GABAERGIC SYSTEM IN THE PREOPTIC MEDIAL AREA. R.C.M.Dornelles, C.R.Franci*, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Brazil. 14049 900.

Luteinizing hormone (LH) secretion in female rats is controlled by several factors, including γ aminobutiric acid (GABA) and angiotensin II (AII). Medial preoptic area (MPOA) contains LH-releasing hormone (LHRH) neurons which are stimulated by All and receive gabaergic inputs. There are also estrogensensitive neurons in this area although is still unkown if this steroid can modulate All and/or GABA effects on LH secretion. The aim of this study was investigate the interaction of All, GABA and estrogen (E_2) on LH secretion. Adult ovariectomized rats with cannula into the MPOA received subcutaneous injection of estradiol benzoate (EB) or vehicle (V) during 3 days. Jugular vein was cannulated one day before the experiment. Blood sample was collected 10 minutes before microinjection of saline, GABA agonists (muscimol, 5 nmol or baclofen, 10 nmol) or GABA antagonists (bicuculline, 60 pmol or phaclofen 120 pmol) in the MPOA. Ten minutes after this first microinjection, saline or All (100 pmol) were microinjected in the same area and blood samples for LH radioimmunoassay were collected immediately before and 10,20,30 and 60 minutes after. GABA agonists and antagonists decrease by themselves the plasma LH in the control group (V) but they had no effect in the EB group. The increase of plasma LH induced by All in the EB group was blocked by GABA agonist and GABA antagonist (bicuculline) but not by the GABA antagonist (phaclofen). Thus, the inhibition of LH secretion by MPOA-GABA system as well as the interaction of AII-GABA system only occur when E2 is in the milieu.

DENDRITIC REMODELING OF ARCUATE NEUROENDOCRINE NEURONS FOLLOWING ORCHIDECTOMY. S.C. Danzer*, N.T. McMullen and N.E. Rance. Depts. of Cell Biology and Anatomy, and Pathology, U. of Arizona, College of Medicine, Tucson, AZ 85724.

A combination of retrograde labeling with systemically injected Fluorogold and intracellular injection of neurons in a fixed slice preparation was used to examine the morphology of neuroendocrine neurons in the rat arcuate nucleus. The same preparation was used to study the effects of orchidectomy on arcuate neuronal morphology. Intracellulary-filled neuroendocrine neurons (8-21 neurons per brain) from intact (N=5) and orchidectomized (N=5) animals were reconstructed in three dimensions using computer assisted microscopy. The morphology of arcuate neuroendocrine neurons in intact animals was relatively simple, with the majority of neurons (79%) having only two primary dendrites and a moderate number of dendritic spines. In comparison to intact controls, arcuate neuroendocrine neurons in the orchidectomized group had significantly larger somatic profile areas and exhibited significant increases in dendrite length, dendrite volume, terminal branch number, and spines per unit length of dendrite. The majority of the increase in terminal branch number in orchidectomized animals was due to the appearance of short (less than 50 µm) branches, giving a striking, claw-like appearance to many of the dendrites. These results provide the first evidence for hormonal regulation of dendritic morphology of arcuate neuroendocrine neurons in adult mammals. (Supported by NIH Grant AG09214 and the Flinn Foundation of Arizona)

SEXUAL DIFFERENCES AND THE EFFECTS OF GONADECTOMY ON EXPRESSION OF FOS PROTEIN IN TYROSINE HYDROXYLASE IMMUNOREACTIVE (TH-IR) NEURONS LOCATED IN SUBDIVISIONS OF THE RAT HYPOTHALAMIC ARCUATE NUCLEUS. <u>S. Cheung*</u>, <u>K.E. Moore and K.J.Lookingland</u>. Dept. of Pharm & Toxicol., Michigan State University, East Lansing, MI 48824

Sexual differences in the activity of tuberoinfundibular dopamine (TIDA) neurons are due to circulating gonadal steroids; i.e. estrogen stimulates, whereas testosterone inhibits neurochemical estimates of the activity of TIDA neurons terminating in the median eminence. Expression of the immediate early gene product FOS also reflects TIDA neuronal activity and permits the determination of the responsiveness of subpopulations of these neurons located in subdivisions of the arcuate nucleus (ARC). In the present study sexual differences and effects of gonadectomy were examined on FOS protein expression in TH-IR neurons in the dorsomedial (DM) and ventrolateral (VL) ARC using dual immunohistochemistry. Frontal sections through the middle ARC were chosen macroscopically, and the number of TH-IR cells and TH-IR + FOS-IR double labeled cells were counted bilaterally. There were no gender differences in the number of TH-IR cells in either the DM- or VL-ARC, but in the DM-ARC there were more double-labeled cells in females vs. males. Ovariectomy decreased the number of TH-IR cells containing FOS-IR in the DM-ARC, but not in the VL-ARC. Orchidectomy increased the number of TH-IR cells containing FOS-IR in both the DM-ARC and VL-ARC. These results reveal that sexual differences in FOS protein expression in subpopulations of TIDA neurons in the DM- and VL-ARC are due to circulating gonadal hormones. (Supported by NIH Grant MH42802)

CHANGES IN GLUTAMATE RECEPTOR SUBTYPE mRNA EXPRESSION IN GONADOTROPIN-RELEASING HORMONE (GnRH) NEURONS DURING THE SEXUAL MATURATION OF THE FEMALE RAT. <u>Ozhan Evigor* and Lothar Jennes</u>. Dept. Anatomy & Neurobiology, Univ. Kentucky, Coll. Medicine, Lexington, KY 40536.

Excitatory amino acids, particularly glutamate, have been associated with the development of puberty in the rat. We have previously shown that, in the adult female rat, GnRH neurons express preferentially the KA2 receptor subtype. The aim of the present study was to determine if the onset or rate of KA2 receptor expression in GnRH neurons can be correlated with the onset of puberty. Dual *in situ* hybridization using digoxigenin labeled GnRH cRNA probes and ³⁵S labeled KA₂ receptor probes, followed by the autoradiography and image analysis was used to measure KA2 receptor mRNA content in 15-50 days old female rats which were sacrificed at 0800 or 1700 hours. The results show that: a) GnRH neurons of 40 days old animals have the highest KA2 mRNA content, b) in 20-40 days old animals more KA2 mRNA is present in GnRH neurons at 0800 when compared to 1700 hrs, while in 45 and 50 days old animals more KA2 mRNA is present in GnRH neurons during the afternoon. Since the timing of highest KA2 receptor mRNA content in GnRH neurons as well as the reversal of diurnal rhythmicity in KA2 receptor mRNA content coincide with vaginal opening, it is suggested that glutamate, acting through KA2 receptors on GnRH neurons is an important factor in the development of puberty. Supported by NIH HD 24697.

HORMONE REPLACEMENT SUPPRESSES NEUROKININ B (NKB) GENE EXPRESSION IN THE ARCUATE NUCLEUS OF OVARIECTOMIZED MONKEYS. T.W. Abel, M.L. Voytko and N.E. Rance* Department of Pathology, University of Arizona College of Medicine, Tucson, AZ 85724 and Department of Comparative Medicine, Bowman Gray School of Medicine, Winston-Salem, NC, 27157.

Human menopause is associated with increased tachykinin gene expression in the arcuate nucleus (Rance and Young, Endocrinology 128:2239, 1991). We have hypothesized that these changes are secondary to ovarian failure and not due to age per se. To test this hypothesis, we determined the effects of hormone replacement upon NKB neurons in the arcuate nucleus of young ovariectomized cynomolgus monkeys. Arcuate proopiomelanocortin (POMC) gene expression was also assessed. Twenty-two months after ovariectomy, monkeys were treated with either roughly thought of the stronger (E2, n = 8), estrogen plus progesterone (E2P, n = 8) or left untreated (n = 8). The animals were sacrificed 30 months later. Every 20^{th} section was hybridized to synthetic radiolabeled 48-base cDNA probes complementary to either NKB or POMC mRNA. Two sections were chosen from each animal for cell counts. In the untreated group, there were 18.3 ± 5.0 (mean ± SEM) neurons expressing NKB mRNA per arcuate section. Hormone replacement of either E₂ or E₂ P resulted in undetectable levels of NKB gene transcripts. In contrast, the number of POMC neurons was unchanged among treatment groups (untreated: 101.2 \pm 7.8; E $_2$: 103.8 \pm 21.3; E $_2$ P: 95.6 \pm 18.1 neurons/arcuate These results indicate that steroid hormones modulate levels of NKB mRNA in the primate hypothalamus and support the hypothesis that the increased tachykinin gene expression in postmenopausal women is due to steroid withdrawal. ESTROUS EWE INTRODUCTION INCREASES FOS EXPRESSION IN A SUBSET OF GONADOTROPIN-RELEASING HORMONE-CONTAINING NEURONS IN THE MEDIAL BASAL HYPOTHALAMUS OF THE MALE SHEEP. R. Boukhliq, R.L. Goodman*, and B.A. Adrian. Physiology Department, West Virginia University Morgantown WV 26506-9229

Previous work, using the early immediate gene product, Fos, demonstrated that a subset of gonadotropin-releasing hormone (GnRH) neurons in the ovine medial basal hypothalamus (MBH) play a role in the increase in pulsatile LH secretion that occurs in response to an opioid antagonist. In this study, we examined the physiological significance of this pharmacological model, by testing the hypothesis that a physiological stimulus that increases pulsatile LH secretion will also induce Fos in MBH GnRH neurons. The specific physiological stimulus used was exposure of intact rams to estrous ewes, which is known to induce pulsatile LH release in the males Seven rams were preconditioned by isolation from ewes for several weeks during the non-breeding season. Five of the rams were exposed to estrous ewes and 2 controls were exposed to another intact male. Rams were bled every 12 min for 4 hr before and 2 hr after introduction of the ewes (or ram) and then killed with an overdose of pentobarbital. After fixation, brains were removed, sectioned, and dual immunostained for GnRH (LR-1 antibody) and Fos (c-Fos K-25 antibody from Santa Cruz, Inc). Exposure of rams to estrous ewes induced a rapid increase in pulsatile LH secretion that lasted at least 2 hr and Fos was found in GnRH neurons in the MBH of all 5 rams. Although the percentage of Fos-containing GnRH neurons was low (5.9 ± 1.5 %), more than 80% of these double-labeled cells were found in the rostral MBH, just posterior to the optic chiasm. No GnRH neurons in this area contained Fos in 2 control rams and almost no GnRH neurons in more rostral areas contained Fos in any of the sections examined from all rams (3 out 2,605 GnRH neurons). These data suggest that a subset of GnRH neurons in the rostral MBH are involved in stimulation of episodic LH secretion following exposure of rams to estrous ewes.(NIH HD17864)

SEXUAL DIFFERENTIATION OF SYNAPTIC INPUT TO GNRH NEURONS IN SHEEP: ROLE OF PRENATAL TESTOSTERONE. S-J. Kim¹, D.L. Foster² R.I. Wood¹. ¹Dept of Ob/Gyn, Yale University, New Haven, CT 06520;

²Depts of Ob/Gyn and Biology, Univ. Michigan, Ann Arbor, MI 48109. In sheep, the control of tonic and surge GnRH secretion is sexually differentiated by testosterone during prenatal development. However, despite marked sex differences in the control of GnRH release, there are despite marked sex differences in the control of GnRH release, there are no differences between male and female lambs in the number, distribution or gross morphology of GnRH neurons. Therefore, this study tested the hypothesis that prenatal steroids influence the synaptic input to GnRH neurons. The approach was to compare the number of synapses on GnRH neurons from male, female and androgenized female lambs (n=5 each). neurons from male, female and androgenized female lambs (n=5 each). Androgenized female lambs were exposed to testosterone prenatally from 30-90 days of gestation (145 days is term). Gonadectomized, postpubertal lambs were perfused at one year of age with 4% paraformaldehyde containing 0.2% glutaraldehyde. GnRH neurons were visualized using the LR-1 antibody (gift of R. Benoit). Individual neurons were punched from the rostral preoptic area at the level of the organum vasculosum of the lamina terminalis for observation at the EM level. Five GnRH neurons were selected from each animal. The number of afferent synapses on each neuron was counted in a single section passing through the plane of the nucleus. GnRH neurons from female lambs received approximately twice as many contacts (2.75±0.3 synapses per neuron) as those of male lambs (1.56±0.2), similar to a previous study performed in rats (*Endocrinology*), 126: 695-702, 1990). In addition, the number of synapses on GnRH neurons from androgenized female lambs resembled that of male lambs, suggesting that prenatal steroids give rise to sex differences in synaptic input to GnRH neurons. MODULATION OF NEUROPEPTIDE Y Y1 RECEPTOR (NPY1R) GENE EXPRESSION IN THE MALE RAT ANTERIOR PITUITARY BY GONADAL STEROIDS. J.H. Urban*, D.M. Gelinas, J.E. Levine. Neurobiology & Physiology, Northwestern University, Evanston, IL 60208.

We have shown that NPY increases luteinizing hormone releasing hormone (LHRH) release from hypothalamic explants in a steroid-dependent man Other reports have shown that the actions of NPY on the stimulation of LH Other reports have shown that the actions of NFY on the stimulation of Lersecretion from the pituitary is dependent upon steroid levels as well.

Ineffectiveness of NPY on LHRH or LH release in tissue from castrated rats
is likely due to changes in NPY receptor levels or signalling systems. The
present studies were designed to examine whether the expression of the NPY1r gene in the pituitary of male rats is regulated by gonadal factors, namely testosterone (T). Reverse transcriptase-polymerase chain reaction (RT-PCR) was used to quantify NPY1r gene expression in RNA extracted from the anterior pituitaries of males that were either castrated (14 d), sham-operated or sham-operated and received physiological levels of T. NPY1r gene expression was quantified as a ratio of NPY1r/tubulin for 4 different dilutions of the RNA, and then expressed as fold change from the sham-operated controls. After castration, there was a significant decrease in the levels of NPYIr gene expression in the anterior pituitary (intacts: 1.00 relative units; castrates: 0.339 ± 0.170 relative units, p < 0.05). This decrease was prevented by treatment with physiological levels of T (0.845 \pm 0.090 relative units). These studies demonstrate that in the male rat, the expression of the NPY1r gene is regulated by T. Work is continuing to map the distribution of NPY1r in the pituitary, and to further understand how the transcriptional regulation of this receptor contributes to alterations in physiological responsiveness. TIME COURSE OF THE EFFECT OF OLFACTORY **BULBECTOMY TO INCREASE SERUM FSH LEVELS IN** MALE GOLDEN HAMSTERS David R. Pieper* and Catherine Lobocki Providence Hospital, Department of Physiology, Southfield, MI, 48037

Bilateral removal of the olfactory bulbs (BX) increases tonic reproductive hormone secretion in male golden hamsters and prevents the testicular regression associated with short photoperiod. The objective of the present study was to study the time course of the facilitatory effect of BX on FSH secretion of hamsters on long photoperiod.

In Experiment I, 12 BX and 12 sham operated (SH) adult male golden hamsters maintained on long (LD 14:10) photoperiod were implanted with atrial catheters and bled at 4, 8, 24, 48hr and at 1 and 2 weeks after surgery. In Experiment II, 12 BX and 12 SH adult male hamsters were bled weekly from the orbital sinus for 11 weeks.

In Experiment I, serum FSH was similar in BX and SH groups at all time points examined. In Experiment II, SH and BX harnsters also had similar FSH levels for the first 3 weeks following surgery, but thereafter serum FSH was

much higher in BX than SH animals at all time points (p < 0.001). In summary, the increase in serum FSH secretion following removal of the olfactory bulbs takes over 3 weeks to become evident. There are various interpretations to these results. The delayed effect of BX may be related to neuronal degeneration of axons to or from the bulbs, the delay may be related to the trauma of the surgery, or the tonic modulatory influence of the olfactory bulbs on reproductive hormone secretion may simply take some time to become evident following removal of the bulbs.

PHOTOPERIOD ALTERS THE NUMBER OF ESTROGEN RECEPTOR (ER), NEUROPEPTIDE Y (NPY) AND & ENDORPHIN (&E)-IMMUNOREACTIVE NEURONS IN THE EWE HYPOTHALAMUS. D.C. Skinner, R.G. Dyer*, and A.E. Herbison, Dept. Neurobiology, Babraham Institute, Cambridge, UK

The reproductive activity of ewes fluctuates markedly with season in response to photoperiodic cues. The neural mechanisms driving the reproductive axis during the reeding season and in anestrus are not well established but appear to involve changes in both gonadal steroid-dependent and -independent components. As gonadorrophin-releasing hormone (GnRH) neurons do not to express nuclear ERs, estrogen (E) may act indirectly to influence their activity. The present study has used immunocytochemistry to examine whether differences exist between breeding and anestrous ewes in the number of cells containing ERs and/or the neurons synthesizing neurotransmitters implicated in the regulation of GnRH neurons. The breeding season was induced by short day (SD; 8L:16D) and anestrus by long day (LD; 16L:8D) artificial photoperiods. Reproductive status was confirmed by progesterone analysis of bi-weekly blood samples and ewes were killed and perfused in SD/LD pairs (n=6). SD ewes were taken in the mid-luteal phase. Perfusion fixed brains were sectioned and immunostained for ER, tyrosine hydroxylase (TH), NPY brains were sectioned and immunostanted for ER, tyrosine hydroxylase (1H), NPT and BE. The cellular density of ER-expressing cells was decreased by approx. 20% (P<0.05) in the preoptic area of LD ewes compared with SD animals but did not change in the ventromedial and arcuate nuclei (ARN). No differences were detected in the number of TH neurons within the A₁₂, A₁₃ or A₁₅ cell groups or in the percentage of TH cells containing ERs (A₁₂:13-17%: A₁₃:15-20%: A₁₅:0%). The number of BE neurons within the ARN was reduced by 35% (P<0.05) in SD compared with LD animals while a 3-fold increase (P<0.05) in the number of NPY immunoreactive neurons was evident within the median eminence (ME), but not ARN, of LD ewes. Around 3 and 7% of NPY cells express ERs in the ME and ARN respectively, and this did not change with season. These results demonstrate that the number of ER-expressing cells within the preoptic area is increased during anestrus while reduced BE, and elevated NPY, -immunoreactive cell numbers within the ARN and ME are associated with reproductive activity in the breeding season.

LUTEINIZING HORMONE-RELEASING HORMONE-HUMAN NEURONS RECEIVE NEUROPEPTIDE-Y SYNTHESIZING IMMUNOREACTIVE INNERVATION. B. Dudás 1, E. Dobó 1, I. Merchenthaler 2 and Zs. Liposits 1* 1 Dept. of Anatomy, Albert Szent-Györgyi Medical University, Szeged, Hungary, and 2 Women's Health Research Institute, Wyeth-Ayerst Research, Philadelphia, USA.

The luteinizing hormone response to luteinizing hormone-releasing hormone (LHRH) is potentiated by neuropeptide-Y. In the present study, we provided morphological evidence for this putative communication in the human prosencephalon by means of double labeling immunocytochemistry utilizing diaminobenzidine (DAB) and silver-intensified DAB chromogens

This study first evaluated the distribution of the LHRH and NPYimmunoreactive (IR) neuronal elements and then analized interrelationship of the two peptidergic systems in overlapping areas. The LHRH-IR perikarya were located mainly in the preoptico-septal, diagonal band of Broca, lamina terminalis, medial preoptic and infundibular areas of the brain. NPY-containing perikarya and fibers were widely distributed in the prosencephalon with high densities in the preoptico-septal, periventricular and infundibular regions. The overlap between the NPY and LHRH systems was apparent in the medial preoptic and infundibular regions. In this loci, brown DAB-labeled LHRH-IR cells received NPY-IR axon terminals marked by black silver deposits. The putative innervation of LHRH neurons by NPY-IR fibers was also confirmed in 1 μ m thick plastic sections by demonstrating juxtapositions.

The present findings suggest synaptic regulation of hypophysiotropic LHRH-synthesizing neurons by the NPY system in the human prosencephalon

EFFECTS OF CASTRATION AND TESTOSTERONE REPLACEMENT ON THE COLOCALIZATION OF ESTROGEN RECEPTORS AND AROMATASE IN THE QUAIL BRAIN. A. Foidart* M. Houbart. N. Harada and J. Balthazart, Lab. Biochemistry, Univ. Liège, Belgium & Molecular Genetics, Toyoake, Japan In Japanese quail, castration decreases (50-80%) and testosterone (T) treatment restores aromatase activity (AA) in the preoptic area. These effects are paralleled by variations in the number and size of the aromatase-immunoreactive (ARO-ir) cells in the medial preoptic nucleus (POM) but the medial are all alteral portions of the nucleus differentially react to the treatments. T-induced changes in AA and ARO-ir cells are ultimately caused, at the cellular level, by estrogens produced by aromatization (positive feedback of the product on its enzyme). This is namely demonstrated by the fact that T no longer affects aromatase in the presence of aromatase inhibitors but, surprisingly, immunoreactive estrogen receptors (ER) are present in only a small fraction (<20%) of ARO-ir cells in the POM. We therefore wondered whether the few ARO-ir cells that are still observed in castrates are those that also contain ER (ARO-HER.ir). Effects of castration (CX) associated or not with T replacement (CX+T) on the number of ARO-ir cells colocalizing with ER were studied in the POM and in the ventromedial nucleus (VMN) of the hypothalamus selected as a control region where the colocalization is more frequent. Because anatomical heterogeneity had been detected in the reaction to endocrine changes of the POM ARO-ir cells, the distribution in space of the ARO+ER-ir cells was also analyzed. This study first confirmed the low degree of colocalization of ARO and ER in the POM ARO-ir cells, the distribution in space of the ARO+ER-ir cells was also analyzed. This study first confirmed the low degree of colocalization of ARO and ER in the POM to the ARO-ir cells) compared to the VMN (30-70%). Castration markedly decreased the number of ARO-ir cells in both nuclei. A proportional decre

INTRACRANIAL IMPLANTS OF THE ANTI-ESTROGEN ICI 182,780 ON VASOPRESSIN EXPRESSION IN THE BED NUCLEUS OF THE STRIA TERMINALIS. W.C.J. Chung, C.J. Auger, G.J. De Vries*. Neuroscience and Behavior program, University of Massachusetts, Amherst. MA 01003-7710.

Vasopressin-immunoreactive (AVP-ir) neurons in the bed nucleus of stria terminalis (BST) and medial amygdaloid nucleus are very responsive to gonadal hormones. After gonadectomy, these neurons lose their AVP immunoreactivity. Testosterone treatment reverses these changes. Estrogen receptor-mediated mechanisms appear to be crucial for this effect, because AVP expression in castrated rats can be stimulated by peripheral administration of estradiol but not by dihydrotestosterone alone. Here we test the idea that estrogen acts directly on estrogen receptors within the BST by implanting the antiestrogen, ICI 182,780 (ICI), into the brain. Intact males were implanted bilaterally with 30-gauge cannulae aimed at the BST. The cannula on one side of the brain was filled with ICI, the other was filled with cholesterol or kept empty. Four weeks after implantation, the animals were perfused and their brains were processed for AVP immunocytochemistry. The number of AVP-immunoreactive cells in the BST was significantly lower on the ICI side than at the cholesterol or blank side (p<0.005). There were no differences in the number of cells between animals with blanks or cholesterol implants, ICI implants eliminated virtually all AVP-immunoreactivity of cells that were within a radius of about 300 µm of the cannula tip, but had a much smaller impact on cells outside that radius. Intracerebral implants of ICI may therefore be useful to study local effects of testosterone on brain mechanisms.

ANDROGEN AND OESTROGEN REGULATION OF CALCITONIN GENE-RELATED PEPTIDE mRNA IN MEDIAL PREOPTIC AREA OF THE MALE RAT. D.P. Spratt and A.E. Herbison. (SPON: Brain Research Association) Laboratory of Neuroendocrinology, The Babraham Institute, Cambridge, CR2 4AT LIK

Previous immunocytochemical studies in this laboratory have identified a substantial female-predominant sex difference in the number of cells expressing calcitonin gene-related peptide (CGRP) in the rat preoptic area (POA). We have found that 27±6% of CGRP neurones in the male POA possess oestrogen receptors (ERs), and that the observed sexual dimorphism results from an inhibitory action of testosterone (T) exerted both perinatally and in adulthood in the male. The current study was undertaken to determine the mechanisms through which testosterone exerts its suppressive influence on CGRP expression. Experiment 1: Double-labelling immunocytochemistry was carried out on adult male rats (n=6) using antibodies directed against α-CGRP and the androgen receptor (AR: PG-21). We observed that 9±4% of CGRP neurones in the male medial preoptic nucleus (MPN), also possessed ARs. Experiment 2: In situ hybridization was used to examine the effects in the adult male rat of gonadectomy and oestrogen (E). To or dihydrotestosterone (DHT) replacement on CGRP mRNA expression in the MPN. The number of cells expressing CGRP mRNA in the male MPN doubled following castration (p<0.03), and was returned almost exactly to intact levels by E. Tor DHT replacement. Likewise, CGRP mRNA expression per cell increased by approximately 30% after gonadectomy (p<0.03), with intact levels being similarly restored by any one of the three hormone treatments. Distribution analysis revealed that the CGRP population responded to the steriod treatments in an homogeneous manner. These findings suggest that the suppressive action of testosterone on preoptic CGRP neurones in the male results at least in part through alterations in CGRP mRNA content and that testosterone could achieve this through either AR- or ER-mediated pathways. The low occurrence of nuclear AR and ER expression by preoptic CGRP neurones by The Lister Institute and The Medical Research Council (UK)

COLOCALIZATION OF NEUROPEPTIDE Y (NPY) Y₁ RECEPTOR mRNA IN ANTERIOR PITUITARY GONADOTROPES. J.M. Lloyd* Dept. of Anatomical Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Neuropeptide Y (NPY) has been implicated in the generation of preovulatory luteinizing hormone (LH) surges through actions at both the hypothalamus and anterior pituitary gland. NPY facilitates gonadotropinreleasing hormone (GnRH)-induced LH release directly at the anterior pituitary by activation of the NPY Y₁ receptor. Recently, it was demonstrated that anterior pituitary NPY Y₁ receptor expression is regulated during the estrous cycle. The present study was designed to assess whether anterior pituitary gonadotropes express the NPY Y1 receptor mRNA using a combined in situ hybridization/ immunocytochemical technique. Regularly cycling female rats were sacrificed at 1000 h on proestrus. pituitary cells were dispersed enzymatically, plated on glass coverslips and processed for dual labelling of a biotinylated NPY-Y1 receptor oligonucleotide probe and immunocytochemical localization of LHB antigen. Expression of the biotinylated NPY-Y1 receptor probe was observed in $80\%\,$ of LH\$-labelled cells which constituted 13% of the total pituitary cell population. These results demonstrate that anterior pituitary gonadotropes do express NPY receptor mRNA. Further studies are in progress to assess whether the number of gonadotropes expressing the NPY-Y1 receptor changes during the estrous cycle. Supported by the Oklahoma Center for the Advancement of Science and Technology, HN3-017.

CHARACTERIZATION OF BRAINSTEM ESTROGEN-RECEPTIVE NEURONS PROJECTING TO THE VICINITY OF THE GONADOTROPHIN-RELEASING HORMONE (GnRH) CELL BODIES IN THE RAT. A.E. Herbison* and S.X. Simonian, Laboratory of Neuroendocrinology, The Babraham Institute, Cambridge CB2 4AT, UK.

Brainstem noradrenergic (NA) neurons exert an important estrogen-dependent permissive influence on the electrical and synthetic activity of GnRH neurons. The present study has used double- and triple-labelling immunocytichemistry combined with retrograde labelling techniques to examine the relationship of estrogen receptor (ER). NA and neuropeptide Y (NPY) expression amongst brainstem cells and determine which of these neurons project to the rostral preoptic area. Exp.1 Brainstem sections from ovariectomized rats (n=6) immunostained for the ER (monoclonal ID5) and dopamine-b-hydrovylase (DBH) revealed that ER-expressing NA neurons were located exclusively in the caudal-most aspects of medulla where 30% of A1 and 60% of A2 neurons were immunoreactive for the ER. Exp.2 Sections from colchicine-treated, ovariectomized rats (n=5) immunostained for NPY tyrosine hydroxylase (TH) and the ER showed a rostrocaudal pattern of NPY expression by NA cells opposite to that of the ER with 100% and 50% TH and NPY co-expression in the rostral A1/C1 and A2/C2, respectively, and less than 10% in the caudal A1 and A2. Of all cells examined, only 2 were triple labelled for TH+NPY+ER. Double-labelling for ER and NPY showed the same almost complete absence of ER expression by brainstem NPY neurons. Exp.3 Fluorescein-labelled latex microspheres (20nl) were injected into the rostral preoptic area of intact female rats (n=3) and brainstem sections immunoreacted one week later for DBH and ER. Five to 7% of NA neurons within the A1 and A2 cell groups were retrogradely labelled and approximately, one third of these A2 neurons were found to express ERs. No triple labelled cells were found in the A1. Summary These findings provide evidence for the differential expression of ER and NPY by brainstem NA neurons and indicate that the NA cells of the A2, and not the A1, are likely to play a role in transmitting estrogen-dependent information to the GnRH cell bodies.

COEXISTENCE OF NEUROTENSIN/NEUROMEDIN N mRNA AND PROGESTIN RECEPTOR mRNA IN HYPOTHALAMIC NEURONS OF THE FEMALE RAT. M.J. Alexander*, E. Bartolák-Suki, and S.E. Leeman-Department of Pharmacology & Experimental Therapeutics, Boston University School of Medicine, Boston, MA 02118.

In the female rat, estrogen stimulates synthesis of neurotensin (NT) in several hypothalamic cell groups important in reproductive neuroendocrine regulation, including neurosecretory cells in the arcuate nucleus as well as neurons in the anteroventral periventricular nucleus (AVPv) and medial preoptic nucleus (MPN). Since these regions also display estrogen stimulated synthesis of progestin receptor (PR), we sought to determine whether NT neurons are capable of synthesizing PR and therefore subject to direct regulation by progesterone. Sections were prepared from brains of estradiol-treated ovariectomized rats, and cRNA probes labeled with digoxigenin or 35 S were used for simultaneous detection of neurotensin/neuromedin N (NT/N) mRNA and PR mRNA in individual cells by doublelabel in situ hybridization histochemistry. The 548-base probe used to detect PR mRNA corresponds to the steroid-binding domain of the receptor and therefore detects both A and B isoforms. Double-labeled cells were numerous in the dorsomedial division of the rostral arcuate nucleus, where as many as 90% of NT/N mRNA-labeled cells also displayed labeling for PR mRNA. Double-labeled cells were also observed in the AVPv and medial division of the MPN. These results imply that multiple populations of hypothalamic neurons, including neurosecretory cells, synthesize both NT and PR in response to stimulation by estrogen and further suggest that NT-synthesizing neurons mediate effects of progesterone on reproductive neuroendocrine systems. Supported by NIH Grants NS 32391 and DK 29876.

THE EFFECTS OF AGING AND STEROIDS ON THE EXPRESSION OF SYNAPSE MARKERS IN THE RAT HIPPOCAMPUS

Helen M. Chao*1, Robert L. Spencer², Randall R. Sakai³ and Bruce S. McEwen¹.

Rockefeller University, Laboratory of Neuroendocrinology, 1230 York Avenue, New York, NY 10021. ²Univ. of Colorado, Dept. of Psychology, Boulder, CO 80303, ³Univ. of Pennsylvania, Dept. of Animal Biology, Philadelphia, PA 19104

New York, NY 10021. Univ. of Colorado, Dept. of Psychology, Boulder, CO 80303, Univ. of Pennsylvania, Dept. of Animal Biology, Philadelphia, PA 19104
The neurons of the hippocampus are vulnerable to the damaging effects of aging and neurodegenerative disease. Adrenal steroids have been shown to influence the morphology and survival of neurons in the hippocampus, and have been implicated in the neuronal loss associated with aging. As a way of investigating the consequences of these changes on synapses in the hippocampus, we have employed molecular probes for the synaptic markers synaptophysin, synaptoporin and synapsin II, to determine whether their expression is altered by age or adrenal steroid manipulation. We have found that there is an age-related decrease in the level of synaptophysin mRNA in the hippocampus, which appears to be independent of adrenal steroid regulation.

While in the mammalian brain the actions of ovarian steroids have primarily focused on the hypothalamus, these steroids have also been shown to affect the neurons of the hippocampus. Low levels of estrogen, as a result of ovariectomy or during the estrous cycle, have been shown to result in a decrease in the dendritic spine density of hippocampal pyramidal cells and the changes in spine density are correlated with changes in synaptic density. We have monitored synapse marker expression following estrogen treatment and our results indicate that in the hippocampus, the level of synaptophysin mRNA appears to be responsive to

LOCAL GLUTAMATERGIC NEURONS IN THE HYPOTHALAMIC ARCUATE NUCLEUS. A.B. Belousov* and A.N. van den Pol. Dept. Biological Sci., Stanford Univ., Stanford, CA 94305 and Sect. Neurosurgery, Yale Univ. Med. Sch., New Haven, CT 06520.

The hypothalamic arcuate nucleus (ARC) contains neuroendocrine

The hypothalamic arcuate nucleus (ARC) contains neuroendocrine neurons that regulate hormone secretion from the anterior pituitary. Many neuroactive substances have been identified in the ARC, but whether or not excitatory neurons exist in this nucleus, and the identity of an excitatory transmitter, have not been investigated physiologically. In the present experiments using whole cell current- and voltage- clamp recording of neurons from cultures and slices of the ARC, we demonstrate that many of the neurons in the ARC secrete glutamate as their transmitter. By stimulating presynaptic neurons in ARC slices electrically or with microdrops of glutamate (n=12) we found that excitatory axons from these neurons make local synaptic contact with other neurons in the ARC, and all evoked excitatory postsynaptic potentials (EPSP) could be blocked by the selective ionotropic glutamate receptor antagonists CNQX (10 µM) and AP5 (100 µM). In ARC cultures (n=63), spontaneous EPSPs were virtually eliminated by glutamate receptor antagonists AP5 and CNQX, underlining the functional importance of glutamate within this part of the neuroendocrine brain. GABA was secreted by another group of ARC neurons. The GABAA receptor antagonist bicuculline (50 µM) released glutamatergic neurons from chronic inhibition mediated by synaptically released GABA, resulting in further depolarization and an increase in the amplitude and frequency of glutamate-mediated excitatory postsynaptic potentials.

MECHANISM OF PROGESTERONE-EVOKED RELEASE OF GONADOTROPIN RELEASING HORMONE (GnRH) FROM GT1-1 NEURONS M. EL-Etr*, K. Shazand, Y. Akwa, P. Robel and E.E. Baulieu. INSERM U.33, 94276 Bicêtre, France. Progesterone (PROG; 0.5-10 μM) stimulates the release of GnRH from hypothalamic GT1-1 cells (Soc.Neurosci., 1995, 21, 547.10). Although PROG receptor mRNA is present in these neurons, GnRH release occurs too rapidly for a genomic mechanism and is also evoked by PROG-3-O-carboxymethyloxime.BSA (PROG-BSA), which does not enter the cells, thus suggesting a membrane site of action. Additionally, the PROG antagonist RU 486, not only inhibits PROG-but also PROG-BSA-induced GnRH release. In spite of a membrane-like effect of PROG, binding experiments performed with ³H-PROG or the synthetic progestin ³H-ORG-2058 (20-50 nM) on GT1-1 cell membranes were unsuccessful. This indicates that the putative membrane PROG receptor might be distinct from the intracellular one. Contrary to its metabolite TH-PROG (3α-OH-5α-pregnan-20-one), PROG does not potentiate the release of GnRH evoked by muscimol, and the GABA, receptor antagonists bicuculline and picrotoxin do not counteract PROG effect. The release of GnRH induced by the 5HT_{1A} receptor agonist 8-OH-DPAT is enhanced by PROG, however the selective antagonist WAY 100635 (0.1-5 μM) does not abolish the effect of PROG alone. Finally, the release of GnRH induced by PROG is blocked by selective antagonists of calcium channels, particularly of L-type. The coupling of these PROG-sensitive calcium channels to G-proteins is under investigation.

625.5

EXTRAHYPOTHALAMIC CORTICOTROPIN RELEASING FACTOR (CRF) NEURONS CONTAIN ANDROGEN RECEPTOR (AR). <u>G. Wishbach, E.M. Wilson and M.Sar*</u>. Departments of Pediatrics (M. S., E.M.W.) and Biochemistry and Biophysics (E.M.W.), School of Medicine, University of North Carolina, Chapel Hill, NC 27599

The influence of gonadal steroids on the regulation of hypothalamic CRF secretion was studied. Although the effects of estrogen on the regulation of CRF in the hypothalamus have been reported, the effects of androgen on hypothalamic CRF remain controversial. Since androgen action is mediated through receptor mechanisms, we investigated whether CRF neurons in brain contain the AR. Colocalization of CRF and AR in rat brain was performed by dual immunocytochemistry using antipeptide antibody CRF and AR32. Adult male Sprague-Dawley rats (n=8) were each treated with testosterone propionate and received colchicine intraventricularly. Twenty four hours later, the rats were perfused with Zamboni's fixative (pH 7.2) and processed for immunostaining. Sections were stained first with AR32 antibody using diaminobenzidine followed by immunostaining with CRF antibody using 4-chloro-1-naphthol. Nuclear localization of AR and cytoplasmic localization of CRF in neurons were observed in several areas of the brain. CRF neurons that contain AR include the cortex, amygdala and bed nucleus of the stria terminalis but not the paraventricular nucleus. AR was localized in 30 - 35 % of CRF cells in the bed nucleus, particularly the lateral part and 25 -30% of CRF cells in the central nucleus of the amygdala. In the cortex, AR was localized in CRF cells of layers 4 and 5. The results demonstrate that a certain population of CRF neurons in extrahypothalamic but not hypothalamic areas contain AR and raise the possibility of androgen regulated events in extrahypothalamic CRF neurons. (Supported by NIH Grant NS - 17479).

625.2

INHIBITION OF HYPOTHALAMIC CHICKEN GONADOTROPIN RELEASING HORMONE (cGnRH-I) BY OPIOID PEPTIDES IN VITRO. Y. Fan* and M.A. Ottinger. Dept. of Poultry Science, Univ. of Maryland, College Park, MD 20742.

In a series of in vitro experiments, we studied the effects of the opioid peptides, met-enkephalin (ENK), endorphin (END) and dynorphin (DYN) on the release of hypothalamic cGnRH-I. Longitudinal hypothalamic slices spanning the preoptic-lateral septal region to the median eminence (POA-MBH) were taken from adult, reproductive male Japanese quail (Coturnix coturnix japonica). Slices from a single brain were placed into a 2.5 ml chamber in a perifusion system (Endotronics, Inc.) and perifused (Medium 199, Sigma) at a rate of 12ml/hr. Samples were collected at 5 min intervals and analyzed for cGnRH-I by EIA. All experiments had the same overall design. Tissue was equilibrated and baseline release was monitored for 2 hrs followed by a 15 min norepinephrine (NE; 10⁻⁸M) challenge and 1 hr recovery period. One of the opioid peptides (10-7M) was then added to the medium for the remainder of the experiment. A second NE challenge was conducted; n=6 for each opioid peptide. Results showed that ENK, END, or DYN exposure all significantly (p<0.05) reduced both baseline cGnRH-I release as well as inhibited NE stimulated cGnRH-I release. Decreased cGnRH-I release was reflected in reduced pulse amplitude with no change in pulse frequency. These results confirm opioid peptide inhibition of the cGnRH-I system in an avian model and suggest direct effects on the cGnRH-I neuron as well as inhibition of NE neuronal input Supported in part by USDA/NRI 92-37023-7742 (MAO)

OLDER MALES SECRETE LUTEINIZING HORMONE (LH) AND TESTOSTERONE MORE IRREGULARLY, AND JOINTLY MORE ASYNCHRONOUSLY, THAN YOUNGER MALES S.M. Pineus, T. Mulligan, A. Iranmanesh*, S. Gheorghiu, M. Godschalk, J.D. Veldhuis, VAMC Salem, VA 24153, Guilford, CT 06437, VAMC Richmond VA 23249, and University of VA, Charlottesville, VA 22908.

New statistical perspectives on the secretory patterns of both LH and testosterone may prove useful in further understanding the aging process, and possibly ultimately for improved diagnosis and treatment of spermatogenetic failure and loss of sexual interest. We examined secretory time-series for LH and testosterone in 14 young (21-34 yr) and 11 aged (62-74 yr) healthy men. For each subject, blood samples were obtained at 2.5 min intervals during an overnight sleep period, average sampling duration 7 h. For each of LH and testosterone, we utilized the model-independent statistic Approximate Entropy (ApEn) to quantify irregularity. To quantify joint LH-testosterone secretory asynchrony, we employed the recently introduced cross-ApEn. Although mean (and SD) LH and testosterone concentrations were indistinguishable in the 2 age groups (P > 0.25), for LH aged subjects had greater ApEn values (1.525 +/- 0.221) than younger subjects (1.207 +/- 0.252), P < nad greater ApEn values (1.25 % -0.221) than younger subjects (1.20 % -0.252), P < 0.003, indicating more irregular LH secretion in the aged cohort. For testosterone, aged subjects also had greater ApEn values (1.622 +/- 0.120) than younger subjects (1.384 +/- 0.228), P < 0.004. Aged subjects had greater cross-ApEn values (1.961 +/- 0.121) than younger subjects (1.574 +/- 0.249), P < 10⁻⁴, with nearly 100% sensitivity and specificity, indicating greater LH-testosterone asynchrony in the older group. In conjunction with previous findings of greater irregularity of insulin and GH release with increasing age, we propose that increased secretory irregularity with advancing age may be a widespread hormonal phenomenon reflecting attenuation of coordinate feed-forward and feedback regulation. Finally, theoretically, we clarify the need for quantifications such as ApEn and cross-ApEn via a study of a "variable lag" pulsatile process, and empirically note the potential wide applicability of cross-ApEn to quantify asynchrony in settings in which network characteristics might be of interest, beyond the study of variables individually. NIH, Veterans Affair Administration

THE AP-1 AND CREB TRANSCRIPTION FACTORS MEDIATE GLUCOCORTICOID REGULATION OF TRH GENE EXPRESSION, LU-GUANG LUO*, EMILY SU, IVOR M.D. JACKSON, DIVISION OF ENDOCRINOLOGY, RHODE ISLAND HOSPITAL, BROWN UNIVERSITY SCHOOL OF MEDICINE, PROVIDENCE, RI 02903.

Glucocorticoids stimulate TRH gene regulation in rat hypothalamic and anterior pituitary cells, but the underlying mechanism has not been elucidated. Accordingly, the purpose of this study was to examine the role of the protooncogenes *cfoskcjun* (AP-1 complex) and CREB in this process. TRH content was measured by radio-immunoassay (RIA) in fetal hypothalamic neurons exposed to Dexamethasone(Dex) at 10-8M and treated with chemical agents which affect protein formation. N-ethylmaleimide (NEM), an alkylating agent, decreased TRH content in a dose-dependent manner (from 87.45 ± 6.05 to 35.20 ± 9.35 fmol/well; p=0.05), while the phorbol ester 12-0-tertadecanoplyhothol-13-acetate (TPA) increased the TRH content, also in a dose-dependent manner (from 50.45 ± 3.85 to 188.02 ± 12.62 fmol/well; p=0.05). In addition, TPA(10-8M) enhanced the Dex (10-8 M) stimulation of TRH expression (374.00 ± 28.60 vs 180.95 ± 13.75 fmol/well; p=0.05). In contrast NEM (10-4 M) reduced the effect of Dex stimulation (89.10 ± 9.35 vs 180.95 ± 13.75 fmol/well; p<0.05). Western blot analysis of AtT20 cells (a pituitary tumor cell line transfected with a cDNA for proTRH) was performed in order to directly determine relative levels of AP-1 and CREB. The findings were consistent with the RIA data. Both Dex and TPA increased the levels of AP-1 and CREB while NEM inhibited the formation of these proteins. As anticipated, the glucocorticoid stimulatory effect was reduced by the addition of NEM. Anterior pituitary monolayer cells, undergoing electrophoretic mobility shift assays (EMSA), were used to determine DNA binding ability to both heprotooncogene protein AP-1 and CREB. The data showed that Dex increases the DNA binding ability to both AP-1 and CREB to the TRH gene. In conclusion, these findings suggest that glucocorticoid stimulation of TRH gene expression is regulated, at least in part, by the protooncogene AP-1 complex and the CREB pathway, associated with enhanced DNA binding.

CHARACTERIZATION OF A PITUITARY CELL LINE PRODUCING THE PEPTIDE GALANIN J.F. Hyde*, A. Cai and J.P. Moore, Jr., Dept. Anatomy & Neurobiology, Univ. Kentucky College of Medicine, Lexington, KY 40536.

We previously reported that the GH- and PRL-producing transplantable pituitary tumor MtTW-10 also synthesizes and secretes the peptide galanin in copious amounts. The MtTW-10 tumor is estrogen responsive and must be maintained subcutaneously in Wistar-Furth rats. During the past several years, we have examined a variety of pituitary cell lines (including GH3, GH4C1 and MMQ) and found that only αTSH cells were found to produce minute amounts of galanin. Harrison and co-workers established a pituitary tumor cell line (RC-4B/C) derived from a male rat in 1977, and they showed that this cell line contains all pituitary cell types as determined by immunocytochemical analysis We have studied the RC-4B/C cell line to determine if they produce the peptide hormone galanin. Northern blot analysis showed that the cell line contains galanin mRNA, identical in size with the normal pituitary galanin mRNA transcript (~0.9 kb). In situ hybridization using an 35S-UTP-labeled cRNA galanin probe revealed that only a subpopulation of the RC-4B/C cells contain galanin mRNA. Immunofluorescent cytochemistry using a specific rat galanin antiserum showed that the RC-4B/C cells produce galanin peptide, and confirmed that only a subpopulation of the cells synthesize galanin. It is not known at present, which pituitary cells type(s) in this pituitary tumor cell line produces galanin mRNA/peptide. This cell line may be useful for studying galanin peptide processing and secretion as well as for studying the regulatory sequences controlling galanin gene transcription. (Supported by DK-45981 and

IMMUNOHISTOCHEMICAL LOCALIZATION OF SNAP-25, A SYNAPTIC PROTEIN, IN THE RAT PITUITARY. <u>L.C. Saland and V. Hernandez</u>. Dept. of Anatomy, Univ. of New Mexico Sch. Medicine, Albuquerque, NM 87131.

SNAP-25 is a neuronal membrane-associated protein which may be involved in docking of synaptic vesicles. We have previously found other proteins, including synaptophysin (SN), in nerve fibers terminating in the rat pituitary neural (NL) and intermediate (IL) lobes (Saland et al, '95, Soc. Neurosci. Abst. 21:1993). Here, adult male Sprague-Dawley rats were halothane anesthetized, perfused intracardially with buffered saline followed by paraformaldehyde, and tissues prepared for paraffin sectioning. Sections were immunostained for SNAP-25 using a monoclonal antibody from Chemicon, dilution 1:50, followed by secondary antibody, Vector ABC reagent, then a peroxidase reaction. A fine network of SNAP-25-positive fibers extended throughout the NL, and among some areas of the IL. Relatively sparse staining contrasts with greater intensity for SN as well as for GAP-43 seen in earlier studies (Saland et al, '93, Mol. Cell. Neurosci. 4:576; Saland et al, '96, Neurosci. Lett., in press). SNAP-25 may be another component of innervation which regulates secretion from the pituitary. Support: NIH GM-08139.

BIOLOGICAL AND IMMUNOLOGICAL CHARACTERIZATION OF A GONADOTROPIN-RELEASING HORMONE (GnRH)-LIKE SUBSTANCE IN A MOLLUSK, *APLYSIA CALIFORNICA*. P.-S. Tsai⁻¹, N.M. Sherwood², and N.L. Wayne¹. ¹Department of Physiology, UCLA School of Medicine, Los Angeles, CA 90095-1751 and ²Department of Biology, University of Victoria, Victoria BC, V8W 2Y2.

GnRH is a neuropeptide central to the initiation and maintenance of reproduction in vertebrates. Members of the GnRH family share almost 100% sequence identity at both amino and carboxy terminals, suggesting remarkable structural conservation over the course of evolution. In this study, we investigate if a GnRH-like molecule exists outside Phylum Chordata in an invertebrate. *Aplysia californica*. Immunocytochemical studies using antisera against dogfish and tunicate I (II) GnRHs revealed the presence of GnRH immunoreactivities in neuronal cell bodies, fibers, and acellular regions of the CNS connective sheath (possible site of neurohormone release) in *Aplysia*. A specific radioimmunoassay for It-GnRH also demonstrated It-GnRH immunoreactivity in acid/acetone extracts of the CNS (28.9 ± 10.6 pg/g tissue) and hemolymph (68 ± 7.8 pg/ml hemolymph). However, the immunoreactive *Aplysia* GnRH is biochemically distinct from other known forms of GnRH as it cannot be successfully retained by the C18 reverse-phase column. *In vitro* administration of 100 nM of chicken II GnRH to the neuroendocrine bag cell clusters (during the nonbreeding season) significantly suppressed the duration of electrical afterdischarge (AD) and the number of action potentials fired during an AD (P ≤ 0.02, n=5), but the secretion of egg-laying hormone from bag cells was not significantly affected. These findings demonstrate the presence of GnRH immunoreactivity and bioactivity in a protostomic invertebrate and suggest that the structural and functional conservation of GnRH may extend beyond phylum Chordata to other members of invertebrate phyla. BASAL PROENKEPHALIN (PENK) GENE EXPRESSION IN THE HAMSTER IS INDEPENDENT OF GLUCOCORTICOIDS <u>Rosa Jimenez and S.O. Franklin*</u>, Dept. of Pharmacology, Cornell U. Med. College, N.Y., N.Y. 10021.

Proenkephalin (Penk) gene expression is low In the rat adrenal medulla and high in the rat striatum, and glucocorticoids play a major role in regulating that gene's expression. In contrast to the rat, preproenkephalin (PPenk) mRNA levels in the adult hamster adrenal are high (90 times rat levels) and comparable to striatal PPenk mRNA levels (Franklin et al, 1991). To determine the role that glucocorticoids play in regulating Penk gene expression in the hamster, male hamsters were either hypophysectomized 14 days prior to sacrifice (HYPOX) HYPOX and treated with the glucocorticoid receptor antagonist RU486 (30 mg/kg/day, sc beginning on day 8) or subjected to treatments known to reduced adrenal cortical glucocorticoid biosynthesis (150 mg/kg/day metyrapone, ip, or 75 mg/kg/day mitotane, sc, bid for 6-7 All treatments reduced plasma glucocorticoid levels. HYPOX + RU486 treatments reduced plasma glucocorticoid levels by as much as 67% and phenylethanolamine-N-methyltransferase (PNMT) mRNA levels by 57% in the hamster adrenal. PNMT, which converts norepinephrine to epinephrine, is influenced by glucocorticoids in the Yet, all applied treatments did not effect basal enkephalin containing peptide levels nor basal PPenk mRNA levels in either the hamster adrenal or striatum. These results suggest that basal Penk gene expression in the hamster is independent of glucocorticoids, despite divergent observations in other species and the presence of glucocorticoid response elements (GRE's) in the hamster Penk gene (Supported by NIDA GRANTS DA09901 and DA05130.)

A PROGESTERONE EFFECT UPON NEOCORTICAL CYCLIC AMP THAT DEPENDS UPON THE GABA_B AGONIST BACLOFEN. M.I.Al-Daḥan*.M.H.Jaililian Tehrani , and R. H. Thalmann, Baylor Coll. of Med. , Houston, TX 77030.

Progesterone, without the necessity of estrogen priming, is associated with increases in GABAB receptor density in neocortex (Al-Dahan and Thalmann, Brain Research, in press). We have begun to examine the interaction of progesterone with second messenger systems and with GABAB receptors. Progesterone or vehicle alone was injected subcutaneously in sesame oil, and the brains were removed four hours later. Neocortical slices were incubated in a Krebs bicarbonate buffer with baclofen (10uM) followed 15 minutes later by forskolin (3uM). Progesterone had little effect upon basal cyclic AMP and produced an insignificant effect upon forskolin-stimulated cyclic AMP (10 mins forskolin exposure). However, when 10uM baclofen was introduced 15 minutes prior to the addition of forskolin, cyclic AMP levels were lower in the presence than in the absence of progesterone (N=4/4 experiments). This evidence for increased GABAB dependent suppression of cyclic AMP after exposure to progesterone may reflect the functional effect of the increased density GABA_B receptors that are detected after a similar exposure to the hormone. (See also Thalmann et al, this meeting). Supported by National Institutes of Health grant NS21713.

CYTOSOLIC Ca²⁺ OSCILLATIONS EVOKED BY PACAP IN MELANOTROPHS OF THE PITUITARY PARS INTERMEDIA OF RATS. <u>K. Tanaka, I. Shibuya, N. Harayama, Y. Ueta*, M. Nomura & H. Yamashita</u> Dept. of Physiol., Univ. Occup. & Environ. Health, Kitakyushu 807, Japan

Melanotrophs of the pituitary pars intermedia (PI) exhibit spontaneous secretion at a high rate, which is maintained by spontaneous Ca2+ entry. This spontaneous secretion is thought to be regulated mainly by the secreto-inhibitory neurotransmitters, dopamine and GABA. We found remarkably high density of mRNA of the type-I receptor of pituitary adenylate cyclase activating polypeptide (PACAP) in PI, which is in a direct contact with the pars nervosa where PACAP is released. To examine the function of PACAP in PI, we measured [Ca2+]; and ionic currents in dissociated melanotrophs of rats. PACAP (10-10-10-7 M) raised [Ca2+], and often initiated phasic [Ca2+]; elevations (Ca2+ oscillations), which were suppressed when extracellular Ca2+ was removed or the Cachannel blocker, nicardipine was added. Moreover, PACAP augmented voltage-dependent Ba2+ currents under voltage-clamp mode of the whole-cell patch-clamp technique. These results suggest that PACAP potentiates Ca2+ entry mechanisms of melanotrophs to initiate cytosolic Ca2+ oscillations and that PACAP may serve as a physiological secretagogue of rat melanotrophs.

DIMORPHIC EXPRESSION OF CALRETININ IN THE MEDIAL BASAL HYPOTHALAMUS FROM PERINATAL MALE AND FEMALE RATS. E. D. LEPHART*, D. R. LADLE AND N. A. JACOBSON. Dept. Zoology - Cell Biol. Div., Brigham Young University, Provo, UT 84602.

Calcium-binding proteins play an important role in mediating cell proliferation, programmed cell death and neurotoxicity. Conversely, evidence exists that hypothalamic and limbic regions display sexually dimorphic structures which are regulated by sex hormones during perinatal development. Calcium-binding proteins such as Calretinin (CALRET) within certain brain areas may regulate these brain regions in concert with the hormonal action of sex steroids during perinatal development. In the present study, we examined the developmental pattern of CALRET expression (via Western analysis) in MBH and AMY tissue homogenates from perinatal male and female rats. Tissue samples were collected on gestational days (GD) 17, 19, 21 and postnatal days (PND) 1 and 3. The CALRET antibody recognized a single protein band with an apparent molecular weight of 29,000 in brain. Notably, males displayed significantly higher CALRET levels compared to females in the MBH (but not the AMY) brain region from GD 19 through PND 1. We have previously shown a dimorphic expression of Calbindin-D_{28K} in the MBH (but not the AMY) from perinatal male and female rats and the present data for CALRET are similar to these earlier studies. The notable sex difference in MBH CALRET (and calbindin) levels suggest that androgens or other hormonal factors may regulate the dimorphic expression of CALRET during perinatal development. Finally, the calcium-binding proteins potentially play an important and critical role in neuronal programmed cell death during perinatal development where females, presumably, exhibit a greater cell loss than males due to the lower abundance of calcium-binding proteins. Supported, in part, by a grant from NSF.

ULTRA-SHORT LOOP FEEDBACK OF GRRH IN THE EWE: DOES THIS INVOLVE GAMMA AMINOBUTYRIC ACID (GABA) NEURONS IN THE PREOPTIC AREA? J.E. Robinson*, N.P. Evans, and J.A. Taylor, Laboratory of Neuroendocrinology, The Babraham Institute, Cambridge CB2 4AT, UK.

CB2 4A1.0K.
There is evidence for an ultra-short feedback loop regulating GnRH release in several species including sheep. Whether this effect involves the direct actions of the decapeptide on GnRH neurons themselves or a self-regulatory action via another neurotransmitter system is unknown. We have explored the latter possibility by using microdialysis to measure the local release of GABA following the infusion of either GnRH or a receptor antagonist, Antide, directly into the preoptic area (POA). Microdialysis probes (5mm membrane; CMA/10) were placed in the POA of 7 ovariectomised Clun Forest ewes via preimplanted guide cannulae and artificial cerebrospinal fluid (aCSF) pumped through the probes at a flow rate of 2-3 µl/min. Beginning 180 min later, samples of dialysate were collected at 20 min intervals for 260 min. Animals received 2 GnRH infusions (10°M in aCSF for 20 min), one 60 min after sample collection began and the second 80 min later. Antide (10°M) was infused for 20 min before the second GnRH infusion. GABA concentrations were variable among the 7 ewes and values were log-transformed for statistical analysis. A significant (p<0.02) increase in POA GABA levels was observed in all animals in the 20 min following the first GnRH administration (20 min before, 1061±339 vs 20 min after, 4971±2453 nM). Infusion of the GnRH antagonist, Antide, rapidly depressed local GABA concentrations (p<0.01): before, 926±499 vs after, 419±236 nM). However, this concentration of antagonist did not prevent the second GnRH infusion from stimulating GABA (p<0.01): before, 419±236 vs after, 3070±1279 nM). These data suggest that endogenous GnRH cverts a tonic stimulatory action of GABA release in the POA that is receptor mediated. As GABA can after GnRH release, then preoptic GnRH and GABA neurons may form the neural substrate for an ultra-short feedback loop by which GnRH is able to modulate its own release. Supported by BBSRC.

INDOMETHACIN (INDO) PREVENTS THE RISE IN PLASMA OXYTOCIN (OT) AFTER INTRACEREBROVENTRICULAR (ICV) INJECTION OF L-NAME BUT NOT NALOXONE. J. Summy-Long*, V. Bui, S. Gestl and M. Kadekaro¹. Dept. of Pharmacology, Penn State Univ., M.S. Hershey Med. Ctr, Hershey, PA 17033, ¹Div. Neurosurg., Univ. Texas, UTMB, Galveston, TX 77555-0517.

Both nitric oxide (NO) and endogenous opioid peptides inhibit OT release from the magnocellular system without affecting glucose utilization. To determine if they share a similar mechanism involving prostaglandins, conscious female control rats or those water deprived (24h, WD) were injected icv with 5µl of Na₂CO₃ or Indo (100µg) 15 min before CSF or NAME (250 μg). Other WD rats were treated similarly except Indo or 0.9% NaCl was given before 0.9% NaCl or naloxone (50 µg) icv. Rats were decapitated 5 min later. Plasma OT was quantified by RIA and changes determined by 2 way AOV and Newman Keuls t. Inhibiting NO synthase with NAME increased (CSF vs NAME; p<0.01) plasma OT (pg/ml \pm SEM; n=7-10) in control (10 \pm 2 vs 48±8) and WD (20±2 vs 72±7) animals, responses prevented (p<0.01) by Indo (Control: $Na_2CO_3+CSF < Indo+CSF = Indo+NAME$ < Na₂CO₃+NAME; WD: Na₂CO₃+CSF = Indo+CSF = Indo+NAME < Na₂CO₃+NAME). However, the rise in plasma OT in WD rats given naloxone (19±2 vs 39±3) was unchanged by Indo (41±4). Thus, NO inhibits the excitatory effect of a prostaglandin(s) on OT release whereas opioid peptides do not. Funded by RO1-25498 and 2RO1-23055

SEROTONERGIC REPRESSION OF CALCITONIN GENE-RELATED PEPTIDE GENE EXPRESSION. P.L. Durham, N.J. Pantazis* and A.F. Russo. Dept. of Physiology and Biophysics, Univ. of Iowa. Iowa City, IA 52242.

We investigated the regulatory effect of serotonergic agents on transcriptional activity of the calcitonin/calcitonin gene-related peptide (CT/CGRP) gene in rat CA77 medullary thyroid carcinoma C-cells. CGRP, a potent vasodilator, plays an important role in cardiovascular homeostasis. High levels of CGRP are associated with vascular headaches, such as migraines. Administration of sumatriptan, a serotonin type-1 (5-HT1) receptor agonist, causes plasma CGRP levels to return to normal, coincident with alleviation of migraine symptoms. Sumatriptan is belived to act through the human 5-HT1p receptor (rat 5-HT1g): to inhibit adenylate cyclase activity via its coupling to a Gi protein. To test whether sumatriptan and serotonergic agents could directly inhibit the expression of CGRP in neuronal cells, we utilized CA77 cells which exhibit a neuronal phenotype and possess characteristics of serotonergic neurons. Treatment of CA77 cells with the 5-HT1g-specific receptor agonist, CGS 12066B maleate (CGS), caused a 2.5-fold decrease in the steady-state level of CGRP mRNA as determined by northern blot analysis. Utilizing luciferase reporter genes containing the rat CT/CGRP promoter and 1.3 kb of the 5° flanking sequence in transfection assays, we determined that sumatriptan or CGS inhibit forskolin-mediated stimulation of CGRP promoter activity. Data from our studies are suggestive that 5-HT receptor agonists downregulate CGRP gene expression via a cAMP-dependent pathway. Furthermore, the CA77 cells will provide a useful neuronal/serotonergic model system to investigate the mechanism by which sumatriptan and other anti-migraine drugs regulate the expression of the vasoregulatory neuropeptide CGRP. This work was supported by NIH grant HD25969.

RAT SPERM IMMOBILIZATION BY ORAL INGESTION OF RUTA CHALEPENSIS AQUEOUS EXTRACT. E. Gijón*, L. Cartas, M. Lorenzana-Jímenez, V. Anaya, and X. García. Dept. of Physiol., Dept. of Pharmacol., and Division of Postgraduate Studies and Research, Sch. of Medicine. UNAM. México D. F. 04510, México.

Ruta chalepensis extract is used in traditional medicine as a vaginal wash before sexual intercourse as it has been suggested to have an anticonceptive action. As a more likely target for the compounds is the sperm if any of the compounds interfered with sperm activation or motility, we showed that Ruta chalepensis extract affects motility of rat and frog sperm in vitro, until complete immobilization of spermatozoa, in a dose dependent form. The aim of this study was to find out if the substitution of drinking water to male rats for aqueous extract of Ruta chalepensis in vivo, might induced any change in sperm motility. After 4 days of this treatment we found under light microscopy and videomicroscopy complete immobilization of spermatozoa obtained from rat testicle while control rat testicle rendered sperm with clear visible motility. As in vitro observations sperm from treated animals showed morphological changes in the tail and head of the spermatozoa. This results support the postulated contraceptive action on male side of Ruta chalepensis extract. Work in progress in our laboratory is looking also for morphological changes on rat testicle or spermatogenesis

INVOLVEMENT OF BETA RECEPTORS IN COMPENSATORY GROWTH OF THE RAT ADRENAL GLAND: AN UNEXPECTED CHANGE IN RECEPTOR FUNCTION AND CAMP SIGNALING, <u>Z. Lacković*, V Trkulja A. Horvat, D. Zdilar and H. Sečić</u>, Lab. Molecular Neuropharmacology, School of Medicine, Zagreb University, Zagreb, Croatia.

Catecholaminergic innervation influences compensatory growth of the adrenal gland remnant after unilateral adrenalectomy. The aim of the present study was to identify the receptors involved. Mature, female Wistar rats were used in 10-day experiments. Several parameters of adrenal growth were determined - wet weight, protein content, and total RNA and DNA. Both splanchnecotomy and chemical sympathectomy (guanethidine or reserpine) prevented the compensatory adrenal growth induced by contralateral adrenalectomy. While β-adrenergic agonist isoproterenol had a stimulatory effect and reversed the effect of guanethidine, β-blocking agents (propranolol, sotalol, atenolol, but butoxamine, too) prevented the compensatory adrenal growth. In contrast, neither the cold stress-induced adrenal enlargement nor the normal adrenal growth followed throughout a 45-day period, were modified by β-blocking agents. 3H-Alprenolol binding did not indicate alterations in β-receptor density or affinity. While isoproterenolol stimulated cAMP formation in the control adrenal gland, in the adrenal gland remnant after unilateral adrenalectomy cAMP formation was inhibited by isoproterenol. This inhibitory effect was clearly antagonized by butoxamine but not by atenolol. These observations suggest that β-receptors stimulate the adrenal growth induced either by adrenalectomy or by denervation of the contralateral gland, changing thereat their physiological function and intracellular signaling mechanism.

Supported by grant from the Ministry of Science, Republic of Croatia.

FURTHER EVIDENCE THAT OSCP, A SUBUNIT OF MITOCHONDRIAL ATP SYNTHASE, IS A STEROID BINDING PROTEIN.

J. Zheng* & V. D. Ramirez. Neurosci. Program & Dept. Mol. & Integrat. Physiol., Univ. of Illinois, Urbana. IL 61801

17β-Estradiol linked to bovine serum albumin at C-6-position (17β-E-6-BSA) has been used as a ligand in our laboratory to demonstrate membrane estrogen binding sties and to purify membrane estrogen binding proteins from affinity columns. One membrane estrogen binding protein has been identified as oligomycin sensitivity-conferring protein (OSCP), a subunit of mitochondrial ATP synthase/ATPase. In order to further clarify the issue that OSCP is an estrogen binding protein, we have used recombinant bovine OSCP (kindly provided by Drs. Y. Hatefi and A. Matsuno-Yagi of the Scripps Research Institute). Ligand blotting and radioligand binding assay revealed that recombinant OSCP bound iodinated 17β-E-6-BSA (17β-E-6-[1251[BSA)]. The binding was completely displaced by 17β-E-6-BSA at 0.5 μM with affinity in the range of 50 nM, and not by 10 μM BSA. Both 17β-E-6-BSA at 0.5 μM with affinity in the range of 50 nM, and not by 10 μM BSA. Both 17β-E-6-BSA at 0.5 μM with affinity in the range of 50 nM, and for the stronger of the strong

TRANSCRIPTIONAL EFFECTS OF ESTROGEN ON THE NEUROTENSIN GENE INVOLVE NON-CLASSICAL SIGNALLING MECHANISMS I. J. Watters* a , P. R. Dobner b , and D. M. Dorsa a,c

Departments of Pharmacology ^a and Psychiatry ^c, Univ. of WA, Seattle, WA 98195 and Dept. Mol. Genetics and Micro., Univ. Mass., Worcester, MA^b

Estrogen is known to regulate the expression of neuropeptide genes whose promoters do not contain classical estrogen response elements (EREs). Neurotensin (NT) gene expression is regulated by estrogen in a sexually dimorphic nucleus of the rat brain, the medial preoptic nucleus (MPO). Although the NT promoter does not include an ERE it does contain several other transcription factor binding sites, including a cyclic AMP response element (CRE). It has been shown that estrogen can rapidly elevate intracellular levels of cAMP in various cell lines and tissues. In addition, we have previously reported that estrogen induces the phosphorylation of the cyclic AMP response element binding protein (CREB) in the MPO, indicating that estrogen could potentially employ this second messenger system to influence gene transcription. To test this possibility in the context of the NT gene, we have used a promoter reporter gene construct, and transient transfection techniques to evaluate estrogen's elffects on transcription using an estrogen-responsive human neurblastoma cell line, Sk-N-SH. In these cells, estrogen elicitis a 2-3 fold increase in transcription at 8 hours, which is preceeded by an increase in intracellular cAMP that appears to be maximal about 90 minutes after estrogen exposure. Additionally, the effects of estrogen on the NT reporter gene construct are blocked by administration of the PKA inhibitor H-89, but not by Cam Kinase or PKC inhibitors. Overexpression of the human estrogen receptor in these cells dramatically enhanced transcription of an ERE reporter gene, but not of the NT construct. Treatment with the estrogen receptor antagonists tamoxifen or ICI 182,780 fails to antagonize, and may potentiate, the effect of estrogen. (Supported by NS20311, and Pharmacological Sciences Training Grant 5T3GM07750).

APOLIPOPROTEIN J AND E MRNA IN THE HYPOTHALAMUS AND HIPPOCAMPUS DURING THE RAT ESTROUS CYCLE DJ Stone, I Rozovsky. CP Anderson, TE Morgan, and CE Finch.* Andrus Gerontology Center and Department of Biology, University of Southern California, Los Angeles, CA 90089

The arcuate nucleus of the hypothalamus and the CA1 region of the hippocampus undergo rapid transient synaptic remodeling during the rat estrous cycle. Synapse number is highest when estradiol levels are high; decreases in estradiol are accompanied by decreases in synapse number. Because the glial apolipoproteins J and E are implicated in synaptic remodeling after injury, we investigated mRNA levels of apoJ and apoE by in situ hybridization in the brains of rats at 4 different points in the estrus cycle (diestrus, proestrus morning, proestrus afternoon, and estrus). During proestrus afternoon, when blood estradiol and synapse number are highest, we observed maximum levels of apoJ mRNA in the hippocampus and hypothalamus. Levels decrease significantly by the morning of estrus when synapse number and estradiol level are lowest. ApoE mRNA in the CA1 region of the hippocampus is highest on the morning of proestrus, and decreased by the morning of estrus. ApoE levels in the arcuate nucleus show a similar but non-significant trend.

These results implicate apoJ and apoE in synaptic remodeling during the estrous cycle in the rat brain. The temporal course of apoJ and apoE mRNA changes where apoJ levels are peaking while apoE levels are decreasing suggests that these mRNAs are differentially controlled in different glial subpopulations and may be involved in different aspect of the remodeling process. TIME COURSE AND SPECIFICITY OF ESTROGEN NEUROPROTECTION AGAINST GLUTAMATE TOXICITY IN PRIMARY CORTICAL NEURONS. C.A. Singer.*, R.H. Batchelor and D.M. Dorsa. Departments of Pharmacology and Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA 09105.

We have previously reported neuroprotective effects of estrogen in rat primary cortical neurons following a toxic glutamate exposure. In these experiments, a twenty-four hour pretreatment with 15 and 50 nM 178-estradiol significantly reduced cellular lactate dehydrogenase (LDH) release by 23% when compared to vehicle treated cells. This effect is specific to estradiol and is not mimicked by pretreatment with related steroids such as progesterone, dihydrotestosterone, dexamethasone or cholesterol. Neuroprotection is elicited, however, by the potent estrogen diethylstilibestrol (DES) at doses of 10°-10 M. The anti-estrogen tamoxifen blocked the protective effects of 176-estradiol suggesting that a classical steroid hormone receptor may be involved and the presence of estrogen receptor in these cultures has been verified by immunoblot. An examination of the time course for this neuroprotective effect has demonstrated that estrogen neuroprotection can occur with a five minute pretreatment of 10°-9 M 176-estradiol. The ability of estrogen to protect against toxicity mediated by different types of glutamate receptors is being evaluated by exposing cultures to various glutamaterigic agonists. Preliminary experiments indicate that 10°-8 M 176-estradiol will protect cultures from cell death induced by a five minute exposure to NMDA, suggesting that estrogen neuroprotection during glutamate toxicity may involve, in part, the NMDA receptor component of glutamate toxicity. This work is supported by a MDA.

17 B-ESTRADIOL MODULATION OF GLUCOSE TRANSPORTER 1 (GLUT 1) EXPRESSION IN BLOOD-BRAIN BARRIER <u>J. Shi* and J. W. Simpkins</u> Center for the Neurobiology of Aging and Department of Pharmacodynamics, College of Pharmacy, University of Florida, Gainesville, FL 32610

The present study was designed to evaluate the 17 β-estradiol (E2) modulation of GLUT 1 protein and mRNA expression in BBB endothelium. Female rats were ovariectomized (OVX) for 12-14 days, then E2 was injected sc. at doses of 1-100 μg/kg at 2-16 hours before sampling. Glucose transport was assessed using 14C-2-deoxyglucose (14C-2-DG) uptake and GLUT 1 protein and mRNA samples of brain microvessel endothelial cells were analyzed by Western and Northern blotting, respectively. E2 treatment caused dose- and time-dependent increase in 14C-2-DG uptake by microvessels and the whole microvessel endothelial cell GLUT 1 protein expression. The peak responses were induced by 10 μg/kg E2 dose at the 4-hour sampling time (36.0% and 31.3% increase, p<0.05, respectively). GLUT 1 mRNA demonstrated a transient increase at 15-minute (55% increase, p<0.05), then decreased to basal level by 2 hours. This study shows that in vivo treatment with E2 increases 14C-2-DG uptake into the BBB endothelial cells and suggests this E2 effect is due to its modulation of GLUT 1 mRNA and protein. (Supported by NIA grant AG 10485)

MOLECULAR MEMBRANE INTERACTIONS OF STEROIDS: IMPLICATIONS FOR A NON-GENOMIC MECHANISM OF STEROID ACTION. G.A. Golden*, R.T. Rubin, P.E. Mason and R.P. Mason. Neurosciences Research Center, Medical College of Pennsylvania and Hahnemann University, Allegheny Campus, Pittsburgh, PA 15212.

Recent experimental evidence points to rapid cellular effects that occur within seconds to minutes of steroid application, a time frame incompatible with a classical (genomic) mechanism of steroid action. In this study, we examined the membrane interactions of two representative steroid hormones, cortisol and 17- β -estradiol. Partition coefficients (Kp) were determined in phosphatidylcholine liposomes at cholesterol-to-phospholipid mole ratios (C:P) ranging from 0:1 to 1:1 in increments of 0.2. Equilibrium partitioning of both steroids was achieved at t<5 min. In liposomes of a physiologically relevant cholesterol content (0.4:1 C:P), the Kp values for cortisol and estradiol were 147 ± 55.0 and 1290 ± 265 , respectively. For estradiol, increasing membrane cholesterol between 0.2:1 and 0.6:1 C:P correlated with a significant reduction in Kp; there were no further changes in Kp above 0.6:1 C:P. In contrast, the Kp for cortisol did not change significantly between 0.2:1 and 0.4:1 C:P, membrane partitioning was highly variable between 0.4:1 and 0.8:1 C:P, and significantly elevated at 1:1 C:P.

Electron density profiles generated from small angle x-ray diffraction of reconstituted human erythrocyte membranes demonstrated that the time-averaged location of cortisol was near the phospholipid headgroup region, while estradiol was located deep within the hydrocarbon core. These data indicate that cortisol and estradiol bind rapidly to energetically favorable locations in the membrane bilayer, and that the extent and location of binding are highly influenced by membrane lipid composition and steroid structure. This study supports a model for rapid steroid action at the cell membrane independent of slower genomic effects.

action at the cell membrane independent of slower genomic effects.

REGULATION OF AROMATASE EXPRESSION IN PRIMARY CELL CULTURES OF DEVELOPING ZEBRA FINCH TELENCEPHALON F. Freking*, B. Ramachandron and B. Schlinger, Depts.of Physiological Science, Psychiatry and Lab of Neuroendocrinology of the BRI, UCLA, Los Angeles, CA 90095.

Aromatase (estrogen synthetase), is expressed in the vertebrate brain, with highest levels often in the hypothalamus-preoptic area (HPOA). In non-songbirds, testosterone (T), estradiol (E2) and 5α -dihydrotestosterone (DHT) can upregulate POA aromatase. This upregulation is a key property of steroid control of reproductive behavior in males. In songbirds, aromatase is expressed at unusually high levels in the telencephalon (Tel). Presumably, regulation of Tel aromatase is important in controlling steroid dependent telencephalic function. To test this idea, we examined factors that might regulate aromatase activity and mRNA expression in $1^{\rm o}$ cell cultures of developing zebra finch Tel. Cultures (+/- serum) were treated for 0 to 72 hrs with sex steroids or db-cAMP. Total RNA was extracted from cultures for Northern blot analyses or they were incubated with ³H-androgen to measure aromatase activity. Northern blots were hybridized with a ³²P-labeled zebra finch aromatase cDNA probe. Compared to control cultures, 1µM E2 reduced aromatase activity on average 58% and mRNA levels by 56%. 1μM T, 5α-and 5β-DHT had no effects on aromatase activity. 400µM db-cAMP increased both aromatase activity and aromatase mRNA by 220%. These results suggest that E2 regulates its own synthesis in the songbird Tel by negative feedback on aromatase expression. Factors that regulate intracellular cAMP levels may also influence Tel aromatase expression. Supported by HD32050 & HD07228.

THE ROLE OF ESTROGEN IN GLIAL GENE EXPRESSION AND GLIAL REACTIVITY IN VITRO. I.Rozovsky*, D.J. Stone, T.E. Morgan, C.P. Anderson and C.E.Finch. Andrus Gerontology Center and Department of Biology, University of Southern California, Los Angeles, CA 90089.

Astrocyte hypotrophy in the response to local neuronal activities and/or damage and increased expression of GFAP were demonstrated during the estrus cycles. Recent studies from our lab showed that two astrocyte lipoproteins, ApoE and ApoJ, which are involved in synaptic plasticity, and modify AB toxicity in vitro (Oda et al., Exp. Neurology, 1995) are also differentially expressed in hippocampus and arcuate nucleus of hypothalamus during the estrus cycles (Stone et al., Neuroscience Abst., 1996). Both ApoE and ApoJ are expressed and secreted by rat cultured astrocytes. However, cultured microglia express high prevalence ApoE mRNA, but no ApoJ mRNA. Treatment of mixed glial cultures with low physiological concentrations of 178-estradiol demonstrated 2-fold increase of ApoE mRNAs. In contrast, pure astrocyte cultures did not show the change in ApoE mRNA level. Heterotypic cell-cell interactions, as well as differential regulation of microglial ApoE by estrogen, might be responsible for the ApoE mRNA increase in mixed glial cultures.

The role of estrogen in controlling astrocyte reactivity in the response to neuronal damage using the in vitro model of "wounding in a dish" was also examined. GFAP was induced in the response to mechanical wounding of astrocyte-neuron co-cultures. Addition of 178-estradiol to these cultures prevented the "wound"-induced increase of GFAP. The role of estrogen response elements in rat GFAP promoter was also defined. (Supported by AG13499-01 to C.E.F.).

FAILURE TO FIND VARIATIONS IN PERFORMANCE ON GENDER-SPECIFIC COGNITIVE TASKS AS A FUNCTION OF MENSTRUAL CYCLE PHASE. K. Epting, K. Barbour, W. Overman*. Psychology Department, Univ. North Carolina at Wilmington, Wilmington, N.C. 28401

Three putative female-sensitive cognitive tests (Purdue peg board, finger tap, spatial array) and three putative malesensitive cognitive tests (mental rotation, rod-and-frame, water-level) were administered twice, at six-week intervals, to 27 college women and 20 men. Counterbalanced for order, women received the tests once during menstruation (low hormone condition) and once during mid luteal phase (high hormone condition). The mid-luteal phase was determined by projection from ovulation, as verified by commercially available ovulation detection kits and by follow up confirmation of subsequent menstruation.

confirmation of subsequent menstruation.

Results showed a significant gender difference for 4 tasks in the expected male- or female- direction; however, for females there was no evidence that cognitive performance differed with menstrual cycle phase. Results are consistent with previous negative findings of effects of the menstrual cycle upon cognition (Sommer, B. in J. Richardson (Ed.), Cognition and the Menstrual Cycle, Springer-Verlag, 1992) and inconsistent with reports of cognitive variations during the menstrual cycle (Hampson, E., Kimura, D. 1988, Beh. Neurosci., 102). Supported by UNC-W Research Fellowship Award to K. Epting and NIMH grant RO1-MH50724-01 to W. Overman.

INTERACTIVE EFFECTS OF ESTROGEN AND MPP UPON CORPUS STRIATAL DOPAMINE RELEASE, K. A. Disshon* and D. E. Dluzen. Dept. of Anatomy, NEOUCOM, Rootstown, OH 44272.

The effects of estrogen upon MPTP-induced neurotoxicity were examined using *in vitro* superfusion. Striatal tissue from ovariectomized rats was infused with MPP* (10uM), or a combination of MPP and estrogen (E) using .1, 1, or 100 ng/ml of estrogen. The infusion of MPP+ resulted in an increase in dopamine release (in pg/mg of tissue/min, 46.8 ± 7.6 , N=20) which was significantly greater than the MPP+ E-100ng/ml (18.6 \pm 3.1, N=5) treated group. Neither the MPP+ E-1ng/ml (41.3 ± 5.5 , N=9) or the MPP+ E-1ng/ml (63.6 ± 3 , N=10) groups were significantly different from the MPP+ group. These results demonstrate that the gonadal steroid hormone estrogen can modulate responses of striatal dopamine neurons to MPP+ by altering the immediate increase in dopamine release which occurs in response to this neurotoxin. This effect showed a dose dependency with only the 100ng/ml E dose significantly reducing the MPP+ response. Supported by an NIH grant to D.E.D.

ESTROGEN RECEPTORS ARE EXPRESSED IN OLFACTORY AND VOMERONASAL RECEPTOR NEURONS M.L. Getchell* ^{1,2}, A. Kulkami-Narla³, R. Marcinek^{1,3}, and T.V. Getchell^{1,2,3}. ¹Otolaryngol., Dept. of Surgery; ²Sanders-Brown Center on Aging, ³Dept. of Physiology, Univ. of Kentucky Coll. of Med., Lexington, KY 40536.

Estrogen receptors (ERs) are ligand-dependent nuclear transcription factors that regulate the tissue-specific expression of numerous genes. ERs have been localized in several central olfactory and vomeronasal pathways. Using molecular and cellular techniques, we demonstrate the localization of ERs in olfactory and vomeronasal receptor neurons (ORNs, VRNs, respectively). Northern blots of total and poly (A)*RNA extracted from nasal mucosa and uterus from 6- and 12-week-old rats probed with a cocktail of 3 ³²P-labeled oligonucleotides with unique sequences in the coding region of the ER gene showed a single 6.2 kb band that was more intense in the older rats. In situ hybridization with these probes labeled with 35S and immunohistochemistry with 2 antibodies recognizing sequences in either the hormone- or DNA-binding ER domains demonstrated the localization of ER message and protein in ORNs and VRNs in female and male rats. No ER immunoreactivity was detected in the nasal cavity at embryonic (E) day 12; ER protein was first detected in both ORNs and VRNs at E14; staining intensity increased at E16 and was maintained at E19, P6, 11, 17, and 20. In contrast to the uniform staining pattern at E14-19, in postnatal animals regions of intensely stained ORNs were intermingled with regions of less intensely stained ORNs. ERs were also immunolocalized in ORNs of adult humans of both genders. Estrogen may influence development, neuronal turnover and plasticity, and reproduction-related chemosensation in these receptor neurons. Supported by NIH grants DC 01715 (MLG) and DC 00159 (TVG).

EFFECTS OF ESTROGEN ON BASAL FOREBRAIN CHOLINERGIC NEURONS VARY AS A FUNCTION OF DOSE AND DURATION OF TREATMENT. R.B. Gibbs*. University of Pittsburgh School of Pharmacy, Pittsburgh, PA, 15261.

Gibbs*. University of Pittsburgh School of Pharmacy, Pittsburgh, PA, 13201.

Immunohistochemical techniques were used to examine the effects of estrogen replacement on the number of choline acetyltransferase (ChAT) and p75NGFR expressing cells detected in the medial septum (MS) and nucleus basalis magnocellularis (NBM) of adult (~250g), ovariectomized, Sprague-Dawley rats.

Animals were maintained on a 12h:12h light:dark cycle. Estradiol benzoate (E; in

Animals were maintained on a 12h:12h light:dark cycle. Estradiol benzoate (E; in 0.1 mL sesame oil, injected s.c.) was administered every other day at a dose of 2, 10, 25, or 100 µg/250g.bw. for a period of 1, 2, or 4 weeks (n=5-7 animals/group). Controls received vehicle alone. Twenty-five micron sections through the basal forebrain were cut and stained for immunocytochemical detection of ChAT (AB144P; Chemicon, Inc.) or p75NGFR (mouse monoclonal AB#192). The number of immunoreactive (IR) cells in each of 3 matched sections/region/animal was counted and compared at each time-point using analysis of variance followed by the Dunnett's test. Average serum levels of estradiol ranged from 14.0-26.3 pg/ml., 379-54.4 pg/ml.

Average serum levels of estradiol ranged from 14.0-26.3 pg/mL, 37.9-34.4 pg/mL, and 439.8-888.3 pg/mL in animals treated with 2, 10, 25, and 100 μg E every other day for 1-4 weeks. Treatment with 2-25 μg E produced a dose-related increase in the number of ChAT-IR cells detected in the MS at 1 week, with the peak increase (30%) detected at the 25 μg dose. No significant increase was detected with the 100 μg dose or following longer periods of treatment. Treatment with 10 μg E for 1 week or with 2 μg E for 2 weeks produced a significant increase (21.6% & 23.3%) in the number of ChAT-IR cells detected in the NBM. In contrast, E administration produced a dose-related decrease in the number of p75NGFR-IR cells detected in the MS (but not the NBM) with the greatest effects detected after 4 weeks of treatment with the 25 μg (-29%) and 100 μg (-28.9%) doses.

25 lig (-29%) and 100 lig (-28.%) doses.

These data demonstrate that the effects of estrogen on basal forebrain cholinergic neurons are dependent on both the dose and duration of estrogen treatment with maximal increases in ChAT-IR detected following short-term replacement with physiological levels of E, and decreases in p75NGFR detected following longer-term treatment with higher levels of E. Supported by NIH grant # RO1-NS28896.

DISTRIBUTION OF PROTEIN KINASE C (PKC) ISOFORMS IN CULTURED PREMOTOR RESPIRATORY NEURONS FROM NEONATAL RAT Miranda Jarnot and Michael S. Dekin, Dept. of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ 08903

An outward rectifying K* channel (K_(QR)) is activated by both serotonin type 1B (5-HT_{1B}) and y-aminobutyric acid type B (GABA_B) receptors in cultured

premotor respiratory neurons (Dekin and Wagner, Soc. Neurosci. Abstr., this volume). While K_(OR) channels activated by 5-HT_{1B} have a much smaller single channel conductance than those activated by GABA_B, both types of channel are inhibited by thyrotropin-releasing hormone (TRH) which is an activator of PKC. In this report, we studied the distribution of PKC isoforms in cultured premotor respiratory neurons and determined how they were modulated by TRH, 5-HT₁₈, and GABA₈. Indirect immunofluorescence was used to detect labeling by antibodies specific for the α , β , γ , ε , δ , and λ isoforms of PKC $PKC(\alpha)$ was localized in the cytoplasmic membranes of unstimulated neurons suggesting that it was endogenously active. $PKC(\gamma)$, $PKC(\delta)$, and $PKC(\lambda)$ were diffusely distributed throughout the cytoplasm suggesting that they were inactive. No staining for PKC(β) or PKC(ϵ) was detected. Preincubation with TRH altered the distribution of PKC(δ) and PKC(δ). PKC(δ) translocated to the nuclear membrane while PKC(δ) translocated to the cytoplasmic membrane. Preincubation with CGS-12066B, a 5-HT_{1B} agonist, decreased membrane. Preincubation with CGS-12066B, a 5-H $_{18}$ agonist, decreased PKC(α) in the cytoplasmic membrane. Exposure to baclofen, a GABA $_{18}$ agonist, did not alter the distribution of any PKC isoforms. These data suggest that translocation of PKC(λ) to the cytoplasmic membrane by TRH is involved in the inhibition of K $_{(OR)}$ channels. The decrease in endogenously active PKC(α) by 5-HT $_{18}$, but not GABA $_{18}$, further suggests that this PKC isoform may play a role in determining the single channel conductance of K $_{(OR)}$ channels. (Supported by NIH Grants HL54666, HL07467, and an AHA-NJ Affiliate Grant)

SEROTONIN 1B (5HT,8) RECEPTORS ARE COUPLED TO A BATINSENSITIVE OUTWARD RECTIFYING KT CHANNEL IN CULTURED PREMOTOR RESPIRATORY NEURONS OF THE NEONATAL RAT. P.G. Wagner* and M.S. Dekin Dept. of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ 08903.

Activation of 5-HT₁₉ receptors in the phrenic motor nucleus of the rat inhibits the release of L-glutamate from premotor respiratory neurons (Lindsay and Feldman, J. Physiol., 461:213, 1993). We have previously demonstrated the existence of a second messenger operated Ba** -insensitive outward rectifying K $^{\circ}$ channel ($K_{(OR)}$) in cultured premotor respiratory neurons from neonatal rats and suggested that this channel is involved in the regulation of neurotransmitter release (Wagner and Dekin, J. Neurophysiol., 69:286, 1993). heurotransmitter release (wagner and Dekin, J. Neurophysion., 59:266, 1993). In this study, we tested the hypothesis that $K_{(QR)}$ channels can be activated via $5HT_{1B}$ receptors. Using the single channel recording technique from cell attached patches we observed that bath application of 0.5 μ M CGS-12066B, a selective $5-HT_{1B}$ receptor agonist, activated $K_{(QR)}$ channels. Mean channel open time probability was typically > 50%. Current-Voltage (I-V) relationships were measured in 140 mM [K] $_{\odot}$ to zero the membrane potential ($V_{\rm m}$). When $V_{\rm m}$ was more negative than 0 mV, the I-V relationship displayed pronounced outward rectification. Neither Ba** nor Cs* had any affect on outward The single channel conductance, measured over the linear portion of the I-V relationship at V_m more positive than 0 mV, was 35 pS \pm 2.3 (n= 8). The reversal potential (E_i) was 0 mV with 140 mM K* in the pipette. When the pipette K* concentration was altered, E_i changed in accordance with the Nemst equation prediction for a K* channel. These data support the hypothesis that $K_{(OR)}$ channels are involved in the modulation of L-glutamate release from premotor respiratory neurons. LONG-TERM SYNAPTIC DEPRESSION IN NUCLEUS TRACTUS SOLITARIUS OF NMDAR1 KNOCKOUT MICE.

C.-S. Poon*, Z. Zhou, and J. Champagnat. Harvard-MIT Division of Health Sciences and Technology, M.I.T., Cambridge, MA 02139, USA and Institut Alfred Fessard, C.N.R.S., Gif-sur-Yvette, France.

Recent studies have shown that mutant mice whose NMDA receptors are genetically disrupted suffer from certain developmental abnormalities in the brainstem and die within the first day of life. We have previously shown that neonatal mice with genetic knockout of the NMDAR1 subunits exhibit severe respiratory depression, although their CO₂ chemosensitivity remain largely intact (Poon et al., 1994, 1995). To investigate whether the respiratory depression was caused by abnormalities in the respiratory controller, we used an in-vitro brainstem slice preparation to study synaptic transmissibility in the nucleus tractus solitarius (NTS) of normal and mutant mice at postnatal day 0. Synaptic strength of NTS neurons was assessed by measuring the postsynaptic excitatory responses using either whole-cell recordings or extracellular field potentials elicited by electrical impulse stimulation of afferent fibers in the tractus solitarius Inhibitory responses via GABA, receptors were eliminated by bath application of bicuculline (20 µM). Low-frequency stimulation (LFS; 5 Hz for 5 min) of TS resulted in long-term depression (LTD) of synaptic transmission of the mutant cells (7 out of 10 cells) lasting > 30 min, but had no effect on any of the normal cells (n = 7). Application of D-APV (50 μ M) had no effect on the response of normal cells to LFS (n = 2). Thus, genetic disruption of NMDA receptor activity may trigger a form of LTD that is absent in normal cells even after acute blockade of NMDA activity. Such LTD in the NTS offers a possible central mechanism for the respiratory depression in NMDAR1 knockout mice. (Supported by ONR grant N00014-95-0414 and NIH grant HL50641)

MULTIPLE NEUROTRANSMITTERS EMPLOY PROTEIN KINASE A (PKA) TO MODULATE OUTWARD RECTIFYING K* CHANNELS IN CULTURED PREMOTOR RESPIRATORY NEURONS. M.S. Dekin* and P.G. Wagner Dept. of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ 08903

The serotonin type 1B (5HT₁₈) receptor agonist CGS-12066B activates a Ba**-insensitive outward rectifying K* channel (K_(oR)) in cultured premotor respiratory neurons (see Wagner and Dekin, Soc. Neurosci. Abstr., this volume). $K_{(08)}$ channels are also activated by γ -aminobutyric acid acting at its β receptor (GABA_B) and inhibited by thyrotropin-releasing hormone (TRH) (Wagner et al., Soc. Neurosci. Abstr., 19(2):1194, 1994). In this study, we tested the hypothesis that all three neurotransmitters modulate $K_{(oB)}$ channels through PKA. Single channel recordings (cell-attached configuration) were made from cultured neurons obtained from neonatal rats. Baclofen, a selective GABA $_{\rm B}$ agonist, activated ${\rm K}_{\rm lost}$, channels with a variable conductance (γ) ranging from 90-200 pS and a mean open time probability (${\rm nP}_{\rm c}$) activated channels had a lower γ and showed much less variability (30 to 40 pS). 5-HT_{IB} channels also had a higher nP_{\odot} (550%). TRH decreased nP_{\odot} in both types of channel to <2% but had no effect on γ . Rpthe classed Π_{P_0} in both types of channel to $\sim 2\sigma$ but that the effect of γ . Appendix of the baclofen activated channel to over 50% and reduced γ to a value comparable to that of the 5-HT₁₈ channel (36.3 pS±2.1, n=10). Rp-cAMP had no effect on either n $P_{\rm O}$ or γ of the 5HT₁₈ activated channel. Rp-cAMP did, however, protect both channel types from inhibition by TRH. These data demonstrate that GABA₈, 5-HT₁₈. and TRH converge on PKA to modulate $K_{(OR)}$ channels. The differential effects of these neurotransmitters on nP_{\odot} and γ also indicates that PKA acts (directly or indirectly) at two distinct sites on the channel. (Supported by NIH Grant HL54666, an AHA-NJ Affiliate Grant, and the Parker B. Francis Foundation).

CALCIUM-CURRENTS IN NEURONS OF THE ISOLATED RESPIRATORY SYSTEM OF MICE. F.P. Elsen*, P. Telgkamp, J.M. Ramirez, D.W. Richter. Department of Physiology, University of Göttingen, 37073 Göttingen, FRG. The transverse medullary slice preparation of mice containing the pre-Bötzinger

complex (pBC) generates spontaneous respiratory rhythmic activity at different postnatal stages (P0-P25). During this time, changes occur in the motor pattern. network organization, responsiveness to neuromodulators and hypoxia (Funk et al 1994. J. Neurophys. 72: 2538: Ramirez et al. 1996. J. Physiol. 491: 799). To understand the underlying mechanisms, whole-cell patch clamp recordings were obtained from neurons within the pBC. Here, we concentrated on the characteristics. erization of calcium currents. isolated by intracellular CsCl [110mM] and TEA [30mM] and by extracellular TTX [1 μ M] (B). Different stimulation protocols and Isomal and by extracellular TTA [I][MY] (D). Different stitution protectors and the application of specific toxins revealed the presence of T- and P-type, as well as high voltage-activated N-type calcium currents. The amplitude of the steady state currents decreased during postnatal development which was most obvious for high-voltage steps from -70 to -10 mV, suggesting that these are developmental changes in the expression of high voltage activated calcium currents. These currents were modulated by the application of adrenaline [SpiM] which led to a reduction in peak (A) and steady state currents (C). Adrenaline also evoked a delayed tail current (C), which was blocked by cobalt [2mM] and ω-conotoxin GVIA [5μM]. Currently, we examine the consequences of these changes for respiratory rhythm generation.

GENERATION OF RESPIRATORY OSCILLATIONS AFTER DISRUPTION OF INHIBITORY NEUROTRANSMISSION DURING POSTNATAL DEVELOPMENT: IN VITRO AND IN VIVO STUDIES WITH MUTANT AND NORMAL MICE. J.C. Smith*, N. Koshiya, and E.S. Simon. Laboratory of Neural Control, NINDS, NIH, Bethesda, MD 20892.

We have proposed that respiratory rhythm in mammals is generated by a hybrid pacemaker-network in which excitatory interneurons with oscillatory bursting properties in the pre-Bötzinger complex (pre-BötC) form the kernel of the oscillator (Smith et al. Science 254, 1991). This model predicts that rhythm generation can occur without network-based inhibitory synaptic interactions. This has been confirmed for neonatal rats (PO-P7) from our in vitro studies with medullary slice preparations that generate respiratory rhythm (ibid.), but has only been partially tested later in postnatal development (Ramirez et al. J. Physiol. 491.3, 1996). We extended earlier work by analyzing the role of synaptic in the mutant mouse oscillator (Human Mol. Gen. 3: 2025, 1994), which has a mutation of the adult isoform of the alpha subunit of the glycine receptor (GlyR) that causes death by P23. This mutation is reported to result in a loss of GlyR function by -P15 when the developmental switch from a normal neonatal to the mutant adult alpha subunit is complete. result in a loss of GlyR function by ~P15 when the developmental switch from a normal neonatal to the mutant adult alpha subunit is complete. These mutants generate a stable breathing rhythm and normal pattern of phrenic motor discharge until death while disturbances, including tremor and rigidity, develop in other motor systems after P15. In in vitro studies, rhythmic activity of respiratory (XII) motoneurons and pre-BötC inspiratory neurons was maintained in slice preparations after simultaneous blockade in the respiratory network of glycine, GABAA and GABAB receptors by bath-application of pharmacological antagonists (up to 50 μ M strychnine, 100 μ M bicuculline, 1 mM hydroxysaclofen). These results are consistent with the hybrid pacemaker-network model.

EXPIRATORY (E-)NEURONS MEDIATE EXPIRATORY LENGTHENING IN A LUNG ATTACHED *IN VITRO* BRAINSTEM-SPINAL CORD PREPARATION. N.M. Mellen*, D.R. McCrimmon & J.L. Feldman. Depts. of Physiol. Sci. and Neurobiology, UCLA, Los Angeles, CA, 90095-1527 & Dept. of Physiology, Northwestern Univ. Med. Sch., Chicago IL, 60611-3008

Lung inflation during expiration activates slowly adapting pulmonary stretch receptors causing expiratory prolongation (Breuer-Hering reflex, B-H). We have used a preparation in which afferent vagal innervation is maintained between lungs and an otherwise isolated neon atal rat brainstem-spinal cord preparation (Murakoshi et al.; *Neurosci. Lett.* 62: 63, *85), to investigate cellular and synaptic mechanisms mediating this reflex. Lung inflation-induced changes in firing patterns of ventral medullary respiratory neurons were studied using extracellular electrodes. We inflated lungs with mock CSF. Inflation was triggered by inspiratory onset monitored at ventral roots C1-C4. Baseline lung pressure ranged between 0-2 cm H₃O and inflation-induced pressure change was 2-5 cmH₂O. We classified cells according to Smith *et al. (J. Neurophys.* 64:1149, '90). Lung inflation led to a sustained increase in activity of phase-spanning E cells and a matching decrease in activity of late-E cells. This enhanced firing or inhibition persisted until lung deflation, triggered by the next inspiratory phase. E-tonic cells were transiently inhibited by lung inflation, and I cells were either inhibited or showed no change in firing pattern. Non-respiratory cells were transiently inhibited or excited by lung inflation. We suggest that activation of phase spanning E neurons and inhibition of late-E neurons provides the mechanism for the expiratory lengthening associated with the Breuer-Hering reflex. This work was supported by NIH grants HL09234 and HL37941.

HYPOXIA ENHANCES PHRENIC NERVE ACTIVITY FOLLOWING DISINHIBITION OF NEURONS IN THE PRE-BÖTZINGER COMPLEX. <u>L.C.</u> Solomon*, N.H. Edelman, and J.A. Neubauer. Dept. of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ

Robert Wood Johnson Medical School, New Brunswick, NJ Recently, we have demonstrated that local hypoxia of neurons located in the pre-Bötzinger (pre-Böt) complex produces a gasp-like pattern in the phrenic neurogram (PN), suggesting that neurons in this region are hypoxia chemosensitive. Further, we have shown that GABA_A-mediated inhibition of neurons in this region plays a role in the suppression of gasping during eupnea, and that prior disinhibition of these neurons unmasks central hypoxia chemosensitivity in response to a hypoxic challenge induced systemically. The combined effect of hypoxic stimulation of this central hypoxia chemosensitive region and the peripheral chemoreceptors on PN output is unknown. We, therefore, examined the effects of hypoxia before and after blockade of GABA_A receptors in the pre-Böt complex in chloralose- or chloralose/urethaneanesthetized vagotomized, paralyzed, mechanically ventilated cats. Approximately 45-60 minutes after a control response to a hypoxic challenge (6-12% O₂ in N₂ for 3 min) was obtained, bicuculline methiodide (BIC; 4.5 mM; 42 nl) was microinjected, and 15-20 minutes later, the hypoxic challenge was repeated. Microinjection of BIC produced either a gasp-like (n=6) or augmented (n=1) pattern in the PN and decreased the frequency of phrenic activity. Before microinjection of BIC, hypoxia increased PN amplitude by 126% and elicited no change in the frequency of phrenic bursts. After microinjection of BIC, hypoxia similarly increased PN amplitude by 124%; however, hypoxia also increased the frequency of phrenic activity by 210%. Subsequent microinjection of sodium cyanide (1 mM; 21 nl) into 3 of these sites similarly increased the frequency of phrenic activity by 210%. Subsequent microinjection of sodium cyanide (1 mM; 21 nl) into 3 of these sites similarly increased the frequency of phrenic activity by 210%. Subsequent microinjection of sodium cyanide (1 mM; 21 nl) into 3 of these sites similarly increased the frequency of phrenic activity by 210%. Subseq

PHARMACOLOGICAL IDENTIFICATION OF GABA RECEPTORS IN THE PHRENIC MOTONUCLEUS OF RAT. H.N. Sapru* and V.C. Chitrayanshi, Departments of Neurosurgery & Pharmacology, New Jersey Medical School, Newark, NJ 07103.

GABAergic terminal arborizations have been reported to be present in the phrenic motonucleus (PMN). In this study phrenic nerve (PN) responses to activation of GABA receptors in the PMN were studied. Experiments were carried out in the adult male Wistar rats, anesthetized with urethane, bilaterally vagotomized, paralyzed and artificially ventilated. A pneumothorax was produced to eliminate movement artifact. All the dorsal and ventral rootlets from C₂-C₆, except those at C₃ segment, were sectioned so that the PN activity represented the output of C₃ phrenic motoneurons only. The PMN was identified by microinjecting (50 nl) of NMDA (5 mM) at C₃ segment; an increase in PN background discharge was observed. Muscimol (3 mM/50 nl) was microinjected into the same site. A decrease in the amplitude of spontaneous PN bursts was observed. Prior injections of bicuculline methiodide (2 mM/50 nl) into the PMN completely blocked the inhibitory effects of muscimol. The inhibitory effect of muscimol was also reversed by microinjections of bicuculline methiodide. Excitatory PN responses to peripheral chemoreceptor activation, by tracheal administration of 100% N₂ for 7 sec, were blocked by prior microinjections of muscimol into the PMN. These results suggest that activation of GABA_A receptors in the PMN results in inhibition of spontaneous PN bursts which is prevented as well as reversed by microinjections of bicuculline.

LUNG INFLATION-INDUCED EXPIRATORY LENGTHENING REQUIRES GABA, RECEPTOR ACTIVATION IN A LUNG ATTACHED *IN VITRO* BRAINSTEM-SPINAL CORD PREPARATION. <u>D.R. McCrimmon*, N.M. Mellen, & J.L. Feldman.</u> Dept. of Physiology, Northwestern Univ. Med. Sch., Chicago IL, 60611-3008 & Depts. of Physiological Science and Neurobiology, UCLA, Los Angeles, CA, 90095-1527

Using a modified neonate rat *in vitro* brainstem spinal cord preparation

Using a modified neonate rat *in vitro* brainstem spinal cord preparation in which lungs and their vagal innervation are preserved, and in which the Breuer-Hering reflex (B-H) can be elicited, we compared the effect of lung inflation on expiratory duration and discharge patterns of ventral medullary respiratory neurons before and after bath application of the GABA_A receptor antagonist, bicuculline (BIC, 5-20 µM). Lung inflation-induced changes in baseline firing patterns of these neurons are described in an accompanying abstract. Lungs were filled and inflated with mock CSF via a cannula inserted into the trachea. Inflation was delivered every 6-12 respiratory cycles, triggered by inspiratory onset monitored at a ventral root (C1-C4). Baseline lung pressure ranged between 0-2 cm H₂O and the change in pressure during inflation was 2-5 cm H₂O. Cells were recorded from extracellularly and classified according to Smith *et al.* (J. Neurophys. 64:1149, '90). BIC markedly and reversibly attenuated lung inflation-induced expiratory lengthening. Expiratory neurons excited by lung inflation under control conditions retained their response under BIC. In contrast, neurons inhibited by lung inflation during control cycles were no longer affected after BIC. These findings identify neurons affected by GABAergic inhibition which mediate the B-H reflex. This work was supported by NIH grants HL09234 and HL37941.

GABA, NEUROTRANSMISSION AND RESPIRATORY MOTOR OUTPUT IN THE BRAINSTEM + SPINAL CORD OF NEWBORN MICE. J. P. Farber. Univ. of Oklahoma HSC; Okla. City, OK 73190. Results of blocking GABA, neurotransmission on respiration-like

Results of blocking GABA_A neurotransmission on respiration-like motor output among in-vitro preparations have been variable. Small changes in respiratory timing are observed in the brainstem + spinal cord of the rat (Pflügers Arch. 417:425, 1990) while the tilted sagittal medullary slice preparation from the mouse shows substantial increases of the interburst interval (J. Physiol. 484:505, 1995). The present studies utilized brainstem + spinal cord from neonatal mice to evaluate effects of the GABA_A antagonist, bicuculline (bic), at 2-10 mM, on the motor output from either hypoglossal or C4 ventral roots. Preparations were superfused using carbogen-saturated ringers solution (K* = 5mM in most cases), with a flow of 4-5 ml/min, at 27-28°C. Newborns, at day 0, in a minority of instances showed relatively short interburst intervals (2-3 sec) which were approximately doubled by bic; motor burst duration was increased. More often, day 0 preparations were not rhythmic, but could be induced to burst with bic. In those instances, motor bursts were comparable to that observed in bic-treated animals which originally expressed a rapid rhythmic output. When treated with bic, preparations from older animals (day 2-3) having spontaneous rhythm showed decreases in interburst interval. Sometimes this response was transient. Changes in the motor bursts were generally minor. Both induction of rhythm and slowing of rhythm after bic could result from the relatively unrestrained influence of a pacemaker, but the original situations of rapid bursting as well as apnea suggest a substantial inhibitory input onto relevant neuronal circuitry. The relatively modest effects of bic occurring after day 0 may be a consequence of more impaired O₂ diffusion through a larger tissue mass. (Supported by HL37318).

CARBACHOL-INDUCED INHIBITION OF PHRENIC MOTONEURONS IS MEDIATED BY M, MUSCARINIC RECEPTORS. <u>V.C. Chitravanshi* and H.N. Sapru.</u> Departments of Neurosurgery & Pharmacology, New Jersey Medical School, Newark, NJ 07103.

Phrenic nerve (PN) responses to activation of cholinergic receptors in the phrenic motonucleus (PMN) were studied. Experiments were carried out in the adult male Wistar rats, anesthetized with urethane, bilaterally vagotomized, paralyzed and artificially ventilated. A pneumothorax was produced to eliminate movement artifact. All the dorsal and ventral rootlets from $C_2 \cdot C_6$, except those at C_3 segment, were sectioned so that only the output of C_3 phrenic motoneurons was represented in the PN activity. The PMN was identified by microinjecting (50 nl) of NMDA (5 mM) at C3 segment; an increase in PN background discharge was observed. Carbachol in different doses (25 nM -5 mM/50 nl) was microinjected into the same site. A dose-dependent decrease in the amplitude of spontaneous PN bursts was observed. This inhibition was not due to some non-specific local actions of carbachol because microinjections of NMDA into the PMN continued to elicit excitatory PN responses. Prior injections of pirenzepine (1 mM/50 nl), but not bicuculline methiodide (6 mM/50 nl) or strychnine (2 mM/50 nl), into the PMN completely blocked the inhibitory effects of carbachol. These results suggest that: (1) muscarinic cholinergic agonists inhibit phrenic motoneurons; this effect was unexpected considering that acetylcholine has been implicated as an excitatory transmitter in the central regulation of respiratory function, (2) the inhibitory effect of carbachol is mediated via M₁ muscarinic receptors, and (3) activation of GABA or glycine receptors does not contribute to the inhibitory effect of carbachol Support: NIH: HL24347 and AHA (NJ).

CORRELATION OF SYNAPTIC VESICLE MORPHOLOGY WITH AMINO ACID CONTENT OF INPUTS TO RAT PHRENIC MOTONEURONS Susan M. Murphy*1, Paul M. Pilowsky and Ida J. Llewellyn-Smith, Departments of Anatomy and Histology¹, and Medicine, Flinders Medical Centre, Bedford Park SA 5042, AUSTRALIA.

AUSTRÁLIA.

The amino acids glutamate (GLU) and γ-aminobutyric acid (GABA), are neurotransmitters in excitatory and inhibitory pathways, respectively, from bulbospinal respiratory neurons to phrenic motoneurons. Another amino acid, glycine (GLY), has not yet been shown to play a role in transmission to phrenic motoneurons, although GLY is involved in inhibitory control of other groups of spinal motoneurons. We retrogradely labelled phrenic motoneurons of spinal motoneurons. We retrogradely labelled phrenic motoneurons by injecting cholera toxin B subunit conjugated to HRP (CT-HRP) into the diaphragm, and used post-embedding immunogold labelling to identify nerve terminals containing GLU, GABA or GLY, that made synapses or direct contacts with CT-HRP-labelled phrenic motoneuron cell bodies or dendrites. We classified nerve terminals into two groups on the basis of the morphology of their synaptic vesicles. S terminals contained round synaptic vesicles. F terminals, contained mixtures of round and flattened synaptic vesicles. S terminals had higher levels of GLU (t=5.0, p<0.001; Wilcoxon two-sample test) and lower levels of GABA (t=4.7, p<0.001) than F terminals. GLY labelling was higher in F terminals than in S terminals (χ²=15.8, p<0.001; median test). These data demonstrate a strong correlation between synaptic vesicle morphology and neurotransmitter content in the inputs to phrenic motoneurons, suggesting that S terminals are excitatory, and F terminals are inhibitory. IN VITRO AND IN VIVO CHARACTERIZATION OF VENTROLATERAL PAG NEURONS PROJECTING TO RESPIRATORY NUCLEI. R. Pásaro*, S.P. Gaytán, and J. Ribas. Dept. of Animal Physiology and Biology, and Dept. of Medical Physiology and Biophysics. University of Sevilla, 41012-Sevilla, Spain.

The Periaqueductal Gray (PAG) is a highly complex structure involved in several autonomic functions. In this report, the PAG link with the Ventral Respiratory Group (VRG) was elucidated by means of electrophysiological identification of the VRG and simultaneous injection of a mixture of Fast Blue (FB) and Fluoro Ruby (FR) fluorochromes. These results showed four different populations of FBlabelled neurons within the PAG and moderate FR-labelled fibers and varicosities. From all of these populations of PAG neurons projecting to the VRG, the ventrolateral one was intracellular recorded in slice preparation. The membrane resting potential of these neurons ranged from 60 to 75 mV and controlled the type of electro-physiological response induced by the depolarizing pulses. The lower membrane potentials were related to tonic firing and the higher ones to burst firing of action potentials, the latter lacked calcium conductance. Furthermore, the ventrolateral PAG neurons were unsensitive to opioid receptor agonists. Supported by a CICYT PB94-1443 grant.

ANATOMICAL LOCALIZATION OF THE VENTRAL RESPIRATORY GROUP AND NUCLEUS AMBIGUUS IN THE NEONATAL RAT. H.H. Ellenberger*. Department of Anatomy & Neurobiology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

In vitro preparations of the neonatal rat have provided fundamental information about the cellular mechanisms underlying respiratory network function. However, the anatomical location of the medullary respiratory neuron populations in the neonatal rat has not been determined. Fluorescent retrograde tracers were utilized to identify the ventral respiratory group (VRG) and nucleus ambiguus (AMB) in the neonatal rat. Sprague-Dawley rats (day zero) were anesthetized with 20µl of 5% Innovar-Vet (I.P.) and received injections of 2% (20-60nl) Fluoro-Gold (FG) into the C4 spinal cord and/or applications of 1% Fast Blue (FB) to the cervical vagus nerve. After a 48 hr survival period, FG labelled bulbospinal neurons were identified within a densely packed column within the ventrolateral intermediate reticular nucleus from the level of the pyramidal decussation to the facial nucleus. This cell column corresponded closely to the location of the VRG of the adult rat. FG labelled neurons were also located in the medial reticular nuclei, raphe pallidus and obscurus, parapyramidal nucleus, and spinal vestibular nucleus. FB labelled vagal motoneurons were distributed throughout the dorsal motor nucleus of the vagus and AMB. Labelled VRG neurons overlapped with the external formation, and partially with the loose formation, but not with the semicompact or compact formation of AMB. These results indicate that the distribution and relative locations of bulbospinal VRG neurons and vagal motoneurons are similar in neonatal and adult rats.

IDENTIFICATION OF SEPARATE SITES RESPONSIBLE FOR GILL AND LUNG RESPIRATORY RHYTHMICITY IN THE IN ITALIAN BRAINSTEM PREPARATION OF THE BULLFROG TADPOLE, RANA CATESBEIANA. M.J. Gdovin*, C.S. Torgerson, and J.E. Remmers. Department of Medical Physiology, University of Calgary Faculty of Medicine, Calgary. Alberta, Canada, T2N 4N1.

We recently described an in vitro brainstem preparation of the bullfrog tadpole Rana catesbeiana in which we were able to distinguish between fictive gill and lung ventilatory activities in cranial nerve (CN) V, VII, and X neurograms (Torgerson et al., 1996). In addition, this in vitro brainstem preparation increased both fictive gill and lung ventilation in response to clevations in superfusate PCO2. The neural substrates responsible for central respiratory rhythm generation of gill and lung ventilation in the tadpole are We recorded efferent activities of CN V or VII, and X during changes in superfusate PCO2 before and after transection of the in vitro brainstem between CN VIII and IX. After transection, robust gill ventilation was recorded from CN X but was absent in CN V and VII neurograms. By contrast, this transection eliminated fictive lung bursts in CN X, while they persisted in CN V and VII. Moreover, the frequency response of lung bursts to increases in superfusate PCO₂, observed before transection, persisted in CN V and VII after transection. We conclude that the neural substrate required for fictive gill and lung ventilation exist in anatomically separate regions such that the gill central pattern generator (CPG) is located in the caudal medulla at the level of CN X, and the lung CPG is located more rostrally in the medulla at the level of CN VII (supported by grant MA-9719 from the MRC of Canada).

RESPIRATORY REGULATION: CHEMORECEPTION AND HYPOXIC RESPONSES

DIFFERENTIAL EXPRESSION OF HEME OXYGENASE ISOFORMS IN THE ROSTRAL VENTROLATERAL MEDULLA OF THE RAT. E Mazza*, S Thakker-Varia, M Zingariello, CA Tozzi, JA Neubauer. Departments of Medicine and Neuroscience and Cell Biology. UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ.

Neubauer. Departments of Medicine and Neuroscience and Cell Biology. UMDNI-Robert Wood Johnson Medical School, New Brunswick, NJ. Neurons in the rostral ventrolateral medulla (RVLM) are directly excited by hypoxia. However, the mechanism by which the RVLM senses changes in O₂ is unknown. Since heme oxygenase (HO) has been shown to be involved in O₂ sensing mechanisms in the carotid body and pulmonary artery, the goal of these studies was to determine if HO is present in the RVLM and whether the expression of HO is altered by chronic hypoxia. Two isoforms of HO have been described; HO-1 which is inducible and HO-2 which is constitutive. To determine whether HO-1 and HO-2 are expressed in the RVLM and whether this expression is altered by chronic hypoxia, RT-PCR was used to measure mRNA in RVLM, cerebellum and whole brain. Sprague-Dawley rats were exposed to hypoxia (10% O₂) for 10 days while corresponding age matched controls were maintained in normoxia (21% O₂). RT-PCR demonstrated expression of HO-2 mRNA in RVLM, cerebellum, and whole brain in both control and hypoxic samples. However, hypoxia induced expression of HO-1 mRNA in RVLM but not in cerebellum or whole brain. In addition, HO-2 was immunocytochemically localized in brain sections (40 μm). HO-2 immunoreactive staining was seen in RVLM, central gray, inferior olivary nucleus, cerebellum, and pontine nuclei. Together, these results indicate that HO-2 is present in the RVLM during chronic hypoxia. We conclude that HO 1 is induced in the RVLM suggesting that it may be important for the O₂ sensing function of this medullary region. THE CO₂ SENSITIVE RESPIRATORY CHEMORECEPTION REGION IN THE ROSTRAL VENTROLATERAL MEDULLA (VLM) IDENTIFIED BY A CO. DIFFLISION PIPETTE

<u>Aihua Li and Eugene E. Nattie.*</u> Department of Physiology, Dartmouth Medical School, Lebanon, NH 03756-0001

In anesthetized rats and cats, work from this lab has demonstrated that central chemoreception is located in many brainstem sites. These include the region of the VLM, at previously identified central chemoreceptor areas, and the regions of the nucleus tractus solitarius, the locus ceruleus, the midline raphe, and the ventral respiratory group. This localization was achieved by one nl injections of the carbonic anhydrase inhibitor, acetazolamide, which result in a focal tissue acidosis limited to 350 µm from the injection center and a significant increase in integrated phrenic nerve amplitude (PNA). These responses last up to 90 min making it difficult to test mechanistic or integrative hypotheses. In this study, we examine the tissue pH and PNA responses following a focal acidosis in the rostral VLM produced by a $\rm CO_2$ diffusion pipette. No tissue injection is made. Instead, a $\rm CO_2$ enriched solution perfused through an inner barrel exits via an outside barrel. The [CO2] at the pipette tip (outside barrel) is constantly renewed allowing diffusion into the tissue. A second attached barrel measures pH at the tip and a separate electrode measures pH at some distance from the tip. In group one (CO₂ diffusion; N=19), 15 of 19 one min diffusion periods resulted in a significant increase in PNA and a significant decrease in tissue pH. The peak pH change at the pipette tip was at 1 min and peak PNA and distal pH change were at about 2 min. PNA and distal pH returned to baseline in about 5 min; pipette tip pH in about 15 min. In group two (control; N=5), use of a non-CO2 solution in the diffusion pipette did not result in any significant change in PNA or pH. This type of diffusion pipette allows study of chemoreceptor induced responses to short periods of focal acidosis in vivo. (Supported by HL 28066).

Effect on breathing of ejecting excitatory amino acid (EAA) receptor agonists on the ventrolateral medullary (VLM) surface of awake goats. H.V. Forster*, T.F. Lowry, L.G. Pan, T. Feroah, A. Whaley, and M.M. Forster. Physiol., Med. Col. Wis., Phy. T. Marquette U., and Zablocki VA Med. Ctr. Milwaukee, WI 53226

In 5 adult goats, 3-4 guide tubes were chronically implanted bilaterally on the VLM about 2 mm caudal to CN VI where cooling While awake 3 to 8 days after under anesthesia caused apnea. surgery, N-methyl-D-aspartic acid (NMDA) or α -amino-3-hydroxy-5-Methyl-4-isoxazolepropionic acid (AMPA) were ejected on the VLM surface. In 4 goats, a single 1 or 10 ul ejection of 250 or 500 mM NMDA increased pulmonary ventilation 100-300% and decreased PaCO₂ 15 mmHg. In 3 goats, the onset, peak and duration of the responses were 2, 10, and 30 minutes after ejection respectively. In the 4th goat, the onset was 5 minutes after ejection and the hyperpnea was sustained for 60 minutes. For most goats, the response was elicited at only 1 guide tube. NMDA did not stimulate breathing when a NMDA antagonist was ejected 15 minutes before NMDA ejection. In a 5th goat, NMDA ejection did not change breathing but AMPA (40 uM) ejection elicited a transient hyperpnea and hypocapnia. AMPA elicited a hyperpnea in only one other goat, but it was delayed and progressive over an hour, eventually resulting in apneustic breathing and terminal apnea. These data suggest a rather discrete population of EAA receptors near this VLM surface which affect breathing and it appears there is a predominance of the NMDA receptor subtype. (Support: NIH25739 and Veterans Administration).

EFFECTS OF CARBONIC ANHYDRASE INHIBITION ON INTRACELLULAR pH IN NTS NEURONS. <u>1.S. Erlichman and J.B. Dean</u>, Department of Physiology & Biophysics, Wright State University, Dayton, OH 45435.

Carbonic anhydrase (CA) catalyzes the reversible hydration of CO₂ and is noncompetitively inhibited by acetazolamide (AZ). It has been hypothesized that CA is involved in CO₂ chemoreception, specifically, in sensing rapid changes in CO₂. It is known that CA inhibition decreases both extracellular buffering power and pH (pHo), however its effects on intracellular pH (pHi) have not been studied. Here we describe the effects of AZ on pHi recorded from neurons located in the nucleus tractus solitarius (NTS), which has been identified as a site of CO₂/H⁺-sensitivity and contains -1/3 chemosensitive neurons. pHi was measured in 200 μm thick slices (P1-13 rat) loaded with the fluorescent pH-sensitive dye, 2'7'-bis-(2-carboxyethyl)-5,6-carboxyfluorescein (BCECF). AZ treatment (10 μ M) had no effect on steady state pHi during normocapnia (5% CO₂), but resulted in a greater acidification of pHi (~0.1 pH unit) during hypercapnic acidosis (10% CO₂) compared to control conditions. In addition, the rate of acidification following exposure to hypercapnic acidosis in 65% of the cells was unaffected by AZ (control: -0.43 ± 0.02 pH unit/min, $r^2 = 0.82$ vs. AZ: -0.37 ± 0.02 , $r^2 = 0.71$). However, 35% of the cells exhibited a decreased rate of AZ: 0.37 ± 0.02 , r = 0.71). However, 35% of the cere exhibited a decreased rate of actidification during exposure to AZ and hypercapnic acidosis (control: -0.43 ± 0.02 pH unit/min, $r^2 = 0.87$ vs. AZ: -0.24 ± 0.02 , $r^2 = 0.86$). In contrast, the rate of increase in pHi following the return to normocapnia was similar in all cells (control: 0.30 ± 0.01 pH unit/min, $r^2 = 0.73$ vs. AZ: 0.30 ± 0.03 , $r^2 = 0.74$). We conclude that inhibitions of the control of the contr tion of CA slows the initial rate of CO2-induced intracellular acidification, suggesting that ~1/3 of the neurons in NTS contain CA. However, since AZ has been reported to decrease pHo, and pHi regulation in NTS neurons is inhibited by decreased pHo, the larger steady state acidification in the presence of AZ and 10% CO2 may be due to inhibition of extracellular and/or glial CA. We are currently investigating the effects of AZ on pHo (NIH HL46308).

EFFECTS OF CYANIDE APPLIED TO THE CAUDAL VENTROLATERAL MEDULLARY SURFACE (CVMS) ON RESPIRATION AND BRAINSTEM C-FOS EXPRESSION. Douglas, R.M.*, Trouth, C.O., James, S.D., Sexcius, L.M., Cheatham, J.G., Johnson, S.M., and Reynolds, M. Department of Physiology and Biophysics, Howard University College of Medicine, Washington, D.C. 20059.

The caudal ventrolateral medullary surface (cVMS) has been implicated in respiratory and cardiovascular chemosensory control mechanisms. The unilateral, topical application of CN- (20mg/ml) to the cVMS induces a transient apnea that can be ameliorated by artificial ventilation. Perfusion of the CN- lesioned animal 2 hr post application reveals the immunocytochemical expression of the c-fos protein bilaterally along the VMS, in the nucleus tractus solitarius, in the A1/C1 areas bilaterally, the midline raphe pallidus, in the dorsolateral pons and other subcortical regions. These results suggest that the cVMS may be involved in the cardiorespiratory responses to hypoxia. (Support: Grant # N00014-94-1-0523)

628.4

MEMBRANE PROPERTIES OF CHEMOSENSITIVE NEURONS IN THE SOLITARY COMPLEX (SC) IN YOUNG RATS. R.-Q. Huang* and J.B. Dean. Department of Physiology & Biophysics, Wright State University, Dayton, OH 45435. The immature rat, postnatal day (P) \leq 21, is used extensively in studies of central

chemosensitivity. However, neural development during the first 3 weeks may change membrane properties, anatomical coupling and chemosensitivity of neurons in the SC (= n. tractus solitarius & dorsal motor n.). The present study employed the rapid perforated-patch recording technique in medullary slices (120-350µm) to determine the effects of age (P0-20) on: responses to hypercapnic acidosis (5 to 10-15% CO₂ 22-25°C), membrane properties, and coupling. Once the effects of age were identified, the relationship between chemosensitivity and membrane properties was determined. Neurons were visualized for recording using infrared-Hoffman modulation contrast video microscopy. There was no relationship between age (P0-20) vs.: action potential amplitude, resting membrane potential and input resistance. Likewise, coupling between CO₂/H*-neurons in SC was unrelated to age (coupled, P8.9 vs. noncoupled, P8.3). During hypercapnic acidosis (n = 151), 35% of SC neurons were excited, 25% inhibited, and 40% insensitive. Type I repetitive firing properties (Dekin et al., 1987) occurred in younger rats (P6.2) compared to Type II (P9.0). Further, CO₂/H²-inhibited neurons were more common in younger rats (P6.2) compared to excited (P8.3) and insensitive neurons (P8.7). CO₂/H⁺-excited neurons were either Type I or II, whereas inhibited and insensitive neurons were Type I, II or III. No other differences in membrane properties were found among SC neurons based on their response to $\mathrm{CO}_2/\mathrm{H}^+$. Coupling did not occur in $\mathrm{CO}_2/\mathrm{H}^+$ -inhibited neurons and only rarely in insensitive neurons. We conclude that $\mathrm{CO}_2/\mathrm{H}^+$ excitation, most membrane properties, and coupling do not correlate with development during P0-20 in SC neurons. However, CO₂/H*-inhibited, Type I neurons are more common during the first week. Finally, CO₂/H*-excited neurons in SC are either Type I or II, but not Type III. (supported by NIH HL 46308).

628.6

COMPARING INTRACELLULAR pH REGULATION OF NEURONS IN CHEMOSENSITIVE AND NON-CHEMOSENSITIVE AREAS OF THE MEDULLA. N.A. Ritucci, J.B. Dean* and R.W. Putnam. Department of Physiology & Biophysics, Wright State University, Dayton, OH 45435.

Central chemoreceptors are thought to modulate respiration by monitoring the level of CO₂ in the blood and making synaptic connections with respiratory neurons tha regulate respiration. The response of these chemoreceptors is believed to be mediated by CO2-induced changes of intracellular pH (pHi). If so, the manner in which they respond to changes in pH, should be different than that of non-chemoreceptors. The present study tests this hypothesis by investigating whether neurons in a chemosensitive area (nucleus tractus solitarius; NTS) respond to pH_i changes differently than neurons in a non-chemosensitive area (inferior olive; IO) at 37°C. We found that pH_i recovery from hypercapnic acidosis at constant pH_o in NTS neurons is 96% inhibited by 100 µM 5-(N-ethyl-N-isopropyl)-amiloride (EIPA) but unaffected by 0.5 mM 4,4'-diisothiocyanato-stilbene-2,2'-disulfonic acid (DIDS). The rate of pH_i recovery from hypercapnic acidosis at constant [HCO₃]_o in IO neurons, however, is inhibited 33% by 0.5 mM DIDS but only 67% by 100 μ M EIPA. We also found that pH, recovery from acidification with NH4Cl prepulses in NTS neurons is completely inhibited by 100 μM EIPA but unaffected by 0.5 mM DIDS. Further, the rate of $pH_{\rm i}$ recovery from acidification with NH₄Cl prepulses in IO neurons is inhibited 24% by 0.5 mM DIDS but only 58% by 100 µM EIPA. The intrinsic buffering power of NTS and IO neurons were calculated to be 23 mM/pH unit and 7 mM/pH unit, respectively. These data indicate that pH, recovery in response to an acidification in NTS neurons is mediated solely by Na^*/H^* exchange but that pH, recovery in response to an acidification in IO neurons is mediated by both Na+/H+ exchange and HCO3dependent transport. MORPHOLOGY OF THE RETROTRAPEZOID NUCLEUS RETROGRADELY LABELED BY HORSERADISH PEROXIDASE IN ADULT CATS. S. Sheng. G. Song ¹, and L. Xin* ². Dept. of Pharmacology and Physiology ¹, Pre-Clinical Medicine Division, Shandong Med. Univ., Jinan, Shandong 250012 P. R. China. ² Dept. of Pharmacology, Temple Univ. Sch. of Med., Philadelphia, PA 19140.

The morphology of the retrotrapezoid nucleus (RTN) in the ventrolateral medulla in adult cats was investigated with retrograde cell labeling techniques. The experiment was performed on 12 cats weighing 2.3-2.8 kg. Following extracellular recording of the multiunits expiratory discharges in the Bötzinger complex (Böt.c) in the vicinity of the retrofacial nucleus, 30 nl. of 5% wheat germ agglutininconjugated horseradish peroxidase (WGA-HRP) was injected into the center of the neuronal activity. The injected WGA-HRP successfully labeled a group of neurons in the RTN. On crosscut sections, three layers of neurons were identified with detailed observation. The near surface layer was about 20 μ m below the ventral surface and two types of neurons were observed: vertically arranged spindle-shaped neurons (10x20 μ m) with dendrite projecting toward and even touching the ventral surface, round or triangle neurons (15 μ m) near or touching the ventral surface. The middle layer was filled with large amount of horizontally arranged small ovoid and spindle-shaped neurons (15x30 μ m). About 80% of the neurons in the RTN clustered in this layer. The inner layer was composed of large multipolar neurons (20-40 μ m). The total thickness of the three layers was around 800 μ m. The morphological characteristics of the RTN revealed in this study were consistent with those proposed for central chemoreceptor. This suggested that the RTN is involved in central chemoreception and respiratory control.

INCREASED TEMPERATURE AUGMENTS CENTRAL CO2-RA. Johnson, and G.S. Mitchell. Dept. of Comparative Biosciences, School of Veterinary Medicine, Univ. of Wisconsin, Madison, WI 53706.

In rentiles, increased temperature augments the ventilatory response to changes in arterial CO₂ (Q₁₀ ~ 2), but the relative effects of temperature on central versus peripheral CO₂-sensitivity are not known. Thus, we tested the effects of CO₂ on respiratory rhythm at two levels of temperature in an isolated turtle brainstem in vitro. Adult turtles (Chrysemys picta) were anesthetized with halothane and cardioperfused with oxygenated ice-cold HEPES and bicarbonate buffer. The brainstem between spinal segment C1 and the optic lobes was isolated and superfused with buffer; suction electrodes were attached to hypoglossal nerve roots. Respiratorywith ounter, studied reterious were anatomic to hypogossan have colors. Respiratory related discharge was highly variable, occurring in single bursts or episodes of two or more bursts. To test for acute effects of increased temperature, bath temperature was increased from 22.8±0.8°C (mean±5.D.) to 31.0±1.2°C at 5% CO₂ (n=3; pH increased from 7.39±0.03 to 7.58±0.04). Burst duration decreased ~35%, but there were variable effects on burst amplitude and frequency. In separate groups of turtles, CO₂ was varied between 1-9% at either low $(21-23^{\circ}\text{C}, n=7)$ or high temperature $(30-23^{\circ}\text{C}, n=7)$ 23°C, n=10). At both temperatures, disharge was abolished at pH≥8.00. With decreasing pH between 7.40-8.00, episode frequency increased progressively to maxima of 0.45/min (slope=-0.85±0.42 episodes/min/pH unit) and 0.59/min (slope=-2.04±1.51, P≥0.05) at low and high temperature respectively. At pH<7.40, (Stope=2.0411.51, F20.03) at low and ingine imperature respectively. As pris-3 frequency was unchanged or decreased slightly. Amplitude was not greatly altered by changes in pH. These preliminary results indicate that: (i) acute increases in temperature alter respiratory pattern formation (ie. shorter burst duration), (ii) burst frequency in the *in vitro* turtle brainstem increases as pH decreases in the range of 7.40-8.00, and (iii) increased temperature increases this CO₂/pH sensitivity. central chemoreceptors may contribute to the increased hypercapnic ventilatory response at increased temperature in reptiles, although it is not likely to account for the entire effect. MECHANISMS OF RAT VENTROMEDIAL MEDULLARY NEURONS SENSITIVE TO

MECHANISMS OF RAT VENTROMEDIAL MEDULLARY NEURONS SENSITIVE TO ACIDOSIS. G.B. Richerson* and W. Wang. Neurology, and Cellular & Molecular Physiology, VAMC & Yale University, West Haven, CT, 06516.

Pacemaker neurons of the rat medullary raphe are highly sensitive to respiratory acidosis in brain slices (J. Neurophysiol, 73:933, 1995). We have used cultured neurons microdissected from this region to examine the mechanisms of this response. Cultures included the medullary raphe and immediately surrounding structures (VMM), and excluded neurons from the ventrolateral and dorsal medulla. Using perforated patch-clamp recordings, cultured neurons displayed baseline firing recording striller to these remined to sent in the proposed of the proposed proporties similar to those previously seen in brain slices. Changes in CO₂ between 3% and 9% with constant HCO₃ (respiratory acidosis) resulted in large changes in firing rate in a subgroup of neurons in solutions blocking chemical synaptic transmission. In neurons sensitive to respiratory acidosis, changes in pH induced by changes in [HCO₃] at constant PCO₂ (5%) (metabolic acidosis) resulted in a similar response (n=5). In some neurons, whole-cell conductance (G_{in}) was measured in voltage clamp using -10 mV hyperpolarizing steps from a holding potential of -60 mV. Neurons from the hippocampus (n = 4) without a change in firing rate in response to acidosis had no change in ($G_{\rm in}$). In most VMM neurons tested with a change in firing rate in response to acidosis, there was also no change in $G_{\rm in}$ in response to acidosis. However, in some neurons stimulated by acidosis, there was a large decrease in net outward current due to a decrease in G_m . We propose that in those neurons sensitive to acidosis without a change in Gin, the currents affected by pH are voltage- and/or time-dependent, and are inactive in the steady state at a holding potential of -60 mV. In order to more quantitatively characterize these currents it will be necessary to use protocols which isolate individual currents, rather than examining resting whole-cell conductance or using ramp protocols. These results also demonstrate unequivocally that the VMM contains all of the elements required for chemosensitivity at the cellular level. Neurons of the medullary raphe project to many functional systems known to be sensitive to acidosis. By responding to changes in pH, raphe neurons could in turn modulate these other systems in response to changes in blood CO₂. (Supported by VAMC, and NIH HL52539).

CHOLINERGIC FINDINGS PERTINENT TO CAROTID BODY (cb) NEURAL ACTIVITY. R.S. Fitzgerald, M. Shirahata*, Y. Ishizawa, B. Schofield, Department of al Health Sciences, The Johns Hopkins Medical Institutions, Baltimore, MD 21205

We have designed several sets of experiments to test the possibility that acetylcholine (ACh) is an excitatory neurotransmitter during the chemotransduction of hypoxia in the carotid body (cb) of the anesthetized cat. Experiments A measured the release of ACh from the in vitro cb with HPLC. Experiments B₁ altered the release of ACh from a postulated "presynaptic" component of the "synapse" (the glomus cell [GC]), and B₂ blocked cholinergic receptors postulated to be on the "postsynaptic" site (neuron apposed to the GC) during a selective perfuson of the cb in situ with pharmacological Experiments C identified cholinergic receptors in the cb with immunocytochemcal technique

(A) Under control conditions the 2 cbs released 316 fmoles/4min, under 0-4, 4-8, 8-12 min of hypoxic/hypercapnic stimulation the 2 cbs released 831, 853, and 1029 fmoles of ACh respectively. (B₁) After 4 min of perfusion with hypoxic Krebs Ringer bicarbonate (KRB) containing 30µM hemicholinium (blocks uptake of choline by GC) cb neural activity was reduced to $\sim\!65\%$ of the control response. (B2) Both atropine and mecamylamine reduced the cb neural response to hypoxic KRB in a dose-related irenzepine (M1 muscarinic receptor blocker) decreased the response to hypoxic KRB, gallamine and AFDX116 (M2 muscarinic receptor blockers) augmented the response to hypoxic KRB. (C) The α4 subunit of the neuronal nicotinic receptor has been identified on GCs in culture and on tissue sections of the cb; cell bodies and nerve fibers in the petrosal ganglion also stain positive for the $\alpha 4$ subunit. These data support an excitatory role for ACh in the cb chemotransduction of hypoxia. nisms and interplay of neurotransmitters remain to be identified Supported by HL 50712.

DEVELOPMENT OF CENTRAL CHEMORECEPTION IN AN IN VITRO BRAINSTEM PREPARATION OF LARVAL RANA CATESBEIANA DURING FICTIVE GILL AND LUNG VENTILATION. C.S. Torgerson, M.J. Gdovin, and J.E. Remmers* Department of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.

The in vitro brainstem of the bullfrog tadpole Rana catesbeiana displays "fietive" gill and lung ventilations. In decerebrate, spontaneously breathing tadpoles, coordinated rhythmic bursting activities in cranial nerves V, VII, and X are temporally linked to fluctuations in buccal and lung pressures and to EMG bursts in the buccal levator (H3a) (Gdovin et al, 1996). PO2 depth profile measurements in completely isolated stage 19 (Taylor-Kollros) brainstems in vitro, superfused with control mock CSF (pH = 7.8, PO₂ = 598 Torr, PCO₂ = 17, at 23 °C), showed PO2 gradients of about 25 Torr/100 µm below the ventral surface, with a minimum PO2 of 217 Torr at 800 µm. The brainstem of stage III-IX tadpoles in vitro displayed fictive gill ventilation with infrequent lung bursts occurring at irregular intervals. Stages X-XIX maintained fictive gill ventilation, and the frequency of fictive lung ventilation gradually increased with maturation. Stages XX-XXV displayed a predominance of fictive lung burst activity. The amplitude of gill ventilation in all stage tadpoles increased with reductions in pH (7.8-7.4) (produced by raising the [CO₂] in the superfusate) and decreased with pH clevation (7.8-8.4), a response that was progressively augmented throughout development. Similarly, the frequency of fictive lung ventilation increased with pH reductions (7.8-7.4) in all stages, but this response was particular striking for stages XX-XXV. We conclude that the nH of the superfusate bathing the tadpole brainstem has a developmentally dependent influence on both fictive gill and lung ventilation, demonstrating the ontogeny of central respiratory chemoreceptive drive in the amphibian. (Supported by MRC grant MA-9719).

RAT VENTROMEDIAL MEDULLARY NEURONS SENSITIVE TO ACIDOSIS ARE BULBOSPINAL. W. Wang* and G.B. Richerson. Dept. of Neurology, VAMC &

Yale University, West Haven, CT, 06516.

Pacemaker neurons from the rat medullary raphe are highly sensitive to respiratory acidosis in brain slices (J. Neurophysiol., 73:933, 1995). We have used nanoinjections of fluorescent latex microspheres centered in the phrenic motor nucleus (PMN) to determine which of these neurons were bulbospinal (Wagner & Dekin, J. Neurophysiol, 69:286, 1993). Neonatal rats (P0-P1) were anesthetized, and rhodamine beads were injected into the region of the phrenic motor nucleus using stereotactic technique. 1-2 days later the medullary raphe and immediately surrounding structures were microdissected from the ventrolateral and other portions of the medulla. Primary dissociated glial-neuronal cultures were prepared and maintained for 10-35 days. All injection sites were visualized to verify their location and size. Perforated patch-clamp recordings were made in Ringer solution with either blockers of GABA and glutamate receptors, or high magnesium (10-20 mM), and low calcium (0.5 mM). In both solutions, increases in CO₂ between 3% and 9% at constant [HCO₃] (respiratory acidosis) resulted in an increase in firing rate in a at constant [PrCO3] (respiratory actions); resident in an increase in firing rate in a subgroup of neurons, a decrease in firing rate in another subgroup, and no change in a third subgroup. Neurons labelled with dye were more likely to be either stimulated or inhibited by respiratory acidosis (n = 16 of 18) than those which were not filled (n = 2 of 8), were from animals that were not injected (n=2 of 7), or were cultured from the hippocampus (n = 0 of 7). These results suggest that chemosensitivity is not a nonspecific response, but is a specialization of neuroanatomically specific subtypes nonspecific response, but is a specialization of neuroanatomically specific suorypes of neurons. It has previously been shown by neuroanatomical and electrophysiologic techniques that there is a major projection by neurons of the medullary raphe to phrenic motor neurons. Our results strongly suggest that raphe neurons that project to the phrenic motor nucleus are chemosensitive. Since the phrenic nerve is the major output pathway for respiration, projections to the phrenic motor nucleus would enable chemosensitive raphe neurons to strongly modulate respiratory output in servence to change in blood CO. (Supported by VAMC and NIH HI S5330) in response to changes in blood CO2. (Supported by VAMC, and NIH HL52539).

CHANGES IN PROTEIN EXPRESSION OF CULTURED CAT CAROTID BODY CELLS. Y. Ishizawa*, M. Shirahata, R.S. Fitzgerald, B. Schofield, Department of Environmental Health Sciences, The Johns Hopkins Medical Institutions, Baltimore, Maryland 21205 Freshly dissociated or cultured carotid body (CB) cells have been frequently

used to study cellular mechanisms of chemotransduction.

A frequently encountered problem in using primarily cultured cells is that the ses involved in dissociation and culturing, as well as culture conditions, may affect basic functions of the cells. The purpose of the present study was to examine the changes in the expression of several proteins in glomus and sheath cells in the CB during two weeks of culture. The expression of the same proteins was also examined in tissue sections of the CB.

We cultured the CB cells from adult cats in serum-free chemically defined We cultured the CB cells from adult cats in serum-ree chemically defined medium. Standard immunocytochemical techniques were applied using monoclonal antibodies against the following proteins; tyrosine hydroxylase (TH), neuron specific enolase (NSE), glial fibrillary acidic protein (GFAP), and neurofilament 160kD (NF). TH, NSE, and GFAP have been observed throughout the two weeks of culture. However, staining for TH and NSE in glomus cells was weak on day 1 compared with the staining later in the period, suggesting dissociation and culturing processes may affect basic protein expression in glomus cells over the initial few days in culture. The stains for GFAP in sheath cells did not seem to change during the culture period. In GFAP in sheath cells did not seem to change during the culture period. was in sheath cells. NF has not been detected in glomus cells and GFAP was in sheath cells. NF has not been detected in glomus cells in culture, or in tissue sections. Although the basic phenotypes for these proteins do not seem to change under these culture conditions, the present results suggest that some functional changes may occur in culture, and that glomus cells might be susceptible to the culturing procedures. Supported by HL47044 and HL50712. tissue sections both TH and NSE were expressed in glomus cells and GFAP

CHEMORECEPTOR RESPONSES OF THE SWINE CAROTID BODY Ayuko Igarashi*, Robert S. Fitzgerald, and Machiko Shirahata. Department of Environmental Health Sciences, The Johns Hopkins Medical Institutions, Baltimore, MD 21205

The swine has been used as an animal model for the sudden infant death syndrome and the sleep apnea. Although the carotid body seems to be involved in the development of these conditions, little is known about neurophysiology of the swine carotid body. The purpose of this study was to obtain basic information as to the effects of natural and pharmacological stimuli on carotid chemoreceptor neural activity (CCNA) of the swine. In vitro studies: Carotid bodies obtained from 3to 4-month-old swine were perfused with modified Krebs solution at a rate of 6 ml/min at 35±0.5 °C. CCNA was recorded from whole carotid sinus nerve with bipolar silver-silver chloride electrodes. interruption, hypoxia (PO₂=30torr), nicotine (1-10 µg), and cyanide (1- $10 \mu g$) increased CCNA significantly. Hypercapnia tended to increase CCNA. Elevation of PCO 2 augmented the hypoxic response. In vivo studies: CCNA and ventilation were recorded in the anesthetized 3month-old swine. Responses of CCNA were similar to those observed in vitro. Under condition of poikilocapnic hypoxia, ventilation was initially stimulated, but subsequently depressed. The addition of CO2 to the hypoxic inspirate attenuated the hypoxic depression of ventilation. Supported by HL52652, HL50712 and HL47044

RESPIRATORY AND BRAINSTEM NEUROCHEMICAL RESPONSES TO REPEATED VS ACUTE HYPOXIA IN PIGLETS. I.R. Moss*, K.A. Waters, A. Laferrière, J. Paquette and C. Goodyer. Developmental Respiratory Laboratory and Endocrinology & Metabolism Division, Dept. Pediatrics, McGill University, Montreal, Québec, Canada H3H 1P3.

Some victims of Sudden Infant Death Syndrome (SIDS) appear to have been exposed to repeated episodes of hypoxia. This study aimed to assess whether repeated hypoxia might increase the risk for SIDS in infants by blunting respiratory responses, and whether such blunting is associated with altered, respiratory-related neuromodulators. Twenty to 33 day-old piglets were instrumented for diaphragmatic electromyogram (EMGdi) measures and for repeated *in vivo* microdialysis from the nucleus tractus solitarius (NTS) via a chronically implanted guide. Experiments were conducted on 5 sequential days. On days 1 and 5, 30 min microdialysis samples were collected during 2 h normoxia, 30 min 10% O₂/90% N₂, then 1 h normoxia. On days 2, 3 and 4, piglets underwent sessions with or without hypoxia, but with no microdialysis. Eight out of the 11 microdialysis probe placements were either within, or $< 200 \mu m$ from the NTS. For met-enkephalin (ME) and substance-P (SP) levels from the dialysates by RIA, the peptide containing fractions were collected after separation by HPLC. Thus far, ME and SP levels at control, 1 h after initial probe insertion, were similar on days 1 and 5. Whereas, on day 1, all piglets had similar EMGdi responses to hypoxia, on day 5, those exposed to the daily repeated hypoxia displayed lower respiratory responses than those subjected to hypoxia on days 1 and 5 only. The possible association of this blunting to changes in select peptide levels at the NTS will be revealed from the ongoing RIAs of the in vivo NTS (HL36939, HD29608; Glaxo/CLA; MCH-RI support) microdialysates.

INHIBITION OF VENTROLATERAL PONTINE NEU-RONAL ACTIVITY REVERSES POST-HYPOXIC FRE-QUENCY DECLINE IN VAGALLY INTACT RATS. <u>S.K.</u> Coles* and T.E. Dick. Dept. of Medicine, Div. of Pulmonary and Critical Care

Medicine, Case Western Reserve Univ., Cleveland, OH 44106
Post-hypoxic frequency decline (PHFD) is characterized by a prolongation in

expiration (T_E) after hypoxic (8% O₂) exposure. PHFD may have a neurogenic component, because it is attenuated following inhibition (10 mM muscimol microinjections) of neuronal activity in the ventrolateral (v1) pons (Coles and Dick, 1994). However, the baseline timing of the breathing pattern is altered by inhibition of the v1 pons in vagotomized rats. To determine if the apparent attenuation of PHFD after vI pontine inhibition results from baseline breathing pattern changes, we tested rats in which vagi remained intact to minimize these

Adult, male Sprague-Dawley rats (360-492 g) were anesthetized with Equithesin Rats (n=4) breathed spontaneously and were exposed to hypoxia (15 min of 15% O₂ in one and 20-60 sec of 8% O₂ in the remaining 3 rats). Diaphragmatic EMG was recorded, and TE was measured before, during, and after hypoxia before and after inhibiting vI pontine neuronal activity. Small volumes (20 nl) of 10 mM muscimol were pressure injected into the vI pons using glass micropipettes. Blood pressure, air flow, pCO2, and body temperature were monitored.

Baseline TEs were similar before and after muscimol injections (0.48 s compared with 0.49 s), but post-hypoxic TEs were significantly shorter after muscimol (0.94 s compared with 0.40 s).

We conclude that the attenuation of PHFD is due to intervention in the vl pons rather than changes in baseline phase durations.

Supported by HL-07288 and HL-42400 (TED).

MODULATION OF CAROTID BODY CHEMORECEPTOR FUNCTION BY ENDOTHELIN. L. He, J. Chen, B. Dinger and S. Fidone*. Dept. of Physiology, Univ. of Utah Sch. of Med., Salt Lake City, UT 84108

Previous immunocytochemical studies in our laboratory showed that endothelin (ET) peptides are contained in chemoreceptor type I cells in the carotid body and that ET-immunostaining is elevated in carotid bodies from animals exposed for two weeks to hypobaric hypoxia (350 torr). We additionally demonstrated that ETs (ET-1 and ET-3) enhance carotid sinus nerve (CSN) activity evoked by hypoxia and also stimulate the production of inositol phosphate (IPn) and cyclic AMP (cAMP) second messengers in this chemosensory tissue. In the present study, we have examined 1), the effects of ETs on intracellular Ca²⁺ levels in type I cells and 2), the role of endogenous ETs in the generation of chemoreceptor activity

Superfusion of cultured rabbit carotid body type I cells in ET-1 or ET-3 (100 nM) did not alter basal [Ca²], whereas peak Ca²*-responses evoked by hypoxia were elevated more than 2-fold. Low O₂-evoked Ca²⁺ responses were depressed by analogs of atrial natriuretic peptide (ANP; also contained in type I cells), and this effect was reversed in the presence of ETs (100 nM). RIA measurements showed that acute hypoxia (breathing 5% O₂, 40 min) reduces carotid body ET-immunoreactivity by 40% (p<0.01) and is consistent with the notion that hypoxia evokes the release of ET from type I cells. Superfusion of normal rabbit carotid bodies in vitro with the specific ET-A receptor antagonist BQ-123 (5 μM) did not alter basal CSN activity, and the drug caused only a slight depression of activity evoked by hypoxia. However, in carotid bodies from chronically (2 wks) hypoxic rabbits the antagonist depressed hypoxia-evoked CSN activity by more than 50%. Our data suggest that ETs modulate type I cell activity by altering cell Ca²⁺ responses and that endogenous ET participates in the physiological adjustments to chronic hypoxia. Supported by USPHS Grants NS12636 and NS07938.

THE RESPONSE TO HYPOXIA IS AFFECTED BY INCREASING THE ATP CONTENT IN THE CENTRAL RESPIRATORY NETWORK OF MAMMALS. B. Wilken*, J.M. Ramirez, I. Probst, D.W. Richter, F. Hanefeld. Depts. Pediatric Neurology, Physiology and Biochemistry, University of Göttingen, 37073 Göttingen, FRG

Newborns are not capable of maintaining enhanced respiratory activity during prolonged hypoxia. This typical neonatal response is retained in the transverse brainstem slice preparation of mice and was used as a functional in vitro model to study the hypoxic response of the respiratory system (Ramirez et al. 1996, J. Physiol.429: 599). In this study we examined the possibility that the inability to maintain augmented hypoxic responses is due to a depletion of ATP, which could affect the hypoxic response by altering various components of ionic metabolism, such as the function of the Na*/K pump or ATP-dependent K* channels. In order to avoid ATP depletion brainstem slices were incubated for 3 h in creatine (200 μ M), which via the production of phosphocreatine, significantly increased ATP concentrations (as measured with a bioluminescence assay). As shown in the table, creating treatment enhanced respiratory activity during the initial period of hypoxia by increasing the amplitude and duration of rhythmic hypoglossal activity. The values obtained for two different age groups represent percentage change from control before hypoxia and during hypoxic augmentation for respiratory burst discharges (amplitude and duration of bursts) recorded from hypoglossal nerve.

P0-5 (control) P0-5 (Creatine) P8-14 (control) P8-14 (Creatine) + 58.5% (p< 0.05) + 11.6 % + 17.9% (p< 0.05) + 14.4 % + 47.8% (p<0.05) Amplitude + 14% Duration + 3% Duration + 21 % (n. s.) Thus, the response of newborns to hypoxia can be stabilized by increasing ATP levels with creatine, which may be beneficial in protecting the nervous system against acute anoxia.

628.20

IN VITRO RESPONSE OF VENTROLATERAL MEDULLARY NEURONS HYPOXIA **FOLLOWING** NORMOBARIC ACCLIMATIZATION.

P.C. Nolan* and T.G. Waldrop. Depts. of Molecular & Integrative Physiology, Neuroscience Program and College of Medicine, Univ. of Illinois, Urbana, IL 61801.

Hypoxic acclimatization involves an initial rapid ventilatory response followed by a more gradual increase in ventilation over a period of 24 to 48 hours in both humans and rats. In addition, the acute ventilatory response to hypoxia is accentuated following hypoxic acclimatization. This laboratory has previously shown that neurons in the ventrolateral medulla (VLM), an area of cardiorespiratory integration, are excited by acute hypoxic exposures independent of synaptic activity. The purpose of the present investigation was to determine if hypoxic acclimatization augments the acute hypoxic response observed in VLM neurons in vitro. Brain slices (400-500 μm) containing the ventrolateral medulla were prepared from Sprague-Dawley rats acclimatized to hypoxia (10% O₂) for 4-5 days (n=4) and 9-10 days (n=4) and from rats maintained in a normoxic environment (n=4). In vitro extracellular recordings demonstrated that there were no significant differences in the basal pattern or discharge rate of VLM neurons from animals exposed to short (10.8±0.9 Hz, n=51), or long $(10.1\pm1.1~Hz, n=59)$ periods of hypoxia compared to control neurons $(10.8\pm1.1~Hz, n=52)$. The proportion of neurons stimulated $(\sim70\%)$, inhibited $(\sim20\%)$ and unaffected (~10%) by an acute bout of hypoxia (10% O2, 90 sec) was also similar among groups. However, acute hypoxia elicited a greater increase in discharge frequency in neurons from rats exposed to the short period of hypoxia compared to the responses from neurons in the control and longer acclimatization groups. These observations suggest the early stages of hypoxic acclimatization result in altered hypoxic responsivity of VLM neurons which may contribute to the respirator responses associated with acclimatization (Supported by NIH32876, AHA-IL Affiliate and HD-07333).

EFFECT OF 6-NITRO-7-SULPHAMOYLBENZO[F]QUINOXALINE-2,3-DIONE (NBQX) ON THYROAREYTENOID (TA) MUSCLE ELECTRO-MYOGRAM (EMG) DURING HYPOXIA. J.M. Bissonnette,* A.R. Hohimer and S.J. Knopp. Oregon Health Sciences University, Portland, OR

In fetal sheep acute hypoxia results in a marked depression of respiratory output often to apnea (J Physiol 243:599, 1974). Using TA muscle activity in unanesthetized animals, as an index of early expiratory (post inspiratory) neuronal activity it has been shown that hypoxia induces a tonic activation which coincides with the arrest of inspiratory activity (The Physiologist, in press). Since neuronal populations rostral to TA motoneurons have been shown to be activated by hypoxia (e.g. Respiration Physiol 100:185, 1995) these studies were undertaken to determine if non-N-methyl-D-aspartate receptor blockade in the spinal cord-brain stem inhibited the tonic TA EMG activity induced by hypoxia. Electrodes were placed in the TA muscle and a catheter in the fourth cerebral ventricle in fetal sheep and experiments carried out 4-5 days later in unanesthetized animals. Hypoxia was induced by having the ewe breath a mixture of 10% O₂, 4% CO₂ in air for 10 minutes which lowers fetal Po₂ from ~21 torr to ~13 torr with no change in CO₂ tension. In experiments in which the hypoxic challenge was preceded by a 100 µg NBQX instillation in the cerebrospinal fluid of the fourth ventricle (a dose which inhibits respiratory activity for 60-90 minutes) in 12 of 18 challenges (8 animals) tonic activity in the TA EMG was seen. This 67% incidence was not different from the 69% observed without NBQX (9 of 13 trials). These results indicate that excitation by glutamate at non-NMDA receptors is not required for tonic output of expiratory neurons during hypoxia and suggests it may result from loss of inhibitory inputs (HL 38039 from NIH)

PRENATAL CARBON MONOXIDE EXPOSURE AND ITS EFFECTS ON RESPIRATORY PRENATAL CARBON MONOXIDE EXPOSURE AND ITS EFFECTS ON RESPIRATORY REGULATION AND BRAINSTEM DEVELOPMENT IN THE NEWBORN GUINEA PIG. H.P. McGregor¹, M. Tolcos², K. Westcott¹, D.W. Walker¹, & S. Rees²*

Department of Physiology, Monash University, Clayton, Australia, 3168.

The effect of prenatal exposure to carbon monoxide (CO), a major component of

cigarette smoke, on fetal & neonatal development is largely unknown. Therefore, we examined the ventilatory responses of newborn guinea pigs to specific respiratory challenges, and the neurochemical development of brainstem nuclei controlling ventilation, after exposing pregnant guinea pigs (n=4) to 200 ppm CO for 10 hours a day from day 25 of gestation until term (68 days). The control group consisted of 4 pregnant guinea pigs housed in an air filled chamber. On postnatal day 4, the ventilatory responses of 9 control and 10 CO exposed neonates were determined during progressive asphyxia and steady state hypercapnia. The brains were then fixed with 4% paraformaldehyde. Basal ventilation was not different between groups but CO exposed neonates had a significantly greater ventilatory response during progressive asphyxia and steady state hypercapnia. Immunohistochemical analysis of the brainstem (CO,n=6; control,n=6) revealed an increase in tyrosine hydroxylase (TH) immunoreactive (IR) fibres in the nucleus tractus solitarius (NTS) and medullary reticular formation, an increase in the number of TH-positive neurons in the caudal NTS, and an increase in Substance P-IR fibres in the NTS, ventrolateral medulla, and the spinal trigeminal nucleus. Proliferation of astrocytes, as determined by GFA-IR, was observed in the area postrema of CO exposed neonates. These results indicate that prenatal exposure to CO affects respiratory responses postnatally. This may be due to modification of chemosensitivity or cardiovascular control mechanisms, which may in part be due to the altered expression of neurochemicals in the brainstem nuclei nvolved in cardio-respiratory control.

DEVELOPMENT OF HYPOXIA-INDUCED FOS EXPRESSION IN THE CAUDAL HYPOTHALAMUS OF THE CONSCIOUS RAT. <u>Eric M. Horn* and Tony G. Waldrop.</u> Neuroscience Program, Department of Molccular & Integrative Physiology and College of Medicine, University of Illinois, Urbana, IL 61801.

Physiology and College of Medicine, University of Illinois, Urbana, It. 61801.

The caudal hypothalamus is an important central nervous system site in the control of cardiorespiratory integration during systemic hypoxia. Previous findings from this laboratory have identified neurons in the caudal hypothalamus of anesthetized rats that are stimulated during hypoxia in vivo and in the in vitro brain slice preparation in the absence of synaptic connections; these electrophysiological responses increase during development. The purpose of the present study is to characterize the induction of Fos in response to hypoxia in caudal hypothalamic neurons throughout postnatal development in the conscious, freely moving rat. Immunocytochemistry was utilized to analyze the expression of the transcription factor Fos, which is induced after neuronal depolarization. Both the transcription factor Fos, which is induced after neuronal depolarization. Both postnatal and adult (3 days through 6-8 weeks) Sprague-Dawley rats from a regulated colony were placed in a normobaric chamber circulated with either 10% oxygen (hypoxic) or room air (normoxic) for a period of three hours. Following the hypoxic/normoxic exposure period, the animals were anesthetized and immediately transcardially perfused with 4% buffered paraformaldehyde. The brains were removed, post-fixed in 4% paraformaldehyde for 24 hours, sliced and analyzed for Fos immunoreactivity using a polyclonal antibody (Zeneca) and the avidin-biotin peroxidase reaction (Vector Labs). Cells were quantified using image analysis software (NIH Image) and reported as a number of neurons demonstrating Fos immunostaining per square millimeter. A significant increase in the number of neurons expressing Fos was observed in the caudal hypothalamus of hypoxic compared to normoxic adult (6-8 weeks) rats. A smaller increase in Fos induction occurred during hypoxia in the caudal hypothalamus of younger (6-12 days) rats. Based on these and previous findings, we believe that neurons in the caudal Based on these and previous findings, we believe that neurons in the caudal hypothalamus are sensitive to hypoxia; this sensitivity follows a developmental time course. RESPIRATORY REGULATION: INTEGRATIVE MECHANISMS

629.1

MICROINJECTION OF N-METHYLNALOXONIUM IODIDE (MN) INTO THE CAUDAL VENTROLATERAL MEDULLA (cVLM) REVERSES RESPIRATORY DEPRESSION INDUCED BY INTRAVENOUS (IV) ALFENTANIL (AL) IN THE CAT. MJ Kelly, RA Gillis, AM Taveira Da Silva. Pulmonary and Critical Care Medicine, Depts of Medicine and Pharmacology, Georgetown University School of Medicine, Washington, DC 20007.

The ventral medulla is an important area were opiates act to depress respiration (Taveira Da Silva, 1983). The caudal subretrofacial area (cSRFA) and the caudal ventrolateral medulla (cVLM) are areas which have been identified as important in the control of respiratory activity in the cat. We have demonstrated that the microinjection of MN into the cSRFA reverses the respiratory effects of continuous IV alfentanil (Kelly, 1996). The aim of this study was to determine if the cVLM is also an important site in opiate-induced respiratory depression. Studies were conducted in 9 choralose anesthetized spontaneously breathing cats while monitoring tidal volume (Vt), respiratory spontaneously Endaning cast while monitoring dual volume (v), respiratory rate (RR), minute ventillation (Ve), and end-tidal CO2 (ETCO2). Respiratory depression was induced by a continuous infusion of AL which caused significant decreases in RR (-9.8±0.9 breath/min, p<0.05) and Ve (-266±22 mL/min, p<0.05); and increases in ETCO2 (+1.6±0.4%, p<0.05) and Vt (+18.4±6.8 mL, p<0.05). Microinjection of MN, 250 ng/side, into the cVLM reversed the effects of AL resulting in an immediate increase in RR (+7±1 breaths/min, p<0.05) and Ve (+228±40 mL/min, p<0.05), and returned Ve to 80±13% of its baseline value. Treatment with 100 and 1000 ng/side of MN returned Ve to 46±22% and 114±44% of its baseline values respectively Microinjection of (+)-naloxone, a stereoisomer of naloxone devoid of opiate receptor activity, into the cVLM failed to reverse AL induced respiratory depression. We conclude that the cVLM is an important medullary site where systemically administered opioids act to influence respiratory activity

NMDA OR AMPA RECEPTOR ACTIVATION IN THE ROSTRAL VENTROLATERAL MEDULLA PRODUCES BRONCHOCONSTRICTION P.J. Mueller, K.J. Dormer, E.J. Zuperku, J.B. Buckwalter, and P.S. Clifford*. Departments of Anesthesiology and Physiology, Medical College of Wisconsin and VA Medical Center, Milwaukee, WI 53295.

Recent evidence implicates glutamate as an important excitatory neurotransmitter in the control of airway tone by the rostral ventrolateral medulla (RVLM). The purpose of this study was to determine which glutamate receptor subtypes are involved in the bronchoconstrictor response observed after glutamate microinjection into the RVLM. Mongrel dogs of either sex (18-20 kg) were maintained under alpha chloralose and urethane anesthesia and mechanically ventilated with room air. Arterial blood gases were monitored and pH was maintained room air. Afterial blood gases were monitored and pri was maintained by bolus injections of sodium bicarbonate. Tracheal smooth muscle tone was assessed by pressure changes in the saline-filled cuff of an endotracheal tube placed at the level of the sternal notch. A multibarreled micropipette was advanced from the dorsal surface of the medulla and positioned in the RVLM (7-8 mm rostral to obex and 4-5 mm lateral to the middine) at the site where microinjections of glutamate (10 metal) resolved the present inspects in tendent to the lateral to the middine). mm lateral to the midline) at the site where micronijections of glutamate (10 nmol) produced the greatest increases in tracheal tone (7.5-18.8 mmHg). Microinjections of NMDA (51-255 pmol) increased tracheal tone (3.1-21.9 mmHg). AMPA (3.6-15.2 pmol) also produced increases in tracheal tone (2.0-15.6 mmHg) when microinjected at this site. Rank order of potency was AMPA>NMDA>glutamate. These results demonstrate that both NMDA and non-NMDA receptors in the RVLM are capable of producing increases in airway tone. are capable of producing increases in airway tone. ALTERED EXCITATORY AMINO ACID NEUROTRANS-MISSION IN BRAINSTEM RESPIRATORY REGIONS OF PORTACAVAL SHUNTED RATS. C.A. Connelly* and S.D. Colquboun. Depts. of Surgery, University of California-Davis, Sacramento, CA 95817, Liver and Pancreas Transplantation, Cedars-Sinai Medical Center, Los Angeles, CA 90048 and The Dumont-UCLA Transplant Center, Los Angeles, CA 90095.

A portacaval (PC) shunt diverts portal venous blood flow from the liver directly

into the systemic circulation. Ammonia and other neuroactive substances then remain in the circulation, cross the blood-brain barrier and may differentially affect NMDA (N-methyl-D-aspartate) receptor function. This study examines the chronic influence of PC shunts on NMDA vs. non-NMDA mediated neurotransmission in brainstem respiratory regions. The non-NMDA (AMPA/kainate) receptor antagonist 6-Nitro-7-sulphamoylbenzo()Quinoxaline-2,3-dione (NBQX, 40 mg/kg, antagonist of vitor of the control o PC shunted rats were significantly elevated compared to unoperated (n=6) or sham-operated (n=6) rats. Following NBQX, respiratory frequency decreased and apnea occurred in 4 of 6 PC shunted rats, lasting 5s (n=1) to \geq 1 hr (n=3). In 2 of 6 rats respiratory frequency decreased, but without apnea.

Combined activation of NMDA and non-NMDA receptors ordinarily underlies excitatory neurotransmission necessary for generation of the respiratory rhythm (Connelly, Soc. Neurosci. Abs. 21:1877, 1995). These results suggest that neuroactive factors not cleared by the liver after a PC shunt can impair NMDA receptor function, causing a shift toward predominantly non-NMDA mediated mechanisms to sustain excitatory neurotransmission in brainstem respiratory regions. INSPIRATORY RESISTIVE LOAD THRESHOLD FOR ELICITING THE EARLY PEAKS OF THE RESPIRATORY RELATED EVOKED POTENTIAL (RREP) IN CHILDREN. P.W. Davenport*. Department of Physiological Sciences, Univ. of Florida, Gainesville, FL 32610.

It has been previously demonstrated that the amplitude of the early exogenous peaks of the RREP, P_1 and N_n increase with increasing inspiratory resistive load magnitude using supra-threshold, easily detected loads. The present study tests the hypothesis that the P₁ and N₂ peaks will only be present with supra-threshold, detectable inspiratory resistive loads. EEG recordings were made from normal children, aged 11-16 years from scalp electrode sites: F₃, F₂, F₄, C₃, C₂ and C₄ (referenced to the joined earlobes). Three magnitudes of resistive loads, R₁=1.6, R₂=3.2, R₃=12.0cmH₂O*L^{-1*}sec, and no-load were presented 100 times each by interruption of inspiration in randomized blocks with 2-4 unloaded breaths separating each loaded breath. The R₁ load was below the reported detection threshold (ΔR_{50}) for normal subjects, R_2 was slightly above threshold and R_3 was easily detectable. A minimum of 50, 350 msec EEG epochs free of EOG artifact for each load (and no-load) magnitude were signal averaged. The averaged traces were examined to determine the presence, latency and amplitude of the P₁ (latency range = 18-40 msec) and $N_{\rm f}$ (latency range = 30-60 msec) peaks. Both peaks were found with increasing incidence and peak amplitude (when present) as the load magnitude increased. These results demonstrate that inspiration as the load Highlands included. These results definished that implication against inspiratory resistive loads that are below the $\Delta R_{\rm Sp}$ does not elicit the P_1 and $N_{\rm f}$ peaks of the RREP. The presence of the early peaks of the RREP may be related to the detectability of these loads. Supported by NIH-NHLBI grant HL48792

PERIPHERAL EFFECTS OF PENTOBARBITAL ON RESPIRATORY MUSCLE ACTIVATION. J.R.Romaniuk*, K.E.Kowalski, G.Supinski, J.R.Romaniuk*, K.E.Kowalski, G.Supinski, MetroHealth Med. Ctr., CWRU, Cleveland, OH .F.DiMarco.

MetroHealth Med. Ctr., CWRU, Cleveland, OH Pentobarbital (Pb) has differential effects on centrally generated expiratory and inspiratory motor activity. The potential effects of the Pb on peripheral muscle activation and contractility are, however, less clear. Electrical stimulation of the lower thoracic spinal roots (SRS) results in the generation of large positive airway pressures (P) consistent with the predominant activation of expiratory muscles. In contrast, upper thoracic SRS results in negative airway pressures and predominant inspiratory muscle activation. We evaluated the efficacy of SRS after administration of increasing doses of Pb in 5 dogs artificially hyperventilated to appea. The efficacy of SRS was assessed by measurements of P during tracheal occlusion. Pb was administered at 2 mg/kg every 5 min. Administration of a cumulative total dose of 24 mg/kg caused P to fall from 44.8 cmH₂O ± 2.7 SE to 16.0 cmH₂O ± 3.6 SE (P < 0.05) during expiratory muscle activation and from -16.6 cmH₂O ± 1.6 SE to -15.9 cmH₂O ± 2.0 SE during inspiratory muscle activation (NS). We speculate that the differential depressive actions of Pb on inspiratory and expiratory pressure generation reflects fundamental differences in the physiological properties of the neuronuscular junction and/or muscle contractile apparatus of the inspiratory intercostal and abdominal muscles. (HL 34143).

LONG TERM MODULATION OF VENTILATORY CONTROL IN EXERCISING HUMANS. <u>Duncan L. Turner*, J.R. Greenwell, H. Lawrence, P. Lyons, M.R. Taylor and Z. M. Iqbal</u>. Dept. Physiology, University of Leeds, Leeds LS2 9NQ, UK.

Repeated associations of exercise (conditioned stimulus) and increased respiratory dead space (ΔVD; unconditioned stimulus) alter future blood gas and ventilatory responses to exercise alone in goats. These results were suggested to represent long term modulation (LTM) of the control system subserving the exercise ventilatory response (i.e. a form of associative learning; Martin & Mitchell, J. Physiol., 470, 601, 1993). The present study was conducted to test the hypothesis that LTM also occurs in The present study was conducted to test the hypothesis that $F^{(1)}$ and the exercising humans. Ventilation (Vt. L_{BTPS}-min⁻¹), carbon dioxide production (VCO₂, L_{STPD}-min⁻¹), heart rate (FH, min⁻¹) and end-tidal PCO₂ (mmHg) were measured and arterial PCO2 was estimated (PaCO2; Jones et al, J. Appl. Physiol., 47, 954, 1979) at rest and during steady state cycling exercise (5-7 min; 80 watts; Δ = exercise - rest) in 9 male subjects. Resting CO₂ responsiveness ($S = \delta V l / \delta P_a CO_2$; +VD = 1.8 L for 7 min; δ = +VD - no added VD) and the feedforward exercise stimulus (GEX = $\Delta V l / \Delta V CO_2$ - $[S(\Delta P_s Co_2/\Delta V Co_2)])$ were calculated (Mitchell, J. Appl. Physiol., 69, 718, 1990). Duplicate measurements were made at least 24 hours before (PRE) and 1 hour after conditioning (POST) with ten, repeated associations of exercise (5-7 min; 80 watts) and added dead space (+VD = 1.35 L). POST vs. PRE values (mean ± SE) were compared by Wilcoxon's Signed Rank Test (*, one-tailed p<0.05).

	$\Delta V_1/\Delta V_{CO_2}$	$\Delta P_a CO_2 / \Delta V CO_2$	S	$S(\Delta P_a CO_2/\Delta V CO_2)$	ΔΕΗ/ΔVC0
PRE	23.8 ± 0.9	3.3 ± 0.4	5.7 ± 1.7	19.2 ± 6.0	39.8 ± 4.3
POST	25.3 ± 0.6*	$2.2 \pm 0.8*$	5.4 ± 1.7	5.6 ± 4.5*	41.5 ± 2.9

GEX increased more after conditioning (4.6 \pm 6.5 vs 19.7 \pm 4.4*; PRE vs POST). The lesser increase in $\Delta P_a CO_2/\Delta V CO_2$ and greater increases in $\Delta VI/\Delta V CO_2$ and GEX after conditioning suggest that LTM also exists in humans. We propose that prior experience may influence the normal exercise ventilatory response (ADF315710).

CARDIOPULMONARY INTERACTIONS FOLLOWING REM SLEEP DEPRIVATION IN SPRAGUE - DAWLEY RATS. S. M. Trbovic, D. W. Carley, T. Thai and M. Radulovacki*_ Department of Pharmacology, University of Illinois College of Medicine, Chicago, IL 60612
Changes in blood pressure (BP) and heart period (HP)during REM sleep have been ascribed to increased baroreflex sensitivity in humans and animal species including rats, but there have not been studies describing cardiopulmonary interactions following selective REM sleep deprivation (REMD). These studies are of interest because REMD has been suggested to impair baroreflexes in Wistar rats. We implanted ten rats with EEG and EMG electrodes for sleep/wake scoring and with a telemetry transmitter for monitoring BP and HP. Control recordings were done 1 week after surgery whereas experimental recordings were done following 48 h of REMD for which the "flower pot" method was used. For each rat, sleep, BP and respiration were polygraphically recorded for 6 hours. We found that BP was highest during waking (W), lower during non - REM sleep (NREM) and lowest during REM sleep and these state dependent decreases were found to be statistically significant in control and experimental conditions (p = .05 to .002). HP exhibited mirror image changes (p < .01). REMD was associated with lower BP and longer HP over all sleep/wake states, although this achieved statistical significance only during REM sleep during the first hour of recovery sleep. There was 15% - 25% decrease in respiratory rate (RR) during REM sleep in comparison to W in the control group. After REMD there was a further decrease in RR in REM sleep compared to control recordings in the same state (p = .039). Minute ventillation (MV) showed the same pattern as RR, i. e. it was lower during REM sleep than in W in the control group. In REM sleep than in W in the control group. In REM sleep promared to control recordings in the same state (p = .039). Minute ventillation (MV) showed the same pattern as RR, i. e. it was lower during REM sle

ROLE OF THE NUCLEUS TRACTUS SOLITARIUS IN CONTROL OF VOMITING. M. S. Siniaia*, K. Shiba and A. D. Miller. Neurophysiol., Rockefeller Univ., New York, NY

The neural pathways responsible for producing vomiting have not yet been completely elucidated. Lesion studies have shown that the essential coordinating circuitry for producing vomiting is located within the medulla of the brainstem. It is known that the nucleus tractus solitarius (NTS) participates in regulation of sympathetic and respiratory outflow and the triggering of vomiting. The importance of the NTS for vomiting was tested using the fictive vomiting model in adult cats that were decerebrated, paralyzed and artificially ventilated. Injections of the neurotoxin kainic acid into the NTS blocked vomiting induced by a combination of abdominal vagus nerve stimulation and the emetic drugs cisplatin, apomorphine, lobeline, protoveratrine, and naloxone. Preliminary studies indicate that vomiting can also be blocked by injections of the serotonin 1A receptor agonist 8-OH-DPAT into the NTS. Thus, the NTS may represent both a site of convergence of different emetic inputs and of the broad spectrum anti-emetic action of serotonin type 1A agonists.

EFFECTS OF NATURAL VESTIBULAR STIMULATION ON RESPIRATORY EFFERENT NERVE ACTIVITY IN THE CAT. <u>C.D. Rossiter*, N.L. Hayden, S.D. Stocker and B.J. Yates.</u> Depts. of Otolaryngology and Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15213

Activity was recorded from inspiratory (phrenic and hypoglossal) and expiratory (abdominal) nerves during natural vestibular stimulation in decerebrate, paralyzed and artificially ventilated cats. Vestibular stimulation was produced by rotating the head of animals with C1-C3 dorsal root transection, carotid sinus and upper airway denervation and vagus nerve transection. Stimuli consisted of sinusoidal pitch, roll and yaw (15-20°) at 0.05 to 1.0 Hz and trapezoidal nose-up pitch (50°) and roll (40°). Phrenic nerve activity increased in 2 of 3 animals during 50° trapezoidal nose-up pitch but not during 40° ear-down roll. Modulation of phrenic nerve activity did not occur using sinusoidal 20° pitch, roll or yaw in 15 of 16 animals. Similarly, hypoglossal nerve activity increased during 50° trapezoidal nose-up pitch but was not effected by sinusoidal 20° pitch, roll or yaw (n=13). Abdominal nerve activity also increased during 50° trapezoidal nose-up tilt (not 40° ear-down roll) in 4 animals. In contrast to the inspiratory nerves, however, sinusoidal 20° pitch and sometimes roll were effective in modulating abdominal nerve activity (n=16). Typically, maximal modulation of abdominal nerve activity was elicited by head rotations within 45° of pitch with increased discharges during the nose-up rotation. The gains of the responses remained relatively consistant across stimulus frequencies and the phases were near stimulus position, consistent with otolith afferent influences. Lesions of the vestibular system eliminated modulation of respiratory nerves during stimulation. These data suggest that the vestibular system influences respiratory muscles as well as those muscles typically considered to have roles in antigravity, movement and posture. Supported by NIH grant DC02644.

BRAIN STEM NEURAL ASSEMBLY SYNCHRONY DURING INDUCTION OF LONG-TERM ENHANCEMENT OF RESPIRATORY ACTIVITY. K. F. Morris*, R. Shannon and B. G. Lindsey, Physiol. & Biophysics, Univ. South Florida Med. Ctr., Tampa, FL 33612.

Stimulation of carotid chemoreceptors results in an immediate increase, an after discharge (short term memory) and long term enhancement of respiratory drive (J. Physiol., 490.2:463). The amplitude of integrated phrenic nerve activity was significantly increased for >10 min. after multiple injections of 200 ml of CO₂ saturated saline solution via the external carotid arteries of 2, anesthetized, vagotomized, artificially ventilated cats. We analyzed spike trains with low or no respiratory fring rate modulation in raphe obscurus and the region of the ventral respiratory group with respiratory cycle-triggered histograms, spike triggered average histograms of phrenic multiunit activity, cross-correlograms and the gravity method. Spark plots were calculated from the results of gravity analysis (Lindsey, et al., these proceedings). We found momentary increases in the impulse synchrony of the monitored neurons associated with chemoreceptor stimulation. Some of these transiently configured assemblies contained neurons that did not change rate during stimulation. These preliminary results are consistent with the hypothesis that chemoreceptor modulation of breathing involves dynamic changes in synchrony not necessarily related to changes in rate of distributed brain stem neural network assemblies. Supported by N.I.H. grant NS19814.

AMACRINE CELLS TRACER-COUPLED TO PARASOL GANGLION CELLS CONTAIN CHOLECYSTOKININ. R. A. Jacoby* and D. W. Marshak. Dept. of Neurobiology and Anatomy, Univ. of Texas Medical Scool, Houston, TX 77225.

Parasol ganglion cells are the large retinal cells in primates that project to the magnocellular layers of the LGN. The goal of this study was to identify the amacrine cells that make gap junctions with parasol cells. Parasol cells from peripheral macaque retina were injected with Neurobiotin, and the retinas were labeled with antibodies to the glycine-extended precursor to cholecystokinin (G6-gly). The first type of tracer-coupled amacrine cell is larger and has sparsely-branching dendrites that give rise to axon-like processes. The second has smaller diameter dendrites and no axons, confirming Dacey and Brace ('92). Processes of the larger amacrine cell were more intensely-labeled with Neurobiotin, but both were G6-gly-IR. The effect of the amacrine cells onto nearby ganglion cells might be excitatory, even though their chemical synapses are likely to be inhibitory. Axon-bearing amacrine cells like the large coupled type would be particularly well-suited for this if the gap junctions were located on the proximal dendrites and the output synapses on the axons. In that case, the ganglion cells that fell within the dendritic field would be excited, but those falling outside would be inhibited. A second possibility is that the gap junctions act to enhance the inhibition of the parasol cell. This would occur if the gap junctions were rectified so that they conduct depolarizing current preferentially from ganglion cells to amacrine cells. When the ganglion cells depolarize, the amacrine cells would also depolarize via the gap junctions and, after a brief synaptic delay, they would inhibit the ganglion cells. Our working hypothesis is that the large amacrine cells mediate the excitatory interactions and the small ones mediate the inhibitory interactions.

STAINING OF NEURONS OF DIFFERENT RETINAL LAYERS VISUALIZED BY INTERFERENCE CONTRAST MICROSCOPY ON AN INVERTED MICROSCOPE. <u>R.Pflug</u>, <u>H.P.Groiss</u>, <u>H.Reitsamer</u>, <u>K.H.Huemer*</u>. Dept. of Gen. and Comp. Physiology, University of Vienna, Schwarzspanierstr. 17, A-1090 Vienna, Austria.

In an isolated superfused rabbit retina preparation we have stained living cells of different layers including horizontal cell networks with Lucifer Yellow. We have used a newly developed set-up that allows us to penetrate cells under visual control without previous labeling.

The retinal preparation is located on the stage of an inverted microscope. Cells are visualized by Nomarski interference contrast. A computer program developed in our department is used to calibrate the position of the electrode and to drive the electrode to any predefined position in the retina. Cells are penetrated by further advancing the electrode with a stepper motor. Dark adapted retinal preparations are observed with a CCD camera sensitive in the infrared range.

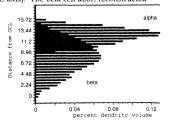

A connected amplifier allows electrophysiological recordings of intracellular potentials in response to light stimuli With this set-up pharmacological modulation of cell coupling as well as influences of light adaptation on gap junctional resistance can be investigated supported by FWF P09670-MED

VOLUMES OF BETA AND ALPHA CELL DENDRITIC ARBORS PEAK IN DIFFERENT STRATA. M. Luo, M. Pu, and P. Sterling*. Dept Neuroscience, U. Penn. Phila. PA 19104

Retinal ganglion cells comprise about 20 types, and for each type the dendritic arbors "tile" the plane of the retina completely and efficiently. But the degree to which arbors of different types intermingle in the inner plexiform layer has not been quantified because conventional optical sections can be thicker than the dendritic strata to be resolved. Hence beta and alpha ganglion cells are assumed to occupy the same strata, the sparsely branched, planar, alpha dendrites insinuating among the densely branched, 3-D beta arbors. Confocal microscopy shows this to be an oversimplification. Adjacent ON beta and ON alpha ganglion cells were injected with Lucifer yellow + neurobiotin and visulized with CY3. Whole mounts were coverslipped in glycerol mounting medium, and the intensely fluorescent neuron arbors were optically sectioned with 100X, 1.4 NA objective (resolution ~ 0.6 um in Z-axis). The beta cell abor, reconstructed

and rotated into vertical view was flat-topped, like a 'crew-cut', and 95% of its volume occupied a stratum from 1 µm to 13 µm above the ganglion cell layer. The alpha cell arbor was flatter: 95% of its volume occupied a stratum from 8 to 14 above the ganglion cell layer. Only the upper 30% of the beta cell's dendritic volume was overlapped by the alpha cell arbor. (EY00828)

630.4

DENDRITIC COVERAGE FACTOR OF CAT RETINAL GANGLION CELLS FROM NEUROBIOTIN FILLED RETINAS. X. J. Zhan and J. B. Troy*. Neuroscience Institute & BME Department, Northwestern University, Evanston, IL 60208

It is generally believed that the dendritic trees of a functionally and morphologically homogeneous class of retinal ganglion cell would cover the retina with a constant degree of overlap. However, direct measurement of the dendritic coverage factor (DCF) has proven difficult, especially for beta cells. A method for direct and systematic evaluation of ganglion cells' DCFs has been developed, and the beta cells' DCF measured directly, across the retina.

Complete dendritic fields together with all ganglion cells in selected retinal areas were revealed, using neurobiotin retrograde transport in an *in vitro* eye cup preparation. The DCF was evaluated directly from the cell density and the dendritic field size of the same type of ganglion cell in the same retinal location.

The newly developed method provided a direct means to measure DCFs. Direct DCF measurement was used to evaluate DCFs for both alpha and beta cells across the retina. The DCF for alpha cells was found to be in good agreement with previously published data, but the DCF for beta cells was found to be significantly smaller than estimated by other investigators using indirect methods.

THE NUMBER OF UNIDENTIFIED AMACRINE CELLS IN THE RABBIT'S RETINA. E. Strettoi and R. H. Masland*, Istituto di Neurofisiologia del C.N.R., Pisa and Howard Hughes Medical Institute, Boston, MA, 02114.

The three largest known populations of amacrine cells in the rabbit retina were stained using fluorescent probes in whole mounts. The cells were counted at a series of retinal eccentricities. The retinas were counterstained using a fluorescent DNA-binding molecule and the total number of nuclei in the inner nuclear layer were counted in confocal sections. From the total number of inner nuclear layer cells and the fraction occupied by amacrine cells (J. Neurosci., 1995) the fraction of amacrine cells made up by the stained populations could be calculated. Starburst cells made up 3%, indoleamine-accumulating cells 4%, and AII cells 11% of all amacrine cells. By referring four smaller populations of amacrine cells to the number of indoleamine-accumulating cells, they were estimated to comprise, taken together, 4% of all amacrine cells.

Thus, 78% of all amacrine cells in the rabbit's retina are known only anecdotally (mostly from Golgi catalogues) if at all. For comparison, horizontal cells make up 2% of all cells in the rabbit's inner nuclear layer. The number of *unidentified* amacrine cells is thus 14 times the total number of horizontal cells: amacrine cells represent the main laterally conducting pathway in the rabbit's retina. The proportion of unidentified amacrine cells in the retinas of the mouse, rat, cat and monkey is similar. Supported by HHMI and EY01075.

CALRETININ AND CALBINDIN-D28k DISTRIBUTION IN PHOTO-RECEPTIVE ORGANS OF THE LIZARD IGUANA. M. S. Grace*, A. Ziyada* and M. Menaker, Dept. of Biology and NSF Center for Biological Timing, Univ. of Virginia, Charlottesville, VA 22903; *Dept. of Anatomy and Histology, Faculty of Medicine, Aleppo University, Svria.

Facuny of Neitorine, Areppo Cinversity, Syria.

Iguanid lizards have at least four different populations of photoreceptors (PRs), located in the lateral eyes, parietal eye, pineal organ, and brain. These sites also contain circadian clocks, one output of which is rhythmic melatonin production. Because calcium is involved in both photoreception and melatonin synthesis, we set out to further characterize known photoreception and melatonin synthesis, we set out to further characterize known photoreception and melatonin synthesis, we set out to further characterize known photoreception and melatonin synthesis, we set out to further characterize known photoreception and melatonin synthesis, we set out to further characterize known photoreception and melatonin synthesis, we set out to further characterize known photoreception and putative "deep brain" photoreceptors (see Grace et al., 1996, J. Comp. Neurol., 367:565) in Iguana, using immunocytochemistry for the calcium-binding proteins calretinin (CaR) and calbindin-D28k (CaB). Anti-CaB stained all PR inner and outer segments in the retina of the lateral eye. Confocal microscopy of retinal whole-mounts confirmed that both large and small single PRs as well as double PRs were immunolabeled. Anti-CaB also stained a subspopulation of bipolar cells in the outer nuclear layer. Anti-CaR and so the stained polar cells in the outer nuclear layer. Immunostained fibers of amacrine cells at the inner border of the inner nuclear layer. Immunostained fibers of amacrine cells formed five distinct bands in the inner plexiform layer. A subset of ganglion cells was weakly stained. In pineal, anti-CaR and anti-CaB immunoreactivities appeared restricted to different populations of pinealocytes. Long cylindrical cell bodies and their outer segments exhibited faint punctate CaB-like staining. Anti-CaR intensely stained ependymal pinealocytes, their outer segments, and their axons. Neither antiserum labeled the opsin- and vasoactive intestinal polypeptide-immunoreactive PR-like cells in t

REGULATION OF GENE EXPRESSION IN THE RETINAL PIGMENT EPITHELIUM OF THE EYE: ANALYSIS OF THE E61 PROMOTER A. Nicoletti¹, P.A. Sieving^{2*}, and D.A. Thompson^{1,2}. Departments of Ophthalmology² and Biological Chemistry¹, University of Michigan Medical School, Ann Arbor, MI, 48105.

The retinal pigment epithelium (RPE) of the eye expresses an abundant 61 kDa protein (E61) whose expression is developmentally regulated and tissue-specific. E61 transcripts are present at high levels in native RPE, and are down regulated in both proliferative and differentiated RPE cells in culture. Although the function of E61 is unknown, these characteristics suggest involvement in the specialized functions of the RPE, as well as regulation by signals from the retina and native environment.

In order to identify the cis-acting elements which mediate the high levels of

In order to identify the cis-acting elements which mediate the high levels of tissue-specific E61 gene expression, the promoter region of the E61 gene has been characterized. Genomic clones containing 7.0 kb of the 5'-flanking region of E61 have been isolated and 4.0 kb proximal to the transcription start site have been sequenced. Potential DNA binding sites for a number of transcription factors are present, including a site for the retina-specific factor, Ret1. In functional studies using luciferase reporter gene constructs, the most proximal 256 bp of 5'-flanking sequence is sufficient to drive expression when transfected into a human RPE cell line, but not when transfected into HeLa cells. Studies focused on the identification of the cis-acting elements in the 5'-flanking region which mediate this tissue-specific promoter activity are in progress.

ANTI-KLH ACTIVITY IN FROG AND TOAD RETINA. E. Kicliter¹¹, D. L. Meyer², A. Reichenbach² and N. Lugo¹, Institute of Neurobiology and Department of Anatomy. University of Puerto Rico Medical Sciences Campus, San Juan, Puerto Rico 00901¹. Department of Neuroanatomy, School of Medicine, University of Göttingen, Germany² and Paul Flechsig Institute for Brain Research, University of Leipzig, Germany³.

Keyhole limpet hemocyanin (KLH) is a large protein which functions as a respiratory pigment in this mollusc. Although KLH has been used as a carrier molecule to be conjugated with low molecular weight neuroactive peptides, antisera to KLH itself have been shown to react with neural elements, for example in the olfactory mucosa. While studying anti-KLH reactivity of olfactory mucosa in anuran amphibians, it was noticed that in some species strong anti-KLH reactivity was present in the outer plexiform layer (OPL) of the retina. This reactivity was observed in processes in the OPL and also in cell bodies. The somata exhibited label only in the cytoplasm. The locations of these labeled somata and processes is consistent with their identification as horizontal cells. Anti-KLH antibody from two sources (U.S. Biochemical and Organon Technika) and two immunochemical detection techniques (PAP and ABC) produced similar results. Labeling of the OPLwas not observed in all of the anuran species tested. Marked labeling was observed in bufonids, hylids, and leptodactylids, but not in pipids, microhylids, ranids or hyperoliids. In all species some activity was also noted in the ganglion cell layer. The strong anti-KLH reactivity of presumed horizontal cells in some species offers the possibility of identification of this cell type when the retina is dissociated. That OPL reactivity was observed only in members of the superfamily Bufonoidea suggests that the reactivity is with a protein whose structure varies between anurans. Differences in OPL reactivity may offer an indication of the closeness of phyletic relation. Supported, in part, by NIH Grants MH-48190 and NS-07464 and the German Science Foundation.

HIGH PRESSURE FREEZING OF RETINAL SLICES FOR ULTRASTRUCTURAL EXAMINATION.

M. T. Wilson*¹, C. J. Karwoski¹, & M. A. Farmer². ¹ Vision Research Laboratory and ² Center for Ultrastructural Research, University of Georgia, Athens, GA 30602.

High pressure freezing (HPF), followed by freeze substitution, can produce excellent ultrastructural preservation of tissues at depths over 10 times that obtained by other cryofixation techniques. However, in the case of neural tissue, the benefits of HPF have not been realized.

In the present study, isolated frog (*Rana Pipiens*) retina was sliced at a thickness of 150 or 350 μ m, rapidly frozen in a Balzers HPM 010 high pressure freezer, and freeze substituted with 1% OsO₄ in acetone. Specially designed HPF chambers and specific freezing media (35% high MW dextran for 150 μ m slices or 15% low MW dextran for 350 μ m slices) were required for adequate freezing.

The quality of preservation throughout the retina was excellent in both the 150 and 350 μ m slices, as compared to chemically fixed slices. Specifically, HPF resulted in excellent preservation of the cellular, mitochondrial and nuclear membranes in all retinal layers. Previous studies with other cryofixation techniques have not been able to adequately preserve these structures in many of these layers. In the nervous system, HPF should be useful for ultrastructural studies of dynamic events and cytochemical localization, as well as studies of extracellular and intracellular matrices. NITRIC OXIDE SYNTHASE TYPE I AND TYPE II DISTRIBUTION IN NORMAL RAT RETINA J.J. López-Costa*, J. Goldstein and J. Pecci Saavedra. Inst. de Biologia Celular y Neurociencia "Prof.E. DeRobertis". Fac. Medicina. UBA. Buenos Aires. 1121. ARGENTINA.

Two isoforms of Nitric Oxide Synthase (NOS) have been described. Type I (constitutive) and Type II (inducible). NOS activity has been reported in vertebrate retina in rod outer segments, rod and cone inner segments and in a subpopulation of amacrine cells. NO is known to activate a soluble guanylate cyclase in photoreceptors, gating a Ca channel with importance in visual transduction and dark adaptation. The aim of this work was to perform a detailed study about the distribution of both NOS isoforms in the rat retina using immunocytochemistry. Adult Wistar rats were anaesthetized with sodium pentobarbital (60 mg/kg) and perfused transcardially with a solution containing 4 % paraformaldehyde in 0.1 M phosphate buffer. Eyes were removed, postfixed in the same solution for 2 hours, cryoprotected and cut on a Leitz cryostat. The sections were immunocytochemically stained employing either a polyclonal rabbit antibody to neuronal NOS (nNOS), type I. (generously provided by Dr. Julia Polak; dil. 1: 2000) or a polyclonal rabbit antibody to macrophagic NOS (mNOS), type II. (Trasduction Lab; dil. 1:400). Sections stained using nNOS antibody showed an immunoreactive band

Sections stained using nNOS antibody showed an immunoreactive band corresponding to inner photoreceptor segments. immunolabeled amacrine cells and nNOS containing fibres in inner and outer plexiform layers. On the other hand mNOS antibody demonstrated immunoreactivity in cells localized in inner nuclear layer and in slender Müller cell processes along inner plexiform and ganglion cell layers. In addition mNOS immunoreactivity was also found in a band corresponding to inner photoreceptors segments showing a punctate immunostaining pattern. The results show a differential distribution of type I and type II NOS in rat retina, the only exception being inner photoreceptor segments where both types of NOS are colocalized.

A COMMON PATTERN FOR A THIRD VISUAL CHANNEL IN THE

A COMMON PATTERN FOR A THIRD VISUAL CHANNEL IN THE PRIMATE LGN. S. H. C. Hendry* and V. A. Casagrande, Krieger Mind/Brain Institute, Johns Hopkins Univ., Baltimore, MD 21218 and Department of Cell Biology, Vanderbilt Univ., Nashville, TN 37232

Two populations of neurons, comprising magnocellular (M) and parvocellular (P) layers of the lateral geniculate nucleus (LGN), are usually thought of as the source of geniculocortical input to primary visual cortex (V1) in primates. Yet a third population of small neurons making up the koniocellular (K) layers has been described repeatedly in the LGN. Using the selective expression by K neurons of the 28kD calcium binding protein, calbindin, we examined this third visual channel across a series of retirate species including prosignans (Galago crassicandatus). Tarsiers protein, calbindin, we examined this third visual channel across a series of primate species, including prosimians (Galago crassicaudatus), Tarsiers, Old World monkeys (Macaca mulatta), New World monkeys (Cebus apella, Samiri sciureus and Aotus trivirgatus), orangutans (Pongo pygmaeus) and humans. A common pattern is evident in which neurons immunoreactive for calbindin occupy four distinct layers, each of which is intercalated between principal layers or between M layer 1 and the optic tract. Consistent also is the large number of K neurons inserted between two P layers, a pattern most obvious in Galago, and between the ventral P and dorsal M layers, seen most clearly in Tarsier. Two specializations in monkeys, orangutans and humans are the expanded K layer ventral to M layer 1 and, where P layers are divided into leaflets (in macaques, orangutans and some humans), the insertion of two additional K layers of layer 1 and, where P layers are divided into leaflets (in macaques, orangutans and some humans), the insertion of two additional K layers of variable thickness. In the context of this pattern, only Cebus apella stands out as anomalous, with the more dorsal calbindin-immunoreactive neurons distributed not in K layers but in P layers. As do calbindin cells in other primates, however, those in Cebus monkeys send axons to V1, specifically to layer I and to the CO-rich puffs of layer III. Thus common to the primate LGN is a robust, neurochemically distinct K channel, in which variations among species likely represent selective adaptations to visual environment. PRINCIPAL COMPONENTS ANALYSIS OF THE TRANSFER OF VISUAL INFORMATION THROUGH THE LGN. T. Ozaki R. Everson, E. Kaplan & K. Purpura*. Biophysics Lab., The Rockefeller University, NY, NY 10021; Applied Math Lab., Ophthalmology, Mt. Sinai Medical Sch., NY, NY 10029; Neurol. & Neurosci. Dept., Cornell Univ. Med. Col., NY, NY 10021

10021; Applied Math Lab., Ophthalmology, Mt. Sinai Medical Sch., NY, NY 10029; Neurol. & Neurosci. Dept., Cornell Univ. Med. Col., NY, NY 10021

The lateral geniculate nucleus (LGN) is strategically placed along the central visual pathway to filter the flow of visual information from the retina to the visual cortex. While the LGN receives its main excitatory input from the retina it also receives connections from the perigeniculate nucleus, brainstem and layer VI of the visual cortex. These non-retinal connections are thought to influence the transfer of information to higher visual areas. We previously reported that the transfer ratios (LGN/Retina) of two cells recorded simultaneously in the LGN were strongly correlated regardless of receptive field proximity, suggesting a global control in the LGN. We seek to better understand the mechanism of this control.

We applied an extension of the Karhunen-Loève (K-L) principal component analysis to recordings of retinal input (recorded as synaptic (S) potentials) and LGN spike output in anesthetized and paralyzed cats. The cats viewed either a blank: CRT or various visual stimuli. The K-L analysis yielded a single component which reflected a change of activity in the LGN output, but not in the retinal input. Furthermore, the time course of this component's strength closely resembled the transfer ratio. The K-L component provides additional information on the nature of the high and low transfer ratio epochs. Results from thalamocortical relay neuron simulations suggest that the cells' resting membrane potential (RMP) is important in the control of transfer ratio. Thus, controlling the RMP provides a convenient mechanism for non-retinal inputs to influence LGN signal transmission. The fact that a single K-L component (which is necessarily uncorrelated with all other components) accounts for the variations in transfer ratio suggests that a single conduit is employed for control. However, the possibility that more than one non-retinal input may exert control via this con

CHANGES IN THE VISUAL ACTIVITY OF TOPOGRAPHICALLY MATCHED PGN AND LGN CELLS. K. Funke* and U.T. Eyel. Inst. of Physiology, Dept. of Neurophysiology, Ruhr-Universität Bochum, D-44780 Bochum, Germany

Relay cells of the cat lateral geniculate nucleus (LGN) are reciprocally connected with the GABAergic cells of the associated perigeniculate nucleus (PGN), thereby forming a negative feedback loop. Anatomical and physiological studies of the past, demonstrating the diversity of afferent inputs to LGN and PGN, have indicated a couple of possible functions for this feedback loop (binocular and long-range lateral inhibition, arousal effects, oculomotor interactions). In an attempt to find evidence for these functions, we performed double-recordings from single, topographically matched LGN and PGN cells in anesthetized (N₂O/O₂ 70:30, halothane 0.4 %) and paralysed (alcuronium chloride 0.15 mg/kgh) cats during the presentation of visual stimuli, and combined with a reversible, local inactivation of PGN activity by sumun, and combined with a reversible, local inactivation of PGN activity by micro-iontophoretical application of GABA or ACh. In most cases, PGN activity was like a mirror-image of LGN activity increasing tonic activity in the PGN was directly followed (<5sec) by a decrease in LGN activity and vice versa. Visually induced activity varied oppositely within milliseconds. Very prominent opposite changes in LGN and PGN activity were found during changes in EEG activity and with visual stimulation by a large uniform stimulus or a moving grating. The latter caused a strong and sustained increase in PGN activity accompanied by a reduced tonic activity in the LGN, but with an enhanced signal to noise ratio for the transient responses elicited by the contrast borders. Preliminary results obtained with reversible inactivation of PGN areas reveal a slight reduction of inhibitory responses in the corresponding LGN regions (e.g. binocular and long range lateral inhibition). The moderate changes obtained with local PGN inactivation indicate that the contribution of single PGN cells to LGN responses may be small, although the correlated changes in PGN and LGN activity are strong at the single cell level. WHAT VISUAL STIMULUS PARAMETERS CONTROL THE AMPLITUDE AND SPATIOTEMPORAL PHASE PATTERNING OF OSCILLATIONS IN THE SUBCORTICAL VISUAL SYSTEM?

Rowshanak Hashemiyoon* and John K. Chapin, Department of Physiology and Biophysics, Hahnemann University, Philadelphia, Pa. 19102

Using simultaneous multielectrode recordings, we have determined that retinally derived subcortical visual system oscillations (SVSOs; 10-40Hz) are ubiquitous throughout the direct retinal receiving zones of the pretectal area, superior colliculus (SC) and lateral geniculate nucleus (LGN) in rats. To elucidate the functional significance of these phenomena, we investigated the effects of various parameters of visual stimulation on the amplitude, frequency, and spatiotemporal phase patterning of these SVSOs via recordings through electrode arrays in the target nuclei. Whereas static light stimulation over the whole visual field markedly decreased the amplitude of oscillatory bursts, it had minimal effect on frequency and did not change spatiotemporal phase patterning. On the other hand, several types of dynamic visual stimulation produced marked changes in both amplitude and spatiotemporal phase patterning. Light flashes produced transient strong oscillatory episodes with phase resetting. The magnitudes of these effects were correlated with the flash frequency, as well as the size and brightness of the flashed area. Small localised flashes produced complex spatial phase patterning consistent with travelling waves. Light/dark edge stimuli moving across the visual field also produced increased oscillatory amplitude and phase resetting, with magnitudes dependent on the movement velocity, size and contrast of the edge. These results suggest that such oscillatory dynamics could play a significant role in the processing of flashing or moving visual stimuli. In particular, the propagation of spatiotemporally complex phase information across the retina may constitute a dynamic-distributed representation of visual information.

SYNCHRONOUS OSCILLATIONS IN THE LGN REFLECT STIMULUS-DEPENDENT LONG-RANGE INTERACTIONS IN THE RETINA. S. Neuenschwander', S. Herculano and W. Singer Max-Planck-Institut für Hirnforschung, Deutschordenstraße 46, 60528 - Frankfurt a. M., Germany. Perceptual binding of stimulus features has been proposed to be coordinated

by synchronization of neuronal activity. So far, most of the experimental work has focused on cortico-cortical interactions, and only a few studies have examined subfocused on cortico-cortical interactions, and only a few studies have examined sub-cortical structures. Recently we demonstrated that synchronous oscillatory responses in the retina are transmitted reliably by the lateral geniculate nucleus (LGN). Here we investigate with multi-electrode recordings the stimulus-dependency of synchronization of oscillatory responses from retinal ganglion cells in anesthetized cats.

Oscillatory responses were evoked best by large stationary stimuli or moving gratings, and also by global changes in luminance, suggesting the involvement of center-surroud interactions in the generation of rhythmic activity.

An important requisite for synchronization over large distances was that cells be activated with a continuous stimulus. Sliding window analysis reveals that activated with a continuous stitutus, studing window analysis receasi moscillatory activity builds up quickly, accompanied by a decrease in oscillation frequency over time. This pattern does not depend on the spiking activity of individual cells, suggesting that synchronous oscillations emerge from population dynamics. The oscillation frequency is in general lower for OFF-(mean 69 & ± 12.2 Hz) than for ON-responses (89.6 ± 11.5 Hz). Interestingly, synchronization is not restricted to cells of similar center type, as ON-center responses of an ON-cell and

On-surround responses of OFF-cells can synchronize.

Our results suggest that depending on its spatial properties, a visual stimulus is capable of organizing large cell populations in the retina into ensembles that cooperate over long distances. Stimulus-dependent long-range synchronization of responses in the retina could signal elementary spatial relations such as size and continuity of the stimuli. Since the temporal patterning of retinal responses is transmitted reliably by LGN neurons, information about basic spatial relations could then be exploited in perceptual grouping at higher levels of visual processing. FEEDBACK IMPROVES THE TEMPORAL ACCURACY OF NEURONAL EVENTS IN THE VISUAL PATHWAY. E. Nelle, K. Funke, B. Li and F. Wörgötter*. Inst. of Physiology, Dept. of Neurophysiology, Ruhr-Universität Bochum, D-44780 Bochum, Germany

The temporal accuracy of the signal transmission in the visual pathway is expected to deteriorate with increasing distance from the retina due to noise and other sources of activity uncorrelated to a driving retinal input. In a set of extracellular recording experiments in anesthetized (N₂O/O₂ 70:30, halothane 0.4%) and paralysed (alcuronium chloride 0.15mg/kgh) cat, using flashed spot stimuli, we find on the contrary that the temporal precision of spike events is in many geniculate relay cells higher than in the corresponding retinal afferents: this histograms of many LGN cells by about 20% as compared to the retinal prepotentials. A mechanism to explain the increased accuracy is proposed and implemented in a biophysically computer model for the dynamics of the membrane potential in the thalamo-cortical network. The action of excitatory corticogeniculate feedback allows a temporal fine-tuning of the spike-pattern in geniculate cells. The temporal correction introduced by the cortex is mainly determined by an averaging process among those LGN cells projecting to one cortical cell. The improved temporal accuracy is accompanied by an increase in the mean firing rate of the geniculate cells. We were able to confirm the theoretical results with experimental data, using reversible inactivation of the visual cortex (cooling or GABA micro-ionophoresis) to switch off the excitatory corticofugal feedback. A disfacilatory effect induced by cortex inactivation was found in about 65% of the LGN cells. Consistently this effect was accompanied by a broadening of the interval distributions. Therefore, it could be speculated that one aspect of feedback loops might be to reduce the temporal dispersion of spike trains.

LOCALIZATION OF METABOTROPIC GLUTAMATE RECEPTORS IN MONKEY LGN AND VPL. M. Xiong*, S.C. Van Horn, D.W. Godwin, A. Erişir, and S. M. Sherman, Dept. Neurobiology, SUNY, Stony Brook, NY 11794-5230. We have recently shown in the cat LGN that different metabotropic glutamate

We have recently shown in the cat LGN that different metabotropic glutamate receptors (mGluRs) have different distributions (Van Horn et al., Soc. Neurosci. Abstr. 21:658, 1995; Godwin et al., Soc. Neurosci. Abstr. 21:659, 1995). Labeling for mGluR1α (a splice variant of mGluR1) mostly labels fibers, which are relay cell distal dendrites at sites of cortical inputs. The mGluR5 antibody mostly labels puncta, which are F2 (dendritic) terminals of interneurons. Labeling for mGluR1α and mGluR5 is also seen in the thalamic reticular nucleus (TRN). However, mGluR2/3 labeling is very heavy in the TRN but light in LGN. We extended these observations to the macaque neavy in the 1RN but light in LGN. We extended these observations to the macaque monkey, using light microscopic immunocytochemistry to reveal staining for the various mGluRs. In the monkey LGN, the mGluR1 α antibody labeled a meshwork of fibers and was dense throughout, although magnocellular (M) laminae appeared more densely stained than parvocellular (P). Laminar borders could not be seen, because the interlaminar zones were also stained. This was similar to the pattern in the cat LGN, interlaminar zones were also stained. This was similar to the pattern in the cat LGN, where the staining in interlaminar zones is due to the fact that many distal dendrites of relay cells cross laminar boundaries. Staining for mGluR5 was mostly punctate and also darker for M than P laminae, but laminar borders were quite distinct, because staining was much lighter in interlaminar zones. This, too, is similar to the pattern in the cat and is explained there by the limitation of all interneuron processes, including all F2 terminals, to the lamina in which the interneuron's soma is located. Thus the staining in the monkey LGN is consistent with the notion that mGluR1¢ labels distal dendrites in the monkey LCN is consistent with the notion that mGluR1 α labels distal dendrites of relay cells and mGluR5 chiefly labels the dendritic terminals of interneurons, as in the cat. We also observed both mGluR1 α and mGluR5 labeling in the monkey's TRN. The labeling for mGluR2.7 was also similar to that in cat: dense in TRN but very light in the LGN. Finally, to extend the observations from LGN to other thalamic nuclei, we investigated the staining pattern seen in monkey VPL. Label for both mGluR1 α and mGluR5 was dense in VPL, but that for mGluR1 α chiefly labeled fibers and that for mGluR5 chiefly labeled puncta. Labeling for mGluR2.7 was much lighter in VPL. (We thank Carl Romano for providing the mGluR5 antibody. Supported by EY03038.)

DIFFERENCES IN SYNAPTOLOGY OF RELAY CELLS BETWEEN LAMINAE A AND A1 OF CAT LGN. S.C. Van Horn, A.Erisir, and S.M. Sherman*. Dept. Neurobiology, SUNY, Stony Brook, NY 11794-5230. The A-laminae of the cat LGN are often viewed as matched structures differing only by ocular input: the contralateral and ipsilateral eyes innervate lamina A, and the

by ocular input: the contralateral and ipsilateral eyes innervate lamina A, and the ipsilateral eye, lamina A1. However, few studies have compared details of circuitry between these laminae. We thus used the EM to investigate synaptology in these laminae, sampling 1191 terminals in 9 sections from 6 brains. We analyzed the distributions for each section of RLP (retinal), RSD (mostly cortical), and F (local inhibitory) terminals, and we used postembedding immunocytochemistry for GABA to distinguish relay cells (GABA-) from interneurons (GABA+). Compared to lamina A, Lamina A1, showed significantly more RSD terminals (57.4±1.8% vs 30.9±1.7%) terminals. Since these sections also contained terminals anterogradely labeled from visual cortex, we were able to determine that the interlaminar difference in RSD terminals can difference in roctical terminals, which display RSD morpholove. However, inputs Since these sections also contained terminals anterogradely labeled from visual cortex, we were able to determine that the interlaminar difference in RSD terminals was due to a difference in cortical terminals, which display RSD morphology. However, inputs to interneurons were statistically similar (lamina A vs A1: 35.6±2.5% vs 33.9±2.7% RSD; 37.0±1.8% vs 37.1±0.7% RLP; and 26.3±1.2% vs 28.9±2.4% F), and included significantly more RLP and fewer RSD inputs than did relay cells, so the interlaminar differences were limited to relay cells (lamina A vs A1: 53.2±1.7% vs 66.7±1.7% RSD; 15.3±0.9% vs 13.9±1.1% RLP; and 31.7±1.5% vs 25.4±2.8% F). Thus relay cells in these laminae received equivalent ratios of RLP inputs, but in lamina A they received significantly more F and fewer RSD inputs than in lamina A1. Other data indicate that relay X cells receive more F and less RSD input than do relay Y cells (Wilson et al., *Proc. Roy. Soc. B.*, 221.411-436, 1984), so our observations are consistent with other evidence (Colby, *J. Neurophysiol.*, 59:1783-1797, 1988) that lamina A1 contains an additional population of Y cells. That is, relay Y cells include a subset that feeds corticotectal circuitry, and while lamina A1 includes this subset, lamina A does not; this subset for the contralateral eye instead relays through lamina C. In any case, our results indicate subtle difference in synaptology between laminae A and A1, and these differences are limited to relay cell inputs. (Supported by USPHS Grant EY03038.)

DORSAL RAPHE AND TUBEROMAMMILLARY NUCLEI MODULATE VISUAL RESPONSES AND FIRING MODE OF LGN RELAY CELLS. J.-T. Xue, J.K. Harting & D.J. Uhlrich* Dept. of Anatomy, University of Wisconsin Medical School, Madison, WI 53706.

Ascending visual signals are actively gated in the thalamic lateral

geniculate nucleus (LGN) under the control of extrinsic modulatory systems. Prior studies have focused on the effects of the brainstem cholinergic projection to the LGN, but *in vitro* pharmacology suggests that other systems should have an important effect as well. Thus, we have examined the effects on cat LGN visual responses of activation of the examined the effects on cat LOTA visual responses of activation of the serotonergic dorsal raphe nucleus (DRN) and the histaminergic tuberomammillary nucleus (TMN) of the hypothalamus. We used the same in vivo extracellular recording methods that we used in studying the cholinergic projection to the LGN (J. Neurophysiol. 73:2428, 1995).

TMN activation usually resulted in an enhancement in visual responses of LGN X and Y cells. If these cells exhibited the burst mode of firing, TMN activation promoted them to the tonic mode. We examined the effects on spatial tuning properties, and found the greatest enhancement high spatial frequencies. In contrast, DRN activation resulted in a pronounced inhibition in the visual responses of most LGN cells, and their firing behavior was switched from the tonic to the burst mode. Spatial tuning curves showed a reduction at all frequencies, often greatest at low spatial frequencies. These results, together with our previous cholinergic data, provide evidence for a continuum of modulatory effects in the LGN. This supports the idea that the LGN is a dynamic spatial and temporal filter whose tuning characteristics are under the control of extrinsic modulatory

COMPARISON OF CORTICAL AND CHOLINERGIC BRAINSTEM PROJECTIONS TO THE LCN IN CATS: AN EM STUDY. A Erisir*. S.C. Van Hom. and S.M. Sherman. Dept. Neurobiology, SUNY, Stony Brook, NY 11794-5230.
Visual cortex and brainstem provide the major nonretinal extrinsic inputs to LGN relay cells and modulate the relay of retinal information. We used the EM to compare the distribution of synaptic terminals from these inputs onto relay cells in the cat's LGN A-laminae. We identified corticogeniculate (CG) terminals via orthograde transport of biocytin into cortical areas 17, 18, or 19; we identified brainstem terminals via immunocytochemical labeling for ChAT or BNOS (all ChAT positive terminals also labeled for BNOS), since >90% of brainstem inputs to LGN derive from ACh & NO containing cells of the parabrachial region (PBR). Most CG and PBR terminals share the same basic RSD morphology (round vesicles, small terminals, 4ark mitochondria) containing cells of the parabrachial region (PBR). Most CG and PBR terminals share the same basic RSD morphology (round vesicles, small terminals, dark mitochondria) and make asymmetric synapses. However, despite a size overlap, PBR terminals were significantly larger. PBR terminals contacted thick, proximal dendrites amongst retinal terminals both inside and outside of glomeruli; this is the retinal recipient zone. CG terminals contacted thin, distal dendrites, where no retinal terminals were found, in the cortical recipient zone. We saw no overlap on relay cell dendrites between the zones of CG and PBR inputs. Of all LGN terminals, 55% are RSD, and despite the lack of supporting data, it has been generally assumed that >95% of RSD terminals are CG and very few are PBR. From our data, we used 3 different means of determining the ratio of CG and PBR inputs. I) a comparison of interneuron (identified by postembedding anti-GABA immunocytochemistry) and relay cell target preferences of unlabeled RSDs and labeled CG terminals, 2) a re-evaluation of the distributions of rulabeled RSDs terminals found in the retinal and cortical recipient zones of relay cell dendrites; and and labeled CG terminals; 2) a re-evaluation of the distributions of unlabeled RSD terminals found in the retinal and cortical recipient zones of relay cell dendrites; and 3) an algorithm based on size distributions of unlabeled RSD, labeled CG, and labeled PBR terminals. All 3 analyses suggest that ½-½ of RSD terminals are PBR, the rest being CG. The surprisingly large number of PBR terminals and their location amongst retinal inputs suggest a stronger than previously thought role for them in gating retinogeniculate transmission. Conversely, the location and number of CG terminals suggests a smaller role than formerly thought for this input. (Supported by USPHS Grant EY03038.)

EVIDENCE FOR ACTIVATION OF FEEDFORWARD GABAERGIC CIRCUITRY IN CAT LGN VIA A SPECIFIC METABOTROPIC GLUTAMATE RECEPTOR. D.W. Godwin*. O. Zhou, and S.M. Sherman, Dept. Neurobiology, SUNY, Stony Brook, NY 11794-5230.

Our prior evidence implicates a metabotropic glutamate receptor (mGluR) in feedforward inhibition through F2 terminals of interneurons in the cat LGN (Zhou et al., Soc. Neurosci. Abstr. 20:133, 1994; Godwin et al., Soc. Neurosci. Abstr. 21:659, 1995): the mGluR agonist ACPD applied in vitro, in addition to depolarizing LGN relay cells, produces in some cells a bicuculline sensitive decrease in input resistance. (R_N.) Immunocytochemical localization shows that mGluR1 receptors on relay cell dendrites are likely responsible for the depolarization via activation from cortical (R_n) Immunocytochemical localization shows that mGluR1 receptors on relay cell dendrites are likely responsible for the depolarization via activation from cortical terminals and that mGluR5 receptors on F2 terminals postsynaptic to retinal inputs are likely responsible for the decreased R_n . We have now performed a preliminary in vivo investigation to extend this interpretation of the inhibitory pathway by studying the effect activating mGluR5 receptors with trans-azetidine-2,4-dicarboxylic acid (tADA), reported to be a selective mGluR5 agonist. The effect of tADA application is fundamentally different from application of ACPD, which generally depolarizes all LGN relay cells and promotes tonic firing instead of burst firing. Application of tADA to most relay X cells suppressed the sustained portion of the response to flashed spots, with less effect on initial peak responses; tADA in some X cells produced nearly total inhibition. In contrast tADA application had very little effect on relax Y cells or cells with less effect on initial peak responses; tADA in some X cells produced nearly total inhibition. In contrast, tADA application had very little effect on relay Y cells or cells thought to be interneurons. Relay X cells are richly innervated by retinal and F2 terminals in triadic arrangements suggestive of feedforward inhibition, since the retinal terminal contacts both the X cell dendrite and the F2 terminal, which in turn, contacts the same X cell dendrite. In contrast, neither relay Y cells nor interneurons receive significant innervation from F2 terminals. Our data are thus consistent with the conclusion that retinal inputs produce feedforward inhibition in relay X cells (but not Y cells or interneurons) via activation of mGIRS on F2 terminals. Since mGIRS may be consistent with the feature of the publication of the contraction that the feature of the publication of the contraction of the contraction that the publication of the publication of the contraction that inhibition is related to the publication of the contraction that inhibition is related to the publication of the contraction that inhibition is related to the publication of the contraction that inhibition is related to the publication of the publ require high frequency afferent input for activation, this inhibitory circuit may be evoked mainly when retinal firing rates are high, and this could serve to increase the dynamic range of LGN relay X cells. (Supported by EY03038.)

BOTH NMDA AND GABA $_B$ SYNAPTIC MECHANISMS CAN ACCOUNT FOR CORTICOFUGALLY-INDUCED CROSS CORRELATIONS IN dLGN OF THE CAT. C. D. Brody*. CNS Program, California Institute of Technology, Pasadena CA 91125

Sillito et. al. [Nature 1994, **369**: 479-482] reported significant cross-correlations (typically centered at 0 ms and of approx. 80 ms width) between the firing of pairs of dorsal lateral geniculate nucleus (dLGN) cells whose receptive fields were 1 to 4 degrees apart in the visual field. The cross-correlations were dependent on intact feedback from visual cortex. Analysis of this data shows that significant cross-correlations exist both when the dLGN cells fire tonically and when they fire in bursts. A model of dLGN cells is used to investigate the biophysical mechanisms necessary to account for the cross-correlations. Computational simulations using model cells indicate that inputs which are common to both cells and which have time courses on the order of tens of milliseconds or longer can generate cross-correlations with a time width similar to those observed *in vivo*. The net synaptic strength required for the strength of the cross-correlations between simulated cells to be similar to that observed in vivo lies in a physiologically plausible range both for NMDA-type synapses and ${\rm GABA}_B$ -type synapses. These may account for cross-correlations during tonic firing. Low-threshold calcium channel-mediated spikes have also been shown to be a mechanism capable of causing the observed cross-correlations (see Kirkland and Gerstein, this volume), and are likely significantly involved during burst firing.

DEVELOPMENTAL CHANGES IN SYNAPTIC EFFICACY IN THE RAT RETINOGENICULATE PATHWAY. F-S Lo¹ & W. Guido. Anatomy & Neuroscience Center. LSU Medical Center New Orleans, LA 70112.

Little is known about the synaptic properties of LGN relay neurons and the prevalence of long-term changes in synaptic efficacy during the development and refinement of connections in the mammalian retinogeniculate pathway. Using intracellular whole cell recordings and extracellular field potentials, in an isolated (in vitro) brainstem preparation, we examined the nature of synaptic transmission in the LGN of rats between postnatal day (PND) 0-32. At all ages tested, field potentials in LGN and EPSP(c)s in relay cells were recorded following electrical stimulation of optic tract (OT) fibers. During the time when connections are still developing (PND 0-4), OT stimulation produced long-lasting (400-800 ms) and purely excitatory responses in LGN. The duration of these were voltage-dependent and APV sensitive. After PND 5, EPSPs were always coupled with nIPSP (EPSP/IPSP pair). The IPSP component had a short duration (40 ms) and was bicuculline sensitive. An additional IPSP emerged by PND 7 that was long-lasting and bicuculline insensitive. Long-term changes in synaptic efficacy were also observed throughout development. Between PND 0-7, tetanic stimulation (6 1-sec trains of 50 Hz pulses at 30-sec intervals) of OT fibers produced strong (>50%) long-term (>60 min) depression (LTD) of synaptic activity (whole-cell recordings and field potentials). After PND 7, tetanus led to a mixed response: periods (10-40 min) of depression coupled with potentiation (5-15 min). By PND 30, tetanus produced a reliable, but moderate (10-20%) long-term potentiation (LTP). Thus many aspects of synaptic transmission are subject to developmental regulation, including the onset and prevalence of NMDA and GABA activity, and long-term changes in synaptic efficacy. These changes may contribute to the activity dependent refinement of retinogeniculate connections seen during development. Support by NSF 9396270 (WG).

AN OPTICAL FRACTIONATOR ANALYSIS OF NEURONAL CHANGES IN THE LATERAL GENICULATE NUCLEUS OF MONKEYS WITH EXPERIMENTAL GLAUCOMA. E.A. Nimchinskyl* J.C. Vickers³, W.G. Young⁴, R.A. Schumer², R.E. Wang², S.M. Podos², J.H. Morrison¹, and P.R. Hoſ¹-². Depts of ¹Neurobiol. and 20phthalmol., Mount Sinai Sch. Med., New York, NY 10029, ³Dept of Pathol., Royal Hobart Hospital, Australia 7000, ⁴Scripps Research Institute, La Jolla, CA 92037.

Hobart Hospital, Australia 7000, 4Scripps Research Institute, La Jolla, CA 92037. Degenerative alterations and cell loss occur in neuronal subsets in the retina and the visual pathways of monkeys with experimental glaucoma. In the present study, pathologic changes were quantified in the lateral geniculate nucleus (LGN) of macaque monkeys with different degrees of glaucoma severity. Glaucoma was induced in one eye by laser photocoagulation of the trabecular meshwork. After a variable period of sustained elevated intraocular pressure, the monkeys were killed and their brains prepared for immunohistochemistry with antibodies to neurofilament protein (NFP) and parvalbumin (PV). Stereologic unbiased estimates of total neuronal numbers were obtained using the optical fractionator in the ipsi- and contralateral magno (M)- and parvocellular (P) layers of the LGN, separately. Results indicated that both M and P layers receiving from the affected eye were severely affected in glaucoma with neuron loss as high as 63%. NFP-containing neurons were less sensitive in the M layers than in the P layers (25 vs 64% loss), whereas PV-positive cells were equally affected in both (50%). Monkeys with early signs of glaucoma had very mild changes in both M and P neuron counts. Comparison of the ipsi- and contralateral P to M total neuron count ratios provided a reliable indicator of glaucoma severity in each monkey, and revealed that PV labeling was less preserved overall than NFP labeling. Since our estimates of total neuron numbers suggest that these proteins are largely colocalized in M and P neurons, a decrease in PV-positive cells exceeded in some cases that of NFP- and NissI-stained cells. These data show that in glaucoma, severe neuron loss in the LGN may occur independently of the presence of NFP and W, and without clear selectivity for the M or P layers. SOMATOSTATIN DECREASES INHIBITORY POSTSYNAPTIC POTENTIALS IN KITTEN DORSAL LATERAL GENICULATE NUCLEUS IN VITRO. E. Asprodini*, Zs. Emri and V. Crunelli. Physiology Unit, School of Medical and Molecular Biosciences University of Wales Cardiff UK.

Immunohistochemical studies have revealed the presence of somatostatin immunoreactivity in cell bodies and primary dendrites of neurones in the nucleus reticularis thalami (A.M. Graybiel and R.P. Elde J. of Neurosci. 1983. Vol. 3 pp1308-1321.). In the hippocampus and septum where GABA and somatostatin are co-localized the modulation of GABAergic neurotransmission by somatostatin has been shown, but in the thalamus similar evidence is lacking.

We studied the effect of somatostatin (3-14) on spontaneous inhibitory potentials (IPSPs) recorded from dorsal lateral geniculate nucleus (dLGN) thalamocortical (TC) neurones of 5-10 days old kittens in vitro. In this age range TC neurones showed spontaneous GABAA receptor-mediated activity either as single IPSP or as bursts of IPSPs. Bath application of somatostatin (1-10 μ M) did not change the passive properties of TC neurones (n=15) but reversibly decreased the frequency of the spontaneous events by 45%. The amplitude of the IPSPs were reduced by 25% and where bursts of IPSPs were present the number of IPSPs within the burst and the duration of the burst were also decreased (n=7). In 1 cell somatostatin (10 μ M) abolished all spontaneous activity.

These results indicate that somatostatin modulates GABAergic transmission in the visual thalamus. Supported by the Wellcome Trust.

DECREASED GABAERGIC INHIBITION IN THE ADULT CAT VISUAL SYSTEM AFTER SENSORY DEAFFERENTATION AS REVEALED BY IN SITU HYBRIDIZATION FOR GAD₆₅ AND GAD₆₇ L. Arckens^{1,2}, E. Van der Gucht^{1,2}, U.T. Eyse³, G.A. Orban², F. Vandesande¹ Lab. Neuroendocr. & Immunol Biotechnol., ²Lab. Neuro- and Psychophysiol., Medical School, Katholieke Universiteit Leuven, B-3000 Leuven, Belgium; ³Dept Neurophysiol., Medical School, Ruhr-Universitet Bochum, D-44770 Bochum, Germany.

The effect of partial central retinal lesions on the GAD $_{\rm e7}$ and GAD $_{\rm e8}$ mRNA levels in the dorsal lateral geniculate nucleus (dLGN), the perigeniculate nucleus (GLGN), the perigeniculate nucleus (GLGN), the perigeniculate nucleus (GGN) and the visual cortex of the adult cat was investigated by in situ hybridization. Three days post-lesion, a decrease in the number of GAD $_{\rm e7}$ expressing cells became apparent in the deafferented dLGN, persisted uptil 12 months post-lesion and became more pronounced with longer survival times. This decrease in GAD $_{\rm e7}$ mRNA was mirrored by a decrease in GAD-immunoreactive cells. GAD $_{\rm e8}$ mRNA levels were low in the dLGN of control cats and remained very low after retinal lesioning. In all the retinal lesion cats we investigated both GAD $_{\rm e8}$ en GAD $_{\rm e7}$ mRNA levels were decreased in a restricted region of the PGN, specifically the region of the PGN above the deafferented portion of the dLGN. In the lesion-affected visual cortex, no changes at the mRNA level were observed for either GAD $_{\rm e7}$ or GAD $_{\rm e8}$ although changes in GAD immunoreactivity have been described (Rosier *et al.*, J. Comp. Neurol. 359.476-489, '95). Hence, in the dLGN, the PGN and the visual cortex, different mechanisms seem to be effective that might lead to decreased GABAergic inhibition in response to sensory deafferentation.

EFFECT OF METABOTROPIC GLUTAMATE RECEPTOR ACTIVATION ON RAT THALAMOCORTICAL NEURONES IN VITRO. J.P. Turner* and T.E. Salt. Dept. Visual Science, Inst. Ophthalmology, UCL, London, U.K.

The activation of postsynaptic metabotropic L-glutamate receptors (mGluRs) results in membrane potential depolarization, an increase in input resistance, action potential broadening and a decrease in spike frequency accommodation, owing to the inhibition of the potassium conductances contributing to the leak, the M and the calcium-dependent afterhyperpolarization (AHP) currents, and activation of a non-specific cation conductance. Previously, it has shown that the prototypical mGluR agonist 1S,3R-ACPD depolarizes the membrane potential of thalamocortical (TC) neurones by reducing a potassium conductance (McCormick & von Krosigk, 1992). Here, the effects of mGluR activation on the action potential, its AHP and firing patterns, together with the type of mGluRs responsible are addressed.

The application of 1S,3R-ACPD (50-300µM) to slices of rat dLGN maintained in vitro, caused a concentration-dependent depolarization of membrane potential (2-14mV), associated with an increase in input resistance. As a result, TC neurones were more excitable in the presence of 1S,3R-ACPD when tested with positive current pulses, and the action potentials elicited were larger in amplitude with a smaller late AHP. In addition, the firing of TC neurones was transformed from a regular pattern in control to an accelerating one in the presence of 1S,3R-ACPD. The type 1 mGluR agonist (RS)-3,5-dihydroxyphenylglycine (50-100µM) produced similar effects to 1S,3R-ACPD, including depolarization of membrane potential (3-11mV), while the type 1 mGluR antagonists (S)-4-carboxyphenylglycine (500-2000µM) and 1-aminoindan-1,5-dicarboxylic acid (200-500µM) depressed responses to 1S,3R-APCD (50-100µM) by up to 50%. In conclusion, the activation of postsynaptic mGluRs on TC neurones in the dLGN produces a number of effects consistent with an increase in neuronal excitability, and that these effects are mediated, in part at least, via type I mGluRs. MULTI-COMPARTMENTAL MODEL OF A THALAMOCORTICAL NEURONE. K. Antal, Zs. Emri, T.I. Tóth and V. Crunelli. Physiology Unit, Sch. Mol. & Med. Biosci., University of Wales Cardiff, Cardiff, UK.

An existing one-compartmental model (Tóth & Crunelli, NeuroReport, 3, 65-68, 1992) of a thalamocortical (TC) neurone was extended to include dendritic regions. The geometry of this multi-compartmental model was chosen according to a representative soma-to-dendritic terminal path of an X cell of the cat dorsal lateral geniculate nucleus. The distances of terminals from the soma, and the number of dendritic branching along the path were based on the reconstruction by Bloomfield et al. (J. Physiol., 383, 653-692, 1987). The dendritic geometric parameters were calculated to yield the total surface area of the reconstructed dendrites, and the dendritic branches were further subdivided in order that all compartments had electrotonic lengths of less than 0.1, reaching thus a total of 25 compartments. The passive parameters and the specific conductances on the soma and on the dendrites were adjusted to produce the following characteristic activity patterns of TC neurones in response to constant injected current: tonic firing when the cell was depolarized above -45 mV, and pacemaker oscillation between -55 and -75 mV. The activity patterns of the multi-compartmental model with different distributions of non-linear ion channels on its dendrites were compared to those of *in vitro* electrophysiological measurements, and to the corresponding responses of the one-compartmental model. We found that the presence of voltage-activated non-linear currents on the dendrites was necessary to evoke pacemaker oscillation. Dendritic distributions of ion channels at which the multi-compartmental model reproduced the tonic firing and oscillatory activity with the same voltage-dependence as measured in vitro will be presented.

CONDUCTANCES COMPUTER-GENERATED THALAMOCORTICAL NEURONES. S.W. Hughes. T.I.Tóth, S.R.Williams, A. Ceci* and V. Crunelli. Physiology Unit, School of Molecular & Medical Biosciences, University of Wales Cardiff, Cardiff, UK.

We describe a system based on the dynamic clamp technique which allows the addition of artificial conductances to thalamocortical neurones maintained in vitro using a combination of mathematical modelling and intracellular recording (J.Neurophysiol. 69: 992-995, 1993). The system is personal-computer-based and functions by simultaneously sampling (≥10kHz) the membrane potential (V_m) and injecting trans-membrane current (I), where I is related to V_m by a system of nonlinear differential equations specifying the desired steady-state and kinetic properties of the conductance(s) to be added. In particular, the technique was used to investigate the effects of modulating the transient low-threshold calcium current (I_T) and noninactivating mixed cation current (Ih) common to thalamocortical neurones. The equations used for I_T and I_h were adopted from a previously developed single-compartment model of a thalamocortical neurone (Neuroreport. 3: 65-62, 1992). We initially tested and refined our mathematical representations of these currents by introducing them with opposite sign into thalamocortical neurones. By fine parameter adjustment, we were then able to abolish the typical effects of their in vitro counterparts over an appropriate voltage range and obtain accurate descriptions of the currents. In the case of IT, we demonstrated how a small increase in maximal conductance, and hence its steady-state window component, gave rise to novel input-output properties and oscillatory activity, and, in the absence of I_h , bistability of the neurone. We then blocked I_h by application of ZD 2788 (300 μ M) and after reproducing the control current-voltage relationship with artificial I_h , revealed how positive shifts in its activation curve affected the input-output properties of thalamocortical neurones. This work was supported by the Wellcome Trust

SODIUM CURRENTS IN THALAMOCORTICAL NEURONES. H.R.Parri, N.Leresche* and V. Crunelli. Physiology Unit, School of Mol. and Med. Biosciences, University of Wales Cardiff, Cardiff, Wales, U.K.

Whole cell patch clamp recordings were made from rat thalamocortical (TC) dorsal lateral geniculate neurones in an intact thin slice preparation and an acutely dissociated cell preparation. Recording solutions were used that blocked K+ and Ca2+ currents. Transient Na+ currents were completely blocked by application of 1µM TTX. The threshold for activation was between -60mV and -50mV in both preparations. Maximum currents were observed around -30mV, and were -2.1±0.8nA (n=7) in the slice and -2.7±0.6nA (n=9) in dissociated neurones. Threshold responses in the slice were characterised by the sudden appearance of delayed large amplitude transient Na⁺ currents. In dissociated neurones, responses to increasing step depolarisations displayed a gradual increase in the Na+ current, permitting the construction of activation curves. Activation, from a holding potential of -120mV could be fitted with a single Boltzman function with V1/2= -40.2mV. Steady-state inactivation was also fitted with a single Boltzman, V1/2=-67mV. Recovery from inactivation at a holding potential of -120mV following a 10ms step to -10mV was rapid, with t1/2<5ms. These results show that Na+ currents from TC neurones in an intact slice preparation display similar properties to those in acutely dissociated neurones. The enhanced space clamp properties of the dissociated neurones, however, permit more accurate kinetic analysis of these currents.

IN MACAQUE V1 LATERAL CONNECTIONS IN LAYER 4B HAVE A DIFFERENT TOPOGRAPHY THAN IN LAYERS 2/3, H.Asi, J.B.Levitt, and J.S.Lund* Dept. Visual Science, Institute of Ophthalmology,

university College, London, U.K.

Pyramidal neurons in layers 2/3 of the adult macaque monkey V1 have laterally spreading axon collaterals making regularly sized and spaced patchy terminal fields (patches 227µm dia., 430µm center to center) in the same layers; these connections link points of similar orientation specificity and ocular dominance. Layers 4B and upper 4Ca also have laterally expreading intrinsic connections but unlike 2/3 contain spreading intrinsic connections but unlike 2/3, contain directionally selective neurons and both spiny stellate and pyramidal cells. The topography of terminal sites within $4B/4C\alpha$ is not known. We have made small $(300\mu m)$ iontophoretic injections of biocytin within layer 4B-upper 4Ca and sectioned the V1 tissue tangential to the pia to investigate the topography of connections within the region; interleaved sections were reacted for cytochrome oxidase(CO) to establish laminar boundaries. In adult and infant (4.5 wks.) the lateral connections establish parallel, bar shaped terminal fields immediately surrounding the injection site; bars are ~200µm wide, 700-2,000µm long, and spaced ~400µm center to center; these break into linear arrays of patches further from the injection site($\sim 260 \mu m$ dia., 545 c/c) in the infant. The difference in connectional topography between layer 4B and layers 2-3 suggests that functional topography between layer 48 and layers 2-3 suggests that functional topography at the two depths may be different, perhaps relating to direction specificity. ROTATED HYPER-ELLIPSES IMPROVE MULTI-UNIT SPIKE SEPARATION. P.

ROTATED HYPER-ELLIPSES IMPROVE MULTI-ONT SPIKE SEPARATION. E. A. Hetherington*, P. Zakarauskas, & N.V. Swindale. Dept. of Ophthalmology, Univ. of British Columbia, 2550 Willow St., Vancouver, BC., Canada V5Z 3N9 Plots of waveform parameters from extracellularly recorded multi-unit spikes typically show clusters (Figure), where each cluster is likely to correspond to the firing of a single neuron. These clusters are often elongated, especially when recorded from cells that fire in bursts, and often overlap when lower-impedance stereotrodes or lattedes are used. tetrodes are used.

Separating overlapping and elongated clusters typically involves manually establishing upper and lower parameter boundaries (Figure, left), and often requires examining many pairs of parameters before a satisfactory separation is achieved. This is a tedious, subjective, and inexact process. An automated method such as hierarchical cluster analysis is ideal, but impractical when many thousands of spikes are considered. K-Means analysis is much faster, but requires pre-specifying the number of units, and is inadequate when clusters are elongated. Hybrid methods combining hierarchical and K-Means (e.g., Mitra et. al., S.N.A., 21, 51.4) are good alternatives, but still split elongated clusters. Computing ratios between the spike amplitudes on two channels ("phase angles") removes elongated clusters, but adds additional parameters and loses absolute spike amplitudes.

We describe a new clustering algorithm that combines hierarchical and K-Means, and which also respects the natural elongated and rotated nature of spike clusters in a multidimensional space. Clusters are either manually or automatically component Analysis (Figure, right). These hyper-moments are clustered to the component of the property of the property of the component of the property of the proper

established as the cluster boundaries using Principal Component Analysis (Figure, right). These hyperellipses are computed within seconds, and can be used to classify remaining spikes. The hyper-ellipse method: (1) respects the rotated and elliptical nature of clusters without losing amplitude information, (2) provides a more natural and tighter fit to clusters, thereby reducing cluster boundary volume and overlap, and (3) uses parameter covariances to significantly improve new spike assignment and automated cluster linkage. Supported by NSERC 82020 and MRC 91400.

A MODEL FOR THE CORTICAL MAP OF DIRECTION PREFERENCE. N. V. Hallowskin of Reliable Columbia, 2550

A MODEL FOR THE CORTICAL MAP OF DIRECTION PREFERENCE. N. V. Swindale.* Department of Ophthalmology, University of British Columbia, 2550 Willow St., Vancouver, BC., Canada VSZ 3N9
Recent optical recording data have suggested that cortical maps of direction preference in cat area 18, ferret area 17, and area MT of owl monkey, have similar properties. The maps are characterized by the presence of half-rotation point singularities in the orientation preference. The line singularities subdivide regions with similar orientation preference. The line singularities subdivide regions with similar orientation preference. The line singularities subdivide regions with similar orientation preference into regions with opposed direction preferences. As observed experimentally (Malonek et al., 1994; Weliky et al., 1996), and suggested on the basis of topological arguments (Swindale et al., 1987), line singularities in direction preference originate in orientation singularities and join them via relatively short routes. These observations suggest that the orientation map is primary, and contrains the self-organization of the map of direction preference.

I present here modelling results in which an orientation map develops according to previously described principles of local continuity and global completeness, and a second direction preference vector is weakly constrained to be (a) locally continuous and (b) orthogonal to the orientation preference while enforcing orthogonally leads to a large number of 180° reversals in direction preference. When a computed map in which the spots mark orientation singularities and lines indicate discontinuities in direction preference. Non-orthogonality between orientation and direction direction preference while enforcing orthogonality leads to a large number of 180° reversals in direction preference while enforcing orthogonality leads to a large number of 180° reversals in direction preference is most marked close to the orientation and direction direction preference is most marked close to

A CORTICAL AMPLIFIER MODEL OF DIRECTION SELECTIV-ITY IN STRIATE CORTEX SIMPLE CELLS. Gary R. Holt*, Rodney J. Douglas, and Christof Koch, Computation and Neural Systems, Caltech, Pasadena, CA 91125; Institute of Neuroinformatics, ETH/UZ, Gloriastrasse 32, CH-8006, Zürich.

The majority of excitatory input to layer IV spiny stellate cells in primary visual cortex comes not from thalamic axons but from other nearby cortical cells. Yet most models so far have ignored the short range excitatory cortico-

Our model consists of two spatially offset populations of integrate-and-fire neurons; each population has 320 excitatory and 80 inhibitory cells. Excitatory cells are connected to other excitatory cells in the same population with the same receptive field, so a small thalamic input is amplified by feedback. Excitatory cells also connect to inhibitory cells in the same population, whereas inhibitory neurons connect to all types of cells in both populations. All model cortical cells, excitatory and inhibitory, are direction selective because in the null direction inhibition from the other population is sufficient to cancel out thalamic input. Although the model has a high gain and NMDA-like synapses with a slow time course, it does not have a long network time constant because adaptation effectively cancels out the slow parts of synaptic input.

This simple model can reproduce the bandpass velocity tuning curves in the

preferred and null direction observed by Saul and Humphrey (1992), as well as the phase advance at high contrast reported by Carandini and Heeger (1994) Unlike the normalization model of Carandini and Heeger, there is only a small change in input conductance in response to stimuli in the null direction because only a small amount of inhibition is required to offset the small thalamic input.

Supported by grants from the Sloan Foundation, ONR, and the Engineering Research Center at Caltech.

STIMULUS SELECTIVITY OF NEIGHBORING CELLS IN MONKEY STRIATE CORTEX. T-D. Shou2*, Y-C. Wang1, M.T. Schmolesky1 and A. G. Leventhal¹. ¹Dept. of Neurobiology and Anatomy, University of Utah, Salt Lake City, UT 84132. ²Dept. of Biology, USTC, Hefei 230027, P.R.China.

It has been reported that direction (D) and orientation (O) sensitive cells

are segregated from D and O insensitive cells in monkey striate cortex. Cytochrome oxidase rich regions (blobs) are said to contain D and O insensitive, wavelength sensitive cells while cytochrome oxidase poor regions contain D and O sensitive, wavelength insensitive cells (Livingstone and Hubel, 1984). This organization is difficult to reconcile with reports that most monkey striate cortical cells are selective oncomitantly for stimulus attributes such as orientation, direction and color (Leventhal et al. 1995).

In this study we compared the D and O sensitivities of striate cortical cells located within 60 - 300 µm of each other. Stimuli consisted of drifting sinusoidal gratings of various spatial frequencies. Our findings indicate that cells located within 120 μm of each other tend to prefer similar orientations and either similar or opposite directions of motion. This tendency is weaker in the upper than in the lower layers of V1. The degree of D and O sensitivity exhibited by wavelength sensitive and broad band cells does not differ. However, neighboring broad band cells exhibit a stronger tendency to prefer similar directions and orientations than do neighboring wavelength sensitive cells.

Our findings do not support the idea that wavelength sensitive and broad band cells are segregated in V1. However, the relatively poor local organization of D and O sensitivity exhibited by wavelength sensitive cells suggests that local regions rich in these cells should respond to a relatively wide range of stimulus parameters. Thus, field potentials, optical recordings and multiunit recordings from wavelength sensitive regions should yield relatively weak D and O sensitive responses. Supported by EY04951 to A.G.L.

MECHANISMS UNDERLYING CONTEXT DEPENDENT INFLUENCES IN PRIMATE VISUAL CORTEX. H.E. Jones' and A.M. Sillito. Dept. of Visual Science, Inst. of Ophthalmology, London EC1V 9EL, UK

Orientation and direction context dependent effects can be seen at subcortical and cortical levels in the visual system (Knierim and Van Essen. J. Neurophysiol. 67: 961-980, 1992; Sillito et al. Exp. Brain Res. 93:6-16, 1993; Sillito et al., Nature 378:492-496, 1995; Cudeiro and Sillito, J. Physiol. 490:481-492, 1996; Jones et al., IOVS 37:S1058, 1996). Here, we consider evidence from cells in V1 that provide insight into these effects. The data suggest 4 mechanisms. Firstly a core mechanism of variable strength for all cells that exerts a non-orientation specific orientation contrast influence, minimising the output of the cell for extended iso-orientation contours. This generates the suppressive surround and depends on coactivation of centre and surround mechanisms. It was seen in non-oriented $4C\beta$ cells, and in some oriented cells when the inner/outer stimulus—boundary was well within the confines of the classical receptive field (CRF). Subcortical mechanisms may contribute to this. Secondly, in orientation tuned cells, a mechanism that seems to be best explained as a cross oriented (with respect to the cell's optimal orientation) disinhibitory influence that appears to diminish the effect of an inner stimulus encroaching on the suppressive surround. Thirdly, a facilitatory influence capable of exerting effects over a long distance, driven by orientation and direction contrast. This might also be brought into the disinhibitory category if the inhibitory contains. This might also be chough and destend through the centre of the field so that even an optimal stimulus drives them. Fourthly, two overlapping processes underpinning orientation tuning, the elongation of the central excitatory field and excitatory connections between iso-orientation columns. The dependence of the suppressive surround on coactivation of centre and surround suggests an "and" type mechanism for the underlying inhibition and is why diminishing centre contrast can make a surround suddenly seem excitatory (because it actually impinges on the CRF). The cross-oriented disinhibition seems to be exerted by a cross oriented stimulus outside the CRF field or one overlying it, hence in some cases the effectiveness of a cross oriented (with respect to optimal) central stimulus and iso-oriented surround stimulus. A MODEL OF PERCEPTUAL GROUPING PROCESSES IN PRIMARY VISUAL CORTEX, P. Mineiro and D. Zipser*. Department of Cognitive Science, UCSD, La Jolla, CA 92092

Research (Lamme (1994) J. Neuroscience 15:2) has indicated that cells in primary visual cortex show changes in their firing patterns when their classical receptive fields fall within a region of the image which is perceptually grouped into a figure versus when it is perceived as part of a homogenous background. This is true even when the input to the receptive field of the cell is held constant. The modulation only significantly affects cells whose receptive field input is stimulating and begins approximately 100ms after initial response to the stimulus, strongly suggesting the firing assymetry is due to recurrent interactions with the rest of the visual brain.

We constructed a neural network model of complex cells interacting via lateral connectivity and optimized it to segment figure from ground for stimuli similar to those used by Lamme. This model shows steady-state activity modulation similar to that found in vivo and demonstrates that some perceptual grouping computations can be preformed efficiently using local lateral connectivity

CHARACTERIZATION AND LOCATION OF SPATIALLY STABLE PHASE SEGMENTS IN STIMULUS-RELATED SENSORY CORTICAL EEGS FOR THE DEMARCATION OF PERCEPTUAL EPOCHS LIM. Barrie and W.J. Freeman*, Dep't of Molecular and Cell Biol., University of California at Berkeley, Berkeley, CA 94720-3200

Arrays of 64-electrodes (8x8 at 0.56, 0.79 mm interelectrode spacing) were chronically implanted onto the epidural surface of the visual, auditory, somesthetic. and prepyriform cortices of the NZW rabbit. Forty records of EEGs were recorded at 6 sec epochs from a series of classical conditioning experiments where the animal had to sec epochs from a series of cassical continuous geoperiments where the animata to discriminate between a CS- and CS+ stimulus randomly delivered in time and sequence. Previous experiments had demonstrated that spatial patterns of normalized EEG amplitude could be classified as either a CS- or CS+ pattern by a process of arbitrary interval pattern reconstruction and subsequent cross-classification. In order arbitrary interval pattern reconstruction and subsequent cross-classification. In order to more precisely locate EEG segments corresponding to endogenous perceptual activity an analysis technique was designed to locate stable phase patterns. With use of data from previous experiments, spatiotemporal patterns of amplitude and phase were reconstructed by FFT decomposing 128 ms segments (at 4 ms intervals) of EEGs. Each phase pattern was 2D-filtered and fit with a conic surface. Stable phase segments were defined as those where the apex of the regressed cone moved less than 0.75 mm per 4 ms step, where the frequency of the FFT was between 20-80 Hz, where the residual of the regression of less than 20%, and where all of the above criteria were satisfied for at least 40 ms. The apex of each phase cone was a random variable per segment indicating the lack of any pacemaker driving the formation of the EEG spatial patterns. The modal phase velocity was 1-2 Mysec and the modal diameter (commonality or binding of the phase signal within ± cos. 45°) was 0.5-1.0 cm. Using the onset and duration of each stable phase segment to parse the EEG amplitude patterns for classification yielded significantly superior spatial pattern separation compared to previous results, in which segment selection was arbitrary. THE ROLE OF CORTICOGENICULATE FEEDBACK IN MEDIATING CONTEXTUAL EFFECTS IN PRIMARY VISUAL CORTEX AND IN PSYCHOPHYSICS, Valentin Dragoi and Robert P. Erickson.* Department of Psychology: Experimental, Duke University, Durham, NC 27708.

tal, Duke University, Durnam, NC 27/08.
Even though it is well known that the primary visual cortex (V1) projects back to the LGN outnumbering thalamocortical projections by a factor of about 10, most models of orientation tuning and context effects neglect the influence of the massive corticogeniculate feedback (CGF), relying instead on feedforward and lateral connections. This study describes a large-scale model that investigates the role of CGF projections, in addition to feedforward excitation and short and long-range horizontal connections, in addition to feedforward excitation and short and long-range horizontal connections, in explaining context denoted the transfer of the project This study describes a large-scale model that investigates the role of CGF projections, in addition to feedforward excitation and short and long-range horizontal connections, in explaining context-dependent distortions in the orientation tuning (Gilbert & Wiesel, 1990) and firing pattern (Knierim & Van Essen, 1992) of cells in V1, as well as their psychophysical correlates demonstrated in the case of geometrical illusions. The model simulates parts of the static form pathway, i.e., LGN Parvo → Vla(layer 4C) → Vlb(layer 2-3) → Vl(layer 5-6) → LGN Parvo. We configure 31,752 LGN neurons arranged on an array of 21 x 21 locations, and 63,504 cortical neurons arranged on two layers that correspond to Vla and Vlb. Both Vla and Vlb cells develop short-range cross-orientation inhibitory connections. Long-range horizontal connections are made onto iso-oriented cells in Vlb within a circular patch of radius 3 at the center. We show that in the presence of an inhibitory oriented surround the long-range horizontal connections contribute to the disinhibition of the orientation detectors along a direction away from the surround orientation, an effect amplified by the CGF projections that control the transmission of information through the LGN. In order to evaluate the combined effect of corticocortical feedback (CCF) and CGF loops, we added recurrent iso-oriented excitatory projections from V1 (layer 5-6) to Vla. Computer simulations showed that although small ratios between the strength of CCF and CGF projections did not disrupt the context effects, as the strength of the excitatory CCF increases further both surround-dependent orientation shift effect and geometrical illusions reduce drastically in magnitude. Our simulations also showed that if we reduce the strength of CGF projections in favor of long-range horizontal connections both surround-dependent orientation in Vl in the presence of a suppressive surround, and that these physiological effects may be connected with psychophysical phenomena such as geometrical illusi

TOPOLOGICAL INTERPRETATION OF FIGURE-GROUND SEGREGATION. S. Barash*, Department of Neurobiology, Weizmann Institute of Science, Rehovot 76100, Israel.

Visual segregation of figure from ground links local with global aspects of vision, low with high levels. Nevertheless, "figure" remains a primitive, undefined concept. There is no overall understanding of the essence of the process of segregation -- let alone of the underlying physiology.

Here I suggest the following: first, segregation is essentially a topological operation. Second, figures are closed, connected regions in a specific topology that is embodied in the activity of LGN and visual cortex Third, segregation is the process by which a well-defined topological interpretation emerges out of the noisy, ill-defined visual input.

One way to define a topological structure is by specifying a particular basis for a topology. Here we will consider three structures -- the LGN, layer 4 of V1, and the cytochrome-oxidase-rich blobs of V1 -- as the processing stages in which the basis for the perceived topology is being defined. In this context, the large increase in receptive field density of layer 4 (relative to the LGN) acquires a specific significance.

The topological analysis suggested here is dynamic. Processing is reinitiated with every new visual scene, probably for each fixation. Processing may end before completion -- depending on context (task). Cognitive context probably modulates the topological analysis via topdown connections. These qualifications do not, however, alter the core of the segregation process that remains, I suggest, as illustrated above. Supported by the McDonnell-Pew Program in Cognitive Neuroscience.

COMPONENT-PERIMETRY: A NEW METHOD TO REVEAL DIFFERENT TYPES OF VISUAL DISORDERS CAUSED BY CORTICAL LESIONS. G. Bachmann', S. Henke-Fahle^{2*} & M. Fahle¹, ¹Sektion Visuelle Sensorik, ²Dept. of Ophthalmology, University Eye Clinic, D-72072 Tübingen, Germany.

Striate and extrastriate lesions of the cerebral cortex usually lead to visual field defects or selective deficits in one submodality of visual perception Striate and extrastriate lesions of the cerebral cortex usually lead to visual field defects or selective deficits in one submodality of visual perception which are often not consciously experienced by the patient. Our aim is to develop a new perimetric method that test different visual tasks or components separately (color, motion, temporal resolution, orientation, and stereoscopic depth) and that examines the visual field in parallel (simultaneous perimetry). Perimetric patterns were generated by a Macintosh computer and presented on a 20°-color monitor. We examined a visual field area of approximately 50° radius. 37 patients with circumscribed cortical lesions had to scan the different stimuli with their minds eye while fixating steadily. If they perceived local differences of the stimulus they outlined these areas on the screen. Ten of 14 patients with extrastriate lesions perceived no local differences, i. e. no defect. Four patients with extrastriate lesions subjectively detected contralesional local differences within their visual field, but only for some of the components tested. The 23 remaining patients with lesions at or below the level of V1 subjectively experienced their visual field defects for all components tested. Three patients of this group experienced areas of local differences in some stimuli that were larger than the visual field defect obtained with conventional perimetry. Component perimetry is thus a new method to detect different types of visual disorders on very different levels of the visual system. A fast screening of the visual field is thus possible not just for the detection of defects in contrast sensitivity-as in conventional perimetry-but for other submodalities of vision and higher visual functions, too. of vision and higher visual functions, too.

FUNCTIONAL ORGANIZATION OF AREAS V1 AND V2 IN THE PROSIMIAN PRIMATE GALAGO REVEALED BY OPTICAL IMAGING. W.H. Bosking*, L.E. White, V.A. Casagrande, D. Fitzpatrick, Dept. of Neurobiology, Duke Univ. Medical Center, Durham, NC 27710 and Dept. of Cell Biology and Psychology, Vanderbilt Univ., Nashville, TN 37232.
Optical imaging of intrinsic signals was used to assess the organization of orientation preference in V1 and V2 of the galago. Polar maps of orientation

preference were constructed by vector summation of data acquired during presentation of 4 stimulus angles. As in the macaque, the map of orientation preference was largely continuous and contained regions over which orientation preference changed along a straight line (linear zones) and point discontinuities around which orientation preference cycled in a radial fashion (pinwheels). In V1, the average size of iso-orientation (+/-45 deg) domains was approximately .12 mm² and the density of pinwheels was approximately 7 pinwheels/mm². In 1.12 mm² and the density of pinwheels was approximately / pinwheels/mm². In V2, a similar pattern of orientation preferences was seen, but with larger iso-orientation domains (.2 mm²) and lower pinwheel density (4 pinwheels/mm²). Despite this difference in the scale of the orientation preference maps, orientation preference was mapped continuously across the V1/V2 border. We compared optical imaging data with the pattern of cytochrome oxidase (CO) staining in V1 and found no consistent relationship between the distribution of CO blobs and any feature of the orientation preference map. For example, blob and interplay regions could not be distinguished on the basis of ninwheel density.

and interblob regions could not be distinguished on the basis of pinwheel density or magnitude of orientation selectivity. These data are consistent with single-unit or maginitude or orientation selectivity. These data are consistent with single-unit recordings in the galago which show little difference in the orientation selectivity of individual neurons in blob and interblob regions. Thus, neither the cytochrome oxidase compartments in VI, nor the VI/V2 border, disrupt the continuous mapping of orientation preference in V1 and V2. Supported by EY01778 and EYO6821.

DIRECTION SELECTIVITY AND HORIZONTAL CONNECTIONS IN LAYERS 2/3 OF FERRET PRIMARY VISUAL CORTEX (V1). L.E. White*. W.H. Bosking, M. Weliky, and D. Fitzpatrick. Department of Neurobiology, Duke University Medical Center, Durham NC 27710.

Duke University Medical Center, Durham NC 27710.

Optical imaging of intrinsic signals in ferret V1 has been used to demonstrate the presence of "iso-direction domains", which represent the activity of clusters of neurons that respond best to the same direction of motion (Weliky M, Bosking WH, Fitzpatrick D, 1996, Nature 379:725-728). In this study, we investigated how horizontal connections in layers 2/3 are distributed in relation to the organization of direction selectivity in ferret V1.

Intrinsic signals were recorded while animals viewed gratings moving in one of two proposite directions extheorough to the orientation of the grating. Vector

two opposite directions orthogonal to the orientation of the grating. Vector summation of data acquired from each stimulus direction was then used to generate maps of direction preference, which guided the placement of small extracellular injections of the anterograde tracer, biocytin, into identified iso-direction domains. The direction selectivity of the target site was confirmed with electrophysiological recording through the micropipette prior to injection. The distribution of labeled synaptic boutons in tangential sections through VI was plotted and aligned with the optical maps; the selectivity of the horizontal connections, with respect to

direction preference, was evaluated quantitatively.

Close to the neurons of origin (<750 µm), the horizontal connections in layers 2/3 show little selectivity. Further away from the injection site (>750 µm), however, long-range horizontal connections preferentially interconnect iso-direction domains. Moreover, domains that share the same orientation preference, but respond best to opposite directions of motion, are not heavily interconnected at these distances. Thus, the specificity of these long-range horizontal projections provides a framework for understanding how these connections might contribute to the elaboration of the direction preferences of neurons in layers 2/3 of ferret V1. BORDERS OF HUMAN STRIATE CORTEX. AN INTEGRATED PET AND CYTOARCHITECTONIC STUDY. Zoltán Vidnyánszky^{1,2}, Balázs Gulyás¹, Per E. Roland^{1,*}, Karl Zilles³, Thorsten Schormann³, and Jan-Erik Litton⁴. ¹Division of Human Brain Research, Department of Neuroscience, Karolinska Institute, S-171 77 Stockholm, Sweden; ²Laboratory of Neurobiology, 1st. Department of Anatomy, Semmelweis University Medical School Budapest, H-1094; ³Department of Anatomy, Heinrich-Heine University Düsseldorf, D-40225 Düsseldorf; ⁴Department of Psychology, Karolinska Hospital, S-171 76 Stockholm

The main objective of the present study was to explore on the basis of various functional, anatomical, and neurochemical landmarks, the extent of area V1 in the human brain. With the help of a computerised brain atlas (HBA, Roland et al., Human Brain Mapping 1(1994):173-184), we have standardised in shape and size (1) the MR images of five normal autopsy brains, Nissl-stained for determining the V1/V2 border on the basis of quantitative cytoarchitectonic criteria, (2) MR and PET images of five normal subjects whose GABAA-benzodiazepine receptor distribution (B_{max}) was measured by ¹¹C-flumazenil (and displayed a clear density difference between striate and extrastriate visual cortex), (3) MR and PET images (made with ¹⁵O-butanol, a flow tracer) of ten normal subjects, undergoing visual stimulation which strongly activated the primary visual cortex, and (4) FDG-PET images of seven normal subjects (displaying a strong metabolic difference between striate and extrastriate visual cortices).

The area borders between V1 and the neighbouring extrastriate

cortex, defined by metabolic, blood flow, receptor- and cyto-architectural landmarks, are in close agreement with each other.

OPTICAL IMAGING OF TREE SHREW AREAS V1 AND V2: MAPS OF ORIENTATION PREFERENCE AND RULES OF INTERCONNECTIVITY. M. L. Pucak*, W. H. Bosking, and D. Fitzpatrick. Dept. of Neurobiology, Duke University Medical Center, Durham, NC 27710.

Optical imaging of intrinsic signal was combined with anatomical techniques to examine the map of orientation preference in V2 and its relation to the patterns of connectivity with V1. The structure of iso-orientation domains was examined using both orientation difference maps, generated by subtracting the response to orthogonal stimuli, and vector maps, generated by vector summation of the maps derived for four different stimulus orientations. Iso-orientation domains revealed derived for four interent similar in diameter (approximately 250 µm) to those in V1. Vector maps of V2 also were comparable to those observed in V1: orientation preference was found to change in a largely continuous manner, forming linear zones and pinwheels. The similarity between the maps in V1 and V2 was especially apparent at the V1/V2 border, where individual iso-orientation

domains often crossed in an uninterrupted fashion.

Injections of the anterograde tracer biocytin into identified iso-orientation domains in V1 demonstrated that, like the horizontal projections within V1, feedforward projections to V2 terminate as discrete patches of labeled boutons. Some patches are continuous across the V1/V2 border in a manner analogous to Some patters are continuous across the VT2 Soriest in a manufacture the continuity displayed by orientation domains. Comparison of the distribution of labeled boutons with the orientation map in V2 reveals that the majority of boutons lie in domains corresponding to the preferred orientation at the injection site. In contrast, feedback projections linking V2 with V1 terminate in a more diffuse manner that shows little correspondence to the map of orientation preference. These observations demonstrate that feedforward projections, like horizontal connections in VI, exhibit specificity for orientation preference, whereas feedback projections are less constrained by this response property. Supported by EY06821.

MULTIPLE ACTIVITY MAPS OF PRIMATE VISUAL CORTEX PRODUCED BY SUSTAINED AND TRANSIENT EXPRESSION OF THE IMMEDIATE-EARLY GENES 21F268 AND C-FOS

<u>. Chaudhuri 1* and J. Nissanov 2</u>

Department of Psychology, McGill University, Montreal

Biomedical Engineering & Science Institute, Drexel University, Philadelphia

Long-term changes in the CNS brought about by alterations of sensory input are thought to be orchestrated by various immediate-early genes, such as *c-fos* and *zif268*. The linkage of transcriptional processing of these genes as c-ros and znizos. The image of transcriptional processing or trass genes to membrane depolarization provides an opportunity to visualize activated neurons by detecting the accumulation of their mRNA or protein products. We report here the results of a double-labeling strategy that exploits the different time course of mRNA and protein induction of these genes.

We have used immunostaining and *in situ* hybridization histochemistry (ISHH) to detect both protein and mRNA products in striate cortex of adult vervet monkeys following monocular deprivation (MD) and reverse-occlusion (RO) procedures. In MD animals, one eye was occluded with an opaque (HO) procedures. In MD animals, the patch was switched to the other eye after this period for 30 minutes. In all cases, chair-restrained awake animals were used. An ocular dominance (OD) pattern was evident with staining for products of both genes in RO animals. A striking OD pattern was also seen in MD animals with zi/268 staining but not with c-fos staining. These findings are consistent with the notion that c-fos expression requires a period of neural quiescence prior to activation whereas zifz68 expression is regulated by the magnitude of ongoing neural activity.

The sustained and transient nature of zifz68 and c-fos expression, when coupled with the different temporal characteristics of their mRNA and

protein induction, provides an opportunity for producing multiple activity maps of the brain in response to separate stimulation conditions.

Supported by MRC Canada (MA12685) and NIH P41RR01638.

ABNORMAL RETINOFUGAL PROJECTIONS AND VISUAL CORTICAL MAPS IN A MUTANT WITH UNILATERAL MISROUTING AT THE OPTIC CHIASM. <u>Dale Hogan. 1* Preston F. Gartaghly.</u> ² and <u>Robert W. Williams.</u> ¹ Dept. Anatomy & Neurobiology,

Preston E. Garraghty.² and Robert W. Williams.¹ ¹Dept. Anatomy & Neurobiology, Univ. Tenn., Memphis,TN and ²Dept. Psychology, Indiana Univ., Bloomington, IN. We are studying a mutation in dogs that increases the uncrossed projection at the optic chiasm. This report concerns a mutant in which most axons from the right eye fail to cross midline, but 30% of the axons from the left eye cross. An injection of WGA-HRP into the left eye shows that the left (monocular) LGN is unlaminated and uniformly labeled. Surprisingly, the binocular LGN is also poorly laminated. Lamination is only seen in the caudodorsal tail. The superior colliculus contralateral to the injection receives binocular input and label is patchy. However, the left colliculus, presumably innervated only by the ipsilateral eye, showed extremely sparse receives binocular input and label is patchy. However, the left colliculus, presumably innervated only by the ipsilateral eye, showed extremely sparse label concentrated in one restricted area. Anterograde label reveals an additional failure of axon guidance. A bundle of axons extends rostral from the right LGN in dorsal thalamus. Multiunit recording in visual cortex showed globally appropriate topography, with regional anomalies. In lower visual space, contralateral receptive fields were recorded from 25° azimuth and progressed into the ipsilateral field. Ipsilateral fields were plotted to 45° azimuth, well into the monocular field of normal dogs. This organization is similar, but opposite in polarity, to that found in Boston-type Siamese cats. Near the horizontal meridian, mirror image reversals in field azimuth were mapped. This implies the existence of hemiretinal dominance columns similar to those found in the cortex of albino cats. We also mapped a cell with bilateral receptive fields in mirror image positions across the vertical meridian. Most units were not orientation selective and responded well to all orientations. This mutant had impaired visual function, including congenital orientations. This mutant had impaired visual function, including congenital nystagmus and failure to make saccades, demonstrating the functional limits of plasticity in dealing with a decussation defect of this magnitude. We also now know that there may be additional defects of axon guidance associated with this mutation. Supported by NRSA EY06560 (DH) and NIH EY06627 (RWW).

SPATIOTEMPORAL CORRELATED FIRING OF VI NEURON: SIMULTANEOUS RECORDINGS FROM 16 ELECTRODES. D. J. Warren, N. D. Hadfield, P. J. Rousche*, R. A. Normann. John A. Moran Laboratory in Applied Vision & Neural Sciences, University of Utah, Salt Lake City, UT 84112.

Neurons at all stages of the visual pathways manifest periodic firing, even in the lack of apparent stimulation. In development, this activity has been shown to be associated with "pruning" of the dendritic arbors and creation of specific neural pathways. This periodic firing may serve to maintain these pathways in adult animals. If so, one should see correlated firing of neurons that make up these local circuits in the absence of visual stimulus.

To pursue this question, we have used a 100 electrode array to record single and multi-unit neural activity simultaneously from groups of neurons in V1 of cats. The electrodes have a 1.1 mm length and are arranged in a regular 10 by 10 grid with 0.4 mm spacing between adjacent electrodes. Subsets of 16 of the 100 electrodes are monitored simultaneously. Data reported herein were obtained from dark adapted animals who had been on a stable anesthetic level for 8 hours.

Periodic firing was seen on all functional electrodes. The period of the firing

varied from animal to animal and within an animal. The firing lasted between 1 and 4 minutes and recurred anywhere from 1 to 10 minutes. The temporal sequence of the firing suggested that it was not associated with waves of activity sweeping across the cortex. Crosscorrelation indicated that neurons separated by 0.8 mm could show highly correlated activity (1 millisecond wide bins). The degree of correlation varied: periods of highly correlated firing were separated by periods of uncorrelated activity. Both correlated and uncorrelated activity can occur within a single firing episode.

While the function of this periodic behavior is unclear, it may serve to maintain the synaptic interconnections that lead to the complex receptive field properties that characterize this cortical region.

BASAL DENDRITIC FIELDS OF LAYER III PYRAMIDAL CELLS IN MACAQUE VISUAL AREAS V1, MT, MST AND LIP.

MACAQUE VISUAL AREAS VI, MT, MST AND LIP.

G. N. Elston, M. G. P. Rosa, M. B. Calford* and D. Pow, Vision, Touch & Hearing Res. Centre, The University of Queensland, AUSTRALIA. 4072

Morphology of layer III pyramidal cells was examined in functionally distinct compartments of the primary visual cortex (VI), as well as in the middle temporal (MT), the medial superior temporal (MST) and the lateral intraparietal (LIP) areas of the macaque. Neurones in fixed (4% paraformaldehyde) flattened cortical slices (250μm) were injected with Lucifer Yellow and processed for a permanent diaminobenzidine reaction product. Dendritic field areas and spine density were compared. Pyramidal cells located in layer IIIC (IVB of Brodmann) of VI had significantly larger basal dendritic fields (n, mean ± s.d.; 25, 35.8 ± 5.5 x 10³ μm²) than those located within the blobs (93, 26.9 ± 10.6 x 10³ μm²) of layers IIIA and B (t = 4.04 b ≤ 0.0001). Furthermore, pyramidal cells layers IIIA and B (t = -4.04 p \leq 0.0001). Furthermore, pyramidal cells located within the blobs had larger basal dendritic fields than those the interblobs (43, 20.1 \pm 10.6 \times 10 μ m²) within layers IIIA and B (t = 4.0 p \leq 0.0005). Thus, dendritic fields of pyramidal cells in V1 reflected the the interblobs (43, 20.1 \pm 10.6 x 10³ μm^2) within layers IIIA and B (t = 4.0 $p \le 0.0005$). Thus, dendritic fields of pyramidal cells in V1 reflected the relative proportion of magnocellular input. Spine density was similar for all pyramidal cells in layer III of V1. Pyramidal cells of layer III in MT had significantly larger basal dendritic field areas (34, 83.8 \pm 10.6 \times 10³ μm^2) than those in layer IIIC of V1 (t = -20.7 $p \le 0.0001$), as did those in MST (40, 85.5 \pm 23.6 \times 10³ μm^2 , t = -10.3 $p \le 0.0001$) and LIP (40, 88.1 \pm 16.0 \times 10³ μm^2 , t = -15.7 $p \le 0.0001$). However there was no significant difference in basal dendritic field area of layer III pyramidal cells between MT, MST and LIP (p > 0.05). Pyramidal cells in MST had the greatest spine density; that of cells in LIP and MT was similar and slightly greater than that in V1. Whilst these findings demonstrate that basal dendritic fields of layer III pyramidal cells in extrastriate areas are larger than those in V1, we found no progressive increase in the rostral areas of the motion pathway.

ESSENTIAL AND ARCHAIC ANATOMICAL FEATURES OF MAMMALIAN VISUAL CORTEX, C.Tyler*, I.Lund, S.Dunlop, A.Harman, J.Dann, R.Lund and L.Beazley. Institute of Ophthalmology, University College, London and Depts. of Zoology and Psychology, Univ. of Western Australia, Perth. Intrinsic organisation of visual cortex has been compared in

a number of species, including eutherians and marsupials, to help determine which features are common elements, and therefore essential components, as opposed to features unique therefore essential components, as opposed to features unique to individual species, and therefore less key to basic function. Despite a 100 fold difference in area and 3 fold difference in depth of V1 between species, the individual pyramidal neurons vary little in size. Layer 4 always includes spiny stellate neurons. Specific patterns of apical dendritic arborization of layer 6 perspitals patrons correlate with stratification of layer 6 pyramidal neurons correlate with stratification of thalamic axon terminals. A common set of interneuron classes are present in at least the superficial layers; of these, only the spatial scale of the large basket neuron axons varies. Superficial layer pyramidal lateral patchy axon connections are present in most species yet appear to be absent in those species with narrow arbor basket neuron axons and VI of small area; overall area devoted to VI as well as spatial relationship between pyramid dendritic field and basket axon may play a phylogenetic diversity there is conservation of specific VI features that raise intriguing questions as to functional constraints. VIRAL ANTEROGRADE TRANSNEURONAL TRACING OF THE LAMINAR TARGETING OF VISUAL THALAMOCORTICAL AND CORTICOCORTICAL CONNECTIONS IN MOUSE M.D. Cassell*, C-J. Shi, N. Sun & S, Perlman Depts. of Anatomy, Pediatrics & Microbiology, Univ. of Iowa, Iowa City, IA 52242

By using the viral anterograde transneuronal tracing technique, the present study investigated the laminar organization of potential recipient neurons of visual thalamocortical and intracortical projections. Herpes simplex virus type-1, strain H129 was injected into the mouse vitreous body of the eye and virally infected neurons were detected using in situ hybridization. Infection of contralateral visual cortex first appeared at day 5-6 following intraocular inoculation. In striate cortex (area Oc1), infected neurons were first present in layers 4 and 5. The labeling in layer 5 was always less intense than that of layer 4 and often disassociated from it, indicating it was targeted by different afferents. Subsequently, labeling appeared in layers 2 and 3 and finally in layer 6. In peristriate cortex, infected neurons were first detected in layer 5 of lateral area Oc2L and this labeling started, in most cases, at the same time as that in striate cortex. Later, labeling extended into layers 6 and 4 and finally all cellular layers exhibited heavy infection. In contrast, area Oc2M was usually infected at a later stage and had no obvious laminar sequence of infection. In temporal cortex, caudal area Te2 was infected simultaneously with area Oc2L and exhibited an identical laminar pattern and sequence of labeling as that of Oc2L. Area Te1 and lateral entorhinal cortex had infection of in layers 6 and 5 respectively when all cellular layers of striate and peristriate cortices were heavily infected. These results suggest that thalamocortical projections differentially target layers 4 and 5 of striate cortex and layer 5 of peristriate cortex, including areas Oc2L and Te2. In striate cortex, layer 4 and/or layer 5 may specifically innvervate supragranular layers (2 and 3) which in turn project to layer 6 neurons. In contrast, thalamic recipient neurons of peristriate cortex innervate adjacent layer 6 and 4 neurons and the latter projects to supragranular layers (Supported by NS24401 and DC01711).

ELECTROPHYSIOLOGY OF THE HORIZONTAL CONNECTION OF KITTEN PRIMARY VISUAL CORTEX. Y. Yoshimura*1, H. Sato^{1,2}, K. Imamura^{1,3} and Y. Watanabe^{1,3}. ¹Dept. Neurosci., Osaka Biosci. Inst., Osaka 565, ²Fac. Health & Sport Sciences, Osaka Univ., Osaka 560, ³Subfemtomole Biorecognition Project, JRDC, Osaka 565, Japan.

To assess the function of the horizontal projections in layer II/III of the kitten primary visual cortex, we performed a combined study of extracellular recording of visual responses $in\ vivo$ and whole-cell recording of postsynaptic events of cells $in\ vitro$. Receptive field positions and response properties of cells were mapped in a few locations in the area 17. To label horizontally connected cells, a fluorescent retrograde tracer was injected into the recording site. After an appropriate survival period, slices of the visual cortex were prepared for the in vitro experiments Focal electrical stimulation applied to single cells, including labeled cells, evoked monosynaptic excitatory postsynaptic potentials (EPSPs) in layer II/III pyramidal cells located at the dye injection site. The hot spot was often found in a vicinity ($<150~\mu m$) of the recorded cells. Stimulation applied 300-1200 μm away from the recording site also evoked the EPSPs via long range horizontal connections. Both proximally and distantly elicited EPSPs showed similar amplitudes and time courses Concurrent activation of horizontal and vertical afferent inputs to the layer II/III cells showed a linear spatial and temporal summation of respective EPSPs. Temporal summation of EPSPs was also found when two successive activation of the horizontal input were applied at the inter-stimulus interval of 10-50 ms. These horizontal connections were visualized by intracellular staining of some of the stimulated cells with neurobiotin

USING LATERAL CONNECTIONS FOR POPULATION CODING. <u>K. Zhang.</u> ¹; <u>A. Pouget² and P. Dayan⁴3. ¹ The Salk Institute, La Jolla, CA. ²Georgetown Institute for Computational and Cognitive Sciences, Washington D.C., and ³Brain and Cognitive Science dpt, MIT, Cambridge, MA.</u>

Coarse codes are widely used throughout the brain to encode sensory and motor variables. Methods designed to interpret these codes, such as population vector analysis, are either inefficient, i.e., the variance of the estimate is much larger than the smallest possible variance, or biologically implausible, like maximum likelihood. Moreover, these methods attempt to compute a scalar or vector estimate of the encoded variable. Neurons are faced with a similar estimation problem, i.e., they must read out the responses of the presynaptic neurons, but, by contrast, they typically encode the variable with a further population code rather than as a scalar. We show how lateral connections in a recurrent network can be used to perform statistically efficient estimations whilst using a coarse code. In the presence of gaussian noise, the variance of the network estimate matches the Cramer-Rao bound, the smallest achievable variance. This work suggests that lateral connections in the cortex may be involved in averaging out uncorrelated noise among neurons representing similar variables. COMPLEX CELL RESPONSES COULD ARISE DIRECTLY FROM CENTER-SURROUND INPUTS: THE SURPRISING POWER OF INTRA-DENDRITIC COMPUTATIONS.

B. W. Mel, D. L. Ruderman, Dept. Biomed. Engin., USC, MC 1451, Los Angeles, CA 90089. & E. Niebur*. Krieger Mind-Brain Institute, Johns Hopkins Univ., Baltimore, MD, 21218.

The classical Hubel-Wiesel model for complex cell responses in V1 involves a hierarchy in which center-surround inputs drive Simple cells, which in turn drive Complex cells. Under typical modeling assumptions, complex cell output can be expressed as a second-order polynomial over the input pixel intensity values [Ohzawa et al., Science, v. 279, 1990]. In previous work, one of us has studied the nonlinear computational properties of neocortical cells, and has shown that second-order polynomial functions of this general kind can be naturally implemented by dendritic trees that contain certain classes of excitatory membrane mechanisms, including NMDA-type synapses, and voltage-dependent Na+ and Ca++ channels [Mel, B.W., J. Neurophysiol., v. 70, 1993]. Here we explore the hypothesis that nonlinear shift- and contrast-invariant complex cell responses could arise de novo in a dendritic neuron that receives only center-surround inputs, i.e. without an intervening layer of simple cells. Using a simple abstract model of a dendritic tree, we demonstrate the feasibility of strong orientation tuning coupled with both shiftand contrast invariance. We are currently extending our simulations to biophysically-realistic conditions using NEURON. This work was funded by the NSF.

THREE DISTINCT TYPES OF GABAERGIC NEURONS IN RAT PRIMARY VISUAL CORTEX. Y. Gonchar and A. Burkhalter*. Dept. of Anatomy and Neurobiology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

In the cortex inhibition is mediated by GABAergic neurons. Although all of these neurons serve a similar purpose it was shown recently that they are immunologically and physiologically heterogeneous (Kubota et al., 1994; Kawaguchi, 1995) suggesting functional diversity. As a first step to understand how different types of inhibitory neurons are integrated into cortical circuits we have examined whether GABAergic neurons can be subdivided into distinct groups. For this purpose we have double-stained rat visual cortex (VI) with antibodies to GABA, parvalbumin (PV), calretinin (CR), somatostatin (SOM), calbindin (CB) and nitric oxide synthase (NOS). The results show that the majority of PV (100%), SOM (94%) and CR (88%) staining neurons are GABAergic. PV staining neurons constitute a distinct group (5% of PV cells colocalize CB) that show no overlap with CR, SOM and NOS expressing cells. PV cells account for 51% of all GABAergic neurons. A second group of SOM expressing neurons accounts for 18% of GABAergic cells. None of these cells colocalize PV Cr CR, but 5% of SOM neurons stain for NOS and 86% show CB immunoreactivity. The third distinct group of CR expressing cells accounts for 15% of GABAergic neurons. All of these cells are PV, CB, SOM and NOS negative. CB expressing neurons represent a heterogeneous group that includes GABAergic and non-GABAergic cells.

Our findings indicate that GABAergic neurons in rat V1 fall into three separate groups that can be identified by the expression of PV, CR and SOM. These cells account for 83% of all GABAergic neurons. These results confirm observations in rat frontal cortex (Kubota et al., 1994) and suggest that previous classifications of GABAergic neurons into two distinct groups of PV and CB expressing cells (Celio, 1990) do not apply to rat visual cortex. STIMULUS-ELICITED NEURONAL RESPONSES IN STRIATE AND INFERIOR TEMPORAL CORTICES ARE WELL-DESCRIBED BY A GAUSSIAN DISTRIBUTION. E.D. Gershon, P.E. Latham, G-X. Jin* and B.J. Richmond. Lab. of Neuropsychology, NIMH, and Lab. of Developmental Neurobiology, NICHD, Bethesda, MD 20892.

Both the dynamic range and the variability of stimulus-elicited neuronal responses determine the ability of a neuron to transmit information. Knowing the variability of neuronal responses would allow analytic calculation of transmitted information and channel capacity. We took single-unit data from previously described experiments carried out in V1 and T7 cortices of awake, fixating rhesus monkeys (Richmond et al., 1990; Eskandar et al., 1992) and compared them to Gaussian, Poisson and boxcar distributions. In the experiments, the neurons were stimulated using 32 or 128 two-dimensional black and white patterns each presented many times for 320 ms. We constructed histograms of the spike counts for each stimulus and made the best fit to each histogram for the three distributions. The Gaussian distribution was best for every cell.

We calculated the stimulus-related transmitted information using the response probabilities derived from the Gaussian fits. These information values in both VI and IT are in close agreement with the values obtained previously using an artificial neural network (Heller et al., 1995); the average difference was 20% for VI, and 10% for IT. It is reasonable to estimate the channel capacity of these neurons using Gaussian-based models.

INFLUENCE OF GABAERGIC INHIBITION ON STRUCTURE AND DYNAMICS OF RECEPTIVE FIELDS IN THE CAT VISUAL CORTEX. J. Pernberg*, K.-U. Jirmann and U.T. Eysel. Dept. of Neurophysiol, Ruhr-Universität Bochum, D-44780 Bochum, Germany.

Cortical cells in area 17 and 18 were investigated electrophysiologically in anesthetized adult cats. Extracellular recordings and iontophoretic application of bicuculline were performed with 3-barrelled micropipettes. A reverse correlation method (DeAngelis et al., J. Neurophysiol. 69:1091, 1993) was used with brief (50 ms) stationary light and dark bars for spatial and temporal receptive field analysis. Stimuli (0.4° x 4°) were presented with preferred orientation as determined previously by moving bars.

ON and OFF excitatory receptive fields of simple and complex cells were documented before, during and after microiontophoresis of bicuculline. Under the GABA_A receptor blocker both, the stimulus-induced and the resting discharge frequency increased and ON and OFF fields changed significantly in space and/or time in a reversible manner. In space, bicuculline widened the receptive field, whereas in time, it shortened the duration of the excitatory cell response. ON and OFF receptive fields separated in space and time (simple cells) or time (complex cells) became less isolated or even superimposed.

Most interestingly intracortical inhibition appears to contribute to the late phase of the excitatory response in simple and complex cells. This could be due to postinhibitory activation on the cellular level or activity dependent multisynaptic effects in the cortical network. DARK-INDUCED SUBCELLULAR REDISTRIBUTION OF CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE II IN RAT VISUAL CORTEX. N. Liu and N. G. F. Cooper*. Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, XY 40292

Calcium/calmodulin-dependent protein kinase II (CaM kinase II) is enriched in the nervous system and plays an important role in synaptic transmission. The expression of CaM kinase II immunoreactive protein and mRNA in the primary visual cortex has been shown to be affected by prolonged ocular deprivation (Hendry and Kennedy, 1986; Benson et al., 1991). The purpose of this study was to determine the changes of CaM kinase II protein in rat visual cortex during short-term dark-adaptation. Primary visual cortex from forty-two-day-old male Sprague-Dawley rats which had been raised in a 12 hr light / 12 hr dark cycle or in the dark for 24 hr before sacrifice was collected, homogenized in 0.32 M sucrose-containing buffer, and subjected to subcellular fractionation. Immunoreactivities of CaM kinase II a and B subunits in the crude tissue homogenates, crude synaptic membrane, and cytosol have been examined with western blotting and enhanced chemiluminescence. No significant differences in immunoreactivities of CaM kinase II were found between the crude tissue homogenates of normal and dark-adapted rats. However, both CaM kinase II α and B subunits displayed significant increases in immunoreactivities in the crude synaptic membrane fractions and corresponding decreases in the cytosolic fractions when the rats were dark-adapted. This study indicates that the total protein level of CaM kinase II was not significantly altered but a translocation of this kinase from the cytosol to the synaptic membrane occurred during short-term darkadaptation. This suggests a post-translational regulation of CaM kinase II expression mediated by neural activity. Supported by grant NSF-EPSCoR 994025.

MOLECULAR AND NEUROCHEMICAL CHANGES OCCURING IN GLUTAMATE RECEPTORS AND TYPE II CALCIUM-CALMODULIN-DEPENDENT PROTEIN KINASE IN ADULT MONKEY VISUAL CORTEX. B. Tighilet and E.G. Jones*. Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Glutamatergic receptors play a crucial role in development and plasticity of the visual cortex. In situ hybridization histochemistry and immunocytochemistry were used to study activity dependent plasticity in the adult monkey visual cortex. Adult monkeys were moncularly deprived for periods ranging from 4 to 7 days by tetrodotoxin injections (TTX 15 μ g) into one eye. After the deprivation period the animals were perfused and sections of brain processed for cytochrome oxidase, in situ hybridization and immunocytochemistry for α , β , δ , and γ oxidase, in situ hybridization and immunocytocinemistry for α , β , δ , and γ subunits of Ca^2 +/calmodulin-dependent protein kinase II, NMDA receptor subunits (NMDAr1, NMDA 2AB), AMPA receptor subunits (Glur1, Glur2/3, Glur4) and kainate receptor subunits (Glur5, δ , 7). The results showed a down regulation of both NMDAr1, Glur2AB, Glur1, Glur4, Glur5, δ ,7 and CaM II β protein particularly in deprived columns of layer IVC of the primary visual protein particularly in deprived columns of layer IVC of the primary visual cortex. When changes were observed at the gene expression level they consisted of a down regulation except for CaM II kinase α mRNA which was up regulated in deprived columns of layer IVC. These data indicate that unilateral suppression of visual inputs induce plasticity in the adult monkey visual cortex. Molecules such as glutamate receptors and type II calcium-calmodulin-dependent protein kinase may have a crucial role.

USE-DEPENDENT RECEPTIVE-FIELD PLASTICITY IN THE VISUAL CORTEX OF ADULT CATS. D. Eyding, G. Schweigart, U.T. Eysel*. Dept. of Neurophysiology, Ruhr-Universität Bochum, D-44780 Bochum, Germany. Single cells in layers II/III of the cat visual cortex (area 17 and 18) were

Single cells in layers II/III of the cat visual cortex (area 17 and 18) were extracellularly recorded in anesthetized adult cats. The excitatory receptive field (RF) was determined and we attempted to elicit heterosynaptic associative plasticity by local synchronous visual stimulation (ON/OFF coactivation) of the RF and an adjacent unresponsive region on one side. A specific enlargement (S) into the costimulated adjacent region was observed in 15 of 33 cells, in 9/33 cells unspecific (U) enlargements into the costimulated and the unstimulated opposite side of the RF were found, and in 9 cases the coactivation failed to elicit any effect (N).

The response amplitude during co-activation turned out to be the most important factor determining the outcome. Low activity during co-stimulation rarely elicited any effect. Higher activity increased the probability of RF size changes - specific or unspecific. However, unspecific RF-enlargements always reflected a stimulus-independent general increase in excitability of a cell, and the increase of RF size was directly correlated to the increase of activity. The recovery-times were in the range of minutes to hours and correlated positively with the increase of responsiveness in the new, formerly unresponsive RF-area in the group with specific RF enlargement (S), whereas no such correlation was observed in the U group. Spontaneous transitions

no such correlation was observed in one case each.

We conclude that synchronous stimulation of a RF and its adjacent region can lead to specific changes in RF size if a sufficient postsynaptic activity is evoked during co-activation. This supports the view that synapses in the adult cat visual cortex are capable of specific use-dependent plasticity based on LTP-like mechanisms in vivo. Unspecific RF enlargements seem to be based on different mechanisms like global intrinsic modulation of synaptic efficacy. Supported by Deutsche Forschungsgemeinschaft Ey 8/23-& SFB 509 - TP C4.

ADVANCES IN THE CHRONIC IMPLANTATION OF THE UTAH INTRACORTICAL ELECTRODE ARRAY. N.D. Hadfield, E.M. Maynard, R.A. Normann*. John A. Moran Laboratory in Applied Vision & Neural Sciences, University of Utah, Salt Lake City, UT 84112

Previous attempts at chronically implanting the Utah Intracortical Electrode Array (UIEA) in feline cortex have had mixed success (Rousche, submitted). These experiments demonstrated that although it is possible to record neural activity using the UIEA for periods in excess of a year, individual neurons were not consistently present for longer than 2 weeks. This instability has been attributed to the encapsulation of the array and its gradual extrusion from the cortex and/or micromotion assosciated with adhesions between the implant and the dura or bone flap.

To improve the recording stability of the UIEA, we have modified the surgical technique used by Rousche. By "sandwiching" the dura between a 0.5 mil layer of nonporous FEP Teflon (Dupont) and a 0.1mm layer of porous Teflon (Preclude, W.L.Gore & Assoc.) cut to the size of the craniotomy, we hoped to eliminate adhesions to the electrode array. The craniotomy was filled with a silastic elastomer and covered with dental acrylic. To date, this technique has been applied to chronic implants in four cats (11 electrodes each) and one monkey (22 electrodes). Gross histological studies of two implants in cats has shown an absence of adhesions to the UIEA. In addition, single unit recording studies conducted in two of the cats have shown a significant number of the neurons (24% and 34%) to be present for 41 and 108 days, respectively. While single unit data from the monkey is incomplete, identified units are still present after three nonths. Our preliminary conclusion is that the use of these thin Teflon films prevents the formation of adhesions to the electrode array which minimizes the amount of electrode movement. The consistent presence of neurons with large amplitudes (100 μ V p-p) further suggests that these electrodes are not being extruded in the manner of

DYNAMIC CORTICAL RECEPTIVE FIELD CHANGES:
NEURONAL ADAPTATION OR CONNECTION PLASTICITY?
Jonathan A. Marshall* & George J. Kalarickal, Department of Computer Scienc
CB 3175, University of North Carolina, Chapel Hill, NC 27599-3175, U.S.A.

Jonathan A. Marshall* & George J. Kalarickal, Department of Computer Science, CB 3175, University of North Carolina, Chapel Hill, NC 27599-3175, U.S.A.

The size, shape, and position of neuronal receptive fields (RFs) change dynamically in response to artificial scotoma conditioning (Das & Gilbert, 1995; Pettet & Gilbert, 1992), retinal lesions (Darian-Smith & Gilbert, 1995), and intracortical microstimulation (ICMS) (Recanzone et al., 1992). We have formulated and tested a neural network model using the "EXIN" learning rules (Marshall, 1995) that exhibits similar RF dynamics and predicts some new experimentally testable RF properties. Two other models – another based on connection plasticity (Sirosh & Miikkulainen, 1995) and one based on neuronal adaptation (Xing & Gerstein, 1994) – were tested for comparison. The EXIN model uses both Hebbian and anti-Hebbian learning rules. In artificial scotoma conditioning, random stimulation in the whole visual field except in a "scotoma" region was followed by whole-field stimulation. In the novel complementary scotoma conditioning, stimulation of two adjacent regions was alternated repeatedly. In ICMS, only postsynaptic neurons were stimulated. The model produced the following effects, corresponding closely to the reported neurophysiology: (1) "iceberg" expansion of RFs in the scotoma center (DeAngelis et al., 1995); (2) asymmetric, centrifugal expansion and increased response of RFs inside the scotoma but away from the scotoma center; (2) the greatest expansion for RFs close to the scotoma boundary; and (5) RF contraction during normal stimulation but not in the absence of stimulation. ICMS of the model produced (6) no size changes of ICMS-site RFs; (7) RF substitution by ICMS-site RFs; (8) RF expansion and centripetal shift of near-ICMS-site RFs; and (9) centrifugal shift of RFs farther from the ICMS site. The model predicts (10) RF expansion for neurons whose initial RFs were on either side of the scotoma boundaries during complementary scotoma conditioning and (11) l

MULTIPARAMETRIC ANALYSIS OF INTRACELLULAR RECORDINGS IN THE CAT STRIATE CORTEX IN VIVO REVEAL FOUR DISTINCT CELL CLASSES. R. Azouz*, L. Nowak, D.A. McCormick and C.M. Grav. Center For Neuroscience, University of California, Davis, CA 95616 and Yale Univ. Med. Sch. 333 Cedar St. New Haven CT 06510.

We have previously demonstrated that cortical cells can be divided into four electrophysiological types 1) Regular spiking, 2) Intrinsic bursting, 3) Fast spiking, and 4) Chattering. In order to determine if this classification represents distinct cell groups or variation along a continuum of cellular properties, we performed intracellular recordings from neurons in cat striate cortex and classified the cells using discriminant analysis of a wide range of parameters extracted from the cellular responses to visual stimuli and intracellular depolarizing pulses. The variables tested came from five broad aspects of physiological properties, (a) the interspike interval distribution, (b) the properties of burst firing, (c) action potential characteristics, (d) membrane potential fluctuations, and (e) the degree of rhythmic activity. Using subjective criteria, our sample of 72 cells consisted of 33 chattering cells, 18 regular spiking cells, 17 intrinsic bursting cells and 4 fast spiking cells. Discriminant analysis confirmed this classification for 91%, 100%, 100% and 75% (mean 94%) of the chattering, regular spiking, intrinsic bursting and fast spiking cells, respectively. Further analysis, utilizing only those parameters obtained from the neuronal spike trains, achieved 91% correct classification. These results demonstrate the presence of at least four well differentiated cell classes. This classification can be achieved on the basis of intrinsic membrane properties or Supported by NEI (CMG) and NSF (DAM, CMG).

THE SHAPE OF STIMULATION-INDUCED INTRINSIC OPTICAL SIGNALS IN RAT CORTICAL SLICES DEPENDS ON CORTICAL AREA. K. Holthoff*1, K. Zilles2 and O.W. Witte¹. Neurologische Klinik der Heinrich-Heine-Universität,²Institut für Hirnforschung, Moorenstr. 5, 40225 Düsseldorf, Germany.

In rat cortical slices columnar-shaped intrinsic optical signals (IOSs) could be

induced by afferent stimulation. The spatial extent of IOSs correlates with the spatial extent of electrical activity (Holthoff et al. (1994), Neurosci. Lett. 180: 227-230). In this study we investigated whether the activated columns differ depending on the brain area involved.

IOSs were studied using near-infrared darkfield microscopy. Experiments were done on coronal cortical slices (between 5 mm and 6 mm behind bregma) of juvenile male Wistar rats (14 days old). IOSs were induce by afferent electrical stimulation in layer VI. By subsequent stimulations IOSs were induced in different cortical areas. After reconstruction, cortical area determination was done using a brain atlas.

The shape and intensity distribution of IOSs induced in the same cortical area were highly reproducible. Crossing a border between different cortical areas yielded a remarkable change in shape and intensity distribution of IOS. In the occipital cortex area 1 (Oc 1), the primary visual cortex, the maximum of optical intensity was obtained in layer IV. In the adjacent lateral occipital cortex area 2 (Oc 2 L) the maximum of intensity was shifted to cortical layer II/III. In the agranular retrosplenial cortex (RSA), optical signals appeared twice as wide as in all other cortical areas. In the granular retrosplenial cortex (RSG) optical signals were restricted to lower cortical layers.

The present data show that IOSs could be used to study the area specific spread of excitation in different cytoarchitectonic areas

PLASTICITY IN MACAQUE VISUAL CORTEX: COMPARISON OF LEARNING-RELATED EFFECTS IN V1 AND V2. G. Bertini*, A. Karni, P. De Weerd, R. Desimone and L.G. Ungerleider. NIMH, NIH, Bethesda MD 20892.

Psychophysical studies suggest that plastic changes at the earliest stages of visual Psychophysical studies suggest that plastic changes at the earliest stages of visual cortical processing underlie improvements in performance following training on some simple tasks. We previously reported that training a monkey to discriminate a target embedded in a background texture results in large, long-term performance gains, similar to those observed in human subjects. This learning is specific to the target's visual-field location and the orientation of the background texture elements. Furthermore, as a consequence of practice, the ability of VI neurons to detect the presence of the target embedded in the trained background extends beyond the classical receptive field (RF) (Bertini et al. Soc. Neurosci. Abs. 1995).

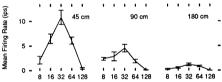

To determine whether the learning-related effects in VI are due to feedback from V2, we recorded the responses of 40 V2 neurons to trained vs. untrained stimuli. The v2, we recorded the responses of 40 V2 neurons to trained vs. uniformless stimular. The animal fixated a spot and performed an irrelevant task in the opposite hemifield. Stimuli were composed of a background array of horizontal (trained) or vertical (untrained) line elements (no-target conditions), or identical arrays but with a target made of 3 oblique line elements presented either within the RF ("inside" targets) or at about 3° beyond it ("outside" targets). As in V1, most V2 neurons responded better to stimuli beyond it ("outside" targets). As in V1, most V2 neurons responded better to stimuli containing a target than to the no-target conditions. This response difference was taken as a measure of target detection ability and depended on the location of the target and on the orientation of the background texture elements. "Inside" targets were detected by V2 neurons when embedded in both trained and untrained backgrounds, with a small bias towards trained conditions. "Outside" targets were not detected by V2 neurons when embedded in the untrained background but, as in V1, a small yet significant degree of target detection was evident for "outside" targets in the trained conditions. This differential response occurred about 40 ms later than in V1.

These results confirm and extend our previous findings, indicating that the ability of early visual cortical areas to perform figure-ground segmentation extends outside the neurons' classical RFs as a consequence of training. Furthermore, the time course of the neuronal responses suggests that target detection by V1 neurons is not a result of feedback activity from V2. Supported by NIMH-IRP.

DISTANCE MODULATES RESPONSE MAGNITUDE IN V4: A POSSIBLE MECHANISM FOR SIZE CONSTANCY.

Allan C. Dobbins* Richard Jeo József Fiser John M. Allman
Division of Biology, Caltech, 216-76, Pasadena, CA, 91125
The majority of neurons in V4 are sharply tuned for stimulus size and shape with the preferred stimulus dimensions usually much smaller than the classical receptive field (Petersen, Baker and Allman, Brain Res., 1980; Desimone and Schein, J. Neurophysiol. 1987). In recordings from V4 in a macaque monkey trained to fixate a spot on a movable monitor, we have found that response magnitude is often strongly modulated by viewing distance. Size-tuned neurons generally have the same preferred retinal image size regardless of distance. Most frequently we have recorded from "nearness" neurons in which response magnitude increases with proximity to the monkey (illustrated here), but we have also recorded from "farness" cells in which response increases with distance.

Retinal Image Size (arc minutes)

In this cell, the distance modulation was dependent on binocular stimulation, but in others monocular input was sufficient for distance modulation. Absolute distance is a crucial parameter governing the responses of many V4 neurons, and distance modulation may underlie computation of size constancy. ROLE OF GABAERGIC INHIBITION IN GENERATION OF VISUAL RESPONSE PROPERTIES OF INFERIOR TEMPORAL CORTEX NEURONS IN THE MONKEY. Y. Wang*, I. Fujita and Y. Murayama, Dept. Cognitive Neurosci., Osaka Univ. Med. Sch., Suita, Osaka 565, Japan.

Neurons in area TE of the monkey inferior temporal cortex respond to particular visual features of objects. Stimuli required for strong activation of most TE neurons are more complex than simple spots, bars or gratings. examples include a T shape, a striped square, or a colored star. known about where and how this stimulus selectivity is generated, although it has been suggested to be created in earlier cortical areas (V4 and TEO). In this study we applied bicuculine methiodide (BMI: a GABA-A receptor antagonist) by microiontophoresis with tungsten-in-glass/micropipette assemblies onto TE neurons to investigate how GABAergic inhibition in the TE contributes to the stimulus-selective response properties. A monkey (Macaca fuscata) anesthetized with a mixture of N2O and O2 was used.

Effects of BMI application on individual TE neurons were stimulusspecific. BMI administration augmented visual responses to some effective stimuli, but did not affect those to others. Moreover, in the presence of BMI, some cells began to respond to stimuli which did not evoke responses in them without BMI application. The latter effect was observed for a particular range of stimuli which often activated other neurons along the same or surrounding recording tracks. A general increase of neuronal excitability such as a lowered threshold does not explain these effects. Application of pH-matched vehicle did not affect the responses. We suggest that a generation process of the stimulus selectivity still goes on in the TE and that GABAergic inhibition contributes to this process.

634.2

TEXTURE SEGMENTATION WITH ATTENTION IN AREA V4 OF THE J Nicholas*, J Reynolds and R Desimone. Laboratory of Neuropsychology, NIMH, Bethesda, MD.

When two or more stimuli are located within a single V4 receptive field (RF), competition between the stimuli is biased in favor of the attended stimulus. We hypothesized that this attentional bias may modulate the interaction between texture-defined stimuli on textured backgrounds in the RF. To test this, neuronal responses in area V4 were recorded to sequences of texture-defined stimuli. The background was either a grey screen or a dense texture composed of line elements with an orthogonal orientation to those composing the stimuli. The degree of segmentation was varied by changing the length of the line elements in the stimuli and backgrounds. The monkey's task was to indicate when a target stimulus appeared in the sequence. One sequence appeared within the RF, and a second, simultaneous, sequence appeared in the opposite hemifield. The monkey's attention was manipulated by cueing it to perform the task at one location or the other.

With attention directed outside the RF, responses to texture-defined stimuli were greater than to a uniform texture background for about half the cells ("segmenting cells"). When segmentation was easy (long line elements), the response to the texture stimulus rapidly reached and sometimes exceeded the response to the same stimulus on a blank background. When segmentation was hard (short line elements), the response to the texture stimulus reached the level of response to the same stimulus on the grey background more slowly. With attention directed to the RF, responses to the texture stimuli defined by short line elements were enhanced, and the time course of the response was accelerated, but only for segmenting cells. There was no enhancing effect of attention for easily segmented stimuli. The results indicate that attention biases the interaction between figure and ground much the same way that it modulates the interaction between discrete stimuli. Supported by NIMH-IRP.

COLUMNAR ORGANIZATION IN INFERIOR TEMPORAL CORTEX OF AWAKE MONKEY. M. Kato*, T. Uka and I. Fujita. Dept. of Cognitive Neurosci., Osaka Univ. Med. Sch., Suita, Osaka 565, Japan

Area TE of the monkey inferior temporal cortex has columnar organization; i.e., neurons showing similar selectivities for visual features of objects are clustered in columns interspersed among columns of neurons with different stimulus selectivities. Evidence of this was obtained by extracellular neuronal recording and by optical imaging. However, both types of studies were performed in anesthetized monkeys; the columnar organization has not been demonstrated in awake monkeys.

A Japanese macaque monkey was trained to fixate on a small spot displayed on a color LCD monitor. During each fixation period, 3-6 different visual stimuli were sequentially presented. Five electrode guiding tubes were implanted perpendicularly to the lateral surface of area TE, which enabled repetitive access to nearly the same electrode tracks. First we recorded extracellular neural activities in the monkey anesthetized with N2O/O2 in order to determine track-specific stimulus features and to examine neural responses to these stimuli in addition to a fixed set of 40 stimuli. Two weeks later, neural responses to the same stimuli were examined along the tracks in the monkey performing the fixation task.

We recorded 62 multiple and single unit activities in each of the anesthetized and awake conditions. Correlation coefficients of normalized response magnitude were calculated among pairs of units in the same (CCs) and different (CCd) tracks. The average CCs in the awake condition was 0.30 while the average CCd was near 0 in both the awake (-0.001) and the anesthetized (-0.002) condition. In the anesthetized condition, the average CCs was small (0.14) but significantly larger (p<0.001) than the average CCd. Twenty-seven percent of the CCs's but only 2 % of the CCd's were larger than 0.5 in the awake condition. These results indicate a stronger correlation among cells within a vertical track than among cells in different tracks, suggesting that the neurons in area TE in the awake monkey are organized into columns. LONG-TERM POTENTIATION AND DEPRESSION IN THE MONKEY VISUAL CORTEX. Y. Muravama*, I. Fujita, and M. Kato. Dept. of Cognitive Neurosci., Osaka Univ. Med. Sch., Suita, Osaka 565, JAPAN

Long-term changes in synaptic efficacy known as long-term potentiation (LTP) and depression (LTD) are possible cellular bases for learning and To determine whether LTP and LTD are elicited in primates, the animal group having the most developed learning abilities, we examined three Japanese macaque monkeys anesthetized with a mixture of N2O and O2

Extracellular field potentials were recorded in layer 2/3 of the inferior temporal cortex (TE) and of the striate cortex (V1) which are the final and first stages of the visual cortical pathway for object recognition. Stimulating electrodes were placed 0.5~1mm lateral to the recording site to activate horizontal axons in layer 2/3. After a high-frequency conditioning stimulus, the amplitude of field potentials evoked by a single shock in the TE gradually increased over 50-70 min to a maximum, and this potentiation lasted for more An identical stimulus protocol did not potentiate field potentials in V1, but instead caused a depression which developed over 5-10 min and remained stable until the end of the recording. Steady state depression with a slow initial development suggests that this depression is a physiological phenomenon not caused by an experimental artifact such as a damage to the stimulating site. In both areas, field potentials evoked from an unconditioned pathway were not changed in their amplitude and wave These findings demonstrate that homosynaptic LTP and LTD are elicited in the adult primate neocortex, and suggest that the TE and V1 differed from each other in their synaptic plasticity. Supported by grants from the Uehara Memorial Foundation and the Inamori Foundation.

ATTENTION DEFICITS AFTER A COMBINED LESION OF AREAS V4 AND TEO IN A RHESUS MONKEY. P. De Weerd*, R. Hoag, R. Desimone & L.G. Ungerleider. Lab Psychology and Psychopathology & Lab Neuropsychology, NIMH, NIH, Bethesda, MD 20892.

Despite the anatomically well-established central position of areas V4 and TEO in the ventral pathway, the nature of the contribution of these areas to form and object perception remains uncertain. In one rhesus monkey, a complete removal of TEO in the right hemisphere was combined with a bilateral lesion in the dorsal portion of V4. While the monkey fixated a fixation target, visual discriminations in the intact upper quadrant of the right hemifield were compared with discriminations in the lower right (V4 lesion), upper left (TEO lesion), and lower left quadrants (V4+TEO lesion). Threshold performance on color, shape and orientation discrimination tasks was largely unaffected by those lesions. However, orientation thresholds obtained with a grating surrounded by three static luminance distractors (black or white solid disks), or by red distractors, rose significantly compared to performance without distractors, an effect that was absent in the control quadrant. A similar detrimental distractor effect was found during blue-green color discriminations in the presence of luminance distractors. The distractor effect was more pronounced in the V4+TEO quadrant than in the quadrants with the V4 and TEO lesions alone. Luminance distractors, however, did not raise signal-to-noise thresholds in a difficult direction-of-motion discrimination task. Thus, V4 and TEO resolve competition between a relevant oriented grating or color stimulus and irrelevant luminance or color distractors, all of which are predominantly processed by the ventral stream. The same areas, however, are not required to resolve competition between a motion stimulus and luminance distractors, probably because the former is mainly processed in the dorsal stream. This suggests that competition for attention between behaviorally relevant and irrelevant stimuli is maximal when both are processed within the same visual cortical stream. (Supported by NIMH-IRP)

STIMULUS DEGRADATION HAS A SIMILAR EFFECT ON STIMULUS-RELATED INFORMATION IN INFERIOR TEMPORAL (IT) NEURONS AND ON THE MONKEY'S BEHAVIOR. M. Shidara*, Z. Liu & B. J. Richmond. Neuroscience Sect., Electrotechnical Lab., 1-1-4 Umezono, Tsukuba-shi, Ibaraki 305, Japan*, & Lab. of Neuropsychology, NIMH, Bethesda, MD20892, USA. We recognize objects even when they are masked with visual states with distance of the contraction which was the second states of the contraction which was the second states of the contraction which was the second states of the contraction which was the second states of the contraction which was the second states of the contraction which was the second states of the contraction which was the second states of the contraction which was the second states of the contraction of the cont

noise. We studied the effect of noise on visual pattern recognition while noise. We studied the effect of noise on visual pattern recognition while we recorded from 26 lateral TE neurons in a monkey performing a sequential delayed match-to-sample task using 8 black and white 2-dimensional patterns. To add noise, we reversed the contrast of the pixel dots with probabilities of 5, 10, 15, 20, and 25%. As the noise increased, the monkey's rate of responding correctly decreased slowly, and above 5% noise the reaction time to bar release to the matching stimulus increased. Although neither the latency nor the peak firing rate of the neural responses to the matching stimulus changed consistently with increasing noise, the responses changed in both strength and pattern.

To quantify the utility of the responses for discriminating among

the stimuli, we calculated the information about the stimuli carried in the neuronal responses (more information means that the response can be used to identify which stimulus appeared with greater certainty). Information rose more slowly and plateaued at lower levels as the noise level increased. The increase in behavioral response latency in the noise condition was closely paralleled by the increase in time necessary for the information carried by the neurons to rise significantly. Thus, these TE neurons generalize across stimulus degradation in a manner that closely parallels the monkey's ability to recognize the stimulus. Support: AIST/MITI and IRP/NIMH/NIH.

DIFFERENTIAL CORTICAL CONNECTIONS OF THE DORSAL AND VENTRAL SUBREGIONS INFEROTEMPORAL CORTEX. OF THE

K.S. Saleem¹, W. Suzuki² and K. Tanaka¹; ¹RIKEN and ²Osaka University.

We have recently found that connections with the perirhinal and entorhinal cortices are stronger in the ventral subregion of the anterior inferotemporal cortex (TEav) than the dorsal subregion (TEad). In this study, we examined the connections of TEad and TEav with the superior temporal sulcus (STS) regions and other paralimbic and limbic regions, by making focal injections of PHA-L and large injections of WGA-HRP into TEad or TEav in 8 Japanese monkeys.

and large injections of WGA-HRP into TEad or TEav in 8 Japanese monkeys. Differential connections of TEad and TEav were found in the rostral part of STS. The labeled terminals were mostly limited to the upper bank in the rostral STS after injections into TEad, whereas, the terminals were mostly limited to the lower bank after injections into TEav. They extended to all the cortical layers in both cases. The distribution of labeled neurons in the rostral STS coincided with that of labeled terminals in both cases. They were equally distributed in the superficial and deep layers or confined to the deep layers. Differential connections of TEad and TEav were also found with the TF/TH, cingulate cortex, insula, and hippocampus. Labeled neurons were found in TF/TH after injections into TEad but not after injections into TEav. Labeled terminals were also found in TF/TH in the TEad cases, but their distribution was more localized into patchy regions than the distribution of labeled neurons.

more localized into patchy regions than the distribution of labeled neurons. Labeled terminals and neurons were found in the CA1 region of the hippocampus in the TEav cases but not in the TEad cases. Connections with the cingulate were only found in the TEav cases, and connections with the insula were stronger in the TEav cases than in the TEad cases.

These differential connection patterns of TEad and TEav, together with the

previously reported differences in their connections with the perirhinal and entorhinal cortices, suggest the functional differentiation between the two subregions: for example, TEad may be more involved in cross-modal integration in STS, whereas TEav more directly interacts with limbic structures.

DELAY ACTIVITY AND VISUAL RESPONSE TO THE SAME IMAGES CAN SHOW LOW CORRELATION. S Sobotka*, MD Diltz & JL Ringo. University of Rochester, Rochester NY 14642.

Single units were recorded from inferotemporal cortex (IT) and the inferior convexity of the frontal lobe (IC) while two monkeys performed a delayed matching-to-sample memory task using only a few highly-familiar images. In this pilot work, we have recorded 102 units. Twenty six percent of the units showed stimulus-selective delay activity during the (usually) 8 second delay, while 24% showed stimulus selective visual activity. Interestingly, the two groups of units were uncorrelated (Chi Square test χ²=0.4, P>0.1). Analysis of the IC and IT units separately produced the same lack of correlation in each area alone (IC, $\chi^2=0.3$, P>0.1 and IT, $\gamma^2=0.01$, P>0.1).

Responses were further analyzed by measuring the difference, for each cell, between the average delay activity following the image which elicited the greatest delay activity minus the average delay activity from that image which elicited the least. We then measured the difference, for each cell, between the average responses to the sample presentations of those same images. Across the 27 units with significant delay activity, the correlation between the delay activity measure and the visual response measure was low (r=-0.21, P>0.1). The correlations were also low when done separately for the IC units with significant delay activity (n=13, r=-0.40, P>0.1) or the similar IT units (n=14, r=-0.22, P>0.1).

The poor correlation between selective visual responses and selective delay responses was unexpected and contrary to at least some ideas which suppose delay activity to be a continuation of the initial visual response, occurring in an overlapping subpopulation. THE INFLUENCE OF BEHAVIORAL CONTEXT OF RESPONSES TO VISUAL STIMULI IN MONKEY INFERIOR TEMPORAL(IT) CORTEX. Zheng Liu, and Barry J. Richmond*. Lab. of Neuropsychology, National Institute of Mental Health, NIH, Bldg. 49 Rm. 1B80, Bethesda, MD 20892

It has been reported that neurons in monkey anterior-medial IT show decreased responses to the matching stimulus during a delayed match-tosample task(DMS). We recorded 17 stimulus selective neurons from lateral TE (lateral to anterior medial temporal sulcus(AMTS)) while a rhesus monkey performed DMS using 8 black and white patterns. On average, the firing rates did not differ across the three conditions (sample, nonmatch, and match). When we used transmitted information to measure response dependent stimulus discriminability (more information means that the response can be used to identify which stimulus appeared with greater certainty). Stimulus-dependent information started to rise on average 100 ms after the stimulus appeared (80 ms was the earliest). 70% of the total information was transmitted in the first $120~\mbox{ms}$ of the information rise. These neurons carried 20% more information when a multivariate code (first 3 principle components plus firing rate) was used to evaluate the responses than when the firing rate alone was used. The amount information about the sample stimuli and about the match stimuli were exactly the same for the whole 500 ms period we examined. However, in the nonmatch condition, the information about the nonmatch stimuli plateaued at 73% of the amount carried in the other two conditions, even though information rose at the same rate during the first 100ms. The relation among responses across the sample, match, and nonmatch parts of the DMS task appeared to be different in the tissue lateral to AMTS than has been reported for responses of neurons medial to AMTS. Support: IRP/NIMH/NIH.

COMPARISON OF VISUAL RESPONSES OF CELLS IN VENTRAL AND DORSAL PARTS OF INFEROTEMPORAL CORTEX. H. Tamura^{1,2*} and K. Tanaka¹, ¹Lab. for Neural Information Processing, RIKEN, Wako, Saitama, 351-01, Japan, ²Lab. for Nervous Informatics, NIBH, Tsukuba, Ibaraki, 305, Japan.

The anterior part of the inferotemporal cortex (area TE) is thought to be important for the object recognition. Recent anatomical studies have shown important for the object recognition. Recent anatomical studies have shown differences in afferent and efferent connections between the ventral and dorsal parts of area TE (TEv and TEd, respectively). In this study, we examined responses of cells in TEv and TEd with a fixed set of 100 pictures composed mostly of color images of objects in awake macaque monkeys (M. fiscaue) performing visual fixation task.

We have a varnified L13 cells recorded from TEV and 100 cells recorded.

We have examined 113 cells recorded from TEv and 100 cells recorded from TEd. The proportion of responsive cells was significantly lower in TEV (58%) than in TEQ (85%). The mean maximum firing rate of the visually responsive cells was lower in TEV (28 spikes/sec) than in TEQ (40 spikes/sec). However, the stimulus selectivity of these responsive cells was comparable between the two areas. On the average, 9.3 stimuli evoked more than 50% of the maximum firing rate in the TEv cells, and 9.9 stimuli in the TEd cells. Highly selective cells showing more than 50% of maximum firing rate to less than 5 stimuli constituted 49% of the responsive cells in TEv and 46% in TEd.

We conclude that 1) visual responses are weaker in TEv than in TEd, and 2) the stimulus selecivity of the visually responsive cells is not significantly different between TEv and TEd, as far as responses are examined with pictures of objects in monkeys performing visual fixation task.

INTERACTION BETWEEN SHAPES IN THE RECEPTIVE FIELD OF NEURONS IN THE INFERIOR TEMPORAL CORTEX. M. Missal*, R. Vogels and G.A. Orban Lab. Neuro- en Psychofysiologie, KULeuven, B-3000 Leuven, Belgium

Neurons in the inferior temporal cortex (IT) of the rhesus monkey (Macaca mulatta) have been found to respond selectively to shapes However, shapes are usually not isolated but appear together with other shapes. We demonstrated previously that the response and shape selectivity of IT neurons are reduced when the shapes partially overlapped another one (Missal et al. 1995). In the present study, we determined in the awake monkey, the influence of the relative position of a second shape in the receptive field of the neuron on its response level. The response of shape selective units (n= 22) was measured first to a single shape presented at different positions and eccentricities. Responses were the strongest at the fixation position and in a part of the visual field contralateral to the recording site. A weaker response was evoked from a symmetric position in the ipsilateral visual field. Shape selectivity remained unchanged across the receptive field. Simultaneous presentation of the two shapes in the receptive field induced a reduction in response strength: 67 % reduction for the two shapes superimposed at the fixation position, 32 % if the second stimulus was contralateral and 11 % if it was ipsilateral with the first shape at the fixation position. These results show that the suppressive effect of a second shape in the receptive field is the strongest if the two shapes are at the same position and weaker if there is a distance between them. In the periphery the suppressive effect of second shape is stronger in the contralateral vs ipsilateral hemifield.

NEURAL CORRELATES OF VISUAL ASSOCIATIVE LEARNING IN INFERIOR TEMPORAL CORTEX OF THE RHESUS MACAQUE C.A. Erickson*, and R. Desimone, Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892-4415.

To gain a better understanding of the neural basis of visual association learning, we first developed a task that allowed us to study implicit learning of visual-visual paired associates. Humans and monkeys were shown a brief cue stimulus at the start of the trial followed 1 second later by a go or nogo choice stimulus. Each choice stimulus was paired with a specific cue on 80% of the trials (valid trials). Typically, both humans and monkeys learned 8 concurrent pairs of stimuli, through trial and error, to a criterion of 90% in less than 200 trials. During probe trials, a cue that normally predicted a specific go or nogo choice stimulus was instead followed by a different choice stimulus, one that required either the same (neutral trials, 10%) or different response (invalid trials, 10%). Reaction times were fastest on valid trials (420 ms), slowest on invalid trials (478 ms) and intermediate on neutral trials (438 ms) for well-learned stimuli, indicating that subjects learned the valid predictor-choice pairings, even though some humans had no explicit awareness of the pairings

Cells were recorded in inferior temporal cortex, a brain region important for learning visual associations, using multiple tetrodes. Consistent with the behavioral results, the cells' response latency to the choice stimuli were more than 10 ms faster on the valid trials, compared to the latency of the same stimuli on invalid and neutral trials. Thus, experience with temporally-linked stimuli can accelerate the sequential activation of neural representations Supported by NIMH-IRP.

COLOCALIZATION OF ACTIVITY IN HUMAN EXTRASTRIATE CORTEX TO FACES AND LETTERSTRINGS USING INTRACRANIAL FIELD POTENTIALS AND furth. A. Puce*, T. Allison, S.S. Spencer, J.C. Gore, D.D. Spencer, and G. McCarthy. Neuropsychology Lab., VA Medical Center, West Haven CT 06516, and Department of Neurology and Section of Neurosurgery, Yale University School of Medicine, New Haven CT 06510.

We have shown that: (i) in intracranial recordings faces and letterstrings evoke a negative field potential at about 200ms (N200) from discrete regions of extrastriate cortex (Allison et al 1994 Cerebral Cortex); (ii) the same region is activated by faces and letterstrings in fMRI studies in normal subjects (Puce et al, 2nd Int Conf on Human Brain Mapping June 1996). Here we address whether, in a given individual, the active regions as determined by these two techniques are colocalized. We studied two epilepsy patients using potential recordings and fMRI to unfamiliar faces and letterstrings. In Pt1 faces produced fMRI activation in the fusiform gyri (FG). Face N200s from electrodes on the right and left FG colocalized with fMRI activation. Letterstrings produced little fMRI activation and no letterstring N200s. In Pt2 fMRI activation to faces occurred over a large extent of the right FG and colocalized with observed face N200s. A face N200 was also recorded from the left FG/OTS. While no letterstring N200s were seen, letterstrings strongly activated the left OTS in the fMRI study. As electrodes overlying a sulcus cannot readily record field potentials from a generator source within its walls, it is unlikely that letterstring N200s would be seen on surface cortex. Pt2 subsequently had an extensive right inferior temporal resection of her seizure focus. Post-operatively she had a left-visual field cut but was able to read words and numbers. She was prosopagnosic and could not match unfamiliar faces. The results provide evidence for perceptually based category-specific processing mainly in the right FG and left OTS for faces and letterstrings, respectively. (Supported by the Dept. of Vet. Affairs & NIMH grant MH-05286.)

SAMPLE-SELECTIVE DELAY ACTIVITY DURING THE PERFORMANCE OF A DELAYED MATCH TO SAMPLE TASK IN THE MONKEY ENTORHINAL CORTEX. W.A. Suzuki*, E.K. Miller², and R. Desimone¹. ¹Laboratory of Neuropsychology, NIMH, Bethesda MD, 20892 and ²Dept. of Brain and Cognitive Sciences, MIT, Cambridge MA, 02139.

Neuropsychological studies in monkeys and rats suggest that both the entorhinal and perirhinal cortices are important for object memory. To investigate the neural mechanisms underlying object memory in the entorhinal cortex, we recorded from neurons in two monkeys performing a modified version of the delayed match-tosample (DMS) task in which multiple and sometimes repeated stimuli could intervene between the sample and the match. To solve this working memory task, the monkey must (1) discriminate the stimuli, (2) maintain a memory of the sample stimulus during delay periods, and (3) evaluate whether a test stimulus matches the sample presented earlier in the trial. We previously reported that similar to cells in the perirhinal cortex, entorhinal cells may play a role in the first and third of these processes, in that they were stimulus selective and responded differentially to the test stimuli depending on whether the stimulus was a match or a nonmatch (Suzuki et al., Soc. Neurosci. Abstr., '95). We now report that entorhinal cells may play a role in the second process, in that some entorhinal neurons exhibit sample-selective activity during the delay intervals of the task and this selective delay activity is maintained across multiple intervening stimuli. By contrast, selective delay activity in perirhinal cortex is abolished by even one intervening stimulus (Miller et al., Soc. Neurosci. Abstr., '95). Preliminary evidence from a third monkey suggests that entorhinal cells also exhibit stimulus-selective activity during the delay intervals of a delayed match to place task. Thus, entorhinal cortex appears to maintain an explicit representation of the sample stimulus throughout the trial. Since the prefrontal cortex is the only other structure known to exhibit this property, these findings highlight an unexpected parallel between the mechanisms underlying working memory for objects and locations in both the entorhinal and prefrontal cortices. NEURONAL RESPONSES IN MACAQUE INFERIOR TEMPORAL (IT) CORTEX DURING LONG TERM LEARNING OF OBJECT SALIENCE. B. Jagadeesh* R. Desimone. M. Mishkin, Laboratory of Neuropsychology, NIMH, NIH, Bethesda, MD 20892.

B. Jagadeesh*, R. Desimone, M. Mishkin, Laboratory of Neuropsychology, NIMH. NIH, Bethesda, MD 20892.

When confronted with a scene containing many different objects, we tend to orient towards objects that are significant to us. In previous studies, we found evidence of neural activity that might account for this behavior: responses of IT neurons to arrays of stimuli are biased in favor of the stimuli that are associated with reward; the responses of cells that are tuned to the other stimuli in the array are suppressed. In these studies, the animals were rewarded for making an eye movement to a particular stimulus (target), which was either switched from trial to trial by presenting a cue at the start of the trial (a working memory paradigm; Chelazzi et al, Nature 1993) or was learned over the course of the session by consistent stimulus-reward pairings (Jagadeesh et al. Neurosci. Abstr. 1995). Since, in both cases, the particular target and nontarget stimuli (once learned) could be anticipated by the animal on each trial before the array was presented, the cells in IT may have been biased by feedback from other cortical areas involved in working memory. Alternatively, consistent target-reward pairings may have induced long-term changes in IT cortex, giving a competitive advantage to cells coding the target stimulus.

To help decide between these possibilities, we recorded IT responses in a monkey that was taught many concurrent target-nontarget discriminations. Because target and nontarget stimuli appearing in a given trial could not be anticipated, active working memory mechanisms were ruled out. When target and nontarget stimuli appeared together in the array the responses of the population of cells in IT were determined primarily by the target stimulus, as in the previous studies; the responses of cells selective for nontarget stimuli were suppressed. The effects were present only when the target and nontarget stimuli were presented alone, there was no effect of learning on the responses. The results sugges

MEANINGFUL IMAGES ENHANCE ACTIVATION IN OCCIPITAL AND LEFT TEMPORAL AND PARIETAL CORTICES. <u>S. Vanni * A. Revonsuo * 2</u>, Saarinen <u>and R. Hari * 1</u> Brain Research Unit, Low Temperature Laboratory, Helsinki University of Technology, 02150 Espoo, Finland, ²Centre for Cognitive Neuroscience, University of Turku, 20520 Turku, Finland 20520 Turku, Finland

Espoo, Finland, "Centre for Cognitive Neuroscience, University of Turku, Espoo, Finland Cortical magnetic fields were recorded with a whole-scalp neuromagnetometer to visual stimuli from 8 right-handed observers. The stimuli were either 'images' (pictures of 200 concrete objects or animals) or 'non-images' (generated from the images by randomly rotating circular areas within them), presented once every 3–5 s for 30, 45 and 105 ms in-between backward and forward maskers. The observers indicated their decision about the stimulus type (image vs. non-image) with index finger lifts. The parieto-occipital 8–13 Hz alfa rhythm was suppressed by both stimuli but the post stimulus rebounds were higher for non-images than images. Most observers (7 out of 8) showed evoked responses in medial occipital cortex, in lateral occipital cortex bilaterally (6) and in superior temporal lobe in or near the midsuperior temporal sulcus (8 left, 6 right), and in the left parietal lobe (6). The occipital and temporal sources peaked on average at 300–380 ms, followed by the left parietal activation around 500 ms. Images induced stronger activation than non-images in lateral occipital (left p < 0.005, right p < 0.05, 2-way ANOVA for each source; main factors image vs. non-image and presentation time), left temporal (p < 0.001) and left parietal (p < 0.001) cortices. The preferential activity for images in lateral occipital areas agrees with previous fMRI findings (Malach et al., PNAS 1995, 92: 8135). The right lateral occipital activity correlated positively with sebasical image affecting the control of the control of the control occipital activity correlated positively with sebasical image affecting the control of the control of the control occipital activity correlated positively with sebasical image affecting the control of the control of the control occipital activity correlated positively with 8135). The right lateral occipital activity correlated positively with behavioral image detection ($r=0.74,\ p<0.001$), suggesting a strong involvement of this area in object detection. THREE COMPUTATIONAL TRADEOFFS AFFECT OBJECT RECOGNITION IN A HIERARCHICAL, RECEPTIVE-FIELD-BASED VISUAL SYSTEM. J. Fiser, Dept. of Computer Science & B. W. Mel*, Dept. of Biomedical Engineering, MC 1451, USC, Los Angeles, CA 90089.

Some neurons in the primate inferotemporal cortex respond selectively to specific conjunctions of contour, texture, and color feature elements [Kobatake & Tanaka, J. Neurophysiol., v. 71, 1994], but are invariant to substantial changes in stimulus position, size, and other viewing parameters [Ito, et al., J. Neurophysiol., v. 73, 1995]. We consider three parameters that constrain the "design" of such conjunctive features, and which highlight algorithmic tradeoffs that influence recognition performance under different ecological conditions. These are (1) conjunctive order, i.e. the number of elemental features that make up a conjunction, (2) locality, i.e. the scale of spatial distribution of feature elements in the visual field that define a conjunction, and (3) invariance characteristics, i.e. those parameters, such as stimulus size and location, that may be changed without significantly altering the magnitude or selectivity of cell responses. We illustrate the performance ramifications of each of these tradeoffs in the context of typeset and handwritten word recognition. This work was funded by the ONR.

DEVELOPMENT OF INVARIANT RESPONSES IN A MODEL OF THE INFEROTEMPORAL CORTEX EMBEDDED IN A BEHAVING REAL WORLD ARTIFACT. N. Almássy, O. Sporns, J. Wray* and G. Edelman. The Neurosciences Institute, 10640 John J. Hopkins Drive, San Diego, CA 92121.

Behavioral discrimination of shapes and patterns requires the ability to detect invariant properties of stimuli and to link the appropriate neuronal responses to motor output. We studied the development of neuronal responses and their linkage to motor structures in a model of the inferotemporal cortex. In order to take into account the role of ongoing behavior during the developmental period we embedded the neuronal model in a real world artifact called "NOMAD." Its environment contains numerous blocks that differ in the visual patterns on their surface and their conductivity, which serves as a value signal ("taste"). Visual input acquired by a video camera is transmitted to an area resembling V1, with units that respond selectively to horizontal or vertical lines, or "blobs" in the visual field. Omitting intermediate areas, V1 is linked directly to IT, which contains locally coupled excitatory and inhibitory units. V1-IT connections are widely divergent and modifiable according to a learning rule allowing for potentiation and depression. Initially, IT units send uniformly distributed connections to motor centers controlling behavior of NOMAD. Successive exposure to objects in the environment leads to changes in the response properties of neuronal units in IT. Before learning, IT responses are weak and show no selectivity for stimulus patterns. After the classification of about 90 blocks, IT units appear more sharply tuned, are selective for distinct stimulus patterns, respond invariantly with respect to their position, orientation or size, and units with similar response properties are spatially grouped together. Due to value-dependent strengthening of connections linking selective units in IT to motor units, NOMAD is able to behaviorally discriminate stimulus patterns based on their visual appearance. This approach allows the comprehensive analysis of both neural and behavioral data over a complete developmen-

VISUAL CORTEX: EXTRASTRIATE-DORSAL STREAM II

635.1

OPTIC FLOW DURING SIMULATED TURNS: SINGLE UNIT RESPONSES IN EXTRASTRIATE CORTEX. H. Sherk*, K.A. Mulligan, & J-N, Kim. Bio Structure, U. Washington, Seattle, WA 98195

Vision provides essential information for the guidance of normal locomotion When a locomoting observer turns, the optic flow field changes abruptly, and these changes might be detected by single neurons in motion-sensitive cortical areas such as MT in primates or LS (the lateral suprasylvian area) in cats. We searched for such neurons in LS in anesthetized cats. Our stimulus displays simulated a natural environment seen by a cat trotting both straight ahead and turning.

The large stimulus display (62x62 deg) represented an environment of small objects of variable contrast that covered the ground and also floated in air. The cat's simulated motion was initially straight ahead; after 200-350 msec it made a simulated turn of 15, 30, or 60 deg to the right or left lasting for 1 sec.

Of 404 neurons, 96 responded to turns, and gave only a transient response, or no response, during the preceding straight-ahead movement. Most commonly, neurons responded best during a turn of one size and direction (e.g., a left turn of 30 deg) Surprisingly, 25% of these neurons responded poorly or not at all to a whole-field texture stimulus that matched the speed and direction of image motion seen by the receptive field during an optimal turn. The texture stimulus differed from movies simulating turns in that it contained no optic flow cues, and was not preceded by whole-field motion in a different direction. Responses to turns frequently had significantly shorter latencies than responses to simple texture motion. Supported by NEI RO1-4847

635.2

EXTRASTRIATE RESPONSES TO SALIENT OBJECTS IN NATURALISTIC OPTIC FLOW FIELDS. K.A. Mulligan*, H. Sherk, & J-N. Kim. Biological Structure, U. Washington, Seattle, WA 98195

Locomoting observers need to detect salient objects in the visual field that might represent obstacles to avoid, or landmarks for guidance. We sought to determine whether neurons in the cat's lateral suprasylvian area (LS) respond to such objects embedded in a large-field (62x62 deg), realistic optic flow simulation

A preliminary study of 60 cells yielded consistently negative results. The salient object in this case was a black bar lying on a layer of small balls covering the simulated ground. We next tested optic flow movies containing a variety of larger and more naturalistic objects. All objects were variants of a bush with a simulated height of 36 cm. The ground was densely covered with the leaves of this bush, and objects were placed on the ground so that during the cat's simulated motion each object passed through the receptive field of the cell under study

These objects proved to be highly effective stimuli. Of 404 cells tested, 220 responded well to one or more objects. Response levels were often comparable to those evoked by an optimal bar moving in the preferred direction. Even bushes whose texture and appearance closely resembled the leafy substrate often elicited strong responses. In general, large objects were more effective than identical ones of half height, even when the latter extended beyond the receptive field

Because a given object was part of an optic flow field, its direction of motion depended only on its position in the simulated environment. Objects thus often moved in directions quite different from that preferred by a particular cell. Surprisingly, about 1/3 of cells responding to objects did so despite this kind of mismatch. Thus cells can respond well to a salient object in an optic flow context moving in a direction which, when tested with an optimal bar on a blank Supported by NEI RO1-4847 background, elicits a much weaker or no response

635.3

LESION-INDUCED CHANGES IN VELOCITY AND DIRECTION TUNING, AND FIRING RATES OF CELLS ADJACENT TO LESIONS IN MONKEY MIDDLE TEMPORAL CORTEX. J. M. STARK, and D. S. Yamasaki*. Dept. of Anatomy, University of Wisconsin Medical School, Madison, WI 53706

Previous reports have shown that rapid recovery of smooth pursuit eye movements following lesions in the Middle Temporal (MT) area is dependent on the surviving cells in these areas. To test whether compensatory changes take place in the cells adjacent to MT lesions, we have recorded direction and velocity tuning the cells adjacent to MT lesions, we have recorded direction and velocity tuning curves, as well firing rates from single neurons in MT. Guide tubes were positioned chronically over MT, allowing us to record from the same sub-population of cells across several weeks. Also, smooth pursuit was recorded every recording day to monitor the behavioral deficits and the recovery times. One electrolytic lesion and two AMPA lesions were made in 3 hemispheres in two monkeys. In two hemispheres, cells showed preferred speeds higher than those seen before the lesion for a given recording site (> 32°(sec). There was a clear decrease in direction electricity in a corbogulation of part lesion calls, however most of the cells did not selectivity in a subpopulation of post lesion cells, however most of the cells did not change. At one recording site (3.5 mm from the lesion center), the range of directional indices (DI) was 1.13-0.26 before and 1.13-0.26 after the lesion. The half-height bandwidths (BW) ranged from 60.32°-143.64° prior to the lesion and 43.91° 360° post lesion. Similarly, there was an increase in both the spontaneous and maximum firing rates in a subset of surviving single units in all three and maximum iring rates in a subset of surviving single units in all utree hemispheres. The range of sponianeous rates in one hemisphere was 0.08-4.45 spikes/sec before and 0.06-10.42 spikes/sec after the lesion, while the maximum firing rates were 4.44-74.12 spikes/sec before and 2.70-100.92 spikes/sec after the lesion. All of these changes were observed during the pursuit recovery period. These results are consistent with a selective loss of inhibitory interneurons near the lesion, leading to an unmasking of latent inputs in the surviving cells. It remains to be shown whether these changes contribute to the pursuit recovery, though they are compatible with such a process. This work was funded by NIH EY09618.

ASYMMETRIC SURROUNDS ENABLE MACAQUE MT NEURONS

TO SIGNAL DIRECTION OF TILT IN DEPTH. D.-K. Xiao , S. Raiguel,*
V. Marcar and G.A. Orban. Laboratorium voor Neuro- en Psychofysiologie,
KULeuven, Medical School, Campus Gasthuisberg, B-3000 Leuven, Belgium.
Our previous work has shown that the antagonistic surrounds of most MT
cells exhibit speed-dependent spatial heterogeneity (Xiao et al., Soc. Neurosci.
Abstr. 21:663, 1995), a property which is useful for extracting 3D shape from
motion cues (Buracas & Albright, Perception 22 suppl.:78, 1993). The present
study investigates the selectivity of MT neurons for direction of tilt as defined by
speed gradients. speed gradients

study investigates the selectivity of MT neurons for direction of tilt as defined by speed gradients.

Fifty-seven MT neurons were recorded in three anesthetized and paralyzed macaque monkeys. We presented tilt stimuli consisting of random dot fields moving in the optimum direction and covering both the classical receptive field (CRF) and antagonistic surround. The speed gradients specified planar surfaces tilted (inclined around the line of sight) in 8 different directions and at three different levels of slant (inclination in depth). Forty-two percent of the cells were selective for the direction of tilt in depth. This selectivity appears to be directly related to the presence of a speed-dependent asymmetric surround: There is a significant correlation between surround asymmetric surround: There is a significant correlation between surround abolished the selectivity in all 7 cells so tested; the optimum direction of tilt and the direction of the line linking the center of the CRF and the center of the surrounding area evoking maximum inhibition tend to lie along the same axis (n=19, χ^2 =4.26, p<0.05). Selectivity for tilt could be explained by the speed tuning of the spatially heterogeneous surround in more than half of the cells (n=9) which were selective for direction of tilt and which had been tested with different speeds in the surround. Our study demonstrates that the speed gradient of a tilted planar surface can modulate the response of cells in area MT via the antagonistic surround. Area MT is therefore capable of signaling the direction of tilt using depth from motion cues. This could be an initial stage in the extraction of shape from motion. NEURAL CORRELATE OF 3-D STRUCTURE FROM MOTION (SFM) PERCEPTION IN AREA MT G. C. Chang¹, D. C. Bradley²,

NEURAL CORRELATE OF 3-D STRUCTURE FROM MOTION (SFM) PERCEPTION IN AREA MT G. C. Chang¹, D. C. Bradley², & R. A. Andersen¹-².¹ Computation and Neural Systems & ²Div. of Biology, Caltech 216-76, Pasadena, CA 91125.

Studies in our lab involving MT lesioning and motion-disparity integration suggested MT may play a role in SFM. To examine this possibility more directly we trained a monkey to report the perceived 3-D structure of a motion stimulus, and compared his perceptual reports with the activity of MT neurons. The animal viewed the orthogonal projection of a hollow, rotating cylinder composed of random dots. Even without disparity cues, the motion in the stimulus causes it to appear 3-D to human observers. However, without disparity cues, the depth assigned to the two oppositely moving surfaces is arbitrary, resulting in a bistable perception of the direction of rotation. If disparity is added to the display, the direction of rotation is no longer arbitrary. The animal's task was to report the direction of perceived rotation for cylinders with varying amounts of disparity. His performance was almost perfect at high disparity values and smoothly decreased to nearly chance performance at low disparities, suggesting that his reports matched his perception.

We recorded from 44 cells in area MT while the monkey performed this task. The cylinder stimulus was positioned in the receptive field such that one of the surfaces was at the preferred direction for the cell. For 18 cells it was found that the neuron's activity varied significantly for identical stimuli depending on the perceived direction of rotation for a least one of the disparities tested, including 0% (t-test, p < 0.05). Of these 18, 16 had responses which positively predicted the monkey's perceptual report. Thus, under low disparity and ambiguous (bistable) conditions, the activity of MT neurons often covaries with the animal's perceptual reports. These data support the hypothesis that area MT plays an important role in 3-D SFM perception. Supported by

A MODEL OF THE NEURAL INTEGRATION OF MULTIMODAL SOURCES OF INFORMATION FOR SELF-MOTION: OPTIC FLOW, STEREO, AND EXTRARETINAL SIGNALS. M. Lappe* & A. Dept. Zoology & Neurobiology, Ruhr University, D-44780 Bochum,

For sensing and controlling self-motion in the real world humans can combine a number of different sources of information. Most models of selfmotion computation have instead considered only the information available from the optic flow field, despite psychophysical studies that showed the inefficiency of optic flow alone under some circumstances. Moreover, recent years have seen first reports of neuronal modulations of visual flow responses in areas MT and MST by disparity, extraretinal eye movement and eye position signals, and even vestibular signals. We present a neural model of heading detection that integrates multiple signals at the single neuron level. A map of direction selective neurons, modelled after area MT, is used as an encoding of the optic flow field. These cells are assumed to average visual motion only within restricted disparity bands, thereby accounting for the recently observed disparity dependence of MT responses to transparent motion. The MT stage forms the input to a heading detection algorithm which models optic flow analysis in area MST. This visual heading detection scheme is supplemented by a set of visual tracking neurons, also located within area MST, which encode the presence of a slow eye movement by means of an extraretinal signal. The model makes a number of predictions about the modulations of visual responses of MST neurons by eye movements or stereoscopic displays. These predictions are compared to recent experimental data.

SHORT-LATENCY OCULAR FOLLOWING AND ITS ASSOCIATED NEURONAL ACTIVITY IN MEDIAL SUPERIOR TEMPORAL AREA (MST): DEPENDENCE ON OCULAR VERGENCE. Y. Inque. A. Takemura. K. Kawano* and F. A. Miles. Electrotechnical Lab., Tsukubashi, Ibaraki, 305, Japan, and Lab. of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892. The short-latency ocular following responses (OFR) elicited by motion of a large-field pattern are mediated at least in part by a pathway that includes MST, dorsolateral pons and ventral paraflocculus (Kawano et al., 1992, 1994; Shidara et al., 1902).

1993), and their magnitude is inversely related to viewing distance (Busettini et al., 1991, 1994). We now report on the dependence of OFR and the associated activity

of MST neurons on the convergence angle of the two eyes in the monkey.

The animal faced a large tangent screen onto which two identical images were back-projected. Crossed polarizers in the projection paths ensured that each eye saw only one of the patterns and mirror galvanometers were used to control the horizontal only one of the patterns and mirror galvanometers were used to control the horizontal and vertical positions of the images. At the beginning of each trial the image seen by one eye was slowly moved (horizontally) to a new position to induce the monkey to adopt a new convergence angle (distance to the plane of fixation ranged from 25 cm to infinity). Then, 50 ms after a centering saccade, both patterns were moved together at constant velocity (conjugate ramp) to the left or right to elicit OFR. The rise in eye speed at the onset of OFR in response to conjugate ramps of a given velocity was directly proportional to the convergence angle. Of the neurons in MST that discharged in relation to OFR, 59% were sensitive to the convergence angle (OS) tests), some responding more vigoricusly with increases in

MST that discharged in relation to OFR, 59% were sensitive to the convergence angle (p<0.05, t-test), some responding more vigorously with increases in convergence (36%) and the remainder responding less vigorously. However, the modulation with convergence [(max-min)/min) x 100%] was on average much lower for the neurons than for OFR: 43% vs 176%. These data suggest that vergence angle can be a major cue in the modulation of OFR with viewing distance, and that either MST neurons mediate only a portion of the OFR and/or most of the modulation of OFR with vergence angle results from changes downstream of MST.

ACTIVITY DIFFERENCES WITH CORRECT AND FALSE DECISIONS IN AREAS MT, MST, AND STPP A. Thiele', S. C. de Oliveira, K.-P. Hoffmann, Dept. Zoology & Neurobiology, Ruhr-Univ. Bochum, 44780 Bochum, Germany

We investigated the neuronal activity of direction selective cells from areas MT, MST, and the upper part of STPp while two monkeys performed a direction discrimination task near contrast threshold. Stimuli consisted of evenly spaced bars, moving in one of the four cardinal directions. Stimulus onset, contrast and direction of motion were randomized. Upon stimulus perception, the monkeys were supposed to indicate the direction of motion by a hand movement to one of four touch bars. Stimulus contrast varied between 2% and 54%. Reaction time and error rate increased with decreasing contrast. To compare the activity between correct and false decisions the normalized population activity was calculated in 5 ms bins according to the direction of the decision. A binwise ANOVA was applied to the data, in order to see whether normalized population activity significantly differed dependent on the direction of the decision. In all three areas the activity was significantly reduced (about 20%) if the preferred direction was presented, but the monkey made an error. Nonetheless the population stimulated in preferred direction still exhibited significantly higher activity as compared to the population corresponding to the decision the monkey actually made.

Although the activity changes can be taken to predict the probability of error occurence, errors themselves cannot be explained by activity changes in one of these areas. If the monkey would rely on rate differences within these areas, an error would not occur, since the population stimulated in preferred direction always exhibits the highest activity

VESTIBULAR RESPONSES DURING LINEAR MOTION IN AREA MST OF THE MACAQUE MONKEY. M.Pekel, M.Lappe, M.Schmidt*, and K.-P. Hoffmann, Dept. Zoology and Neurobiology, Ruhr-University, D-44780 Bochum, Germany

Area MSTd in the anterior part of the superior temporal sulcus has been shown to be involved in the processing of optic flow stimuli that simulate egomotion. Since vestibular information is usually present during real but not visually simulated egomotion we investigated the responses of single neurons in area MST of the macaque monkey to a real linear movement along the naso-occipital axes. This movement results in stimulation of the otolith organs which are sensitive to linear acceleration. The monkey chair was placed on a parallel swing. The monkey was trained to fixate a central spot of light (0.4 deg diameter). The duration of one cycle (back and forth) was 4s. The swing amplitude was 1.0 m and the vertical displacement was 0.03m. Each trial started with backward movement and lasted for one cycle. We tested the responses to sinusoidal movement in the darkness (the pure vestibular response). We also compared the single cell responses to real motion in the light with visual stimulation simulating identical egomotion. Half of the recorded cells showed clear responses to vestibular stimulation or clear differences between the real and simulated egomotion during visual stimulation. Cells responding to the pure vestibular stimulation often showed transient responses in the start and/or end phase. Phasic as well as tonic response differences over the whole movement period were observed when real and simulated egomotion were compared. We conclude that vestibular information resulting from linear acceleration is integrated with visual self- motion processing in area MST.

RESPONSE TO SPEED GRADIENTS IN AREA MST. N. Ghani* and J-P. Roy. Montreal Neurological Institute, McGill University, Montreal, Quebec H3A

When an observer moves in a direction different from her line of sight, the images of objects at different depth move at different speeds. We examine MST neurons for a sensitivity to such differential motion.

MST cells were presented with random dot stimuli containing motion at three speeds, over the same area of the visual field. The response to these stimuli e compared to a control stimulus with only one speed of motion, the average of the three speeds presented in the speed gradient. The disparity of the speed gradient and the control were always the same. We used three disparity conditions: fixation, 2 degrees preferred, or 1, 2 and 3 degrees preferred. In the last condition, the slowest speed was presented at the smallest disparity, the fastest at the largest. This is the expected correlation during observer motion in a static environment.

15/42 (37%) cells give a significantly (t-test, p<0.01) higher response to speed gradient stimuli as compared to the control containing only one speed. This response is not a consequence of the speed tunings of these cells. We measure speed tunings at the plane of fixation and in disparity at all values used for the speed gradient stimuli. The optimum response of an MST cell to stimuli containing one speed does not predict the response to stimuli containing multiple speeds. In addition, an analysis of variance shows no effect of disparity in cells which respond to speed gradient stimuli.

THE DEVELOPMENT OF OPTIC FLOW SELECTIVITY IN MSTd NEURONS USING BACK-PROPAGATION NETWORKS S.A. Beardsley 1, L.M. Vaina 1, T. Poggio^{2*} Boston University, Department of Biomedical Engineering, Boston MA¹. Center for Biological and Computational Learning, MIT, Cambridge MA²

In neurophysiological experiments examining the responses of MSTd neurons to visual motion components of optic flow stimuli in monkeys, Duffy & Wurtz (1991) reported neurons with double-component (plano-radial and plano-circular) and triple-component (plano-radial-circular) selectivities while Graziano et al. (1994) reported neurons selective to spiral optic flows. Here we address the apparent disagreement of these reported findings under simulated experimental conditions. To examine the development of optic flow selectivities in the hidden units of a three layer back propagation network, we constructed two computational models by using different input layer formats. The first simulation used a sparse optic flow. The input format consisted of eight circular MT receptive fields placed in the MSTd receptive field such that the MT receptive fields were radially symmetric without overlap. Each MT receptive field corresponded to eight directionally selective MT neurons which equally divided the directional vector space. The second simulation used a dense optic flow. The input format consisted of 67 overlapping MT receptive fields of normally distributed diameter placed pseudo-randomly in the MSTd receptive field. Each MT receptive field corresponded to 16 directionally selective MT neurons which equally divided the directional vector space. The hidden units were classified as MSTd neurons whose receptive fields were coincident and encompassed the MT receptive fields from the input. The output layer of the network consisted of four MSTd neurons with the same receptive fields as the hidden layer. To minimize the effects of biasing, the output selectivities were designated as expansion, contraction, clockwise rotation, and counterclockwise rotation (consistent with MSTd selectivities found in both experiments). In both sets of simulations we found hidden units whose selectivities were consistent with the visual motion components of optic flow stimuli reported by Duffy & Wurtz and Graziano et al.

STATIONARY SURROUNDS ENHANCE THE RESPONSE OF MSTI NEURONS TO MOVING STIMULI. S. Eifuku and R. H. Wurtz*. Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, MD 20892.

We investigated the importance of foreground-background segregation on the response of monkey (Macaca mulatta) MSTI neurons to moving stimuli: whether the presence of a patterned background altered the response of the MSTI neurons to motion in their field center, and whether the neurons responded preferentially to motion of a patterned "object" or to motion of the same size patterned motion seen through an aperture

Monkeys fixated on a tangent screen while random dot motion was projected onto the previously determined central receptive field of the neuron. Responses were measured for motion in the preferred and non-preferred directions for each cell. Object motion consisted of a random dot pattern (e.g. 10 deg in diameter) moving across the receptive field area; aperture motion consisted of the same pattern moving behind a window, (e.g. a window 10 deg in diameter). We then tested the effect of

replacing the usually dark background with a patterned surround stimulus.

The neurons studied all were on the anterior bank and floor of the superior temporal sulcus as determined from an MRI, and their preferred stimuli were consistent with those of MSTI: typically large receptive fields but directionally selective responses given preferentially to small stimuli in the the larger field. We found that the response to the preferred stimulus motion was almost always increased when the normally dark surround was replaced by a patterned stimulus. This is in contrast to a general lack of such an increase in response in MT neurons when surround stimuli were added (Olavarria et al. 1992). We also found that many (but not all) of these neurons gave more vigorous responses to object motion. conclude that stimulus factors that would alter the segregation of foreground from background change the response of MSTI neurons. TOPOGRAPHIC ORGANIZATION OF CORTICO-TECTAL PROJECTIONS FROM AREA LIP OF MONKEYS JW Gnadt* and MF Kritzer. Dept Neurobiology & Behavior, SUNY at Stony Brook, NY 11794

Prior physiologic studies have failed to identify a coherent topographic map in area LIP. Anatomical studies show that area LIP links diverse visual and pre-motor inputs with cortical and subcortical oculomotor centers, including the superior colliculus (SC). Only one synapse away, the SC has a "motor map" that is is orderly and well established. Thus, we sought to determine area LIP topography in relation to its outputs for the generation of saccades via the superior colliculus.

We used standard microstimulation techniques to determine the topographic map of saccades in the intermediate layers of the SC. We then used this map to place multiple injections of distinguishable retrograde tracers (0.3-0.5 µl) into known positions of the tectal map. The resulting retrograde label in area LIP was then plotted separately for each tracer, and together on a common set of coordinates.

All collicular injections labeled pyramidal neurons in cortical layer 5. consistent finding was that individual SC injections produced anterior/posterior bands of labeled cells along the sulcus. In some cases, labeling arched across the sulcus in a continuous band. In other cases the label was discontinuous, leaving open the possibility of interdigitation with other distinct populations, or for repeating patches of collicular representations along a line across the sulcus. Comparison of labeling within subjects revealed unique patterns of label for individual injection sites that were spatially overlapping in some cases. Comparison between subjects for injections at similar tectal loci revealed ideosynchracies in both the pattern and location of retrograde label. Future studies will emphasize intra-subject injection patterns placed along saccadic iso-direction and iso-amplitude lines within the superior colliculus. DYNAMIC CHANGES IN VISUAL RECEPTIVE FIELD ORGANIZATION IN THE MACAQUE LATERAL INTRAPARIETAL AREA (LIP) DURING SACCADE PREPARATION. S. Ben Hamed, J-R. Duhamel*, F. Bremmer and W. Graf, CNRS-Collège de France, F-75270 Paris Cedex 06, France.

The spatial structure of the receptive field (Rf) of single visual neurons in area LIP was found to vary systematically depending on foveal attention or saccade preparation (Duhamel et al., Soc. Neurosci, Abstracts, 21, 1759, 1995). The present study examines the spatial and temporal characteristics of these effects. Responses were recorded extracellularly from 50 neurons in two hemispheres of one rhesus monkey who performed memory-guided saccades: during foveal fixation, a cue was turned on for 80ms at one of several possible positions inside, near or away from a given neuron's Rf; after a 2.3s delay the monkey was instructed to make a saccade to the cued location. Rfs were mapped during the delay period with rapid sequences of flashes randomly selected from a 9x9 array of predefined locations.

In about one half of the cells, the direction of the upcoming saccade did not modify significantly Rf characteristics or produced changes that were uncorrelated with eye movements. In the other half of the sampled neuron population, Rf activity was displaced in the direction of at least one saccade. This displacement could result from a global shift of the Rf, a shift of the location of the peak within the Rf, or an expansion of one of the Rf borders. Time-dependent changes in Rf structure were analysed by subdividing the delay period into three epochs to determine when these changes were at maximum in the interval between the sensory encoding of the saccade location and the execution of the motor response. Two main behaviors were seen: (a) the Rf remained fixed but the overall activity level changed over time, (b) there was a gradual shift of the Rf borders across the three epochs of the delay, while the overall activity was constant for a given saccade direction. Such dynamic reorganization of Rfs in response to changes in sensory, attentionnal and motor signals may be crucial for the encoding of visual space. RESPONSES OF LIP NEURONS TO CHANGES IN STIMULUS UTILITY. M.L. Platt and P.W. Glimcher. Center for Neural Science, New York University, New York

We examined the effects of changes in stimulus utility on the responses of single LIP neurons in head-fixed, awake-behaving rhesus monkeys. First, th single LIF neutrons in nead-tixed, awake-behaving friesds motikeys. First, the response field of each unit was measured at a 2° resolution using 100-400 trials of a delayed saccade task. Next, unit responses were recorded while animals performed a Selection task and a Distributed Selection task which differed only in the utility of a distractor stimulus. On both tasks, subjects initially fixated a central yellow LED for 200-800 msec. Two eccentric yellow LEDs were then co-illuminated for 200-800 msec, one above and one below the horizontal meridian. The fixation LED then changed color to either red or green, specifying either the upper or lower LED, respectively, as the saccade goal. On the sel tion task, fixation offset cued movement initiation, whereas on the distributed selection task distractor offset provided the initiation cue. This permitted us to examine the responses of the unit to a distractor both when it was irrelevant and when it cued movement onset. In both tasks, most cells responded about 50% more strongly when an LED at the center of the response field served as a saccade target than when the same LED served as a distractor. Overall, population selectivity for saccadic targets was unaffected by our manipulation of distractor utility.

tractor utility. We also examined the effects of changing the utility of a target stimulus by changing the probability that a particular target location would serve as the saccade goal in a series of delayed saccade trials. The response field of each unit was measured by varying the saccadic goal randomly throughout the response field of the unit under study when 1) all possible target locations were equally likely, and 2) when one particular location was much more likely to serve as the saccadic goal than all other locations. The response field properties of some units changed when target utility was altered in this manner.

NEURONAL SELECTIVITY TO RETINOTOPIC CENTERS OF MOTION IN AREA 7A OF THE BEHAVING MONKEY. J.F. McCollum* & R.M. Siegel. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark. NJ 07102. Area 7a in the inferior parietal lobule is the apex of visuos-spatial processing in macaques. Optic flow stimuli (planar rotation and radial motion), which provide powerful cues for the analysis of egocentric motion (heading) and extra-personal space, have been found to activate neurons in area 7a. Selectivity to the retinotopic position of the flow field has been reported (Siegel & Read.) 1994). The present study determines whether a retinotopic selectivity to the center of optic flow (i.e. axis of motion) can be found in the absence of changes in location of the border of the flow field. Such changes in the center of optic flow occur with variations in egocentric motion or eye position in the orbit. The activity of area 7a neurons was recorded during presentation of random dot optic flow fields that covered 50° of the visual field. The center of a flow field could be placed at 9 different retinal loci (3x3 array) without altering the position of the luminance border of the display. Monkeys performed a reaction time task in which they fixated a small square and attended to changes in the structure of the flow field. A two-way ANOVA was used to quantitatively determine the selectivity of neurons to the type of optic flow, the fraction of structure of the flow field. A two-way ANOVA was used to quantitatively determine the selectivity of neurons to the type of optic flow for structure. Varying the retinotopic location of the optic flow swell as its fraction of structure. Varying the retinotopic location of the center of optic flow altered the response of about 25% of the motion-sensitive neurons. These selective responses were modeled with linear and quadratic terms; maxima in the response were found both ipsilateral and contralateral to the recorded hemisphere. These data provide strong evidence that area 7a

THE REPRESENTATION OF EYE POSITION IN THE PARIETO-OCCIPITAL SULCUS IN THE MONKEY. <u>K. Nakamura* H.H. Chung, M.S.A. Graziano, and C.G. Gross.</u> Dept. of Psychology, Princeton Univ. Princeton, NJ 08544.

Princeton, NJ 08544.

We recorded single neuron activity in the parieto-occipital sulcus of two monkeys (Macaca fascicularis) and found that for 47% of 141 neurons the neural activity depended on the position of the eyes during spontaneous eye movements even in the dark. Thirty-four of these eye-position dependent neurons were tested in a task in which the monkey was required to fixate a spot for 1.5 sec. On interleaved trials the fixation point was presented at 1 of 9 locations arranged in a square grid with 12 degrees between adjacent locations. All of the neurons fired more strongly when the animal was fixating at a peripheral location; none fired best at the central location For some neurons the response profile was best at the central location. For some neurons the response profile was planar; they fired best at one edge of the grid and least at the opposite edge. Every one of the 34 neurons showed sustained firing throughout the 1.5 second fixation period. Thirteen of the eye-position neurons were tested in a saccade task. In this task, the monkeys were required to fixate a center spot and to make a saccade toward 1 of 8 peripheral locations. All of the neurons changed their activity only after the eye reached the peripheral location.

Histological examination of the brain of one monkey indicated that the eye position neurons were located either dorsal to Area PO or in the dorsal portion of Area PO, in the anterior bank of the parieto-occipital sulcus. These data suggest that neurons in this area represent eye

FIBROBLAST AND INSULIN-LIKE GROWTH FACTORS STIMULATE PROLIFERATION OF RAT UTRICULAR EPITHELIAL CELLS IN VITRO. J.L. Zheng . C. Helbig and W.-Q. Gao. Dept. of Neuroscience, Genentech, Inc., South San Francisco, CA 94080.

CELLS IN VITRO. J.L. Zheng*, C. Helbig and W.-Q. Gao. Dept. of Neuroscience, Genentech, Inc., South San Francisco, CA 94080.

Proliferation of supporting cells in the inner ear is the early, major event occurring during hair cell regeneration following acoustic trauma or aminoglycoside treatment. In the present study, we have examined the possible influence of 30 growth factors on the proliferation of pure rat inner ear epithelial cells in culture. Utricular epithelial sheets were separated and partially dissociated from early postnatal rats using a combined enzymatic and mechanical method. The cultured utricular epithelial cells expressed exclusively epithelial cell antigens but not fibroblast, glial or neuronal antigens. With tritiated thymidine incorporation assays, we found that several fibroblast growth factor (FGF) family members, insulin-like growth factor-1 (IGF-1), IGF-2, transforming growth factor-α (TGF-α) and epidermal growth factor (EGF) stimulated proliferation of the utricular epithelial cells. In contrast, neurotrophins and other growth factors did not elicit any detectable mitogenic effects. Of all of the growth factors examined, FGF-2 was the most potent mitogen. When FGF-2 was added as a combination with IGF-1 or TGF-α to the medium, combined effects were seen. These results were confirmed with BrdU immunocytochemistry. Therefore, the present culture system provides a rapid and reliable assay system to screen novel growth factors involved in proliferation of mammalian inner ear supporting cells. Furthermore, immunostaining revealed that the cultured utricular epithelial cells expressed FGF receptor and IGF-1 receptor and utricular hair cells produced FGF-2 in vivo. This work suggests that FGF-2 and IGF-1 may regulate the proliferation step during hair cell development and regeneration.

IN VIVO GROWTH FACTOR (TGFα, IGF-1, RETINOIC ACID) TREATMENT OF AMINOGLYCOSIDE-DAMAGED UTRICLES SIGNIFICANTLY INCREASES THE RATE OF HAIR CELL RENEWAL. R. Kopke¹, R. Gabaizadeh¹, H. Staecker¹, B. Malgrange², P.P. Lefebvre^{1,2}, T.R. Van De Water^{1,2*}. ¹Albert Einstein College of Medicine, Bronx, N.Y. 10461; ²University of Liege, Liege, Belgium.

Vertigo and disequilibrium are common clinical problems that often share a common etiology of a loss of hair cells from the vestibular sensory receptors of the inner ear. We have developed a model for studying vestibular hair cell loss in vivo, which is a gentamicin-induced loss of utricular hair cells in the guinea pig. The inner ear is exposed to gentamicin by injecting a vestibulotoxic dose of this drug into the middle ear cavity. Delivery of growth factors to the inner ear is accomplished via direct infusion of a growth factor solution into the vestibular perilymphatic space over an 8 week period by an Alzet miniosmotic pump. Infusion of a combination of growth factors (i.e. transforming growth factor alpha, TGFα; insulin-like growth factor one, IGF-1; and retinoic acid, RA) over a period of 2 months significantly enhanced (i.e. a 3 fold increase) the renewal of the utricular hair cell population over that observed for either untreated or saline infused vestibulotoxin-exposed animals. Comparison of vestibulotoxin-exposed, untreated utricules to vestibulotoxin-exposed, growth factor treated utricles has shown that while there is some attempt at repair in the untreated utricles (i.e. a sparse population of renewing hair cells) in contrast the hair cell density in the growth factor treated utricles had returned to a near normal population density. These results suggest that growth factor therapy may one day be used in the treatment of inner ear disorders of balance

ESTABLISHMENT OF IMMORTALIZED UTRICULAR SUPPORTING CELL LINES USING A RETROVIRUS-MEDIATED GENE TRANSFER TECHNIQUE. W.-Q. Gao*, J. Valverde and J.L. Zheng. Dept. of Neuroscience, Genentech, Inc., South San Francisco, CA 94080.

Supporting cells in the inner ear sensory epithelium are most likely the progenitors for hair cells. To establish an in vitro model system of hair cell differentiation, we have transferred the tsA58 allele of the SV40 large T antigen oncogene into early postnatal utricular supporting cells using retrovirus. Utricular epithelial sheets containing supporting cells and pair cells were separated from early postnatal SV40 large I antigen oncogene into early postnatal utricular supporting cells using retrovirus. Utricular epithelial sheets containing supporting cells and hair cells were separated from early postnatal rats and plated on polylysine-coated culture dishes in serum supplemented medium. The cultured cells were transfected with a retrovirus containing temperature sensitive SV40 large T antigen. The transfected cells were subcloned and characterized with different markers. Immunocytochemical labeling confirmed that these cells were successfully transfected and expressed tight junction protein, an epithelial cell marker, but not fibroblast, glial or neuronal markers. The cell lines have been maintained for more than 9 months and grown for more than 20 passages. They exhibited similar features as those of the primary utricular supporting cells. For example, they grew in patches and assumed polygonal morphology. Although the immortalized cells grew rapidly in serum medium, their proliferation was limited when cultured in serum free medium. Several FGF family members, EGF and TGF-α promoted the proliferation of these immortalized cells cultured in serum free medium. Preliminary immunocytochemical labeling revealed that the immortalized cells have the capacity to differentiate and express hair cell markers. Therefore, the established utricular supporting cell lines could potentially provide an invaluable system for studying hair cell differentiation and regeneration.

DIFFERENTIAL LECTIN BINDING REVEALS A SUBPOPULATION OF SENSORY HAIR BUNDLES IN AVIAN VESTIBULAR ORGANS M.E. Warchol* Dept. of Otolaryngology-HNS, University of Virginia, Charlottesville VA 22908. Dept. of Otolaryngoogy-flav, Christisty of Ynginia, Charlottestiff VA 22500. Lectin binding studies have identified subclasses of sensory hair cells as a result of differing glycosylation of ciliary bundles. For example, peanut agglutinin (PNA) selectively labels the ciliary bundles of type II hair cells in the vestibular organs of chicks [R. Goodyear and G. Richardson, J. Comp. Neurol. 345: 267 (1994)]. Here I report that lectin from Griffonia simplicifolia -Isoform B4 (GS-IB4) labels subpopulation of hair cells in the chick utricle, but does not label hair cells in the mature cochlea.

Utricles and cochleae from post-hatch chicks (P10-P20) and utricles from E12 chick embryos were fixed and processed for lectin-binding histochemistry. Video microscopy was used to quantify labeled ciliary bundles in whole mounts and in plastic sections. PNA- and GS-IB4-labeled cells were counted in selected 10,000 μm² regions of sensory

PNA- and GS-IB4-labeled cells were counted in selected 10,000 μm² regions of sensory epithelia. Quantitative results were obtained from the extrastriolar region (cotillus) of utricles, which lacks type I hair cells [J.M. Jørgensen, J. Morphol., 201: 187 (1989)]. PNA labeled nearly every citia bundle in the cotillus of mature utricles, with density of 172.1±6.2 PNA+ bundles/10,000 μm² (mean±sem, n=40). In contrast, GS-IB4 labeled only a fraction of ciliary bundles in the cotillus (15.2±1.3/10,000 μm², n=50). When viewed in whole mounts, GS-IB4+ ciliary bundles appeared smaller than the PNA-labeled bundles. The density of GS-IB4+ hair cells was higher in embryonic specimens. Utricles from E12 embryos contained 88.7±5.0 GS-IB4+ cells/10.000 µm² (n=32). No GS-IB4 * hair cells were observed in mature cochleae (n=10 cochleae).

Avian vestibular organs continually produce hair cells during post-embryonic life

The observation that GS-IB4+ ciliary bundles are smaller and less numerous than PNA+ bundles, in combination with the high level of GS-IB4 labeling that was observed in embryonic utricles, suggests that GS-IB4 might selectively label the bundles of immature hair cells

LOCALIZATION OF GAMMA-GLUTAMYL TRANSPEPTIDASE IN THE CHICK INNER EAR SENSORY EPITHELIA. <u>I. Kil*</u>, <u>M.H. Hanigan²</u>, <u>P.T. Taylor Jr.³ and G.T. Hashisaki¹</u>. Depts. of Otolaryngology-HNS¹, Cell Biology², and Obstetrics and Gynecology³, UVa Med School, Charlottesville, VA 27908.

Gamma-glutamyl transpeptidase (GGT) is a surface bound enzyme that cleaves gamma-glutamyl bonds such as those occuring in glutathione and glutathione bound conjugates. When GGT activity is irreversibly inhibited with activicin, a glutamine analog, the destruction of renal proximal tubule cells normally induced by cisplatin treatment is prevented (Hanigan et al., 1994, Cancer Res, 54:5925-5929). Given the similarities in aminoglycoside and cisplatin ototoxicity and nephrotoxicity, we have examined whether GGT is also present in the inner ear sensory epithelia using an affinity purified polyclonal antibody against human GGT (APS.1).

Inner ear sensory organs were dissected from three week-old White leghorn chicks and fixed in 4% paraformaldehyde. J M PBS for periods of one hr. Tissues were placed in 90% MeOH/0.3% H₂O₂ for 15 mins (x2), incubated in a series of aviden and biotin blocking solutions for 15 mins, followed by a 1.5% goat serum solution for 10 mins. A 1:1000 dilution of primary antibody was added to the tissues for 45 mins at room temperature. Tissues were incubated with a biotinylated secondary antibody for 10 mins at room temperature followed by an aviden binding complex solution for 10 mins. Specimens were stained in diaminobenzidine/H₂O₂ for 3 mins. Under light microscopy, GGT immunoreactivities were observed along the cellular membranes of cochlear and vestibular hair cells. Greater concentrations of label appeared along the luminal surface of these cells as compared with the basolateral membrane. Control inner ear sensory epithelia and kidney sections were devoid of label. Results demonstrate that AP5.1 can be employed to label cells within the chick inner ear sensory epithelia and kidney.

DISTORTION-PRODUCT OTOACOUSTIC EMISSION AMPLITUDE CHANGES IN THE AGING C57 MOUSE. A.M. Jimenez^{†‡}, B.B. Stagner[‡], G.K. Martin^{†‡}, and B.L. Lonsbury-Martin*^{†‡}, [†]Neuroscience Program, [‡]Univ. of Miami Ear Inst., Miami, FL 33101.

Mutant strains of mice have proven to be very helpful in elucidating normal and abnormal mechanisms of hearing. Based upon the time course of hair-cell degeneration, the C57 (C57BL/6J) inbred mouse has been proposed as a model of early-onset presbycusis. In order to better understand and characterize this animal model, the basic features of distortion-product otoacoustic emissions (DPOAES), at 2f₁-f₂, 2f₂-f₁, and 3f₁-2f₂, were studied at 3,7,8,9,10,11, and 12 months of age. DPOAE level as a function of geometric-mean (GM) frequency from 4-16 kHz (DP-grams) were obtained at three stimulus levels (L1=L2=55,65,75 dB SPL). Additionally, growth of DPOAE level [input/output (I/O) functions] at a constant GM frequency (5.6,8.0,11.3,16 kHz), as a function of systematic 5-dB increases in primary-tone level, from 25-85 dB SPL, were also obtained, along with DPOAE level at a fixed f₂ frequency (f₂-8,11.3,16 kHz), as a function of primary-tone ratio (f₂/f₁-1-1.5). The major finding was that DPOAE amplitude for DP-grams, I/O functions and ratio functions systematically decreased with increasing age, for frequencies >8 kHz. These data support the notion that the C57 mouse shows gradual and systematic degeneration of cochlear outer hair cells with age. THE AUDITORY RECEPTOR OF THE EPILEPTIC HAMSTER STRAIN GPG/VALL. R. Cantos (1), R. Riquelme* (2), N. García-Atares (3), M.L. Sala (1), M.D. López (2) and J. Rueda (1). (1) Dtp. Histol., Fac. Medicina., Instituto de Neurociencias, Univ. Alicante; (2) Dpto. Biol. Cel. y Patol., Fac. Medicina., Univ. Salamanca; (3) Dpto. Anat. Fac. Medicina. Univ. Valladolid. SPAIN.

Salamanca; (3) Dpto. Anat. Fac. Medicina. Univ. Valladolid. SPAIN.

In the present work, basic morphological techniques have been used to study the auditory receptor of the hamster strain GPG/Vall, which shows genetic audiogenic scizures. Nothing is known about the auditory structures altered in such animals. The present results dealt with the description of the peripheral end of the auditory pathway, as a first attempt to characterize its changes in the mentioned animals.

In six hamsters (<u>Mesocricetus auratus</u>) of the GPG/Vall strain, the cochleae were removed, fixed with a mixture of alhehydes and embedded either in glycolmetacrilate or Epon. The cochleae of three other animals were studied by means of SEM. Hamsters of the same species were used as controls.

The overal morphology of the cochlea was not modified in the epileptic hamster. However, a number of changes were observed in both the organ of Corti and the spiral ganglion. The sensory epithelium appeared flattened in its lateral portion, where the outer hair cells disappeared except, occasionally, in the basal coil. The supporting cells of this area also showed an abnormal morphology. Inner hair cells were present along the cochlea, except in the very apex. The tectorial membrane appeared slightly swollen, and vacuoles were observed in the interdental cells, suggesting changes in the molecular composition of the membrane or in its hydration status. The spiral ganglion had a lower density of neurons than in normal animals.

These data suggest that, in absence of the outer hair cells, the auditory pathway could be overstimulated, participating in the genesis of the seizures.

SELECTIVE INNER HAIR CELL LESIONS REDUCE THE SPONTANEOUS AND DRIVEN DISCHARGE RATE OF CHINCHILLA AUDITORY NERVE FIBERS. R.J. Salvi*, J. Wang. D. Ding and N. L. Powers. Hearing Research Lab, SUNY University at Buffalo, Buffalo, NY 14214.

Current theories assume that outer hair cells (OHCs) provide the inner ear with its exquisite sensitivity, sharp tuning and several of its nonlinear responses whereas inner hair cells (IHCs) are mainly responsible for transmitting this information to the central nervous system through the auditory nerve. To further evaluate this model, we selectively destroyed 25-35% of IHCs in the chinchilla using the antineoplastic agent, Carboplatin (50 mg/kg). Surviving OHCs were functionally intact as evidenced by normal distortion product otoacoustic emissions and cochlear microphonic potential. Auditory nerve fibers that synapse on surviving IHCs had low thresholds, sharp tuning, and two-tone suppression equivalent to those from normal controls. These results are consistent with current theories. However, the spontaneous discharge rate and maximum discharge rate to tones were reduced significantly. These deficits are presumably due to subtle pathologies in the surviving IHCs or their afferent synapses.

GDNF PROTECTS BOTH COCHLEAR HAIR CELLS AND AUDITORY NEURONS AGAINST OTOTOXINS.

F. Collins and J-C Louis. Department of Neuroscience, Amgen Inc., Thousand Oaks, CA 91320

Sensorineural hearing loss results from the degeneration of hair cells and/or auditory neurons (spiral ganglion neurons) in the cochlea of the inner ear. Aminoglycoside antibiotics, such as neomycin (Lemer et al, N. Engl. J. Med. 302: 1106-1109, 1980), and anti-neoplastic drugs, such as cisplatin (Strauss et al., Laryngoscope, 143: 1263-1265, 1983), are known ototoxins, that cause damage to hair cells and auditory neurons in humans and animals. We tested the effects of GDNF on the survival of cochlear hair cells and auditory neurons exposed to ototoxic treatments. Explants of P3-P4 rat cochleas were cultured floating in medium. Under control conditions, there was no significant decline in the number of hair cells after 4 days in vitro. Treatment with ototoxins for three days, starting 24 hours after plating, caused marked hair cell death: only 21.2 ± 6.0% hair cells survived the exposure to 35 µg/ml cisplatin and 7.4 ± 4.7% were found after neomycin (0.6 mM) treatment. GDNF (1-10 ng/ml), administered together with the ototoxins, increased the number of hair cells surviving cisplatin and neomycin toxicity to 46.7% and 37.4%, respectively. In dissociated cultures of 4-week-old rat cochleas, the number of auditory neurons declined to reach 48.5 ± 4.5% of their initial number after 4 days in culture. GDNF (1-10 ng/ml) increased the number of surviving neurons to 71.6 ± 7.4%. After exposure to cisplatin (5 µg/ml given 24 hr after seeding), only 6.1 ± 1.2% auditory neurons survived after 4 days. However, when GDNF (10 ng/ml) was given together with cisplatin, the number of surviving auditory neurons increased to 32.8 ± 1.0% of their initial number. These data demonstrate the protective effects of GDNF for both hair cells and spiral ganglion neurons and suggest that GDNF may be useful for treating sensorineural hearing loss. (supp: AMGEN)

DIFFERENTIAL DISPLAY IDENTIFIES UPREGULATION OF A MITOCHONDRIAL GENE DURING HAIR CELL REGENERATION IN THE CHICK AUDITORY SYSTEM. C. Helbig*, J.L. Zheng, A. Goddard and W.-Q. Gao . Dept. of Neurosci. and Molecular Biology, Genentech, Inc., South San Francisco, CA 94080.

Although it is well established that hair cells can regenerate successfully in chicks, the molecular biological mechanisms for this regeneration remain unknown. In the present study, we have employed the differential display technique in order to identify genes involved in or triggering hair cell regeneration in chicks following aminoglycoside treatment. Differential display is a rapid method to

identify differentially expressed genes with small amounts of tissue. Hair cell death was induced by daily injection of gentamicin (50 mg/kg, i. m.) into 3 days old white leghorn chicks for 9 days. Animals were sacrificed and the cochlear sensory papillae were dissected. Total RNA was extracted and differential display was performed using a primer kit from Display Systems. Of the one hundred and three upregulated bands identified, 35 bands were reamplified, cloned and sequenced. To confirm their upregulation, we employed RT-PCR and slotblot hybridization. Using RT-PCR and GAPDH as an internal control, the mitochondrial gene NADHubiquinone oxidoreductase was upregulated in the cochlea collected from gentamicine-treated chicks. Similar results were obtained using slotblot hybridization. These results suggest that mitochondrial activity is enhanced during the regeneration of hair cells and imply that agents promoting mitochondrial activity may facilitate hair cell repair and regeneration.

DIFFERENTIATION AND THE EXPRESSION OF S-100 IMMUNOREACTIVITY IN SENSORY HAIR CELLS OF THE VERTEBRATE EAR. P.J. Lanford, J.C. Presson and A.N. Popper.* Univ. of MD, College Park, MD 20742.

We are investigating the differentiation of sensory hair cells in the ear of the goldfish, Carassius auratus. In the goldfish saccule, hair cells in the rostral end of the epithelium stain positively with the antibody against S-100, a calcium binding protein (Saidel, et al. <u>Br. Behav. Evol.</u> 46: 362-370). It has been suggested that calcium binding proteins like S-100 may act as a means of buffering intracellular calcium in hair cells. The timeframe at which new hair cells begin expressing S-100 antigenicity may thus be an important developmental "moment". In this study, immunohistochemistry and autoradiography were used to determine the timeframe after S-phase at which new hair cells express S-100 immunoreactivity. The status of hair cell morphology at this timeframe was then assessed.

Post-embryonic goldfish were injected with a single dose of ³H thymidine and allowed to survive 2, 3, 4, and 5 days post-injection. The saccules were dissected, fixed in paraformaldehyde and then processed as whole tissues for S-100 immunohistochemistry. The tissues were then embedded in epoxy resin, sectioned, mounted on glass slides, and dipped for autoradiography. After 10-14 days incubation time, the slides were developed and then assayed for the presence of double-labeled (S-100/3H thymidine) hair cells. The results show that new hair cells first stain positively for S-100 at four days post-injection with ³H thymidine. At the light level, the shape of these new cells is elongate, unlike surrounding mature hair cells which are more rounded or pear-shaped. However, apical structures such as the cuticular plate and a kinocilium are present in the new cells. We are currently using transmission electron microscopy to determine the status of ultrastructural development in these new cells and to elucidate the possible relationship between S-100 and hair cell function. 636.12

AUDITORY BRAINSTEM RESPONSE AS AN INDICATOR OF THE FUNCTIONAL CONSEQUENCES OF AMINOGLYCOSIDE OTOTOXICITY IN FISHES. <u>H.Y. Yan and T.N. Kenyon</u>. T.H. Morgan School of Biological Sciences, University of Kentucky, Lexington. KY 40506-0225.

The ototoxic effects of aminoglycoside antibiotics are a serious limitation to their effective use in fighting infection in humans. At least one species of fish, the oscar cichlid, Astronotus ocellatus, suffers similar ototoxic reactions (i.e., selective damage to striolar hair cells of the inner ear) to gentamicin (GE), making the oscar a possible candidate for a wide range of ototoxicity studies. An additional useful aspect of the fish auditory system is that unlike most mammalian examples, damaged hair cells in fishes are capable of at least morphological regeneration. However, no data exists documenting the functional consequences of observed ultrastructural effects in fishes. largely because GE-dosed fishes suffer severe side effects, particularly edema due to GE nephrotoxicity, making them unresponsive to behavioral paradigms. Hence, we have employed auditory brainstem response (ABR), a method previously underutilized in lower vertebrates but widely applied in similar studies with birds and mammals, as an indicator of functional changes associated with known ultrastructural changes.

ABR waveforms in the oscar were obtained via implanted electrodes in response to tone burst stimuli. Relative frequency-specific ABR thresholds followed behavioral thresholds closely in untreated animals. Waveform amplitude decreased, and auditory thresholds increased after four daily injections of 20 mg/kg gentamicin Ultrastructural evidence indicates loss of hair cell ciliary bundles in the striolar regions occurring 5-10 days post GE treatment, and subsequent regeneration of ciliary bundles occurring 10-20 days post treatment. ABR recordings indicate a decrease in waveform amplitude before visible signs of structural damage, with continued decreases through the tenth day post-treatment. These results also provide the first clear evidence of an important striolar contribution to auditory function in fishes.

AUDITORY SYSTEMS: CENTRAL PHYSIOLOGY-PRIMATE CORTEX

CORRELATION CODING IN A STOCHASTIC NETWORK MODEL OF AUDITORY BINDING. R. Ritz* and T. J. Sejnowski. The Salk Institute, Computational Neurobiology Laboratory, POB 85800, San Diego, CA 92186, USA.

DeCharms, Schreiner, and Merzenich (Soc. Neurosci. Abstr. 21:1177, 1995) have provided evidence for stimulus-dependent changes in the correlations between spike trains of simultaneously-recorded pairs of neurons from the auditory cortex of marmosets even when there was no change in the average fir-

Most of the characteristics of these experimental observations can be repro duced by a simple model based on neurons having leaky integration, fire-andreset spikes and with Poisson-distributed, balanced input. The source of synchrony in the model was common sensory input. Spike frequency adaptation was implemented by sensory-driven, delayed inhibition. The outputs of neurons in the model appear noisy (almost Poisson) owing to the stochastic nature of the input signal, but there is nevertheless a strong central peak in the corre lation of the output spike trains

The experimental data and this simple model clearly demonstrate how even a noisy-looking spike train can convey basic information about a sensory stim-

ulus in the relative spike timing between neurons.

We address the binding problem and show why synchrony without periodicity might be advantageous in representing multiple objects at the same cortical site simultaneously. However, this binding scheme depends on different cells receiving common input which may restrict it to limited populations of neurons. In this context we discuss lateral interactions between the cells as well as active processing in the dendritic trees.

SELECTIVITY FOR CLICK RATE IN A CENTRAL REGION OF MAR-MOSET PRIMARY AUDITORY CORTEX P. Bedenbaugh*, S. Cheung, C.E. Schreiner and M.M. Merzenich, Department of Otolaryngology and Keck Center for Integrative Neuroscience, Univ. of California at San Francisco,

We examined how the responses of cortical neurons to simple stimuli parametrically varied for frequency, intensity and modulation rate relate to their responses to natural vocalizations and other spectro-temporally complex stimuli. In the primary auditory cortex of the common marmoset (Callithrix jaccus) we mapped multi-unit responses to pure tones, entrainment to periodic click trains, and responses to marmoset vocalizations and other complex stimuli. Sharpness of tuning was measured by Q30dB. Tuning for click rate was assessed by vector strength, a normalized measure of phase locking of neural responses to click stimuli. Entrainment to the vocalizations and complex stimuli was assessed by R_s , the area in a 1/2 Hz wide bin centered at the stimulus envelope best repetition frequency (Wang et. al. J. Neurophysiol., 1995).

In one pentobarbitol anesthetized monkey (95 recording sites) we found a central region of A1 extending across the entire tonotopic axis where the vector strength was larger for click rates near 8 - 12 Hz than for slower or faster click rates. The responses in or near this click-rate tuned region were more likely to be non-monotonic with respect to intensity and had some tendency sharper tuning (higher Q30dB). In this region, adjacent penetrations found consistently high entrainment to vocalizations and other complex stimuli.

As in many species, responses of marmoset A1 neurons are tuned sound frequency, intensity and modulation rate. Our results suggest that there may be a map of temporal response properties on the medio-lateral axis,

orthogonal to the tonotopic axis.

HARMONIC COMPLEX TONES ELICIT RESPONSES DEFINED BY SPECTRAL COMPOSITION RATHER THAN PITCH IN PRIMARY AUDITORY CORTEX (A1) OF THE AWAKE MONKEY. Y. I. Fishman, D. H. Reser, S. Seto*, C. Arezzo and M. Steinschneider., Albert Einstein College Of Medicine, Bronx,

Neuromagnetic studies in humans and single-unit studies in monkeys have engendered conflicting views regarding the role of A1 in pitch encoding. While the former support the notion that A1 exhibits a topographic organization based on the pitch of complex tones, the latter have failed to provide evidence for the existence of pitch selective cells. In contrast, single-unit studies support the classical tonotopic organization of A1 defined by the spectral composition of the stimulus. It is unclear whether the incongruity of these findings is due to spatial resolution limitations of scalp recordings or whether the discrepancy genuinely reflects pitch representation based on population encoding, a dimension of analysis that eludes single-unit recording. To bridge the gap between these experimental approaches, we examined neuronal ensemble responses in A1 using auditory evoked potential, multiple unit activity, and current source density techniques.

Pure tones and harmonic complex tones missing the fundamental frequency (3rd, 4th, and 5th harmonics of 100, 250, 500, 1000, 1500, and 2000 Hz) were delivered at 60 dB SPL to the ear contralateral to the hemisphere from which recordings were obtained. Laminar response profiles in A1 reflected the spectral composition rather than the pitch (missing fundamental frequency) of the compound stimuli. Consistent with single-unit data, these findings indicate that cochleotopic organization is preserved at the level of A1. Thus, it appears that pitch encoding of complex sounds is more complicated than suggested by noninvasive studies based on the assumption is more comprisated than suggested by individuals classed in the assumption of a single dipole generator within the superior temporal gyrus that corresponds to the fundamental frequency. Supported by DC00657 and MH06723 and the Institute for the Study of Music and Neurologic Function of Beth Abraham Hospital.

RESPONSES TO COMPLEX SOUNDS IN THE LATERAL BELT AREAS OF AUDITORY CORTEX IN AWAKE RHESUS MONKEYS. B. Tian* and J. P. Rauschecker, Lab. Neuropsychology, NIMH, Bethesda, MD 20892 and Georgetown Institute for Cognitive and Computational Sciences, Washington, DC 20007

The posterior part of the superior temporal gyrus (STG) in anesthetized rhesus monkeys contains neurons that respond to various types of complex sounds, such as monkeys contains neurons that respond to various types of complex sounds, such as bandpassed noise (BPN) bursts, frequency modulated (FM) sweeps, and monkey calls. On the basis of BPN best center frequencies (BFc), three areas in this lateral belt region can be identified, which have been termed AL. ML, and CL. (Rauschecker et al., Science 268, 1995). We now examine the responses of neurons in these areas to complex sounds in awake restrained animals to eliminate any effects of anesthesia. The existence of three maps of BFc along the lateral fissure was confirmed in two awake monkeys with BPN bursts. The use of chronic recording techniques permitted more complete mapping in each animal. As in the anesthetized monkey, neurons in all three areas responded generally better to BPN and FM stimuli than to tone bursts (nct.) 0.5: mignet Lets.) Most neurons were tuned to specific center frequencies as well

(p<0.05; paired t-test). Most neurons were tuned to specific center frequencies as well as bandwidths. Best bandwidth (BBW) generally increased when the electrode was moved more laterally. Neurons in awake monkeys also were specific for the rate and direction of FM sweeps. The degree of specificity and the overall preference of neurons in the three areas did not differ from that in anesthetized animals. Neurons in AL preferred FM rates around 50 Hz/ms, whereas ML preferences were twice as high. Overall, 66% (46/70) of the neurons were FM-direction selective. When monkey vocalizations were used for stimulation, temporal and/or spectral combinationrectalizations were used to similaration, emporar animol spectra. Combination sensitivity was found in 7 out of 34 neurons. In 15 out of 32 neurons the response to the original vocalization was at least twice as good as the same vocalization played backwards, which indicates a fair amount of selectivity for monkey calls.

Thus far, the present results from awake monkeys fully confirm the findings from

isofluranc-anesthetized monkeys. The existence of neurons sensitive to specific combinations of call elements indicates that the lateral areas may be involved in the processing of communication sounds. Similar neural mechanisms in the posterior STG of the human brain may be used for the phonological decoding of speech.

COMPARATIVE ANALYSIS OF COMPLEX SOUND ENCODING IN AUDITORY CORTEX OF MONKEYS AND HUMANS. M Steinschneider*!, I_Volkov², D Reser¹, M Ollendieck², Y Fishman¹, H Damasio², J Arezzo¹ and M Howard, III². Albert Einstein College of Medicine¹, Bronx NY, 10461 and University of Iowa College of Medicine², Iowa City IA, 52242.

Caution must be exercised when using animal data to identify neural

mechanisms important for human speech and music perception. We tested the relevance of animal data by examining auditory evoked potentials (AEP intracortically recorded from a multicontact electrode implanted within the right auditory cortex of a human patient. We compared these responses with laminar profiles of AEPs, multiunit activity and current source density recorded from primary auditory cortex of awake monkeys. Stimuli were synthetic syllables that varied in their consonant place of articulation (POA) and voice onset time (VOT), click trains, and 2-note music intervals.

Similar response patterns were observed in both species. POA was reflected by larger initial "on" responses that varied with the tonotopic specificity of the recording sites. VOT was reflected by single "on" responses for voiced consonants, and "double on" responses for unvoiced consonants. Categorical-like behavior of the "double on" response was observed across a 20-40 msec boundary for both the syllables and the 2nd pulse of click trains. Repetitive stimuli elicited phase-locked activity at rates of 100 Hz. Dissonant music intervals elicited a low frequency "roughness" in the evoked responses that was diminished in the responses to consonant music intervals. Cross species similarities in early auditory cortical response patterns evoked by speech and music stimuli suggest that animal models are relevant for clarifying initial auditory cortical mechanisms involved in human complex sound processing. AMPLITUDE MODULATED TONES: EFFECTS OF CARRIER FREQUENCY ON PSYCHOPHYSICAL DISCRIMINATION AND RESPONSES OF PRIMARY AUDITORY CORTICAL NEURONS IN THE OWL MONKEY. R.E. Beitel*, C.E. Schreiner, X. Wang, S.W. Cheung, and M.M. Merzenich. Keck Center, UCSF San Francisco, CA 94143.

Several distinct calls in adult owl monkeys contain amplitude modulated phrases with energy concentrated in the spectral region below 3-kHz. We have investigated the ability of monkeys to discriminate changes in the cadence of amplitude modulated (AM), low frequency tones (AM=4 to 40-Hz; carrier=0.5 to 2.0-kHz) that simulated temporal and spectral features that occur naturally in their vocalizations. Stable threshold and suprathreshold performance was obtained with carriers of 0.5-kHz and 1.0-kHz, but the monkeys were unable to discriminate changes in cadence of a 2.0-kHz carrier. Following training, the 0.3-kHz to 3.0-kHz region of primary auditory cortex was mapped with metal microelectrodes in the anesthesized monkeys. Multiunit neuronal responses (number of spikes, vector strength, interspike intervals) were analyzed as functions of AM and carrier frequencies. Preliminary results indicate that: 1) the number of spikes at recording locations with best frequencies (BFs) between 1.7-kHz and 3.0-kHz was greater than the number of spikes for locations with BFs between 0.3-kHz to 1.2-kHz; 2) the proportion of interspike intervals (ISIs) that were grouped around the period of the AM envelope was smaller for locations with BFs between 1.7-kHz and 3.0-kHz; and 3) the signal to noise ratio (S/N=# periodic ISIs / # nonperiodic ISIs) was relatively low for locations with BFs between 1.7-kHz and 3.0-kHz. The results suggest that the proportion of periodic ISIs varied with carrier frequency and may have influenced the monkeys' ability to discriminate changes in the cadence of AM signals. DISCHARGE PATTERNS OF AUDITORY CORTICAL NEURONS EVOKED BY SPECIES-SPECIFIC VOCALIZATIONS AND SYNTHETIC COMPLEX STIMULI IN ALERT MACACA MULATTA. M.J. Tramo*, B.F. Bellew, & M.D. Hauser. Depts. of Neurobiology, Neurology, Psychology, and Anthropology, Harvard University, Cambridge, MA 02138

Lesions of auditory cortex in humans and non-human primates can

Lesions of auditory cortex in humans and non-human primates can profoundly impair the perception of vocal communication sounds with relatively subtle effects on elementary psychoacoustic functions. Neurons in monkey and cat auditory cortex often exhibit greater sensitivity, response magnitude, and/or response complexity over time when vocalizations and synthetic complex stimuli are presented than when steady-state pure tones are presented, especially in awake preparations. We are investigating the relationship between these neuronal response properties and the acoustical features of vocalizations along the depth of microelectrode penetrations into the dorsal surface of the posterior STG containing neurons with pure tone BFs below 2 kHz at 70-90 dB SPL. Our preliminary observations suggest that patterns of neuronal excitation and inhibition unfold over time in relation to the envelope of the acoustic waveform and the "instantaneous" spectral energy distribution of the vocalization. The temporal pattern of excitation and inhibition over tens to hundreds of milliseconds, rather than, or in addition to, the magnitude of excitation at one or more points in time, may be an important element in the neural code used to represent different vocalizations. Constancy of the temporal response pattern in the face of minor variations in spectral content may confer neuronal response invariance within a given vocalization class.

SIMULATIONS OF SELF-ORGANIZING FEATURE MAPS IN PRIMARY AUDITORY CORTEX. N.N. Ge, C.E. Schreiner, H.L. Read*, Coleman Laboratory, Keck Center for Integrative Neuroscience, UCSF, San Francisco, Ca 94143

Auditory cortical map has a functional and structural patchiness that is inherent to self-organized, topology-preserving projections. A cochleotopic representation is along one surface axis of primary auditory cortex (AI) and the bandwidths of single-neuron and multiple-neuron tuning curves are systematically arranged along the orthogonal axis. The intensity and the binaural coding were also indicated to be oriented orthogonally to isofrequency contours. Self-organizing feature maps suggest a process in which there is a decomposition of independently varying dimensions in the input space, which are mapped onto an output space. In this study we experimented with different simulation models using Kohonen associative learning rules to study the resulting feature maps. We used a 5 dimensional independently varying input space with the parameters uniformly distributed within a certain range to map to a plane, and the neighborhood size was defined as a function of the number of training epochs. When all inputs were randomly selected from within the same range and started at the same time, the resulting decomposed feature maps assumed randomly varying spatial features and relationships to each other. However, when we varied the dynamic range, delay of onset, and slope of rise or fall in the five input parameters in accordance with a few basic aspects of the maturation of auditory cortical response properties (J.J. Eggermont, ARO Vol. 19, p. 113, 1996) the resulting feature maps showed reproducible properties and interrelationships similar to those seen in physiological experiments. Our results suggest that the Kohonen learning rule can be used to capture the key characteristics of AI cortical feature maps, and specific features of the maps, such as, different degrees of patchiness, spatial frequency, and interrelationships, may be partially understood as consequences of early maturational processes.

ELECTRICAL STIMULATION OF HUMAN AUDITORY CORTEX. M.A. Howard I.O. Volkov M. Ollendieck H. Damasio P. Abbas B.Gantz³. ¹Div. of Neurosurgery, ²Dept. Neurology, ³Dept. Otolaryngology, University of Iowa School of Medicine, Iowa City IA 52242.

Useful insights concerning sensory cortex function may be gained by studying the effects of electrical stimulation in awake humans. In the current investigation, hybrid clinical-research depth electrodes (HDEs) were placed into the non-dominant (right) Heschel's gyrus of four epilepsy surgery patients (2 acute intraoperative, 2 chronic) as part of their clinical treatment plan. In addition to clinical EEG data, microelectrode recording and electrical stimulation data was gathered using the HDEs without placing patients at increased risk. A wide variety of electrical stimulation induced auditory perceptions were described. Most often patients "heard" these perceptions in the contralateral (left) ear. The quality of most percepts were similar to those described previously by Penfield and others (e.g. "propeller like", "whooshing", "sound of a fast jump rope"). In one patient, stimulation of lateral Heschel's gyrus resulted in prolonged suppression of hearing, or "muffling", that involved both hemifields and persisted beyond the duration of electrical stimulation. A new finding was noted in one patient whereby pure tone perceptions of differing frequency were consistently evoked from a small region of Heshel's gyrus. The critical experimental variables appear to be; the exact anatomical (MRI) and electrophysiologically defined location within Heschel's gyrus, stimulus waveform, frequency and polarity These findings demonstrate a highly complex organizational pattern within the human auditory cortex (supported by Carver Trust, Hoover Foundation, and DC00120)1

ABSENCE OF AUDITORY N1 IN CHILDREN. H.J. Gould1, D.F. Rose*2, R.E. Greenblatt³, AND M.A. Pousson¹, ¹Univ. Memphis and ²Univ. Tenn. Memphis TN 38105, and ³Source/Signal Imaging, San Diego CA 92102.

The N1 is a consistent feature of the auditory evoked response (AEP) in adults, occurring approximately 100 msec following stimulus onset. compared AEPs from 10 normal adults (ages 20-30) and 20 normal children (ages 5-12) and observed clear differences between adults and children in the 75-150 msec latency range.

880 hz 30 msec Blackman-windowed tone bursts were presented unilaterally (ISI randomly varying between 0.5 and 1 second), using insert headphones (Etymotic). The data were recorded continuously from 62 scalp electrodes (Electrocap) + 2 eye movement electrodes, digitized at 200 sec 1 (Neuroscan SynAmps) and filtered from DC to 40 hz. Data were averaged off-line following artifact rejection and baseline correction, and analyzed using source estimation (EMSE, Source/Signal Imaging).

All adult Laplacian maps showed a prominent N1 maximal sink in the midline frontocentral scalp region with a latency of 100-115 msec, corresponding to a voltage negativity, when appropriately referenced. In contrast, the children's Laplacian maps show a prominent frontal source in the latency range 95-120 msec, corresponding to a voltage positivity. The estimated generator for this peak has a contralateral temporal location similar to the adult, but the children's principal generator orientation is opposite that of the adult. After 175 msec a frontal negativity in children was inconsistently present and differed in distribution from the adult N1.

The absence of auditory N1 in children under these stimulus conditions and its consistent presence among adults may be a useful marker of cortical This work was funded in part by an NIMH grant to REG and a Herbert and Mary Shainberg Neuroscience Program grant to DFR and HJG.

FREQUENCY AND LOCATION GROUPING EFFECTS IN PERCEPTION OF TONE SEQUENCES, K. N. O'Connor* and M. L. Sutter. Center for Neuroscience, University of California, Davis CA 95616.

ence, University of California, Davis CA 95616.

The capacity of the auditory system to resolve distinct events comprising an acoustic stream is limited by the stream's spectral and temporal structure. Studies of this ability have typically required observer identification of order or pattern in rapidly cycling sound sequences (auditory streaming). We have used a variant of this technique to quantitatively examine human detection for reversal in order of two repeated target tones as a function of 1) varying one tone's frequency, 2) the presence or absence of a repeating background tone, and 3) the spatial separation between target and background. The background and constant target tone were 1 and 1.03 kHz, respectively; the other target tone varied between 1.045 and 8.50 kHz over trials. Tones were 50 ms in duration (5-ms rise/fall), presented in the free-field at 48 +/- 2 dB, at 50-ms intervals.

Performance in the absence of the background tone was nearly errorless at all but the smallest target frequency difference (Δf). In the presence of the background, reversal detection was described by an inverted U-shaped function that approached symmetry when plotted against log Δf . Specifically, performance: 1) was close to chance levels at the smallest Δf value (15 Hz), 2) rose rapidly with increasing Δf , reaching a maximum of about 90% correct in most subjects at about 100 Hz (range $\sim 50-250$ Hz), and 3) declined slowly with further increases in Δf , reaching a minimum again close to chance at $\Delta f = \sim 4-8$ kHz. Preliminary results indicate that reversal detection was improved by spatially separating the location of the target and background. and background.

These results are consistent with the views that 1) detection of change in the temporal organization of an acoustic stream follows known principles of auditory segregation and grouping, and 2) that free-field source location may play an important role in segregating distinct elements within a stream.

TWO-DIMENSIONAL SOUND LOCALIZATION OF BROAD-BAND AND BAND-PASSED NOISE IN NORMAL HUMAN SUBJECTS. D.C. GUARD, M. L. PHAN, & G.H. RECANZONE* Center for Neuroscience, Dept. of Neurobiol., Physiol., and Behav., and Neurosci. Grad. Group. U. C. Davis, Davis, CA 95616.

Previous studies have shown that humans are fairly accurate in absolute localiza-

tion of broadband noise stimuli (Makous and Middlebrooks, JASA 87:2188-2200, 1990). We have extended these studies to include 1-octave hand passed stimuli with different center frequencies in order to determine the relative contributions of different

requency components to absolute sound localization ability.

All experiments were conducted on normal hearing subjects (aged 21-26 yrs.) in a darkened sound booth with echo-attenuating foam. Subjects were required to orient their heads within 2 deg of directly forward (0,0) to initiate a trial. Head position was measured using a magnetic search coil. A 200 msec (5 msec rise/fall; 60 +/- 3 dB SPL) free-field acoustic stimulus was presented from one of 125 possible locations (4)- 30 deg in azimuth and elevation), and the subjects was asked to orient their heads directly toward the perceived location of the sound. Stimuli consisted of broadband noise, low frequency (750-1500 Hz), mid-frequency (3-16 kHz) and high frequency (5-10 kHz) noise. Localization accuracy was measured as the difference between the real location and the mean final head position. Localization precision was measured as the vector strength calculated by defining a vector with the base at (0.0) and the tip at the final head position for each trial.

Accuracy was similar for broadband and high pass noise stimuli. Mid-range noise

accuracy was moderate and low-pass noise localization was least accurate. Precision was also best for broadband noise and high-pass noise. Mid-range noise showed the lowest precision, with low-pass noise only slightly better.

These data indicate that the highest frequencies (5-10 kHz) provide the most salient

cues for absolute localization in both azimuth and elevation, and that these frequencies can account for much of the accuracy and precision of sound localization to broadband noise stimuli. Funded by PHS DC-02371 and the Alfred P. Sloan Foundation.

TEMPORAL ORDER JUDGMENTS AND RELATIVE SOUND LOCALIZATION ABILITY IN NORMAL HUMAN SUBJECTS. M.L. PHAN*, P.G. GEIGER, D.C.

GUARD, AND G.H. RECANZONE Center for Neuroscience, Neuroscience Graduate Group, Dept. of Neurobiol., Physiol., & Behav., U. C. Davis, Davis, CA 95616. The functional role of the auditory system is similar to that of the visual system, namely to determine the spatial location and to resolve the characteristics of the stimulus. To characterize the relationship between these two abilities, normal hearing subjects (21-26 yr.) were asked to detect either a change in location ("where") or temporal order ("what") of tone-pip sequences on randomly interleaved trials.

All experiments were conducted in a darkened sound booth lined with echo-attenuating foam. Stimuli were four tone-pip sequences presented in the free field every 600 msec (56 +/- 3.5 dB SPL). Each stimulus was identical for 3-8 presentations before either changing location or temporal order. Pip duration and inter-pip interval was held at a constant ratio of 3:5 for each four-pip sequence, but the pip duration varied randomly from 15 to 45 msec within a trial. For the temporal order task, subjects had to detect a change in the order of the frequency of the four tone pips from a comparison sequence (standard-high-low-standard) to a target sequence (standard-low-high-standard) using 1, 2 and 4 kHz as standard frequencies. For the localization task, these same stimuli were presented initially at 32 degrees to the right and then moved to one of 5 other locations toward the midline. On 1/2 of the trials, the subjects received a cue to indicate whether the stimulus would change in location or temporal order; on the other 1/2 of the trials, the subjects did not receive a cue. Sound localization performance for all subjects was dependent only on the standard

requency. Temporal order performance was dependent on pip duration, pip number, and the difference in frequency between the pips. Performance when only the middle two pips were presented was better than when four tone pips were presented. There was no significant effect of directed (cued) or divided (non cued) attention on either task. These results suggest that human subjects are able to process both types of information independently, indicating that independent neuronal mechanisms may underlie these perceptual abilities. NEURONAL PROCESSING OF PERIODICITY PITCH MAY EXPLAIN THE DIFFERENCE BETWEEN 'RELATIVE' AND 'ABSOLUTE' PITCH PERCEPTION
G. Langner and Stefan Bleeck. Zoological Institute of THD, 64287 Darmstadt, Germany

Acoustic signals with the same periodicity have the same pitch, nearly independent of waveform or spectral content. While only few people with 'perfect' or 'absolute' pitch are able to determine without effort the pitch of harmonic sounds according to musical nota-tion, most people have relative pitch- the ability to identify or even name tonal intervals. A theory based on mechanisms of temporal periodicity analysis in the auditory midbrain (Langner, Hearing Res.60, 1992), provides an explanation for these complementary percepts, and is supported by new psychophysical experiments. The model makes use of a temporal representation of frequencies of fundamentals and their harmonics and includes internal reference periods provided by intrinsic neuronal oscillations. Due to their oscilla-tory and integrative properties, neurons in the cochlear nucleus produce synchronized and delayed responses to periodic envelopes which coincide on neurons in the auditory midbrain. The model may explain the percept of the missing fundamental and the pitch shifts elicited by anharmonic amplitude modulations. For relative pitch neuronal processing may be described in the following way. An integrating circuit which generates spike intervals multiple to the period of a harmonic is triggered by each envelope cycle. Provided the signal periods match, the resulting spikes coincide with spikes from the intrinsic oscillator which are triggered one envelope period later. The corresponding coincidence neuron thus may indicate which harmonic relates to a certain fundamental frequency ('binding'). However, the coincidence relation is ambiguous (many-valued). because it may be fulfilled by a number of (harmonically related) fundamentals. These ambiguities in temporal processing are necessary for relative pitch perception. In the case of absolute pitch intrinsic oscillations provide a reference for the measurement of signal periodicities. Oscillations synchronized 1:1 to fundamentals are compared by coincidence periodicities Oscinations synicinomized 1.1 of indinationals are compared by Souries-detection to appropriate multiples of the periods of harmonics. Since the tuning of intrin-sic oscillations removes the ambiguity and prevents a response to more than one funda-mental, this mechanism is inappropriate for the detection of harmonic relationships and may account for difficulties of subjects with absolute pitch in relative pitch tasks.

AUDITORY EVOKED POTENTIALS IN IDENTICAL QUADRUPLETS, S. A. Curtis and L. J. Achor*. Dept. of Psychology and Neuroscience, Baylor Univ., Waco, TX 76798-7334 Auditory evoked potentials were recorded in identical 19-year-

old female quadruplets to assess consistency in evoked potentials. Brief tones were presented through headphones at 1/second for fifty trials. Recordings were obtained from the vertex using linked mastoids as reference. The EEG was amplified and filtered with a Grass P-15 amplifier. A signal averager sample the EEG (one msec dwell time) with a 36 msec pre-stimulus period and a 476 msec post-stimulus period. The averaged data was downloaded to a microcomputer for baseline adjustment and off-line analysis.

Morphology of the waveforms from the four subjects was very similar with distinct positive peaks at about 60 msec (P1) and 150 msec (P2) post-stimulus. Less distinct negative peaks were evident at approximately 80 msec (N1) and 215 msec (N2). Amplitude varied substantially between the four individuals. Latencies for N1 and N2 were difficult to determine as the peaks were broad and irregular. Latencies for P1 and P2 could be determined more readily as the peaks were sharply defined. Across the four subjects P1 and P2 varied within a very small range (59-62 msec for P1 and 147-150 msec for P2).

The small range of latency values for P1 and P2 are suggestive of a genetic basis for processing speed.

INTRACRANIAL EVOKED POTENTIAL AND SINGLE UNIT RESPONSES TO AUDITORY STIMULATION RECORDED IN HESCHL'S GYRUS. <u>C.L.Wilson</u>* R.J. Staba K.A. McDonald, I.Fried, Brain Research Institute, Depts. of Neurology, Psychiatry and Div. of Neurosurgery. UCLA Center for Health Science. Los Angeles, CA 90024.

Angeles, CA 90024.

Studies of primary auditory cortex in lower primates show a tonotopic organization in which of high and low frequencies occupy spatially distinct areas (Merzenich and Brugge, Brain Res.1973,50:275-296). In humans, the primary auditory cortex (area 41) occupies the middle part of the anterior transverse gyrus and a portion of the posterior transverse gyrus, but there is little direct evidence

concerning its receptive properties.

A patient with intractable partial complex seizures underwent bilateral depth electrode implantation in six areas of the temporal and frontal lobes in order to electrographically localize the origin of his seizure onsets. Because transient loss of electrographically localize the origin of his seizure onsets. Because transient loss of hearing was sometimes associated with his seizures, electrodes were placed in right and left transverse gyrus. Electrode contacts were spaced at 6mm intervals spanning the mediolateral extent of the superior temporal gyrus. Nine platinum microwires (40µm diam) extended a few mm beyond the tip of each electrode. Clicks and tone bursts (90 dB) were delivered at rates from 14.3 to 1.1 Hz and 10 to 20 msec tone bursts were tested at 10 frequencies, ranging from 250Hz to 8kHz.

Evoked responses were most prominent in the gyrus contrateral to the ear stimulated, and in the more medial contacts of the electrodes. Onset latencies ranged from 16 to 22 ms, with a major negative peak at 60 msec. Of 6 microelectrodes in right transverse gyrus, 3 recorded cells response to auditory stimuli. Differential response to bilateral vs unilateral stimulation, frequency specificity of deep vs

response to bilateral vs unilateral stimulation, frequency specificity of deep vs shallow electrode placements and properties of cells responsive to auditory stimulation will be presented. Supported by NIH grant NS02808

BINAURAL SOUND LOCALIZATION AND HEMISPHERECTOMIZED PATIENTS. N. Lessard*1, F. Leporé1, P. Poirier2, J. Villemagne 1 and M. Lassonde 1. 1. Groupe de Recherche en Neuropsychologie Expérimentale, Univ. de Montréal, Canada, H3C 3J7. 2. Dept. of physiology, Kansas Univ. Med. Ctr., Kansas City, KS, 66160.

The present study was carried out to evaluate how subjects having unilateral cortical damage localize sound in three dimensional space. Response accuracy to monaurally and binaurally presented auditory targets on the horizontal plane was thus examined in hemispherectomized subjects (Hs). It is possible with these subjects to evaluate not only their ability to use binaural cues with their residual auditory cortical structures but also to compare the relative contribution of the ipsilateral and controlateral pathways to localization performance. The latter aim was examined using monaural stimulation. Three Hs and ten control (Cs) subjects were asked to localize broad band noise bursts (BBNBs) of fixed intensity presented on the horizontal plane in an anechoic chamber. BBNBs were delivered randomly through 16 loudspeakers, which were mounted at 10° intervals on a calibrated perimeter frame. Two conditions were tested: i) localization of a fixed-sound; ii) localization of rrame. Two conditions were tested. I) localization of a fave-soulid, in localization to the beginning and the end of a simulated moving sound. Listeners had to report the apparent stimulus location by pointing with the index finger its perceived position. Results indicated that Hs were as accurate as the Cs in binaural localization, indicating that one hemisphere and/or subcortical structures are sufficient to analyze the binaural cues to localization. Under monaural testing conditions, Hs performed as well as Cs when using the ipsilaterally projecting pathway but responded significantly better than Cs when using the controlateral pathway. This suggests not significantly offer than Cs when using the controlled a partway. The suggests only that the ipsilateral pathway is quite adequate by itself to use the spectral information to localization sound but also that Hs learn to better utilize this information projecting to the normal cortex via the contralateral pathway, possibly to compensate for the lack of the supplemental contribution to localization which would normally be assured by the absent hemisphere.

INDEPENDENT COMPONENT ANALYSIS APPLIED TO AUDITORY EVOKED GAMMA BAND AND 40 HZ STEADY STATE FIELDS. K. H. Kresge Hearing Research Lab. Louisiana State Knuth*. University Medical Center, New Orleans, LA, 70112, B. J. MEG Laboratory, Scripps Research Institute, La Schwartz. Jolla, CA 92037.

The magnetic fields from auditory click evoked gamma band responses (AEGBRs) and 40 Hz auditory evoked steady state responses (SSRs) driven by a 40 Hz click train were examined using a 37-channel biomagnetometer. Our past work has suggested that the AEGBRs are generated by two independent sources and that the SSR is mostly likely generated by a nonlinear superposition of the transient AEGBRs evoked by the individual clicks in the click train. In this study we use independent component analysis (ICA) to separate the independent sources responsible for the responses. The results from the ICA are compared to the results obtained from the equivalent current dipole fits to obtain a better understanding of the behavior of the generators of these responses.

PHYSIOLOGICAL CORRELATES OF BINAURAL CLICK TRAIN FREQUENCY ILLUSIONS IN MACAQUE AUDITORY CORTEX. DH Reser*, YI Fishman, JC Arezzo, and M Steinschneider Albert Einstein College of Medicine, Bronx, NY 10461

Psychophysical investigations of interaural switching time (IST) in humans have shown that at frequencies greater than 10 Hz, subjects consistently underestimate click rate by 35-50% when component clicks alternate between subjects' ears vs presentation to one ear alone. This limit on system performance may affect auditory streaming, particularly the sequential integration of stream components. Streaming seems to be critically important for processing time variant stimuli (e.g. speech and music), however, the underlying physiological processes are not known. Using a multichannel intracortical electrode in awake macaques, we recorded auditory evoked potentials, multiunit activity, and derived current source density, in response to 500 msec click trains presented at 60 dB SPL. Stimuli ranged in frequency from 5 to 1000 Hz, and were separated by 500 msec.

Phase locked activity (PLA) in response to single ear, binaural, and alternating presentations accurately reflected the stimulus frequency below 10 Hz. Above 10 Hz, PLA in binaural and single ear conditions matched the click rate, while PLA in response to alternating clicks was approximately 1/2 of the stimulus frequency. This effect was confirmed by Fourier analysis of digitized waveforms

These results indicate that the upper frequency limit for accurate encoding of laterally alternating click trains in monkey auditory cortex is on the order of 10 Hz, which is in agreement with human behavioral data. This frequency limit may be important for assigning individual sounds to perceptual streams and for auditory encoding of stimulus movement. The ability to model these parameters in nonhuman primates will allow physiological investigation into the role of binaural interaction in extracting individual sound sources from complex auditory environments. INTERHEMISPHERIC BINDING OF ACTIVITY IN THE AUDITORY CORTICES A.A. Ioannides^{1,2,*}, L.C. Liu¹, J. Gross¹, J. Dammers¹, H.-W. Müller-Gärtner¹, Institute of Medicine, Research Centre Jülich, D-52425 Jülich, Germany¹; Physics Department, The Open University, Milton Keynes MK7 6AA, U.K².

The present study examines how cell assemblies of the bilateral auditory cortices in humans interact during sound perception. A 1KHz, 50 ms iong tone was presented, in separate runs, to the left, right or both ears of 5 male, right handed subjects. The magnetic field was recorded over the left and right temporal areas using the twin (2x37 channel) MAGNES probe of BTi. Estimates of the electrical activity in the superficial areas of each auditory cortex were computed insec by msec, for a one second period beginning 200 msec before the onset of the tone. A separate estimate was computed for each one of the 120 tone presentations in each separate estimate was complied to each one of the 120 to be presentations in dead condition. During the prestimulus interval no temporal correlation was evident between the activity peaks in the left and right auditory cortex. The arrival of the stimulus established a temporal correlation, which we have quantified in terms of the delay time between peaks of activity in the left and right auditory cortices. For each condition an exponential form factor with a characteristic decay time, τ , described the distribution of trials at different interhemispheric delay times. Similar but not identical values for τ were appropriate during different poststimulus periods. The mean and standard deviation of τ across the five subjects during the dominant M100 period was 16 \pm 7 (mean \pm SD), 16 \pm 4, and 23 \pm 18 msec for binaural, left and right ear delivery respectively, when the left auditory cortex led, and 19±6, 23±12 and 16±3 msec when the right auditory cortex led. The data show that the activity evoked by an external stimulus establishes a co-activation of distant, and in our case homologous areas, with a characteristic binding time of a few tens of msecs.

RELATIVE CONTRIBUTIONS OF THE C1 AND C3 ZONES OF THE CEREBELLAR CORTEX TO EYEBLINK CONDITIONING IN THE FERRET M. Ivarsson*, G. Hesslow and P. Svensson. Dept. of Physiology and Neuroscience, Lund University, Sölvegatan 19, S-223 62 Lund, Sweden.

The aim of the experiments was to study the contribution of different cerebellar cortical areas controlling eyeblink to the generation of a conditioned eyeblink response. Ferrets, decerebrated rostral to the superior colliculus and the red nucleus were trained in a classical conditioning paradigm. The conditioned stimulus (CS) was a train of electrical stimuli (15 pulses, 50 Hz, 1 mA) applied to the forelimb and the unconditioned stimulus (US) was a train of electrical stimuli (3 pulses, 50 Hz, 3-4 mA) to the periorbital region. The EMG was recorded from the orbicularis oculi muscle. The animal received CS-US trials (ITI 20-60s) until conditioned eyeblink responses (CRs) occurred on virtually every trial. Eyeblink related areas in the cerebellar cortex were localised by recording surface potentials on periorbital stimulation. A c3 area and a tentative c1 area were localised. A small lesion restricted to the c1 area abolished the CRs, while a much larger aspiration of the c3 area had no effect on the CRs. A filter paper (1x1 mm) soaked in lignocaine was placed on the different zones and the effect on the CRs was studied. Application of the filter paper on the cl zone had a marked effect on the CR. This was not observed when applying the filter paper on the c3 zone

In conclusion, the eyeblink related area in the c1 zone seems to be of greater relative importance than the c3 area in the generation of a conditioned eyeblink

CRITICAL ROLE OF MOSSY FIBRES IN TRANSMITTING CONDITIONED STIMULUS INFORMATION IN CLASSICAL EYEBLINK CONDITIONING IN DECEREBRATE FERRETS. G. Hesslow*, M. Ivarsson and P. Svensson. Dpt of Physiology and Neuroscience, Sölveg 19, S-223 62 Lund, Sweden

Several lines of evidence suggest that a major site of synaptic plasticity for classical eyeblink conditioning is located in the cerebellum. It has been suggested that the conditioned stimulus (CS) information is transmitted to the cerebellum via the mossy fibres whereas the unconditioned stimulus (US) activates climbing fibre afferents, causing plastic changes to occur in the cerebellar cortex and/or nuclei. We tested the first part of this hypothesis in ferrets which had been decerebrated rostral to the superior colliculus and red nucleus. The animals were trained with a 300 ms, 50 Hz cutaneous electrical train stimulation of the forelimb as the CS and and periorbital electrical stimulation as the US. When the animals had learned to respond reliably with an eyeblink conditioned response (CR) to the forelimb CS, this was replaced with direct 50 Hz train stimulation of mossy fibres in the middle cerebellar peduncle (brachium pontis). Such stimulation immediately, i.e. without any further training, evoked characteristic CRs. If the response to the forelimb CS was extinguished by unpaired CS presentations, the mossy fibre stimulus no longer evoked a CR. When unpaired presentations of the mossy fibre CS were given until CRs to this CS had extinguished, the forelimb CS also failed to evoke a CR. These observations suggest that the mossy fibre stimulation activates the CS pathway and that the conditioned stimulus is transmitted via the mossy fibres. The results thus provide strong support for a cerebellar mechanism of conditioning.

INFLUENCE OF THE CEREBELLUM ON THE COUGH MOTOR PATTERN. Fadi Xu, Donald T. Frazier, Zhong Zhang, and Roger Shannon* Dept. Physiology, Univ. Kentucky, Lexington, KY 45036, and Dept. Physiology, Col. Med., Univ. So. Florida, Tampa, FL 33612. The cerebellum modulates respiratory muscle activity, in part via influence on the central respiratory pattern generator (JAP 77:1232, 1994; Brain Res 705:53, 1995). Since coughing requires wellcoordinated respiratory muscle activity, studies were conducted to determine if the cerebellum influences the centrally generated cough motor pattern. Phrenic and lumbar efferent neurograms (PN and LN) were monitored in decerebrated, paralyzed and ventilated cats. Fictive coughing was produced by mechanical stimulation of the trachea. Decerebellation (n=5) resulted in a significant decrease in the cough frequency without any consistent change in PN and LN amplitudes. Areas within the cerebellum known to have respiratory involvement (the fastigial nucleus, FN; and the interposed nucleus, IN) were selectively ablated to determine their potential role in the cough response. The cough frequency and LN amplitude were not altered by ablation of the FN (n=7), but were significantly reduced by lesion of the IN (n=7). PN amplitude was not affected by either FN or IN The baseline cardio-respiratory variables were not markedly changed following FN or IN lesions or decerebellation. These results suggest that the interposed nucleus is a putative site involved in regulation of the coughing reflex. (HL 49813 and HL 40369)

638.2

EFFECT OF CONDITIONED STIMULUS (CS) FREQUENCY ON THE LATENCY OF THE CONDITIONED EYEBLINK RESPONSE USING FORELIMB AND MOSSY FIBRE STIMULATION AS CS

P. Svensson*, M. Ivarsson, G. Hesslow. Department of Physiology and Neuroscience, Lund University, Sölvegatan 19, S-223 62 Lund, Sweden

The conditioned eyeblink response has a latency to peak that coincides with the onset of the unconditioned stimulus (US). If the interval between the conditioned stimulus (CS) and the US is increased, the CR peak is delayed so that it tends to occur at the new US onset. This makes functional sense because it maximizes the protective effect of CR. The neuronal basis underlying this timing mechanism is unknown

The aim of the present study was to analyze the role of the cerebellum in the temporal delay of the CR. Decerebrate ferrets were classically conditioned with forelimb train stimulation as CS and periorbital stimulation as US. The CRs were recorded as EMG of the orbicularis oculi muscle. When the CRs appeared in each trial and the CR latency was stable, forelimb stimulation was replaced by stimulation of the brachium pontis (BP). This stimulation evoked true CRs. When the frequency of the BP stimulus train was increased (from 50 Hz to 100 Hz) both the CR onset- and peak-latencies were immediately decreased. When the CS frequency was reset, the latencies returned to initial values. Interestingly, when the CS frequency was kept high during a longer period the CR latency gradually shifted back to the original values. Identical results were obtained upon increasing forelimb stimulation intensity (from 1 mA to 2 mA).

These observations support the view that the cerebellum or/and the cerebellar output pathways are responsible for the delay of the CR.

DIZOCILPINE (MK-801) BLOCKS HARMALINE-INDUCED TREMOR AND

DIZOCILPINE (MK-801) BLOCKS HARMALINE-INDUCED TREMOR AND IMPAIRMENT OF LEARNING IN RABBITS. W. Du*, V.J. Aloyo and J.A. Harvey. Div. of Behavioral Neurobiology, Dept. of Pharmacology, The Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA 19129.

Harmaline is known to produce tremors and retard learning as measured by acquisition of the rabbit's nictitating membrane response. Both of these effects have been attributed to harmaline's ability to increase the rhythmic bursting of cells in the inferior olive which give rise to climbing fibers that project directly onto Purkinje cells in cerebellar cortex. However, the precise receptor systems involved in harmaline's actions remain unknown. This study examined the role of the NMDA receptor in harmaline's actions. Harmaline (10 mg/kg, s.c.) produced intense tremors and severely retarded learning. Both of these effects of harmaline were significantly blocked by the prior administration of the noncompetitive NMDA channel blocker, dizocipine (DIZ, 0.01 mg/kg, s.c.). This dose of DIZ had no effect on CR acquisition when given alone. A higher dose of DIZ (0.1 mg/kg) completely blocked the tremorogenic effects of harmaline. We found that NMDA receptors are present in the inferior olive of the rabbit as reflected by the specific binding of ['H]dizocilpine to washed membranes and this binding was reduced by harmaline. Since, NMDA receptors occur in the inferior olive but not on Purkinje cells, the sole input of climbing fibers in cerebellar cortex, we conclude that harmaline's ability to activate the inferior olive and thus produce tremor and retardation of learning requires the normal activity of the NMDA receptor. Supported by MERIT award MH16841.

MODULATION OF SOMATOSTATIN INDUCED CEREBELLAR TOXICITY WITH GROWTH HORMONE IN SPRAGUE-DAWLEY RATS, J.T.Robicheau, C.D.Balaban and J.D.Porter* Dept of Pharmacy and Therapeutics and Otolaryngology, Schools of Pharmacy and Medicine, University of Pittsburgh, Pittsburgh, PA 15260

Somatostatin (SRIF) is an endogenous neurotransmitter/modulator and regionally selective neurotoxin. Small intracerebroventricular doses of SRIF (20-40 μ g) selectively damage sagittal Purkinje cell (PC) bands in the cerebellar anterior lobe, posterior lobe and hemisphere. Since SRIF participates in the regulation of growth hormone (GH) secretion, we tested the hypothesis that centrally administered GH may modulate SRIF toxicity in the cerebellum. Adult male SD rats were anesthetized and implanted stereotaxically with osmotic minipumps (Azlet® #2002 infusion rate, 0.5µl/hr) for the 14 day icv infusion of 1.8 ng or 18ng/0.5µl/hr. On the tenth postoperative day, animals were given an icv injection of SRIF bolus (30 µg/5µl) via the implant. Rats were euthanized on post-SRIF day 4 with a pentobarbital overdose (100mg/kg i.p.). The brains were stained for degeneration with a modified cupric-silver stain. Acute barrel rotation (BR) after the SRIF bolus was prevented by GH. The incidence of BR was 2/13 in GH-treated rats and 5/5 in aCSF treated rats (Yates Corrected χ^2 and Fisher's Exact Test, p > 0 .01). The appearance of PC degeneration was scored as mild (damage confined to lobule I-III), moderate (additional damage to damage lobules IX-X) or severe (additional hemispheric damage) or the absence of tissue damage. Animals that did not display BR had absent or mild damage. Conversely, animals that showed BR had severe damage. Rats which had pronounced SRIF-induced postural effects, but without BR displayed mild to moderate damage. These results suggest a neuroprotective effect of the GH infusion against SRIF-induced cerebellar toxicity in rats. (Support: University of Pittsburgh, Internal Funds)

EFFECTS OF SEROTONIN ON CEREBELLAR GRANULE CELL ELECTRICAL PROPERTIES Huo Lu* and L.J. Larson-Prior. Dept. of Neuroscience & Anatomy, Penn State Univ. College of Med., Hershey,

Serotonin has been hypothesized to play a role in state dependent setting of motor output in the cerebellum. Immunocytochemical and autoradiographic studies have been shown that all layers in the rat cerebellum receive serotonergic input. Serotonin has been shown to affect a transient outward potassium current, I_A and an inwardly rectifying current, I_h in cerebellar Purkinje cells (Wang et al., Brain Res. (1992) 571:345; Li et al., Brain Res. (1993) 617:87). Since these two currents exist in the cerebellar granule cell (GC), serotonin may affect GC

currents exist in the cerebellar granule cell (GC), serotonin may affect GC processing in a similar manner. Thin slices from rat vermal cortex were used to examine the effect of bath applied serotonin (1 μ M) on GC electrical properties. Using patch clamp recording in the whole cell configuration, GC electrical responses were investigated under current and voltage clamp. Serotonin produced a minor increase on firing rate to depolarizing current injection, consistent with a reduction in I_A . This effect was confirmed under voltage clamp. Changes in the voltage response to hyperpolarizing current injection in the presence of serotonin were consistent with a reduction in I_h . These observations were further investigated using our recently developed compartmental model of a cerebellar GC (Lu et al., Soc. Neurosci. Abstr. (1995) 21:916), by totally or partially removing either one or both of these potassium conductances from the somal compartment where those channels are located. Under these conditions, the response of the soma to hyperpolarizing and depolarizing current

the response of the soma to hyperpolarizing and depolarizing current injection mirrored changes seen in whole cell recordings under current clamp. Thus, serotonergic effects on granule cell processing are partially mediated by changes in potassium conductances. Supported in part by Penn. State Univ., NS 30759 and IBN-9514844 (LLP).

CORTICOTROPIN RELEASING FACTOR IN THE CEREBELLAR NUCLEI OF THE CAT. Georgia A. Bishop* Dept. of Cell Biology, Neurobiology and Anatomy and Neuroscience Program. The Ohio State University, Columbus, OH 43210

and Neuroscience Program. The Onio State University, Columbus, Ort 43210 Corticotropin releasing factor (CRF) has been localized throughout the cerebellar nuclei of the adult cat (Cummings, JCN 289:657,1989). In this study the brainstem nuclei which give rise to CRF afferents to the cerebellar nuclei are identified. Fluorescent-labeled microspheres were injected into the nucleus interpositus (IP) of Fluorescent-labeled microspheres were injected into the nucleus interpositus (IP) of the cat to retrogradely label neurons that project to this area. The same sections were then processed for CRF immunohistochemistry using the PAP technique. Double labeled cells, (i.e. neurons that are both immunoreactive and retrogradely labeled) were localized using fluorescent microscopy. Using Berman's terminology, the following nuclei were found to give rise to CRF afferents to the IP: 1) the inferior olive; 2) the central inferior nucleus; and 3) the locus coeruleus. In addition, preliminary studies have been carried out to determine the physiological effects of CRF on nuclear neurons. To date, iontophoretic application of CRF increases the firing rate of both spontaneous and amino acid-activated nuclear neurons. CRF also has been applied to spontaneous and ammo acid-activated nuclear neurons. Crr also has been applied to neurons that were activated by stimulation of the inferior cerebellar peduncle (ICP). Activation of this pathway produces a depression in the overall firing rate of nuclear neurons. If CRF is applied during the period of stimulation the firing rate increases, although it does not return to control levels. Likewise, if CRF is iontophoresed onto nuclear cells prior to activation of the ICP the extent of stimulation-induced suppression is reduced. In conclusion, these data indicate that CRF afferents to the cerebellar nuclei are derived from brainstem sources that also give rise to climbing fibers, mossy fibers, and a beaded plexus of fibers in the cerebellar cortex of the cat. At present it is not known if the nuclear input is derived from collaterals of afferents continuing on to the cortex or from a unique population of neurons within the nuclei of origin. The physiological data indicate that the amino acid-or stimulation-induced output of the cerebellum can be modulated if the peptide CRF is present in the local micorenvironment of nuclear neurons. MAPPING ESTRADIOL-SENSITIVE OSCILLATING NEURONAL CLUSTERS WITHIN THE INFERIOR OLIVE. R.S. Markowitz*, R. C.-S. Lin, J.K. Chapin, and S.S. Smith. Dept. of Neurobiology and Anatomy, Medical College of Pa. and Hahnemann Univ., Philadelphia, PA 19102-1192.

Ongoing studies from this laboratory have demonstrated that estradiol can enhance rhythmic discharge recorded from neuronal clusters within the inferior olivary (IO) complex during rhythmic behavior. In the present study we have examined the topographical localization of these estradiol-sensitive clusters. Towards this end, female rats were implanted with bundles of 15-16 microwires (50 μ, NB Labs, Denison, TX) within the IO. Olivary discharge was then recorded from as many as 32 neurons simultaneously during spontaneous whisking behavior before and after administration of estradiol (2 μgs, i.p. in oil for 2 days) using software from Spectrum Scientific (Dallas, TX). At the end of the recording session, brains were removed, fixed in formalin, sectioned at 50 μ and stained with Cresyl violet for verification of electrode placement. Under control conditions, rhythmic olivary discharge was observed in phase with rhythmic whisking (8-9 Hz) in 20-30% of the neurons recorded. Estradiol increased the spatial extent of synchronized, oscillations by an average of 150 μ ± 45 μ (P<0.0001 versus control) as well as the frequency (P<0.05 versus control) in medial and caudal portions of the MAO and DAO, with almost no effect within the PO. As gap junctions within the IO have been shown to play a role in synchronizing oscillations, a second experiment was conducted to test for the possibility that hormone treatment increased gap junction formation as has been demonstrated in uterus and brain, using connexin43 as a marker protein (Zymed Labs). Treatment with estradiol increased IO levels of connexin43 above control values, which suggests that increases in circulating levels of estradiol expand clusters of rhythmically discharging olivary neurons, possibly mediated via increase

CORTICOTROPIN RELEASING FACTOR (CRF) IN THE EMBRYONIC MOUSE CEREBELLUM, T. L. Overbeck,* G. A. Bishop and J. S. King Dept. of Cell Biology, Neurobiology and Anatomy and The Neuroscience Graduate Program, The Ohio State University, Columbus, 0H 43210

CRF is present in climbing and mossy fibers in the cerebellar cortex of several mammalian species where it functions to modulate the responsiveness of Purkinje cells to both excitatory and inhibitory inputs. This peptide also is present during early stages of cerebellar development; however its function is unknown. We propose to stages of cerebellar development; however its function is unknown. We propose to use transgenic mice to block the expression of CRF or its receptor. Before these studies can be carried out, the developmental history of this peptide in the mouse cerebellum must be determined. An antibody to CRF, provided by W. Vale, was used to localize CRF immunoreactivity. The current data indicate that CRF is present as early as embryonic day (E)15. At E15 and E17, CRF is present in two distinct fiber bundles that traverse the junction between the brainstem and cerebellum. Immunoreactive varicosities are abundant at these same ages and are located than the contractive varicosities are abundant at these same ages and are located than the contractive varicosities are abundant. immunoreactive variosities are abundant at these same ages and are located throughout the cerebellum, primarily within the nascent Purkinje cell layer, and the intermediate zone of migrating cells. A few varicosities are present in the external granule cell layer (EGL) but none are seen in the ventricular layer. CRF immunoreactive cell bodies are present within the cerebellum at E15 in the intermediate zone, the subventricular zone and the ventricular layer especially in the medial regions of the cerebellar anlage. At E17, CRF cell bodies extend to the lateral medial regions of the cerebellar aniage. At E17, CRF cell bodies extend to the lateral regions of the developing cerebellum and are present primarily in the intermediate zone of migrating cells. CRF positive cell bodies are no longer present in the cerebellum after postnatal day 3. These data represent the first account of a transient expression of CRF in the developing cerebellum. A riboprobe for the CRF, receptor was used for in situ hybridization and revealed that the mRNA for the CRF, receptor is present in in start hydridization and revealed that the interval of the CRF, receptor is present in the EGL, the nascent Purkinje cell layer and the intermediate zone at E17. These data support our hypothesis that CRF regulates early developmental events in the cerebellum including cell survival and differentiation. THE ORIGIN OF CALCITONIN GENE RELATED PEPTIDE (CGRP) WITHIN THE

MOUSE INFERIOR OLIVARY COMPLEX, A. C. Peltier, K. V. Gregg, J. S. Kinge* and G. A. Bishop. Dept. of Cell Biology, Neurobiology & Anatomy, and The Neuroscience Graduate Program, The Ohio State University, Columbus, OH 43210. Neurons within the inferior olivary complex (IOC) are the source of climbing fibers to the cerebellar cortex. The activity of neurons in the IOC is regulated by both excitatory and inhibitory amino acids derived from various afferent systems. This excitatory and inhibitory amino acids derived from various afferent systems. This neuronal activity may be modulated by peptides released by one or more of the same afferents to the IOC. The peptide CGRP is present in small varicosities which have an extensive distribution throughout the IOC as well as a population of larger profiles which have a more restricted distribution (Gregg et al. 1994 Neurosci.Abst.201759). CGRP has been shown to modulate olivary activity (Gregg & Bishop, Neurosci.Abst.21:1192). The intent of this study is to determine which brainstem nuclei give rise to CGRP varicosities within the IOC. Fluorescent labeled microspheres were injected into the caudal IOC to identify neurons which project to the nucleus. Sections from these cases also were processed for immunohistochemistry using a primary antibody to CGRP to identify neurons which contain the peptide. Retrogradely labeled neurons were located in all nuclei previously shown to give rise to olivary afferents. CGRP labeled cells were present in several brainstem nuclei retrogradely ladered neurons were located in all nutrier previously shown to give rise to olivary afferents. CGRP labeled cells were present in several brainstem nuclei including three which are known to project to the IOC, namely the locus coeruleus (LC), subparafascicular nucleus (SPF), and the zona incerta/Fields of Forel. Double labeled neurons were frequently seen in the ventral aspect of the LC, bilaterally. In addition, a few scattered double labeled neurons were present in the SPF. The addition, a few scattered double labeled neurons were present in the SPF. The afferents from the LC may distribute as the small CGRP-positive varicosities located throughout the olivary complex. CGRP derived from the SPF may distribute as the larger varicosities which have a more restricted distribution. The transmitter of the SPF is unknown. However, the LC is the primary source of norepinephrine (NE) to the cerebellum and other areas of the neuraxis. Future studies will be designed to determine if CGRP is co-localized with NE in olivary afferents or if the projection arises from an independent population of LC neurons. (Supported by the Roessler Foundation, OSU College of Medicine and NSF INT9319449).

CHOICE REACTION TIME IN CEREBELLAR DISEASE, S.E. Grill*. Dept. of Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD, 21205.

Simple reaction times are prolonged in human subjects and animals with cerebellar lesions and disorders. In the present study, reaction times of 7 normal subjects and 11 patients with cerebellar degenerations were compared during choice reaction time tasks with varying stimulus-response compatibility. Subjects initially depressed a "home" button. After a random interval, a

Subjects initially depressed a "home" button. After a random interval, a visual stimulus appeared indicating which of 7 buttons arranged in a semicircle around the home button should be pressed, as rapidly as possible. For each trial, the number of active buttons (choices) varied randomly from 1 to 7.

the number of active buttons (choices) varied randomly from 1 to 7.

Four tasks with different stimuli but the same response (button press) were done: 1) All buttons initally red; subjects press button which turns green; 2) Each button a different color; subjects press button corresponding to color presented just above home button; 3) Each button a different color; subjects react to word spelling the color; 4) Each button a different color; subjects presented with list of 3 letter names associated with a color and react to presentation of a name. Seventy trials for each task were run.

presentation of a name. Seventy trials for each task were run. Simple reaction times of patients (1047 + 1 - 524) were greater (p < 0.02) than those of normal subjects (383 + 1 - 33). However, slopes of the relations between reaction time and number of choices were similar for the two groups for each task including the task with greatest stimulus-response compatibility (task 1). Patients with cerebellar disease are able to take advantage of stimulus-response compatibility.

639.3

POSTURAL RESPONSES TO CHANGING TASK CONDITIONS IN CEREBELLAR PATIENTS.

Timmann, R.A.W. Galuske*, H. Schicks, D. Böring', A.F. Thilmann', H.C. Diener and F.B. Horak', Depts. of Neurology. University of Essen and Fachklinik Rhein/Ruhr, 45122 Essen. FRG: "Posture Control Lab., R.S.D. Neurological Sciences Inst., Portland, OR 97209.

The aim of the present study was to investigate the role of the cerebellum in postural adaptation for both changes in the width as well as the direction of the support surface displacements. A total of 24 patients with chronic, isolated lesions of the cerebellum and 21 sex- and age-matched controls were tested. Both control and cerebellar subjects showed an immediate change in the response amplitude of the medial gastrocnemius and anterior tibial muscles when the direction of perturbation changed from a translation to a rotation and vice versa. Both control and cerebellar subjects also changed postural strategies with changes in the width of the support surface. A similar proportion of cerebellar patients and normals modified their postural strategies to include more hip strategy control when balancing across a narrow beam.

In conclusion, the integrity of the cerebellum does not seem to be critical for adaptation of postural synergies to changing task conditions. The present results confirm previous findings suggesting that the cerebellum's main role in automatic postural responses may be gain control.

639.5

SPEECH PERCEPTION AND PRODUCTION IN CEREBELLAR DISORDERS: THE CONTRIBUTION OF TIMING

S. Graeber*, H. Ackermann, I. Hertrich, I. Daum Dept. of Neurology and Inst. of Medical Psychology, Univ. of Tuebingen, Hoppe-Seyler-Str. 3, 72076 Tuebingen and Gartenstr. 29, 72074 Tuebingen, FRG

A role of the cerebelluin as an "internal clock" has been proposed for a variety of motor and perceptual tasks, nevertheless an involvement in the processing of durational parameters of the perceived and produced acoustic speech signal has not yet been found (Gopal and Ivry, 92). In order to further investigate this issue we studied the performance of cerebellar patients (CERE) in a speech perception and production task. The results were also compared to matched groups of normal controls (NC) and patients with parkinson disease (PD). In the perception task the paradigm of categorical perception was applied using German words as minimal pairs which were manipulated with respect to the duration of voice-onset-time (VOT), sowel length (VL) and duration of closure (DCL). In the production task minimal pairs were spoken by the subjects and the duration of the parameters VOT and VL was analyzed.

The CERE group showed specific deficits in perception as in production tasks. The production of the VCT was significantly more variable compared to NC. In the perception task the CERE group did not show deficits in the perception of either VOT or VL. But there were clear deficits in the perception of the DCL. These results indicate that the cerebellar patients are not impaired in measuring time intervals in speech if they can utilize additional cues for discrimination (for example, acoustic energy). However, deficits are observed when these additional cues are not available and explicit temporal computation is required. In contrast, the perfonning of the PD group in the perception and production tasks differed markedly from that of the CERE group. These experiments suggest that there are specific cases of timing phenomena in oral language that specifically involve the cerebellum as a timing device. Supported by the German Reseach Society (DFG; SFB 307/B10)

639.2

MODIFICATIONS OF POSTURAL RESPONSES DURING PERTURBED STEP INITIATION IN CEREBELLAR SUBJECTS. D. Timmann* and F.B. Horak. R.S. Dow Neurological Sciences Institute, Portland, OR 97210 and Dept. of Neurology, University of Essen, Hufelandstr. 55, 45122 Essen, Germany.

The aim of the present study was to investigate both the possible role of prediction of perturbation amplitude and the involvement of the cerebellum in the mechanisms involved in postural adaptation for voluntary movements. Nine cerebellar subjects and nine control subjects were instructed to either maintain stance or step forward in response to predictable and unpredictable amplitudes of backward surface translations. The size of the suppressed postural response was the same independent of prediction of perturbation amplitudes in both control and cerebellar subjects. Cerebellar subjects were able to suppress their initial postural responses to the same amount as normal subjects when instructed to step forward as soon as they feel the platform move backward, despite their hypermetria.

In conclusion, the dynamic interaction between automatic postural responses to an external perturbation and anticipatory postural adjustments for step initiation seems independent of prediction of perturbation amplitude and the integrity of the cerebellum. (Supported by NIA grant R01-AG06457 and Deutsche Forschungsgemeinschaft Ti 239/1-1)

TIMING OF MENTALLY SIMULATED MOVEMENTS IN PATIENTS WITH CEREBELLAR DISORDERS. Florian A Kagerer 1*. Vlastislav Bracha². George E Stelmach². James R Bloedel². Motor Control Laboratory, Arizona State University, Tempe, AZ 85287, ²Barrow Neurological Institute, Phoenix, AZ 85013. Temporal features of mentally simulated actions were shown previously to correspond

well to the temporal features of the same movement when actually performed. The purpose of this experiment was to examine whether mental simulation times (MSTs) reflect the increased movement times (MTs) resulting from the ataxia exhibited by patients with cerebellar pathology. Three patients with unilateral cerebellar lesions, 1 patient with cerebellar and cortical pathology, and 3 age- and sex-matched controls participated in the study. The movement execution part of the task required subjects to move a hand-held stylus horizontally on a digitizing tablet along a specified movement path (two conditions: pathwidth 3.5" and .75"); movement direction between start and endpoint changed three times. Subjects were instructed to move as straight as possible and at a comfortable speed. The mental simulation component required subjects to imagine the arm movement along the path without performing it. Subjects "started" the simulated movement in response to a tone and reported vocally when they had finished. 16 trials of mental simulation and 16 trials of movement execution were alternated; performance and simulation with both hands were assessed. Results show that 1) both the patients and normal subjects showed an increased MT as well as MST when executing or simulating movements through the narrower path, 2) cerebellar patients had substantially greater MTs and MSTs than controls, and 3) both the MTs and the MSTs of the patients were greater on the affected side than on the unaffected side. The findings suggest that the cerebellar pathology present in these patients did not disrupt their ability to simulate mentally their movements. Furthermore, their MSTs reflected the time required to execute their ataxic movements

639.6

CADHERIN EXPRESSION IN PARASAGITTAL DOMAINS OF THE DEVELOPING CHICKEN CEREBELLUM, <u>K. Arndt* and C. Redies</u>, Institute for Biology III, University of Freiburg, Schänzlestr. 1, D-79104 Freiburg i. Brsg., Germany.

The adult cerebellar cortex consists of functional compartments which have been characterized physiologically and biochemically. These functional domains form parasagittal stripes and emerge during development.

By immunohistochemistry and in situ hybridization, we show that, in the embryonic chicken cerebellum, three cadherins (R-cadherin, cadherin-6B and -7) are transiently expressed in parasagittal domains at embryonic day E11, E15, and E19. Cadherins, a family of calcium-dependent cell-cell adhesion molecules, are known to be involved in morphoregulatory processes. The position of the cadherin-expressing domains in the embryonic cerebellum overlaps with that of functional domains in the adult: E.g., R-cadherin is expressed in domains A, C, E and F (see Arends and Zeigler, J. Comp. Neurol. 306:221-244). Efferents of these domaines terminate in deeper cerebellar nuclei which also express R-cadherin.

Cell type specificity of cadherin expression changes from E11- E19. At stage E11, all three cadherins are expressed by Purkinje cells and granule cells. At stage E19, cadherin-6B expression is restricted to Purkinje cells and cadherin-7 expression to the internal granular layer. R-cadherin is expressed in a subpopulation of cells in the internal granular layer.

These results suggest that cadherins are involved in the formation of the functional cerebellar architecture, possibly by providing transient adhesive cues during development.

THE MOLECULAR MECHANISM OF CEREBELLAR GRANULE CELL DEVELOPMENT IN MOUSE. M. OZAKI*, T. HASIKAWA** and R. YANO Lab. for Cellular Information Processing, **Lab. for Neural System, Frontier Research Program, RIKEN, Saitama 351-01, JAPAN.

The cerebellar granule cell represents one of the most amenable classes of CNS neurons for developmental studies. A key feature of granule cell development, revealed by fate mapping of the cerebellar cell population, is that the granule neuron arises from a germinal zone that gives rise to only one class of neuron and then migrates to localize internal granule layer (IGL). The granule cell completes the development by makeing synaptic connection with mossy fiber. Studying this system characterized well phisiologically means revealing the basical concept of neurogenesis in CNS from the aspect of molecular biology. Indeed it's thought that some gene expression are required for processes of migration from external granule layer (EGL) to IGL and of innervation by mossy fiber. Herein we focused on neuregulin (also called NDF heregulin, GGF and ARIA) and it's receptor because neuregulin is thought to be critical factor for innervation in neuromuscular junction. Neuregulin is a member of the EGF family which induces growth and differentiation of epithelial, glial and muscle cells in culture. Furthermore neuregulin can bind erbB. To know the destribution of each gene of neuregulin and the receptor's family, in situ hybridization was carried out. In addition we are studying also innervation by mossy fiber to granule cell by neural staining. We will report the relationship between innervation of mossy fiber and gene expression here.

639.9

SINGLE-UNIT ACTIVITY OF CEREBELLAR PURKINJE CELLS IN THE AWAKE GENETICALLY DYSTONIC RAT. M.S. LeDoux*1, and J.F. Lorden². Dept. of Neurology¹, Univ. of Tennessee Coll. of Medicine, Memphis, TN 38163; Dept. of Psychology², Univ. of Alabama at Birmingham, Birmingham, AL 35294.

The genetically dystonic (dt) rat, an animal model of generalized idiopathic dystonia, develops a motor syndrome by Postnatal Day 12 that progresses rapidly. Lesion studies have established cerebellar output as critical for the expression of the dt rat motor syndrome. In the awake dt rat, cells in the deep cerebellar nuclei (DCN) exhibit an abnormal pattern of bursting The amount of bursting increases with age and the Single-unit recordings from severity of the motor syndrome. cerebellar Purkinje cells were obtained from awake dt (N=29) and normal (N = 23) rats at Postnatal Days 12 to 26 to determine the cerebellar cortical correlates of abnormal DCN activity. spike frequency (mean ± SEM) was 40.43 ± 2.86 Hz for normal (39 cells) and 45.25 ± 4.74 Hz for dt (35 cells) rats. Complexspike frequency was significantly higher in normal (1.48 ± 0.07 Hz) than in dt (0.88 ± 0.09 Hz) rats. Simple-spike frequency increased with increasing postnatal age in both normal and dt rats Abnormal cerebellar output in the dt rat may be a consequence of its low Purkinje cell complex-spike firing rate or a loss of DCN (Supported by NIH K08 sensitivity to Purkinje cell activity. NS01593-01 and the Dystonia Medical Research Foundation)

SELECTIVE PERTURBATION OF THE VESTIBULOCEREBELLUM IN TRANSGENIC MICE. J. Oberdick³. D. Redd², F. Bian³, M. Ostrowski², and A. S. Berrebi*¹. ¹Departments of Otolaryngology and Anatomy, West Virginia Univ. School of Med., Morgantown, WV 26506; ²Departments of Molecular Genetics and ³Cell Biology, Neurobiology, and Anatomy, and the ³Neurobiotechnology Center, The Ohio State University, Columbus, OH 43210.

Genetics and 3 Cell Biology, Neurobiology, and Anatomy, and the 3Neurobiotechnology Center, The Ohio State University, Columbus, OH 43210. In order to elucidate the role of the ras pathway in terminal differentiation of neurons, a dominant-negative form of the ras GTPase has been overexpressed in cerebellar Purkinje cells. The mutated gene Ha-ras-N17 which encodes a form of ras believed to act by competing with the wild-type protein for binding to GDP exchange factors, was linked to the Purkinje cell-specific promoter, pcp-2(L7). Eight founders, each carrying greater than ten copies of the transgene, were obtained, none of which showed any overt signs of ataxia. One male founder never produced offspring and another showed a considerable delay in reproductive capacity. This delay correlated with high expression of transgenic RNA and the mutated ras protein with respect to three other founders that were good sires. The founder male that never produced young, and mice from the line that was established after a considerable lag, showed an obvious decrease in size of the paraflocculus clearly visible in whole mount upon dissection of the brains. Upon histological analysis, it was found that both the flocculus and paraflocculus were affected. These regions are characterized by thinner than normal molecular and granule cell layers, and the paraflocculus in particular by a change in the pattern of foliation. Purkinje cells in these regions appeared qualitatively normal by expression of a number of marker proteins. However, aberrant dendritic morphologies were observed by the Golgi method. Interestingly, calretinin+ cells seem to be missing from the more caudal aspect of the paraflocculus and flocculus. In situ hybridization analysis clearly shows uniform expression of the transgene throughout the cerebellum, at least after the first postnatal week. These data suggest either an early critical period of ras involvement in cerebellar development or a selective role for ras in vestibulocerebellar development. (Supported by

CONVERGENT CEREBRAL CORTICAL AND SOMATOSENSORY INPUT TO THE PRIMATE BASILAR PONTINE NUCLEI, G.A. Mihailoff, Departments of Anatomy and Neurology, University of Mississippi Medical Center, Jackson, MS 39216-4505.

Although regarded primarily for its role in the transfer of signals from the cerebral cortex to the cerebellum, recent studies from our laboratory and others have indicated that the basilar pontine nuclei (BPN) receive afferent projections from a much more diverse array of cell groups than was previously recognized. For example in the rat, earlier studies revealed that the BPN received a substantial projection from the dorsal column nuclei and the terminal fields of this projection overlapped with the terminals of sensorimotor corticopontine axons. Subsequent experiments in rats using electrophysiological recording revealed that single BPN units received convergent input following activation of deep and cutaneous receptors on the forepaw in combination with input from the forepaw representation in the sensorimotor cortex. Electron microscopic studies using double labeling methods confirmed that axons from the dorsal column nuclei and the forelimb sensorimotor cortex formed synaptic contacts with single BPN projection neuron dendrites. In the present experiments, we seek to investigate whether such circuitry also exists in the BPN of non-human primates (Macaca fascicularis). Previous studies in the monkey have shown that (1) axons course ventrally from the medial lemniscus to reach the subjacent dorsal regions of the BPN where they form multiple, small foci of terminal aggregates, and (2) corticopontine axons from SI cortex, premotor cortex, and parietal areas 5 and 7 also terminate throughout this same dorsal BPN region. When SI corticopontine axons are labeled by orthogradely transported biotinylated dextran amine (BDA) and dorsal column nuclear axons are caused to degenerate by ablative lesions of the cuneate and gracile nuclei, electron microscopy reveals that both types of axons form synaptic boutons with single dendrites in the BPN neuropil. Further, both types of afferent synaptic terminals participate in serial synaptic arrangements where they always form the presynaptic element in contacts with other vesicle containing profiles. Thus in primates as in rodents, BPN input from the dorsal column nuclei appears to converge with the input from sensorimotor cerebral cortex. This finding highlights the integrative functional role of the BPN. Supported by USPHS grant NS12644-16

Purkinje cells (Pc) in the cerebellar C1-C3 compartments, receive climbing fiber (CF) afferents from the rostral part of the accessory olives, and project their axon to the interposed nuclei. Olivocerebellar fibers design, within these compartments, multiple cortical body maps, and recent tract-tracing studies have shown that maps are linked by axon collaterals of individual olivary neurons. Neurons in the deep nuclei were also found to project back to the cortex following this pattern of somatotopic topography and axon collateralization. Our study was aimed at ascertaining how homologous areas of the CF projection maps are translated, through the Pc projections, to the neuronal groups within the deep nuclei, and hence to the interposed output stations, the red nucleus (RN) and the motor thalamic (VA-VL) nuclei. Retro-anterograde markers were injected into the face-forelimb related (FL) areas of the cortical maps, in compartments C1-C3 of the anterior lobe, paramedian and ansula lobules. Anterogradely labeled Pc axon terminals were analysed in the interposed nuclei, and direct comparison was made with the topography of retrogradely labeled olivary and deep nuclear neurons, projecting to the injected cortical areas. Pc projections from homologous cortical areas were found to converge only in part on the same FL nuclear neurons, always leaving significant adjacent patches of non overlapping terminal areas. These results are taken to indicate that: I) Pcs in individual FL areas of the cortical body maps in the intermediate cerebellar compartments have a finely differentiated pattern of projections to specifically localized neurons in the FL nuclear groups; II) this differentiated projection pattern is likely to be reflected in the cerebellar output to RN and VA-VL nuclei.

ELECTROPHYSIOGICAL IDENTIFICATION OF CLIMBING SAGITTAL ZONES IN THE CEREBELLAR ANTERIOR LOBE OF THE RAT.

C.F. Ekerot*, H. Jörntell, M. Garwicz and X.-L. Lou. Dept. of Physiology and Neuroscience, Lund University, Lund, Sweden

The investigation was performed to elucidate the zonal organization and information carried by climbing fibres to the cerebellar anterior lobe of the rat. Climbing fibre field potentials evoked on electrical stimulation of the skin were recorded with microelectrodes in barbiturate anaesthetized rats. The microelectrode penetrations were made in the sagittal plane usually starting in lobule VI and aimed at the rostral part of the anterior lobe.

In the hemivermis the a, x and b zones were identified. The a zone in lobule II-V received a short latency, topographically well organized climbing fibre projection mainly from the hind part of the ipsilateral body. Caudally to this projection the a zone received a long latency bilateral projection from the forelimbs. The x zone characterized by a short latency input from the ipsilateral forelimb, seemed to form a caudal extension of the short latency projection to the a zone. The b zone in the lateral vermis received a long latency, often bilateral, climbing fibre projection.

In the pars intermedia the c1 and c2 zones were identified. The c1 zone received

a short latency climbing fibre from the ipsilateral side of the body. The distal forelimb was represented in lobule VI-IV and the hindlimb further rostrally. In the rostralmost parts in lobule II and III there was a representation of proximal and axial structures. The c2 zone received a bilateral input dominated by input from the contralateral forelimb. In the narrow remaining area lateral to the c2 zone there were no short latency climbing fibre responses suggestive of a c3 zone

The detailed somatotopical organization in the a zone is an important new finding suggesting that vermis controls not only posture but also distal movements.

Descending hypothalamic projections to the basilar pontine nuclei studied with light and electron microscopy in the rat. Hao Liu* and G. A. Mihailoff Department of Anatomy, Univ. Mississippi Medical Center, Jackson, MS 39216

The projections from a variety of hypothalamic nuclei to the basilar pontine nuclei (BPN) in the rat were traced utilizing the anterograde transport of biotinylated dextran amine (BDA). Those hypothalamic nuclei with projections to the BPN included the anterior hypothalamic nucleus (AH), dorsomedial hypothalamic nucleus (DMH), lateral hypothalamic nucleus (LH), lateral mammillary nucleus (LMN), medial mammillary nucleus (MMN), premammillary nucleus (PMN), posterior hypothalamic nucleus (PH), supramammillary nucleus (SMN), tuber cinereum (TC), and ventromedial hypothalamic nucleus (VMH). Light microscopic observations revealed that the LMN, MMN, PH, and the caudal 1/3 of LH give rise to densely labeled terminal fibers that reach the medial and dorsomedial BPN. A few labeled terminals from the TC and PMN were also seen in the BPN, but no labeled fibers reached the basilar pons from the AH, DMH, SMN, and VMH. The labeled hypothalamic axon terminals were distributed bilaterally in the BPN with an ipsilateral predominance. With electronic microscopy, almost all labeled axon terminals contained round synaptic vesicles while a few contained a mixture of round vesicles and dense-core vesicles. The labeled terminals formed asymmetric synaptic junctions with dendrites of various sizes including a characteristic structure in the BPN neuropil, the glomerular synaptic complex. Very few synaptic contacts were seen with BPN neuronal somata. The present studies indicate that the hypothalamus projects predominantly to the medial portion of the BPN, and may play an excitatory role in activating pontocerebellar neurons. Supported by USPHS Grant NS12644

PUNCTIONAL CORRELATION OF PARALLEL FIBER ACTIVITY AND PARASAGITTAL BANDS ELUCIDATED BY SINGULAR VALUE DECOMPOSITION OF OPTICAL IMAGES C. Hanson*, G. Chen, T.J. Ebner Graduate Program in Neuroscience and Departments of Neurosurgery and Physiology, University of Minnesota Medical School, Minneapolis, Minnesota 55455.

The highly regular cellular lattice and circuitry of the cerebellar cortex and its afferent systems are organized around several spatial plans. Optical imaging can be utilized to accurately map the patterns of activity in the cerebellar cortex. In this study, we used singular value decomposition (SVD) to extract spatial patterns of activity from onical images of rat cerebellar cortex evoked by either direct cortical or electrical from optical images of rat cerebellar cortex evoked by either, direct cortical or, electrical and/or mechanical peripheral stimulation. Further, this method of analysis allowed us to investigate functional correlation, and connectivity between these varied spatial

patterns.

Optical signals from stimulus evoked fluorescence changes in Crus II were recorded Optical signals from stimulus evoked fluorescence changes in Crus II were recorded with a frame transfer equipped, digital, CCD camera in anesthetized rats (ketamine / xylazine). The cortex was stained by superfusion (2.5mg/ml) and intravenous injection (10mg/ml) of the pH sensitive dye, neutral red. Stimuli consisted of direct cortical stimulation to evoke parallel fiber activity, or electrical and/or mechanical stimulation of the face to elicit parasagittal banding.

SVD of the images obtained with direct cortical stimulation revealed spatial patterns of activity consistent with activation of a band of parallel fibers, while SVD images of bipolar electrical or mechanical stimulation of the ipsilateral face demonstrated patterns of parasagital banding. Remarkably, facial stimulation evoked "parallel fiber" like

bipolar electrical or mechanical stimulation of the ipsilateral face demonstrated patterns of parasagittal banding. Remarkably, facial stimulation evoked "parallel fiber" like patterns of activity in the higher order components. Similarly, during direct cortical stimulation "parasagittal" like patterns were detected. Additionally, some components showed both "parallel fiber" and "parasagittal" like spatial patterning. Therefore, SVD offers the potential to not only separate out various sources of fluorescence change, but also to quantify these changes and analyze how various sources of signals correlate temporally and spatially. COINCIDENCE OF OLIVOCEREBELLAR CLIMBING FIBER ZONES AND ZEBRIN-POSITIVE AND -NEGATIVE PURKINJE CELL ZONES IN NODULUS AND UVULA OF THE RAT .Voogd*and T.J.H.Ruigrok. Dept.of Anatomy, Erasmus University Rotterdam, Box 1738, 3000 DR Rotterdam, The Netherlands.

Axonal transport of Phaseolus vulgaris in climbing fibers(cf) was combined with immunostaining with an antibody against zebrin-I, a marker for a zonally distributed subpopulation of Purkinje cells (Hawkes and Leclerc, 1987, J.Comp.Neurol., 256:29). Purkinje cells of nodulus (NOD) and rostral half of ventral uvula (UV) are all zebrin-positive. In UV a zebrin positive midline band (P1+) and three bands P2/4+, separated by narrow, zebrin-negative slits P1/3are present. Three complex cf zones can be distinguished; their borders are located in the middle of P1/3+. The medial zone is

innervated by caudal group beta, the middle zone by rostral beta, lateral zone by dorsomedial cell column (DMCC) and rostral medial accessory olive (rMAO). In NOD medial and lateral zones merge with dorsal cap (DC)-innervated zones, middle zone with cf from ventrolateral outgrowth (VLO). Zebrin-negative slits P2and P3- are innervated by caudal MAO and dorso- medial cell group (DM). Funding: FGG EUR ANA 110209

OPTICAL IMAGING OF THE PARASAGITTAL ORGANIZATION IN THE RAT CEREBELLAR CORTEX EVOKED BY ELECTRICAL AND NATURAL STIMULATION OF THE FACE. G. Chen*, C. Hanson, T.J. Ebner. Depts. of

Neurosurgery & Physiology, Univ. of Minnesota, Minneapolis, Minnesota 55455 There is growing evidence that cerebellar afferents, Purkinje cells, and their efferent projections are compartmentalized parasagittally. Using optical imaging and immunostaining techniques, we demonstrate in this study that both electrical and tactile stimulation of the rat face evoke responses consisting of parasagittal bands in the cerebellar cortex, and that there is a close spatial correspondence between these patterns and the parasagittal zonation revealed by anti-zebrin immunostaining

Crus I and II in anesthetized rats (ketamine/xylazine) were exposed and stained with the pH sensitive dye, neutral red. After washout, images of the cortex were acquired before, during, and after ipsilateral facial electrical or tactile stimulation with a Ling Dynamic probe. A statistical analysis based on z-scores yielded a spatial and temporal map of the pattern of activation in Crus I and II. Following the optical recording, immunostaining of zebrin II was carried out by incubation of the cerebellar sections with anti-zebrin II (a gift from Dr. R. Hawkes), and perioxdase-conjugated secondary antibody. Immunoactivity was revealed by using a peroxidase substrate. The optical responses to face electrical stimulation consisted of 2-7 parasagittal bands of change in fluorescence. The bands varied in width from 100-500 µm and generally extended antero-posteriorly across the entire field of view. Ipsilateral tactile stimulation of the face evoked parasagittal bands similar to those produced by electrical stimulation. Zebrin positive bands unveiled by immunostaining techniques corresponded with the bands defined by the optical imaging techniques.

The present study demonstrates that functional parasagittal compartments exist in the rat cerebellar cortex and that the Purkinje cell zebrin positive subgroups may be anatomically related to this functional organization.

SOMATOTOPICAL ORGANISATION WITHIN THE INFERIOR OLIVE PROJECTION TO THE POSTERIOR LOBE OF THE RAT CEREBELLUM. M. J. Atkins and R. Apps. (SPON: Brain Research Association).

Dept. of Physiology, School of Med. Sci., University Walk, Bristol BS8 1TD, UK.

The cerebellar cortex of the cat can be divided into a number of olivocerebellar zones, however it is not established whether a similar zonal organisation exists in the rat. To test this possibility both electrophysiological and anatomical techniques were used to map the olivocerebellar projection to the posterior lobe of the rat cerebellum.

Using electrophysiological techniques, in male rats anaesthetised with sodium pentobarbitone (Sagatal, 60mg/kg), three different areas were identified within the Paramedian Lobule (PML: areas 1-3) and two areas within Copula Pyramidis (CP: areas 4-5). Each area was characterised as follows according to the site of peripheral electrical stimulation that evoked the largest climbing fibre responses within that area: area 1 (contralateral face), area 2 (ipsilateral forelimb), area 3 (ipsilateral and contralateral forelimbs), area 4 (tail) and area 5 (ipsilateral hindlimb). The olivocerebellar connections of these areas were then investigated by placing single, small (150-200nl) injections of retrogradely-transported fluorescent microspheres into the centre of each electrophysiologically defined area. After 6-10 days survival time, the rats were transcardially perfuse-fixed and the brainstem sectioned and analysed for cell labelling in the inferior olive.

The results suggest that from mediolateral in PML: area 1 has input from caudal Medial Accessory Olive (cMAO); area 2 has input from medial rostral Dorsal Accessory Olive (rDAO) and rMAO; area 3 has input primarily from rMAO, but also rDAO. In CP, from medial to lateral: area 4 has input from the lateral most part of middle DAO and area 5 has input primarily from a rostro-caudal column of cells in lateral DAO. These results suggest at least zones A, C1 and C2 may be present within the posterior lobe of the rat cerebellum. (Funded by The Wellcome Trust.)

RECONSTRUCTIONS OF SINGLE CLIMBING FIBER COLLATERALS IN THE DEEP CEREBELLAR NUCLEI OF THE RAT. I. Sugihara*, H. Wu and Y. <u>Shinoda</u> Department of Physiology, Tokyo Medical and Dental University School of Medicine, 1-5-45 Yushima, Bunkyo-ku, Tokyo 113, Japan

School of Medicine, 1-5-45 Yushima, Bunkyo-Ku, Tokyo 113, Japan

The olivocerebellar climbing fiber (CF) system, especially its innervation of
the deep cerebellar nuclei (CN), was investigated in the rat with
reconstructions of single axons labeled with biotinylated dextran amine (BDA).
A small number of CFs were stained by making a small and localized injection of BDA in the inferior olive nucleus (IO). This enabled us to trace single of BIA in the interior once nucleus (tO). This enabled us to trace single identified axons and their branches from serial sections throughout the cerebellum and medulla oblongata. In all of five CFs reconstructed so far collaterals terminating in the CN were given off from stem axons projecting to the cerebellar cortex. The number of nuclear collaterals per CF ranged from one to six. These collaterals bifurcated one to several times to give rise to terminal branches. Primary nuclear collaterals and terminal branches were much thinner than CF stem axons innervating cortical Purkinje cells, and bore en-passant and terminal varicosities as reported (Van der Want et al., 1989). When many CFs were labeled collaterals of many CFs made dense plexuses. The dense plexuses suggest significant convergence of CF fibers on cerebellar nuclear cells, while no convergence of CF fibers occurs at the level of a Purkinje cell in the cerebellar cortex. The area in which nuclear collaterals originating from a single CF made terminal branches with varicosities was relatively localized (about 100-300 µm in width in either direction within the CN). This suggests the precise topographical relationship in the olivocerebellar system between subnuclei of the IO, subdivisions of the CN and cerebellar cortical zones. THE EFFERENT PROJECTIONS OF THE INTERPOSED NUCLEUS OF THE CEREBELLUM: A PHA-L STUDY IN THE RAT. <u>J.M. Lockard* and D.G. Lavond.</u> Dept. of Biol. Sci., University of Southern California, Los Angeles, CA 90089.

From previous anatomical data it has been suggested that the Interposed Nucleus (IP) is merely an output relay from the "spinocerebellar" cortex. Connections with the brainstem motor relay nuclei and motor thalamus have been Connections with the brainstem motor relay nuclei and motor thalamus have been emphasized (Allen & Tsukahara, 1974; Chan-Palay, 1977; Asunama et al., 1982). However, others have demonstrated connections to centers concerned with planning and execution (Uchida et al., 1983; Vaudano & Legg, 1992), with nociception (Basbaum & Fields, 1978), and a variety of autonomic centers and affective behaviors (Haines et al., 1990; Ikai et al., 1992). It is for these reasons that we decided to do a systematic reexamination of the IP efferents using the sensitive anterograde tracer PHA-L. PHA-L was stereotaxically injected into 30 rats to describe the overall pattern of efferent projections from the IP. Here we report projections to the following: Spinal Cord, Rostral Linear and Parafascicular Raphe' Nuclei, N. Prepositus, Med. and Sup. Vestibular N., Med. Terminal N., Edinger-Westphal N., N. of Darkschewitsch, Red N., Inf. Olive (da, ma, po), VTA, Zona Incerta, Snc, Interstitial N. of Cajal, Mesencephalic Reticular N., PAG, Sup. Colliculus, Post. Hypothalamus, N. Post. Commissure, Lat. Hypothalamic Area, Pons, VM, VAL, VPL, VPM, Central Medial, Rhomboids, Medial Dorsal, Paracentral, and the Parafascicular Thalamic Nuclei. The well-established cerebellar cortical projection was also observed, in addition to a

established cerebellar cortical projection was also observed, in addition to a commissural projection to the contralateral IP.

Judging from its projections, the IP might coordinate or modify many functions of the nervous systems in much the same way as it has been shown to regulate muscular activity.

THE CYTOSKELETON OF UNIPOLAR BRUSH CELLS OF THE MAMMALIAN CEREBELLUM. Maria R. Dino*, Gabriela Sekerkova, Shane Cunha, Lester Binder' and Enrico Mugnaini¹ Northwestern University Institute for Neuroscience and ¹Dept. of Cell and Molecular Biology, 320 E. Superior Street, Chicago, IL 60611-3010
Unipolar brush cells (UBCs) are a special type of neuron newly unipolar brush cells (UBCs) are a special type of neuron newly

discovered in the granular layer of the mammalian cerebellar cortex. These small neurons are intermediate in size between Golgi cells and granule cells and display several unusual cellular features. UBCs usually have a single, stout dendrite that terminates in a brush-like bunch of dendrioles and a thin axon. The dendrioles receive an extensive and powerful synapse from a single mossy fiber rosette and establish dendrodendritic synapses with granule cells, of which they represent the presynaptic element. Despite being only 8-12 µm in soma diameter, UBCs are particularly rich in neurofilaments. These peculiarities suggest that their cytoskeleton is highly differentiated.

By fluorescence and electron microscopy we show that UBCs possess an extraordinary postsynaptic array of actin filaments and their somato-dendritic compartment is rich in tubulin, MAP 2, MAP 1B and tau-1. While actin indicates a high degree of motility in the dendrioles, the well developed microtubular apparatus may be essential for somato-dendritic transport of synaptic proteins directed to postsynaptic and presynaptic sites. Supported by grant NS 09904 and AG06969

ORGANIZATIONAL FEATURES OF THE DENTATO-THALAMO-CORTICAL PROJECTION. R.A.West*1 and P.L. Strick². 1.²Research Service, VA Medical Center and ²Departments of Neurosurgery and Physiology, SUNY Health Science Center, Syracuse, NY, 13210.

We used anterograde transneuronal transport of the H129 strain of the herpes simplex virus type 1 (HSV1) to determine the pattern of cerebellothalamocortical projections. Injections were placed into a caudal and ventral portion of the dentate nucleus in cebus monkeys (cebus apella, n = 2). Following a five day survival period, discrete patches of "second order" neurons were labeled in area X and ventralis lateralis pars caudalis (VLc) of the thalamus. The patches had a mean diameter of approximately 380µm and some patches extended up to 1mm rostrocaudally. "Third order" neurons were labeled in several cortical regions, but were primarily found in areas 6 and 9. These neurons were most often located in layer III. In one animal, several dense 'columns' of labeled neurons were found in the portion of area 6 which lies medial to the superior limb of the arcuate sulcus. The labeled neurons in these columns were most concentrated in the middle cortical layers, but could extend from layer VI to layer II. Columns had a mean width of approximately 480µm and measured 0.5 to 1mm rostrocaudally. These observations indicate that portions of the dentate nucleus project to an assembly of rostrocaudally oriented rods in the thalamus. These rods in turn innervate clusters of oriented columns in specific areas of cortex. A RETROGRADE TRANSPORT STUDY OF THE CONNECTIONS BETWEEN THE CEREBELLAR NUCLEI AND THE MEDULLARY RETICULAR FORMATION IN THE CAT. M.-J. Rho., T. Cabana and T. Drew. Depts. of Physiology and Biological Sciences, U. Montréal, Québec,

Previously we have examined the functional organization of the connections between the pericruciate cortex and the reticular formation of the brainstem (Rho et al. Soc. Neurosci. Abstr. Vol 20: p985) with the goal of better understanding the neural mechanisms that may underlie the integration of posture and movement. We have now extended these studies to examine the pattern of projections from the cerebellar nuclei to the medullary reticular formation (MRF). Small injections (0.15-0.6 μ L) of either Texas Red or Fluorescein were made into restricted regions of the MRF in 5 cats, and labelled cells in the cerebellar nuclei were identified using fluorescent microscopy. In contrast to the projections from the pericruciate cortex to the MRF, which are largely bilateral in origin, the majority of labelled cells in the cerebellar nuclei were located contralateral to the injection site (mean = $93\pm4\%$ of the total). Although there was appreciable labelling in the contralateral dentate nucleus (mean = $19\pm9\%$ of the total) the majority of the labelled cells (mean = 56 + 19% of the total) were localised within the fastigial nucleus. It is suggested that this unilateral projection from the fastigial nucleus to the MRF might be largely involved in the modification of muscle tone in response to feedback signals from the limbs. This is in contrast to the corticoreticular projections which we suggest would provide a bilateral feedforward signal to the MRF. (Supported by the MRC, FRSQ and FCAR).

UNIPOLAR BRUSH CELLS ARE PRESENT IN CEREBELLAR GRANULE CELL CULTURES. R.Anelli, R.E. Kettner* and E.Mugnaini Northwestern University Insti. for Neuroscience and Dep. of Physiology*, 320 E. Superior Street, Chicago, IL 60611-3010

A type of neuron, termed the unipolar brush cell (UBC), has recently

A type of neuron, terme the unipolar orusn ceu (UBC), has recently been characterized in the granular layer of the mammalian cerebellar cortex with several procedures including light and electron microscopic immunocytochemistry. The UBCs possess many distinctive features that make them easily distinguishable from other cerebellar neurons. The cell body usually emits a thin axon and is provided with a single, large dendritic trunk which the processing the property of dendricing comparison, with a more fiber research. terminates with a bunch of dendrioles synapsing with a mossy fiber rosette. UBCs are densely immunostained with antisera to calretinin, secretogranin II, GluR2/3. In primary cultures of cerebellar granule cells derived from rats of different postnatal ages (P2-P8), we observed three neuronal cell types, presumably granule cells, Golgi cells and UBCs, that demonstrate calretinin immunoreactivity after 3-12 days in vitro. The granule cell body is moderately stained. Golgi cells are moderately stained in the somatodendritic compartment. while UBCs are entirely strongly stained in a Golgi impregnation-like manner. The data suggest that the peculiar configuration of the UBC is largely cellautonomous and confirm that calretinin is a useful cell population marker both in vivo and in vitro. In vitro, granule cells are densely stained by antisera against NF-H, and these are not useful to differentiate UBCs from other cerebellar neurons, contrary to the situation in situ. We are in the process of expanding these data by immunostaining with antisera used to identify UBCs in the adult cerebellum, as well as by standard electron microscopy and co-colturing with neurons that may provide mossy fiber afferents.

CHARACTERIZATION OF GOLGI INTERNEURONS IN THE RAT CEREBELLUM. S. <u>Dieudonné and J.S.Kehoe*</u>, Lab. de Neurobiologie, Ecole Normale Supérieure, Paris, France.

Ecole Normale Supérieure, Paris, France.

We have performed a patch clamp study of Golgi cells in thin slices of the young rat cerebellum. The Golgi cells, first identified visually by the large size of their cell body, were filled with biocytin during patch clamp recordings for later histological evaluation. Recorded cells had the characteristic features of Golgi cells: a large and branching axonal plexus, small and stout basal dendrites in the granular layer and one or two apical dendrites crossing perpendicularly the Purkinje cell layer to form an ascending tree into the molecular layer up to the pia. They had a triexponential capacitive transient corresponding to a capacity of 30 to 100 pF (first two components). Some cells had lost most of their axon and could be identified by the small size of the third capacitive component. In the cell attached configuration cells were spiking regularly at 1 to 10 Hz

(first two components). Some cells had lost most of their axon and could be identified by the small size of the third capacitive component. In the cell attached configuration, cells were spiking regularly at 1 to 10 Hz.

Excitatory currents with NMDA and non-NMDA components could be evoked either by electrical stimulation of the parallel fibers in the molecular layer or by granule cell stimulation. The unitary AMPA current had an amplitude of 20 to 100 pA (at -70 mV) and a decay time of about 1 ms. The total charge necessary to evoke an action potential in current clamp was equivalent to that of 20 to 100 such excitatory events. GABAergic inhibitory currents were evoked by stimulations applied in the vicinity of the Purkinje cell bodies, suggesting that basket cells can inhibit Golgi cells. Glycinergic currents were recorded in frontal slices when the Purkinje cell layer was stimulated, suggesting that glycinergic axons travel perpendicular to the

sagittal plane.

AND EXPRESSION OF DIFFERENTIAL GAT-1 GAT-3 IMMUNOREACTIVITY IN THE RAT CEREBELLAR CORTEX. S. Morara ¹ A. Rosina ¹ N. Brecha ² and L. Provini ³ Itstituto Neuroscienze Bioimmagini, CNR, Milano, Italy, ²Dept. Neurobiology, CURE, UCLA, Los Angeles, CA, ³Ist. Chim. Biol. Fisiol. Gen., Univ. Milano, Italy. Specific Na ¹ and Cl ²-dependent, high affinity GABA transporters (GAT) are located on GABA-containing neurons and glial cells, and are thought to inactivate GABA's action by removing it from the vicinity of its receptors into presynaptic terminals and/or glial cells. Four cDNAs encoding GAT (GAT-1,2,3,4) have been cloned, and in rat, GAT-1 and -3 have been localized to neural cells. To detect the distribution and cellular localization of GAT-1 and -3 in the cerebellar cortex, double immunofluorescence experiments used GAT-1 and GAT-3 antisera with antibodies for synaptophysin or GFAP. High levels of GAT-1-IR were seen around Pcs, in cone-like structures that, due to position, shape and positivity to synaptophysin were identified as the pinceau formed by basket cells. GAT-1-IR fibers and terminal-like structures were also found in the molecular layer (ML). Lower levels of GAT-3-IR were found in the Pc layer, confined to GFAP-IR structures that were identified as Golgi epithelial cells. Punctate GAT-3-IR structures were also found in the ML. Very low levels of GAT-1- and GAT-3-IR were detected in the granular layer. Thus, GAT-1 and GAT-3 display a differential distribution in the cerebellar cortex, where GAT-1 is preferentially localized to neurons and GAT-3 is preferentially expressed in astroglia. Accordingly, previous observations indicated that in the cerebellum, a high affinity GABA uptake system is present only in interneuronal and glial cells. One can further speculate that the predominant role of GAT-1 is in terminating GABA's action at interneuronal inhibitory synapses, whereas the predominant role of GAT-3 is in regulating the extracellular levels of GABA

640.1

AN ANALYSIS OF NEUROBIOTIN-FILLED STELLATE CELL AXONS IN THE RAT CEREBELLUM. <u>C. Pouzat* and S. Kondo.</u> Arbeitsgruppe Zelluläre Neurobiologie, Max-Planck-Institut für Biophysikalische Chemie, Am Faßberg, D-37077 Göttingen, Germany.

Stellate cells located in the upper molecular layer of the cerebellar cortex are known to inhibit Purkinje, basket, and stellate cells. They are usually separated into two classes, the short-axon type, supposed to mediate local (on-beam) inhibition and the long-axon type supposed to mediate distal (off-beam) inhibition. In order to understand their relative contribution to on-beam versus off-beam inhibition, especially for the long-axon stellates, we performed a quantitative description of their axonal arborization. Stellate cells from slices of rat cerebella (between 21 and 34 days postnatal) were filled with neurobiotin during tight-seal whole-cell recording, and stained with horseradish peroxidase/diaminobenzidine enhanced with nickel ammonium. 7 stellate cells were recovered with a well-filled and intact axon. 5 cells were of the long-axon type and 2 of the short-axon type. On 4 of them varicosities could be clearly seen. Quantitative analysis showed that the total length of the axon was 970±370 µm (m±5D) for the long-axon cells and 520 and 930 µm respectively for the two short-axon stellates. For the long-axon type the length of the main branch of the axon was 290±64 µm and the number of collaterals and their extension decreased markedly with the distance from the soma. Varicosities were homogeneously distributed along the axon. The average interval between varicosities was 6.8±2 µm. Homogeneous distribution of varicosities along the axon and condensed collateral distribution around the soma suggest, in contrast to the prevailing view, that the main role of long-axon stellate cells is on-beam rather than off-beam inhibition.

SPECIFICATION OF CORTICAL AND SUBCORTICAL POPULATION OF NEURONS REVEALED BY MONOCLONAL ANTIBODY 8B3. A. F. Pimenta*. P. L. Strick and P. Levitt. Dept. of Neuroscience and Cell Biology, UMDN:-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854 and Depts. of Physiol. and Neurosurg., SUNY-HSC @ Syracuse and VA Med. Ctr. Syracuse, NY 13210.

We previously generated a monoclonal antibody 8B3 that recognizes a condroitin sulfate proteoglycan expressed on the surface of somata and proximal dendrites of a subpopulation of neurons. In cortical areas, the staining pattern is characterized by a single row of cells on the border of layer I/II that is present in old world monkey and human, but absent in new world monkey, cat and rat, suggesting an evolutionary specification. There is a scattered population of neurons and intense neuropil staining in deep layers V and VI that is continuous over all cortical areas. A variable number of neurons are stained with stellate morphology in layers II through upper V depending upon the analyzed area. A large number of interstitial neurons is observed in the white matter of adult primate and human, whereas very few are observed in cat and rat, consistent with the fate of subplate neurons in these species. In the visual cortex 8B3 clearly demarcate the borders of area 17/18. At the subcortical level, 8B3 stains spiny stellate neurons in the striatum clearly defining a compartment that may correspond to the matrix. Neurons in the reticular nucleus of the thalamus are intensely labeled. In addition, in the rostral portions of the ventrolateral thalamus labeled cells form clusters. At more caudal levels, a large number of neurons are labeled and these are more evenly distributed. In the cerebellum, 8B3 marks the deep nuclei with striking ventral to dorsal gradient in the dentate. In the cerebellar cortex, a subpopulation of neurons with Golgi morphology is stained in the upper granular layer. Few neurons are labeled in deeper aspects of the granular cell layer. Within regions, 8B3 appears to be a marker for specific subpopulation of neurons that correspond to functional domains. Supported by NIMH grant MH45507 and VA Medical Research Service

POSTURAL RESPONSES TO LATERAL SURFACE PERTURBATIONS. S.M. Henry, * J.Fung, F.B. Horak. R.S. Dow Neurological Sciences Institute, LGSHMC, Portland, OR 97209.

The purpose of this study was to compare and contrast automatic postural responses to lateral and anterior/posterior (A/P) surface perturbations in narrow and wide stance in order to examine the neural and biomechanical factors characterizing postural strategies. Healthy adult subjects stood on a moveable platform with each foot on a force plate in both narrow and wide stance while undergoing 9 cm lateral and A/P surface translations at 35 cm/s. Bilateral 3-D ground reaction forces, joint positions, and lower limb and trunk muscle EMGs were recorded. For A/P translations, the EMG activation pattern was distal to proximal with a trunk flexor or extensor added early. In contrast, for lateral translations, the proximal tensor fascia latea muscle was activated first, followed by cocontraction of the distal muscles in the loaded leg. The EMG activation pattern did not change from narrow to wide stance, but the EMG amplitude was decreased in wide stance. The forces exerted by the feet against the surface during both lateral and A/P translations were primarily vertical. With A/P translations, there was loading/unloading of the A/P part of the foot whereas with lateral translations, there was loading/unloading of the right/left foot. For A/P and lateral translations, the kinematic corrective response was a shank, thigh, trunk pattern, allowing maintenance of a relatively erect trunk position. Thus, the trunk orientation goal is achieved using vertical contact forces and similar kinematic patterns via very different EMG synergies that are specific to the biomechanical constraints of A/P and lateral movement in order to maintain equilibrium. POSTURAL CONTROL IN A PATIENT WITH TOTAL BODY SOMATOSENSORY LOSS. F.B. Horak, Y. Lamarre, J.M. Macpherson*, C. Jones, S.M. Henry. R.S. Dow Neurological Sciences Institute, LGSHMC, Portland, OR 97209.

The critical role of somatosensory information for postural control.

The critical role of somatosensory information for postural control was apparent in a patient (GL) with complete large fiber neuropathy below cranial nerve VIII. The patient could stand unsupported up to 30 seconds only by using visual feedback in a mirror to prevent knee collapse. Bursts of muscle activity in the legs and neck in response to surface translations and rotations were directionally specific, although significantly late (270-800 ms). With eyes closed and auditory cues masked, however, postural responses were absent. Anticipatory postural adjustments prior to rapid arm raising were also absent. These results demonstrate that somatosensory information is essential for both réactive and predictive postural activity, although voluntary responses to perturbations can partially compensate using visual or auditory cues. Body tilt in response to bipolar, galvanic vestibular stimulation was opposite to the normal direction suggesting that somatosensory information is also critical for interpreting vestibulospinal disruptions of orientation of the body in space. Supported by NIA (RO1-AGO6457), NIDCD (R01-DC01849), and NIDCD/NASA (P60-DC02072).

FLEXIBILITY IN POSTURAL COORDINATION: THE EMERGENCE OF TASK-SPECIFIC POSTURAL PATTERNS. J. J. Buchanan* and F.B. Horak. R.S. Dow Neurological Sciences Institute, LGSHMC, Portland, OR 97209. Normal subjects and patients with profound bilateral vestibular loss stood on a sinusoidally translating platform (disp. = 12cm) whose frequency of motion varied across trials from 0.1 Hz to 1.0 Hz. Arms were folded across the chest with the feet shoulder width apart. For each platform frequency, the eyes were either open or closed. Subjects each platform frequency, the eyes were either open or closed. Subjects were instructed to maintain their balance without using their arms or hands, but were not given specific instructions on how to accomplish narids, but were not given specific postural coordination patterns emerged as a function of platform frequency: (1) head fixed to moving surface; and (2) head fixed in space. For platform frequencies equal to or less than 0.5 Hz, subjects rode the platform and the head moved in-phase with the platform (pattern 1). At platform frequencies above 0.5 Hz, subjects fixed their head in space relative to the platform, while the hips, knees and ankles flexed and extended in various combinations. (pattern 2). These observed changes in postural patterns were very similar with and without vision. Vestibular patients with their eyes opened produced postural patterns consistent with normal subjects, but marked differences with their eyes closed, i.e., large sway and stepping. Such results demonstrate that the CNS flexibly assembles task-specific postural coordination patterns as a function of displacement frequency and availability of sensory information. HEAD STABILIZATION IN LABYRINTHINE DEFICIT PATIENTS DURING HORIZONTAL AND VERTICAL PLANE ROTATIONS. K.J. Chen, E.A. Keshner. and B.W. Peterson*. Dept. of Biomed. Eng., Northwestern Univ. and Sensory Motor Performance Program, Rehab. Inst. of Chicago, Chicago, IL 60611

In previous studies (Keshner & Peterson 1995, Keshner et al. 1995) we found that both rotational frequency and instructional set influenced head stabilization. We have begun to study patients with bilateral labyrinthine loss. Head velocity and neck muscle EMG responses to 10° ramp and sum-of-sine (SSN) rotations of the trunk (0.025-3.15 Hz in yaw; 0.35-5 Hz in pitch) were examined in 3 patients and 8 healthy subjects. Subjects were seated in the dark and voluntarily stabilized their heads with (VS) or without (NV) visual feedback, or were mentally distracted (MA). In both planes, EMG responses to ramp rotations exhibited < 200 ms latencies. Neck muscle of healthy subjects exhibited activation that was compensatory to trunk motion, while patients exhibited no directionally consistent activation. In VS, SSN rotations in both planes produced compensatory head responses at low frequencies in both healthy subjects and patients. But in NV at low frequencies, normal subjects compensated for trunk rotations while patients could not. In MA, both normal subjects and patients showed no compensation during yaw rotations; in pitch, most normal subjects show reduced gains but compensatory phases, whereas patients' phases led compensation by 20°-40°. At high frequencies (>1 Hz), no differences were found between healthy subjects and patients in all paradigms. Yaw rotations caused increasing gains and decreasing phases of head velocity with resonance appearing between 1-2 Hz. Pitch rotations caused scattered gains and phases. Resonance occurred in the pitch plane in some subjects in the range of 2-5 Hz. EMG responses indicate that patients have diminished directional compensation of the muscles. During voluntary stabilization at low frequencies, patients required visual feedback in order to produce compensatory head motion. Variability at high frequencies in pitch may be due to individual system mechanics. Supported by NS22490, DC02072, DC01125.

DISTANCE-DEPENDENT SOMATOSENSORY DRIVE FOR HUMAN POSTURAL CONTROL: PRELIMINARY RESULTS. P. Ribeiro. K.S.Oie, Department of Kinesiology, University of Maryland, College Park, MD

When a subject lightly touches a moving surface with merely the fingertip whole-body entrainment to the moving somatosensory input is observed despite the fact that contact forces are inadequate to move the body. Small changes in contact force across the fingertip are thought to drive postural sway. The main focus in the present study was to investigate the influence of somatosensory cues at different locations relative to the body. The question was to determine if changing the distance and the height of a somatosensory stimulus relative to

the body affects its influence on head and body sway.

Six subjects were tested in a heel-to-toe stance while touching a rigid metal horizontal plate positioned laterally (on the right side) to the subject. Subjects were required to maintain contact forces below one Newton throughout each trial. The plate moved sinusoidally, 4 mm peak-to-peak, at 0.2 Hz in the medial-lateral plane in each condition. The three experimental conditions had the plate positioned: 1) close to the subject at waist level (Low-Close); 2) close to the subject at shoulder level (High-Close); and 3) at arm's length from the subject at shoulder level (High-Far). The results showed strong coupling between the somatosensory stimulus and body sway in all conditions. However, in the High-Close condition, head gain was greater than in the other conditions, which showed equivalent gain levels. These results suggest that somatosensory input is interpreted in a similar manner as visual cues, that is, stimuli far away from the body are interpreted as smaller than those close to the body, even when the ctual stimuli are of equivalent magnitude.

VESTIBULAR LOSS PATIENTS SHOW JOINT TORQUE RESPONSES ABNORMAL PERTURBATIONS

CF Runge, 1,2 CL Shupert, * 4 FB Horak, 4 FE Zajac, 1,2,3 | Rehab. R&D Ctr., VA Palo Alto HCS (153), CA 94304, Depts. of ²Mech. Eng. & ³Funct. Restoration, Stanford Univ., CA 94305 & ⁴R. S. Dow Neurol. Sci. Inst., Portland,

Normal subjects maintain balance during fast, rearward, supportsurface translations by combining hip strategy with ankle strategy. We hypothesized that patients with bilateral vestibular loss, who are unable to use hip strategy to control balance on beams, should show abnormal responses to these translations. Patients with profound bilateral vestibular loss and age-matched controls underwent 20-cm rearward support surface translations with velocities ranging from 5-35 cm/s presented in random order. As previously shown in normals, early (<50 ms) head accelerations increased systematically with platform velocity, and the range of head accelerations was similar for patients and normals in this study. However, using Karhunen-Loeve expansion techniques on the torque responses to 30-35 cm/s perturbations, we show that the stabilizing net joint torques at the hip and/or knee were abnormal and uncharacteristic of hip strategy in the patients. In contrast, trunk muscle burst onset patterns were not consistently different in the two groups. We conclude that while the vestibulospinal system may not be solely responsible for triggering the observed muscle responses, the magnitude and pattern of force produced by the muscles depend at least partially on westibular cues resulting from early head movements. SO WHAT HOLDS THE HEAD UP ANYWAY? G.C.Y. Peng*, T.C. Hain, B.W. Peterson. Northwestern University, Chicago, IL 60611

Holding one's head upright rarely requires any conscious effort. Yet, the head on the neck is intrinsically an unstable system. Particularly in the sagittal plane, the location of the head center of mass, anterior to the pitch axis, causes gravity to pull the head forward. Roberts (1967) postulated static positional reflexes act on the neck muscles, and suggested that these reflexes are driven by vestibular and proprioceptive inputs. We extended our sagittal plane head movement model, reported last year, to further explore these mechanisms. The extensions consisted of adding static otolith (sVCR) and positional neck (sCCR) reflex feedback to the existing dynamic feedback loops of the vestibulocollic (dVCR) and cervicocollic (dCCR) neck reflexes.

Our simulations demonstrated that without any reflex control, a smoothed 6° step input to the trunk caused the head to fall to 90°. This steady-state position is achieved when the moment due to the passive stiffness of the head cancels out the moment due to gravity. We found that either sVCR or sCCR control was individually capable of compensating for the effects of gravity. We tested our head holding mechanisms by changing the initial head and trunk posture to 30°. The head continued to remain aligned on the trunk, despite the additional gravitational torque at the offset angle. On adding the dynamic reflexes, head oscillations were significantly diminished, and caused the head with respect trunk movement to fall significantly diministred, and caused the feath with respect durin involvement within the range of human frequency response data. Although the sVCR is an accurate gravity compensator, combining the sCCR provided a better fit to human data. Utilizing the sCCR in conjunction with the sVCR required the otoliths to only compensate for 70 percent of the gravitational torque. We speculate that the redundant effects produced by both sCCR and sVCR allow for adaptive adjustments in one system to compensate for any weakness of the other. Supported by NS22490, DC02072.

FINGERTIP CONTACT SUPPRESSES THE DESTABILIZING EFFECTS OF LEG MUSCLE VIBRATION, J.R. Lackner*, P. DiZio, J.J. Jeka and E.Rabin. Ashton Graybiel Spatial Orientation Laboratory and Volen Center for Complex Systems, Brandeis University, Waltham, MA 02254.

Fingertip contact with a stationary surface greatly attenuates postural sway even at applied force levels (<100g) inadequate to provide mechanical stabilization. Sensory cues from the fingertip and proprioceptive information about arm configuration provide alternative spatial information about posture critical to stabilization (Jeka & Lackner, 1994. Exp Brain Res, 103:267-276). We studied here whether fingertip contact (<100g) could stabilize posture under conditions of instability induced by leg muscle vibration.

Subjects (N=10) were tested, eyes closed, in a heel-to-toe stance in four conditions involving either contact of the right index finger with a laterally placed surface at waist height (T) or no contact (NT), and with mechanical vibration at 120 Hz of the right peroneus brevis and longus muscles to elicit tonic vibration reflexes (PV) or without (NV): (NT NV), (T NV), (NT PV), (TPV).

Fingertip contact suppressed virtually completely the profoundly destabilizing effects of peroneus vibration on postural stability. Mean sway amplitudes and mean total powers of center of pressure and head showed the following pattern (NT PV) > (NT NV) > (T NV) = (T PV) with all differences significant (p<.01). In T trials, applied fingertip forces were always <100g. These observations point to the use of haptic cues in enhancing postural stability and locomotion in individuals with balance disorders

EVENT-RELATED POTENTIALS DURING THE EXECUTION OF VOLUNTARY AND COMPENSATORY REACH AND GRASP. W.E. McIlroy*!, W.R. Staines, J.D. Brooke and B.E. Maki! Sunnybrook Health Science Centre, Toronto, Ontario, M4N 3M5, and Department of Human Biology and Nutritional Sciences, University of Guelph, Ontario, N1G 2W1, Canada.

Complex compensatory limb movements, such as grasping, are commonly executed in response to whole-body postural instability. It has been proposed that the control of such compensatory reactions, which are initiated very early after the onset of perturbation, is distinct from voluntary grasping. To address this issue, the present study explored the temporal and spatial characteristics of cortical activity associated with compensatory and voluntary grasping. Subjects sat in a chair on a movable platform. Grasping reactions of the right upper limb to a handle located in front were cued by a light or by movement of the platform (backward translation). Samples were also collected during trials featuring whole body movement with no arm reaction to evaluate the event-related potentials (ERPs) associated with the sensory array arising from whole-body movement. ERPs were recorded from standard international 10-20 sites (C3, C4, P3, P4, F3, F4, T3, T4, Cz, and Cz') referenced to the left earlobe. EMGs were collected from deltoid, biceps and extensor digitorum of the right arm. Latencies of the perturbation-cued reaction, measured from EMG and measured from ERP onsets, were far more rapid than light-cued reactions. This occurred even though subjects were instructed to react 'as fast as possible' under both stimulus conditions. In spite of these temporal differences the underlying pattern of ERPs was similar between the two task conditions suggesting similarities in the involved cortical loci. Are these the ERPs for a triggered reaction? Specific behavioural correlates of ERP spatial loci are presently being explored.

The Stability of Standing Perturbations in Elderly and Young adults: A Dynamic Systems Perspective. M. Hoffman*, R. M. Angulo-Kinzler & D. M. Koceja, Motor Control Lab, Indiana University, Bloomington, IN 47405.

The control of the standing posture is essential for effective functional behavior. Humans are complex systems that demonstrate emergent solutions to motor problems. The preferred movement patterns that each individual demonstrates are called attractors. The stability of the attractor can be measured by its relaxation time after a perturbation. We investigated the stability of 9 elderly (age= 71.7 yrs) and 9 young (age= 27.2 yrs) adults' motor responses to perturbed standing. We elicited a 100% Mewave excitation (1 ms square wave pulse) in the left and right soleus while subjects were standing on a force platform with their eyes open. This perturbation produced a disequilibrium in the backward direction. Six trials were administered, but only the last four were included in the analysis. We analyzed the characteristics of the COP divided into three periods: preperturbation, active, and post-active. The active period was defined from the onset of the perturbation to the recovery of similar stability as in the pre-perturbation period. Significant differences were found in the duration of the active period between elderly and young adults (p=0.014). Furthermore, elderly show a tendency to converge to a different point in the state space after the perturbation. These results suggest that the standing strategy that elderly use is less stable than young adults and therefore, the effects of perturbations may place them more easily at risk.

MULTIVARIATE MEASURES OF POSTURAL CONTROL DURING ALTERED SENSORY CONDITIONS RA Speers, AD Kuo² and FB Horak² Program in Bioengineering and Dept. of Mechanical Engineering and Applied Mechanics, The University of Michigan, Ann Arbor, MI 48109-2125; Pa.S. Dow Neurological Sciences Institute, Portland, Oregon, 97209

Human postural sway is conventionally defined as a univariate measure of movement, usually of the center of gravity or center of pressure. We propose that sway is actually multivariate in character, such that more than one descriptor is necessary to fully characterize postural control during various sensory conditions.

The Sensory Organization Test (SOT) (EquiTest, Neurocom International,

The Sensory Organization Test (SOT) (EquiTest, Neurocom International, Clackamas, Oregon) examines postural response to six sensory conditions which alter the available visual and proprioceptive information. The SOT was used to collect data from a normal population of 12 young adults. Covariances of body kinematics during the SOT protocol were used as a general measure of multijoint sway, and are a superset of univariate COM or ankle sway. For multivariate sway, the covariances exhibit changes which a univariate measure such as COM variance might not detect. Multivariate sway descriptors based on the covariances were computed for each of the six SOT conditions for each of the subjects. Multivariate ANOVA found significant differences (p < 0.05) among the mean multivariate descriptors for the 6 SOT conditions. Discriminant analysis further identified contributions to postural response due to vision, platform sway-referencing, and visual surround sway-referencing, which univariate measures such as COM variance cannot capture. A computational model of sensorimotor integration and control supports these findings.

EFFECT OF TARGET DIRECTION ON REACHING MOVEMENTS IN YOUNG AND ELDERLY SUBJECTS. H. Chai and M.M. Gross. Center for Human Motor Research, Division of Kinesiology, University of Michigan, Ann Arbor, MI 48109-2214

Decreased postural stability in the elderly is associated with increased risk for falling.

Decreased postural stability in the elderly is associated with increased risk for falling. Although the effect of reaching on postural stability has been described for young and elderly subjects in the forward direction, less in known about postural stability during reaching in lateral directions. It is important to understand the effect of reaching direction on postural stability because lateral reaching is a common activity of daily life. Further, the risk of hip fracture is increased in falls with impact on the side of the hip.

The purpose of this study was to examine the effect of target direction on reaching movements in young and elderly subjects. We hypothesized that reach distance would be maximum when reaching towards targets located in the direction, would decrease when reaching for lateral targets, and would be less in the elderly subjects than the young for all target directions. Healthy elderly (> 65 yrs) and young adults (20-30 yrs) participated in the study. Subjects were asked to reach as fast as possible in each of four target directions (0°, 45°, 90° and 120° from the subject's midline). Markers were placed on the hand, wrist, elbow, shoulder, hip, knee, ankle, and MTP joints, and kinematic data were recorded with a 3D video-based motion analysis system. Subjects stood on a force platform and center of pressure excursions were calculated from the ground reaction force data. Reach distance was calculated as the difference between maximum reach and arm's length reach for the wrist marker.

Age affected movement speed and maximum reach distance. For the elderly subjects, movement time was greater but reach distance was less than in the young subjects for all target directions (p<01). The effect of target direction was the same for elderly and young subjects. Reach distance was maximum in the forward direction (0°) and minimum in the lateral direction (90° (p<01). However, reach distance was greater in the posterolateral direction (120°) than in the lateral direction (9°). Results showed postural stability was decreased during reaching in lateral directions for all subjects. However, instability was greater for the elderly regardless of reach direction.

641.12

CROSS-CORRELATION ANALYSIS OF THE HIP-KNEE COORDINATION STRATEGIES OF SQUATTING MOVEMENT IN HUMANS. A. Bengoetxea, J.P. Drave, B. Dan, M. Bourgeois, T. Pozzo and G. Cheron*. Lab. of Movement Biomechanics. Univ. of Brussels, U.B. Brussels, Belgium.

Nine normal human subjects were asked to perform rapid self-paced standing up movement from a initial squatting position. The whole body movements in the frontal plane were recorded by means of a 100 Hz optoelectronic ELITE system, that computed the coordinates of 11 small reflective markers placed on the principal joints. Electromyograph (EMG) patterns of 8 lower limb muscles on one side were recorded using telemetry, rectified and integrated. A four-link kinematic model was used to calculate body center of mass (COM) position in the sagittal plane. Angular velocity and acceleration signals of the hip, knee and ankle were obtained by digitally differentiating angular position signals. The goal of the study was to determine the strategies involved during the active phase of the standing up movement. For this purpose, a subset of each measured series of the angular acceleration were subjected to conjugate cross-correlation analysis. This analysis performed at the level of the hip, h(t), and knee, k(t), joints strongly indicates that there exist two common strategies denoted "in -phase" and "out-of-phase" strategy. For the "in-phase" strategy, recorded in 5 subjects, the cross-correlation function (CCF) between h(t) and k(t) presents a positive peak (the Z transforms of the CCF range from 0.6 to 1.15). Conversely, for the "out-of-phase" strategy, recorded in the 4 others subjects, the CCF presents a negative peak (from -0.45 to -1.7). Quantitative analysis of the first 100 ms of the EMG patterns (integrated area) of the mono-and biarticular muscles of the thigh and of the initial COM partition does not revealed any significant difference between the 2 strategies. Taken together these results suggest that the emergence of these strategies is not dependent on the initial conditions or the initial relative activation of the muscles but mainly reflects a more sublet time partitioning of the neural command.

641.14

Modulation of soleus H-reflex with varying visual and auditory input. G.A. Novak and D.M. Koceja*. Motor Control Laboratory and Program in Neural Science, Indiana University, Bloomington, IN. 47405.

Previous research demonstrates modulation of Hoffmann reflex amplitude with changes in visual input. However, we are unaware of any published studies investigating the modulatory effects of auditory and combined visual-auditory stimuli on H-reflex amplitude. In this study the effects of manipulating auditory and visual input were investigated in eight subjects (mean age = 24.4 years) under five experimental conditions: (1) control, (2) no visual input - no auditory input, (3) visual stimulus - no auditory input, (4) auditory stimulus - no visual input, (5) control. Subjects performed ten trials in each condition. The H-reflex was electrically elicited at the beginning of each trial by delivering a 1 ms square wave stimulation to the tibial nerve in the popliteal fossa of the right leg while standing. Average soleus background EMG, average tibialis anterior background EMG, (40 ms bin) and peak to peak amplitude of the soleus H-reflex were measured online for each trial (sampling rate = 2 kHz). A repeated measures ANOVA revealed significant decreases in H-reflex amplitude (p < 0.05) for all experimental conditions while background EMG remained constant. These results suggest that supraspinal mechanisms, possibly due to presynaptic or recurrent inhibition, modulate H-reflex amplitude across varying modes of sensory input.

RELATIONSHIP AMONG PRESYNAPTIC INHIBITION, H-REFLEX MODULATION, STATIC STABILITY, AND RECOVERY FROM POSTURAL PERTURBATION. R.G. Mynark^{1,2*}, D.M. Koccja^{1,2}, and C.A. Lewis¹. Motor Control Laboratory. ²Program in Neural Science, Indiana University, Bloomington, IN 47405

As the demands placed upon the body by movement increase, a subsequent decrease in the amplitude of the monosynaptic reflex response can be observed Recent studies have correlated this modulation to changes in presynaptic inhibition of la afferent nerve fibers prior to their synapse onto α -motoneurons. It has been hypothesized that the modulation of the H-reflex may be related to the ability to maintain static stability and recover from acute postural perturbation. The purpose of this study was to correlate the supine to standing changes in presynaptic inhibition and H-max/M-max ratio with measures of static stability and recovery from acute perturbation of balance. Changes in presynaptic inhibition from supine to standing were measured in six subjects (4 females/ 2 males; age = 31.8 \pm 6.7) using a heteronymous facilitation protocol as described by Hultborn et al. (1987). Modulation of H-max/M-max ratio between conditions was also measured. Static stability was tested during normal standing with eyes open on a Kistler force platform. Recover from acute postural perturbation was tested under the same conditions with perturbation elicited by a bilateral supramaximal tibial nerve stimulation. Results indicated a 46.9% increase in presynaptic inhibition, and a 13.0% decrease of the H-max/M-max ratio from supine to standing. Static stability testing yielded a mean sway area of 22.29 mm/s, while perturbation testing yielded a mean recovery duration of 1.81 seconds. Correlation analysis revealed a strong association between presynaptic inhibition and H-max/M-max ratio. Furthermore, results demonstrated a possible link between mechanisms of reflex modulation and the ability to recover from acute postural instability.

MECHANICS AND DYNAMICS

642.1

NEURAL COMPUTATIONS UNDERLYING THE EXERTION OF FORCE: A MODEL. B. Amirikian', A. V. Lukashin, A. P. Georgopoulos. Brain Sci. Ctr., Dept. of Veterans Affairs Med. Ctr., Minneapolis, MN 55417; and Dept. of Physiology and Neurology, Univ. of Minnesota Med. Sch., Minneapolis, MN 55455.

We have developed a model that simulates possible mechanisms by which supraspinal neuronal signals coding forces could converge in the spinal cord and provide an ongoing integrated signal to the motoneuronal pools whose activation results in the exertion of force. The model consists of a three-layered neural network connected to a two-joint-six-muscle model of the arm. The network layers represent supraspinal populations, spinal cord interneurons, and motoneuronal pools. We propose an approach to train the network so that, after the synaptic connections between the layers are adjusted, the performance of the model is consistent with experimental data obtained on different organisms using different experimental paradigms: the stiffness characteristics of human arm; the structure of force fields generated by the stimulation of the frog's spinal cord; and a correlation between motor cortical activity and force exerted by monkey against an immovable object. The model predicts a specific pattern of connections between supraspinal populations coding forces and spinal cord interneurons: the weight of connection should be correlated with directional preference of interconnected units. Finally, our simulations demonstrate that the force generated by the sum of neural signals can be nearly equal to the vector sum of forces generated by each signal independently, in spite of the complex nonlinearities intervening between supraspinal commands and forces exerted by the arm in response to these commands.

POSTURE DEPENDENT SENSITIVITY OF CHANGE IN GEOMETRICAL CHARACTERISTICS OF HUMAN ARM STIFFNESS ELLIPSE. H. Gomi 1 & R. Osu 2* INTT Basic Res. Labs. Kanagawa, Japan, 2ATR HIP Res. Lab. Kyoto, Japan. The sensitivities of the geometrical characteristics of arm stiffness at hand during force control in the horizontal plane were investigated, which are indexed by shape and orientation of stiffness ellipse and characterized by arm posture and ratios between shoulder, elbow, and double-joint stiffness. The subjects, four people 23-33 years old, were restrained by straps in front of a manipulandum controlled by a position servo. The hand was tightly coupled with the handle of the manipulandum and supported in the gravity direction. The subjects were requested to push the handle and keep a specified force (0, 5, 10, 15 N) in a certain direction (among 8 directions) assisted by a force vector on a computer monitor without cocontraction. To keep muscle activities constant through one condition, rectified and filtered EMG of six muscles were also monitored. The hand was slightly pushed and pulled back in randomized eight directions within a brief period (0.3 s) (24 times under each condition). The arm stiffness parameters under each condition were estimated by least square error method.

International control of the desired in the reach condition were estimated by least square error method.

At the distal hand position, as previously studied, geometrical characteristics, shape and orientation of stiffness ellipse, derived from arm stiffness matrix, were not much altered under different requested conditions. At the proximal hand position, those characteristics, however, were much altered. On the other hand, the ratios between joint stiffness components were greatly changed according to the force direction at any hand positions, although double-joint stiffness values mainly contributed by double joint muscles were always lower than the elbow and shoulder single joint stiffness mainly contributed by single- and double-joint muscles. From sensitivity analyses, it has been revealed that the shape and orientation of ellipse are insensitive to the changes of the joint stiffness ratios at the distal hand position, and are sensitive to those changes at the proximal hand position. In other words, slight changes of goint stiffness ratios. The experimental results partially support the opinions that the human can change not only size but also geometrical characteristics of stiffness ellipse by regulating joint stiffness ratios (Hogan 1985), and that joint stiffness values under force resisting conditions are related to joint torques (Gurevich 1993).

TRANSFORMATION OF SPIKING ACTIVITY OF MOTOR-CORTICAL CELLS INTO MOTOR OUTPUT OF AN ACTUATOR. A. V. Lukashin B. Amirikian, A. P. Georgopoulos. Brain Sci. Ctr., Dept. of Veterans Affairs Med. Ctr., Minneapolis, MN 55417; and Dept. of Physiology and Neurology, Univ. of Minnesota Med. Sch., Minneapolis, MN 55455.

Neurophysiological studies have shown that the direction of motor output (movement or isometric force) is markedly related to the activity of motor cortical cells. One problem in motor control concerns the mechanism whereby the central nervous system translates the motor cortical command encoded in temporal series of action potentials (spike trains) into balanced activation of limb muscles to produce precisely directed movement or force. The aim of the present report is to examine whether and how the natural spiking activity obtained from recordings in the motor cortex of monkeys while the animals performed a visuomotor task can be transformed into the motor output of a simulated actuator that mimics the primate's arm. The transformation is done by an artificial neural network using experimental spike trains as the input activity, whereas the output activity controls the contraction of actuator "muscles". The actuator responds to the motor cortical signals with surprising fidelity, both for the temporal and the spatial characteristics of the performance, often matching the performance of trained monkeys. Moreover, we show that the motor output at each instant of time may be controlled by spiking activity of as few as 15 motor-cortical cells. These results suggest a simple analog scheme for real-time biological signal processing.

AFFINE DIFFERENTIAL GEOMETRY ANALYSIS OF HUMAN ARM PRAJECTORIES.

T. Flash, A. A. Handzel. Dept. of Applied Mathematics and Computer Science, Weizmann Institute of Science, Rehovot, 76100, Israel.

A mathematical framework based on differential geometry, Lie group theory and Cartan's moving frame method was developed for the analysis of human hand trajectories. According to Lacquaniti et al. (1983) drawing movements obey the two-thirds power law: $A=KC^{2/3},A,C$ and K are the angular velocity, Euclidean curvature and the piecewise constant velocity gain factor. We show that within each segment the unimodular affine arc length ($\sigma = \int C^{\frac{1}{3}} ds$) is proportional to movement time. The trajectories of a one-parameter subgroup of unimodular affine transformations are conics or straight lines $x = x_0G$; detG = 1. The affine curvature χ is conserved in this process and is constant along the trajectory and the curve has no inflection points. Thus, conics (the parabola, ellipse and hyperbola with $\chi=0,>0,$ and <0, respectively) are the orbits of some point under the action of $G=\epsilon^{\sigma v}$ where v is the Cartan matrix with zero trace that depends on χ which is the simplest non-trivial affine differential invariant. Parabolas are the unimodular affine geodesics. The time scaling property of human movements is equivalent to keeping the affine arc length invariant under speed changes. For an ellipse $L=2\pi^2A_r^{\frac{1}{3}}=KT$ where L, A_r and T are the ellipse's perimeter, area and movement duration, respectively. Georgopoulos et al., (1988) and Schwartz (1993) showed that the movement velocity vector is represented by N, the neural population vector. We show that a variational principle based on Nand $\frac{dN}{dt}$ leads to the two-thirds power law and is consistent with a Kepler's like law whereby $(\frac{d\sigma}{dt})^3 = N \times \frac{dN}{dt} = K$. Affine differential invariants were used to examine movement segmentation and classification

RECONSTRUCTION OF JOINT EQUILIBRIUM TRAJECTORIES DURING UNRESTRAINED ARM MOVEMENTS. <u>M.L. Latash* and A.S. Aruin.</u> Department of Kinesiology, The Pennsylvania State University, University Park, PA 16802, USA.

The framework of the equilibrium-point (EP-) hypothesis was used to reconstruct equilibrium trajectories (ETs) in the elbow and in the wrist during fast voluntary movements in one of the joints. Natural movement variability was used as the source of perturbations that are necessary to reconstruct ETs based on a series of trials at the same motor task. A second-order linear model was used to calculate the instantaneous position of the joint compliant characteristic at different times during the movement. Time patterns of active joint torques were calculated using the inverse dynamics techniques. ETs in the focal joint were N-shaped, similar to ETs described earlier for single-joint movements. ETs in the "postural" joint represented a single oscillatory cycle whose peaks coincided with the peaks of the N-shaped ETs in the focal joint. Peak-to-peak ET amplitude in the wrist during elbow movements could be of a similar amplitude or even bigger that peak-to-peak ET amplitude in the elbow. Note that the actual trajectory in the "postural" joint was an irregular, low-amplitude flapping while the actual trajectory in the focal joint was a typical, sigmoid curve. Reconstructed ETs corresponded well to the EMG patterns in the flexor-extensor pairs recorded during the same movements. We suggest an explicit relation among control variables to the two joints as suggest an explicit relation among control variables to the two joints as the foundation of a simple synergy whose purpose is to preserve control over the trajectory of the limb's endpoint in the presence of joint coupling. Origins of the Power Law Relationship between Movement Velocity and Curvature: The Effects of Muscle Mechanical Properties and Limb Dy-

Paul L. Gribble* and David J. Ostry, McGill University, Montreal, Canada.

When subjects trace patterns such as ellipses, the instantaneous velocity of movements is related to the instantaneous curvature of the trajectories according to a power law --- movements tend to slow down when curvature is high and speed up when curvature is low. It has been proposed that this relationship is centrally planned. However, kinematics are the result of the interaction of central control with muscle mechanics and limb dynamics, and even under isometric conditions, muscle mechanical properties can affect the development of muscle forces and torques. Thus without a model which accounts for these effects, it is difficult to distinguish between kinematic patterns which are attributable to central control and patterns which arise due to dynamics and muscle properties and are not represented in the underlying control signals. In this paper we address the role of muscle mechanical properties and dynamics in the emergence of the power law. We use a mathematical model of arm movement control based on the λ version of the equilibrium-point hypothesis. We demonstrate that simulated elliptical and circular movements, and elliptical force trajectories generated under isometric conditions, obey the power law even though there was no relation between curvature and speed in the modelled control signals. We suggest that limb dynamics and muscle mechanics specifically, the spring-like properties of muscles -- contribute significantly to the emergence of the power law. This research was supported by grants from NSERC, Canada, and FCAR, Quebec

COUPLING OF MUSCLE ACTIVATION IN SINGLE AND TWO JOINT PLANAR MOVEMENT ABOUT THE WRIST AND ELBOW. E. Oguni*, K.K. Maitra and J. D. Cooke. Appl. Health. Sci., Univ. Western Ont., London, ON, Canada N6G 1H1.

London, ON, Canada N6G 1H1.

In this study we address the issue of whether the central nervous system compensates for reaction torque at the elbow due to wrist movement. We examined the relation between movement in the phasic muscle activation in planar arm wrist movement. We examined the relation between movement kinematics, dynamics and the phasic muscle activation in planar arm movements involving wrist and elbow. Movements were made with different loads (0 -1.0 kg) at the hand. Subjects made movements about only wrist (amplitude 10 - 50 deg), only elbow (amplitude 10 - 70 deg) or both in a step tracking paradigm. In movements involving only the wrist or elbow the other joint was not restrained.

Movement about the wrist alone caused small (<10 deg) transient and oppositely directed elbow movement. These were amplitude and load dependent. Movement about the elbow only caused wrist movement in the same direction (< 20 deg), the amplitude varying with elbow amplitude but not load. In two joint movement, wrist movement always started and ended ahead of elbow

movement, wrist movement always started and ended ahead of elbow movement. In all cases agonist-antagonist activation pattern at the elbow and wrist were time locked with each other. However, magnitude of activation depended on the torque and task specification. Compensation for reaction torque was observed at the wrist but occurred at the elbow only during two-joint movement with

The data suggest that the CNS utilizes common programming for movements of any or all of the elbow-forearm-wrist-hand segments. EMG magnitudes are matched to the task and force requirement.

MUSCULOSKELETAL CONSTRAINTS ON THE NEURAL CONTROL OF REACHING. C. A. Buneo*, J. F. Soechting, and M. Flanders. Dept. of Physiology, Univ. of Minnesota, Minneapolis, MN 55455

We have previously described a method for obtaining in vivo estimates of human shoulder muscle actions across a range of arm postures (Buneo et al., 1995). To completely characterize the variations in muscle action with changes in arm posture, a multiple regression analysis was performed. The analysis revealed that muscle actions depended linearly on the parameters describing three-dimensional arm posture; the inclusion of nonlinear (quadratic and/or cubic) terms did not substantially improve the fit to the data. For most muscles, the actions predicted by this analysis could be approximated by models of musculoskeletal geometry which included effective origins and insertions that remained fixed to the body and arm, respectively, during changes in arm posture. The actions of some muscles (e.g., Middle Deltoid), however, could only be adequately described by allowing for movement of the effective origins and insertions relative to their respective body segments. The results demonstrate that muscle lines of action do not move entirely with the arm, an important consideration in the design and interpretation of experiments pertaining to neural representations of arm posture. MUSCLE PROPERTIES PREDOMINATE IN DETERMINING FORM OF DYNAMIC MOVEMENTS. A.M. Krylow, J.D. Given*, and W.Z. Rymer. Sensory Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, IL 60611,

and Department of Biomedical Engineering, Northwestern Univ., Evanston, IL. 60208. In models of motor control, it is often assumed that muscles act as simple torque generators or conservative springs. Likewise, it has been suggested that reflexive inputs active during movement strongly modify muscle actuator properties. Such reflex modifications are often presumed to be so powerful that comparisons with mechanical properties observed in areflexive muscle preparations are irrelevant to movement control issues. We studied the influence of muscle properties in human subjects on the control of inertially loaded, single DOF movements at the wrist. Comparisons were also made

to mechanical behavior of reduced animal preparations under similar loading conditions.

Two experimental protocols were performed. In the first, subjects moved a simulated inertial load as quickly as possible by flexing their wrist from an initial angle. In the second, subjects moved the loaded wrist between specified initial and final angles in the second, subjects invest the coacted wisto detected in the analysis in the flexion direction. Additionally, they were required to match the peak decelerating torque to a predefined level (~20% of MVC). Loads ranging from 1 to 50 times the hand inertia were applied. Wrist angle, velocity, net torque, and electromyographic (EMG) signals from one primary wrist flexor (FCR) and extensor (ECRB) were recorded.

Results of the first protocol show characteristic torque time courses and peak values

that vary substantially and systematically with load. Larger loads allow production of larger torques at the expense of movement speed. Very similar force profiles are produced in inertially loaded, isolated muscle using constant electrical stimulation. The second protocol shows that although time scaled angle and torque profiles, and normalized velocity profiles are nearly superimposable, agonist EMG amplitudes scale strongly with changes in load with matched torques. This scaling of EMG amplitude is absent in the antagonist. These findings indicate that 1) muscle mechanical properties like those seen in isolated preparations provide strong constraints on dynamic performance of intact subjects, and 2) the asymmetric muscle responses observed in isolated shortening versus lengthening muscle are clearly operating during normal movements, with little evidence of strong reflex modification. SIMULTANEOUS ACTIVATION OF MUSCLES FOR TWO-JOINT ARM MOVEMENTS IN DOWN SYNDROME M. M. E. A. Inoue, G. L. Almeida, D. M. Corcos and Z. Hasan*. Universidade Estadual Paulista, SP, Brazil, Universidade Estadual de Campinas, SP, Brazil, and University of Illinois, Chicago, U.S.A. Studies on individuals with Down Syndrome (DS) have suggested that their

multijoint arm movements may involve an abnormal, distal-to-proximal sequencing of muscle activity.

We examined the kinematics and electromyographic (EMG) activity for horizontal-plane arm movements in 8 DS and 8 age-matched NN subjects. Th rested on supports that could slide freely on the surface of a table. Subjects moved "as fast as possible" to a visible target, and returned immediately to the initial position. Four target locations were employed, for which the required elbow angle excursions were comparable, but the required shoulder angle excursion varied from 10 deg abduction to 75 deg adduction. EMG onsets were determined from pectoralis major, posterior deltoid, the biceps and triceps brachii muscles.

The movements of DS subjects were slower and less smooth than NN's; we did not, however, observe abnormalities at motion reversal such as those described for deafferented subjects. The EMG onsets for DS subjects were markedly different from deatterented subjects. The EMG onsets for DS subjects were markety unfertent mothose for NN subjects. For the latter, the EMG onset time difference for any 2 of the 4 muscles varied systematically with target location. The 6 pairs thus examined included muscles antagonistic to each other, and muscles acting primarily on different joints. DS subjects, in contrast, exhibited almost simultaneous activation of all 4 muscles, and the onset time difference for none of the 6 pairs of muscles varied with target location.

Our results do not support the idea that DS individuals use a distal-to-proximal sequence of muscle activation; instead, their coordination deficit is reflected in an inability to modulate the onset times of different muscles with changes in task

AUTOSCALING OF PERCEIVED MUSCLE OUTPUT, G.I. Boorman, V.R. Edgerton, J.A. Hodgson, C. Goulet, A. Garfinkel*, Dept. Physiol. Sci. Univ. California, Los Angeles 90095-3149.

Perception of muscle force derives preferentially from central signals related to the output pathways. Most studies of force perception have examined either single output levels or narrow ranges of muscle contraction. Reports of experiments examining the full range of muscle output are contradictory when describing the shape of the relationship, with some reporting a linear form, and others reporting a curvi-linear relationship. The present study was undertaken to characterize perception of the full range of muscle output. Isometric muscle contractions were examined at both the ankle and elbow in 14 subjects who were requested to contract muscle groups at levels which were described as a percentage of maximal output. At each request the subject contracted the muscle group at an output level perceived to match the request. No feedback relating to the muscle contraction was given to the subject. The relationship between measured and requested outputs, as determined by examining actual torque and EMG outputs across the full range, was well fit by a line with slopes commonly close to unity. Moreover, when torque levels were reduced by altering the joint angles, the slopes and y-intercepts of the relationships were unchanged. These observations demonstrate that autoscaling of perceived muscle output occurs, such that the nervous system continually senses a constant range of muscle output. The simplest model which explains these findings is that, as suggested by others, force is perceived by way of a corollary discharge of the motor output. Additionally, these data examining the full output range demonstrate that the corollary discharge is an invariant proportion of the output signal, a scheme which might benefit higher motor centers by reducing the time required to rapidly appraise novel plans for changes in ongoing motor outputs.

THE RELATIVE IMPORTANCE OF OPEN-LOOP AND ERROR-DRIVEN MECHANISMS IN HUMAN LOAD HANDLING. P.R. Burgess*, C.F. Buhler, T.A. Cooper and L.F. Jones. Dept. Physiol., Univ. Utah Sch. Med., Salt Lake City, UT 84108.

The relative importance of open-loop and error-driven mechanisms in normal motor behavior is a fundamental question which remains unresolved in spite of long-standing recognition of its importance. In this study, subjects raise a weight an unspecified distance and then lower it in their own time. The kinesthetic and visual feedback loops are then opened by making muscular force generation isometric and the precision and accuracy of the subject's force control is again evaluated. The kinesthetic and visual loops are not opened in the sense of being physically cut in the isometric situation but are dissociated from subsequent mechanical events; a motor feedback pathway is functionally open when it can no longer respond to changes in muscular force produced by the open-loop controller. Under isometric conditions, the subject can produce muscular force either with the aid of force feedback or with an unregulated openloop model, whichever is most effective. Thus, this approach defines an upper limit for open-loop capability and will overestimate that capability if, as seems likely, force feedback enhances performance. In preliminary studies where the subject is to raise the lighter but not the heavier of two weights, force control under isometric conditions (weight not lifted) is relatively poor compared to force control under isotonic conditions (weight lifted). The current conclusion is that open-loop performance is poor compared to the force control required by the mechanics of load handling.

NONLINEAR DAMPING PROPERTIES OF THE MUSCLE/REFLEX SYSTEM WITH INERTIAL LOADS. D.C. Lin* and W.Z. Rymer. Depts of Biomedical Eng.

WITH INERTIAL LOADS. DC. Lin* and W.Z. Rymer. Depts of Biomedical Eng. and Physiology, Northwestern Univ., Chicago, IL. 60611.

The dependence of reflex response on length, velocity, and frequency has been well characterized in length controlled conditions. However, the maintenance of posture requires these properties to interact via a load, often dominated by inertia, and it is difficult to extrapolate how they combine to damp perturbations. Therefore the objectives were: (1) to identify special damping properties of the muscle/reflex system with an inertial load and (2) to determine if there is compensation for load variations.

Data were collected from the soleus muscle in a decereberate cat. A background

Data were collected from the soleus muscle in a decereberate cat. A background force was generated by the crossed-extension reliex and a force impulse was then imparted on the load, stretching the muscle and resulting in an oscillatory motion. Both the magnitudes of the impulse and inertia were varied.

Damping within a given trial was measured by calculating the logarithmic velocity decrement of each oscillation cycle. For a given mass, the damping increased with the amplitude (both displacement and velocity) of oscillation. The force-length plot

amplitude (both displacement and velocity) of oscillation. The force-length plot revealed that energy dissipation occurred almost exclusively during the shortening phase of the cycle, while the lengthening phase behaved like a mass-spring system. Damping across masses was assessed with two methods. First the slope of the damping-displacement relationship should decrease as mass increases because velocity decreases as mass increases for a given amplitude. Yet the slope did not statistically decrease, implying that damping also increased with mass. Secondly, the calculated time constant of exponential decay decreased by approximately m 1/3, compared to the m-1 decrease of a linear system.

compared to the m 'decrease of a linear system.

The nonlinear damping properties of the muscle/reflex system are significant in determining the response of an inertial load to a perturbation. The amplitude dependent relationships provide more damping for bigger oscillations which can result from either a larger perturbation or inertia. In addition, the decrease in damping was not as sensitive to an increase in inertia as a linear system, indicating the reflex response is well tuned for compensating for load variation.

THE CONTRIBUTION OF STOCHASTIC PROCESSES TO VARIABILITY IN CONTINUOUS FORCE PRODUCTION

A.B. Slifkin* and K.M. Newell. Depts. of Biobehavioral Health and Kinesiology, Penn State University, U. Park, PA 16802.

Traditionally variability in motor behavior has been viewed as a reflection of the stochasticity (noisiness) of perceptual-motor processes. The purpose of the present research was to provide an explicit test of the assumption that a positive correlation exists between variability and noise in force production. Accordingly subjects (n = 10) produced force over continuous, extended periods (30 s) at different levels (3, 6, 12, 24 & 48%) of their maximum voluntary contraction (MVC). Here, measures of variability were the within-subject standard deviation (SD) and the coefficient of variation (CoV) for force production. Approximate entropy (ApEn) and the power spectrum (PS) were used to index the noise content of force output. For example, a pure sine wave, reflecting an absence of noise, has low ApEn and a PS with all power at a single frequency. On the other hand, random white noise, which has been taken as the signature of maxir stochasticity, has high ApEn and equal power at all frequencies of the PS. Results revealed that the SD increased exponentially and CoV of force output decreased exponentially as the criterion level of force increased. Despite increases in target force level, the PS remained sharply peaked with almost all power confined to a narrow bandwidth (1-5 Hz). Furthermore, ApEn was quite low and did not change across the range of force requirements. These findings suggest that the increment of force variability with level of force output is not due to greater noise as reflected in greater randomness of force output. The concepts of variability and noise are not synonymous in motor control.

MAXIMAL USE OF REFLEXES IN THE CONTROL OF THE FASTEST MOVEMENTS: REFLEX-DEPENDENT CHANGES IN THE ONSET TIME OF AGONIST ACTIVITY M. F. Levin*, S. V. Adamovich and A. G. Feldman, Institut de réadaptation de Montréal, Montreal, Qc H3S 2J4, Canada & Institute for Information Transmission Problems, Acad Sciences, Moscow

The convergence of descending and reflex pathways on common interneuron and motoneurons implies that active movements may result from changes in reflex parameters produced by control signals. We hypothesized that control systems may exploit rather than suppress reflexes during fast movements. Consequently, external perturbations may be ineffective in eliciting additional reflex modifications of EMG patterns unless they are relatively strong. This may account for the relatively weak effects of perturbations on the initial agonist EMG burst (Agl) observed in fast movements. On the other hand, there may be robust reflex modifications of the timing and shape of Ag1 in response to strong perturbations. In control trials, subjects made fast unopposed 60° elbow flexions (peak velocity >500°/s) in response to an auditory signal. In random test trials, a brief (50 ms) torque of 8-15 Nm either assisting or opposing the movement was applied 50 ms after this signal. Subjects had no visual feedback and were instructed not to correct arm deflections. In all subjects, the onset time of the Ag1 depended on the direction of perturbation: about 37 ms less in opposing compared to assisting load conditions. Assisting torques caused a short latency (37 ms) additional antagonist EMG burst preceding the Ag1. Our results suggest that the direction-dependent changes in the onset and duration of Ag1 as well as the antagonist activation preceding Ag1 resulted from stretch reflex activity elicited by the perturbations rather than from a change in the control strategy. Results are consistent with the hypothesis that control systems exploit proprioceptive reflexes in the production of even the fastest movements. INTERLIMB COORDINATION PATTERNS DURING ASSYMETRICAL REACHING MOVEMENTS. <u>V. Hatzitaki¹ and P.A. McKinley²*</u>, Dept of Physical Education¹, School of Physical and Occupational Therapy², McGill University, Montreal Canada, H3G 1Y5

The purpose of the present study was to examine intersegmental dynamics and muscle activation patterns of discrete asymmetric bilateral reaching movements. Our goal was to determine if torque production at the joint is scaled according to the level of asymmetry introduced by bilateral variations in movement amplitude as previously suggested (Marteniuk et al, Quart J Expt Psych 36A: 335-365, 1984; Walter & Swinnen, Brain & Cognit 14:185-200, 1990). Adult, right-handed male subjects (N=10) executed bilateral reaching movements in the horizontal plane. Randomized block trials (n=40) consisted of symmetrical full-reach movements and 2 asymmetrical movements where the preferred arm reach was reduced to $\,75\%$ and 50%of full-reach respectively. EMG from the pectoralis, deltoid, triceps and biceps muscles was filtered (15-500Hz), collected online (1000Hz) and synchronized with kinematic data from shoulder, elbow and wrist(240Hz, Ariel systems). Inverse dynmamics were used to generate inertial, muscle and net joint torques which were expressed with respect to an interlimb decoupling coefficient (right:left integrated torque or T). During the acceleration phase, constrained limb antagonist muscle onsets were earlier and muscle T scaled according to the level of asymmetry at both the shoulder and elbow, across subjects. By contrast, agonist muscle onset was immutable, while inertial T was preferentially affected by only one of the levels of asymmetry, and was subject specific. During deceleration, degree of asymmetry was reflected primarily in inertial T. Taken together, these results suggest that decoupling is effected during the acceleration phase by a mutable onset of the antagonist muscles which scale the muscle torque and limb stiffness. This controlling behavior results in the inertial \emph{T} differences observed in the deceleration phase. Supported by NSERC

CATS USE MULTIPLE COORDINATION PATTERNS TO ACHIEVE THE SAME MOTOR TASK UNDER DIFFERENT INERTIAL LOADS. K. D. Statler. E. A. Keshner*, S. L. Delp, and B. W. Peterson. Sensory Motor Performance

E. A. Keshner*, S. L. Delp, and B. W. Peterson. Sensory Motor Performance Program, Rehab. Inst. of Chicago, Dept. of Biomedical Engineering and Dept. of Physiology, Northwestern University, Chicago, IL 60611.

Simultaneous video-fluoroscopic and neck muscle EMG data were recorded from one cat performing ±15° sinusoidal (0.25 Hz) head tracking movements in the sagiital plane. The cat performed the movement in a standing body posture with two different starting neck orientations and four different inertial loads. Radio-opaque markers were inserted into the anterior/posterior and lateral aspects of the occipital ridge and C₁-C₇ to measure vertebral displacement. Kinematic data of the head and neck were analyzed using a computer model. The model was used to characterize the limits of movement in the cervical The model was used to characterize the limits of movement in the cervical spine and to estimate the moment arms of the neck muscles at different orientations of head-neck movement. Experimental results showed that for each initial neck orientation the cat utilized a distinct set of vertebral alignments. relative joint movements, and muscle activation patterns to achieve the same movement outcome. As inertial load increased, vertebral alignments and relative joint movements were constant, but muscle activation patterns varied. The model predicted that muscle moment arms would vary little for the different the model predicted that muscle moment arms would vary little for the difference vertebral alignments chosen by the cat to complete the task. Increasing the mass on the cat's head was expected to produce a generalized increase in EMG responses. We found, however, that rectus capitis and splenius EMG gains increased with increased mass, but complexus EMG gains decreased with increased mass. Biventer cervicus and occipitoscapluaris EMG gains initially increased, but then remained constant as mass was increased. EMG phases were not affected by changing the mass of the system. The data indicate that different muscle activation patterns were used to maintain the same kinematic pattern when the cat completed the tracking task with increased inertial loads. EMC PATTERNS: AGE DIFFERENCES IN A SELF INITIATED, SPEED CONSTRAINED MOVEMENT R. D. Seidler & G. E. Stelmach*, Motor Control Laboratory, Arizona State University, Tempe AZ 85287-0404

The purpose of this investigation was to explore the ability of elderly adults to control braking force activity. The issue addressed was whether antagonist activity is improperly timed in the elderly. Constant amplitude, submaximal speed elbow flexion movements were performed under three different inertial load conditions. Seven young adults and seven elderly adults performed the elbow flexion movements through the horizontal plane while grasping a lever manipulandum. Lever movements were represented in real time by corresponding left (for elbow flexion) and right (for elbow extension) movements of a cursor on a monitor located in front of the subjects. Movement times were constrained via a metronome for both groups to the range of 650-950 ms for a 30 degree flexion movement; trials not meeting the duration criterion were excluded from further analysis. Fifty trials were performed for each of the load conditions. Results demonstrated that the elderly scaled both agonist (AG) and antagonist (ANT) activity to increasing load in a similar manner to young subjects. Despite this, the elderly did not consistently time the cessation of ANT activity such that the offset preceded the initiation of the AG1 burst. In addition to this temporal activation error, the elderly exhibited high tonic ANT activity throughout the movement, possibly to increase control over the manipulandum. This tonic ANT cocontraction combined with the incomplete ANT cessation prior to AG1 initiation resulted in velocity profiles that were flatter and more symmetrical for the elderly than for the young. Results are discussed in terms of implications regarding the aging motor control system.

CHARACTERIZATION OF ARM MUSCLE ACTIVITY IN A FREELY MOVING OCTOPUS (Octopus vulgaris), Y. Gutfreund¹, G. Fiorito³, T. Flash², I. Segev¹ and Y. Yarom¹, B. Hochner*¹. ¹Department of Neurobiology, The Hebrew University, Jerusalem, Israel. ²Department of applied mathematics. The Weizmann Institute of Science, Rehovot, Israel. ³Department of Neurobiology, Zoology Station, Naples, Italy.

The extreme flexibility of the octopus arm enables it to perform a large repertoire of different movements. Combining kinematic studies of arm movements with physiological studies of muscle activation provides an important step towards understanding of the neuronal control mechanism underlying the generation of these movements. In a previous study we described a basic invariant motor structure in arm extension - a bend in the arm that travels from its base towards its tip. In the present study we measured the muscle activation (EMG) that accompanied this movement. Stainless steel, electrodes were implanted in the arm musculature of an anesthetized octopus. Following recovery from anesthesia, a target was lowered into the water to initiate arm movements. The movements were recorded on videotape synchronously with muscle activity. The results show that the traveling bend is associated with a propagating wave of muscle activity. Maximal muscle activity was recorded slightly before the traveling bend reached the recording site and occasionally tonic activity was maintained afterwards. In order to correlate the level of activity to the movement velocity the EMG signals were rectified and integrated over various time windows. The integrated EMG measured at the time in which the bend passed the electrode site, was positively correlated with the peak velocity of the bend movement. The peak velocity usually occurred distally to the recording site. Based on this observation and on the invariance of the bend velocity profile we suggest that the velocity of the bend propagation is controlled, in a feed forward way, by adjusting the level and velocity of propagation of muscle activity. CONTROL OF POSTURE AND MOVEMENT: KINEMATICS

643.1

KINESTHETIC CONTROL OF A THROWING MOVEMENT. W.G. Darling* M. Pizzimenti, M. Treinen Department of Exercise Science, Iowa, Iowa City, IA 52242.

Recent studies on the role of proprioception in control of throwing-type movements by Cordo and colleagues (e.g., Cordo; J Neurophysiol 64:161) have used a constrained task involving supported horizontal plane motion of the forearm at the elbow. However, when throwing under less constrained conditions the motions usually involve more joints and release time of the ball may be a function of the forearm position relative to an external axis such as gravity. It is well known that humans have an excellent static sense of forearm angle relative to gravity. Thus, the purpose of this study was to examine the use of kinesthetic information on forearm angle in space during dynamic throwing movements.

We investigated this issue by examining kinesthetically guided throwing movements. Seven subjects were instructed to move the arm in the sagittal plane and to release the ball when the forearm was horizontal. Six different experimental conditions involving manipulations of initial shoulder, elbow, and trunk/head angles during active throwing and in a passive task in which the forearm velocity was varied by attaching weights to the forearm were studied. Forearm angle at ball release averaged about 0.4 rad above horizontal and did not differ in the different conditions. Thus, subjects were not accurate in their estimation of horizontal forearm position in this dynamic task. Variability of forearm angle at release was similar in unconstrained throwing and when starting elbow and shoulder angles were manipulated. In contrast, manipulation of trunk angles increased such variability (p < .05). These data show that our dynamic perceptions of forearm angle relative to horizontal are rather poor and that manipulations of trunk/head angles strongly influence such perceptions.

VELOCITY PROFILES OF ARBITRARY DRAWING MOVEMENTS ARE WELL PREDICTED BY A MODIFIED MINIMUM-JERK PRINCIPLE. E. Todorov, M. Jordan, E. Bizzi*, Brain & Cognitive Sciences, MIT, Cambridge MA.

The trajectories of simple arm movements are well described by the minimum-jerk principle (Flash & Hogan '95), which states that arm movements constrained to pass through a set of via-points are maximally smooth (the mean squared jerk is minimized). However, it is not clear how to apply this principle to tasks where the spatial constraints are not specified as via-points. Furthermore, it fails to predict the observed arm trajectory in some single via-point tasks (Uno et al. '89). Here we demonstrate that in multiple via-point tasks the deviations from the minimum-jerk trajectory are rather large, and vary within and across subjects. We propose a modification that solves both problems: for a specified path of the movement, the tangential velocity along the path is such that the mean squared jerk is minimized. This modified principle cannot predict the path of the movement (which, we argue, is quite variable); it only predicts the velocity profile for an experimentally observed path. We present data from two experiments, in which subjects were asked to move a cursor, i) through a set of via-points; ii) along a completely specified path. We tested arm, wrist, and finger movements, and in all cases the modified minimum-jerk principle fit the observed velocity profiles well.

An alternative theory that predicts velocity as a function of path is the power

law (Lacquaniti et al. 83), which states that tangential velocity is proportional to the curvature of the path, raised to the power -1/3. Here we analyze the power law, and show that in 2D and 3D it is mathematically equivalent to setting to zero the jerk along the normal vector. For movement paths with high curvature the power law is a computationally efficient approximation to minimizing jerk (since suboptimal velocity profiles produce high jerk along the normal). For many paths the velocity predictions of the power law and the modified minimum-jerk principle are indistinguishable, except for some specific position along the path. The observed velocities at such positions are much closer to the minimum-jerk prediction, suggesting that the power law may be a consequence of an underlying motor strategy to produce smooth movements.

HAND SPACE, JOINT SPACE AND PERCEIVED SPACE IN A VISUAL ENVIRONMENT. J.D.Cooke and K.K.Maitra. Appl. Hlth. Sc. Univ. of Western Ont., London, Canada N6G 1H1.

As part of the study to explore the hypothesis whether motion planning is organized in a visually perceived space, we studied two-joint planar arm movements involving the wrist and elbow under explicit visual guidance. Subjects were shown a joint space representation of their movements (wrist Vs elbow angle) on a computer monitor. They were asked to move naturally between two self chosen points in joint space with no instruction of path profile. In another session, they were asked to move between the two self chosen points in a straight line. In a third and fourth session, the subjects were shown a hand space representation of their movements and the two paradigms (i.e., to move naturally and to move in a straight line between two self chosen points) were repeated.

With visual feedback of joint space subjects did not naturally move in a straight path in a joint space. However, they did so when instructed to move in a straight line. This they did without changing the workspace region they used in the natural movements. Similarly, with visual feedback of hand space, they did not move naturally in a straight path in hand space rather produced extremely curved hand paths utilizing large area of hand space. When instructed to move in a straight line hand path, they utilized comparatively limited area of hand space and moved in a minimally curved hand path. Interestingly, this generated a straight path in joint

The results suggest that movement planning and organization are two different processes. In visually guided motion, planning is done in visual space where a superposition of visual perception and visuomotor transformation is necessary for proper trajectory formation. Such superimposition may be done by a third process which is instruction or intention dependent. On the other hand, the trajectory is organized in joint space. Support: NSERC, Canada.

INTER- AND INTRA-LIMB COORDINATION IN ARM TREMOR S.

Morrison and K. M. Newell.* Pennsylvania State University, PA 16802

Inter- and intra-limb coordination in arm tremor was examined in adult subjects under vision and no vision conditions using accelerometery techniques. Standard time and frequency domain analyses were performed as was a measure of the regularity of the acceleration time series using an approximate entropy (Ap En) measure. Data analysis was structured to examine the hypothesis that there is a functional compensatory relation between the motion (tremor) of the limb segments in the arm coordination postural pointing task.

The level of acceleration was shown to increase from proximal to distal within a single arm and was symmetrical across homologous arm segments. Analysis revealed no linkage between the arms, suggesting that the neuronal commands underlying normal tremor are not derived from a common central oscillator within the central nervous systrem but are organized in a parallel fashion. The strength of the intra-limb coupling varied according to the particular adjacent limb links with significant correlations and coherence being observed between upper arm and forearm, and, between hand and finger. The Ap En analysis revealed that there was more regularity to the upperarm and hand accelerometer signals than the forearm and finger signals. No effect for vision were observed.

The findings show that the intra-limb coordination of the arm links in a two-limb postural pointing task is effected by a compensatory synergy organized about the action of the wrist and shoulder joints. This compensatory synergy reduces the coordination of the 4 within-limb degrees of freedom (arm links) to in effect a single degree of freedom arm control task that is not coupled in organization to the motion of the other limb or the torso. It is proposed that this coordination solution reduces the degrees of freedom independently regulated for realization of the task goal but preserves independent body segment control in critical degrees of freedom for potential adaptation to postural perturbations.

DIFFERENTIAL EFFECT OF TASK CONDITIONS ON ERRORS IN DIRECTION AND EXTENT OF REACHING MOVEMENTS. J. Messier, Y. Lamarre* et J.F. Kalaska. CRSN, Dépt. de Physiologie, U. Montréal, Québec, Canada H3C 3J7

Canada H3C 317
Invariant patterns in motor behaviour are presumed to reflect the general organizing rules and sensorimotor transformations by which the CNS plans and executes movements. Invariant patterns in the distribution of the end points of reaching movements have been used to suggest that two important movement parameters of reaching movement, direction and extent, are planned by two independent processing channels. This study examined this hypothesis by testing the interdependency of direction and extent variable errors in two task conditions. In task 1, subjects made planar horizontal reaching movements to 25 targets located at 5 different distances and directions on the horizontal workspace. Subjects closed their eyes before moving the arm and did not receive knowledge of their performance. In task 2, arm movements were made to the same target locations in the same horizontal task 2, arm movements were made to the same target locations in the same horizontal workspace, but target location was displayed on a vertical screen in front of the subjects. Also, there was a scaling factor of 1:2.4 between the movement amplitude displayed on the screen and the amplitude of movement made by subjects. These changes imposed additional sensorimotor transformations in task 2. Subjects could not see their arm before movement in task 2, but they were shown their movement trajectory after each trial. For both tasks, variable errors of movement extent (on-axis error) were greater than for movement direction (off-axis error). Also, both on and off-axis variable errors increased with movement amplitude. The main difference between the results of these two tasks was that the off-axis/on-axis error ratio values between the results of these two tasks was that the off-axis/on-axis error ratio values remained constant at different movement amplitudes in the first task, while they increased linearly with movement amplitude in the second task. This result suggests that variable errors of direction and extent can be modified independently by changing task conditions. The modification of the relation of these variable errors to movement extent can be considered evidence that at some point in the planning of reaching movements, direction and extent are processed independently. Supported by MRC Group Grant in Neurological Sciences (JK), and FCAR studentship (JM).

HAND SPACE, JOINT SPACE AND PERCEIVED SPACE IN A NON-

VISUAL ENVIRONMENT. K.K.Maitra and J.D.Cooke. Appl. Hith. Sc. Univ. of Western Ont., London, Canada N6G 1H1.

Recent studies predict that motion planning can be made in either hand space or in joint space depending upon the space in which subjects perceive the motion. We examined this hypothesis by comparing two-joint planar arm movements involving the wrist and elbow in blindfolded subjects. In one session, subjects were instructed to make a "natural" movement of their hand at their own speed between two, self-chosen points. No instruction was given as to the path the hand should follow. In a second session they were also blindfolded and asked to move between two self-chosen points in a straight line.

When instructed to move naturally, the subjects utilized a large area of the hand work space. Handpaths were extremely curved while the joint paths (crossplots of wrist and elbow joint angles) were linear. In contrast, when the subjects were asked to move their hand in a straight line, they utilized a very limited area of the workspace and adopted a different strategy by altering the hand-forearm configuration. This approach produced a minimally curved hand paths

and, once again, highly linear joint paths.

The data suggest that in the absence of visual information, the CNS organizes motion in joint space to produce a perceived motion in hand space. This implies that perceptual space and organizational space for motion planning are different. Superposition or dissociation of these two spaces may be task or intention dependent.

SUPERPOSITION OF TWO FUNCTIONALLY INDEPENDENT SYNERGIES IN ARM-REACHING MOVEMENTS INVOLVING THE TRUNK. P. Pigeon, L.H. Yahia, and A.G. Feldman. Centre de Recherche, Institut de réadaptation de Montréal, Montréal, Québec, Canada, H3S 2J4.

To resolve the redundancy problem in the number of degrees of freedom for reaching tasks involving the trunk, the nervous system may use two functionally independent synergies: one synergy involves only arm joints to produce an arm endpoint trajectory (the arm reaching synergy), while the other coordinates movements of the trunk and arm joints leaving the position of the arm endpoint unchanged (the compensatory synergy). To determine whether the two synergies are similarly superimposed during pointings with opposite trunk motions, elbow and shoulder angles were recorded during reaching tasks involving the trunk. Subjects made fast planar movements of the index finger (the arm endpoint) from a near to a far target situated in the contralateral workspace at a 45° angle to the sagittal midline of the trunk. The arm movements were performed alone (control movements) or combined with a forward (in-phase movements) or a backward (out-of-phase movements) sagittal motion of the trunk. The movements were repeated with vision blocked upon initiation of the arm endpoint movement. The elbow angle recorded during control movements was compared to the semi-sum of elbow angles recorded during reaching with in- and out-of-phase trunk motions. The same procedure was applied to shoulder joint traces. Linear regressions for each joint produced correlation coefficients ranging from 0.9868 to 1,000 for both visual conditions. This indicates that the coordination between joint angles produced by the compensatory synergy unfolds with a similar timing for in- and out-of-phase movements performed with or without vision. These results support the hypothesis that multi-joint reaching movements result from the superposition of movements produced by independent synergies, solving, in such a way, the redundancy problem. Supported by NSERC, MRC and FCAR grants.

THE EFFECTS OF ACCURACY CONSTRAINTS ON HAND-TO-MOUTH MOVEMENTS DURING FEEDING. R.M. Dorcy, A.M. Gordon, T.R. Kaminski* & A.M. Gentile. Teachers College, Columbia University, New York, NY 10027.

Feeding behavior in humans involves movement between the hand and mouth, which must be spatially accurate and temporally coordinated to achieve the task objective. The present study examined the coordination achieve the task objective. The present study examined the coordination of hand and head movement during transport of a glass to the mouth under various constraints of accuracy (levels of fluid). Subjects were instructed to transport a 42 ml capacity glass to the mouth without spilling. The glass was placed at a standard height at two distances: near (40% of arm length), and far (80% of arm length). The three levels of accuracy constraint were: high (full glass), moderate (three-quarters full), low (one-quarter full). Our findings showed that the extent of hand and head displacement depended upon accuracy demands. With higher accuracy constraints (full glass), head displacement increased and hand displacement decreased. Remarkable within-subject consistency was observed in location of the hand-mouth point of coincidence, and in the direction and amplitude of hand and mouth movement within each accuracy constraint-level and distance. The degree to which trunk movement contributed to movement of the head varied between subjects in both the near and far distances, particularly during transport under high constraint. In the near movement of the head varied between subjects in both the near and far distances, particularly during transport under high constraint. In the near condition, some subjects demonstrated a strategy involving forward excursion of the trunk while others used primarily head/neck movement to displace the head. However in the far condition, all subjects incorporated the trunk into the movement. These findings suggest that the transport phase of feeding requires precise, accuracy dependent specification of a common end-point parameter (in extrinsic space), which links the organization of the two movement subcomponents into a single action.

TASK DEMANDS AND MANUAL ASYMMETRIES IN REACHING. E.A.Roy. Department of Kinesiology, University of Waterloo, Waterloo, Ontario. Canada N2L 3G1

The influence of task demands on manual asymmetries was examined in a reach and place task involving three conditions which increased in precision demands. Ten right-handed young adults participated in this study. In all conditions subjects reached for, grasped and picked up a small dowel. The subsequent movement defined the precision demands of the task. In one condition the dowel was tossed into a large receptacle. The other two conditions involved placing the dowel into either a small receptacle (small-place) about the same size as the dowel or a large receptacle (large-place). Subjects performed each task condition with each hand with the order of condition randomized for each subject. Movements of the arm (transport component) and the hand (grasp component) were recorded using an optoelectric analysis system (OPTOTRAK). The effect of precision demands on kinematic measures of the transport component (movement time, peak velocity and time in acceleration and deceleration) was most clearly seen in the second (move and place the object) as opposed to the first phase (reach and pick up the object) of the task. The small-place movements exhibited longer movement times, lower peak velocities and more time in deceleration than the large-place movements. Analyses of hand differences in performance revealed an advantage for the right hand only in the transport component and only in the second phase of the task, with the right hand exhibiting shorter movement times, higher peak velocities and less time in deceleration. These findings reveal that the magnitude of hand differences in performance depends on task demands with the hand differences being observed when the precision demands of the task are most apparent. The implications of this findings for a skill interpretation of

THE CURVATURE OF HAND PATHS IN MULTI-JOINT REACHING MOVEMENTS: DEPENDENCE ON ARM POSTURE AND MOVEMENT DURATION E. Nakano^{1,2}, H. Imamizu¹, R. Osu¹, Y. Uno¹, and M. Kawato², ATR Human Information Processing Res. Labs., Kyoto, Japan ²Graduate School of Science and Technol., Kobe Univ.

In multi-joint movements, possible trajectories to a given target are infinite, but actually have certain invariant features. It has been discussed whether trajectories of the human arm are planned in extrinsic (kinematic) space or in intrinsic (dynamic) space. Hand paths planned in the former are predicted to be always straight, while those in the latter are generally curved. Both Uno et al. (1989) and Osu et al. (1994) reported that actual hand paths tended to significantly curve for some specific arm postures, movement distances, and movement durations. We have extended the previous studies using various initial and final positions located within a workspace and examined if the curvature of a trajectory quantitatively varies with arm posture when humans make point to point reaching movements on a 2D horizontal plane. A hand position was measured by using a marker attached to a subject's hand. Curvatures of measured hand trajectories were linearly estimated from elbow and shoulder joint angles at initial and final positions. Movement durations and initial and final elbow joint angles significantly contributed to curvature. Then, in the second statistical analysis, curvatures were estimated from initial and final positions in Cartesian space and movement durations. However, initial and final positions in Cartesian space and movement durations. However, initial and final positions in Cartesian space and movement duration. These results suggest that trajectory curvature depends on arm posture and is in accordance with predictions made under planning in the intrinsic space, rather than in the extrinsic space. Further, the result that a longer movement duration causes a larger curvature is in agreement with the predictions of Uno and Kawato (1994), in which a longer movement duration makes paths expand toward the outer side because of an effectively larger viscosity ratio.

THE INFLUENCE OF MOVEMENT SEGMENT DIFFICULTY ON MOVEMENTS WITH TWO STROKE SEQUENCE. M.K. Rand*, J.L. Alberts, J.R. Bloedel, G.E. Stelmach, Motor Control Laboratory, Arizona State Univ., Tempe, AZ, 85287; Barrow Neurological Institute, Phoenix, AZ, 85013.

Arm movements in the horizontal plane consisting of two segments were examined to determine whether the difficulty of the second segment influenced the kinematic characteristics of the first segment. Based on Fitts' law, the index of difficulty (ID) of the second segment varied between 3.0 and 4.83. The direction of the first segment was an elbow extension movement away from the trunk and remained constant. The direction of the second segment varied between elbow extension and flexion movements. All movements were recorded by a x-y digitizer.

Variations in the ID of the second segment produced kinematic changes in the performance of the initial segment. Movement duration lengthened when the ID was increased by reducing target size for both extension-extension sequence and extension-flexion sequence. Peak velocity decreased, time to peak velocity and deceleration time increased for higher ID targets. In addition, changing ID of the second segment influenced the time between the two segments (intersegment interval). Context-dependent characteristics, defined as one movement segment influencing another, were stronger in the extension-flexion sequence than in the extension-extension sequence. These data suggest that planning processes consider the accuracy demands of both segments of a sequence.

SINGLE- AND MULTI-JOINT ARM MOVEMENTS: ARE THEY CONTROLLED THE SAME WAY? R. A. Scheidt, W. Z. Rymer* Northwestern Univ., Evanston, II. 60201, SMPP, Rehab. Inst. of Chicago, Chicago, II. 60611.

The objective of this study was to evaluate whether single-joint and multi-joint goal-

directed, arm movements are controlled in a similar fashion (Hong, Corcos and Gottlieb, 1994). Two human subjects made movements in the horizontal plane supported against gravity via an air-bearing system. Two types of movements were compared: 1) single-joint, point to point movements of 60° extent (at the elbow) made in the presence of a mechanical constraint which disallowed translation of the elbow, and 2) two-joint, point-to-point movements between the same initial and final targets as in 1), yet in the absence of the constraint. The subjects were asked to make the blocks of 150 movements "from point A to point B as accurately as possible in 200 ms". Shoulder and el-bow muscle electromyograms (EMGs) and limb kinematics were captured with an OptoTrak 3010 system. Kinematic and EMG metrics were examined to assess the performance and control behavior of the subjects as a function of constraint condition.

Our data reveal that, with the exception of the obligatory curvature of single joint endpoint paths, there were no systematic differences in the movement kinematics between the single- and multi-joint movements tested (ANOVA and Tukey tests; p≤0.01). One subject exhibited a small increase in shoulder antagonist activity with the addition of the constraint (p<0.01); however, no systematic changes in the relative timing of EMG activity during single- and multi-joint movements were found. Constancy of EMG activity under very different biomechanical conditions is surprising since the addition of a shoulder constraint should allow the CNS to exploit modes of control not available in the unconstrained case. Specifically, the energetically efficient mode of minimal shoulder activity was not observed. This study suggests that single-joint, goal-directed arm movements may be considered constrained multi-joint movements and are controlled in a manner indistinguishable from the multi-joint case. Although it is conceivable that adaptation to the constraint may occur with prolonged exposure or practice, such adaptation effects were not evident within the two hour span we tested. NIH NS19331.

Obstructed versus unobstructed reaching to stationary and moving targets in humans. B.J. McFadyen*, Dép. physiothérapie, Univ. Laval, Québec, G1K 7P4, Canada; H. Camahan, Dept. Kinesiology, Univ. Waterloo, Canada.

The study of anticipatory strategies underlying obstructed reaching in humans has been limited. The present work details the three dimensional kinematics, moments of force, and mechanical powers in the upper limb during unobstructed and obstructed reaching to both stationary and moving targets. Electromygraphic activity of certain muscles was also recorded. Eight normal young subjects (mean age, 24.5 yrs.) were tested. Unobstructed reaching was initiated by either simultaneous control by the elbow and shoulder flexors, or elbow flexor control through a combination of a decreased shoulder flexor moment with an increased elbow flexor moment. Initial sole control by the elbow flexors predominated obstructed reaching with increased moments of force and powers over unobstructed trials and a greater phase disparity between elbow and shoulder patterns. This elbow strategy also provides initial passive shoulder flexion. The moving targets required greater reaching speeds, but initial reaching strategies were relatively unaffected. The control required while closing in on the target was more dependent on both environment and target characteristics. These results suggest a basic initial reaching behaviour that exploits intersegmental dynamics, and may parallel work presented for forelimb reaching in the cat (Martin et al., 1995). The greater emphasis on active control by a more distal joint during obstructed movement has similarities with patterns seen during the lower limb avoidance of obstacles in gait (McFadyen et al., 1991). REACHING ARM MOVEMENTS: THE PROCESS OF DIRECTIONAL SPECIFICATION IS NOT INFLUENCED BY CHOICE NUMBER. M. Favilla*. Istituto di Fisiologia Umana, v. Fossato di Mortara 17, I-44100 Ferrara, Italy. We have previously found that extent and direction of hand trajectories aimed at visual targets located in a two-dimensional

We have previously found that extent and direction of hand trajectories aimed at visual targets located in a two-dimensional workspace can be independently specified. The specification of each parameter is not influenced by the need of concurrently specifying the other, at least as long as the number of the possible targets (choices) is maintained constant. We now study the effect of varying the number of choices on the time course (or rate) of response specification, while keeping constant the number of parameters (only one, direction).

Subjects moved a hand-held cursor on a digitizing tablet from a common start point; targets and a screen cursor were displayed on a computer monitor. Movements were initiated in synchrony with the last of a series of regularly interspaced tones; targets appeared at unpredictable times before the last tone.

Three series of experiments were run, in which 2, 4, 8 targets were presented in different directions, all at the same distance from the starting point. Response directions were correlated with target directions, within bands of progressively longer stimulus-response intervals and the time course of these correlations compared across the experiments. The time course of directional specification of reaching arm movements was uninfluenced by the number of possible choices. Subjects are able to specify responses to different numbers of targets at the same rate. Source of support: Government grant from M.U.R.S.T.

A NEW VIEW ON HICK'S LAW. O. Bock*, Dep. Physiol., German Sports University, Köln, Germany.

Hick's law states that manual reaction time (RT) increases logarithmically with the number of response alternatives. Unfortunately, many studies claiming support for that law confounded two variables: as the number of alternatives increased, so did the area of space in which responses could occur. We undertook two experiments to deconfound these variables.

In Exp. A, possible response positions were *precued* by presenting: 5 discrete locations on a 90 deg arc about the starting point of the pointing finger; 3 locations on a 90 deg arc; 3 locations on a 45 deg arc. These precue types reduced RT in descending order, which suggests that both the number of alternatives and their spatial extent are relevant.

In Exp. B, precues were: a continuous arc of 60 deg an 30 cm radius; 60 deg and 7.5 cm radius; 15 deg and 30 cm radius. These precues reduced RT in descending order, which confirms Exp. A, and suggests that spatial extent is coded in polar rather than Cartesian coordinates.

We conclude that RT depends both on the number of alternatives and on the range of possible response directions, thus reflecting the response selection and the movement preparation stage of the motor system.

INDIVIDUAL DIFFERENCES IN OROFACIAL MOVEMENT COORDINATION WITH VARIATIONS IN SPEECH RATE. M.D. McClean.* Audiology and Speech Center, Walter Reed Army Medical Center, Washington, D.C. 20307-5001.

To understand pattern generating networks regulating speech production, it is important to quantify orofacial movement coordination and assess the range of individual variation. Subjects produced a nonsense utterance ("a bad daba") numerous times at slow, normal, and fast speech rates. An electromagnetic system was used to transduce two-dimensional displacements of the upper lip, lower lip, tongue tip, and jaw in the midsagittal plane. Tangential velocity patterns were derived for each structure, and the peak velocities were measured for vocal-tract opening and closing gestures associated with the consonants /b/ and /d/. Within subjects, the magnitude and timing of peak velocities were strongly conditioned by speech rate, and the peak velocities of different structures were often well-correlated. However, the pattern of these associations differed markedly across subjects. For example, some subjects showed positive correlations between lip and tongue opening velocities, while others showed positive correlations between tongue-opening and tongueclosing velocities. Negative correlations between tongue and jaw opening velocities were seen in some subjects, indicating motor equivalence; but this pattern was not present in others. These results suggest that individuals use different pattern generating networks or network organizations to produce the same speech utterance.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CIRCUITRY AND PATTERN GENERATION V

644.1

INTERMITTENCY: A FEATURE OF RHYTHMIC MOVEMENTS IN INTACT ANIMALS. <u>G.E. Gerstner*</u>. Dept of Biol. & Mat. Sci., Sch. of Dent., Dept of Psychol., Univ. of Mich., Ann Arbor, MI 48109-1078.

Rhythmic movements, like mastication and gnawing, appear to be produced by central pattern generating circuits (CPG). Evidence suggests that in infact animals, rhythmic movements occur intermittently, i.e., in sequences of 1-3 s rhythmic bursts interdigitated with 0.2-1 s pauses. It has been hypothesized that catecholaminergic circuits play an important role in producing this intermittency. The current study further hypothesized that catecholaminergic drugs, that are typically used to elicit rhythmic behaviors, disrupt this intermittency by activating CPG or pre-CPG circuits for artificially long time periods. The current study was undertaken to test this hypothesis. Ten albino guinea pigs were videotaped while masticating, and six albino guinea pigs were given 0.5 mg/kg i.m. apomorphine and videotaped while gnawing. Software developed in the laboratory was used to score mastication and gnawing bursts and to characterize the intermittencies of these behaviors using an autocorrelation method. Results indicated that a 1-3 s intermittency was a feature of mastication: however, intermittency was not a feature of the apomorphine-associated gnawing. These results support the hypothesis that catecholaminergic drugs disrupt intermittency in rhythmic movements. A model will be presented as to how the intermitteney arises. and why catecholaminergic drugs and certain diseases disrupt the intermittency. This model posits that catecholaminergic pathways are involved in maintaining rhythinic movements; however, intermittency results from these pathways inability to perpetuate output for > 3 s time spans without recurrent initiatory input from other circuits. Supported in part by NIH grant DE10625.

EFFECT OF INCREASING RESISTANCE ON MOTOR PATTERNS DURING SWIMMING IN CHICKS. A. Bekoff*, B. C. Hurtt and J. L. Ryan. EPO Biology Department and Center for Neuroscience, University of Colorado, Boulder, CO 80309.

We are interested in examining the role of sensory input in modulating rhythmic motor patterns. We analyzie the role of increasing resistance to leg movements during swimming in chicks because this is a simple, symmetrical locomotor behavior.

because this is a simple, symmetrical locomotor behavior.

Previous studies in our lab have characterized swimming in chicks using both kinematic (Johnston & Bekoff, 1992. J. Exp. Biol. 171: 143) and EMG recordings (Johnston & Bekoff (J. Comp. Physiol. in press). In contrast to walking, swimming motor patterns are symmetrical: extension and flexion durations are similar. During walking extension duration increases with increasing cycle period while flexion duration does not. In swimming both extension and flexion durations increase to a moderate and similar extent.

In the present study, we alter resistance for both extension and flexion by having chicks swim in fluids of three different viscosities. Chicks are videotaped during swimming and markers are digitized to determine hip, knee and ankle joint angles. From these data, cycle period, flexion and extension at each joint, phase values, and joint excursions can be calculated. Results suggest that the motor pattern becomes increasingly asymmetric with increasing resistance. This suggests that extension is more readily modulated than flexion.

AN EXPECTATION-BASED MODEL OF ADAPTABLE AND FLEXIBLE PREY-CATCHING IN ANURANS. F. J. Corbacho*, K. C. Nishikawa, J-S. Liaw, M. A. Arbib, Ctr. Neural Eng., Univ. Southern Cal., Los Angeles, CA 90089 and Dept. of Biol Sci. N. Arizona Univ., Flagstaff, AZ 86011.

Biol. Sci., N. Arizona Univ., Flagstaff, AZ 86011.

Prey catching in anurans involves the coordination of several motor commands in a highly flexible and adaptable manner. Behavioral observations demonstrate that prey catching is guided by visual input about the prey and sensory feedback about the jaws and tongue. We have developed a simple model that accounts for a variety of data on modulation of prey catching by visual input and sensory feedback, as well as interactions between them. The model includes:

1) jaw muscles Depressor Mandibulae (DM) and Levator Mandibulae (LM); 2) tongue muscles; 3) corresponding premotor control circuits in the reticular formation (RF); 4) an efference copy of the motor command to DM through excitatory connectivity from premotor DM to an interneuron (INT) in RF; 5) sensory feedback from motion of the tongue through mechanoreceptors in the hypoglossal nerve (HG); and 6) sensory feedback from motion of the jaw through muscle spindles in the LM muscles, which inhibits INT. The model explains patterns of motor pattern selection based on parameters of the visual input. When frogs see large prey, INT receives low frequency inhibitory input from the optic tectum. When active, INT inhibits premotor LM, giving rise to jaw prehension. When frogs see small prey, INT receives high frequency inhibitory input from the optic tectum and is not active enough to reach its threshold. In this case, premotor LM is inhibited by HG instead of by INT, giving rise to tongue prehension. The model also replicates observations on motor learning in toads after hypoglossal transection. INT detects incoherences about mouth opening by subtracting the signal carrying the efference copy of the command to DM and the feedback signal from the muscle spindles in LM. The strength of inhibitory connections between HG and INT and between INT and premotor LM (Y) are both adapted during learning. The model accounts for variability across individuals (faster vs. slower learners) by varying Y based on past experience. (Sup

644.4

EFFECT OF SENSORY INPUT DURING RHYTHMIC EMBRYONIC MOTILITY. A.A. Sharp* and A. Bekoff. EPO Biology Department, University of Colorado, Boulder, CO 80309.

The integration of sensory information into functional rhythmic motor patterns during development is not well understood. Hamburger et al. (1966, J. Exp. Zool.) demonstrated that sensory information is not required for maintenance of embryonic motility in chicks, but this does not mean that sensory-motor synapses, which first appear on the seventh day of embryogenesis (E7) (Lee et al., 1988, J. Neurosci.), are not utilized during embryonic motility. For example E7 embryos produce reflex responses to tactile stimulation and the reduction of buoyancy of E9 embryos causes a greater covariance of wing joints during rhythmic motility (Chambers et al., 1995, Exp. Brain Res.). We are using kinematic and EMG recordings to determine if localized sensory information provided by sustained perturbations of one leg are incorporated into rhythmic leg movements.

E9 chick embryos are prepared for recording, in ovo, by first gluing two paddles to the back. This prevents rolling of the embryo during motility. A third paddle is placed under the right foot such that the resting leg position is similar to that during post-hatching stance. This configuration allows the embryo to press against the pad with its right foot during extension of the leg and to lift the foot from the paddle during flexion. The paddles reduce the amplitude of possible leg extension. Kinematic measurements of the right leg reveal that the amplitude of joint excursion at both the knee and ankle are reduced, but that the hip is unaffected. The duration of ankle extension is increased resulting in a phasing delay for ankle flexion. This is similar to the response of a post-hatching chick to loading during walking (Johnston and Bekoff, 1992, J. Exp. Biol.). The duty cycle of hip and knee extension and flexion are unaffected. Synchronous kinematic and EMG recordings are being performed to determine if these changes are the result of active sensory-motor interactions or passive physical constraints. TRANSIENT CONFIGURATIONS OF BRAINSTEM CARDIO-RESPIRATORY NEURONAL ASSEMBLIES: DETECTION AND DISPLAY OF REPEATED MOTIFS. B. G. Lindsey*, K. F. Morris, R. Shannon, and G. L. Gerstein. Dept. of Physiology & Biophysics, Univ. of South Florida Med. Ctr., Tampa, FL 33612 and Dept. of Neuroscience, Univ. of Pennsylvania, Philadelphia, PA. 19104.

We previously identified moments of synchrony in distributed assemblies (Soc. Neurosci. Abst. 21:145, 1995). Jumps in gravity particle condensation rates were defined and displayed as a set of vectors with a common origin. The direction of each vector in a plane identified the neuron pair represented; vector length indicated the aggregation velocity of corresponding particles. Because of the appearance of the vectors in animations of successive planes 'through time', these graphs are called 'spark' plots. Next we described a method to determine if particular patterns of impulse synchrony in a group of neurons recur more frequently than expected by chance (FASEB J., 10: A410, 1996). Here we report results of the combined application of these approaches to data sets of 8 or more spike trains recorded simultaneously in the medullary raphe nuclei and ventrolateral medulla of anesthetized, vagotomized, artificially ventilated cats. Spatiotemporal patterns of synchrony with a significant number of recurrences were detected in each of 3 animals. In one sample, a spark motif repeated exclusively during a period of increased baroreceptor stimulation and decreased respiratory drive; a second motif was confined to other times. The reiterated patterns were not apparent in either corresponding firing rate histograms or the conventional gravity representations from which the results were derived. These approaches may have a general utility in screening time series for evidence of transient 'states' of neuronal assemblies linked to sensory processing, motor control, and the induction and expression of memories (Morris et al., these proceedings). Support: NIH grant NS19814.

ELECTRICAL AND L-GLUTAMATE STIMULATION OF THE PRECOMMAND NUCLEUS (PC) REVEALS EXCITATORY INPUTS TO PC AND COMMAND NUCLEUS IN GNATHONEMUS PETERSII. G. von der Emde*, J.C. Prechtl and C.J.H. Wong, Zool. Inst., Univ. Bonn, 53115 Bonn, Germany and Scripps Inst. of Oceanography LICSD 1 a July CA 9 2003

CJ.H. Wong, Zool. Inst., Univ. Bonn, 53115 Bonn, Germany and Scripps Inst. of Oceanography, UCSD, La Jolla, CA, 92093.

Mormyrid weakly electric fish display extensive changes in the rhythm of electric organ discharges (EOD) associated with various stimuli and behavioral states. The EOD rate is determined by the bulbar command nucleus (CN) located in the caudal medulla. CN receives input from the pre-command nucleus (PC) which is a small nucleus located in the midbrain tegmentum, ventral and caudal of the posterior commissure. Injections of neurobiotin into PC retrogradely labeled cells in known afferent structures including the ventro-posterior nucleus of the torus. In addition, neurons in several other brain areas were labeled. There was also transsynaptic anterograde transport of tracer across up to three synapses into structures associated with the electric organ corollary discharge pathways. Characteristic field potentials recorded within PC showed partial temporal overlap with CN field potentials. In addition, single units within PC fired spikes between EODs, but were silent during a period immediately following the generation of an EOD. Inottophoretic injection of L-glutamate with negative currents into PC for several seconds caused a tonic increases in EOD rate, similar to the effect elicited by long-term electrical stimulation of PC with depolarizing current. The amount of EOD acceleration depended on current strength up to a saturation level both in chemical and electrical stimulation. Turning off a longer period of stimulation with L-Glutamate caused a short, transient EOD acceleration that resembled the 'novelty response', a behavioral response to novel sensory stimuli. These data suggest that PC itself is in receipt of excitatory input and exerts an excitatory effect on the CN. ANALYZING NEURONAL DISCHARGE; ELIMINATING FORMAT BIASING EFFECTS AND DETECTING CHANGES IN STATE. J. L. Johnson*. Dept. of Physiol. & Pharmacol., USD School of Medicine, Vermillion, South Dakota 57069.

Previously, it was shown that the reciprocal frequency (Hz) and interval (ms) formats were oppositely biased in their ability to appreciate variability in discharge sequences [Brain Research, 666 (1994) 125-127]. These format biasing effects (which are not mirror image distortions) must be overcome and eliminated entirely if we are ever to accurately detect changes of state in functioning neurons. It was discovered that, for any given discharge sequence, by plotting sum(INT; sequential interval data) vs sum (Hz; sequential frequency values for the same data) ALL format biasing effects were canceled out and changes in state could be readily detected. The slope of the regression line for any single state [sum (Hz)/sum (INT)] can be converted to an equivalent average interval value which is to be applied over the duration of the state. The regression coefficient for this regression equation reflects the state variability about the mean (slope) in the complete absence of any format biasing. If the above approach is not employed, the use of the interval format alone will amplify low frequency variability in a discharge sequence and the use of the frequency format al will amplify high frequency variability in the discharge sequence. Such format biasing should only be included if the functional effect regulated by the discharge input also exhibits the property of format biasing. In conclusion, the sum (Hz) vs sum (INT) plot must be critically examined for its potential usefulness is assessing changes in discharge patterns in a manner that does not include any biasing distortions which are an integral property of reciprocal functions. The above specified method of utilizing both reciprocal formats (INT & Hz equivalent) together in the analysis of discharge patterns may enable us to more precisely relate changes in input patterning in an unbiased way to the regulated function.

INFLUENCE OF MULTISEGMENTAL COORDINATING FIBERS ON RHYTHMICITY OF DISTANT SEGMENTS IN THE LAMPREY SPINAL CENTRAL PATTERN GENERATOR. W.L. Miller and K. A. Sigvardt*. Department of Neurology and Center for Neuroscience, University of California, Davis. CA 95616

Little is known about the distribution and functional effects of propriospinal projections in the lamprey spinal cord. We are interested in how these projections contribute to intersegmental coordination. Our previous electrophysiological studies suggested that propriospinal neurons can influence the timing and variance of ventral root activity as many as 20 or more segments away. In the present experiments on the isolated silver lamprey spinal cord (Ichthyomyzon unicuspis), we combined mechanical entrainment of the ends of the preparation with blockage of local activity in the middle of the preparation, in order to further quantify the properties of the multisegmental coupling. Rostral and caudal entrainment frequency range, and rostro-caudal coherence and phase were measured for blocking lengths of 4-20 middle segments in 4-segment steps. In a second experiment, we separately measured the extent of ascending (rostrally-directed) and descending (caudally-directed) coupling.

and descending (caudally-directed) coupling.

DIFFERENCES BETWEEN THE PRODUCTION OF PRECISELY REPLICATING TRIPLETS AND DOUBLETS IN VI CORTICAL CELLS.

R. Lestienne*, Institut des Neurosciences, 9 quai St Bernard 75005 Paris.

Temporal patterning in visual cortical spike trains was assessed by measuring

Temporal patterning in visual cortical spike trains was assessed by measuring the number of replicating triplets (NT2) and the number of doublets present three times (ND3), in successive windows of duration 100 ms, when the maximum total duration of individual patterns was 25 ms and the precision of replication of each interval was <= .5 ms. Temporal organization of spike discharges was evaluated using the NT2/ND3 criterion, because of its relative insensitivity to changes in the cell firing rate (Soc. for Neur. Abst. #18.1, 1994; Biol. Cybern. 1996, 74:55-61).

Seven data samples were processed, each comprising between 38,000 to 157,000 spikes, from single unit and multi unit recordings in primary visual area of anesthetized and behaving animals. NT2/ND3, NT2/spike and ND3/spike were separately measured, as a function of firing rate, and compared to Monte-Carlo produced data, obeying a Poisson renewal process modified to introduce refractory periods.

In all samples, similar trends of NT2/ND3, NT2/sp and ND3/sp ratios were observed. At low firing rates (~30-100 Hz), discharges markedly deviate from prediction of the Poisson-like model, mostly because they contain an excess of precisely replicating triplets with respect to the latter, while the replicating doublets production remains closer to the level predicted by the model. In kittens, the number of replicating patterns rises quite rapidly with age, from 4-6 weeks to 9-13 weeks, at the same time as the average firing rate increases. NT2/ND3 ratios also show a tendency to increase with age.

OPTICAL STUDIES OF AN ENTERIC NETWORK: SIMULTANEOUS RECORDING OF ELECTRICAL ACTIVITY FROM SEVERAL INTERCONNECTED SUBMUCOUS GANGLIA WITH SINGLE CELL RESOLUTION. <u>AL. Obaid*, M.A. Farries, M.A. Kisley, T. Sakai, and B.M. Salzberg.</u> Dept. of Neuroscience, Sch. of Medicine, and The David Mahoney Institute of Neurological Sciences. UPENN, Phila. PA 19104-6074.

The enteric nervous system is a self-contained network capable of generating complex behaviors in isolation. Its neurons are arranged in plexuses [submucous (SM) and myenteric] confined to distinct planes in the gut wall. Since the neurons of SM ganglia of the guinea pig small intestine lie in the same optical plane, they are particularly amenable to Multiple Site Optical Recording of Transmembrane Voltage (MSORTV). One problem that can be addressed using this technology is the identification of functional units within the SM network. Are these units the SM ganglia themselves, or are they distributed, supraganglionic networks that overlie each other and share the anatomical scaffold of the SM plexus? To answer this, we have begun to examine whether sets of functionally connected neurons are found primarily within single ganglia or are distributed among several ganglia. We use the technique of MSORTV [Salzberg et al., J. Neurophysiol. 40:1281, 1977; Grinvald et al., J. Neurophysiol. 45:829, 1981], the fluorescent potentiometric dye di-8-ANEPPS [Bedlack et al., Neuron 9:393, 1992], and a 40X, 1.3 n.a. objective (Olympus), to record simultaneously the action potentials from neurons of up to 5 interconnected ganglia. The data are acquired at 2 kHz, with 18 μm spatial resolution, using 32 selected outputs of a 464-element photodiode array mounted on an inverted microscope equipped for epifluorescence. The light source is a 150 W Xe short arc, and the filter combination is 530+25 nm/ 560/ OG570. Spike sorting analysis of the raw optical data is used to identify the active neurons and isolate their individual spike trains. Our records are not yet long enough to generate statistically significant conclusions, but quasi-synchronous bursts of activity from cells in separate ganglia suggest the existence of a supraganglionic organization. Supported by USPHS grant NS16824, and a travel fellowship (T.S.) from the Ministry of Education, Science and Culture of Japan.

DIAGONAL LIMB RESPONSE FOLLOWING SPINAL CORD COMPRESSION INJURY IN CATS.

W.M., Norman, F.J., Thompson, C.J., Vierck, Jr., D.R., Howland*, and D.K., Anderson. Dept. of Neuroscience, Univ. of Florida Coll. of Med. and VAMC Gainesville FL 32610.

A preliminary study was designed to determine if thoracolumbar spinal cord compression injury in adult cats alters the diagonal limb postural response (DLR). Cats were trained to stand on force detectors made from saline-filled bags containing pressure transducers. Rapid fluid removal from one of the bags initiates the DLR. The polarity and magnitude of the change in the vertical vector of the ground reaction force exerted against each paw was recorded. Normal cats load the diagonally opposing pair of limbs, while the stimulated limb and its diagonal, unload. Injured cats show a direction-dependent response. Hindlimb (HL) stimulation elicits a response from the expected diagonal limb pair in all injured cats. Although the pattern response was normal in the more moderately injured cats, the magnitude of the response was diminished. In the more severely injured cats, the DLR was either diminished or absent. In contrast, forelimb (FL) stimulation induced bilateral extension of the HL instead of invoking the DLR. These findings suggest that the injury disrupts normal neural networks underlying the DLR. The DLR of some of the injured cats to HL stimulation is likely mediated by neural circuits that survive the injury but which differ from the normal anatomical substrate. In addition, in the most severe injuries, perhaps passive, mechanical forces may account for some of the response pattern. We are beginning to perform more detailed analysis of this and other postural responses using force plates, EMG, and kinematic analyses. THE STORAGE OF LONG-TERM MOTOR MEMORIES AT PARALLEL FIBER SYNAPSES ONTO STELLATE/BASKET CELLS IN THE CEREBELLAR CORTEX. <u>G.T. Kenyon</u>* Department of Neurobiology and Anatomy, University of Texas Medical School, 6431 Fannin, Houston, TX 77030.

Climbing fiber-dependent plasticity at granule-to-Purkinje (Gr→Pkj) synapses in the cerebellar cortex has been implicated in several forms of motor learning. use a mathematical model of the cerebellar cortex and its reciprocal interactions with the inferior olive to show how an additional site of plasticity at granule-tostellate (Gr -> St) synapses could facilitate the storage of long-term motor memories. It has been widely postulated that movements are initiated by brief pauses in Purkinje cell activity, and that climbing fiber inputs produce such pauses by selectively inducing long-term depression (LTD) in Gr-Pkj synapses active during the intended movement. Our results suggest that the selective induction of long-term potentiation (LTP) in coactive Gr-St synapses could also produce similar pauses in Purkinje cell firing. The present model depends on the following experimentally testable predictions: 1) Golgi cells experience an abrupt depolarization during the execution of a learned movement due to a release from tonic Purkinje cell inhibition. 2) Rapid depolarization produces a calcium-mediated pause in tonic Golgi cell firing. 3) Pauses in Golgi cell activity initiate bursts of granule cell firing. 4) Bursts of Gr-St synaptic activity promote the induction of LTP, while normal activity produces LTD. 5) Increased inhibition from stellate/basket cells can block the rapid depolarization of Golgi cells during the execution of learned movements, thus providing negative feedback. We conclude that rapid motor adaptation is mediated by climbing fiber-dependent plasticity at $Gr \rightarrow Pkj$ synapses but long-term storage results from the transfer of this plasticity to Gr→St synapse during continued reinforcement training (NIMH #1 F32 MH10683-01).

CEREBELLAR SINGLE CELL ACTIVITY RELATED TO BIMODAL CONDITIONED EYEBLINK RESPONSES. J-S Choi* and J.W. Moore, Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003.

Conditioned eyeblink responses (CRs) predict the timing of the US. Rabbits trained with a mixture of two CS-US intervals develop bimodal CRs with amplitude peaks at the loci of the US. Bimodal CRs are predicted by real-time computational models such as Sutton and Barto's TD model.

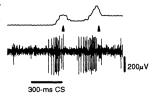

In the present study rabbits were trained with a fixed-duration tone CS of 300 ms and an eye-shock US. The two CS-US intervals were 300 and 700 ms. Only one US occurred per training trial. Recordings from single cerebellar cells showed activity highly predictive of both amplitude peaks of bimodal CBc.

The figure shows a typical bimodal CR (upper trace) and the firing pattern of a single cell in nucleus interpositus (lower trace) on a single CS-alone probe trial. The arrows mark the times of the US on training trials.

The firing of some Purkinje cells ceased in anticipation of each amplitude peak of bimodal CRs.

These observations are consistent with schemes that implement learning and CR timing within the cerebellum.

CLASSICAL CONDITIONING UNDER TEMPORAL UNCERTAINTY: SIMULATION OF RESPONSE STRATEGIES BY THE TD MODEL. D.H. Brunzell, J-S Choi, and J.W. Moore*, Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003.

Program, University of Massachusetts, Amherst, MA 01003.

Rabbits were trained in an eyeblink conditioning task in which the CS-US Rabbits were trained in an eyeblink conditioning task in which the CS-US interval (300 and 700 ms) results in bimodal CRs with amplitude peaks 300 and 700 ms after CS onset. A mixture of three CS-US intervals (300, 500, 700 ms) results in either of two response strategies: a fail-safe strategy in which the CR resembles a voluntary response or a conditional expectation strategy in which the CR consists of three successive peaks of increasing amplitude.

All three response strategies (bimodal, fail-safe, conditional expectation) can be described by a real-time version of Sutton and Barto's Time-Derivative (TD) learning rule which assumes that CS-US intervals can be decomposed into ordered sequences of time-tagged components. In the model, connection weights between one such component and the US are computed by the following equation: $\Delta V(t) = \beta[\lambda(t) + \gamma Y(t) - Y(t-1)] \times \alpha \bar{X}(t)$. The amplitude of the CR at t is given by $Y = V \times X$. λ represents the US, and X represent the on-off status of the CS component (X = 1, if CS on; else 0). \bar{X} is the eligibility of the CS component for modification: $\bar{X}(t+1) = \bar{X}(t) + \delta[X(t) - \bar{X}(t)]$. α , β , δ , and γ are constant positive fractions. Response strategies can be simulated by various combinations of parameter values and assumptions about the structure and modulation of timing mechanisms.

645.4

 TD MODEL OF CLASSICAL CONDITIONING: RESPONSE TIMING AND CEREBELLAR IMPLEMENTATION.

J.W. Moore, J-S Choi, and A.G. Barto*, Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003.

Sutton and Barto's Time-Derivative (TD) learning rule can describe the timing and topography of conditioned responses, if the CS–US interval is decomposed into an ordered sequence of time-tagged components. Connection weights between one such component and the US are computed by the following equation: $\Delta V(t)=\beta[\lambda(t)+\gamma Y(t)-Y(t-1)]\times\alpha\bar{X}(t).$ The amplitude of the CR at t is given by $Y=V\times X$. λ represents the US, and X represent the on-off status of the CS component (X=1, if CS on; else 0). \bar{X} is the eligibility of the CS component for modification: $\bar{X}(t+1)=\bar{X}(t)+\delta[X(t)-\bar{X}(t)].$ $\alpha,\beta,\delta,$ and γ are constant positive fractions.

The TD model has been particularly successful in describing classical eyeblink conditioning, a behavior that depends on the integrity of the cerebellum and associated brain stem circuitry. We present a scheme for implementing the TD model in the cerebellum. In terms of the model, X is represented by mossy fiber activity from the pontine nuclei, λ is represented by climbing fiber activity from the inferior olivary nuclei, Y(t-1) is represented by mossy fiber activity from the spinal trigeminal nuclei, and Y(t) is represented by mossy fibers from the red nucleus. The scheme assumes that ΔV is computed through LTD of parallel fiber synapses on Purkinje cells.

The scheme is consistent with known anatomy (Rosenfield & Moore, Behavioral Neuroscience, 109, 1106-1118). It gives rise to testable predictions, e.g., that inactivation of the red nucleus would not preclude first-order conditioning (consistent with Clark & Lavond, Behavioral Neuroscience, 107, 264-270), but it would prevent second-order conditioning.

IMPAIRED CLASSICAL EYEBLINK CONDITIONING IN MUTANT MICE (STARGAZER) WITH LOCALIZED DEFICIENCY IN BDNF EXPRESSION IN THE CEREBELLUM L. Chen*, S. Bao, X. Qiao, B. Knusel and R. F. Thompson. Neuroscience Program, Univ. of Southern Calif., Los Angeles, CA 90089-2520.

Gene knockout mice have been proven to be a powerful approach to study the biological basis of learning and memory. But, because the loss of the genes is global, it may be difficult to interpret the behavioral deficits. In the present study, we tested classical eyeblink conditioning in spontaneous mutant mice called stargazers (stg). The stg mice show deficient BDNF expression in cerebellar cortex during the entire life span. The BDNF expression in other brain regions and the expression of other neurotrophins appear to be normal. The cerebellar cytoarchitecture in adult stg mice also appear to be normal. also appear to be normal.

Adult male stg mutant mice (n=11) and normal littermates (n=10) mice underwent standard delay eyeblink conditioning. The eyelid muscle electromyograph was recorded to score CRs. The stg mice exhibited a severe impairment in the acquisition of delay eyeblink conditioning in comparison to their normal littermates. There was no difference between the mutant and wild-type mice in their sensitivities to the US or their UR to the periorbital shock. In addition, we tested the sensitivities of the two

their UR to the periorbital shock. In addition, we tested the sensitivities of the two groups of mice to hot plate induced pain and startle responses to a loud 1kHz sound. The stg mutant mice showed no significant differences in either tests compared to normal littermates. Thus the impairment was not due to sensory deficits.

The stg mice also exhibit non-convulsive seizure. To test the possible effects of the seizure activities on classical eyeblink conditioning, we trained another type of mutant mouse called tottering (tg) for eyeblink conditioning. Despite seizure activity similar to stg mice, tg mice learned eyeblink conditioning as well as wild type littermates.

The fact that mice with localized cerebellar BDNF deficiency are impaired in classical eyeblink conditioning strongly supports the idea of essential involvement of classical eyeolink conditioning strongy supports the fuel of essential involvement of the cerebellum in this type of learning. It also suggests that the neurotrophins may be important in learning and memory.

EFFECTS OF HIPPOCAMPAL AND INTERPOSITUS REVERSIBLE LESIONS ON LEARNING OF THE RABBIT CLASSICALLY CONDITIONED EYELID RESPONSE. <u>Eliasradeh</u>, P., Tocco G., Thompson J. K.* & Thompson R.F. Neurosciences program, Univ. Southern California, Los Angeles, CA 90089-2520.

Reversible inactivation with either muscimol, lidocaine or DNQX was used to identify neural substrates which might mediate learning and/or consolidation of the rabbit's conditioned evelid response. While the cerebellum is necessary and rabbit's conditioned cyclid response. While the cerebellum is necessary and sufficient for the learning of the classical conditioning of the nictitating membrane, in a delay paradigm, the hippocampus is required for the learning of a trace paradigm when at least 300 ms separate the end of the CS from the US onset. While the interpositus nucleus is absolutely necessary for the performance of a previously learned trace conditioning task, its importance during the acquisition phase is not well understood. On the other hand the hippocampus, seems to be important during the acquisition phase and only for a short period of time after the learning In an attempt to clarify the role of these structures in the different phases of learning (acquisition, retention/consolidation?) reversible inhibition of these brain areas were performed with various drugs (muscimol, DNQX, lidocaine) either during of after conditioning in a trace paradigm.

Male New-Zealand white rabbits were implanted with one cannula in the both hippocampi and/or one cannula in the interpositus nucleus. ipsilateral to the stimulated eye. Rabbits were then trained in a trace paradigm and infused with inactivating drugs either during acquisition trials or in training session after they reached criterion.

Our results show that an intact cerebellum is necessary at all times for learning and consolidation of a trace paradigm while the hippocampus is only necessary for

the acquisition of a learned response and for a short period of time thereafter.

INFUSION OF PROTEIN KINASE INHIBITOR H-7 INTO THE CEREBELLUM IMPAIRS THE ACQUISITION OF CLASSICAL EYEBLINK CONDITIONING IN RABBITS. G. Chen*, and J. E. Steinmetz. Dept. of Psychology/Neural Sciences, Indiana Univ., Bloomington, IN 47405.

Eyeblink conditioning in rabbits has been well studied and it has been demonstrated that cerebellum is critical to this simple associative learning. Yet, its molecular mechanism is still unclear. Previous studies have shown that protein kinases are mechanism is still uncrear. Frevious studies have shown that protein kinasas are involved in many non-associative and associative learning paradigms in Aplysia. Hemissenda and LTP in hippocampus. This study is an attempt to assess whether protein kinases may also be involved in the eyeblink conditioning and to verify whether the memory trace of this learning is located in the cerebellum.

Rabbits were implanted with cannula just dorsal to the interpositus nucleus (IP)

bilaterally. After recovery, the rabbits received standard delay eyeblink conditioning for 8 days (60 trials each day). All animals received unilateral injection of H-7 (3 uL. 20 ug/uL) and a contralateral injection of the same amount of saline (0.9%) as a control during different period of the experiment. Injections were made either immediately before or during the training (at a rate of 3uL/15min). The sides and order of treatment were designed to let different sides of each animal be its own control and the possible transfer effect be counterbalanced between experimental and control groups. Well-trained control animals were also injected with H-7 to test its effect on performance or retention. The effectiveness of the cannula locations were verified with lidocaine or muscimol

Our preliminary results from 4 rabbits show that rabbits injected with H-7 learned slower than control rabbits. It appears that H-7 may have some long-term effect on this learning. Our results also suggest that H-7 is unlikely to affect the performance or retention of the learned response after the animals are well-trained. These results indicate that protein kinase activity in the IP may be involved in the acquisition of eyeblink conditioning and implicate the IP as a site of plasticity. EYEBLINK CONDITIONING-RELATED NEURONAL MODEL IN LATERAL PONTINE NUCLEUS ARE DRIVEN BY CEREBELLUM S Bao* L Chen and ONTINE NUCLEUS ARE DRIVEN BY CEREBELLUM. S. Bao*, L. Chen and F. Thompson. Neuroscience Program, Univ. of Southern Calif., Los Angeles, CA

Inactivation of the ipsilateral cerebellar interpositus nucleus (i-IP) has been shown to abolish classical eyeblink conditioning induced neuronal models in several brain regions, such as the red nucleus, whereas inactivation of the red nucleus and brain stem motor nuclei did not abolish the model in i-IP. In the present study, we examined wheather the neuronal model in contralateral lateral pontine nucleus (c-LPN) is driven by the i-IP.

LPN) is driven by the i-IP.

New Zealand white rabbits were surgically implanted with two stimulating electrodes in ipsilateral lateral reticular nucleus (i-LRN), two recording electrodes and a guide cannula in c-LPN, and in i-IP. After recovery, the animals were trained with delay classical eyeblink conditioning with LRN stimulation as the CS and airpuff as US. When they reached the criteria (9 CRs out of 10 trials), the CS was changed to tone and the animals were trained to criteria again. Then, muscimol was infused into i-IP, and the animals were tested with mixed training (50 tone/air and

infused into i-IP, and the animals were tested with mixed training (50 tone/air and 50 LRN/air trials). After one day recovery and mixed training, the animals were infused with TTX into c-LPN and tested with mixed training. Finally, some of the animals received electrolytic lesions in the c-LPN and the others received lesions in the i-IP. After one day recovery, the animals were tested with mixed training. The multiple unit activities in c-LPN and i-IP were and recorded during training. Inactivation of i-IP abolished CRs when the CS was tone or LRN stimulation. Inactivation of c-LPN only abolished CRs to tone, but not to the LRN stimulation When LRN stimulation was used as the CS, inactivation of i-IP abolished the neuronal model in the pontine region, while inactivation of c-LPN had little effect on the neuronal model in i-IP. Thus, the learning induced neuronal model in c-LPN is very likely driven by i-IP. These results suggest that the lateral pontine nucleus is not a locus of memory storage for the conditioned eyeblink response, but simply acts as a sensory relay nucleus for acoustic stimuli. Supported by grants from NSF (IBN9215069), NIMH (MHS2194), ONR (N00014-95-1-1152) and Sankyo Co., Ltd.

Reversible Inactivation of Red Nucleus With Cooling Has No Effect On Tone Evoked and Learning Related Unit Activity In Central Regions of The Lateral Pontine Nuclei. M.C.Cartford*, E.Gohl, M. Singson, E. Wang, L. Tasa, D.G. Lavond. University of Southern California, Depts of Psychology and Neurobiology, HNB 501, University Park, Los Angeles, California 90089-2520.

In simple delay classical conditioning of the rabbit nictitating membrane response conditioned stimulus (CS) tone information projects to the cerebellum via the lateral pontine nuclei (LPN). Steinmetz et al. have shown that stimulation of this region can itself serve as a CS (Bull, Psych Soc., 23, 1985, pp.245ff) and that LPN lesions abolish conditioned responses to a tone (Proc Nat'l Acad Sci, <u>84</u>, 1987, pp.353ff).

Additional studies have shown that unit activity recorded in the pontine

nuclei shows evoked and learning related responses when animals are trained with a tone as the CS. Reversible inactivation of the cerebellar interpositus nucleus (IP) abolishes this learning related unit activity in the LPN but has no effect on tone evoked neural responses (Gohl et al., Neurosci Abst, 19, 1993, p.1000).

We have now tested the effects of red nucleus cooling on evoked and

learning related unit activity in LPN in rabbits trained to a tone CS. Our results indicate that cooling red nucleus abolishes learning and tone results indicate that cooling ted nucleus abbilishes learning and tone related unit activity throughout the pons except the mid level area of the lateral pons. This area is known to project to the IP (Steinmetz, et al., Behav. Neur. Bio, 60, 1992, pp.172ff) and to receive reciprocal projections (Watt et al., Neurosci Abst, 5_ 1979, p.108). Together these data support the hypothesis that the IP participates directly in the expression of learning related unit activity in the LPN.

HIPPOCAMPAL LESIONS DO NOT DISRUPT THE LEARNING-DEPENDENT TIMING OF CLASSICALLY CONDITIONED RABBIT EYEBLINK RESPONSES. M.T. Allen * & J.E., Steinmetz. Prog. in Neural Science, Psychology Dept. Indiana University. Bloomington, IN 47405.

Rabbits are able to discriminate between two different tone frequencies that are used as conditioned stimuli (CS) when paired with an air puff unconditioned stimulus (US) at a long or short inter-stimulus interval (ISI) (Mauk & Ruiz,

<u>Behavioral Neuroscience.</u> <u>106</u>. 1992). The timing of CRs in well trained animals is adaptive for maximal eyelid closure immediately prior to US onset for both the long and short ISi intervals. The hippocampus has been implicated in playing a role in the timing of the CR, so we were interested in testing the effects of ibotenic acid hippocampal lesions on the acquisition and retention of these differentially timed CRs. Rabbits in the acquisition groups were given either hippocampal or sham lesions during aseptic surgery prior to training. Rabbits were trained by using two different tone frequencies paired with the US at either a long (747 msec) or short ISI (249 msec) in a standard delay paradigm. Each rabbit received 96 paired presentations of a tone CS and an air puff US and 24 tone alone test trials in daily sessions. On half of the trials, a 249 msec period was allowed between CS and US onsets while on the other half of the trials, a 747 msec period was allowed. Criterion was defined as 75% CRs to both tone/ISI pairings with the mean peak latency within 100 msec of the actual ISI length on tone alone trials. Rabbits in the retention group were given either hippocampal or sham lesions following two sessions of criterion responding. Hippocampal lesions had no detrimental effects on the acquisition or retention of the timing of the long and short latency CRs. Hippocampal lesions did facilitate acquisition and led to larger amplitude CRs Overall, it appears the hippocampus is not necessary for the precise timing in this differential ISI paradigm. CONTEXTUAL DISCRIMINATION DURING CLASSICAL EYELID CONDITIONING IN RABBIT. R.F. Rogers*, D.M. Shock & J.E. Steinmetz

Department of Psychology, Indiana University, Bloomington, IN 47401 Contextual discrimination of the conditioned eyeblink response (CR) was investigated. Animals were exposed (80 trials/d) to a single CS (tone; 350 ms) which was either presented alone or coterminated with a corneal airpuff (US; 100 ms). In conjunction with this discrete training, animals experienced two different contextual backgrounds during the intertrial interval and trial presentation. These contexts were defined by either the presence or absence of a diffuse oscillating chamber light. Consequently, for half the animals, paired CS-US trials were signaled by the presence of light and CS alone trials were signaled by darkness The remaining animals were trained under the opposite contextual contingency.

The results indicate that in rabbits, conditioned eyelid responding to a single CS is subject to contextual modulation. Specifically, early in conditioning, animals developed CRs in both the reinforced and nonreinforced contexts, but with subsequent training, began to respond differentially (72% in reinforced and 27% in nonreinforced) to the CS as a function of the context. In order to further demonstrate contextual control over responding, a subset of animals were exposed to contextual extinction trials in which all trials occurred within their nonreinforced context. With the contextual contingency removed, animals came to respond equally on CS-alone (75% CRs) and paired (72% CRs) trials. Moreover, when the contextual contingency was reestablished, differential responding was again observed. This paradigm has several advantages for neurophysiological investigations into contextual processing during discrete motor learning, most prominent are, 1) the contextual information used by the animal has been restricted to a single sensory modality, and 2) contextual shifts are performed on a trial-bytrial basis, thus facilitating neural recording and allowing a within subject analysis of the data. PURKINJE CELL RESPONSES IN PONTINE STIMULATION-TRAINED RABBITS ARE SIMILAR TO THOSE FOUND IN TONE TRAINED ANIMALS. J. Tracy* and J.E. Steinmetz. Department of Psychology and Program in Neura Science, Indiana University, Bloomington, IN 47405.

Evidence of cerebellar involvement in cyeblink conditioning includes extracellular unit recordings of Purkinje cells which show learning-related, as well as stimulus evoked, discharge patterns. Responses correlated with conditioned behavior include changes in firing rates that precede the behavior by 20 to 100 ms (Bertheir & Moore, 1986). Peripheral stimuli typically used in this paradigm reach the cerebellum via mossy fibers emanating from the pontine nuclei. As such, pontine stimulation serves as a highly effective CS. Although pontine stimulation supports learning when used as a CS, and earlier studies have shown that unit responses in the cerebellar nuclei show the same patterns of activation as those evoked with a tone stimulus, it has not been established that the same holds true for the cerebellar cortex

The current study examines the responses of cerebellar cortical cells to shortlatency pontine stimulation in trained rabbits. Animals were surgically prepared by implanting bipolar stimulating electrodes in the dorsolateral region of the pons. A microdrive adaptor was implanted over the cerebellum. After a week recovery period, animals were trained to criteria using 25 ms, 200 Hz trains of pontine stimulation as the CS (10-100 uA pulses of 0.1 ms each) paired with airpuff (US).

Single unit recordings of Purkinje cells in trained rabbits reveal patterns of responses very similar to those seen in rabbits trained to a tone CS. Thirty six percent of all recorded cells show a significant change in firing frequency during the CS period, prior to onset of the US. In addition, many very short latency changes in simple spiking patterns are observed which appear to be directly related to mossy fiber activation from the pontine stimulation. CONDITIONED ANTINOCICEPTION IN SPINAL RATS: SSOCIATIVE LEARNING VERSUS PROTECTION FROM HABITUATION. R.L. Joynes* & J.W. Grau. Dept. of Psychology, Texas A&M University, College Station, TX 77843.

Conditioned antinociception can be demonstrated in spinalized rats

by pairing stimulation (10-s, 1-mA shock) to one hind leg (the conditioned stimulus [CS]) with an intense (2-s, 3-mA) tailshock (the unconditioned stimulus [US]). After 30 CS-US pairings, tail-flick latencies are assessed during the CS. Relative to a CS that was presented in an unpaired fashion (the CS-), rats exhibit longer tail-flick latencies during the paired CS (the CS+) (Grau et al., *Behav. Neurosci.*, 104, 489, 1990). The present study explores the mechanisms that underlie this learning.

Prior work has shown that our CSs elicit some antinociception prior to training and that presenting the CS alone attenuates (habituates) its antinociceptive impact. But when the CS is paired with the US, no habituation is observed. Does the US simply "protect" the CS from habituation, or does it support a simple form of associative learning? These two alternatives can be distiguished by varying the intertrial interval (ITI) and the number of training trials. If associative learning is involved, increasing the ITI and the number of CS-US pairings should strengthen the CS+/CS- difference, while a habituation account anticipates the opposite; increasing the ITI should reduce the CS+/CS- difference by decreasing habituation to the CS-, whereas increasing the number of CS-US pairings should reduce it by facilitating habituation to the CS+. Our results indicate that protection from habituation underlies learning in our spinal paradigm. Supported by MH48994 to J.W.G.

INTERPOSITUS LESIONS ALTER THE TIMING OF, BUT DO NOT RABBIT CEREBELLAR CORTEX. D. B. Katz* & J. E. Steinmetz. Department of Psychology/Program of Neural Science, Indiana University, Bloomington, IN

The interpositus nucleus (INP) appears to be integrally involved in the production of conditioned eyeblinks in the rabbit. The involvement of the cerebellar cortex (CTX) has been more difficult to ascertain, despite theoretical work anticipating cerebellar cortical coding of motor learning. In the present study, 20 male albino New Zealand rabbits were trained to blink to a 1kHz tone paired with a 3 psi airpuff (the interval between the onsets of stimuli was 250 msec). Following attainment of conditioning criterion, rabbits received either kainic acid or sham lesions of the INP,

after which training was resumed. Single Purkinje and granule cells were recorded during post-lesion training.

Lesioned animals failed to produce appreciable numbers of conditioned eyeblinks in post-lesion sessions (sham animals were unimpaired), but did demonstrate "conditioning-related" firing patterns in a subpopulation of cerebellar cortical neurons. Purkinje and granule cells showed patterns of activity that preceded the onset of the UCS by varying amounts. The temporal properties of peri-trial histograms were affected by the INP lesions, however: Complex patterns of activity, sometimes involving two distinct subperiods of excitation in the CS-period, could be discerned in the firing of cortical neurons in lesioned animals. In both lesioned and unlesioned animals, the same neurons that appeared conditioning-related in paired and CS-alone trials often responded phasically to the airpuff in UCS-alone trials.

Results suggest that the CTX supports conditioning-related activity independent of the INP, but that the timing of neural activity in relation to eyeblink activity may be a function of the entire cerebellar system. Supported by NIH grant #MH51178 to JES.

CEREBELLAR INTERPOSED NUCLEUS AND THE CLASSICALLY CONDITIONED AND AVOIDANCE LIMB WITHDRAWAL RESPONSES IN THE CAT K.B. Irwin, J.R. Bloedel, and V. Bracha*. Barrow Neurological Institute, Phoenix. AZ 85 013.

Previously, we demonstrated that inactivation of the cerebellar interposed nucleus (IN) blocks the limb flexion component of the classically conditioned forelimb withdrawal response (FWR). This finding supports suggestions of the critical role of the IN in the organization of learned anticipatory noci-fensive reflexes. To examine organization of real red anticipatory notations referees. To examine the generality of this notion, we tested IN involvement in the FWR in a paradigm which allowed the animal to avoid the unconditioned stimulus (US) by generating the conditioned response. FWRs were first classically conditioned using a cutaneous airpuff as a conditioned stimulus (CS) and electrical stimulation of the forelimb as an US. Then, IN sites critical for classically conditioned FWRs were identified by muscimol microinjections. Subsequently, the same animals were trained in an avoidance paradigm using the same CS and US. Finally, the animals were retrained in the classical conditioning paradigm. Inactivation of sites at which the drug blocked the classically conditioned FWR produced an appreciably smaller effect on the avoidance FWR. Surprisingly, injections at the same sites in cats retrained from avoidance to classical conditioning increased the conditioned responses. It is concluded that the classically conditioned and avoidance FWRs are subserved by different neural networks and that the effects of IN inactivation on classically conditioned responses are dependent on the previous experience of the animals.

DIFFERENTIAL CHANGES IN PKC-IMMUNOREACTIVITY IN ASTROCYTES AND NEURONS IN RABBIT CAI AFTER ASSOCIATIVE LEARNING. E.A. Van der Zec. M.A. Kronforst-Collins. and J.F. Disterhoft. CM Biol., Northwestern Univ. Med. Sch., 303 E. Chicago Ave., Chicago, IL 60611, USA

Protein kinase C (PKC) modulates one E. Chicago Ave., Chicago, 16. 00011, USA Protein kinase C (PKC) modulates neuronal activity in the hippocampus in relation to learning and memory, partly through the phosphorylation of K* channels. PKC is expressed in both neurons and astrocytes. A two-fold trace eyeblink conditioning-induced increase in the immunoreactivity for PKC γ , but not $-\alpha$, $-\beta 1$, or $-\beta 2$, was found in principal neurons of the dentate gyrus, CA3 and CA1 (but not the subiculum) of the rabbit hippocampus (Van der Zee et al., 1995, Soc. Neurosci. Abstr. 21:1218). Here the number of PKC-immunoreactive astrocytes in the subiculum and CA1 of naive (N, n=7), pseudoconditioned (P, n=7) and trace conditioned (T, n=7) female NZW rabbits was determined 24h after reaching an 80% CRs/session criterion.

PKC α , - β 1, - β 2, and - γ are differentially expressed in astrocytes. A significant decrease in the number of PKC β 2 and - γ -positive astrocytes was found in the CA1 region, whereas no differences were found for PKC α or - β 1. No alterations occurred in the subiculum. These results suggest a selective down-regulation of PKC β 2 and - γ in astrocytes in a brain region we have shown to be involved in associative learning. We speculate that the down-regulation of glial PKC relates to the K buffering function of astrocytes. Down-regulation of PKC should reduce the phosphorylation of K channels and enhance the efficacy of K buffering in astrocytes of conditioned over naive and pseudoconditioned animals. HIPPOCAMPAL LESIONS IMPAIR SPATIAL LEARNING, BUT NOT REINSTATEMENT OF EXTINGUISHED APPETITIVE PAVLOVIAN CONDITIONING IN RATS. G.D. Fox¹, M. Gallagher¹, and M.E. Stanton¹*¹, P.C. Holland². Dept. Of Psychology, Univ. North Carolina, Chapel Hill, NC; ²Dept. Psychology, Duke Univ., Durham, NC.

Male, Long-Evans rats with ibotenic acid lesions of the hippocampus and non-lesioned control rats were conditioned in a Pavlovian appetitive procedure in which a visual stimulus was paired with food. Conditioned responding was then extinguished. After extinction, one group of lesioned and one group of non-lesioned animals were given presentations of the food US in the original conditioning chambers. The remaining animals were placed in the chambers but did not receive US presentations. Finally, all rats received a test of conditioned responding to the light CS alone. Rats that received the post-extinction US presentations showed higher levels of conditioned responding than the rats that had only been placed in the chambers. This reinstatement of conditioned responding to the light CS was not effected by hippocampal lesions. A sample of lesioned animals from this study did, however, demonstrate impaired performance in a water-maze task known to be sensitive to hippocampal damage. These data are in contrast to those of Wilson, Brooks, and Bouton (Behav. Neurosci., 109, 828-836), who have demonstrated that reinstatement of aversively conditioned behavior is abolished with lesions of the fornix.

PRETRAINING LESIONS OF THE INTERMEDIATE MEDIAL HYPERSTRIATUM VENTRALE IMPAIR SICKNESS-CONDITIONED LEARNING IN DAY-OLD CHICKS. T. A. Barber*, P. D. Howorth, and C.C. Cho. Department of Psychology, Dickinson College, Carlisle, PA 17013-2896.

The intermediate medial hyperstriatum ventrale (IMHV) is necessary for learning a one-trial passive avoidance task (Patterson, Gilbert, & Rose, 1990; Patterson & Rose, 1992). We examined the effects of pretraining IMHV lesions in one-trial sickness-conditioned learning, which is similar to passive avoidance since the chick must remember visual cues in order to respond correctly. However, the two tasks differ in type of aversive stimulus (sickness vs. bitter taste) and CS-US separation (30 min delay vs.

Day-old chicks were given either bilateral, unilateral or sham lesions of the IMHV. At training, chicks pecked a dry 3 mm chrome bead and 30 min later were injected (IP) with either saline or lithium chloride (LiCl; 0.1 ml 1.0 M). Chicks were tested four hours after training by presentation of a 3 mm chrome bead. Chicks that pecked the bead after receiving LiCl were considered amnesic for the association.

Bilateral IMHV lesions impaired sickness-conditioned learning, similar to results found for passive avoidance. Unilateral left or right IMHV lesions also impaired sickness-conditioned learning, suggesting that memory formation for this task is dependent on intact functioning of both left and right IMHV. These results are in contrast to those for passive avoidance in which only unilateral left IMHV lesions produced amnesia.

The IMHV appears to play a general role in memory formation in the chick, differences in lateralization may be related to the specific paradigm under study.

DISCRIMINATIVE HIPPOCAMPAL NEURAL RESPONSES TO SPATIAL CUES IN RABBIT CLASSICAL CONDITIONING M.A. Seager*, R.L. Borgnis, A.A. Kendall & S.D. Berry. Center for Neuroscience and Department of Psychology, Miami Univ., Oxford, OH 45056.

The predominant theory of hippocampal function in the rodent has been that this structure creates a cognitive representation or "map" of the animal's environment. Lesions to the hippocampus or its connections typically result in spatial learning and memory deficits. Another very different line of research has investigated the role of the hippocampus during classical conditioning in the rabbit. Pyramidal cells in this structure become highly engaged during learning and performance of `NM/eyelid and jaw movement conditioned responses. Additionally, lesions to this structure produce behavioral deficits (e.g., disruptions in the timing and form of responses) during a subset of conditioning tasks.

It was our goal to bring these two disparate lines of research together. To accomplish this, we developed a spatial classical conditioning task. Rabbits were trained using a modified delay NM paradigm which incorporates a spatial dimension. A click train CS varied in location (either 45 degrees to the left or to the right of the animal). The click train coming from only one of the spatial locations was followed by a 100 ms air puff.

Hippocampal unit data was analyzed by averaging spike counts in the PRE-CS, CS, and US periods across trials in a session. These hippocampal unit averages revealed a clear discriminative response between the CS+ and the CS- trials, whether or not the animal was discriminating behaviorally.

A ROLE FOR THE DORSOLATERAL STRIATUM IN EXPRESSION OF CONDITIONED ORIENTING RESPONSES. J. S. Han¹*, R. W. McMahan¹, P. C. Holland², and M. Gallagher¹. Dept. of Psychology, Univ. of North Carolina, Chapel Hill, NC 27599, ²Dept. of Psychology, Duke University, Durham, NC 27708. Prior studies have shown that neurotoxic lesions of the amygdala central nucleus (CN) impair conditioned orienting responses (OR) that

Prior studies have shown that neurotoxic lesions of the amygdala central nucleus (CN) impair conditioned orienting responses (OR) that are acquired with conditioned stimulus (CS)-unconditioned stimulus (US) pairings. The integrity of an amygdalo-nigrostriatal pathway is critical for the development of conditioned ORs; aasymmetrical lesions of CN and dorsolateral striatum (STR), but not unilateral lesions of each of these structures, abolish conditioned ORs. Here we used a reversible inactivation of the STR combined with a contralateral CN ibotenic acid lesion to test whether the STR is necessary for the acquisition or only for the expression of conditioned ORs. Each session was comprised of 4 trials, consisting of a 10-sec light (CS) followed by 2 food pellets. The STR was inactivated with a lidocaine (1 µl) infusion before each session for 8 consecutive days, but then no infusions were made for 6 subsequent daily sessions. Rats in the asymmetrical group (lobtenic acid lesion of CN with STR inactivation contralaterally) failed to exhibit conditioned ORs during the inactivation sessions. However, these ORs emerged during the first session without inactivation and did not increase with subsequent training. Rats in the symmetrical group (ibotenic acid lesion of CN with STR inactivation ipsilaterally) showed normal conditioned ORs. These results show that the STR is critical for expression of a conditioned OR. EFFECTS OF IBOTENIC ACID INDUCED LESIONS ON MEMORY FOR A VISUAL DISCRIMINATION TASK. R.A. Deyo. P. A. Baukol, L. J. Edelbach, T. J. Finne and G. E. McKenney. Department of Psychology, Winona State Univ., Winona, MN 55987.

The pebble floor visual discrimination task is an economical method of screening nootropics in chicks that generalizes very well to other animal models, and more importantly to effects on human memory (e.g., Deyo & Hittner, 1995; Neurobiol. Learn. Mem., 64, 10-16). However, there still is very little known about which areas of the chick brain learn and remember visual discriminations. Thus, the present experiment was designed to study the localization of visual discrimination memory in the chick brain.

chick brain. Five-day-old male chicks received 100 acquisition trials on the "pebble floor" visual discrimination task. Immediately after the last trial, chicks received 1 μL injections of 0, or 1 μg/μL ibotenic acid. All drugs were injected bilaterally within the intermediate hyperstriatum ventrale (IMHV) using a 10 μL Hamilton microsyringe that was fitted with PE tubing to insure an injection depth of 4 mm. The IMHV was selected on the basis of previous studies of avoidance learning in chicks that suggest the IMHV is required for learning and memory (e.g., Freeman, et al., 1995, Neurobiol. Learn. Mem. 63, 291-295). Forty-eight hours after treatment, chicks received 20 retention trials. After the last trial, each brain was removed and fixed in a buffered formalin solution for at least two weeks. Histological analyses were completed following cresyl violet staining for rell hodigs.

Ibotenic acid treated chicks made significantly more errors 48 hr after treatment. Analyses of the histology revealed significant cell loss in the IMHV. These data suggest that retention of the visual discrimination task is dependent upon the integrity of the IMHV.

LESIONS OF THE MEDIAL PREFRONTAL CORTEX AND APPETITIVE JAW MOVEMENT CONDITIONING IN THE RABBIT. Joselyn McLaughlin* & D.A. Powell. VA Medical Center and University of South Carolina, Columbia, SC 29209.

Sham and medial prefrontal (mPFC) lesioned rabbits received classical conditioning in which a tone served as the conditional stimulus (CS) and an intraoral 1 cc pulse of sugar water was the unconditional stimulus (US). Conditioned jaw movement and heart rate changes were explicitly unpaired tone and sugar water presentations. mPFC lesions had no effect on jaw movement conditioning, but abolished the early-occurring decelerative heart rate changes obtained in sham-lesioned animals. Later-occurring increases in heart rate, associated with asymptotic jaw movement responding were, however, augmented by prefrontal lesions. These results are comparable to those obtained in a previous study, indicating that the early-occurring decelerative conditioned HR changes during appetitive classical conditioning are attenuated by mPFC lesions but the later occurring increases in heart rate are augmented. Thus both components of the HR CR are affected by mPFC lesions.

EFFECTS OF BLOCKING THE PAVLOVIAN CONDITIONING OF TONES ON THE RAT AUDITORY SYSTEM MAPPED WITH CYTOCHROME OXIDASE HISTOCHEMISTRY. A. Poremba*, F. Gonzalez-Lima, and D. Jones, Dept. of Psych. and Inst. for Neurosci., Univ. of Texas, Austin, TX, 78712

The Kamin blocking phenomenon occurs when behavioral conditioning to a novel stimulus fails in the presence of a previously conditioned stimulus. Quantitative histochemistry of cytochrome oxidase (C.O.), a mitochondrial enzyme of oxidative metabolism, was used to evaluate cumulative changes in metabolic capacity resulting from the entire training experience of Pavlovian conditioned suppression of drinking. Rats in Group 1 (Blocking) received pairings of a light conditional stimulus (CS; flashing at 10 Hz) with a mild footshock to elicit conditioned suppression of drinking during Phase 1 training. Rats in Group 2 (Excitor) received random presentations of the light CS and shock stimuli. Both groups then received the same Phase 2 training consisting of a tone CS (1 - 2 KHz FM) and the light CS presented simultaneously, paired with footshock. The Excitor Group exhibited significant suppression of drinking (p < .05) to tone only presentations after training and as expected, the Blocking Group did not. Metabolic mapping results for the auditory system demonstrate significantly elevated levels of C.O. activity in the central nucleus of the inferior colliculus and the dorsal cochlear nucleus for the Blocking Group versus the Excitor Group, specifically in the region of the CS tonotopic representation (p<.05). These findings suggest that 1) distinct neural changes in the response to the tone CS can be attributed to the blocking phenomenon and 2) specific changes in C.O. activity can be linked to behavior. (Supported by NIH grant RO1 MH4333).

CLASSICAL CONDITIONING RESULTS IN DENDRITIC EXCITABILITY AND OCCLUDES LONG-TERM DEPRESSION. B. G., Schreurs*, D. Tomsic, P. Gusev and D. L. Alkon. LAS, NINDS, NIH Bethesda, MD 20892. Intradendritic recordings in Purkinje cells (n=89) from parasaggital slices of

cerebellar lobule HVI obtained from rabbits given paired presentations of tone and periorbital electrical stimulation resulted in increased membrane and synaptic excitability relative to cells (n=63) from animals given explicitly unpaired stimulus presentations (p's < .01). The location of cells with low thresholds for local dendritic calcium spikes suggested that there are specific sites within lobule HVI where learning-related changes take place. These areas may correspond to learning "microzones" and are consistent with the locations of some learning-related changes in Purkinje cell activity recorded in vivo. Application of 4-aminopyridine, an antagonist of the potassium inactivating current I_a, reduced the threshold for dendritic spikes in slices from naive animals to levels found in slices from trained animals (p < .01). Following 20 pairings of a brief, high frequency train of parallel fiber stimulation (8 pulses, 100 Hz) with a brief, lower frequency train of climbing fiber stimulation (3 pulses, 20 Hz), Purkinje cell excitatory post synaptic potentials (EPSPs) underwent a long-term (> 20 min) reduction in peak amplitude (-24%) in cells (n=12) from animals given in vivo unpaired stimulus presentations but to a far less extent (-9%) in cells (n=20) from animals given in vivo paired training (p <.01). In fact, whereas 92%of cells from unpaired animals showed pairing-specific depression, 50% of cells from paired animals showed no depression and in several cases actually showed potentiation. The threshold level of stimulation required to elicit the 6-8 mV EPSP as well as a 4-mV EPSP (n=30) and a Purkinje cell spike (n=56) was found to be significantly lower in slices from animals given paired training than those given unpaired stimulus presentations. It is suggested that this enhanced synaptic excitability and not a learning-induced synaptic depression occludes pairing-specific long-term depression.

FUNCTIONAL CONNECTIVITY BETWEEN FRONTAL CORTICAL NEURONS DURING REVERSAL CONDITIONING IN THE DOG. A. Kozlov*, V. Shabaev. Pavlov's Physiol. Dep., Inst. Exp. Med., St. Petersburg, 197376, Russia

We studied spatiotemporal patterns of correlations between simultaneously recorded spike trains in the frontal cortical areas of the dog which performed a task of reversal conditioning. Using developed in our lab approach for the correlation analysis of neuronal firing we revealed that functional connectivity between cortical cells was organized in the "interspike interval-specific" manner. This type of temporal relations between spike occurrences in two impulse trains was expressed as a different probability of the spike generation by one unit to the interspike intervals (ISI) of various durations of another neuron. It was found that parameters of ISI-dependent correlations (it's "strength", duration of effective ISI) have varied among situations with different types of behavioral responding (rewarded vs. unrewarded conditioned reactions, maintenance set vs. behavioral set shifts). These findings indicate that reorganization of stimulusresponse associations is accompanied by a shift in a tuning characteristics of neuronal networks as it was expressed in dynamic of the ISI-specific interneuronal connectivity.

BRAIN IMAGING OF EXCITOR VS BLOCKED TONES: CONDITIONING EFFECTS ON AUDITORY PROCESSING OF IDENTICAL STIMULI. D. Jones* & F. Gonzalez-Lima, 1 Dept. of Psych., Univ. of Texas, Austin TX, 78712 USA.

Neural processing of a tone conditioned as an excitor was compared to processing of the same physical tone when excitatory conditioning was blocked by previous experience with a light. Fluorodeoxyglucose (FDG) autoradiography was used to assess changes in the auditory processing of the conditioned tone. Auditory regions (18) were compared in Long-Evans rats trained under a typical 3-phase blocking protocol (Kamin Blocking Effect). A conditioned suppression protocol was used. In phase I, Group Blocked received presentations of light (L) paired with footshock (US) and Group Excitor received unpaired presentations. Phase II training was identical for both groups, consisting of compound tone/light (TL) presentations followed by the US. The pairing of L-US in phase I results in decreased conditioning to T in phase II. Optical density of FDG uptake during exposure to T alone was measured. Significant group differences in 7 auditory regions were revealed using z-scores transformations. Changes in the patterns of intercorrelations of the auditory regions were also seen. Findings suggest that neuronal encoding of a stimulus changes the activity interrelations of auditory regions when the stimulus has acquired different meanings. To our knowledge, this is the first demonstration of changes in the patterns of auditory system processing of a tone due to excitatory vs blocked conditioning. (Supported by RO1 MH43353 and NSF grant IBN 9222075.)

SENSITIZATION OF THE EYEBLINK RESPONSE IN THE RESTRAINED MOUSE.

M.A. Kronforst-Collins*, C. Weiss and J.F. Disterhoft, CM Biology, Northwestern University Med. Sch., 303 E. Chicago Ave., Chicago, IL 60611 USA.

University Med. Sch., 303 E. Chicago Ave., Chicago, IL 60611 USA. Eyeblink conditioning is a popular paradigm used in the investigation of the neural substrates of learning and memory. With the recent increase of genetic manipulation capabilities, the mouse has become an appealing experimental animal for use in the study of learning and memory. A total of 60 mice were used to adapt the restrained rabbit eyeblink conditioning paradigm to the mouse. Balb/c, B6C3F1 and C57BL/6J mice were used to compare the effects of strain differences on eyeblink conditioning. Prior to training, a 2-56 x 5/8" machine screw was implanted on the skull with skull screws and dental acrylic to serve as a headbolt. During training subjects were restrained in plastic tubes with a stock over the neck to secure the body, and the headbolt was used to secure the head. Subjects were trained in either the Delay 250 or Trace 500 paradigms, or were used as pseudoconditioned controls. Subjects were trained in pairs in a sound-attenuated chamber. The conditioned stimulus (CS) consisted of an open-field 350msec (Delay 250) or 100msec (Trace 500) tone at 1, 6 or 10kHz and 70 - 90dB. The unconditioned stimulus (US) was a 150msec, 1.3psi airpuff directed at the cormac. Conditioned stimulus (US) was a 150msec, 1.3psi airpuff directed at the cormac. Conditioned responses (CRs) were measured by an infrared reflective sensor placed in front of the eye. Conditioned subjects received 40 paired trials per day for 5 - 15 days. Pseudoconditioned subjects received 80 explicitly unpaired trials per day for an equal number of days as their conditioned cohort. The CS was manipulated between sets of mice in an attempt to maximize conditioning and minimize sensitization. Regardless of the manipulation, comparable levels of responding, as measured by percent CRs and area of the CR, were observed in both conditioned and pseudoconditioned subjects. Our data demonstrate the high level of responding in differentiating associative CRs from sensitized responses in the mo

Eyeblink Conditioning in the Freely Moving Mouse C. Weiss,* M.A. Kronforst-Collins, and L.F. Disterhoft, Dept. of Cell and Molecular Biology, Northwestern University Medical School, Chicago, IL. 60611

Eyeblink conditioning is a powerful paradigm for examining the neuronal mechanisms of learning and memory. Our current series of experiments uses the mouse to take advantage of recent genetic advances and other benefits related to long-term aging studies, i.e., smaller size, shorter life span and lower expenses.

long-term aging studies, i.e., smaller size, shorter life span and lower expenses.

Male C57BL/6 mice were anesthetized with ketamine and xylazine for the surgical implantation of eyelid EMG recording wires and a skull mounted connector which served to couple the light conditioning stimulus (CS), airpuff unconditioned stimulus (US) and EMG recording leads. Mice were randomly assigned to either a conditioning group which received paired presentations of the CS and US, or to a control group, which received explicitly unpaired presentations of the stimuli. The CS (a 350ms flash from an LED) and US (a 100ms puff of air) were presented in a delaw paradium and the conditioned responses were analyzed delay paradigm, and the conditioned and unconditioned responses were analyzed from the rectified and integrated EMG activity

The results indicate that the visual CS minimized sensitization and maximized associative learning. Mice which received paired presentations of the stimuli had a greater percentage of trials with conditioned responses than mice which received unpaired presentations of light and airpuff. The responses from conditioned mice were also greater in amplitude and area of response than the responses from mice which received unpaired presentations of the CS and US.

This experiment indicates that eyeblink conditioning in the freely moving mouse is a useful model system for the genetic analysis of age-related learning and memory impairments. Learning in this paradigm may also be correlated with learning in other tasks, e.g., spatial mazes, and with physiological and pharmacological data to obtain tasks, e.g., spatial mazes, and with physiological and pnarmacological data to obtain a more complete understanding of learning mechanisms. This combination of tasks is practical to do in the mouse, and should help to fill a void in the behavioral database that is developing as the genetic and molecular effects of age-related diseases, e.g., Alzheimer's disease, become more well known. WHERE NO PAVLOVIAN LEARNING PARADIGM HAS GONE BEFORE. EYEBLINK CONDITIONING IN SPACE. R. J. Servatius J. Shors 2, R. Peterson 3, C. Amberboy 3, D. Grounds 3 & W. N. Tapp 1, 1 Dept. Of Neuroscience, New Jersey Medical School, 2 Dept. Of Psychology, Princeton University, 3 Johnson Space Center, Houston, Texas

Space travel remains a perilous adventure. The mental stresses of spaceflight are compounded by prolonged exposure to a microgravity environment. Our challenge for Neurolab, the shuttle mission dedicated to Neuroscience, is to measure nonassociative and associative learning in astronauts in terms of visceral and motoric responses. We have developed a compact, portable stimulus generation box (SGB) to accomplish these tasks. The SGB has an air pump (DC 12/16 NK Furgut Industries, distributed by MRM International) which fills an air filter resevoir (type 9933-11-BX filter tube, Balston Filter Products) through a check valve (#302PPb-3", Smart Products, Inc.). A solenoid valve with 0.089" diameter orfice (CS-1744, Clippard Industrial Laboratory, Inc) controls air puff outflow. A quick disconnect is the interface between the SGB and a headset (Model H10-56, David Clark Co.). The microphone armature on the headset has been adapted to deliver the airpuff. The SGB also has the capability to produce acoustic stimuli, white noise for tests of sensory reactivity (105, 90, 75 dB) and pure tones for two-tone discrimination (1500 and 800 Hz tones at 90 dB). To complete the system, electromyograph, electrocardiograph and respiration signals will be amplified and passed to a PCMCIA AID card (DAQ 700, National Instruments). An IBM 755C notebook computer running Labview software (National Instruments) will control the delivery of stimuli and the acquisition of the physiological signals. We will present schematics for this equipment as well as a working model. This NASA-designed equipment is amenable for use in nontraditional experimental venues. Supported through NASA contracts to TJS and RJS

EFFECTS OF TRACE INTERVAL ON THE LEARNING OF CONDITIONED FEAR IN A CO2 PAVLOVIAN CONDITIONING PARADIGM: CONDITIONING FOLLOWING A ONE HOUR TRACE INTERVAL. D. L. Mongeluzi*, B.C. Caldarone, H. S. Stock, & R. A. Rosellini. The University At Albany, State University of New York, Department of Psychology, Albany, NY 12222

Previous studies in our laboratory have shown that 30 s exposure to 100% CO2 can serve as an effective US in a Pavlovian conditioning paradigm The present study began to determine the effective interval for trace conditioning with the CO2 preparation (i.e., either 0, immediate, 5, 15, 30, or 60 min). Results indicated that the shorter the trace interval during CO2 exposure, the higher was the level of conditioning as represented by conditioned freezing and tail-flick latencies. Trace intervals of immediate, 5, 15, 30, and 60 min produced elevated levels of freezing twenty-four hours following conditioning relative to controls. Moreover, there existed a positive monotonic relationship between trace interval and resistance to extinction as measured by freezing, ranging from relatively little resistance to extinction with a 30 and 60 min trace interval to a great deal of resistance with an immediate and 5 min trace interval. This positive and monotonic relationship between trace interval and level of conditioning to the context was also evident on the tail-flick measure. Immediate and five minute trace intervals resulted in the highest elevation of tail-flick latencies, a 15 min trace interval resulted in intermediate tail-flick latencies, and 0, 30, and 60, min trace intervals resulted in latencies equivalent to baseline. Supported in part by a SUNY Graduate Student Organization grant to DLM.

A COMPARISON OF DELAY AND TRACE PAVLOVIAN EYEBLINK CONDITIONING IN DEVELOPING RATS. <u>D. Ivkovich*¹ and M.E. Stanton²</u>, ¹Duke University, Durham, NC 27708-0086 & ²U.S. EPA, RTP, NC 27711.

Classical eyeblink conditioning (EBC) may be a useful model system for studying the neural basis of learning and its disorders during ontogeny. In adult rabbits acquisition of delay EBC, in which the CS and US overlap and coterminate, is dependent solely on cerebellar-brainstem circuitry. In contrast, trace conditioning, in which a temporal gap separates the CS and US, additionally involves the hippocampus. In the rat, both cerebellum and hippocampus are known to continue to develop postnatally, and acquisition of delay EBC develops between postnatal day 17 (PND17) and PND24 (Stanton, Freeman, & Skelton, 1992, Behav. Neurosci. 106, 657-665). The present study compares development of acquisition of delay and trace conditioning in PND23 and PND30 rats.

In standard delay conditioning, rat pups experienced a 380 msec, 2.8 kHz, 90 dB

tone CS and 100 msec, 2 mA periocular shock US (Stanton et al., ibid). Trace conditioning consisted of the same tone and shock stimuli separated by a 500 msec trace interval. Animals were given 6 sessions of training, three 100-trial sessions/ day, over two days. Percent CRs increased significantly across the 6 sessions for all subjects with no significant effect of age or conditioning paradigm. For CR amplitude, responses were greater in delay than trace conditioning (p<.01) but did not differ significantly across age (although in trace conditioning responses tended to be greater for PND30 than PND23 rats). UR amplitude did not differ between training groups or age groups. These findings suggest that by PND23, rats have sufficiently developed cerebellar and hippocampal circuitry to support both delay and trace conditioning. SUPPORTED BY U.S. EPA

GENETIC MODELS: NATURAL MUTANTS

A PANEL OF CONGENIC MOUSE STRAINS FOR SYSTEMATIC, CONTROLLED STUDY OF A COMPLEX GENETIC TRAIT, EPILEPSY M. E. Legare, W.N. Frankel*, The Jackson Laboratory, Bar Harbor, ME

In the EL/Suz and SWXL-4 mouse strains, several unidentified susceptibility genes produce recurrent, tonic-clonic seizures that resemble the most common human epilepsies. Quantitative trait locus (QTL) mapping in various intercrosses and backcrosses of EL with ABP (a low-seizure strain) have identified four seizure frequency QTL on three different chromosomes. QTL mapping of SWXL-4 with ABP has identified at least two seizure frequency QTL on two different chromosomes. Major conclusions from these studies were that no single mapped QTL is

somes. Major conclusions from these studies were that no single mapped QIL is necessary and sufficient for frequent seizures, and that the effects of some loci were unusually dependent on very specific allelic combinations.

We are simplifying the models by breeding high seizure alleles from EL or SWXL-4 onto an ABP background, using DNA flanking-marker selection. For El genes, introgression of El1 (Chr 9), El2 (Chr 2) or El3 (Chr 10) led to three ABP EL congenic strains, and one compound congenic (El1, El4 plus El2). In homozygotes, significant trait differences were found so far: EL strain (0.72 seizure frequency) > El1, El2, El4 (0.50), El2 (0.35) > El1, El4 (0.22) > El3, ABP strain (0.09). Crosses (El El El El (1.04 El) (0.05) = Crosses (El El El (1.04 El) (0.05) = Crosses (El El El (1.04 El) (0.05)). of E11,E12,E14 and E12 congenics are currently underway to determine whether the seizure frequency increase in the compound congenic maps to E11 or E14. Testing of early generations of similar ABP SWXL-4 congenics for Szf/ (Chr 7) and Szf/ (Chr 16) suggests that at least Szf/ homozygotes will have a seizure frequency of -0.30.

This panel of congenic strains with identical genetic backgrounds will offer a high level of control for multiple goals, including examination of genes that regulate or respond to introgressed seizure frequency loci, and better mapping (towards cloning) seizure frequency genes themselves. To this end, meiotic recombinants from within the El2 interval are being tested. So far, with seizure frequencies of ~0.20, the distal half of the segment explains only part of the full congenic phenotype suggesting that El2 may itself be encoded by more than one gene.

ULTRASTRUCTURAL IMMUNOCYTOCHEMICAL ANALYSIS OF DRUG-AND CONVULSION-NAIVE WSP AND WSR MICE. <u>J.F. Buckman* and</u> C.K. Meshul, Oregon Health Sciences Univ., Dept. of Behavioral

C.K. Meshul. Oregon Health Sciences Univ., Dept. of Benavioral Neuroscience and the V. A. Medical Center, Portland, OR 97201.

Withdrawal Seizure Prone (WSP) and Withdrawal Seizure Resistant (WSR) mice were selectively bred in replicate for differential ethanol withdrawal susceptibility, as measured by handling-induced convulsions (HICs). However, it has been established that some WSP mice exhibit HICs prior to drug exposure. This then raises the possibility that the selection process resulted in differences in general susceptibility to convulsions in addition to differential ethanol withdrawal responses. The convulsions in addition to differential etnahol withorawal responses. The activity of the glutamatergic system is thought to influence susceptibility to both ethanol withdrawal symptoms and seizure-related disorders. WSP mice exhibit a genetic propensity for both of these states suggesting that alterations in glutamate functioning may exist. Furthermore, a strong foundation for specific hippocampal involvement in seizure-related disorders has been established. Quantitative ultrastructural immunocytochemistry is useful in determining, at the synaptic level, the density of neurotransmitters within nerve terminals. Using the tever, the detrisity of includinatinities within helve terminals. Sang the CA1 region of the hippocampus (CA1) and layer II of the somatosensory cortex (SSC), we determined that the density of intracellular glutamate immunoreactivity in the CA1, but not in the SSC, was significantly higher in both replicate lines of WSP mice when compared to WSR mice. These results suggest that WSP mice, as compared to WSR mice, may exhibit an increased susceptibility to convulsions due to an inherently higher

level of glutamate in brain regions associated with seizure activity.
