To address this issue we have utilized infections of EGF-generated SVZ progenitor cells with retroviral vectors at clonal titers. We used a vector expressing *lac-Z* appended to a nuclear localization signal to facilitate analysis of dissociated plated, serially-passaged SVZ cells cultured in the presence of EGF. The frequency of clones and the number of labelled cells per clone was analyzed to estimate the frequency of stem-like cells within EGF-generated neurospheres. Infected cells were then selected with G418 and subsequently passaged and differentiated to fulfill the criteria necessary to characterize EGF-generated SVZ progenitor cells as stem-like cells Using this technique, we are evaluating the effects of various factors on the lineage-commitment of SVZ stem-like cells

A CELL SURVIVAL FACTOR ALTERS THE FATE OF PROLIFERATING SUBEPENDYMAL CELLS IN THE ADULT MAMMALIAN FOREBRAIN. C.M. Morshead* and D. van der Kooy. University of Toronto, Neurobiology Research Group, University of Toronto, Toronto,

Ontario, Canada
The adult mammalian forebrain contains a population of constitutively proliferating subependymal cells which line the lateral ventricles and extend rostrally to the offactory bulb. These mitotically active cells have a cell cycle time of 12.7 hours and comprise up to 33% of the subependyma in the rostral dorsolateral corner of the lateral ventricle. Under baseline conditions the constitutively proliferating cells proliferate in a steady-state mode of division whereby a single cell gives rise to two progeny, one of which continues to proliferate and the other undergoes cell death. Some of the progeny of the constitutively proliferating cells will not die but continue to proliferate and migrate to the offactory bulb (ob). The relative percentage of cells which undergo these 2 possible fates (i.e. cell death

versus migration to the ob) is not known.
We have used a cell survival factor N-acetyl-L-cysteine (NAC) which is known to have survival effects without concomitant proliferative effects on cells in vitro. We hypothesized that infusion of this factor in vivo would result in the survival of the cells which normally undergo cell death and hence we could examine the resulting fate of cells spared from death. Accordingly, we can ask if preventing cell death is sufficient to keep cells in a proliferative mode. By examining the magnitude of the increase following infusion we can further address the percentages of the cells dying versus those migrating to the ob. Animals received injections of a replication deficient retrovirus (RV) containing the beta-galactosidase (B-gal) gene. RV injections were made into the lateral ventricles on day 0

galactostases (pgal) gene. We highertons were made into the lateral verificities of day of followed by implantation of osmotic pumps on day 1. Saline or 0.1M NAC was infused for 5 days at which time the animals were sacrificed (day 6). Preliminary findings reveal a 5X increase in the total number of B-gal positive cells in NAC animals compared to controls. The cells were confined to the subependyma and not observed in the subrependyma. The same relative increase in total number of cells was observed in the ob and the subependyma surrounding the lateral ventricles. These data suggest that infusion of a cell survival factor is able to keep the normally dying cells alive, some of which are able to migrate to the ob. (MRC Canada and Neurospheres Inc)

IN VITRO DIFFERENTIATION OF NEURONS AND ASTROCYTES FROM JUVENILE SVZ CELLS: RESCUE OF PROGENITORS FATED TO DIE? Young, G.M., Albrecht, P.J., and Levison, S.W*.,
Dept. of Neuroscience and Anatomy, M.S. Hershey Med. Ctr.
Penn State College of Medicine, Hershey, PA 17033
The juvenile subventricular zone (SVZ) normally produces
oligodendrocytes. To determine whether cells residing within this

germinal zone were determined glioblasts, we retrovirally labeled juvenile SVZ cells in vivo by stereotactic injection and determined the cellular composition (using cell morphology and antigen expression) within clones that had expanded for 1 week in vitro. Many homogeneous clones of neurons, astrocytes or oligodendrocytes were observed, with large type 1 astrocyte clones most common; however, mixed oligodendrocyte/type 1 astrocyte clusters represented 15% of the total clones. Immature neurons were present in 25% of the total clusters, and 8% of the clones contained neurons, astrocytes and and 8% of the clones contained neurons, astrocytes and oligodendrocytes (of 128 clones examined). Analyzing apoptosis in the juvenile brain by in situ end labeling revealed that over 60% of all apoptotic cells were within the SVZ and some apoptotic cells in the SVZ expressed markers of differentiated cells. We conclude that the juvenile SVZ is a mixture of lineage restricted, bipotential and multipotential neural progenitors, and suggest that the limited output of the SVZ to a single lineage in the juvenile animal is due to a non-permissive. single lineage in the juvenile animal is due to a non-permissive environment rather than the absence of potential neuroblasts or glioblasts. Supported by NS 33251 (awarded to SWL).

ORIGIN OF ADULT NEURAL STEM CELLS, EPENDYMA OR SUBEPENDYMA? Bernard J

Chiasson*, Vincent Tropepe, Cindi M. Morshead and Derek van der Kooy, Neurobiol. Res. Group, Dept. of Anat and Cell Biol., Univ. of Toronto, Toronto Ont. Canada, MSS 148. The lissue surrounding the lateral ventricle of the adult mammal consists of a 1 cell thick clilated ependymal layer closest to the ventricle and an immediately adjacent 2-4 cell thick layer called the subependyma. In the rostral forebrain subependyma up to 1/3 of the cells are cycling with a cell cycle time of approximately 12 hours (constitutively proliferating) whereas another population of cells surrounding the ventricle, much smaller in number, cycle approximately every 2-4 weeks (relatively quiescent). The relatively quiescent cells cycle approximately every 2-4 weeks (relatively quiescent). The relatively quiescent cells are believed to be neural stem cells which give rise, in vitro, to clonal aggregates called neurospheres in the presence of epidermal or basic fibroblast growth factor (EGF or bFGF). Earlier work established that the tissue surrounding the adult lateral ventricle is necessary and sufficient for the generation of neurospheres, however, it is not clear whether the population of neural stem cells reside within the subependyma and/or ependyma. Preliminary observations using EGF and bFGF receptor (EGFR and bFGFR) antibodies suggested that a population of subependymal cells slightly farther from the ventricle possesses only EGFR. Since bFGF is capable of giving rise to neurospheres in culture this suggests that at least some neural stem cells could be located within the ependyma. Here we attempt to isolate the neural stem cells further by subdividing the subependyma from the ependyma. Dissections of the adult mammalian forebrain were performed and the ependyma as S-100B, and labelling the constitutively proliferating subependymal population with bromodeoxyuridine allowed us to establish a protocol for separating these cell layers. We cultured ependyman and subependymal cells separately to examine the feasibility of cultured ependymal and subependymal cells separately to examine the feasibility of generating neurospheres from either tissue in the presence of EGF or bFGF. Our preliminary evidence suggests that the ependymal cells may also give rise to clonal aggregates. Some aggregates contain ciliated cells and show rotational behaviour in suspension, further suggesting their origin from ciliated ependymal cells. However, we have yet to determine if these aggregates are self-renewing and multipotential as are neurospheres. Supported by MRC and NCE Canada.

A NEW SPONTANEOUS MUTATION AFFECTING LATER STAGES OF NEURAL DEVELOPMENT IN THE RAT. K.S. Bittman, V. Leung, K. Borodezt, J.J. LoTurco* and S.R. D'Mello. Dept. of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06269.

Mutations that disrupt specific aspects of neural development can be used to define unique developmental stages and to ultimately identify the molecules underlying these stages. We report here an initial description of Flathead (fh), an autosomal recessive mutation that arose spontaneously in an inbred colony of Wistar rats. Affected rats display resting tremor, impaired coordination of hindlimbs, are unable to rear, and die on postnatal day 23-27. On the day of birth fh/fh rats and unaffected littermates have comparable overall body size, however, the brains of fh/fh rats are reduced in size by 40%. The reduction in brain size is not associated with hydrocephaly, and is most pronounced in the forebrain and cerebellum. The reduction in brain size is clearly detectable at birth, but not at E15, indicating that the primary deficit is during late or post neurogenesis. In addition to a reduction in overall brain size there is a dramatic dysgenis within the cerebellar cortex and dentate gyrus. At PO there are far fewer cells in the external granule cell layer of cerebellar cortex, and by P21 the inner granule cell layer has failed to form with cells persisting in the egl. In the hippocampus, there is a drastic reduction in the number of dentate granule cells, and the remaining cells fail to form a well defined layer. BrDu incorporation and TUNEL assays were performed at PO and P3 in order to determine whether the developmental abnormalities in fh/fh are due to a decrease in proliferation, or to an increase in cell death. Within the egl of cerebellum the mitotic index is comparable in affected and non-affected brains. The number of apoptotic cells, as judged by positive TUNEL staining is currently being determined.

CLUSTERS OF RAT CNS PROGENITOR CELLS ECTOPICALLY PLACED IN THE EMBRYONIC RAT BRAIN DIFFERENTIATE ACCORDING TO THEIR ORIGIN. L.Magrassi* ¹ M.Ehrlich ² G.Butti ¹ S.Pezzotta ¹ S. Govoni ³ E. Cattaneo ⁴ N. Neurosurgery Dept. of Surgery, IRCCS S. Matteo 27100 Pavia; 2.NYU Medical Center. NY, USA; 3. Institute of Pharmacology, Pavia; 4. Institute of Pharmacological Sciences, University of Milano, 20133 Milano, IT CNS progenitor cells dissociated from the embryonic striatum and implanted into the brain of embryos of the same species generate both cells that disperse and integrate as single cells into the host brain and cells that reaggregate through the forming again, proported in the control of Cuttome 1004. We were interested.

CNS progenitor cells dissociated from the embryonic striatum and implanted into the brain of embryos of the same species generate both cells that disperse and integrate as single cells into the host brain and cells that reaggregate together forming easily recognizable clusters (Cattaneo,1994). We were interested to study if the cells in the clusters differentiate according to their final location as shown for some of the single integrated cells (Campbell, 1995; Brustle1995; Magrassi 1996) or if they were able to acquire a striatal phenotype. We transplanted into the embryonic rat brain cells dissociated from the E14 rat striatum primordia as well as from the two ganglionic eminences. We found clusters of BrdU and Dil labelled donor cells located in the central grey, colliculi, midbrain, hypothalanus, cortex, striatum and hippocampus. There was no apparent preferential bias for the striatum, the region where their progenitors were harvested. This was true both at short survival and long survival times. Immunocytochemical analysis was performed on cryostal sections of brains of animals that survived 21 days and 3 months after the in utero transplantation. We found that many cells within the clusters stained positively with antibodies against DARPP-32 and ARPP-21 two antigens typically present in striatal cells. Only occasional cells within the clusters were GFAP positive. Nestin expression was not detected. Clusters located close to substantia nigra were always TH negative, while a strong staining for DARPP-32 and ARPP-21 was present. These data suggest that cells in the clusters differentiate according to their origin despite their ectopic integration and their single cells exposure for the first hours after the transplant to the host environment (partially supported by the Hereditary Disease Foundation, USA and by the Center Grossi Paoletti, Italy).

INDUCTION OF THE HOMEOPROTEIN PBXI FOLLOWING NEURONAL DIFFERENTIATION OF CORTICAL PROGENITOR CELLS BY NT-3. M.C. Mione¹, L. Edelmann², J.G. Parnavelas¹, and M.A. Morabito^{3*}. ¹Dept. of Anatomy, UCL, Gower St., London WCIE 6BT, U.K., ² Biocenter, Univ. of Basel, Klingelberg Str. 70, Basel, Switzerland, ³ Dept. Pharmacology, Yale Univ. School of Medicine, New Haven, CT.

The regulation of proliferation, cell fate determination, and

The regulation of proliferation, cell fate determination, and differentiation of cortical progenitor cells is thought to be achieved by the modulation of their transcription factors activity and gene expression in response to various extracellular signals. The homeodomain protein PBXI, a cofactor of other homeotic proteins, is expressed in the developing telencephalon indicating that it may play a role in cortical neurogenesis [L. Redmond, S. Hockfield, and M.A. Morabito (1996) J. Neuroscience 16: 2972-2982].

An antibody generated against recombinant rat PBX1 protein was used to investigate the expression of PBX1 during the differentiation of cortical progenitor cells in cultures prepared from E16 rat dorsal telencephalon and maintained in serum-free medium. In these cultures, bFGF was found to regulate the proliferation of undifferentiated progenitor cells, whereas the addition of NT-3 promoted cell cycle withdrawal and neuronal differentiation. After treatment with bFGF for 3 days, most cells showed features of undifferentiated progenitors and labeled by BrdU uptake; they showed low levels of PBX1 immunoreactivity. Subsequent addition of NT-3 induced expression of MAP2 (a marker of postmitotic neurons) and reduced the uptake of BrdU in these cultures. The MAP2 cells were strongly immunoreactive for PBX1.

The induction of PBX1 immunoreactivity following neuronal

The induction of PBX1 immunoreactivity following neuronal differentiation of cortical progenitor cells by the addition of NT-3, indicates that PBX1 expression is positively regulated by this neurotrophin and suggests that PBX1 may regulate the transition from proliferating progenitor cells to terminally differentiated neurons.

NESTIN MAPPING IN THE ADULT RAT BRAIN I. Johnson, U. Hasselrot, D. S. K. Magnuson* and D. J. Morassutti, Dept of Neurological Surgery, U. of Louisville, Louisville, KY. 40292

Nestin is a novel intermediate filament, expressed in embryonic radial glia, neuronal precursors, myoblasts, schwann cells (Lendahl et al.., Cell 1990), and reactive astrocytes (Clarke et al., Neuroreport 1994). It has recently been found in adult EGF-responsive CNS stem cells which are derived from the adult rat lateral ventricle subependymal zone (Morshead et al., Neuron 1994). In this study we further characterized the distribution of nestin in the adult rat/mouse CNS.

We utilized a double-label immunocytochemical technique to examine the expression of Nestin, Vimentin, and Glial Fibrillary Acidic Protein (GFAP) and NF160 (neurofilament) in the CNS of normal, striatal ibotenic acid lesioned adult Sprague-Dawley rats and normal CD-1 mice. Nestin is distributed in the subependymal zone where it appears in several subpopulations, some of which colocalize GFAP or Vimentin. It is also present in cells of the median eminence, spinal central canal, dentate gyrus and in a sparse population of cells in the septal nucleus and striatum. Most interestingly, it is expressed around capillary vessels throughout the brain, where it is colocalized with GFAP. This colocalization is best seen in the reactive astrocytes found within the injured striatum.

Our data suggest that nestin is expressed in several subpopulations of neural precursor and non-precursor cells, and may play a role in the blood-brain barrier. Supported by the Alliant Community Trust Fund.

Fate Restriction and Differentiation of CNS Stem Cells. <u>K.K. Johe, T.G. Hazel, T. Muller, K. Wolter, C. Vicario-Abejon*, R.D.G. McKay.</u> Laboratory of Molecular Biology, NINDS, National Institutes of Health, Bethesda, MD 20892.

Identifying the mechanisms that generate cellular diversity is fundamental to understanding the development of the central nervous system. We have isolated from embryonic rat CNS multipotential cells that can be clonally expanded through multiple passages and retain their capacity to differentiate into neurons, oligodendrocytes, and astrocytes. Lineage analysis of accutely dissociated E16 hippocampal cells by retroviral marking suggests that these multipotential cells are abundant in vivo. We have identified several extracellular factors that influence the pathways of determination and differentiation of CNS stem cell into mature cell types in culture. CNTF can stably restrict mitotic multipotential stem cells into unipotential astroblasts. T3 generates unipotential oligodendroblasts. PDGF acts to restrict the differentiating stem cells toward the neuronal fate. In contrast to these factors which influence lineage determination, other extracellular factors such as EGF and neurotrophic factors influence the differentiation and maturation of CNS stem cells. These results suggest that progressive action of growth factors plays a critical role in the differentiation of multipotential precursors in the vertebrate CNS.

SPECIFICTY OF AN INDUCTIVE SIGNAL THAT REGULATES LIMBIC FATE IN THE DEVELOPING CEREBRAL CORTEX. K.L. Eagleson* and P. Levitt. Dept. of Neurosci. and Cell Biol., Robert Wood Lobbson Medical School JIMDNI Piccatanay. N. J. 18854

K.L. Eagleson* and P. Levitt. Dept. of Neurosci. and Cell Biol., Robert Wood Johnson Medical School-UMDNJ, Piscataway, N.J. 08854.

The differentiation of the cerebral cortex includes the parcellation of functional areas in the tangential domain. We previously utilized the expression of the limbic system-associated membrane protein (LAMP), a cell adhesion molecule unique to limbic cortical areas, to identify an interaction between transforming growth factor (TGF)α and collagen type IV that induces this area-specific phenotype in vitro. When grown in the presence of this inductive signaling system, precursors derived from the sensorimotor cortex, a non-limbic region of the cerebral wall, express LAMP. In contrast, when grown in non-inductive environments, which include laminin or fibronectin as the matrix component, only precursors derived from presumptive limbic regions express LAMP. In the present study, we further examine the specificity of the TGFα/collagen type IV inductive signal. When collagen type I is used in combination with TGFα, LAMP induction in the sensorimotor population is variable and, at best, only half that seen on collagen type IV. In addition, the profile of LAMP induction in precursors derived from presumptive visual cortex, a different non-limbic region of the cerebral wall, is identical to that in the sensorimotor population when grown on laminin, collagen I and collagen IV, both in the presence and absence of TGFα. Thus, collagen type IV is most effective in inducing LAMP expression, most likely by more efficiently modulating the activity of TGFα or enhancing the responsiveness of the precursors to the growth factor signal; other members of the collagen family, however, are able to partially substitute as the matrix component. The observation that the same signal can induce a limbic fate in different non-limbic progenitors indicates that, during corticogenesis, spatially segregated signals within the ventricular zone may operate to produce neurons with a molecular feature unique to a di

SPECIFICATION OF LAMINAR-SPECIFIC CHARACTERISTICS OF DEVELOPING CORTICAL NEURONS. <u>J.M. Weimann*, K. Mackarehtschian and S.K. McConnell.</u> Dept. Biological Sciences, Stanford University, Stanford, CA

Previous transplantation studies have demonstrated that cortical progenitors become committed to a specific laminar fate during their final cell cycle. Here we ask whether all layer specific characteristics of cortical neurons are specified in a single step or rather in sequential specification events. To address this question we asked when newly born neurons acquire their laminar-specific axonal and dendritic morphologies and their

physiological membrane properties.

Cortical progenitors from E29 ferrets, which are generating deep layer neurons, were dissociated and labeled with ³H thymidine and rhodamine (PKH26), and then ussociated and accept while "I mylindine and inodamine (FKE26), and then transplanted into the VZ of P1 ferrets, which are generating superficial neurons. As previously reported (McConnell & Kaznowski, 1991), transplanted neurons migrated into either layer 6 or layer 2/3 depending on their position in the cell cycle at the time of transplantation. Recording from transplanted neurons with Neurobiotin electrodes revealed that these cells had axonal and dendritic morphologies and physiological properties appropriate for the layers into which they had migrated. This result suggests that transplanted neurons can integrate normally into the cortex and that their projection patterns and physiological properties are specified at or after the time that laminar

position is determined.

To determine whether the laminar-specific characteristics are specified in the VZ or during later stages of cortical development, labeled E29 progenitor cells were placed ectopically into layer 2/3 of P23 ferrets. PKH26-labeled neurons displayed two ectopically into layer 2/3 of P23 terrets. PKH26-labeled neurons displayed two phenotypes when viewed 4 days after transplantation. One type had a pyramidal morphology with axonal branches in layers 2/3 and the deep layers, typical of normal layer 2/3 neurons. The second type extended axons 1-3mm along layer 1. These data suggest that local cues within layer 2/3 can induce the formation of upper layer neurons from some early progenitors.

NEURAL STEM CELLS CAN BE ISOLATED IN bFGF, INDEPENDENT OF EGF SIGNALLING. V. Tropepe*, M. Sibilia*, C.G. Craig, E.F. Wagner* and D. van der Kooy. Neurobiology Research Group, Department of Anatomy & Cell Biology, University of Toronto, Toronto, Canada M5S 1A8; *Institute of Molecular Pathology, Vienna, Austria A-1930.

The presence of self-renewing, multipotential neural stem cells in the mammalian embryonic ventricular zone and adult forebrain subependyma suggests that a population of neural stem cells is established very early in neural development and that this population self-renews throughout life, retaining the capacity to generate progeny that give rise to both neuronal and glial lineages. We asked whether the known mitogens for mouse neural stem neuronal and glial lineages. We asked whether the known mitogens for mouse neural stem cells in serum-free media, epidermal growth factor (EGF) and basic fibroblast growth factor (bFGF), have differential roles in stem cell behaviour during development. Embryonic day (E)14 forebrain neural stem cells respond to either EGF or bFGF to generate clonal aggregates of cells (neurospheres) in vitro that are self-renewing and multipotential. At low concentrations EGF is an order of magnitude more effective than bFGF in generating neurospheres, but at higher concentrations both growth factors produce the same plateau number of neurospheres. However, the generation of E14 neurospheres in bFGF is not dependent on EGF signaling. The number of E14 neurosphere generated in EGF from the brains of EGF-receptor null (EGFR**) mice is decreased by >90%, but the generation of large numbers of E14 neurospheres in bFGF alone was not affected in these mutants. A similar nature of results was seen using a synthetic inhibitor which selectively blocks similar pattern of results was seen using a synthetic inhibitor which selectively blocks intracellular signalling through the EGF receptor. Consistent with the idea that bFGF allows for the isolation of E14 neural stem cells independently of EGF signalling, we found that neurospheres can be generated in serum-free media from E8.5 anterior neural plate in the presence of bFGF alone, but not in EGF alone. There are two possible explanations for these results. The first is that the neural stem cell possesses only bFGF receptor signalling at E8.5, but by E14 has developed both bFGF and EGF receptor signalling capacity, either of which alone is sufficient to activate the neural stem cell in defined media. The second possibility is that the bFGF-responsive stem cell at E8.5 is the precursor in a lineage to the EGF-responsive stem cell, and that both of the separate EGF and bFGF responsive stem cells are present in the E14 forebrain ventricular zone and adult subependyma Supported by MRC and NCE Canada.

COORDINATED REGULATION OF CNS LINEAGE DEVELOPMENT BY CYTOKINES, EXTRACELLULAR MATRIX, AND CELL CONTACT. P. Mabie, M.F. Mehler, R. Marmur, and J.A. Kessler*, Dept. of Neurology and Neuroscience, Albert Einstein Col. of Medicine, Bronx, NY 10461.

Multipotent progenitor cells (MPs) from forebrain proliferative zones generate lineage-restricted progenitor intermediates that give rise to all three CNS lineages. In addition to the influence of soluble factors (growth factors), cell surface and extracellular matrix (ECM)-associated signals are likely to modulate the fate of MPs and their progeny. To examine how non-diffusible signals modulate the responsiveness of MP progeny to growth factors, dissociated EGF-derived progenitors from mouse embryonic day 15 cortex were plated on alternate substrates and treated with a series of growth factor paradigms designed to enhance specific lineage development. The relative proportion of undifferentiated progenitors, neurons, and glia could be manipulated by specific combinations of soluble growth factors and substrates. The optimal conditions for selecting immature post-mitotic neurons were with low concentration EGF on poly-D-lysine (PDL) or with no added growth factor on laminin. Optimal astrocyte differentiation occurred with BMP treatment; this maturational effect was associated with either cell cycle exit (PDL) or with proliferation (laminin). Undifferentiated progenitors were optimally selected by EGF treatment on a non-adhesive substrate. The rate of differentiation was delayed when cell-cell contact was preserved by plating cells as undissociated neurospheres. These studies suggest that the lineage fate of MP progeny can be selectively modulated by interactions between soluble and non-diffusible cell surface and ECMassociated signalling pathways. Further, they provide a basis for investigating the relationship between extracellular signalling, MP cell cycle regulation and lineage commitment necessary for designing rational regenerative therapies for CNS disorders. (Sponsored by MDA and Hirschl Trust (MFM) and NIH (JAK) grants).

Glial cells exhibit differential effects on the survival of two immortalized neuronal cell lines. E.Bongarzone, L.Foster¹, V.Schonmann, S.Howard and A.T.Campagnoni. Mental Retardation Research Center, UCLA, Los Angeles, CA. ¹ La Jolla Cancer Research Foundation, La Jolla, CA

Primary cell cultures established from embryonic (E13) and newborn (P2) mouse brains were conditionally immortalized by infection with a retrovirus containing the temperature-sensitive mutant SV-40 large T antigen oncogene. Two clonal cell lines (CN1.4 from E13 cultures and SJ3.6 from P2 cultures) were isolated and stably maintained in vitro. They express a number of neuron specific markers like neurofilaments, GAD 67, the BG21 isoform of Golli-MBP and NSE but do not express any glial marker. Both cell lines proliferate well at the permissive temperature of 34°C. Under these conditions, CN1.4 cells have small pyramidal cell bodies with short processes and SJ3.6 cells show small round cell bodies and their processes are longer. When CN1.4 cells are grown at 39°C, there is an abrupt decrease in the proliferation rate accompanied with an elongation in some of the neurites but the cell survival is not compromised. In contrast, SJ3.6 cells do not survive beyond 3 days at 39°C. The death of SJ3.6 cells is accompanied by fragmentation and condensation of the DNA within the nucleus. Interestingly, when these cell lines are co-cultured with either oligodendrocytes or astrocytes, there is a marked increase in the SJ3.6 survival and outgrowth of their neurites but there is no effect on the CN1.4 cells. This differential capacity to survive in vitro suggests that these two cell lines might represent neuronal cells at different stages of maturation. SJ3.6 cells seem be more mature than CN1.4 since their ability to survive in vitro depends on the presence of glial cells. In fact, the absence of survival signals from glial cells might activate a programmed cell death mechanism. These results also indicate that the survival effect of glial cells might depend upon the differentiation state of the neurons. Glial cells might promote survival and differentiation in more mature neurons but not in less mature neurons. (Supported by NIH grants NS23022 and NS33091).

ISOLATION AND ANALYSIS OF GENES WHICH ENCODE **DLX-2 INTERACTING PROTEINS**

Guoying Yu and John Rubenstein* Nina Ireland Laboratory of Developmental Biology, UCSF, San Francisco, Ca., 94143.

The molecular mechanisms underlying regional specification, morphogenesis, and differentiation of the mouse forebrain are now possible to study through the functional analysis of homeodomain-containing proteins (e.g. DLX, EMX, OTX and NKX) that are expressed in regionally-restricted patterns in the embryonic forebrain. To identify proteins that modulate the function of the DLX proteins, we have used a yeast two-hybrid approach. Two novel proteins were identified that interact with DLX-2, and were named as DIP1 and DIP2 (for DIX Interacting Proteins). DIP1 and DIP2 genes are expressed nearly ubiquitously within the developing CNS, but at different stages of differentiation. Deletion analysis identified distinct domains within DLX-2 that interact with DIP1 and DIP2. Present studies are aimed at elucidating the functional significance of the DIP-DLX interactions

DLX-1 OR DLX-2 IS NECESSARY FOR THE DEVELOPMENT OF GABA IMMUNOREACTIVITY IN THE MOUSE ISOCORTEX SA Anderson*, M-S Qiu, D Eisenstat, J Meneses, R Pederson and JLR

Rubenstein, Dept. of Psychiatry, UCSF, San Francisco, Ca., 94143.

Dlx-1 and Dlx-2 are homeobox-containing transcription factors with restricted patterns of expression in the embryonic basal forebrain, including the lateral ganglionic eminence (LGE). Null mutant mice for either Dlx-1 or Dlx-2 have an ostensibly normal LGE, but mice lacking both of these genes appear to have an abnormal subventricular zone of the LGE, leading to aberrant striatal differentiation.

Other histological defects are also found in these mice. Interneurons of

Other histological defects are also found in these mice. Interneurons of the olfactory bulb, many of which migrate from the SVZ in the region of the LGE, are undetectable using immunohistochemistry for granule cell and periglomerular cell markers (e.g. GABA).

Analysis of the cortex of Dlx-1/Dlx-2 homozygous mutants, although limited by the death of these animals at PO, also shows almost no GABA immunoreactivity (IR) in cell bodies or processes. This defect, particularly in layer 1, begins abruptly around the boundary of the piriform and isocortex. GABA-IR is also lacking in the subiculum and hippocampus.

Dlx-1, and to a less clear extent, Dlx-2, begin to be expressed in the developing isocortex near the striatopallial angle at about E12.5. By E14.5 Dlx-1-IR and expression is detectable throughout the cortical primordium. At PO, Dlx-1 and Dlx-2-IR cells can be found scattered in all cortical layers except the cortical ventricular zone, with most cells located in the developing cortical plate and layer 1. This pattern of development is similar to that reported for GABA-IR in mice and rats. Moreover, double labeling reveals overlapping populations of Dlx-1 and GABA-IR cells in the cortex reveals overlapping populations of Dix-1 and GABA-IR cells in the cortex and olfactory bulb. Ongoing studies are designed to determine the sources of cortical GABA and Dlx-1-containing cells. S.A. is supported by a NARSAD Young Investigator Award

MIGRATION IN THE DORSAL PREOPTIC AREA/ANTERIOR

MIGRATION IN THE DURSAL PREOFIT. AREA/AN ERIOR HYPOTHALAMUS. S.A. Tobet* and I.K. Hanna, Prog. Neuroscience, The Shriver Center and Harvard Medical School, Waltham, MA 02254. The preoptic area/anterior hypothalamus (POA/AH) displays numerous sex differences in neural morphology. We have proposed that there are significant influences on the region that derive from dorsal origins, based on the pattern of radial glial fibers that enter the POA/AH by going around, or through the anterior commissure (AC) during development (Tobet et al., J Neurobiol 26:75, 1995). We conducted video microscopy and immunocytochemical studies to assess the potential roles of the dorsalventral (DV) oriented radial glia. We utilized video microscopy to follow whether training flat. We thinked the migration of Dil-labeled cells in coronal 250 μ m brain slices from embryonic day 15 mice maintained in scrum-free media. There was approximately 70% more migration along a DV (43.3 \pm 8.7%) than a medial-lateral (ML: 25.6 \pm 4.4%) orientation as defined by using the percentage of migrating cells per video field (n=11). The average speed of migration was similar in both orientations (approximately 23µm/hr). In the absence of sex steroids there were no significant sex differences. We used absence of sex steroids there were no significant sex differences. We use immunocytochemistry to examine the distribution of cells containing raminobutyric acid (GABA) in embryonic rats and mice. Prenatally, we found dense accumulations of cells containing GABA within the dorsal POA/AH, and additional cells within the AC. A GABAergic mechanism has previously been shown to alter the differentiation of the sexually dimorphic nucleus of the medial POA. The transient presence of neurons in the AC may be indicative of cells with unique migration bistories which in the AC may be indicative of cells with unique migration histories which may ultimately reside in, and influence, the developing POA/AH. The DV migration of cells provides one avenue for dorsal influences in the POA/AH. Supported by NSF-IBN-9421697.

QUANTITATIVE ANALYSIS OF TANGENTIALLY MIGRATING INTERMEDIATE ZONE NEURONS IN EMBRYONIC RAT NEOCORTEX N. Tamamaki*, K. E. Fujimori, R. Takauji Dept. of Anatomy, Fukui Medical School, Matsuoka, Fukui 910–11 Japan

It is well known that neuroblasts produced in the ventricular zone of the neocortex migrate radially toward the neocortical surface and form neocortical cell layers. Recent studies, however, revealed that the tangentially migrating cells in the intermediate zone were not negligible functions. To have better understanding on the tangentially migrating cells, we quantified the number of tangentially migrating cells, we quantified the number of tangentially migrating focal injections of Dil into various mediolateral levels of the embryonic neocortex in utero. Two days after Dil injection, strongly labeled migrating cells with leading processes were found outside of the injection site. In every case of injections, most tangentially migrating cells were found medially to the injection site in the intermediate zone. rangentially migrating cells were found most when the injection was made into the lateral ganglionic eminence. When injection site was shifted toward medially more less number of migrating cells were found. These migrating cells seemed to correspond to the Tul1positive cells (Menexes and Luskin, J. Neurosci. 14:5399, '94), GABAergic cells (Van Eden et al. J Comp. Neurol. 289:213,'89), and MAP2-positive cells (Cobas et al. Neurosci. 40:375,'91) in the lower intermediate rose. intermediate zone. These observation suggested that more tangentially migrating cells originated in the lateral ganglionic eminence and directed to the medial structures. On E17, these migrating cells reached the midline structure coinciding with the formation of the corpus callosum.

CELL DISPERSION PATTERNS IN THE CEREBRAL CORTEX OF MOUSE CHIMERAS. S-S Tan*1, K. Sturm2, P.P.L. Tam2, B.E.Reese3 and B. Faulknerlones¹. 1Dept of Anatomy & Cell Biology, University of Melbourne, Victoria 3052, Australia; ²CMRI, Westmead NSW, Australia; ³Neuroscience Research Institute, University of California at Santa Barbara, CA 93106.

Previous studies in our laboratory using transgenic mosaics have shown that neurons and glia in the developing cortex both follow radial and tangential dispersion patterns. Although a significant proportion of migrating neurons follow the radial pathway, it is still unclear whether there might be progenitors that are committed to generating only radiallydispersing progenies. To address this issue, we have made an ES cell line from the H253 transgenic mouse which we used to construct mouse chimeras. The reduced colonization by lacZ-expressing cells in the cortices of wild-type mice provided improved resolution of cellular dispersion patterns and their clonal relationships. Adult cortices showed two predominant distributions of lacZ-expressing cells. A diffused mosaic of scattered lacZ-expressing cells spanning across all cortical layers was detected in a number of cerebral hemispheres. More strikingly, single columns with inverted cone shapes were observed in random locations, although their frequency decreased in the lateral domains of the cortex. These results demonstrate early commitment of certain progenitors to generating radially-dispersing cells only. They also suggest that cells in the deeper layers tended to remain in close register with a point source in the VZ, while upper layer constituents appear to fan out horizontally. It remains to be determined whether the upper layer spreading is due to horizontal movement of progenitor cells in the VZ, or within the cortical plate. Funded by the NH&MRC of Australia.

DYNAMICS OF CELL MIGRATION FROM THE LATERAL GANGLIONIC EMINENCE IN THE RAT. J.A. De Carlos*, L. López-Mascaraque and F. Valverde, Neuroanatomy, Instituto Cajal (CSIC), 28002 Madrid, Spain.

From previous developmental studies it has been proposed that neurons of the ventro-lateral cortex, including the primary olfactory cortex, differentiate from progenitor cells of the lateral ganglionic eminence (LGE). The objective of the present study was to test this hypothesis. The first-generated cells in the forebrain of the rat migrate to the surface of the telencephalic vesicle E12. Using 3H-T we found that most of these cells contributed to the formation of the deep layer III of the primary olfactory cortex. To study their migratory routes we made localized injections of the carbocyanine fluorescent tracers Dil and DiA into various parts of the LGE in living embryos at E12- E14. The embryos were maintained in a culture device for 17- 48 h. After fixation, most migrating cells were located at the surface of the telencephalic vesicle while others were seen coursing tangentially into the preplate. Injections made at E13 and in fixed tissue at E15, showed that migrating cells follow radial glial fibers extending from the ventricular zone of the LGE to the ventro-lateral surface of the telencephalic vesicle. The spatial distribution of radial glial fibers was studied in Golgi preparations. These observations provided further evidence of the existence of long glial fibers extending from the ventricular zone of the LGE to the ventro-lateral cortex. We conclude that cells of the primary olfactory cortex derive from the LGE and that some early-generated cells migrating from the LGE transgress the cortico-striatal boundary entering the preplate of the neocortical primordium. Supported by Research Project PB91-0066 from Ministerio de Educación y Ciencia of Spain.

COINCIDENCE OF ARRIVAL TIME OF MIGRATING LOWER INTERMEDIATE ZONE NEURONS TO THE MIDLINE STRUCTURE WITH THE CORPUS CALLOSUM FORMATION. K.E.Fujimori*, R.Takauji and N.Tamamaki Department of Anatomy, Fukui Medical School, Fukui 910-11, Japan.

Although corpus callosum is a conspicuous projection in the cerebral cortex, the mechanism of the formation of corpus callosum is not known. In rats, callosal axons start to cross midline structure at embryonic day (E) 17. Recently it has been shown that a subpopulation of early generated cells migrate tangentially in lower intermediate zone (IZ) and reach the corpus callosum. To know whether the migrating lower IZ neurons are involved in the initiation of callosal formation, we investigated the distribution and migration of the lower IZ neurons in the embryonic rat neocortex

GABA immunohistochemistry was performed on vibratome sections of E17 rat neocortex. As it was previously reported, many GABAergic neurons were observed in the lower IZ with having leading processes medially. MAP2 immunohistochemistry also revealed a similar population on serial paraffin sections. Both GABA immunoreactive (IR) cells and MAP2 IR cells were found at midline structure at the time of corpus callosum formation. Double labeling of BrdU and MAP2 immunohistochemistry was also carried out to decide the birthdate of MAP2 IR cells in lower IZ and the corpus callosum. In addition, in vivo Dil-labeling study revealed that migrating lower IZ neurons reach the midline structure by E18. These findings support that the arrival of the lower IZ neurons into the midline structure coincides with the formation of corpus callosum. The migrating lower IZ neurons may play a certain role in the corpus callosum formation.

MIGRATION OF NEURONAL AND GLIAL PRECURSORS IN CULTURED NEOCORTICAL SLICES. <u>I.M.Edgar</u> and <u>D.J.Price</u>. Dept. of Physiol., Univ. Med. Sch., Teviot Place, Edinburgh EH8 9AG, U.K.

In vivo, cells destined for the cerebral cortex are generated in the telencephalic ventricular and subventricular zones. They then migrate to their final positions. Transplant studies have suggested that newborn cortical cells receive instructions on how to migrate at the end of S-phase and in G2 of the cell cycle. Cortical precursor cells that are born in vivo still migrate from the particular consistency and in G2 personal frequency of the control of the cell cycle. cell cycle. Cortical precursor cells that are born in vivo still migrate from the ventricular zone if telencephalic slices are then placed in organotypic culture. In these experiments, factors either within or outwith the telencephalon might have instructed cortical precursors to migrate. We asked whether the factor(s) that permit and/or regulate the migration of neuronal and glial precursors the in developing mouse cortex have a cortical and/or subcortical origin.

Telencephalic cortical slices were cultured in serum free medium (i) in isolation or (ii) with thalamic explants. Proliferating cells were labelled with 5-

isolation or (ii) with thalamic explants. Proliferating cells were labelled with 5-bromo-2-deoxyuridine (BrdU) in vitro and the relative locations of these cells were assessed after two, five or seven days in culture using standard immunohistochemical techniques. Initial results showed that cells in cocultured slices migrate to their normal laminar position after two days. After five and seven days their distribution is distorted. Cells in isolated cortical slices do not show normal lamination at any of the stages investigated. These results suggest that the thalamus assists normal migration early on but that factors that sustain lamination are absent in the culture environment. This work was supported by the Wellcome Trust.

MIGRATIONAL DEFECTS AMONG CORTICAL CELLS FROM SMALL-EYE MICE D.J. Price[±], D. Carie[‡], K. Gillies, R.E. Hill[‡] and S.K. McConnell², Dept. Physiology, Univ. Med. Sch., Teviot Place, Edinburgh, U.K., [‡] MRC Human Genetics, Crewe Road, Edinburgh, U.K., [‡] Dept. Biological Sci., Stanford University, California, USA.

The small-eye (Sey) phenotype results from a point mutation in the Pax-6 gene. This gene encodes a transcription factor containing a paired domain and a homeodomain, and is expressed at several sites throughout the developing forebrain, including the cerebral cortex. In the cortex, Pax-6 is expressed mainly in the ventricular and subventricular zones. Homozygous Sey mice show defects in the eyes and in the thalamus. Previous studies have suggested that the mutants also have defects of cortical migration. In this study, we investigated the migration of cortical cells by labelling them with the thymidine analogue, bromodeoxyuridine (BrdU). We found that cells born early during cortical neurogenesis (at embryonic day 13) migrate to appropriate positions in the cortical plate, but that most cells born later (at embryonic day 16) fail to migrate. Rather, they remain in the ventricular zone, which expands considerably in thickness. Staining with glial-specific antibodies revealed that the tradial ghal cells are present in the Sey mice. These results raise the interesting question of whether the cortical defect is intrinsic to the migrating cells, or is secondary to a defect in the environment through which they migrate. This could be tested by transplanting cortical cells from +/+ or Sey/Sey embryos into the brains of normal rats at embryonic day 16, then examining the positions that they adopt in the normal cortex.

ABNORMAL PROLIFERATIVE PATTERN IN PAX6 MUTANT CEREBRAL CORTEX. <u>LH. Martin ¹. R.L. Maas ². S. Wawersik ². R.A. Segal ¹ *. <u>C. Waish ¹.</u> ¹Dept of Neurology. Beth Israel Hosp.: ²Div. of Genetics, Brigham and Women's Hosp.. Boston, MA 02115.</u>

Homozygous Pax6 mutant mice show a severe cortical phenotype but the nature of the malformation is not clear. We have examined the role of Pax6 by using antibody staining for cell type-specific markers, retroviral labelling, and confocal microscopy of the homozygous Pax6 mutant Small eye (Sey Neu) mouse strain

Retroviral labelling experiments showed greater labelling in proliferative regions and less in the developing cortical plate of fetal homozygous mutant micrompared to wild type mice, reflecting the previously described arrest of cell migration into the cortical plate (Schmahl, et al., Acta Neuropath, (1993) 86:126. Immuno-staining with Notch1 antiserum in E13 embryos revealed a somewhat broader band of staining in the ventricular zone of homozygous mutants compared to normal littermates. CR-50, an antibody to Cajal-Retzius neurons of Layer 1 revealed the presence of these neurons in E14 mutant embryos, despite previous suggestions that Layer 1 is absent in Sev mutants. Confocal microscopic analysis of Syto-11 (nucleic acid stain) stained E14 fetal brain sections showed M-phase cells in the proliferative region of homozygous mutants differed from wild type, since in mutants the mitoses were not localized as precisely to the lining of the ventricles. Frequently, mitoses were located up to 25µm from the ventricular surface. These data suggest that mice mutant for Pax6 show abnormalities in cell proliferation and are defective for the normal interkinetic nuclear migration of proliferating cells in the ventricular epithelium of the cortex.

NEOCORTICAL BIRTHDATING ANALYSIS ON SCRAMBLER. A NOVEL MOUSE MUTANT. REVEALS A REELER-LIKE PHENOTYPE. J.L. González^{1,2} C. Russo¹, H. Sweet³, M. Davisson³, D. Goldowitz¹, and C. Walsh*^{1,2} 'Neurology Dept., Beth Israel Hospa; 'Prog. in Neuroscience, Harvard Med. Sch., Boston. MA 02115; 'The Jackson Lab., Bur Harbor, ME, 'Univ. of Tenn., Memphis, TN

Mice homozygous for the scrambier (scm) mutation display unstable gait, trembling and ataxia similar to mice homozygous for the reeler (rt) mutation. Genetic analysis showed that rt and scm map to different chromosomes (Sweet et al. submitted). Histological examination of scm/scm forebrain shows abnormalities similar to rt/rt. Both mutants show abnormal hippocampal cytoarchitectonics, with marked disruption of pyramidal and granule layers. Furthermore, scm/scm neocortex shows poor lamination and an absence of the marginal zone, as in rt/rt mutants.

In order to test the hypothesis that the scm mutant has a reeler-like, outside-in gradient of neocortical development, we performed birthdating analysis on scm/scm mice. Timed-pregnant, heterozygous or homozygous, dams were injected with 5-bromo-2-deoxyuridine (BrdU) at E10-E19. Animals were sacrificed several weeks after birth and brain sections analyzed to assess the position of BrdU-labeled neurons in the neocortex of scm/scm and normal littermates. In general, BrdU-labeled neurons in the neocortex of scm/scm mice displayed a broader laminar distribution when compared to normal littermates. In addition, the distribution peaks in scm/scm and normal neocortex are approximately inverted for E12-, E15-, and E16-labeled neurons. For example, more than 95% of E16-BrdU-labeled neurons occupy the superficial half of a normal cortex, whereas only approximately 30% occupy the same portion in scm/scm mutants. These results are strikingly similar to those observed in rUrl neocortex, providing further support for the resemblance of the defect in the two mutants, and suggesting a related role for the two genes in the development of neocortical lamination.

CORTICAL DEFECTS IN THE SMALL EYE (SEY) MOUSE. D.Caric*, D.J. Gooday', D.J. Price and R.E. Hill. MRC Human Genetics Unit, Western General Hospital. Crewe Road. Edinburgh. EH4 2UX and 'Dept of Physiology. University of Edinburgh. Teviot Place. Edinburgh. EH8 9AG.

We are studying the cellular mechanisms involved in the development of the abnormal cortex in the Small eye mouse. In Small eye homozygous mice (which results from a mutation in the Pax-6 gene), the development of the ordered cellular layers in the cortex is disrupted; many cells which fail to migrate to the cortical plate give rise to clusters of cells in the subventricular and intermediate zones. We are interested in finding out the origin and birth dates of these cells, and also in their adhesion properties.

First, we have used BrdU to label cells during various stages of neurogenesis and have examined their fate at embryonic day 19 (E19) in both wild type and mutant. After BrdU injection on E13 and E14, no densely labelled cells were found in the clusters. After injection on E16 and E17 the clusters contained many labelled cells. We concluded that these clusters contain cells born after

Second, we compared the distribution patterns of the adhesion molecule L1 in the cortices of both Sey homozygotes and wild type embryos using immunocytochemistry. This revealed that although the intermediate zone in both sey homozygotes and wild type was heavily labelled, the clusters of cells in the homozygotes were devoid of L1 staining.

We concluded that the clusters of cells found in Sey homozygotes arise from cells born later in neurogenesis which do not express the L1 adhesion molecule, and although they can be displaced from the ventricular and sub-ventricular zones, they are unable to gain access to the intermediate zone.

DISRUPTION OF CORTICAL HISTOGENESIS IN THE CROOKED TAIL (Cd) MOUSE BRAIN ML Carter*, F. Zhang, C ladecola, & ME Ross, Dept of Neurology, Univ of Minnesota, Minneapolis, MN 55455.

Cd is a semidominant mutation in which heterozygotes have kinked tails and homozygotes have a high incidence of exencephaly, a rostral neural tube defect related to anencephally. Approximately 28% of Cd homozygotes escape exencephally but express a runted phenotype (SMALL) in which Cd/Cd animals weigh ≤40% of age-matched normal siblings. We sought to characterize the morphological effects of the Cd mutation in the SMALL phenotype. In thionin-stained, fresh-frozen sections, the volume of the brain (mm³) was measured using an image analysis system (JCBF&M 12:962). The whole brain of SMALL mice was 30±7% smaller than that of normal sibs (n=8; p<0.05; 1-test). However, the cerebral cortex in SMALLs appeared relatively more affected than subcortical structures. To quantitate this difference, the volume of the cerebral cortex and subcortex were measured separately. To correct for differences in whole-brain volume, cortical volumetric data were normalized to those of subcortex and compared between the SMALLs and their normal sibs from postnatal day 4 (P4) to P18. SMALL cortical volumes were reduced by 49±11% in frontal cortex and 52±14% in occipital cortex (p<0.01), but were not affected in parietal cortex (-0.75±0.3%; p>0.05). Cortical cytoarchitecture was examined by MAP2 immunocytochemistry. Cortical laminae were less well defined in SMALLs than in normal sibs. Medium sized pyramidal neurons were displaced into layer I, extending to the subpial surface. This was most readily apparent in the frontal and occipital regions. The parietal region was less affected while no cytoarchitectural abnormalities were observed in the hippocampus. Thus, SMALL brains reveal preferential volume reduction in the frontal and occipital cortex, and neuronal heterotopia consistent with a cortical migration defect. We conclude that the Cd gene is involved in rostral neural tube closure and the establishment of normal cortical cytoarchitecture as well. (Supported by NINDS and the MMF)

SEROTONIN PROMOTES THE SURVIVAL OF RAT CORTICAL NEURONS IN VITRO. A. E. Dooley , I. S. Pappas and J. G. Parnavelas (SPON: Brain Research Association). Dept. of Anatomy and Dev. Biology, University College London, London WCIE 6BT, U.K.

Earlier studies have provided evidence for a role of serotonin (5-HT) in the maturation of the mammalian cerebral cortex. More recent studies have suggested that local environmental signals regulate the growth and differentiation of progenitor cells in the developing cortex. 5-HT is present in the cortex at this early stage, and here we investigated its actions during corticogenesis using a dissociated cell culture preparation. Primary cultures were established from embryonic day 14 (E14), E16, and E18 rats. These cultures were grown in a defined medium containing 1% FCS, or additionally exposed to 5-HT (25 μ M) for 1-11 days in vitro (DIV). Using the MTT assay, we found that 5-HT significantly increased the survival of cells in these cultures in a concentration dependent manner. Specifically, there was a 1.3-fold increase in the number of cells at 9 DIV in cultures prepared from E14 embryos, a 2-4-fold increase at 7-9 DIV in E16 cultures, and a 1.6-2.2-fold increase at 2-4 DIV in E18 cultures. This survival was mimicked at all ages by the 5-HT_{2a/2c} agonist amethyl-5-HT (25 μM), in contrast to the 5-HT_{IA} agonist 8-hydroxy-2(di-npropylamino) tetralin (25 µM) which showed no effect. Survival was predominantly of postmitotic neurons immunopositive for the microtubule-associated protein-2 (MAP-2). Consistent with increased survival was the observation of reduced cell death in 5-HT treated cultures compared to controls. These results support the importance of 5-HT in the survival of cortical cells and particularly of postmitotic neurons within this environment.

Supported by the Medical Research Council.

SEROTONIN INCREASES THE PROPORTION OF GLUTAMATE CONTAINING NEURONS IN ORGANOTYPIC SLICE CULTURES OF EMBRYONIC RAT CORTEX. A. A. Lavdas and J. G. Parnavelas (SPON:ENA) Dept. Anatomy & Dev. Biol., University College London, London WC1E 6BT, UK.

Serotonin (5-HT), present in the developing brain long before it assumes its neurotransmitter function, is regarded as a strong candidate for a role in the maturation of the cerebral cortex. In this study, we sought to investigate the possible effects of 5-HT on the generation and differentiation of cortical neuronal cell types. Slice cultures were prepared from the cortices of E16 rat embryos and kept in vitro for one week, either in defined medium (DM) or in DM plus 250 µM 5-HT. At the end of this period the proportion of cells immunoreactive for Glutamate (Glu) or GABA, the neurotransmitters utilized by cortical pyramidal and nonpyramidal neurons respectively, was estimated for both conditions. We found that the proportion of Glu-positive neurons was significantly increased in the 5-HT-treated group (mean=38.1%) as compared to the control group (22.8%). A number of cocultures of E16 cortical slices and slices containing the raphe nuclei taken from E18/E19 embryos were subsequently prepared and kept for the same period in DM. After the innervation of the cortical slices by serotonergic fibers had been immunocytochemically demonstrated, the proportion of Glu positive neurons was assessed and found to be also significantly higher (29%) than in the control group, albeit lower than in slices exposed to 5-HT. To investigate whether this effect of 5-HT was the result of changes in cell proliferation, we exposed a number of slices, cultured both in DM and in DM + 5-HT, to 10⁵ M bromodeoxyuridine (BrdU) for 16 hrs every day. The proportion of BrdU immunoreactive cells was established at each day and was similar for the 5-HT treated and the comntrol groups. These results suggest that 5-HT promotes the survival and/or differentiation of cortical Glu-containing neurons. Supported by the Wellcome Trust.

GENERATION AND DIFFERENTIATION OF CORTICAL CALRETININ-EXPRESSING NEURONS IN VITRO. I. S. Pappas and J. G. Parnavelas*. Dept. of Anatomy and Developmental Biology, University College London, Gower street, London WC1E 6BT, U.K.

We examined the role of growth factors on the development of the cortical cell types focusing on the subpopulations of neurons defined by the presence of the calcium-binding protein, calretinin (CR). CR-containing neurons in the cortex comprise two groups: the early generated Cajal-Retzius cells of layer I, and the somewhat later generated group found throughout the cortical plate. Treatment of primary cultures prepared from E16 rat cortices with BDNF or NT-3 increased c-fos expression in Cajal-Retzius cells at 1 day in vitro (DIV), and promoted their survival and morphological differentiation after longer treatment. We also found that bFGF increased dramatically the number of CR-expressing neurons that are generated in culture and characterized by bipolar morphology. Using BrdU to mark dividing progenitor cells, we observed that CR-expressing neurons are generated during the first 2-3 days in culture and subsequently begin to differentiate. Other growth factors (neurotrophins, EGF, IGF-I) did not appeared to promote the proliferation of the progenitors that give rise to CR-expressing neurons, but EGF sustained the proliferative mode of these progenitors after short exposure to bFGF. Retinoic acid (RA) promoted the differentiation of CR-expressing neurons and, when applied with bFGF, it increased further their frequency. In conclusion, neurotrophins NT-3 and BDNF promote the survival and differentiation of Cajal-Retzius cells, and bFGF and RA enhance the generation and differentiation of CR-expressing neurons in the rat cerebral cortex.

TRANSPLANTATION OF EMBRYONIC STEM CELL-DERIVED NEURAL

O. Brüstle, A.C. Spiro, S. Okabe, and R.D.G. McKay*. Lab. of Molecular Biology, NINDS, NIH. Bethesda, MD 20892

Biology, NINDS, NIH, Bethesda, MD 20892

The *in vitro* generation of neurons and glia from embryonic stem (ES) cells offers exciting prospects for the study of early neural development and the generation of "designer cells" for transplantation studies. We have recently established a cell culture protocol which allows efficient production of neural precursors from ES cells and their subsequent differentiation *in vitro* (Okabe *et al.*, submitted). To investigate the developmental potential of ES cell-derived neural precursors *in vivo*, cell suspensions at various stages of differentiation were transplanted into the telencephalic vesicles of embryonic rats. The implanted cells were traced using species-specific antibodies and *in situ* hybridization with a probe to mouse satellite DNA. Cells leaving the ventricular system formed clusters within the subependyma and incorporated as single cells into various brain regions. They acquired mature neuronal and glial phenotypes with the donor-derived neurons producing an extensive axonal network throughout the host brain. In addition, cells remaining inside the ventricular system formed neural tube-like epithelial structures when transplanted at an early stage of *in vitro* differentiation. structures when transplanted at an early stage of in vitro differentiation. These structures contained abundant radially oriented nestin-positive processes and exhibited a centrifugal gradient of neuronal differentiation. Our data suggest that ES-cell derived neural precursors have the potential to form neural tube-like structures but are recruited to mature glial and neuronal phenotypes when exposed to embryonic brain parenchyma. Incorporation into the developing CNS of neurons and glia derived directly from genetically modified ES cells will allow the *in vivo* analysis of a targeted gene inactivation without generation of a knock out animal.

Supported by the NINDS.

EARLY SPECIFICATION OF STRIATAL PROJECTION NEURONS AND INTERNEURONAL SUBTYPES IN TRANSPLANTS OF THE LATERAL OR MEDIAL GANGLIONIC EMINENCE. M. Obson*, K. Campbell and A. Björklund, Wallenberg Neuroscience Center. University of Lund. Lund, Sweden.
Fetal striatal grafts derived from the striatal primordium including both the medial (MGE) and the lateral ganglionic eminence (LGE) of the embryonic day (E) 14-15 rat forebrain display regions which are striatum-like. i.e. contain immunopositivity for striatal projection neurons and interneuronal subtypes. In such grafts, however, the striatum-like regions only constitute 30-50% of the total graft area with the remaining portion of the transplant expressing non-striatal phenotypes, Interestingly, grafts derived from the selectively dissected LGE are highly enriched in striatal projection neurons as detected by DARPP-32 expression (up to 90%) while MGE transplants are only sparsely positive (<10%). These studies, however, have not adressed whether striatal interneuronal subtypes also are contained within the LGE transplants or are derived from the MGE.

The purpose of this study was to adress the contribution of the LGE and MGE, respectively, to striatal projection neurons and interneuronal subtypes at an early-(E12.5) and mid-point (E15) in striatal neurogenesis. Briefly, the LGE or MGE were dissected from E12.5 to E15 rat embryos and dissociated into a single cell suspension, injected into the ibotenic acid lesioned adult striatum. After 6 weeks postgrafting the animals were sacrificed and sections were analyzed using in situ hybridization histochemistry with probes recognizing DARPP-32, choline acetyltransferase (ChAT) or preprosomatostain (PPSS) mRNA's. As described previously, the E15 LGE grafts were, in contrast to the MGE, highly enriched in DARPP-32 expression. Interestingly, this predominance in DARPP-32 expressions was also observed in the LGE grafts with somewhat lower expression in the E15 MGE grafts. Additionally, a few positive cells were detected in the E

CLONAL ADULT RAT HIPPOCAMPAL PROGENITORS MIGRATE AND DIFFERENTIATE AFTER IMPLANTATION INTO EMBRYONIC BRAIN LO. Suhonen*, J. Takahashi, M. Takahashi, T. Palmer, J. Ray and F.H. Gage. Laboratory of Genetics, The Salk Institute, La Jolla, CA 92037

Adult hippocampal progenitors can be cultured for over two year in the presence of basic fibroblast growth factor (FGF-2). When grafted back to adult rat brain, they can migrate to specific structures and undergo site-specific neuronal differentiation. Now we have genetically modified these cells with retrovirus vector to express E. Coli LacZ gene in the nucleus or cytoplasm of the cells and isolated clones of normal diploid multipotent progenitors from adult rat hippocampus.

To examine the developmental capacity of these clonal adult progenitor cells in vivo the cells were implanted into embryonic (E17) rat brain. At 9 to 40 days postnatal age, brains were fixed and processed for 8-Gal immunoreactivity and neuronal and glial markers. The progenitors implanted into the neuroepithelium of the telencephalon and mesencephalon migrated into the developing hippocampal formation and cerebellar cortex where some cells acquired region-specific morphologies and expressed site-specific neuronal markers, i.e. calbindin and NeuN. Grafted progenitors were found in various other areas undergoing neurogenesis at or after the time of implantation, i.e. striatum, septum, and late developing nuclei of

These findings indicate that clonal adult hippocampal progenitors grafted into the fetal brain migrate and integrate into the host brain cytoarchitecture and they can undergo site-specific neurogenesis during embryonic rat brain development.

ADULT CNS STEM CELL FATE CAN BE MODULATED BY ALTERING THE EXPRESSION OF TROPHIC FACTOR RECEPTORS. <u>I. Takahashi, T.D. Palmer, F.H. Gage.</u> Laboratory of Genetics, The Salk Institute, La Jolla CA, 92037

The ability to propagate central nervous system stem cells in continuous culture provides a valuable resource for examining factors that regulate the early stages of fate determination and differentiation. Once multipotent progenitors exit the cell cycle, the culture environment has a significant effect on differentiation and can be used to influence the ratios of each neuronal or glial cell type generated. We are using adult rat hippocampal stem cell cultures to examine the role of neurotrophins in the commitment and consolidation phases of neuronal differentiation. Proliferative multipotent precursors express trk B and C receptors and the survival and maturation of newly committed neurons are enhanced by treating cultures with the cognate ligands, brain derived neurotrophic factor and neurotrophin-3. Trk A and low affinity nerve growth factor receptor (p75) are not expressed and accordingly, nerve growth factor (NGF) has little effect on differentiation. However, following retinoic acid stimulation, both trkA and p75 are upregulated and NGF is subsequently able to stimulate an immediate early signal transduction cascade as indicated by an activation of c-fos. Ongoing work examines how the sequential application of exogenous agents such as forskolin, glucocorticoids, retinoids and phorbol esters can be used to influence early fate choice events and modulate trophic or growth factor receptors. The ability to alter a progenitor's responses to external cues suggests that the repertoire of adultderived hippocampal progenitors may be much larger than indicated by the default status of untreated progenitors. This plasticity may have broader significance in cellular replacement strategies if progenitors can be primed to appropriately respond to a particular CNS environment so that specific neuronal differentiation cascades are activated following grafting into the aged or injured CNS. Supported by NIH AG08514 and Kyoto University Medical School, Department of Neurosurgery.

CHARACTERIZATION OF NEURAL PROGENITOR CELLS ISOLATED AND CULTURED FROM DIFFERENT REGIONS OF ADULT RAT SPINAL CORD. L. Ray*, L. Shihabuddin and F. H. Gage. Laboratory of Genetics, Salk Institute for Biological Studies. 10010 N. Torrey Pines Road, La Jolla, CA 92037

FGF-2 responsive neural progenitor cells have been cultured from different adult brain regions. Here we have explored whether similar progenitor cells can be cultured from different levels (sacral, thoracic, lumber and cervical) of adult rat spinal cord and whether they give rise to neurons and glia as well as spinal cord specific neurons (e.g. motoneurons).

specific neurons (e.g. motoneurons).

Sacral, thoracic, lumber and cervical areas of adult rat spinal cord (>3 months old) were micro-dissected and neural progenitor cells were isolated and cultured in serum-free medium containing FGF-2 (20 ng/ml) through multiple passages. Although all areas generated rapidly proliferating cells, the cultures were heterogeneous in nature and cell morphology varied within a given area as well as between areas. A large number of cells in cultures from all areas of the spinal cord expressed A2B5, GFAP, MAP2 and GAD K2 as well as p75, CGRP and ChAT, markers for motoneurons. Cells expressing the latter markers are large and have morphology similar to that of motoneurons in these cultures may indicate that some cells are undergoing spontaneous differentiation. Comparison of the properties of neural progenitors isolated from different areas of the spinal cord with adult rat hippocampal cells will provide insight as to whether analogous populations of progenitor cells are present within sub-areas of a given region and in different regions of adult CNS. Supported by grants from NIA, APA, ISRT and Hollfelder Foundation.

CNS PRECURSOR CELLS THAT EXPRESS TRK RECEPTORS: INDUCTION OF DIFFERENT CELL FATES BY NEUROTROPHINS. M.V. Lachyankar, P.J. Condon, P.J. Quesenberry, N.S. Litofsky, L.D. Recht and A.H. Ross*. Worcester Foundation for Biomedical Research, Shrewsbury, MA 01545 and University of Massachusetts Medical Center, Worcester, MA 01655.

Neurosphere cultures grown from murine striatum in the presence of epidermal growth factor (EGF) contain multipotential precursor cells capable of neuronal, astrocytic and oligodendroglial differentiation. In this study, we tested whether neurotrophic factors induce differentiation of these neural precursor cells. We find that these cells express receptors for multiple neurotrophic factors, including TrkA, TrkB, TrkC, the low-affinity nerve growth factor (NGF) receptor and ciliary neurotrophic factor (CNTF) receptor a. In the presence of the mitogen, EGF, treatment of stem cells with neurotrophic factors had no apparent effect. Removal of EGF resulted in cessation of cell proliferation and pronounced astrocytic differentiation. In the absence of EGF, treatment with NGF or brain-derived neurotrophic factor (BDNF) induced neuronal differentiation. Treatment with neurotrophin-3 (NT-3) or CNTF resulted in both neuronal and oligodendroglial fates. These studies suggest that local cues, such as neurotrophic factors, may induce production of different types of neural cells during development or in response to other stimuli, such as injury.

RETINOIC ACID AND BDNF INDUCE THE DIFFERENTIATION AND MATURATION OF NEURONS GENERATED FROM EGF RESPONSIVE PRECURSORS. L. Frazer, A.E. Rosser*, M.G. Terborg and C.N. Svendsen MRC Cambridge Centre for Brain Repair. University of Cambridge, UK EGF promotes the division of a CNS precursor cell which retains the ability to

differentiate into either neurons, astrocytes or oligodendrocytes. It has previously been shown that serum. BMP or CNTF can induce the differentiation of these cells into glia. BDNF has been shown to increase the maturation of neurons developing from EGF responsive precursors while not increasing the total number of neurons. In this study EGF responsive precursors from the embryonic rat striatum were isolated and expanded for 14 days in vitro. Cells were then plated onto poly-lysine coated coverslips and allowed to differentiate for one week in the absence or presence of various combinations of RA and BDNF. Dose response curves with RA showed that at 0.25 or 0.5µM there was a significant reduction in overall cell survival but at the same time a significant increase in the number of neurons, astrocytes and oligodendrocytes assessed using βtubulin III, GFAP and GAL-C immunocytochemistry suggesting that RA had induced a large proportion of the cells to label with these markers in addition to promoting significant cell death. Surprisingly, at the highest dose of 1.0µM RA there was less cell death than at the lower doses and significantly fewer cells labelled with either of the above markers showing that RA acid is not simply toxic to a proportion of cells. BDNF had no effect on the number of neurons differentiating but did significantly increase neuronal size, BDNF combined with RA was no different to RA alone with regard to cell death and neuronal number and still led to an increase in neuronal size. These results show that RA has powerful differentiation effect on EGF responsive precursor cells in addition to triggering a cell death mechanism, and that BDNF specifically affects the maturation of these neurons without preventing the RA induced cell death. Supported by the Wellcome Trust and MRC.

ANALYSIS OF MOTILE O-2A PROGENITOR CELLS IN LIVING BRAIN SLICES AND IN CULTURE. C. Schmidt, C. Ohlemeyer, T. Walter and J. Schmitzer*. Max Delbrück Center for Molecular Medicine (MDC), Berlin-Buch, Germany.

O-2A progenitor cells are purported to migrate over long distances (1-4) into the various brain regions where they differentiate into oligodendrocytes and fulfill their appropriate tasks, i.e. myelination of axons. The aim of this study was to visualize and characterize motile cells in vivo and in vitro. We performed video-time-lapse analysis of cells in living brain slices of the corpus callosum from 1- to 5-day-old rats. Motile cells were analyzed electrophysiologically and filled with Lucifer Yellow. All motile cells have a simple morphology bearing only very few processes. They migrate with a velocity of 10-100 µm/h within the corpus callosum. The main direction of their movement is towards the cortex. However, cells change and even reverse direction of their movement. We also observed dye-coupling between migrating cells and other yet unidentified cells within the corpus callosum. Patch clamp analysis of the motile cells confirmed that they belong to the O-2A lineage: they showed delayed outward rectifying currents (K+pg) which is characteristic for these cells (5). All motile cells examined show inward currents upon perfusion with GABA or kainate at a holding potential of -70 mV.

A combination of video-time-lapse, electrophysiological and morphological analyses of primary cultures of rat neonatal O2-A progenitor cells revealed comparable results: Migration is confined to cells with a simple morphology. Coincidentally, the majority of the motile cells express the A2B5 epitope. Migration ceases, when they are strongly O4-positive. As seen in the living brain slice, they show delayed outward rectifying potassium currents (K+pg). When cells are plated on laminin in the presence of the growth factors PDGF and bFGF, both the number and the velocity of the cells is significantly enhanced in comparison to poly-L-lysine.

TIME-LAPSE ANALYSIS OF CELL DIVISION, MOVEMENT AND SHAPE DURING GASTRULATION AND NEURULATION IN ZEBRAFISH. Miguel L. Conchal. Richard J. Adams Let University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, U.K. 2Facultad de Medicina, Universidad de Chile, Casilla 70005 Correo 7, Santiago, Chile.

In this study we have taken advantage of the optical transparency of zebrafish

In this study we have taken advantage of the optical transparency of zebrafish embryos to investigate the patterns of cell division, movement and shape during early stages of development of the central nervous system. Gastrula and neurula embryos were imaged using time-lapse DIC Nomarski optics and 3-dimensional confocal microscopy. Images were analysed quantitatively using customised routines written for NIH-Image. (1) The onset of gastrulation is accompanied by major changes in cell behaviour within the epiblast. Cells begin to move co-ordinately in a vegeto-dorsal direction, become densely packed and the plane of cell division becomes aligned in the anterior-posterior (AP) plane. These behaviours begin at the blastoderm margin and propagate in a gradient towards the animal pole. (2) As the neural plate differentiates cells undergo extensive convergence movements towards the dorsal midline and a gradual transition to a medio-lateral (ML) plane of division is observed. This becomes the predominant orientation of division during neural keel and nerve rod stages. From late neural keel stage ML divisions concentrate at the dorsal midline and generate bilateral progeny. (3) Surprisingly, ventral (epidermal) cells also orient their divisions in the ML plane. (4) The factors that may determine the plane of division were investigated. The spatial distribution of AP divisions during gastrulation suggests that a common mechanism (e.g. chemical or mechanical) may determine this plane of division at different dorso-ventral positions. Cell movement and shape appear to account for regional differences in this pattern. ML divisions, on the other hand, occur in both epidermal and neural cells. The ML alignment of epidermal divisions is well correlated to cell shape. ML divisions ocurring within the neuroepithelium, however, seem to be dependent upon more factors. Changes in cell movement, shape and the state of polarisation during neuralation have been analysed. Supported by MRC Research Centre in Brain and Behaviour; CONICY

PRENATAL STRIATAL DEVELOPMENT IN ORGANOTYPIC SLICE CULTURES. E.I. Barragan* E. Fusco and A.M. Graybiel Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139

The mammalian striatum is divided in two major compartments: the striosomes and the matrix. The mechanisms that regulate the emergence of striosomes during embroarie development ages not well, such as the company of the company

The mammalian striatum is divided in two major compartments: the striosomes and the matrix. The mechanisms that regulate the emergence of striosomes during embryonic development are not well understood. To achieve the possibility of studying compartment formation in a system accessible to external manipulations, we have adapted the organotypic slice culture method elaborated by Liu et al. (1993) to the embryonic striatum. Striosomal cells (S cells) and matrisomal cells (M cells) were labeled with the thymidine analog Bromo-deoxyuridine (BrdU) in their birthdate windows, i.e. embryonal days 11.5 (B11.5) for S cells and E15 for M cells, by 1 injection of 100 mg/kg to the mothers. Coronal brain slices 300 microns thick were cut at E16. E17 and at days P1 and P2 as a control to confirm S and M cell birthdate injection times. We stained with the neurodifferentiation-marker MAP-2 to test the viability of the tissue. When we cultured S cell labeled slices harvested at E16-E17 for 0-5 days and afterwards applied immunohistochemistry for BrdU, we observed dispersed nuclei, some forming small clusters in the lateral striatum. In parallel experiments, we cultured M cell labeled slices harvested at E17 for 0-12-24 hr and 2-5 day periods. M cells first appeared in and near the ventricular zone (VZ), and later spread into the striatal primordium With increasing time in vitro. M cells deeply penetrated the striatum, reaching its lateral edge caudally. This shift in position is unlikely to be due simply to the flattening of the cultures, because when we pulse labeled and cut at E17, and then cultured the slices for 5 days, most M cells were still in the VZ, subventricular zone and medial striatum. We conclude (1) that it is feasible to maintain embryonal striatal slices in culture, (2) that in such cultures S and M cells can survive for at least 5 days, and (3) that M cells can successfully migrate from the VZ into the striatum. We poported by NIH 2R01 HD 28341.

ABNORMAL DEVELOPMENT OF THE OPTIC CUP, OLFACTORY PIT, CRANIAL GANGLIA AND ANTERIOR CARDINAL VEIN IN VITAMIN A-DEFICIENT RAT EMBRYOS. J. C. White & M. Clagett-Dame*. School of Pharmacy, Univ. of Wisconsin-Madison, WI 53706. Vitamin A is required for reproduction and normal embryonic development. Retinoic acid (RA), a metabolite of vitamin A, is believed to support the functions of the vitamin during early embryogenesis. Experiments were performed to determine how much RA is needed to support normal development from embryonic day 0.5 to 12.5 (E12.5) and to identify structures that are retinoid dependent. Female rats were depleted of stored vitamin A and maintained on 12 μg all-trans RA (atRA) until mating. At E0.5, dams were fed control diet (12 μg atRA/g diet + 100 IU/day retinyl palmitate) or one of four experimental diets containing 12, 6, 1.5 or 0 μg atRA/g diet, At E12.5, the percent of dead or resorbed embryos was ~30% for all diet groups with the exception of dams receiving 0 μg atRA/g diet, in which it was ~70%. Embryos from the control group and those receiving 12 μg atRA/g diet were similar in size and morphology. Embryos from the 6 μg atRA/g diet group were similar in size to control embryos, but showed enlargement of the anterior cardinal vein (ACV). Embryos from dams receiving 1.5 μg atRA/g diet were more variable in size and exhibited marked ACV enlargement. Otic vesicles were reduced in size in the 1.5 μg atRA/g diet group and/or absent in the 0 μg group. Embryos in the 0 μg RA/g diet group developed optic vesicles, but showed no evidence of optic cup or neural retina formation. Olfactory pits and cranial ganglia VII/VIII, IX, and X were also not observed. In conclusion, developmental abnormalities were observed in embryos from dams receiving 6 μg atRA/g diet or less. This work supports a role for RA in the development of the ACV, optic cup, olfactory pit, otic vesicle and cranial ganglia VII/VIII, IX and X. Supported by NIH-DK14881.

TIME LAPSE PHOTOGRAPHY OF HINDBRAIN EXPLANT CULTURES. P.M. Kulesa* and S.E. Fraser. Div. of Biology, Beckman Institute (139-74), Calif. Inst. of Tech., Pasadena, CA

The segmented nature of the developing hindbrain shows many parallels to the well studied segmented body pattern seen in the developing *Drosophila*. The correspondence of molecular activity with these segments and the development molecular activity with these segments and the development of specific structure makes it an ideal system for understanding the basic mechanisms of embryonic patterning. However, the *in ovo* and *in utero* nature of chicken and mouse development make it difficult to directly observe the entire process over the course of hindbrain development. To study the dynamic aspects of hindbrain segmentation we utilize an *in vitro* hindbrain explant culture. Hindbrains can be readily discorted from developing Hindbrains can be readily dissected from developing system. Hindbrains can be readily dissected from developing chicken or mouse embryos and cultured for 2-3 days, during which normal cell movement and differentiation continue to occur. Individual cells and small populations of cells in cultured hindbrains can be labeled in situ by microinjection with DiI or fluorescent dextrans and visualized with epifluorescence and confocal microscopy. Generation of time lapse recordings of the movements and differentiation of these cells will allow for a better understanding of rhombomere boundary formation, as well as a comparison of such segmented structure with genetic expression domains. such segmented structure with genetic expression domains. DIFFERENTIAL DORSOVENTRAL DISPERSAL AND CONTRALATERAL MOVEMENT OF NEURAL PRECURSORS IN EARLY CHICK NEURAL TUBE. L. Erskine* and J.D.W. Clarke. Dept. Anatomy & Developmental Biology. University College London. Gower Street, LONDON WC1E 6BT, UK.

Dept. Anatomy & Developmental Biology, University College London, Gower Street, LONDON WC1E 6BT, UK.

Little is known of cell movement within the early neuroepithelium. We have assessed the dorsoventral (DV) dispersal of neural precursor cells in chick hindbrain and spinal cord during the first 48 hrs of neural development. Using iontophoresis, 5-10 neighbouring neuroepithelial cells at identified positions in the neural plate or early neural tube were labelled *in ovo* with the lipophilic dye Dil. The dispersal of these cells and their progeny was examined 48 hrs later in flattened wholemount preparations of the hindbrain or spinal cord.

The position and degree of dispersal of the descendent precursors was dependent on the initial position of the labelled cells. Particularly in the hindbrain, dispersal of cells was not uniform but related to their initial position along the DV axis of the neural tube. Spread of lateral or dorsolateral cells was much more widespread than those labelled ventrally. Thus, not all regions of the neural plate contribute equally to the development of the neural tube. Additionally, considerable overlap and mixing of cells from different DV domains occurred.

Surprisingly, in the spinal cord but not the hindbrain, in 56% (19/34) cases, contralateral movement of neural precursor cells was observed. This produced 2 discrete clusters of labelled cells, usually separated by regions of unlabelled cells, at similar DV positions on either side of the floor plate. Movement of cells through both roof plate and floor plate appears possible. This is direct evidence that precursor cells are able to move large distances within the ventricular zone. Moreover, the symmetrical nature of the bilateral clusters suggests that at least some precursor cells may be specified early for particular regions along the DV axis of the neural tube.

ALTERATION OF RADIAL GLIA PATTERN IN SPINAL CORDS OF NOTOCHORDLESS XENOPUS <u>C. E. Maier* and R. H. Miller</u>¹ Depts of Anatomy* and Neurosciences¹, Case Western Reserve Univ., Cleveland

Normal neuronal and oligodendrocyte patterns in Xenopus spinal cord are altered when animals are made notochordless as the result of UV irradiation of the uncleaved, fertilized egg. Neuronal numbers are modified while cell bodies are found in atypical locations and axons have unusual patterns. Oligodendrocyte differentiation is delayed and may not occur at all in the spinal cord of notochordless Xenopus.

The influence of the notochord on astrocytes and their radial glia cell precursors has not been determined. To begin to study this impact unfixed frozen sections of experimental and clutchmate control Xenopus at stage 45 were labeled with anti-GFAP antibodies and viewed by indirect immunofluorescence. During normal development continuous GFAP+ processes radiate from the central canal to the pial surface of the spinal cord. Preliminary data suggests that the GFAP+ pattern is variously altered in spinal cords of Xenopus made notochordless by UV irradiation. GFAP+ cells are present but their radial orientation is frequently lost. Labeling of radial processes may be interrupted. Cell bodies are concentrated in the ventral spinal cord in some notochordless animals. The pattern of radial glia/astrocyte development appears to be influenced by an absence of the notochord but in a less predictable form than neurons or oligodendrocytes. Funding: NS25597-08.

EFFECT OF N-CADHERIN ANTIBODIES ON HISTOGENESIS OF THE EARLY DEVELOPING CHICKEN BRAIN. S. Gänzler* and C. Redies. Institute for Biology III, Univ. of Freiburg, Schänzlestr. 1, D-79104 Freiburg, Germany.

Cadherins are a family of transmembrane glycoproteins which mediate calciumdependent cell-cell adhesion by a preferentially homophilic binding mechanism. During development of the brain, N-cadherin, a member of this family, is expressed throughout the neuroepithelium, with strongest expression in the

We studied the role of N-cadherin during brain morphogenesis by injecting functionally blocking N-cadherin antibodies into the tectal ventricle during early stages of development (embryonic day 3 to 5; E3-E5). To detect mitotic cells, BrdU was injected one hour before fixation at E6. The effect of blocking Ncadherin was analyzed by immunostaining coronal cryostat sections with antibodies against N-cadherin, R-Cadherin, BrdU, Ng-CAM/G4, and as marker for radial glia, with the antibody R5.

Brains treated with N-cadherin antibodies show invaginations of the ventricular lining and the formation of rosettes, most prominently in the tectum and diencephalon. The histological organization of these structures is basically similar to that of the normal neuroepithelium. Their center consists of ventricular lining which is surrounded by an inner ("ventricular") layer of mitotic (BrdUincorporating) cells and an outer ("mantle") layer of post-mitotic (Ng-CAM/G4expressing) neurons. In some regions, radial glia extends from the center of the rosettes to the outer layer. In the diencephalon, R-cadherin-expressing early neurons aggregate into nuclear anlagen (see Gänzler & Redies, J. Neurosci., 1995, 15:4157) but their form is distorted. These results show that blocking N-cadherin function disrupts the sheet-like neuroepithelial structure but seems to have little effect on the differentiation of neural cell types.

RETINOIC ACID ADMINISTRATION TO EARLY POSTNATAL MICE CAUSES NEOTENIC TRANSFORMATION, J.E. Crandall*, M. Yamamoto, G.

Schwarting, O. Koul, P. McCaffery, C.K. Deutsch and U. C. Dräger. The Shriver Center, Waltham, MA 02254 & Harvard Med. Sch., Boston. The transcriptional activator retinoic acid (RA) acts as an endogenous morphogen for the developing organism. In many cases, it terminates growth and initiates differentiation programs. Endogenous RA synthesis occurs at restricted locations, resulting in diffusion gradients of decreasing RA concentration. Systemic flooding of the early embryo, during the formation of organ anlagen causes severe malformations, presumably due to abolishment of morphogenetically significant concentration gradients and spatially inappropriate activation of differentiation. While RA teratogenicity in embryos has been extensively described, our observations indicate that RA-sensitive morphogenesis described, our observations indicate that RA-sensitive morphogenesis extends to postnatal development. When early postnatal mice are injected with a single dose of RA and allowed to grow to adulthood, they maintain partially juvenile characteristics in different systems. They have baby-like faces that appear rounder and shorter. The cranium has an overall altered shape, affecting multiple bones and consistently resulting in skulls with a pronounced ventral bend. This malformation reflects an altered shape of the brain; the pontine flexure remains partially curved. Similarly, the postnatal maturation of the olfactory system is disrupted in the RA-treated mice; the entitle arecentor sheet is significantly thinger. the RA-treated mice: the epithelial receptor sheet is significantly thinner and the number of glomeruli in the olfactory bulb is decreased. We conclude that a retinoid overdose in neonatal mice interrupts morphogenetic maturation, causing neoteny, a lifelong arrest at partially juvenile features. Supported by NIH grants DC00953, HD04147 & EY0193

PATTERNS OF EMBRYONIC DEVELOPMENT OF THE BRAIN AND SENSORY ORGANS STUDIED IN THREE MARINE TELEOST SPECIES

Holmayist B. J. *, Forsell J. and Helvik J.V. Lab. for Marine Molecular Biology, Univ. of Bergen, Norway, and Dept. Zoology, Univ. of Lund, Sweden

We have undertaken to study the development of the brain and sensory organs in early life stages of Atlantic halibut (Hippoglossus hippoglossus), herring (Clupea harengus) and cod (Gadus morhua). Here we present data from studies performed from 30 d° (age in days times rearing temp. in C°) to hatching (Hh and Gm hatching at ca 90d°, and Ch at ca 120d°). Immunocytochemical techniques were used for detection of acetylated tubulin (AT), a cytoskeletal protein present in early axons; serotonin (5HT), a neurotransmitter and precursor to melatonin; tyrosine hydroxylase (TH), the rate limiting enzyme for catecholamine synthesis; and opsin (OP) and S-antigen (SA), molecules involved in the phototransduction cascade.

5-analger (5A), indecures involven in the pistodia/struction cascater.

In the brain, the first AT immunoceactive (ir) neuronal populations and major axonal tracts start to form at ca 30d° in the first AE immunoceactive (ir) neuronal populations and major axonal 4dd° in hering, 50d° in cod and 4dd of an daford at 60 and 80d°, respectively, in halibut. 5HIT and THI neurons appear around 4dd° in hering, 6dd° in cod, and at 70 and 90d°, respectively, in halibut. Pineal 5HIT redls appear at ca 6dd° in hering, and at 90d° in cod, and at 70 and 90d°, respectively. cod and halibut. The retina of both herring and cod displays ATir (ganglion) cells at 40d°, and 5HTir and THir cells at ca 90d°. A Tir axons gradually appear coursing in the optic nerve, optic tract and into the optic tectum between 40 and 70d° in herring and cod. In the halibut, no immunoreactivity is present in retina or in the central visual system. Neuromasts and associated axonal projections are strongly ATir in the halibut, appearing at 60d°. however, not detected in cod or herring. In all species, cells and projections in the olfactory placoides and bulb were strongly ATir from about 40-60d° to hatching

The results indicate that the pineal organ is the first differentiated sensory organ in the species studied, possessing

putative photoreceptor and light mediator functions already in the embryonic stage. The olfactory system also appears to be relatively well developed in all species at hatching. The visual system, retina and central projections, is relatively differentiated prior to hatching in herring and cod, whereas the mechano-receptor system is well developed prior to hatching only in halibut. Serotonin and catecholamines appear to be among the first neural messengers in the brain, as previously indicated in other teleosts. Variations in the relative timing of differentiated sensory/brain systems are suggested to reflect species specific adaptations to different environmental life conditions.

NEUROTROPHIC FACTORS: BIOLOGIC EFFECTS-BDNF AND NT-4 I

396.1

BDNF DELETION ALTERS GUSTATORY PAPILLA AND TASTE BUD SIZE AND NUMBER IN POSTNATAL MOUSE. C.M. Mistretta*, K. Goosens', I. Farinas² and L.F. Reichardt². ¹School of Dentistry, Univ. of Michigan, Ann Arbor, MI 48109 and ²Howard Hughes Med. Center, Univ. of California, San Francisco, CA 94143.

Although gustatory papillae do not depend on sensory innervation for induction and early development, subsequent papilla growth and sustained taste bud development are neurally dependent. We have examined gustatory papillae and taste buds in postnatal BDNF null mutant homozygotes to learn if associated deficits in taste neuron populations affect the peripheral taste system. The geniculate (innervates taste buds in fungiform papillae), trigeminal (innervates nontaste epithelium in fungiform papillae) and petrosal (innervates circumvallate papilla and resident taste buds) ganglia are reduced in volume by 40, 16 and 44%, respectively, in these animals. Tongues were dissected from homozygote and wild type mice at postnatal days 15 and 25. Fungiform and circumvallate papillae were stained with hematoxylin and eosin and measures were made of the number and diameter of papillae and taste buds. Fungiform papillae were reduced in number by about 50% on the anterior quarter of tongues in P25 BDNF -/- mice compared to +/+ tongues. Although each papilla in both null and wild type mice contained a taste bud, the buds were about 36% smaller and papillae were about 40% smaller in -/tongues. The single circumvallate papilla at P25 was 46% smaller in -/tongues compared to +/+. Also, total number of taste buds was reduced by about 60% and taste buds were 50% smaller in BDNF null circumvallate papilla. The data demonstrate quantitative relations among the reduction in gustatory ganglia and decreased gustatory organ size and receptor number, and support a role for BDNF in taste organ development. Supported by NIDCD, NIH Grant DC00456 to CMM.

BDNF-, BUT NOT NT4-KNOCKOUT MICE ARE DEFICIENT IN DOPAMIN-ERGIC VISCERAL SENSORY NEURONS AND DISPLAY SEVERE DEVELOPMENTAL DEFICITS IN CONTROL OF BREATHING. J.T. Erickson*1, <u>I.C. Conover², V. Borday², J. Champagnat³, and D.M. Katz¹. ¹Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106, ²Regeneron Pharmaceuticals, Inc., Tarrytown, NY and ³Institut Alfred Fessard, 91198 Gif-Sur-Yvette Cedex, France.</u>

Brain-Derived Neurotrophic Factor (BDNF) and Neurotrophin-4 (NT4) support survival of predominantly separate populations of visceral sensory neurons (Conover et al., Nature 375:235.1995). In particular, a subset of dopaminergic afferents thought to be important for controlling ventilation is depleted only in BDNF-deficient animals (Erickson et al., Soc. Neurosci. Abst., 1995). We therefore postulated that loss of these neurons would lead to perturbations of respiratory control in BDNF-deficient (BD) mice. To test this possibility, we compared resting ventilation in newborn wild type (WT) and BD mice, using whole body plethysmography. Minute ventilation (VE) in BD mice was decreased by 50-70% compared to WT controls. Moreover, BD mice displayed a two-fold increase in breath-to-breath variability of tidal volume and V_E, and long periods of apnea. In contrast, resting ventilation was not depressed in newborn NT4-deficient mice. Hyperoxia (100% O2), which in normal animals decreases activity in the peripheral chemoreceptors and thereby depresses ventilation, decreased V_E by 30% in WT animals but did not change V_E during resting breathing in BD mice. Hypoxia (12% O₂), on the other hand, elicited a 27% greater ventilatory depression in BD animals than in WT controls. These data indicate that BDNF, but not NT4, is required for expression of normal breathing behavior in newborn animals. The deficits in BD mice appear to reflect diminished chemoafferent drive, consistent with the loss of chemoafferent neurons in these animals. Thus, despite the fact that BDNF and NT4 are equivalent in supporting sensory neuron survival in vitro, neuronal dependencies in vivo indicate distinct physiologic roles for the two TrkB ligands. Supported by HL-42131 (DMK) and the Francis Families Foundation (JTE)

THE NEUROTROPHIC SUPPORT OF THE DEVELOPING EAR! A COMPARISON OF BDNF/NT-3 WITH TRKB/C KNOCKOUT MICE. B. Fritzsch*, #I.Silos-Santiago, @L. Bianchi, \$I. Farinas, \$L. Reichardt, @J. Conover, @R.M. Lindsay and #M. Barbacid. Creighton University, Omaha, NE 68178, # BMS, Princeton, NJ, @Regeneron, Tarrytown, NY, \$UCSF, San Francisco, CA

Recent years showed that the developing sensory cells of the ear produce two neurotrophins, BDNF and NT-3, which support the innervating ganglion cells via two receptors, TrkB and TrkC. Double mutants of both neurotrophins and their receptors show complete loss of all innervation but normal development of hair cells at least until PO. Apparent discrepancies in different studies have prompted us to analyze all four mutants employing the same techniques, DiI labeling, SEM and TEM. BDNF/trkB ko mice lose innervation of semicircular canals, reduce utricular and saccular innervation and reduce innevation to outer hair cells in the apex of the In contrast, NT-3/trkC ko mice show a pronounced qualitative effect on the cochlea with a reduction (trkC) or complete loss (NT-3) of ganglia near the base. Quantitative comparison of the cochlea shows the least effect in BDNF ko mice, intermediate effect in trkB and trkC ko mice and the most pronounced effect in NT-3 ko mice. Surviving cochlear ganglion cells expand to cover a larger area of the cochlea than normal Electron micrographs show innervation of the outer hair cells by both afferents and efferents in trkB ko mice at the base. In contrast, NT-3 ko mice retain this innervation at the apex. We propose a basal (NT-3/trkC) to apical (BDNF/trkB) gradient of dependency for spiral ganglion cells.

LACKING AND MALFORMED GUSTATORY PAPILLAE IN BDNF KNOCK-OUTS. P. Ernfors, C. A. Nosrat, J. Blomlöf, M. Metsis*, S. Lindskog, L. Olson. Dept. of Medical Biochemistry and Biophysics, Dept. of Neuroscience, Karolinska Institute, S-171 77 Stockholm, Sweden; Dept. of Oral Diagnostics, Div. of Oral Pathology, Karolinska Institute, S-141 04 Huddinge, Sweden.

In our prior studies, we reported that neurotrophin mRNA species are expressed in the developing and adult lingual sensogustatory system of rats. BDNF mRNA is exclusively present in the developing gustatory epithelium and as the animals become older the labeling is found in a fraction of taste cells within the taste buds. In the present study, we have evaluated the morphological appearance of the tonsue in

come older the labeling is found in a fraction of taste cells within the taste buds. In the present study, we have evaluated the morphological appearance of the tongue in normal and BDNF null mutated mice using scanning electron microscopy (SEM). Further, although still in preparation, the possible innervation changes in the peripheral gustatory apparatus of normal versus knockout mice were evaluated. We observed striking morphological differences in the knockouts compared to the normal animals. The circumvallate papilla showed a much higher keratinization tendency and was barely visible. The fungiform papillae were of smaller size and some of them were lacking a visible taste pore. Remarkably, no foliate papillae could be found in SEM although immunohistochemistry revealed a few taste buds surrounding a short lumen in the area where foliate papillae were to be expected. Protein gene product 9.5 immunoreactive fibers and cells could be observed in taste buds of all the gustatory papillae, although the immunoreactive cells had a somewhat

gene product 9.5 immunoreactive fibers and cells could be observed in taste buds of all the gustatory papillae, although the immunoreactive cells had a somewhat deranged morphology.

Based on the morphological differences between normal and knockout animals we suggest that BDNF, apart from its classical role as a neurotrophic factor, is also involved in the initiation and maintenance of normal morphology in these papillae either by acting directly and/or through attraction and maintenance of proper gustatory innervation. Disappearance of taste pores in some fungiform papillae in BDNF—/— mice is also indicative of loss of function. It is hypothetized that NT3 expression in fungiform papillae of BDNF—/— mice might offer partial papillary and taste bud rescue.

NEUROTROPHIN-4 (NT-4) IS REQUIRED FOR THE DEVELOPMENT OF A SUBCLASS OF CUTANEOUS SENSORY NEURONS C.L. Stucky*.

M. Koltzenburg, T. Dechiara*, R.M. Lindsay* & G.D. Yancopoulos* Dept. of Neurology, University of Würzburg, D-97080 Würzburg, Germany & *Regeneron Pharmaceuticals, Tarrytown, NY

NT-4 is a member of the neurotrophin family which is important for the development, survival and function of sensory neurons. Here, we used standard neurophysiological techniques to study the properties of single afferent fibers innervating hairy skin in adult transgenic mice lacking NT-4 (NT-4 -/-) or wildtype (NT-4 +/+) controls. Neurons were characterized in vitro by their conduction velocity and response properties to controlled mechanical or thermal stimuli. Large myelinated fibers were either slowly adapting (SA) mechanoreceptors, which respond tonically to a sustained mechanical stimulus, or rapidly adapting (RA) mechanoreceptors, which respond only at the on- or off-set of a stimulus. There was no difference in the percentages of SA and RA fibers in NT-4-/- (SA = 49%; RA = 51%; n = 70) or NT-4 +/+ (SA = 46%, RA = 54%; n = 83) mice. In contrast to transgenic mice lacking BDNF, in which SA fibers display markedly reduced mechanical sensitivity (Koltzenburg et al., Soc. Neurosci. Abstr. 21, 1054), there was no difference in the stimulus-response functions of SA or RA receptors in NT-4 -/- and NT-4 +/+ mice. Thin myelinated fibers were either sensitive D-hair receptors, which supply hair follicles, or A-fiber mechanonociceptors (AM). Whereas D-hair receptors make up 34% (n=91) of thin myelinated fibers in NT-4 +/+ mice, they are almost completely absent in mice lacking NT-4 (4%, n=52). Concomittantly, the percentage of AM fibers increased to 96%. The receptive properties of unmyelinated nociceptive afferent fibers (n=39) were not different in either mice strain. Thus, NT-4 is specifically required for the development of D-hair receptors, but not for the survival or function of other types of cutaneous mechanosensitive neurons. Peripheral application of NT-4 increases excitability and decreases somal size of gastrocnemius motoneurons in the adult rat. M. Gonzalez* and W.F. Collins, III. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

Recent findings indicate that the muscle-derived neurotrophins, NT-4 and BDNF, are important in the maintenance of adult motoneuron (MN) properties (Gonzalez and Collins, '95; Munson, Shelton and McMahon, '95). The present study was undertaken to characterize further the influence of NT-4 on adult MNs.

Male Sprague-Dawley rats (300-450 g) were treated for 14 days with NT-4 (6.24 µg/day, 6 rats) or bovine serum albumin (BSA, 108 mg/day, 6 rats) applied locally to the left medial gastrocnemius (MG) muscle via miniosmotic pumps (Alzet, model 2002). The rats were then prepared for in vivo intracellular recording and electrical properties of MG MNs in the NT-4 (n=26) and BSA-treated (n=36) rats were measured. In a parallel study, the left MG muscle was injected with cholera toxin B (CTB) on day 11 of NT-4 or BSA treatment. On day 14, the rats were sacrificed. The spinal cords were processed to visualize CTB, and somal cross sectional areas of randomly selected CTB-labeled MG MNs (30 MNs x 6 rats / treatment group) were measured. Data were analyzed using ANOVAs.

MG MN rheobase, total cell capacitance, equalizing time constant and somal cross sectional area were significantly reduced in NT-4-treated, compared to BSA-treated, rats. In addition, an increase in conduction velocity and a decrease in membrane time constant were noted in NT-4-treated rats but were not statistically significant. No significant treatment effect was observed in MN resistance, after-hyperpolarization amplitude and duration, membrane potential sag, action potential height, and electrotonic length

hyperpolarization amplitude and duration, memorane potential sag, action potential height, and electrotonic length.

These results suggest that MN properties, particularly excitability and size, are regulated by muscle-derived NT-4. Furthermore, this regulation likely involves specific effects on MN dendrites and ionic conductances. Supported by grants from NIH and NSF. NT-4 was generously provided by Regeneron Pharmaceuticals, Inc.

RECIPROCAL EFFECTS OF BDNF/TRKB AND NT-3/TRKC NEUROTROPHIN SYSTEMS ON THE DEVELOPMENT OF THE MONOSYNAPTIC EPSP IN MOTONEURONS OF THE NEONATAL RAT. B. S. Seebach* and L. M. Mendell, Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

From postnatal day (PND) 0-8, motoneurons become larger but monosynaptic EPSPs remain about the same size suggesting an increase in synaptic efficacy, Previously, we demonstrated that systemic administration of BDNF (PND 0,2,4,6) results in reduction of EPSP amplitude at PND 8, using dorsal root- evoked monosynaptic EPSPs recorded intracellularly in motoneurons in the *in vitro* nemisected rat spinal cord preparation (Soc. For Neurosci. Abstr., 1995). In the present studies similar administration of NT-3 had the opposite effect, i.e., increase in EPSP amplitude. Antagonists to both neurotrophins (fusion molecules *trkB/IgG* and *trkC/IgG*) resulted in effects that were opposite to the neurotrophins themselve (increase and decrease in EPSP amplitude, respectively). The same reciprocity was not observed for changes in motoneuron properties. Three of the 4 treatments led to similar relatively small increases in rheobase and decreases in motoneuron resistance; only NT-3 had no effect on motoneuron properties.

These results indicate that neurotrophins have a complex effect on the development of the monosynaptic reflex, more complex than their effect in determining survival of afferent classes such as muscle spindle afferents which depend virtually completely on the availability of NT-3. The BDNF- and trkC/IgG-induced EPSP amplitude decreases may have been influenced by increased motoneuron size. However, the increase in EPSP amplitude was uniformly larger than that predicted by the decrease in motoneuron size suggesting a direct effect on synaptic input even in these cases. However, the nature of this influence (structural or functional) remains to be elucidated.

BDNF Prevents and Reverses Adult Rat Motor Neuron Degeneration and Induces Axonal Outgrowth.

Y. Ishige, T. Tatsuno , C. Nakayama* and H. Noguchi.

Pharmaceuticals Research Center 1-98, Kasugadenaka 3-chome, Konahana-ku, Osaka 554, Japan

To assess and foresee the therapeutic potential of brain-derived neurotrophic factor (BDNF) in clinics, the effects of BDNF on adult motor neuron were extensively investigated using rat spinal root avulsion model. Intrathecal administration of BDNF immediately after the spinal root avulsion greatly protected the motor neuron cell death. BDNF also showed a protective effect on the reduction of transmitter-related enzymes (ChAT and AChE) and on the atrophy of soma size. Very interestingly, BDNF induced axonal outgrowth of severely damaged motor neurons at the avulsion site. The BDNF administration following 2 weeks-treatment with PBS after avulsion terminated the further deterioration of the cell death and relatively restored the cholinergic transmitter-related enzyme deficiency BDNF was demonstrated to possess a wide variety of biological effects on survival, soma size, cholinergic enzymes and axonal outgrowth of adult motor neurons. These results give a rationale for BDNF treatment against motor neuron diseases such as spinal cord injury and amyotrophic lateral sclerosis.

LOCAL APPLICATION OF NT-4/5 TO THE PROXIMAL CUT END OF A NERVE LIMITS THE DEVELOPMENT OF FULL BLOWN AXOTOMY RESPONSE. <u>L.M. Mendell*</u>, R.D. Johnson² and J.B. Munson² Dept Neurobiol. and Behav., SUNY-Stony Brook¹, Dept. Neurosci., Univ. Florida².

In previous studies the decline in conduction velocity of axotomized motoneurons in the adult rat has been shown to be largely attenuated by application of the rkB ligand, NT-4/5 (Munson et al., Soc. Neurosci. Abstr., 1995). The present experiments were designed to extend these studies into a different species (the cat) in order to test the generality of the finding and to apply more extensive electrophysiological analysis of the cellular and synaptic changes associated with axotomy (Mendell et al., J. Neurophysiol., 1995). NT-4/5 was applied at a rate of 60µg/day to the cut end of the medial gastrocnemius nerve for 4 weeks in 3 cats. Controls were 2 cats, one treated similarly with saline, the other axotomized for 5 weeks with no treatment. Findings after NT-4/5 include a population of cells (about 15%) whose values of rheobase were higher than any in the axotomized control population and some cells with unusually high axonal conduction velocities. The range of AHP values was less compressed after NT-4/5 in in the control group, which exhibited the compression in AHP range seen normally after axotomy. The amplitude of monosynaptic la EPSPs was relatively unchanged after NT-4/5 although many EPSPs exhibited positive amplitude modulation during high frequency stimulation (32 shocks at 167 Hz), not seen in axotomized controls. Overall, these data point to an effect of NT-4/5 in preventing axotomized cells from fully expressing changes characteristic of axotomy although with the current protocol the effect is relatively limited. Supported by NIH. NT-4/5 courtesy of Genentech, Inc.

Neuroprotection of CNS Neurons by Retrograde Transport of Neurotrophic Factor Genes with Adenoviral Vectors Baumgartner, BJ* and Shine, HD Department of Neurosurgery, Baylor College of Medicine, Houston, Texas 77030 Replication-defective adenoviral vectors were constructed that carried

genes for neurotrophic factors (Adv.RSV-nf) and included genes for BDNF, CNTF, GDNF, and NGF. Cultured cells transduced with Adv.RSV-nf expressed biologically active neurotrophic factors in vitro. In vivo, the Adv.RSV-nf were retrogradely transported to motoneurons of the facial nucleus or spinal motoneurons and expressed the gene products as determined by RT-PCR and immunocytochemical analysis. Several reports have shown that the application of CNTF, BDNF, or GDNF to the transected facial nerve of neonatal rats protects a portion of the facial motoneurons from axotomy-induced death. To test whether the same effects would be produced by retrograde transport and expression of Adv.RSV-nf genes, we injected Adv.RSV-nf into the muscles of the terminal field of the facial nerve of neonatal (1 day-old) rats. Two days later the facial nerve was cut and 7 days after nerve transection the surviving neurons of the facial nuclei were counted and compared to the untreated nuclei on the contralateral side. Treatment with Adv.RSV-GDNF produced a robust survival effect (53.3 \pm 6.5%) and treatment with Adv.RSV-CNTF (18.2 \pm 4.4%) or Adv.RSV-BDNF (16.5 \pm 3.6%) produced slight but statistically significant survival effects. Protection by Adv.RSV-NGF (11.4 ± 4.7%) was not significantly different from vehicle (5.7 \pm 2.1%) or Adv.RSV- $\beta gal~(7.9\pm5.1\%)$ controls.The retrograde transport and expression of neurotrophic factor genes may therefore be a useful strategy to protect neurons of the CNS from trauma. NEUROTROPHIC FACTOR PROTECTION AGAINST

NEUROTROPHIC FACTOR PROTECTION AGAINST OXIDATIVE STRESS D. Hornfeld, N. Déglon, P. Aebischer, and A.D. Zurn*. Gene Therapy Center and Surgical Research Division, University Medical School, 1011 Lausanne, Switzerland.

Normal cellular metabolism produces reactive oxygen species which are neutralized within cells by antioxidant enzymes (glutathione peroxidase, superoxide dismutase, catalase) and other antioxidants. An imbalance between oxidants and antioxidants may be responsible for neuronal degeneration in neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS) and Parkinson's disease (PD). The purpose of the present work was to evaluate whether brain-derived neurotrophic factor (BDNF), glial cell line-derived neurotrophic factor (GDNF), and ciliary neurotrophic factor (CNTF), which have been shown to promote survival and/or differentiation of motoneurons and dopaminergic neurons in vitro and decrease axotomy-induced degeneration of these cells in animal models of ALS and PD, can protect cultured spinal motoneurons and mesencephalic dopaminergic neurons against oxidative stress induced by hydrogen peroxide. We demonstrate that CNTF, but not GDNF, can protect motoneurons against peroxide toxicity. BDNF has only a partial protective effect. In contrast, both BDNF and GDNF protect human neuroblastoma. cells against oxidative stress. We are currently evaluating whether this protective action is mediated via an increase in the expression of antioxidant enzymes.

AUTOCRINE BDNF SECRETION ENHANCES THE SURVIVAL AND SEROTONERGIC DIFFERENTIATION OF GRAFTED RAPHE NEURONAL PRECURSOR CELLS AND LUMBAR TRANSPLANTS ALLEVIATE CHRONIC NEUROPATHIC PAIN.

M.J. Eaton 1.2, D.I. Santiago¹, H.A. Dancausse 1 and S.R. Whittemore 1.3. The Miami Project 1, Departments of Neurological Surgery 2 and Physiology & Biophysics³, University of Miami School of Medicine, Miami, FL 33136.

We have utilized RN46A cells, an immortalized serotonergic neuronal cell line derived from the E13 raphe (J.Neurosci. 14:6744,1994), as a model for transplant of serotonergic cells. RN46A cells require BDNF for increased survival and serotonin (5HT) synthesis in vitro and in vivo (Dev. Biol. 170:169, 1995). RN46A cells were transfected with the gene for rat BDNF, and the autocrine BDNF-secreting cell line 46A-B14, was subcloned. After transplantation into the cerebral cortex and hippocampus, 46A-B14 cells survived longer than 2 the cerebral cortex and hippocampus, 46A-B14 cells survived longer than 2 weeks, differentiated with a complex morphology, and were able to synthesize 5HT. Sciatic nerve constriction (SNC) was then used to induce chronic neuropathic pain in adult rats. Mechanical and thermal allodynia and hyperalgesia were assessed after SNC and SNC followed by transplants of 46A-B14 cells into the subarachnoid space of the lumbar spinal cord. 46A-B14 cells survived up to 6 weeks around the spinal cord after transplantation and immunohistochemically stained for 5HT. Transplants of 46A-B14 cells alleviated mechanical and thermal surveyages; and the SNC mechanical and thermal allodynia, and thermal hyperalgesia induced by the SNC. Transplants of RN46A cells transfected with the vector alone, which did not synthesize 5HT, had no effect on chronic neuropathic pain. Collectively, these results suggest autocrine BDNF secretion upregulates differentiation and the serotonergic phenotype in vivo and 5HT delivered near the dorsal horn after peripheral nerve injury can offer a potential treatment modality for chronic neuropathic pain. THE EFFECTS OF BDNF ON c-FOS AND NOS EXPRESSION IN DORSAL HORN NEURONES OF THE ADULT RAT SPINAL CORD. D.L.H. Bennett*, J.S. French, J.V. Priestley and S.B. McMahon, Dept. Physiol., UMDS, London,

We have investigated the effects of BDNF (which is expressed in primary afferent neurones) on dorsal horn neurones of the spinal cord. To investigate its effects on c-fos expression, saline or BDNF (50 µg, human recombinant, gift of Regeneron) were administered to the spinal cord via intrathecal cannulae and the animals sacrificed after 3 hrs. BDNF produced a significant increase in the number of dorsal horn neurones expressing c-fos (703±97 and 227±48 cells/section for BDNF and saline treatment respectively, p<0.05 unpaired t-test) and this difference was most marked in superficial

Another group of animals received injections of untreated or BDNF coated fluorescent latex microsphere into the dorsal horn (1µl), NOS expression was studied 5 days later using immunohistochemistry. Fluorescent microspheres labelled dorsal horn neurones both rostral and caudal to the injection site BDNF coated bead injections doubled the percentage of labelled cells expressing NOS compared to control bead injections (p<0.05, unpaired t-test). The NOS labelled cells also showed an increase in mean cell size following BDNF treatment.

These findings demonstrate that BDNF may have both rapid and more prolonged effects on gene expression in dorsal horn neurones, which could have an impact on neuronal signalling within the spinal cord. This may be of relevance to conditions such as axotomy and inflammation when there is an increase in BDNF expression in DRG cells. Supported by the MRC of Great

REGULATION OF QUANTAL SECRETION BY NEUROTROPHIC FACTORS AT DEVELOPING MOTONEURONS. W.M. Fu* and J.C. Liou. Department of Pharmacology, College of Medicine, National Taiwan University, Taipei, Taiwan.

Neurotrophic factors derived from postsynaptic muscle cells may play important roles in the development and maintenance of presynaptic neuronal functions. In 3-d old Xenopus nerve-muscle cultures, embryonic spinal neurons that had made natural contact with co-cultured myocytes exhibited spontaneous release of larger packets of ACh quanta than those released by isolated neurons not in contact with any myocyte. However, neurons which made natural contact with fibroblast did not show such an increase in quantal size. Our previous study has shown that activity-dependently released retrograde factor NT-3 from muscle target enhances the maturation and/or maintenance of the presynaptic nerve terminal in the developing Xenopus nerve-muscle co-cultures. We further investigated the effect of other neurotrophic factors. Chronic treatment of native neurons for 2 days with neurotrophin-4, brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF) or glial cell line-derived neurotrophic factor (GDNF) but not basic fibroblast growth factor, insulin-like growth factor-1 increased the average size of quantal ACh packest at newly formed nervemuscle synapse. BDNF and CNTF, which act via different mechanisms showed additive effect on the increase of quantal size. Furthermore, cotreatment of the culture with d-Tc and neurotrophic factor of BDNF, CNTF or GDNF partially reversed the inhibitory effect of d-Tc on the quantal size. These results suggest that there is target specificity for the maintenance of synaptic function and many kinds of neurotrophic factors may participate in the maintenance of normal transmitter packets in developing neurons.

CNTF INDUCES RAPHE NEURONAL PRECURSORS TO SWITCH FROM A SEROTONERGIC TO A CHOLINERGIC PHENOTYPE IN VITRO

S.R.Whittemore' 1-3, M.J.Eaton 1-2, P.Mather', R.M.Lindsay 4, and J.S.Rudge 4. The Miami Project 1, Departments of Neurological Surgery 2 and Physiology & Biophysics', University of Miami School of Medicine, Miami, FL 33136 and Regeneron Pharmaceuticals', Tarrytown,NY 10591

Ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF) specifically reduced the number of serotonergic neurons by 90% in E14 raphe culture without affecting the total number of neurons. This effect was reversible, as the number of 5HT-positive neurons increased after removal of CNTF from the culture medium. In the immortalized serotonergic neuronal cell line derived from E13 raphe (RN46A; J.Neurosci. 14:6744, 1994), which is induced to become serotonergic by brain-derived neurotrophic factor (BDNF) (Dev. Biol. 170:169, 1995), the addition of CNTF suppressed tryptophan hydroxylase (TPH) and 5HT synthesis and increased choline acetyltransferase (ChAT) expression by 6-fold and ChAT activity by 20-fold over 12 days. Removal and replacement of CNTF with BDNF after 4 days resulted in a partial restitution of 5HT expression. Other members of the CNTF-cytokine family that use gp130 and/or LIF receptor β as their signal transducing receptors-LIF, oncostatin M, IL6, and IL11, had similar effects on increasing ChAT activity and reducing 5HT expression in RN46A cells. Analysis of 5HT levels in CNTFRα knockout mice at birth KN40A Cells. Analysis of 5H1 levels in CNTFR α knockout mice at offen showed no difference compared to wild type mice suggesting that the potential to switch phenotype mediated through CNTFR α is a latent property of neuropeithelial precursors in the raphe nucleus. This work was supported, in part, by The Miami Project To Cure Paralysis, General Reinsurance, NS26887 (SRW) and the Spinal Cord Research Foundation of the Paralyzed Veterans of America (MME). America (MJE).

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) INCREASES OPIOID RECEPTOR mRNA EXPRESSION IN THE PAG. J. A. Siuciak*, D. Lewis, R. M. Lindsay, F. G. Williams2, Regeneron Pharmaceuticals, Inc., Tarrytown, NY 10591 and 2 Dept. of Vet. Biol., Univ. of Minn., St. Paul, MN 55108

Previous studies have demonstrated that midbrain infusion of BDNF, a member of the NGF/neurotrophin family, produced analgesia and increased beta-endorphin levels within the brain and spinal cord (Siuciak et al., 1995). The present study investigated the regulation of mu, delta and kappa opioid receptors in the rat brain after chronic BDNF administration. Adult rats were infused with BDNF (12 ug/day) or PBS into the midbrain, near the PAG/dorsal raphe (Siuciak et al., 1994). Image analysis was performed on autoradiograms containing either areas of the ventromedial and ventrolateral PAG adjacent to the infusion site or the striatum. Comparison of the levels of mRNA for opioid receptors in PBS and BDNF-treated rats showed BDNF infusion produced significant increases in delta and kappa opioid receptor mRNA levels in the PAG near the infusion site, with delta and kappa riboprobe hybridization signal increased by 39% and 56%, respectively. BDNF administration did not lead to any statistically significant changes in the administration did not lead to any statistically significant changes in the level of mu opioid receptor mRNA within the PAG. No significant changes in riboprobe hybridization signal were found for either opioid receptor within the striatum. These results suggest that BDNF induces a selective, local upregulation of delta and kappa opioid receptors in the midbrain. Supported by Regeneron Pharm. and NS 28016 (FGW).

CORRELATION OF BDNF EXPRESSION DEFICIT DELAYED GRANULE CELL MIGRATION IN THE CEREBELLUM OF STARGAZER MUTANT MOUSE X. Qiao*, F. Hefti, and B. Knusel Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089.

We have discovered a selective failure of BDNF mRNA expression in the cerebellar granule cells of a spontaneous ataxic mutant mouse, stargazer (stg, chr. 15). To test the effect of BDNF on the cerebellar granule cell during the development, we examined the migration and synaptic formation of the granule cells in the stg mouse. At postnatal day 15 (P15), a clear external layer of granule cells was found in the stg cerebellum in comparison with a few scattered cells in the same region of control mouse. Quantitative cell count (n=3 of each genotype) have shown significantly more external granule cells (+126%, p < 0.01) in the mutant cerebellum than the corresponding control. This external granule cell layer had completely disappeared in P20 stg mouse. Although the migration of granule cells is delayed in the mutants, cerebellar ultrastructure was grossly normal in the adult animal at electron microscopic level. Synapses in the glomeruli and the molecular layer of the granule cells were identified in the stg mouse with no significant difference to the wildtype control mice. The only noticeable changes were that some of the granule cells displayed oval shaped nuclei and were studded with clumps of coarse chromatin, resembling migrating immature granule cells. These results indicate that lack of BDNF expression in granule cells may underlie delayed migration of these neurons, but does not affect gross synaptic formation of their input and output connections.

These studies were supported by research grants from NIA AG09793, AG10480, NINDS NS22933, Sankyo Co., Ltd, and NIH F32 NS09985 (XQ).

NEUROTROPHINS PROTECT AGAINST CYTOSINE ARABINOSIDE-INDUCED APOPTOSIS OF CULTURED NEURONS. P. Leeds, X.-M. Gao*, and D.-M. Chuang. Section on Molecular Neurobiology, Biological Psychiatry Branch, NIMH, NIH, Bethesda,

MD 20892.

The mechanism of neurotrophin inhibition of apoptosis was investigated using immature cultured cerebellar granule cells (CGC) from 8-day-old rats and hippocampal cells from 19-gestation-day fetal rats. Cell death was confirmed by morphological inspection and quantified by MTT was confirmed by morphological inspection and quantified by MTT assays 24 hrs after the induction of apoptosis which was by treatment with cytosine arabinoside (AraC) (500 µM), a pyrimidine metabolite used in the treatment of leukemia. AraC-induced apoptosis was most robust when added to CGC on the day of culture, causing up to 75% cell death. A dose-dependent (50-500 µM) apoptotic induction, up to 50% cell death, was observed when added 24 hrs after plating. Additions made after 48 hrs had no apoptotic effect across the dose range. CGC were also treated with Brain Derived Neurotrophic Factor (BDNF), Neurotrophin-3 (NT-3), or Neurotrophin-4/5 (NT-4/5) 2 hrs after plating, followed 24 hrs later with AraC. BDNF and NT-4/5, but not NT-3, reversed AraC-induced apoptosis at 0.5-1 ng/ml concentrations. Only higher concentrations, 50 ng/ml. of NT-4/5 prevented AraC-induced apoptosis in hippocampal apoptosis at 0.5-1 ng/ml concentrations. Only nigner concentrations, 50 ng/ml, of NT-4/5 prevented AraC-induced apoptosis in hippocampal cultures. Neither the protein kinase C (PKC) inhibitor calphostin C (10-50 ng/ml), nor the tyrosine kinase inhibitor genestein (1-10 μM) prevented neurotrophin protection. Furthermore phorbol myristate acetate (1 nM-1μM), a PKC activator, failed to influence either AraC-induced apoptosis or neurotrophin-mediated protection. These results indicate that neither the PKC nor the tyrosine kinase pathway is implicated in neurotrophin restriction against AraC-induced apoptosis. Supported by NIMH NIH. protection against AraC-induced apoptosis. Supported by NIMH, NIH.

NEUROTROPHIC FACTORS: BIOLOGIC EFFECTS-BDNF AND NT-4 II

EXPRESSION OF THE LOW AFFINITY NEUROTROPHIN RECEPTOR BY SUBEPENDYMAL ZONE PROGENITOR CELLS IN ADULT RAT BRAIN EFFECTS OF NEUROTROPHIN ADMINISTRATION. S.J. Wiegand* N. Cai, P. Ge, T. Zigovat, K.D. Anderson, M.B. Luskint and R.M. Lindsay. Regeneron Pharmaceuticals, Inc. Tarrytown, NY 10591 and

Dept. Anat. and Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA 30322
Cells which express the p75 low affinity neurotrophin receptor are distributed within discrete regions of the subependymal zone (SEZ) of adult rat forebrain, in a pattern which corresponds precisely to that of constituitively proliferating neural progenitor cells as determined by BrdU incorporation. The expression of p75 is bilaterally symmetrical and restricted to the cells of the SEZ; neither ependymal cells nor differentiated neurons and glia in the surrounding parenchyma are p75-positive. Infusion of BDNF or NT-4 into the lateral ventricle results in an increase in the number of p75-positive cells within the ipsilateral SEZ. In addition, numerous p75-immunopositive cells become apparent in the addition, numerous p75-immunopositive cells become apparent in the immediately adjacent neural parenchyma (septum and striatum). These cells are morphologically heterogeneous, but typically much more complex than those within the SEZ proper, having extensively branched processes and the general appearance of mature neurons or glia. In neurotrophin-treated animals, p75-positive cells with differentiated phenotypes are found most frequently in association with the rostral part of the SEZ. Changes in the pattern of p75 immunostaining are evident as early as 5 days following the initiation of neurotrophin treatment, and are maintained for at least 14 days. These effects of BDNF and NT-4 appear to be mediated via TrkB, as infusions of NGF or NT-3 do not produce similar cytological changes in the SEZ. Double-labeling experiments are in progress to determine definitively the phenotypes of p75 and BrdU-positive cells in BDNF-treated animals.

RDNE INCREASES SURVIVAL OF FETAL. MESENCEPHALIC DOPAMINERGIC NEURONS AND ENHANCES THEIR RECOVERY AFTER TREATMENT WITH 6-HYDROXYDOPAMINE M, Cik, A. S. Lesage, M. De Ryck* and J. E. Leysen. Janssen Research Foundation, Turnhoutseweg 33, 2340 Beerse, Belgium

Mesencephalic dopaminergic neurons (MDNs) have been widely used to study the effects of brain-derived neurotrophic factor (BDNF). MDNs are the target of neuronal degeneration in Parkinson's disease. Primary culture of fetal MDNs are used as an experimental model for neuronal degeneration caused by 6-hydroxydopamine (6-OHDA) and the drug-derived toxin 1-methyl-4-phenylpyrdinium (MPP). It has been reported that BDNF attenuate toxicity of both, 6-OHDA and MPP*. It has also been shown that 6-OHDA can not be considered as a selective neurotoxin for catecholaminergic neurons in vitro. Here we show that exposure of rat MDNs in primary culture to BDNF (50 ng/ml) for 6 days increases survival of dopaminergic neurons by 1.5 fold, as measured by [³H]DA uptake. Exposure to 6-OHDA at DIV 6 for 24 h destroyed all types of neurons in a concentration dependent manner (EC₅₀ 48 μM) as revealed by Calcein-AM measurement. A concentration dependent reduction of [3H]DA uptake was also seen (IC₅₀ 27 μM). Pretreatment of MDNs with BDNF for 6 days did not affect 6-OHDA toxicity, nor did it affect the 6-OHDA mediated reduction in [3 H]DA uptake (IC $_{50}$ value of 6-OHDA 28 μ M). In contrast, when at the end of the toxic treatment the medium was changed to the toxin- and BDNF-free medium and the cells were allowed to recover for 3 days, BDNF treated cultures were protected from continuation of cell death and showed better recovery. Under these conditions, [3H]DA uptake was not different from control level. Our results suggest that BDNF increases survival of dopaminergic neurons in culture and stimulates their recovery after exposure to 6-OHDA. This is in agreement with the recent finding that BDNF protection against MPP* toxicity is seen after a recovery period, rather than at the end of the toxic treatment as previously published.

MIDBRAIN DOPAMINE NEURONS REQUIRE GROWTH FACTORS AND ADDITIONAL EXTRACELLULAR SIGNALS FOR OPTIMAL

AND ADDITIONAL EXTRACELLULAR SIGNALS FOR OPTIMAL SURVIVAL. J. Engele* and B. Franke. Dept. Anatomy and Cell Biology, University of Ulm, 89069 Ulm, Germany.

By using growth factor-induced c-fos expression as a marker for efficient signal-transcription coupling, our previous studies have demonstrated that a large number of midbrain dopaminergic neurons represent the primary targets for brain-derived neurotrophic factor (BDNF), glial cell line-derived neurotrophic factor (GDNF), and neurotrophin 3 (NT-3). These studies further revealed that the effects of neurotrophin-3 (NT-3). These studies further revealed that the effects of these growth factors on dopaminergic cell survival are rather marginal and not additive. Based on these findings, we have speculated that optimal dopaminergic cell survival depends on the presence of additional extracellular signals. To test this hypothesis, the survival-promoting effects of BDNF, GDNF, and NT-3 on dopaminergic neurons were assessed in serum-free dissociated cell cultures of the E15 rat mesencephalon in which second messenger levels were manipulated with dibutyryl cAMP (dbcAMP) or NMDA. dbcAMP (100 µM) significantly cannot be supported the contraction of the con potentiated the survival-promoting effects of BDNF (50 ng/ml), GDNF (5 ng/ml), and NT-3 (10 ng/ml) on dopaminergic neurons after 3 and 6 days in vitro. A similar potentiation of the survival-promoting activity of BDNF occured in the presence of NMDA (10 µM). dbcAMP or NMDA alone did not significantly affect the number of surviving dopaminergic neurons. Together these findings suggest that the action of growth factors on midbrain dopaminergic neurons are modulated by other extracellular signals. APOPTOSIS AND DOPAMINERGIC NEUROTROPHIC FACTORS (DNTFs) IN RAT MESENCEPHALIC DOPAMINERGIC NEURONAL CULTURES. T. Takeshima^{1*}, J.W. Commissiong², K.Mishima¹, K. Nakashimal ¹Div. Neurol., Inst. Neurol. Sci., Tottori Univ. Fac. Med., 36-1 Nishimachi Yonago 683, Japan. ²LMB-NINDS-NIH, Bldg. 36/3D02, Bethesda, MD 20892

We have previously reported (J. Neurosci. 14:4769-4779, 1994) that serumdeprivation accelerates neuronal death of E14 mesencephalic dopaminergic neurons in vitro. Mesencephalic dopaminergic neuronal death in serum-deprived cultures was characterized using DNA electrophoresis and terminal deoxynucleotide transferase (TdT) DNA-break labeling techniques. fragmentation (laddering pattern) was detected at 12 and 24 hr in vitro. Using the TdT labeling method (ApopTag, Oncor), DNA breaks were detected in situ. At 8 hours in vitro, 40% of mesencephalic cells were positively stained with ApopTag, while no striatal cell was stained with ApopTag at this stage. We concluded that apoptosis is involved in dopaminergic neuronal death accelerated by serumdeprivation. Apoptosis is observed in cultures from whole forebrain or striatum, however, the apoptotic process in mesencephalic neurons progressed faster than in striatal neurons. Dopaminergic neurotrophic factors (DNTFs), which have been reported to increase neuronal survival, were tested in mesencephalic serum-free cultures, and the number of ApopTag positive cells in cultures were quantified to evaluate the protective effect of trophic factors against neuronal apoptosis. Supplementation with fetal calf serum, brain derived neurotrophic factor (BDNF), platelet derived growth factor (PDGF), and glial cell line-derived neurotrophic factor (GDNF) significantly reduced the number of ApopTag positive cells in mesencephalic cultures at 12 hr. Basic fibroblast growth factor (bFGF) had no protective effect in this culture

INTRAVENTRICULAR ADMINISTRATION OF TRKB IMMUNOADHESIN DELAYS KINDLING DEVELOPMENT IN THE RAT. D. K. Binder¹*, T. E. Ryan², G. D. Yancopoulos² and J. O. McNamara¹. ¹Epilepsy Research Laboratory, Departments of Medicine, Neurology, and Neurobiology, Duke University Medical Center, Durham, NC 27710, and 2Regeneron Pharmaceuticals, Inc., Tarrytown, NY 10591

Kindling is a model of temporal lobe epilepsy in which repeated initially subconvulsive seizures induced by daily electrical stimulation evolve into more intense partial and generalized convulsive motor seizures. Recent studies have shown that neurotrophic factors are upregulated at both mRNA and protein levels following kindling or chemoconvulsant stimulation. For example, both BDNF and trkB mRNAs are increased severalfold following seizure. However, whether this upregulation is functionally related to kindling development is as yet unclear. In this study, we chose to attempt functional blockade of trkB neurotrophin receptor activation throughout kindling development in the rat via chronic ICV administration of trkB immunoadhesin. Rats were implanted with bipolar electrodes in the right amygdala and left hippocampus and an indwelling cannula in the right lateral ventricle that delivered 50 µg/day trkB-IgG (n=4), 50 µg/day control human IgG (n=5) or saline (n=2) via a subcutaneous osmotic minipump (Alza Corp.). Animals were allowed to recover 4 days following surgery and then were stimulated twice daily via the amygdala electrode. While animals receiving saline or 50 μ g/day human IgG ICV showed no difference in number of stimulations to the fully kindled state (8.5 \pm 1.5 vs. 10.4 \pm 0.7 respectively), animals receiving 50 µg/day trkB-IgG ICV required significantly more stimulations to reach the kindled state (20.2 \pm 1.3; p<0.01 vs. controls). These results suggest that trkB receptor activation may be causally linked to kindling epileptogenesis.

INCREASED CALCIUM CHANNEL CURRENT IN HIPPOCAMPAL NEURONS FOLLOWING TREATMENT WITH BRAIN-DERIVED NEUROTROPHIC FACTOR. M.M. Rose*, P.W. Landfield and N.M. Porter. Department of Pharmacology, College of Medicine, University of Kentucky, Lexington, KY 40536.

Recent studies have shown that necrotic cell death in serum-maintained cortical cultures is exacerbated by pretreatment with brain-derived neurotrophic factor (BDNF) (Koh et al., 1995). The toxic effect of BDNF is accompanied by an increase in neuronal 45Ca uptake suggesting that Ca2influx via voltage- or ligand-gated channels may play a role in the toxic effect of BDNF. Whole-cell voltage-gated Ca2+ currents in cultured basal forebrain neurons maintained in serum-free conditions are unaffected by pretreatment with BDNF (Levine et al., 1995). However, we report here that in serum-maintained cultures of embryonic rat hippocampus, pretreatment with BDNF (100 ng/ml) significantly increased single voltagegated L-type Ca2+ channel activity as assessed by cell-attached patch We also subjected primary hippocampal cultures chronically pretreated with BDNF to partial medium replacement which appears to induce a moderate glutamate-dependent insult (Rosenberg et al., 1991). Cell death was significantly greater in BDNF-pretreated cultures (100 ng/ml) following medium replacement. Taken together, these results suggest that a BDNF-mediated increase in Ca²+ channels may in part contribute to recent observations that growth factors can have deleterious effects on neuronal survival depending on the nature of the traumatic insult. AND LONG-TERM REGULATION OF HIPPOCAMPAL SYNAPTIC N.J. Tang* and D.C. Lo. TRANSMISSION BY BDNF. Neurobiology, Box 3209, Duke University Medical Center, Durham, NC 27710.

Recently, we and others have observed rapid enhancement of synaptic transmission following acute exposure to neurotrophins. However, the long-term effects of neurotrophins on synaptic transmission, and how these might relate to their short-term, neuromodulatory effects, remain unknown. In this study, we compared the effects of BDNF on excitatory synaptic transmission following short-term (minutes) and long-term (days) treatment using hippocampal CA1 neurons in "microdot" culture. In these cultures, individual neurons are confined to grow on isolated glial islands and thus form synapses only upon themselves ("autapses")

Acute application of BDNF to autaptic CA1 neurons induced a 2- to 6-fold increase in the frequency of TTX-insensitive, miniature EPSCs (mEPSCs), but had no effect on the distribution of mEPSC amplitudes. This enhancement was rapid, occurring within twenty minutes of BDNF application, and was stable for the duration of recording (>1 hr). Interestingly, action potential-evoked EPSCs were not affected by acute application of BDNF. In contrast, CA1 neurons treated with BDNF for 8-16 days showed an average 2.1-fold increase in the amplitude of AMPA-type, evoked EPSCs, with no substantial change in average frequency or amplitudes of mEPSCs. These findings indicate that the acute, modulatory effects of neurotrophins can be quite different from their long-term, regulatory effects on synaptic transmission.

Neurotrophins were generously provided by Regeneron Pharmaceuticals; this rch was supported by grants from the Alfred P. Sloan Foundation and the NIH (NS32742 and MH11058).

EFFECTS OF IN VIVO BDNF INFUSION ON AMYGDALA KINDLING, SPROUTING, AND HILAR AREA. P. Osehobo¹. B. Adams². M. Sazgar ¹. J. Verdi ². R. Racine². M. Fahnestock¹. ¹Department of Biomedical Sciences and ²Department of Psychology, McMaster University, Hamilton, Ontario, Canada; ³Amgen Institute, Toronto, Ontario, Canada.

Kindling is an animal model of human temporal lobe epilepsy in which epileptogenic reactivity is permanently enhanced by repeated stimulations. This procedure also increases the expression of NGF, BDNF, and BDNF receptor mRNAs in both the hippocampus and cerebral cortex. We have recently shown that intraventricular NGF infusion enhances the development of kindling and increases kindling-induced mossy fiber sprouting in adult rats. In addition, antibodies to NGF retard amygdaloid kindling and reduce kindling-associated mossy fiber sprouting in the stratum oriens of hippocampal area CA3. The physiological role of BDNF in kindling is not as clear as for NGF. BDNF infusion in rats reportedly slows kindling development, whereas transgenic mice heterozygous for a deletion of the BDNF gene also show a marked suppression of kindling. This study attempts to clarify these apparently contradictory roles of BDNF in kindling. Intrahilar infusion of hrBDNF was performed; rats recieving 1 mg/ml (n=9) and 5 mg/ml (n=4) required 16 and 19 stimulations respectively to reach the fully kindled state, compared to control rats (PBS-infused, n=8) that required 12 stimulations. In addition, unlike NGF, BDNF did not protect against kindling-induced decreases in hilar cell density or increases in hilar area measurement. There was also no significant effect on mossy fiber sprouting as measured by Timm stain densitometry.

We conclude that BDNF inhibits kindling but has no effect on kindling-induced mossy fiber sprouting or changes in hilar area. The mechanisms for kindling inhibition in heterozygous BDNF knockouts and for the opposite effects of BDNF and NGF infusions on kindling are not clear. Various means of blocking BDNF activity are currently being explored, and preliminary results will be reported. Supported by grants from the MRC of Canada and the NCE NeuroScience Network.

SEIZURES INDUCE BRAIN-DERIVED NEUROTROPHIC FACTOR SELZURES INDUCE BRAIN-DERIVED NEUROTROPHIC FACTOR IN HIPPOCAMPAL MOSSY FIBERS: POSSIBILITY OF ANTEROGRADE TROPHIC SUPPORT. M. A. Smith*¹, L. X. Zhang¹, and L. A. Mamounas². Biological Psychiatry Branch¹, NIMH/NIH, Bethesda, MD 20892, and Molecular Neurobiology Unit², NIA/NIH, Baltimore, MD 21224

Neurotrophic factors such as brain-derived neurotrophic factor (BDNF) are assumed to provide trophic support via a classic, target-derived, retrograde mechanism of action. However, recent studies strongly suggest that neurotrophic factors can act in an autocrine fashion and perhaps even in an anterograde direction similar to neurotransmitters. and perhaps even in an anterograde direction similar to neurotransmitters. To further explore this hypothesis, we compared the neuroanatomical pattern of BDNF mRNA and protein in response to electroconvulsive seizures (ECS). Using *in situ* hybridization, we found that ECS, given every other day for 2 wk, induced BDNF mRNA markedly and predominantly in the granule neurons of the dentate gyrus. However, immunohistochemistry with a turkey anti-BDNF antibody revealed that ECS increased endogenous BDNF in the mossy fibers, which are composed of axons projecting from the dentate gyrus to the CA3 pyramidal layer of the hippocampus. This suggests that BDNF was transcribed and translated in granule neuron cell bodies but transported in an anterograde direction to CA3 neurons. Interestingly, following ECS, an anterlogiade direction to CA3 interestingly, following EC3, the mossy fiber pathway appeared to be larger and more dense by Timm staining. The exact role of BDNF in the regulation of CA3 hippocampal neurons remains to be determined. However, our results suggest that BDNF support of CA3 pyramidal neurons may be derived in large part

from the dentate gyrus.

BRAIN-DERIVED NEUROTROPHIC FACTOR POTENTIATES DENDRITIC Ca²⁺ TRANSIENTS IN CULTURED HIPPOCAMPAL NEURONS. <u>B. Berninger* & H. Thoenen</u> Dept. Neurochemistry, Max Planck Institute for Psychiatry, D-82152 Martinsried, FRG.

Recently, neurotrophins have been shown to modulate transmission at hippocampal synapses involving both pre- and postsynaptic mechanisms. Using fura-2 fluorescence microscopy we investigated the effect of brain-derived neurotrophic factor (BDNF) on the occurrence of spontaneous Ca2+ transients in dendritic processes of cultured hippocampal neurons. After 3-8 weeks in vitro hippocampal neurons showed spontaneous oscillations in intracellular $Ca^{2+}([Ca^{2+}]_{i})$. These oscillations were blocked by tetrodotoxin $(1 \, \mu M)$ indicating that they originated from endogenous synaptic activity. Within dendritic processes maximal changes in [Ca2+]i were localized to varicosities, i.e. to presumable sites of synaptic contacts, suggesting that they resulted from Ca²⁺ influx during synaptic events. Within one minute after bath application of BDNF (40 ng/ml), both the frequency and amplitude of spontaneous Ca²⁺ transients in dendritic varicosities increased markedly. The potentiation of Ca²⁺ signals in dendritic varicosities may directly reflect the synaptic enhancement induced by BDNF. This work was supported by the Max-Planck-Gesellschaft.

PROTECTIVE EFFECTS OF BRAIN-DERIVED NEUROTROPHIC FACTOR IN TWO MODELS OF EPILEPSY IN THE RAT.

S. Reibel¹, Y. Larmet², B.T. Lê¹, J. Carnahan³, H. Nawa⁴, C. Marescaux¹ and A. Depaulis ¹ INSERM U. 398, Université Louis Pasteur, Strasbourg, France, ²URA 1446 CNRS, Université Louis Pasteur, Strasbourg, France, ³Amgen Center, Thousand Oaks, Los Angeles, USA, Beckman Neurosciences Center, Cold Spring Harbor Laboratory, New York, USA.

Several data have recently suggested the involvement of neurotrophins in the cascade of events occurring during seizure development. In particular, expression of both brain-derived neurotrophic factor (BDNF) and its high affinity receptor TrkB mRNAs increase in the hippocampus and the amygdala after convulsive seizures. The physiological relevance of this increase was investigated by chronic hippocampal perfusion of BDNF in two models of epilepsy in the rat: kindling and pentylenetetrazole-induced seizures.

A seven-day perfusion of BDNF in the dorsal hippocampus, blocked the kindling process in a dose-dependent manner, as evidenced by a significant reduction of seizure scores and afterdischarges. This effect was observed without any electroencephalographic abnormalities nor motor impairments and was independent of any lesional effect. A seven day perfusion of BDNF in the basolateral amygdala, partially blocked the kindling process, as evidenced by a reduction of amygdala afterdischarges but without effects on seizure scores. Moreover, a seven day bilateral pefusion of BDNF in the dorsal hippocampus prevented in a significant number of rats the occurrence of generalized tonic-clonic seizures induced by an injection of PTZ (50 mg/kg, ip). These results provide in vivo evidence for a protective role of BDNF in the control mechanisms of epilepsy and epileptogenesis in adult brain.

RECOMBINANT BONF RESCUES DEFICITS IN HIPPOCAMPAL LTP AND BASAL SYNAPTIC TRANSMISSION IN BDNF KNOCKOUT MICE. S.L. Patterson*, T. Abel, T.A.S. Deuel, and K.C. Martin. HHMI, Ctr. Neurobio & Behav., Columbia Univ., NY, NY 10032.

The neurotrophin brain derived neurotrophic factor (BDNF) is expressed at high

levels in hippocampal neurons and its expression is modulated by neural activity. The production of mice with targeted disruption ("knockout") of specific genes allows one to study the roles of molecules like BDNF in synaptic plasticity with more molecular specificity than is possible using traditional pharmacological approaches. However, the disrupted gene product is absent in all tissues, throughout the life of the animal; this absence may have developmental consequences that complicate the interpretation of deficits in the adult. approach to overcoming this limitation is to perform rescue experiments to acutely restore the missing gene product. We have found that treatment of hippocampal slices from BDNF knockout mice with recombinant BDNF significantly improves deficits in basal synaptic transmission and completely reverses deficits in long-term potentiation (LTP) at the Schaffer collateral-CA1 synapse. The physiological rescue of LTP takes time, with full recovery after 5 hrs of treatment. Results obtained using immunocytochemistry suggest that a significant portion of the time required for the rescue of LTP represents the time required for BDNF penetration into the slice. Because the rescue of LTP was complete and much more rapid than the partial rescue of basal synaptic transmission (which takes 8-12 hrs), it is unlikely that the deficit in LTP was simply a reflection of impared basal synaptic transmission. Instead, our results suggest an acute requirement for BDNF in some forms of LTP above and beyond any developmental effect this neurotrophin may

have on establishing the number and strength of synapses in the hippocampus.

CNS MONOAMINES AND METABOLITES IN HETERO- AND HOMOZY-GOUS BDNF NULL-MUTATED MICE. K. Trok*, E. Lindqvist, P. Ernfors8, L. Olson. Dept. of Neuroscience and 8Dept. of Medical Biochemistry and Biophysics, Karolinska Institute, S-171 77 Stockholm, Sweden

BDNF mRNA is widely expressed by CNS neurons during development. In the adult, levels are generally lower, but expression is rapidly upregulated in response to different forms of neuronal stress. While disturbances in the peripheral nervous system of BNDF-deficient null-mutated mice have been characterized, less is known about the potential CNS effects. Here we have used HPLC with electro-chemical detection to measure levels of monoamines and metabolites in the brains of two-week-old BDNF +/- and BDNF -/- animals and in adult BDNF +/- animals. We find a spectrum of disturbances of regional levels of monoamines and metabolites with the most severe changes seen in 15-day-old -/- animals, moderate changes in 15-day-old +/- animals, and only minor changes in adult +/- animals. 5-HT was increased in the 15-day -/- caudate, while 5-HIAA was strongly increased in the olfactory bulb, cerebral cortex, olfactory tubercle, caudate, substantia nigra and accumbens of 15-day -/- mice. 5-HIAA was also increased in the 15day +/- cortex. NA was markedly increased in the 15-day -/- olfactory tubercle and moderately increased in the caudate. DA was markedly increased in cortex cerebri of both 15-day +/- and -/- mice. DOPAC was markedly decreased in the 15-day -/- accumbens, while we found no significant changes of HVA levels in the nigra or caudate. Taken together, the results demonstrate significant regional changes of both monoamine levels and metabolite levels of a magnitude that should have functional consequences

BDNF PROTECTS THE NEONATAL RAT BRAIN FROM HYOPXIC-ISCHEMIC INSULTS. Y. Cheng*. A. Shah, D-H. Xia, J. Gidday and D. M. Holtzman. Dept. of Neurology, Neurosurgery, Mol. Biol. & Pharmacology and CSNSI. Washington Univ. Sch. of Med., St. Louis, MO 63110. Neurotrophic factors (NTs) such as NGF, BDNF and NT-3 have been shown to

Neurotrophic leadors (NTS) such as NGF, BDNF and NT-5 have been shown to protect certain neurons from transient ischemia and excitotoxicity in some animal models. NTS initiate their signaling cascades by activating their respective receptors. Although only a small number of CNS neurons express the NGF receptor, trkA, we have recently demonstrated that intracerebroventricular NGF receptor, trkA, we have recently demonstrated that intracerebroventricular (ICV) injection of NGF significantly reduces hypoxic-ischemic (H-I) injury in the striatum, hippocampus and cerebral cortex of neonatal rats. In contrast to trkA receptors, the receptor for BDNF, trkB, is widely expressed in the developing brain. Thus, we asked whether BDNF is as or even more protective than NGF against H-I insult in neonatal brain. To approach this question, we first asked whether the exogenous NTs would activate trk receptors following ICV injection. NGF, BDNF and NT-3 were injected into postnatal day (PD) 7 rats, and trk receptor activation was detected by assaying trk phosphorylation 30 minutes after injections. A dose-dependent increase of trk phosphorylation was induced by NGF, BDNF and NT-3 (0-30 µg, peak by 10 µg) in the ispilateral as well as contralateral striatum, hippocampus and cortex. The magnitude of the response was BDNF>NT-3>>NGF. Interestingly, intrahippocampal injection of BDNF failed to induce significant level of trk phosphorylation in PD21 and adult rat hippocampus. Given the widespread expression of the trkB receptor in most CNS neurons and the strong trk phosphorylation response to BDNF in the adult rat hippocampus. Given the widespread expression of the trkB receptor in most CNS neurons and the strong trk phosphorylation response to BDNF in the PD7 brain, we have determined whether BDNF would be protective against H-1 injury in the neonatal brain. Using the modified Levine procedure, we found that ICV injections of BDNF (10 µg) either before or after H-1 treatment significantly protected against H-1 brain injury at PD7 in all brain regions examined. These findings along with the results from the phosphorylation studies suggest that a direct effect of BDNF on most neurons is resulting in significant neuroprotection. (funding: NIH NS32553)

PROGRAMMED CELL DEATH IN THE DEVELOPING RAT STRIATUM AND ATTENUATION BY BDNF BUT NOT NT-3 Thomas J. Mahalik^{1*} and C. Anthony Altar². ¹Dept. of Cellular and Structural Biology, Univ. of Colorado Health Sciences Center. 80262. Regeneron Pharmaceuticals, Tarry Denver, Colorado,

In the striatum programmed cell death (PCD) plays an important role during the development of the mammalian nervous system where up to 25-30% of the generated neurons die during development. Much of this death may be due to the failure of neurons to compete successfully for limiting amounts of trarget derived neurotrophic factors. In the present study, an in situ method for labeling fragmented DNA (Gavrieli et al., 1992) was used to examine PCD in the striatum on postnatal days 0,4,6,8 and 10 in detail. groups of pups were given intraventricular injections of BDNF and NT-3 during the first postanatal week to determine whether these factors could rescue striatal cells. From birth (P0) to postnatal day 6 (P6) there was a 4-fold increase in the density of apoptotic cells in the striatum. After its peak at day 6, there was a 50-fold decrease in PCD by P10. Multiple injections of BDNF, but not NT-3, attenuated striatal cell death at P6. These results indicate that there is a sharp peak in cell death on P6, and this may be the

time when target derived growth factors become limiting.

In a number of in vitro systems, the activation of 1 rk tyrosine kinase receptors by the neurotrophins has been shown to mediate the survival and neuritic outgrowth of cultured neurons. Much less is known about the physiologic role of Trk receptor activation in in vivo neuronal systems. In rat cortex, brain-derived neurotrophic factor (BDNF) stimulates the sprouting of both intact (uninjured) and chemically lesioned serotonergic (5-HT) axons (Mamounas et al., 1905). The present in vivo study examined whether doses of BDNF which stimulate serotonergic axon sprouting can also induce the activity of the TrkB/BDNF receptor as assessed by receptor tyrosine autophosphorylation. To evaluate the effects of BDNF on the 5-HT innervation, BDNF (0.1-12 µg/day) was continuously infused into the cortex of p-chloroamphetamine lesioned rats for two weeks. Serotonergic axon sprouting was first observed after infusion of 400 ng/day of BDNF with a maximal sprouting response found at 4 µg/day of BDNF. The same doses of BDNF were also infused in cortex to assay for levels of tyrosine phosphorylated TrkB at several time points after the start of the BDNF infusion. With continuous infusion of BDNF for 24 hr, TrkB tyrosine phosphorylation was detected at doses of BDNF. as low as 400 ng/24 hr and reached maximal levels at 4 µg/24 hr of BDNF. Thus, the dose-response profiles for BDNF in stimulating 5-HT axon sprouting and in activating TrkB receptor activity mediating the in vivo sprouting response of serotonergic axons. the neurotrophins has been shown to mediate the survival and neurite outgrowth of receptor activity mediating the *in vivo* sprouting response of serotonergic axons. Further studies are currently being conducted to examine the role of other components of TrkB signal transduction pathways in the sprouting of 5-HT axons. Research sponsored by the National Cancer Institute, DHHS, under contract with ABL (WEL, DRK), and a National Research Council-NIA/NIH award (LAM).

BDNF STIMULATED SPROUTING OF SEROTONERGIC AXONS

BDNF STIMULATED SPROUTING OF SEROTONERGIC AXONS IS IMPAIRED IN THE AGED RAT BRAIN. L.A. Mamounas*, W.E. Lyons, M.E. Blue and C.A. Altar. Molecular Neurobiology Unit, NIANIH, Baltimore, MD 21224; Molecular Ontogenesis, ABL-Basic Research Program, NCI-FCRDC, Frederick, MD; Kennedy-Krieger Research Institute, Baltimore, MD; and Regeneron Pharmaceuticals, Tarrytown, NY. In normal aging, there is a substantial loss of the serotonergic (5-HT) axon density in rat cortex, concomitant with the emergence of many degenerating, structurally abnormal 5-HT axons. Brain-derived neurotrophic factor (BDNF) stimulates the sprouting of both intact (uninjured) and chemically lesioned serotonergic axons in the young adult rat cortex (Mamounas et al., 1995, J. Neurosci., 15:7929-7939). The present study evaluated whether BDNF could also promote the sprouting of 5-HT axons in the serotonin-compromised aged rat brain. In young adult animals (2-3 months of age), continuous intracortical infusions of BDNF (1-12 µg/day for 2-3 weeks via an osmotic minipump) caused a robust animals (2-3 months of age), continuous intracortical infusions of BDNF (1-12 µg/day for 2-3 weeks via an osmotic minipump) caused a robust sprouting of both intact and p-chloroamphetamine (PCA; 10 mg/kg, subcutaneous) lesioned 5-HT axons around the BDNF infusion cannula. In contrast, infusions of BDNF (4, 12 or 36 µg/day for 3 weeks) in the cortex of aged rats (21-23 months of age) caused a minimal increase in 5-HT axon density in a few animals, but, in the majority of animals, failed to stimulate any serotonergic axon sprouting. These findings suggest an impaired response to BDNF by serotonergic neurons in the aged brain. Our current tudits are discorded to substitute reports echanges to simple traceduction.

response to BDNF by schollength cutoffs if the aged train. Our cuther studies are directed at evaluating receptor changes or signal transduction mechanisms in response to BDNF in the young versus aged brain.

A MODEL OF OCULAR DOMINANCE COLUMN DEVELOPMENT BY COMPETITION FOR A TROPHIC FACTOR. A.E. Harris^{1,2,3}. G.B. Ermentrout^{2,4}, and S. L. Small^{1,2,3,*}, Department of ¹Neurology. ²Neural Processes in Cognition Program, ³Intelligent Systems Program, and ⁴Department of Mathematics and Statistics: University of Pittsburgh, Pittsburgh, PA 15261.

Several lines of experimental evidence have suggested that the segregation of lateral geniculate nucleus (LGN) afferent axons to form ocular dominance (OD) columns occurs by an activity dependent competition for a post-synaptic trophic factor. Recent evidence has shown that application of excess amounts of certain neurotrophic factors, such as brain-derived neurotrophic factor (BDNF) and NT-4/5, prevents OD column development in a local area. One possible interpretation of these results is that excess trophic factor eliminates the competition between the incoming afferents, permitting connections from both eyes to innervate the cortical cell and thereby preventing OD column development in that area.

We present a computational model with three main features that accounts for

these findings: 1) activity dependent changes in connection strength via long-term potentiation (LTP) and long-term depression (LTD), 2) positive feedback between the rate at which individual axons take up trophic factor and the rate at which connection strengths increase due to LTP, and 3) stabilization of this positive feedback by competition for a limiting supply of trophic factor. Center-surround lateral connectivity in the cortex is sufficient for self-organization of developing cells into OD columns. All terms in our equations are supported by specific neurobiological evidence. OD columns form by spontaneous symmetry-breaking with positive inter-eye correlation and without ad-hoc weight normalization mechanisms. Application of excess trophic factor prevents OD column development in a local area. Finally, several experimentally testable predictions arise from the model.

BRAIN DERIVED NEUROTROPHIC FACTOR INDUCES A TRANSIENT CALCIUM INCREASE IN CORTICAL NEURONS. B. Yang, R. Remington, L. Kojic, M. Cynader*, Q. Gu. Dept. of Ophthalmology, University of British

Columbia, 2550 Willow St., Vancouver, BC, Canada V52, 3N9.

Brain derived neurotrophic factor (BDNF) is now well established as crucial to the survival of several neuronal populations. Recently, BDNF has also been implicated in synaptic plasticity. In this study, we have examined the acute effects implicated in synaptic plasticity. In this study, we have examined the dealer of BDNF on intracellular calcium concentrations in cultured cortical neurons derived from embryonic rats. The calcium sensitive dye fluo-3 was employed in conjunction with a laser based confocal microscope to image calcium concentrations. Acute intracellular calcium increases induced by BDNF were conserved. The response was found to be largely dependent on interneuronal interactions, because the presence of TTX in the medium greatly reduced the number of cells responding to BDNF. Nevertheless, in the presence of TTX, a small percentage of cells responding to BDNF was consistently observed. suggesting that BDNF can induce calcium increase through more than a single mechanism. When calcium was removed from the perfusion medium, the intracellular calcium increase was no longer observed in either the absence or presence of TTX, suggesting calcium entered from the extracellular space. To further assess the mechanisms responsible for these acute responses to BDNF, we examined the effects of blocking NMDA receptors. APV was found to be able to block the calcium response in most neurons, while the voltage-dependent calcium channel blocker nifedipine could not block the BDNF induced calcium increase. However, when TTX was included in the medium, the APV blockade effect was less obvious than in the TTX-free situation. In addition, when magnesium was less do tous than in the TTA-containing perfusion medium, no significant change in calcium response to BDNF was noted. These data suggest that BDNF can induce acute increases of intracellular calcium in cortical neurons, and that the mechanism may involve glutamergic receptors of both NMDA and non-NMDA classes. DIFFERENTIAL EFFECTS OF NEUROTROPHINS ON THE FUNCTIONAL ORGANIZATION OF THE ADULT BARREL CORTEX IN VIVO. N. Prakash*, Cohen-Cory¹, & R. D. Frostig. Department of Psychobiology, University of California, Irvine, CA 92717; ¹Mental Retardation Research Center, University of California Los Angeles, School of Medicine, Los Angeles, CA 90024-1737.

Neurotrophins and their receptors are expressed during development and have been implicated in several aspects of developmental plasticity. They are also expressed in the adult cortex, making them good candidate molecules to play additional roles in aspects of adult cortical plasticity. Using quantified intrinsic signal imaging we examined the effects of topical application of different neurotrophins on the functional representation of a single whisker. As we have reported in the past, topical application of BDNF resulted in a rapid (minutes) and long-lasting (hours) decrease in both the size of the functional representation and the amplitude of the activity-dependent intrinsic signal evoked by whisker stimulation (Frostig, et al., Soc. Neurosci, Abstracts, 1995). In contrast, topical application of NGF resulted in a rapid but transient increase in both the size of the functional representation and the amplitude of the activity-dependent intrinsic signal (Prakash, et al., Nature, in press, 1996). We are now examining the effects of NT3 and NT4/5 in the same system. We found that topical application of NT4/5 did not significantly change either the size of the whisker representation or the amplitude of the activity-dependent intrinsic signal. These findings suggest that although BDNF and NT4/5 share the same highaffinity receptor, they differ in the mechanisms by which they exert their modulatory effects. The mechanisms underlying these differential effects, and the effects of NT3 application are being investigated.

Supported by the Markey-UCI Program in Human Neurobiology, NSF IBN-9507936, NSF IBN-9405146, and the UCI Medical Scientist Training Program. We thank Genentech, Inc. for the generous gifts of NT3 and NT4/5.

NITRIC OXIDE MEDIATES POTENTIATION OF NEUROTOXICITY BY NEUROTROPHINS

A. Samdani, C. Newcampi, A. Resinki, F. Facchinetti, V. L. Dawson, T.M. Dawson, Dawson, Depts. Of Neurol., Phys., and Neurosc., Johns Hopkins Sch. Of Med., Baltimore, MD 21287.

Neurotrophins participate in multiple developmental processes including neuronal survival, axonal growth, and reduction of neuronal cell death following ischemia. Recently in primary neuronal/glial cultures it has been shown that 24 hour pre-treatment with neurotrophins results in potentiation of shown that 24 hour pre-treatment with neurotrophins results in potentiation of neuronal cell death induced by oxygen-glucose deprivation or NMDA exposure. In this study using primary cortical cultures, a role for nitric oxide (NO) in neurotrophin mediated neurotoxicity is established. Rat and mouse cortical neurons from embryonic day 15 were cultured either on a glial feeder layer or polyornithine plates. Cultures were treated on day in vitro 13 with BDNF (100 ng/ml) and experiments conducted day in vitro 14. In pure neuronal cultures BDNF attenuates NMDA mediated cell death which is primarily a nitric oxide (NO) mediated process. In neuronal/glial cultures BDNE attenuates console district social culture studies (NO) or measured. BDNF markedly induces neuronal nitric oxide synthase (nNOS) as measured by NADPH diaphorase staining and western blot analysis. NT-3, NT-4/5, GDNF, but not NGF, also induce nNOS expression. BDNF potentiates NMDA neurotoxicity in neuronal/glial cultures and this cell death is reversed by the NOS inhibitor L-NAME. Confirming that NO mediates the increased neuronal death associated with neurotrophins, cultures from transgenic neuronal NO synthase (NOS) null (nNOS-) mice exhibit no potentiation of NMDA neurotoxicity after BDNF treatment. These data support the role of NO in the increased neuronal death caused by neurotrophins in primary neuronal/stial_culture

BDNF (BRAIN-DERIVED NEUROTROPHIC FACTOR) REDUCES RETINAL CELL DAMAGE CAUSED BY CHEMICALLY INDUCED EX VIVO HYPOXIA AND HYPOGLYCEMIA IN RATS.

HYPOGLYCEMIA IN RATS.

Kazuhito Ikeda, Tohru Tatsuno*, Chikao Nakayama and Hiroshi Noguchi.

Sumitomo Pharmaceuticals Research Center, 1-98, Kasugadenaka 3-chome, Konohana-ku, Osaka 554, Japan.

Retinal ganglion cells and inner nuclear cells (INL) have been shown to express high affinity receptors for BDNF, Trk B, and BDNF has been reported to protect these cells from either ischemic or traumatic damage. In this study, we examined whether BDNF can reduce hypoxic and hypoglycemic damage of INL. Acute necrotic cell death of INL was observed after incubation of isolated eyeballs of rats (Wistar, male, 8 weeks) with 5 mM potassium cyanide (KCN) for 30 min in Krebs-Ringer solution. BDNF (0.1, 1,and 10 µg), injected intravitreally two days before KCN-exposure, spared the inner nuclear cells from cell death in a dose-dependent manner. The number of surviving cells was 283 ± 9, 193 ± 5, and 252 ± 8 (mean ± S.E.M. cells/880 µm) in control, KCN-exposed, and BDNF(10 µg) pretreated KCN-exposed eyeballs, respectively. The glutamate (Giu) level in the vitreous body was elevated by KCN exposure. Glu antagonist treatment or the removal of external Ca 2+ partially prevented KCN-induced cell death. These results suggested that the Glu receptoractivation and Ca 2+-influx were involved in the mechanism of cell activation and Ca2+-influx were involved in the mechanism of cell death. BDNF pretreatment increased calretinin positive cells (200%) in INL, and reduced the elevation of Glu by KCN-exposure (62%). These data demonstrated that BDNF protected on INL against chemically induced hypoxia and hypoglycemia via up-regulation of calretinin and / or reduction of Glu content in the retina.

ABERRANT MYELINATION IN THE CNS OF BDNF -/- MICE. P. Carroll'W, A. Cellerino#, G. Kreutzberg, H. Thoenen and Y.-A. Barde. Max-Planck Inst. for Psychiatry, 82152 Martinsried, Germany. Y, INSERM U. 382, IBDM, Case 907 Luminy, 13288 Marseille 09, France. # Dept. Neuroophthalmol., Uni. Eye Clinic, 72076 Tuebingen, Germany.

The neurotrophins (NGF, BDNF, NT-3, NT-4/5) have been well-characterised with respect to their effects on the survival and differentiation of PNS neurons and neuronal precursors. However, the expression patterns of neurotrophins in the CNS, their effects on processes which involve synaptic plasticity and the apparent absence of morphological defects or cell loss in the CNS of null mutant mice suggests that they may play other roles in this tissue. We examined a defined population of CNS neurons (retinal ganglion cells, RGCs) in BDNF mutant mice. BDNF is a survival factor for RGCs in vitro and BDNF can rescue such cells after axotomy. Axon counting in the optic nerve at P13 and P21 shows that BDNF-/- mice have no loss of RGCs compared with +/+ littermates. However, the axons in the optic nerve of mutants are reduced in diameter and the proportion of myelinated axons is reduced by 40 %. This effect was CNS-specific in that the same parameters were unchanged in the PNS of mutant mice. Hypomyelination was confirmed in other CNS structures by Northern analysis using probes for the myelin proteins proteolipid protein (PLP) and myelin basic protein (MBP). PLP and MBP mRNA levels were dramatically reduced in the hippocampus and cortex, but hardly at all in the cerebellum, of BDNF -/- mice. Markers for other CNS cell-types; NF-L for neurons and GFAP for astrocytes, were not altered in the mutant mice. Whether these effects are due to direct or indirect effects of BDNF on oligodendrocytes remains to be established. Funded by the Max-Planck Society.

TREATMENT WITH BONF DOES NOT PREVENT NORMAL CHICK RETINAL GANGLION CELL DEATH IN OVO K. Drum*, M.E. Forbes, S.W. Wang and JE Johnson Dept. of Neurobiology and Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, N.C. 27157
Like many other neuronal populations, retinal ganglion cells (rgc) appear to

depend upon target-derived factors for survival during development. Results from studies by several investigators have demonstrated that brain-derived neurotrophic factor (BDNF) can substitute for retinal targets by directly supporting the survival of isolated rat or chick rgc in vitro. Most (70%) of these cells are BDNF dependent when isolated during target innervation. We have shown than postmitotic chick rgc express BDNF receptor, trkB, throughout development (E6-E21). BDNF is expressed in both the target optic tectum and the retina. Tectal production appears to increase with retinal ganglion cell innervation during normal cell death and then subsequently decrease.

BDNF was, therefore, applied to chick embryos to determine if elevated levels of exogenous factor can prevent physiological cell death during development in ovo. BDNF (1-10µg/day, Amgen) was applied systemically to the chorio-allantoic membrane prior to and during the cell death period (E6-E16). This treatment has been shown to prevent normal cell death in other CNS neurons (ION) during a similar time period. No significant differences were observed in either the rate of cell death (density of pyknotic nuclei) or the total number of rgc with this BDNF treatment. We conclude that the majority of chick rgc either enjoy access to excess endogenous factor or instead do not normally depend upon limited amounts of BDNF for survival. These results are in sharp contrast to rgc axotomy or target-deprivation experiments where exogenous BDNF and/or NT-4 have marked effects on survival. BDNF may normally be expressed to regulate other developmental events in the chick visual system (ie. differentiation and connectivity). Sponsored by 5R01 EY11127 (JJ)

BDNF PROMOTES SURVIVAL OF CULTURED RETINAL BIPOLAR CELLS VIA A MULTI-RECEPTOR PATHWAY. O. Berkovich, E. Wexler and S. Nawy*. Depts of Ophthalmology & Neuroscience, Albert Einstein College of Med., Bronx NY 10461.

Retinas from P10 rats were dissociated, plated onto coverslips coated with poly-d-lysine and cultured in media containing 5% FCS and supplemented with mito+ serum extender. Bipolar cells were identified by selective labeling with an antibody to PKC, by their morphology and electrophysiological properties. BDNF (100 ng/ml) increased the number of PKC-positive cells by nearly 4-fold after 1 week in culture. Since rodent retinas are fully differentiated at P10, with few if any uncommitted progenitor cells remaining, we believe that the increase in the number of bipolar cells in the presence of BDNF is due to an increase in survival rather than further proliferation or differentiation of uncommitted cells.

The ability of BDNF to promote survival of bipolar cells was reduced in the presence of NGF. Furthermore, incubation of cultures with BDNF and anti-rex, an antisera which blocks function of the low affinity neurotrophin receptor (p75), reduced survival of bipolar cells to control levels. This block was dose-dependent with 50% block at approximately 300 ng/ml, and complete block at 36 μ g/ml of the antisera. An antisera that specifically blocks function of the trkA receptor had no effect. Bipolar cell survival was not increased by p75 receptor activation in the absence of trkB activation, since ligands that bind p75 but not the trkB receptor (NT-3 and NGF) did not augment survival. Our data suggest that BDNF promotes survival of bipolar cells through coordinated activation of both the trkB and p75 receptors, and that activation of either receptor type alone is insufficient. NEUROTROPHINS ENHANCE NEURITE OUTGROWTH FROM ADULT RAT RETINA IN VITRO. M. Takano*, Y. Iijima, M. Sato, H. Horie, T. Takenaka, S. Ohno, Departments of Ophthalmology and Physiology, Yokohama City Univ. Sch. of Med., Yokohama 236, JAPAN.

Recent studies have clarified that neurotrophins promote axonal regeneration from adult rat retina in vitro. In their culture systems, retina was dissected from an animal one week after transection of the optic nerve, and then cultured, because the pre-treatment activates neurite outgrowth from adult retinal explants. In the present study, we employed retinal explants from adult rat without the pre-treatment. The dissected retina was cultured in a collagen gel with a serum free medium, and the effects of neurotrophins on neurite regeneration were examined. Neurites stared to appear at day 3 in the culture either with or without neurotrophins. The relative increase of neurite numbers with neurotrophins were 78% (NGF), 59% (BDNF), 12% (NT-3) and 105% (NT-4) compared to the culture without neurotrophin at day 3. At day 9, these became 15, 88, 31 and 101%, respectively. BDNF and NT-4 kept high levels of the increase during the culture, but the enhancement by NGF decreased with culture days. In conclusion, adult rat retina exhibits a capability of neurite regeneration without pretreatment in vitro. BDNF and NT-4 could enhance this ability continuously, but NGF showed the enhancement only initial period of

PROTECTIVE EFFECTS OF NEUROTROPHINS FROM APOPTOSIS OF MERKEL CELLS IN MONOLAYER CULTURE. Jun Fukuda*, Shingo Tsukada and Taku Iwamoto. Laboratory of Molecular and Cellular Physiology, Department of Physiology, National Defense Medical School, Tokorozawa, Saitama 359, Japan.

Merkel Cells are sensory cells in the skin that transmit signal of pressure to the primary sensory nerve fibers. Culture of these cells has not been successful. We report here that an almost pure culture of Merkel cells was achieved in a serum-free medium by dissociating them from whiskers of newborn rats. We also report that these Merkel cells underwent apoptosis and that this apoptosis was inhibited by neurotrophins, actinomycin D or sera added to the medium. Merkel cells were isolated from cores of follicles of whiskers dissected from newborn rats by pippeting, and were then grown on coverglass coated with poly-L-lysine. Merkel cells were identified by uptake of quinacrine with poly-L-lysine. Merkel cells were identified by uplace of quinacrine that emits fluorescence by UV light. Quinacrine-fluorescence-positive Merkel cells occupied more than 85 % of the cells that were platted in a dish at the start of culture. During incubation in the serum-free medium, population of Merkel cells was decreased in time. Staining of nuclei with TUNEL method represented that Merkel cells underwent apoptosis during culture. Addition of actinomycin D or sera to the culture reduced the population of Merkel cells that were stained with TUNEL method. NT-3 reduced number of TUNEL-stained Merkel cells, while NGF, BDNF, CNTF, bFGF or EGF did not. NT-4 appeared to have a small protective effect against apoptosis of Merkel cells. Altogether, it is likely that Merkel cells that transmit sensory signals to the nerve fibers are also regulated by them by means of releasing neurotrophins.

FUNCTION OF NEUROTROPHINS IN SUBPOPULATIONS OF DEVELOPING DRG NEURONS. D. J. Liebl*, L. Klesse, S. M. Colvin and L.F. Parada. Center for Developmental Biology, UTSW Med. School, Dallas,

LEF. Parada. Center for Developmental Biology, UTSW Med. School, Danas, TX 75235

Analysis of neurotrophin gene-targeted knockout (KO) mice deficient in NGF, BDNF and NT-3 has indicated losses in the number of dorsal root ganglia (DRG) neurons. Experiments were conducted to examine neurotrophic dependencies in DRG neurons during embryonic development by employing individual neurotrophin KO mice and mice deficient in two neurotrophins (i. e. BDNF and NT-3, BDNF and NT-5, & NT-3 and NT-5). Our cell count studies indicate that DRG neurons acquire neurotrophin dependence for BDNF and NT-3 at about E-11.5. Trk (A, B & C) expression studies, primary culture assays, and cell losses in neurotrophins(s) KO mice are consistent with the model that the DRG contains subpopulations of neurons that are dependent on either individual or multiple neurotrophins. In addition our studies support and elaborate previous observations (Tesserollo et al., 1994) which indicate that initial neurotrophic dependencies occur prior to the period of programmed cell death as originally proposed in the neurotrophic theory.

NT-3 binds and activates the high affinity receptor. TrkC, which mediates neuronal survival. However, NT-3 can also bind and activate TrkA in cultured PC-12 cells, and, whether this occurs in vivo remains unclear. We observe losses of TrkA expressing neurons in NT-3 KO mice, suggesting that in some cases NT-3 may support survival of developing DRG neurons via TrkA receptor. Local actions of neurotrophin-3 prevent the death of proliferating sensory neuron precursor cells

W. M. ElShamy and P. Ernfors* Dept. of Medical Biochemistry and Biophysics, Laboratory of Molecular Neurobiology, Doktorsringen 12A, Karolinska Institute, 171 77 Stockholm, Sweden.

The role of neurotrophin-3 (NT3) in early development of the dorsal root ganglion was investigated. Excessive cell death in the dorsal root ganglion of mice that carry a deleted NT3 gene (NT3^{-/-} mice) preceded the period of programmed cell death, detected by the TUNEL method, and caused a reduction in the number of proliferating precursor cells without altering the proportion of proliferating cells to total number of neurons, indicating that NT3 prevents the cell death of proliferating sensory precursor cells. Furthermore, the majority of proliferating cells detected by bromodeoxyuridine incorporation also stained with the TUNEL method. NT3 mRNA was expressed locally in the embryonic, but not the postnatal dorsal root ganglion. In contrast to neurons with an intact NT3 gene, most cultured early embryonic NT3^{-/-} neurons as well as wild-type neurons when cultured with NT3 neutralising antibodies died in the absence of exogenously added NT3. Thus our results suggest that NT-3 acts locally to prevent the death of proliferating sensory precursor cells during neurogenesis. These findings raise the possibility that NT3 can inflict constraints on the number of proliferating precursor cells and thereby affect the number of neurons generated during development of the peripheral nervous system. INCREASED NUMBERS OF MYENTERIC NEURONS ARISE IN TRANSGENIC MICE THAT OVEREXPRESS NEUROTROPHIN-3 (NT-3) DIRECTED TO THE ENTERIC NERVOUS SYSTEM (ENS) BY THE DOPAMINE β-HYDROXYLASE PROMOTER. T. Pham¹,

BY THE DOPAMINE P-HYDROXYLASE PROMOTER. 1. Phami.
P. R. Wade¹, A. Chalazonitis* S.L. Skirboll², M. Bothwell², & M.D. Gershon¹. 1. Dept. of Anat. & Cell Biol., Columbia Univ. New York, NY.10032. 2. Dept. Physiol. Biophys., Univ. Washington, Seattle, WA NT-3 promotes the development of enteric neurons in vitro. An ENS is present, however, in mice lacking NT-3. The current study was thus carried out to determine whether NT-3 affects enteric neuronal development in situ. Neural crest-derived precursors of a subset of enteric neurons are translatily establishering of the control of neuronal development *in situ*. Neural crest-derived precursors of a subset of enteric neurons are transiently catecholaminergic (TC). These cells express DBH; the DBH promoter thus directs the expression of genes to the ENS. Transgenic DBH-NT-3 mice overexpress NT-3 in the gut, but survive and gain weight normally. Laminar preparations of myenteric and submucosal plexuses were dissected from the small intestine. Total numbers of neurons were counted in tissue stained with cuprolinic blue. The numbers of neurons in the myenteric plexus were significantly greater in DBH-NT-3 than in contrast the numbers of submucosal NT-3 than in control mice. In contrast, the numbers of submucosal neurons were only slightly elevated. Calcitonin gene related peptide (CGRP)-containing and other neurons that develop from a precursor lineage that is non-TC, mash-1-independent, and born late were present in the same numbers in DBH-NT-3 and control mice. These observations confirm that NT-3 promotes neuronal development in situ and suggest that NT-3 may preferentially affect the TC, mash-1-independent, precursor lineage. Grants NS12969 and NS15547.

RAPID EFFECTS OF NEUROTROPHIN-3 (NT-3) ON THE ELECTRICAL PROPERTIES OF NEURONS OF THE MESENCEPHALIC TRIGEMINAL NUCLEUS (MES-V). Pose, I., Yamuy*, J. Morales, F.R., and Chase, M.H. Departamento de Fisiología, Facultad de Medicina, Montevideo, Uruguay, and Department of Physiology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA, 90024.

Mes-V neurons have been shown to express high-affinity receptors for NT-3 (trkC) (1); they also receive trophic support from NT-3-producing proprioceptors (2). We have recently reported that nerve growth factor is capable of rapidly increasing the excitability and enhancing the membrane potential oscillatory activity of Mes-V neurons (3). Accordingly, we were interested in examining whether the application of NT-3 results in a change in the electrical properties of Mes-V neurons.

Intracellular recordings from Mes-V neurons were obtained utilizing brainstem slices of adult rats. Microdroplets of NT-3, at a concentration of 0.5-1.0 µg/µl were applied locally in the vicinity of the recording electrode.

slices of adult rats. Microdroplets of NT-3, at a concentration of $0.5\text{--}1.0~\mu\text{g/}\mu\text{l}$ were applied locally in the vicinity of the recording electrode. Within 4 to 20 sec. of NT-3 application, there was an increase in the amplitude of the depolarization-induced membrane potential oscillations (4) and a decrease in the rheobase. Increased oscillations and spikes appeared at the break of the hyperpolarizing current pulses. The resting membrane potential was depolarized by 1-4 mV. The spike configuration and the AHP potential remained unchanged. The duration of these NT-3-induced effects was approximately 3 minutes. The present data suggest that NT-3, in addition to its known long term trophic effects, is capable of rapidly modulating the electrophysiological activity of Mes-V neurons.

NT-3 STIMULATES THE ADRENERGIC PHENOTYPE OF SYMPATHETIC NEURONS IN VIVO BUT UNLIKE NGF DOES NOT PRODUCE HYPERALGESIA V. Wong*, C. Jackson, J.A. Siuciak, D. Lewis, T. Do. P.S. DiStefano, and R.M. Lindsay. Regeneron Pharmaceuticals, Tarrytown, NY

NGF is an essential survival factor for developing sympathetic neurons and is required for their maintenance in the adult. Although exogenous NGF NGF is an essential survival factor for developing sympathetic neurons and is required for their maintenance in the adult. Although exogenous NGF attenuates damage to sympathetic (and sensory) neurons produced by nerve injury or toxic agents, the potential therapeutic benefit of NGF may be confounded by the finding that systemic NGF administration produces hyperalgesia in both rodents and man. Recent evidence has shown that neurotrophin-3 (NT-3) also plays an important role in developing sympathetic neurons, e.g., mice bearing an NT-3 null mutation show a 50% reduction in neurons in the superior cervical ganglion (SCG). Here we have compared the effects of exogenous NT-3 versus NGF on phenotypic markers of sympathetic neurons in the adult rat. Vehicle, NGF or NT-3 was administered to adult rats by s.c. injection daily for 4-7 days. Animals were evaluated for pain sensitivity by a paw thermal stimulation test. Target catecholamine levels were unaffected by either NGF or NT-3. NT-3 administration stimulated TH activity in the SCG and celiac ganglia to the same extent as did NGF. Only NT-3 increased TH levels in the superior mesenteric ganglion (SMG). At doses which produced equivalent increases in TH, NGF, but not NT-3, decreased paw withdrawal latency, suggesting that NT-3 did not induce hyperalgesia. NGF-, but not NT-3-treated rats showed swelling and redness of face and limbs, frequent scratching, and increased tissue serotonin levels, indicative of mast cells degranulation. Thus, NT-3 may be as effective as NGF in attenuating sympathetic neuron dysfunction, but benefit from the absence of hyperalgesia. Differences in the molecular signalling of NGF and NT-3 in sympathetic neurons are being investigated. Research supported by Regeneron Pharmaceuticals, Inc.

NEUROTROPHIN- 3 INCREASES THE PROPORTION OF NEURONS IN DISSOCIATED CULTURES OF POSTNATAL RAT MYENTERIC PLEXUS M.J. SAFFREY*, J.N. DAISLEY, T.M. WALKER, T. WARDHAUGH Dept. of Biology, The Open University, Milton Keynes, MK7 6AA, UK

Neurotrophin-3 has previously been found to stimulate the differentiation of neteric neurons and glial cells from precursors isolated from the embryonic gut in vitro. Since NT-3 transcripts have also been detected in the gut postnatally, we examined the effects of NT-3 on myenteric ganglia isolated from the postnatal rat gut and grown in dissociated cell culture. Segments of the positional radius and goom in ussentiace for extension segments of the muscularis externa from 6-8 day Wistar rats were incubated in Img/ml collagenase. Myenteric ganglia were then separated from the smooth muscle by mechanical agitation. After rinsing, freed segments of plexus were dissociated in trypsin. Cells were seeded in medium 199 containing 10% FCS at a density of 0.75 -1.5 x 10⁴ cells/200µl on to 16mm poly -L lysine coated coverslips. After 1.73 x 10° cells/200µ to 10 folimin py-2 rysine charter ovaries charter oversigns. Amorphism of the containing 100pg, 1ng or 10ng/ml NT-3. Cells were fixed after 48 hours and immunolabelled using an antiserum to PGP 9.5. The numbers of neurons and non-neuronal (glial) cells were counted. The proportion of neurons:non-neuronal cells was elevated in the NT-3- treated cultures at all three concentrations compared to untreated controls (n=4). The increase was significant in 3 out of 4 experiments (p<0.05; ANOVA). In general, the increase appeared to be due to an increase in the number of neurons, which was consistently seen in these experiments but which was not significant in all cases. These observations indicate that NT-3 has actions in the postnatal enteric nervous system; this may be a direct effect on myenteric neurons, but may also involve enteric glial cells, or precursors which may also be present in enteric ganglia at this stage of development.

EFFECTS OF NT-3 OVEREXPRESSION IN MUSCLE ON THE TRIGEMINAL MESENCEPHALIC NUCLEUS. T.A. Henderson, D.E. Wright, W.D. Snider & M.F. Jacquin, Neurology and the Center for the Study of Nervous System Injury, Washington University School of Medicine, St. Louis, MO 63110.

An accompanying paper (Wright et al. '96) describes the effects of NT-3 overexpression in skeletal muscle (Myo/NT-3 transgenic mice) upon proprioceptive DRG neurons that innervate muscle spindles. These results confirm that the survival of proprioceptive neurons in the DRG is powerfully regulated by the levels of target derived-NT-3, since the absence of NT-3 results in the loss of proprioceptive neurons and NT-3 overexpression increases proprioceptive neuron survival. This is in striking contrast to findings in the trigeminal (V) system, where proprioceptive neurons in the mesencephalic nucleus (MesV) that innervate jaw muscle spindles seem only partially affected by the absence of NT-3 or its receptor trkC (Ernfors et al. '94; Arends et al., '96). To investigate potential differences in the trophic requirements of spinal and V proprioceptive neurons, we examined MesV proprioceptive neurons in Myo/NT-3 mice. Nissl-stained profiles of MesV cell bodies with nucleoli were counted in complete series of paraffin-embedded "thin" sections from 3 Myo/NT-3 (15 day-old) and 6 wild-type mice. NT-3 overexpressors had 1,166, 1,150, and 1,107 Mes V cells vs. an average of 638 Mes V cells (range: 529-813) in wild-type controls. Our results reveal that muscle-derived NT-3 is capable of rescuing MesV neurons from naturally occurring cell death to a similar extent as proprioceptive DRG neurons. Whether increasing the number of surviving MesV proprioceptive neurons has secondary effects on cell numbers in the principal and spinal V nuclei will also be reported, as well as the status of whisker-related patterns Supported by NIH DE07734, NS17763 in the brainstem.

ACTIVITY-DEPENDENT EXPRESSION OF NT-3 IN MUSCLE CELLS MEDIATES SYNAPTIC POTENTIATION AT THE DEVELOPING NEUROMUSCULAR JUNCTION. K. Xie. T. Wang, P. Olafsson, and B. Lu* Roche Inst. of Mol. Biol., Nutley, NJ. 07110 and Lab. of Devel. Neurobiol., NICHD, NIH, Bethesda, MD 28920-4480.

While traditionally viewed as trophic factors regulating neuronal survival and differentiation, neurotrophins have recently been shown to acutely enhance transmitter release and to chronically facilitate synaptic maturation at the neuromuscular junction. The neurotrophins BDNF, NT-3 and NT-4/5 are expressed in the postsynaptic muscle cells, while their receptors TrkB and TrkC are expressed in the presynaptic motor neurons. We have investigated activity-dependent neurotrophin expression in muscle cells, and its role in developing neuromuscular synapses. Membrane depolarization, elicited either by depolarizing agents or repetitive electric stimulation, rapidly and specifically increased the levels of neurotrophin-3 (NT-3) mRNA in developing Xenopus muscle cells in culture. NT-3 gene expression was also enhanced by ACh, the neurotransmitter that causes muscle membrane depolarization. The effects of depolarization were mediated by increasing intracellular calcium concentration. Moreover, the depolarization-induced NT-3 potentiated synaptic activity at the developing neuromuscular synapses. The frequency of spontaneous synaptic currents recorded from neuromuscular synapses was markedly increased after treatment with conditioned medium from depolarized muscle cultures. This effect of conditioned conditioned incumin from topicalized misor protein, a specific scavenger of NI-3. These results suggest that muscle-derived NT-3 may serve as a retrograde message for activity-dependent synaptic strengthening at the developing neuromuscular junction. We also thank Dr. D. L. Shelton from Genentech for the gift of TrkC-IgG fusion protein. P. O. is supported by a Swiss NSF postdoctoral fellowship, and a grant from Ciba-Geigy Jubiläums-Stiftung.

EFFECTS OF NT-3 TREATMENT ON GALACTOSE-INDUCED NEUROPATHY. A.P. Mizisin*, K.C. Dines, M.W. Kalichman, M. Bache, R.M. Lindsay, P.S. DiStefano. University of California, San Diego, La Jolla, CA 92093 and Regeneron Inc., Tarrytown, NY 10591

In galactose intoxication, Schwann cell injury and axonal dwindling are ameliorated by inhibiting aldose reductase, suggesting that these abnormalities are linked to polyol pathway metabolism. How inhibition of aldose reductase, localized to Schwann cells and skeletal muscle, can restore axonal caliber is puzzling unless polyol accumulation disrupts the synthesis and/or release of trophic substances capable of influencing axonal structure and function. The present study investigated the effect of NT-3, a neurotrophic factor expressed in sciatic nerve and skeletal muscle, on myelinated fiber disorders of galactose-fed rats. Adult, female Sprague-Dawley rats were fed diets containing complete micronutrient supplements and either 0% D-galactose (control) or containing complete micronutrient supplements and either 0% D-galactose. One group of galactose-fed rats received NT-3 (15 mg/kg) by thrice weekly subcutaneous injections. After two months, sciatic sensory and motor nerve conduction velocity (SNCV and MNCV) were measured and the sciatic nerves and dorsal and ventral roots processed for light microscopy. The contralateral sciatic nerves were analyzed for polyol content. Compared to controls, there was marked accumulation of dulcitol and water in the sciatic nerves of galactose-fed animals that was not affected by NT-3 treatment. Galactose feeding reduced SNCV by 23% and MNCV by 10% compared to control values. NT-3 treatment attenuated the sensory conduction deficit seen in untreated galactose-fed rats such that SNCV was increased to 86% of control values, but had no effect on MNCV in galactose animals. In 80% of control values, but had no effect on MNCV in galactose animals. In galactose-fed animals, myelin sheaths of fibers in the dorsal and ventral roots were characterized by splitting that occurred at the intraperiod line. Treatment with NT-3 did not attenuate myelin splitting in either the dorsal or ventral roots. These observations indicate that NT-3 can attenuate sensory, but not motor, conduction deficits in galactose neuropathy. Determination of whether the effect of NT-3 on sensory function is related to the restoration of axonal caliber depends on completion of ongoing morphometric studies. Supported by NIH Grant NS32339.

DIFFERENTIAL EFFECT OF NT-3 ON GAP-43 AND TUBULIN $\alpha 1$ mRNA LEVELS IN AXOTOMIZED RETINAL GANGLION CELLS. P. Kittlerova, G. M. Bray and A.J. Aguayo*. Centre for Research in Neuroscience, McGill University and Montreal General Hospital Research Institute, Montréal, Québec, H3G 1A4.

We have previously shown that the effects of NT-3 on axotomized retinal ganglion cells (RGCs) in adult rats include stimulation of intraretinal axonal growth and a dramatic upregulation of GAP-43 in certain RGCs (Kittlerova et al., Soc. Neurosci. Abstr. 20: 1098, 1994). These effects presumably involve a subset of RGCs that express the high-affinity receptor TrkC (Kittlerova et al., Soc. Neurosci. Abstr. 21: 1550, 1994).

We have extended these observations on GAP-43 by investigating the expression pattern of another growth-associated protein, tubulin. We performed quantitative in situ hybridization using a tubulin al (Tal) radiolabelled cRNA probe on retinal sections 1, 2 and 4 weeks after optic nerve (ON) transection and a single injection of NT-3 or PBS. We observed a progressive reduction of $T\alpha 1$ hybridization signal in both NT-3- and PBS-treated RGCs. At 2 weeks after ON cut and NT-3 injection, the Tal mRNA levels were about one-half those of the contralateral intact eyes. This result is different from the previous finding of a 3-4 fold upregulation of GAP-43 message by NT-3 treatment, suggesting that the expression of these two molecules in injured retinas is differentially regulated by NT-3. We are currently investigating the possible role of GAP-43 in the modulation of specific features of RGC axon branching patterns in axotomized retina. SUPPRESSED KINDLING EPILEPTOGENESIS AND PERTURBED BDNF AND TrkB GENE REGULATION IN NT-3 MUTANT MICE.

M. Kokaia*, E. Elmér, P. Ernfors†, I. Ferencz, Z. Kokaia, and O. Lindvall. Section of Restorative Neurology, Department of Clinical Neuroscience, Wallenberg Neuroscience Center, S-221 85 Lund, Sweden; †Laboratory of Molecular Neurobiology, Department of Medical Biochemistry and Biophysics, Karolinska Institute, S-171 77 Stockholm, Sweden.

In the kindling model of epilepsy, repeated electrical stimulations lead to progressive and permanent intensification of seizure activity. We In the kindling model of epilepsy, repeated electrical stimulations lead to progressive and permanent intensification of seizure activity. We find that the development of amygdala kindling is markedly retarded in mice heterozygous for a deletion of the neurotrophin-3 (NT-3) gene (NT-3+/- mice). These mice did not reach the fully kindled state (third grade 5 seizure) until after 28±4 days of stimulation as compared to 17±2 days in the wild-type animals. The deficit in the NT-3+/- mice reflected dampening of the progression from focal to generalized seizures. The number of stimulations required to evoke focal (grade 1 and 2) seizures did not differ between the groups, but the NT-3 mutants spent considerably longer time (13±3 days) than wild-type mice (2±1 days) in grade 2 seizures. As assessed by test stimulation 4+12 weeks after the tenth grade 5 seizure, kindling was maintained in the NT-3 mutants. In situ hybridization showed 30% reduction of basal NT-3 mRNA levels, and lack of upregulation of TrkC mRNA expression at 2 h after a generalized seizure in dentate granule cells of the NT-3+/-mice, whereas the seizure-evoked increase of brain-derived neurotrophic factor (BDNF) and TrkB mRNA levels was enhanced (by 130 and 38%, respectively). These results indicate that NT-3 might be involved in kindling epileptogenesis, and suggest a link between NT-3 and BDNF gene regulation in dentate granule cells.

ACTIVATION OF NEUROTROPHIN-3 RECEPTOR INDUCES APOPTOSIS IN A MEDULLOBLASTOMA CELL LINE. S.L. Pomeroy*, T.A. Cho, S. Khoxayo, C.D. Stiles, R.A. Segal, L.C. Goumnerova, M.A. Sutton. Depts of Neurol and Neurosurg, Children's Hosp, Dept of Neurol, Beth Israel Hosp, Dept of Cell Mol Biol, Dana-Farber Cancer Inst, Harvard Med Sch, Boston MA 02115

We demonstrated previously that patients with tumors expressing high levels of the neurotrophin-3 (NT-3) receptor, TrkC, have a significantly better survival than those with low levels of expression (Segal et al., Proc Natl Acad Sci, USA, 1994; 91:12867-71). Here, we address whether TrkC activation alters the growth of medulloblastomas.

TrkC expression was upregulated in the medulloblastoma cell line Daoy by transfection with an expression plasmid encoding the full length TrkC receptor. A higher proportion of cells expressing high levels of TrkC were found to undergo apoptosis (0.52 ± .04; mean ± S.D.), defined by nuclear condensation and fragmentation, when grown in the presence of 50 ng/ml NT-3 than when they were grown under identical conditions but without NT-3 (.05 \pm .01; P < .0001, Student's t test). Neither BDNF nor NGF increased apoptosis rate. These results are consistent with the view that endogenous TrkC activation influences medulloblastoma outcome by induction of apoptosis in cells expressing

INFLUENCES OF NT-3 ON PROPRIOCEPTIVE AXON PROJECTIONS TO SPINAL MOTONEURON POOLS. S. Ozaki*, D. E. Wright, L. Zhou and W. D. Snider. Department of Neurology, CSNSI, Washington University School of Medicine, St. Louis, MO 63110.

Work with the prototypical neurotrophin, NGF, suggests that neurotrophic factors can regulate axon arbors. A variety of lines of evidence extend this concept to other reurotrophins and to axon projections in the CNS (see Thoenen, 1995, for a review). Proprioceptive sensory neurons that project to motoneuron pools in the ventral spinal cord express TrkC and require NT-3/TrkC signaling for survival. NT-3 is known to be intensely expressed in the ventral horn prior to the onset of the proprioceptive axon collateral branching in the spinal cord, suggesting that NT-3 may have tropic and/or trophic effects on proprioceptive axons. To address the functions of NT-3 related to the development of proprioceptive axon arbors, NT-3 levels in the spinal cord were altered by generating two kinds of transgenic mice: Tα1-NT-3 mice in which an NT-3 transgene is overexpressed by all spinal and DRG neurons under control of the α -tubulin promoter (Gloster et al., 1994) and myogenin-NT-3 x NT-3(-/-) mice in which NT-3 is expressed in muscle but not in the spinal cord. Primary afferent projections were visualized using DiI placed in the thoracic nerves of the transgenic animals on postnatal day 0. In Tol-NT-3 mice, overexpression of NT-3 has striking effects on spinal cord development: dorsal columns are larger than the controls and there is a large increase in axons projecting to the Clark's column, suggesting that there are many more proprioceptive sensory axons. Surprisingly, the basic pattern of the afferent projections to the ventral horn is similar to the wild type, despite the diffuse availability of NT-3 in the spinal cord. In myogenin-NT-3 x NT-3(-/-) mice, proprioceptive sensory neurons are "rescued" by the NT-3 transgene overexpressed in muscle. Again, the basic pattern of proprioceptive afferent projections is similar to the controls. These results indicate that NT-3 is unlikely to have tropic effects on proprioceptive afferent projections (see Oakley et al., 1995, for a similar result in the chick). Whether NT-3 has trophic effects on axon arborizations and bouton formation should be amenable to analysis in these animals. Supported by NIH

NEUROTROPHIN-3 TREATMENT OF DIABETIC RATS SELECTIVELY PREVENTS REDUCED SENSORY NERVE CONDUCTION VELOCITY.

N.E. Garrett, P. Fernyhough, L.T. Diemel and D.R. Tomlinson *.

Department of Pharmacology, St. Bartholomew's and The London School of Medicine and Dentistry, QMW, Mile End, London E1 4NS, U.K.

Reduced sensorimotor conduction velocity and distal axonal shrinkage are hallmarks of diabetic neuropathy. In animal models the latter derives from deficient production of the neurofilament proteins with breakdown of the axonal endoskeleton. In myelinated sensory fibres this may be controlled by target cell-derived neurotrophin-3 (NT-3) and the present study examined the effect of administration of its human recombinant form in streptozotocin-diabetic rats (65mg/kg i.p.). NT-3 (1mg/kg s.c. 3x/week) was given for the last 4 weeks of 12 weeks of diabetes; another diabetic and a non-diabetic (control) group received vehicle. Finally motor and sensory nerve conduction velocities (MNCV/SNCV) were measured (under halothane anaesthesia) and lumbar dorsal root ganglia removed for measurement of expression of two neurofilament protein (NF-M, NF-H) mRNA and the NT-3 receptor (trkC) mRNA.

In vehicle-diabetic rats MNCV and SNCV were reduced (respectively 76% and 84% controls; both p<0.01); NT-3 did not affect MNCV (79% control; p<0.01). but increased SNCV to 110% non-diabetic rats (p<0.01). In vehicle-diabetic rats there were reductions in mRNA (% control) for NF-H (62), NF-M (45) and trkC (43; all p < 0.05).

These deficits were unaffected by NT-3 treatment. These data implicate NT-3 in deficient sensory conduction, with therapeutic possibilities for correction, but not in neurofilament impairment in diabetic rats

RESPONSE OF PRIMARY SENSORY NEURONS TO PERIPHERAL NERVE INJURY IN P75 DEFICIENT MICE, L.A. Karchewski* & V.M.K. Verge
Dept. of Anatomy and Cell Biology & Cameco MS/Neuroscience Research
Center, University of Saskatchewan, Saskaton, Canada S7N 5E5.

Center, University of Saskatchewan, Saskatoon, Canada S7N 5E5.

The functional significance of the low-affinity neurotrophin receptor is not clear. p75 may modulate neurotrophin sensitivity, mediate retrograde transport of select neurotrophins, play a role in apoptosis and/or be involved in neurite extension. Peripheral nerve injury invokes a number of cell body responses believed influenced by alterations in trophic support and/or altered expression of p75 and trk receptors. As a first step in elucidating the role of p75 in intact and injured sensory neurons, unilateral sciatic nerve transection time course studies were performed on mice carrying a null mutation in the p75 locus and compared to host strain mice. In situ hybridization to detect p75, trk receptors, various neuropeptides, cytoskeletal and immediate early gene mRNAs were performed on pairs of experimental and control DRG cryostat sections. Preliminary results show that, although these DRG contain ~ 50% fewer neurons (a lack of primarily small size neurons), there is not a proportionate loss of trkA, trkB, trkC, BDNF small size neurons), there is not a proportionate loss of triA, triAB, triC. BDNF or CGRP expressing neurons. Time course analysis of injury responses indicate that at 4d &7d, reduced expression of triA, triC, CGRP, SP and elevated expression of GAL, NPY and GAP43 are much more dramatic in the p75 deficient mice than in controls. However by 5 weeks, p75 deficient mice show enhanced levels of hybridization signal detecting triA, SP, CGRP and snow enhanced levels of hybridization signal detecting trial, S.F., CGHP and BDNF mRNAs as compared to control mice. These results suggest that availability and/or response to NGF may be altered in these mice, perhaps through altered p75/ftk ratios, different endoneurial trophic support and/or retrograde transport of NGF following injury. Whether axonal regeneration is altered in p75 knock-out mice is being determined. Supported by the Neuroscience Network for the Centers of Excellence, Canada.

THE ROLE OF NT-3 IN THE REGULATION OF GAP-43 AND $\tan 1$ -TUBULIN IN INTACT AND INJURED PRIMARY SENSORY NEURONS <u>K.A. Gratto</u> & <u>V.M.K.Verge*</u> Dept of Anatomy and Cell Biology & Cameco MS Neuroscience

N.M., Verige - Cell to Anatoning and Cell biology & Calineto Mis neutrosciente. Research Center, University of Saskatchewan, Saskatoon, Canada S7N 5E5 Exogenous NT-3 has been shown to modulate the injury-induced expression of its receptors (trk C, p75), NFM, cJUN, and a number of neuropeptides towards normal levels, thus implicating a role for this expression of its receptors (trk C, p75), NFM, cJUN, and a number of neuropeptides towards normal levels, thus implicating a role for this neurotrophin in the maintenance of aspects of the intact, differentiated states of responsive adult primary sensory neurons (Gratto et al., 1994, 1995). As a continuation of these studies, NT-3's ability to mitigate the expression of two regeneration-associated genes, GAP-43 and $t\alpha$ 1-tubulin was examined. Adult rat right sciatic nerves were proximally cut. 14d after injury NT-3 was intrathecally infused for 7d in half of the rats. Serial cryostat sections of intact and injured DRG with and without NT-3 infusion were processed for *in situ* hybridization to detect mRNAs encoding trkC, GAP-43, and $t\alpha$ 1-tubulin. Computer-assisted image-analysis was used to determine relative hybridization signal intensities. Results indicate that NT-3 infusion is, at least partially, effective in mitigating the axotomy-induced increases in GAP-43 and tubulin mRNA levels. Preliminary quantitative data show that while only ~20% of trkC-positive neurons coexpress GAP-43 in the intact state, virtually all of this population strongly expresses mRNA for this marker following injury (~70% express signal, with the remainder exhibiting levels < 35X background. That NT-3 appears to downregulate the expression of both GAP-43 and $t\alpha$ 1-tubulin (as well as cJUN) mRNA *in vivo* implies that this trophic factor may function in depressing the regeneration process. The influence of this neurotrophin on the numbers and growth rates of regenerating axons is being determined. *NT-3 generously supplied by Regeneron Pharmaceuticals, Tarrytown, N.Y. NEUROTROPHIC FACTORS: RECEPTORS AND CELLULAR MECHANISMS III

399.1

TRUNCATED TrkB VARIANTS ARE DEVELOPMENTALLY REGULATED NEGATIVE MODULATORS OF BDNF SIGNALLING IN SENSORY NEURONS Natalia Ninkina, Jimi Adu, Anne Fischer, Luzia G. P. Pinon, Vladimir L. Buchman and Alun M. Davies* Bute Medical Buildings, University of St. Andrews, St. Andrews, Fife KY16 9AJ, Scotland, UK.

Mouse trigeminal neurons survive independently of neurotrophins when their axons are growing to their targets and are transiently supported by BDNF during the early stages of target field innervation before becoming NGF dependent. During the stage of low levels. During the stage of BDNF responsiveness, a 9 kb trkB transcript encoding the kinase-containing, catalytic receptor required for BDNF signalling is expressed at high levels. As the neurons lose responsiveness to BDNF, there is a concomitant increase in the expression of 8.2 and 2.5 kb *trkB* transcripts which encode truncated TrkB variants that lack the tyrosine kinase domain, suggesting that the increased expression of these variants may account for the loss of the BDNF survival response. To test directly whether truncated TrkB modulates BDNF signalling via catalytic TrkB, we microinjected TrkB expression plasmids into NGF-dependent postnatal sympathetic neurons. Whereas expression of catalytic TrkB alone conferred a survival response to BDNF, co-expression of truncated TrkB substantially reduced the BDNF survival response but had no effect on the NGF survival response. Our results suggest that BDNF responsiveness in developing sensory neurons i modulated by the relative levels of catalytic and truncated TrkB.

LIGAND-INDUCED DOWNREGULATION OF TRKB IN ULTURES OF CEREBELLAR GRANULE CELLS

E. Hoppe, M.T. Serejo, B. D. Carter, and Y.-A. Barde. Max-Planck-Institute for Psychiatry, Depa Neurobiochemistry, D-82152 Martinsried, Germany. Department of

The mechanism of desensitization of TrkB receptors by neurotrophic factors was investigated in cultures of cerebellar granule cells. Exposure of cells to BDNF resulted in a loss of binding of radiolabeled BDNF to TrkB. This reduction of binding correlated with a downregulation of gp145^{TrkB} protein as shown by Western blotting of total cell lysates. In contrast to the full length TrkB, no regulation of the truncated gp95^{TrkB} isoform could be observed. Consistent with an effect induced by direct receptor activation, the regulation of TrkB could be induced by BDNF and NT4/5 but not by NGF or NT3. The addition of BDNF resulted in a rapid reduction in the amount of TrkB with a half life time of 2-3 hours suggesting an involvement of cellular proteases. Accordingly, the ligand-induced downregulation was prevented by pretreatment of the cells with different protease inhibitors, with acetyl-leu-leu-norleucinal and lactacystin being the most potent ones. Therefore, the data suggest that proteases associated with the proteasome could be important for promoting the efficient

BDNF DEFICIT IN THE CEREBELLUM OF STARGAZER MUTANT MICE: **EFFECTS** ON TRKB TRANSDUCTION. B. Knusel*, K. Rice and X. Qiao, University of Southern California, Los Angeles, CA 90089.

The BDNF deficit in the cerebellum of the mutant mouse stargazer (stg) presents a spontaneous model to study the effects of chronic BDNF deprivation on signal transduction of its transducing receptor, TrkB. We have earlier found TrkB mRNA in sig to be expressed at levels identical to control mice. In the present study we have analyzed TrkB protein levels and ligand-induced (NT-4/5) tyrosine phosphorylation of TrkB and some of its signal transducing molecules. By wheat germ lectin precipitation of glycoproteins and TrkB probing of western blots we have found normal levels of full-length and truncated TrkB protein in adult stg cerebellum. However, treatment of brain slices from stg cerebellum in vitro under physiologic conditions with NT-4/5 revealed a consistent deficit of TrkB signal transduction. Whereas the protein levels of the TrkB tyrosine kinase target phospholipase-Cy1 (PLC) was elevated in stg cerebellum, PLC tyrosine phosphorylation after NT-4/5 stimulation was reduced when compared to slices from cerebellum of matched control mice. Similarly, NT-4/5-induced tyrosine phosphorylation of Erk1 and Erk2 were also reduced. Our data indicate a regulatory effect of BDNF on the effectiveness of TrkB signal transduction without changes in the level of BDNF receptor protein.

INHIBITION OF GABAA SYNAPTIC RESPONSES BY BDNF IN RAT HIPPOCAMPUS, T. Tanaka*, H. Saito and N. Matsuki. Dept. Chemical Pharmacology, Fac. of Pharmaceutical Science, The Univ. of Tokyo. Tokyo 113,

Brain-derived neurotrophic factor (BDNF) is one of neurotrophins involved in the development and maintenance of both the peripheral and central nervous systems (CNS). Although the expression of BDNF and its receptor Trk B still occur in adult stage, their physiological role in the mature CNS is still not fully understood In the present study we examined in detail the possibility that BDNF can modulate synaptic neurotransmissions using patch clamp technique in rat hippocampal CA1 region. BDNF (20-100 ng/ml) did not show any apparent effect on evoked EPSCs. but reduced evoked IPSCs amplitudes markedly within 5 min (55.6±9.9 % of control) and this reduction was persisted while BDNF was present. BDNF also attenuated GABAA receptor-mediated response to applied GABA (64.6±8.8 % of control). However, BDNF failed to attenuate IPSCs when the postsynaptic pyramidal neuron was loaded intracellularlly with K252a by the patch pipette containing 200 nM K252a, an alkaloid that inhibits the kinase activity of Trk receptor family. Intracellular application of 200nM K252b, a weaker inhibitor of Trk type kinase, did not affect the inhibition. The attenuating effect was also prevented by postsynaptic injection of U73122 (5 µM), a broad spectrum PLC inhibitor, and by strong chelation of intracellular Ca2+ with 10 mM BAPTA. These data suggest that BDNF modulates GABAA synaptic responses by postsynaptic activation of Trk type receptor and subsequent Ca21 mobilization in the mature CNS. IDENTIFICATION OF THE RECEPTORS WHICH BIND THE

IDENTIFICATION OF THE RECEPTORS WHICH BIND THE NEUROTROPHINS BDNF AND NT-3 DURING RETROGRADE AND ANTEROGRADE AXONAL TRANSPORT. C.S. von Bartheld*. Department of Physiology, University of Washington, Seattle, WA 98195 Retrograde and anterograde axonal transport of neurotrophins is a receptor-mediated process. BDNF and NT-3 are retrogradely transported to the isthmo-optic nucleus (ION), and NT-3 is anterogradely transported by retinal ganglion cells to the optic tectum in chick embryos (Nature 379:830-833; J. Neurosci., in press). To determine which receptors (p75, trkB or trkC) bind BDNF and NT-3 before, during, and after axonal transport in the developing visual system, neurotrophins were iodinated transport in the developing visual system, neurotrophins were iodinated and injected into the eyes of E15-16 chick embryos. After 20 hours, the retina, chiasm, ION and optic tectum were dissected, lysed, and the neurotrophins crosslinked to their receptors with EDC or DSS, and immunoprecipitated with antibodies specific for chicken p75, trkB or trkC. For examination of only retrograde transport (10-15% of total transport), anterograde transport (85-90%) was abolished with monensin. Retrograde transport: NT-3 bound to p75:trkC with a ratio of 1:1 in the chiasm during retrograde transport to the ION, and 2:1 in the ION. BDNF bound to p75:trkB with a ratio of 3:1 in the retina, 2:1 in the chiasm, and 1:1 in the ION. These data indicate that BDNF transfers from p75 to trkB in the ION or that the p75-bound BDNF dissociates or is degraded faster than the trkB-bound BDNF. Anterograde transport: NT-3 bound to p75:trkC with a ratio of 2:1 in the retina, 3:2 in the chiasm, and 1:2 in the optic tectum. These data indicate that NT-3 is transported by both p75 and trkC to the terminals of retinal axons in the tectum, and that NT-3 is preferentially released from p75 and/or binds predominantly to trkC after axodendritic transfer to tectal neurons. I am currently examining if full-length or truncated trkC receptors bind NT-3 in the chiasm, ION and optic tectum. Neurotrophins: courtesy of R. Lindsay, Regeneron. Antibodies: courtesy of G. Weskamp. L. Reichardt, E. Lefcon, L. Clary. Supported by NH grant HD 29177.

399.4

BDNF AND NT-4/5 ACTIVATION OF TRKB RECEPTORS AND INITIATION OF INTRACELLULAR SIGNALING CASCADES IN VIVO. J. Blahos, II* and L.F. Kromer. Dept. of Cell Biology, Georgetown University Medical Center, Washington, DC 20007

The function of the trkB receptor ligands, BDNF and NT4/5, in adult rat brain remains disputable. Previous in vitro experiments using slice preparations indicated that there is little or no BDNFinduced trkB phosphorylation in CNS tissue obtained from rats after postnatal day 14, despite similar levels of full-length trkB receptors. This reduced phosphorylation response correlates with increased expression of truncated trkB (trkB-tr). Thus, it was hypothesized, that the presence of trkB-tr receptors results in the inhibition of the ligand effects. In the present study both a developmental time course and dose dependence for BDNF and NT-4/5 activation of *trkB* signaling pathways *in vivo* were evaluated. Intraparenchymal injections of BDNF or NT-4/5 into the neocortex and striatum induce trkB receptor phosphorylation and activate intracellular signaling cascades. Activation of trkB receptors is associated with phosphorylation of ERK1/2 that correlates with the degree of trkB receptor phosphorylation. The magnitude of these responses is dose dependent (10ng < 100ng) and varies with age. Our findings demonstrate that despite high levels of trkB-tr receptors in the adult CNS, even low amounts of trkB ligands (e.g. 10 ng BDNF/1µ1 CSF) result in the induction of intracellular signaling events associated with trkB receptor activation. Supported by NIH grant NS-31445.

399.6

Activation of Phosphatidylinosital (PI-3) Kinase by Brain Derived Neurotrophic Factor (BDNF) Gene Transfection Y.H.Qiu, K.Yang*, X.Zhao, G.L.Clifton, R.L.Hayes,

Neurosurgery, U of TX Health Science Ctr., Houston, TX 77030
Brain derived neurotrophic factor (BDNF) has therapeutic potential for treatment of the injured central nervous system (CNS). Gene transfer treatment of the injured central nervous system (CNS). Gene transfer is an alternative method of introducing BDNF into the CNS. The transient expression produced by cationic lipid-mediated gene transfection may limit its application in diseases caused by genetic defects. However, cationic lipid transfection of neurotrophins may prove useful for treatment of CNS injury. Our laboratory is conducting systematic studies of the potential of cationic lipids for gene transfection in CNS (Yang, et al., Neurosci.Lett. 182:287;290, 1994). We recently reported reduced neurofliament loss in traumatized septohippocampal primary cell cultures by lipofectin-mediated BDNF CDNA transfer (Hayes, et al., Neurosci. Lett. 191:121, 1995). However, the mechanism of this effect is unknown. Recent studies have shown that the ability of NGE to proport constraints. the ability of NGF to prevent apoptosis is mediated by a Pi-3 kinase signaling pathway in PC-12 cells (Yao, et al., Science 267:2003, 1995). We examined the consequence of cationic lipid-mediated gene transfection of BDNF in primary septo-hippocampal cell cultures (Whitson,J.S., et al., Brain Res. In press). Two days after BDNF gene transfection in primary cell cultures, PI-3 kinase activity assayed by thin-laws observables. layer chromatograph (TLC) was significantly increased. The increased PI-3 kinase activity could also be inhibited by Wortmanin. Our studies suggest cationic lipid-mediated BDNF cDNA transfection involves PI-3 kinase signaling pathways in primary septo-hippocampal cell cultures. Further experiments are needed to more rigorously examine the possible role of PI-3 kinase activation in BDNF mediated effects on recovery from neuronal injury. (Supported by NIH grant PO1 NS 31998 and RO1 NS 21458).

BDNF LOCALIZATION IN SYNAPTOTAGMIN-CONTAINING VESICLES OF PC12 CELLS AND IN SYNAPTOSOMAL FRACTIONS OF RAT BRAIN James P. Fawcett, Peter S. McPherson, Raquel Aloyz, Freda Miller and Richard Murphy* Montreal Neurological Institute, McGill University, Montreal, Canada

NGF, BDNF, NT-3 and NT-4 play an important role in the development and survival of both CNS and PNS neurons. Neurotrophins produced in nonneuronal target tissues exert their action on innervating neurons, a mechanism described in the PNS. In the CNS, neurotrophins are produced and are exchanged by neurons. As well, some neurons can synthesize more than one neurotrophin. Neurotrophins can be released in an activity dependent fashion (Thoenen, H. (1995) Science 270:593-597) and radiolabelled neurotrophins can be anterogradely transported down CNS axons and released trans-synaptically (von Bartheld, C.S. et al. (1996) Nature 370:830-832). We have now begun to investigate possible biochemical mechanisms for this anterograde transport. Using a vaccinia virus system, we have expressed human recombinant BDNF in undifferentiated PC12 cells and detected mature BDNF and BDNF precursor by western blotting. Using well characterized methods of sucrose density centrifugation, we detected mature BDNF and BDNF precursor in fractions containing synaptotagmin, a known secretory vesicle marker; only a small amount was detectable within ER-containing fractions, as identified by calnexin antibodies. BDNF precursor containing samples in cell homogenates were digested by proteinase K in the presence but not absence of Triton X 100. Further, in mature rat brain, BDNF immuno-reactivity was enriched in a microsomal fraction isolated from lysed synaptosomes. In the brains of animals treated with kainic acid, a sharp increase occurred in BDNF immunoreactivity within this fraction. These results are consistent with a model in which BDNF and its precursor are transported within a population of intracellular vesicles, the precise nature of these vesicles is yet to be characterized

Work supported by NCE, Canada. We thank Dr. Nabil Seidah for providing the BNDF vaccinia virus.

Neurotrophic factors play a role in activity-dependent plasticity and

survival. The NGF family of neurotrophins, BDNF, NT-4 and NT-3 act via preferential activation of the trk family of tyrosine kinase receptors. NGF binds to trkA, BDNF and NT-4 to trkB and NT-3 to trk. It is well established that cortical neurons depend on BDNF to develop and survive, and that they express both BDNF and the trkB receptor. Studies of embryonic cortical neurons in vitro suggest that BDNF acts via an autocrine loop in an activity-dependent fashion. In vivo studies have shown that the organization of visual cortex depends on visual input, and that BDNF is involved in this process. In these studies we determined whether activation of afferent input to adult cortical neurons can stimulate trkB activation in vivo. We injected adult mice with reserpine (5mg/kg) or yohimbine (2mg/kg) and 20 to 30 minute later sacrificed the mice, removed the brains, and (2mg/kg) and 20 to 30 minute later sacrificed the mice, removed the brains, and dissected out the cortex on ice. The tissue was then homogenized, immunoprecipitated with pan-trk antibodies and the precipitates were analyzed on western blots with antibodies specific for phosphotyrosine or different domains of trkB. Our results suggests that pharmacologically-induced depletion of noradrenergic terminals induces trkB phosphorylation in vivo. Whether the BDNF responsible for the trkB activation originates from the noradrenergic afferents or indirectly from cortical neurons is not known. However, the presence of BDNF in axons immunoreactive for DBH suggest that anterograde secretion of BDNF could account for these results

MICE OVEREXPRESSING AN ISOFORM OF THE TRUNCATED TRKC RECEPTOR DEVELOP A NEURONAL PHENOTYPE SIMILAR TO THAT OF NT-3 DEFICIENT MICE. M.E. Palko, J. Blair-Flynn, S.W. Reid and L. Tessarollo*. Molecular Ontogenesis Group, ABL-Basic Research Program, NCI-FCRFDC, Frederick, MD 21702.

Recent knockout experiments in mice have confirmed a direct role for the Trk family tyrosine kinase receptors in mediating the function of the Nerve Growth Factor family of neurotrophins during development of the nervous system. This family of receptors includes three known members; the prototype trkA, trkB and trkC. These three loci encode for receptors with a catalytic tyrosine kinase domain. The trkB and trkC loci also encode for other isoforms some of which lack the catalytic domain. Whereas the function of the kinase active isoforms has been widely investigated and their role in signalling is relatively well understood, almost nothing is known about the in vivo role of the receptors lacking the tyrosine kinase domain It has been proposed that this truncated receptor may act in vivo as a dominantnegative inhibitor of the full length isoform or by sequestering soluble neurotrophic factor therefore regulating the amount of neurotrophin interacting with the tyrosine kinase receptor. In order to address the mechanism by which this truncated receptor might exert its function we generated a transgenic mouse line overexpressing an isoform of the trunkated trkC receptor. Surprisingly, mice expressing high levels of the truncated trkC die within the first 2-3 days after birth and some of them exhibited the behavioral phenotype attributed to defects in proprioception. To discriminate the behavioral phenotype attributed to detects in proprioception. To discriminate between a dominant-negative or a neurotrophin-sequestering effect, we counted populations of neurons from sensory and sympathetic ganglia. These counts revealed severe sensory and sympathetic neuronal deficits similar to those observed in the NT-3 knockout mice. This result suggests that, physiologically, the truncated form of this receptor may act by sequestering soluble neurotrophic factor, therefore regulating the amount of neurotrophin available to interact with the receptor with the tyrosine bitmes demise. kinase domain

FUNCTIONAL trkB NEUROTROPHIN RECEPTORS ARE COMPONENTS THE ADULT BRAIN POSTSYNAPTIC DENSITY

K. Wu*, H.T.J. Mount, E.S. Levine, J.L. Xu, P.C. Suen, S.Y. Lin, Y.Y. Huang and I.B. Black, Dept. of Neuroscience and Cell Biology, Robert Wood Johnson Med. Sch., Univ. of Medicine and Dentistry of New Jersey, Piscataway, NJ 08854; [‡]Dept. of Neuroscience, New York State Psychiatric Inst. and Dept. of Psychiatry, Coll. of Physicians and Surgeons, Columbia Univ., New York, NY

Neurotrophins have long been thought to act as target-derived factors that regulate the survival and differentiation of afferent neurons. Recently, brainderived neurotrophic factor (BDNF) was shown to elicit a rapid increase in synaptic activity of cultured rat hippocampal neurons via enhanced responsiveness to excitatory input (Levine et al., 1995, Proc. Natl. Acad. Sci. USA 92: 8074-8077). These findings suggest a postsynaptic localization of neurotrophin receptors. In this study, we examined expression of trkB, a high affinity receptor for BDNF, in the postsynaptic density (PSD), a proteinaceous specialization of the postsynaptic membrane. Western blot analyses with antibodies to trkB the postsynaptic membrane. Western blot analyses with antibodies to trkB revealed localization to the PSD in adult rat cerebral cortex and hippocampus. Only the full-length, active form of trkB was detected in PSD samples. BDNF treatment of cortical PSD resulted in a 5-fold increase in trkB autophosphorylation, supporting the contention that the PSD contains functional trkB. Truncated trkB, which does not contain the tyrosine kinase signaling domain, though present in membrane fractions, was undetectable in the PSD. In addition, there was a selective developmental increase in trkB in the PSD relative to the synaptic membrane fraction. The presence of trkB in the PSD during development and maturity is consistent with a role for neurotrophins in the regulation of synaptic activity through direct postsynaptic mechanisms. regulation of synaptic activity through direct postsynaptic mechanisms

DISTRIBUTION OF BDNF IMMUNOREACTIVE PROCESSES IN THE MOUSE FOREBRAIN. J.H. McLean J.J.P. Fawcett 2, R.S. Aloyz C.G. Causing 2, S.X. Bamiji and F.D. Miller 2. 'Div. of Basic Med. Sci., Memorial Univ. of Nfld., St. John's, Nfld., A1B 3V6 and 2 Centre for Neuronal Survival, McGill Univ., Montreal, P.Q., Canada H3A 2B4.

The presence of brain derived neurotrophic factor (BDNF) in the CNS has been described mainly in cell bodies and dendrites. However, there is evidence that BDNF is trafficked anterogradely in axons (von Bartheld et al., 1996). In this study, we examined the distribution of BDNF-like immunoreactive (IR) processes in the mouse brain using a sensitive polyclonal antibody to BDNF. Specificity of the IR label was determined by competition with the BDNF peptide immunogen which totally eliminated label, or by preincubation with NT-4, a similar neurotrophin to BDNF, which resulted in no change in IR label. Similar results of competition were observed on western blots. The immunoreactivity showed a distribution of BDNF similar to that described by others but, in contrast to previous reports, the BDNF was only observed in processes (axons and possibly dendrites). Using confocal microscopy, densities were observed within many processes, suggestive of vesicles within axons. Especially dense label was observed in tracts such as the lateral olfactory tract, corpus external and internal capsule. Process label was heterogeneous in the cortex with most intense label observed consistently in the deeper layers. Thus, the results are consistent with the possibility that BDNF is trafficked in axons and secreted anterogradely. Supported by the MRC and NCE of Canada.

TARGET DEPENDENT AND INDEPENDENT EXPRESSION OF trkC TRANSCRIPTS IN DEVELOPING SENSORY NEURONS R. A. Oakley*, A.S. Garner, T. H. Large and E. Frank. Dept. of Neurosiology, University of Pittsburgh, Pittsburgh, PA 15261 and Dept. of Neurosicience, Case Western Reserve University, Cleveland, OH 44106. We are analyzing the developmental expression of rrkC transcripts during the interaction of chick sensory neurons with their peripheral targets. Prior to target contact, most sensory neurons express trkC transcripts as revealed by in situ labeling with a probe to the extracellular domain of the receptor. After two days of target interaction, two distinct classes of trkC+ neurons can be distinguished on the basis of cell size and position; small dorsomedial (DM) and larger ventolateral (VL) neurons. By the end of the cell death period. trkC transcripts are only detected in the large VL neurons. These two populations can be further distinguished on the basis of target dependence. Early removal of the limb bud leads to a selective loss of the VL population. These results suggest that most sensory neurons express trkC during early phases of differentiation, before becoming dependent on peripheral targets.

To determine if both populations of trkC+ neurons could potentially respond to NT3, we also examined trkC expression using a probe specific for transcripts encoding catalytic forms of trkC as do sensory neurons that have yet to contact their peripheral targets. In addition, RT-PCR was used to examine the other splice variants of trkC. These experiments show that by the end of the cell death period, DRG neurons express transcripts encoding full length, kinase-insert, kinase-truncated and kinase-deleted forms of the trkC was expessing that all these splice variants are expressed in the trkC+VL neurons that survive the cell death period.

Supported by grants from NINDS and the MDA.

REGULATION OF TRKB ACTIVATION BY ALTERNATIVE SPLICING IN THE EXTRACELLULAR DOMAIN. K.L. Boeshore . A.S. Garner, and T.H. Large* Dept. of Neurosciences, CWRU, Cleveland, OH 44106-4975.

The generation of multiple trkB isoforms by alternative splicing suggests that receptor function is regulated, in part, at the level of receptor structure. An extracellular deletion (ED) isoform of trkB lacks suggests that receptor function is regulated, in part, at the level of receptor structure. An extracellular deletion (ED) isoform of trkB lacks 11 amino acids near the ligand binding region (Garner et al. 1996 J. Neurosci. 16: 1740), suggesting that it may exhibit altered neurotrophin binding properties. To test this hypothesis, ED or full-length (FL) isoforms were expressed in chicken embryonic fibroblasts (CEFs). NT-4/5 and BDNF were equally effective (maximum response at 25ng/ml) in activating the FL and ED isoforms, as determined by anti-phosphotyrosine Western blot analysis. In contrast, the maximum phosphotyrosine response to NT-3 was 10-fold lower for the ED receptor, compared to the FL receptor. The diminished response to NT-3 could be due to either a decrease in the number of phosphotyrosine residues on activated receptors or a decrease in the activation rate of the ED isoform. Although BDNF, NT-3, and NT-4/5 activated FL trkB receptors expressed in fibroblasts, only BDNF stimulated process outgrowth from PC12 cells expressing the FL isoform. Since PC12 cells, but not CEF cells, express endogenous p75 low-affinity neurotrophin receptor, we are now testing the ability of p75 to restrict ligand binding/activation of trkB isoforms. Thus, NT-3 activation of trkB receptors can be regulated by two distinct mechanisms: co-expression with neuronal elements, such as p75, or alternative splicing of the extracellular domain. (Supported by NIH EY08885).

TRUNCATED *TRKB* RECEPTORS ARE INHIBITORY TO NEURITE OUTGROWTH *IN VITRO*. L.F. Kromer*, R.H. Fryer, and D.R. Kaplan*. Dept. of Cell Biology, Georgetown University Medical Center, Washington, DC 20007 and The Montreal Neurological Institute, Montreal, Quebec, Canada H3A 2B4

Currently the function of truncated *trkB* receptors (*trkB*-T1) on glia in the adult CNS and their role in promoting or inhibiting axonal regeneration are unknown. Our data indicate that mature CNS glia in myelinated pathways up-regulate *trkB*-T1 receptors in response to axonal degeneration, whereas PNS Schwann Cells down-regulate this receptor. Given the failure of CNS regeneration, these observations suggest that *IrkB*-T1 receptors on non-neuronal cells may hinder axonal regeneration. To further evaluate this hypothesis. *IrkB* expressing SY5Y neuroblastoma cells were seeded on monolayer substrates of 3T3 fibroblasts or stably transfected 3T3 cells expressing Given the failure of CNS regeneration, these observations substrates of 3T3 fibroblasts or stably transfected 3T3 cells expressing trkB-T1 receptors. Phosphorylation of trkB receptors and neurite outgrowth (at 48hr) were evaluated at various concentrations of BDNF (0, 5, 25, and 100ng/ml). In the co-culture experiments, trkB-T1 on 3T3 cells reduced the percentage of SY5Y cells developing neurites and greatly inhibited both BDNF-induced neurite extension and trkB receptor phosphorylation on SY5Y cells. These results suggest that trkB-T1 on non-neuronal cells can block activation of neuronal trkB receptors and inhibit neurite outgrowth by a transcellular mechanism. Thus, truncated trkB receptors may contribute to the lack of axonal regeneration from BDNF responsive neurons that is observed following CNS lesions in adults. Supported by NIH grant NS-31445 by NIH grant NS-31445.

FUNCTIONAL ANALYSIS OF THE TRKB RECEPTOR TYROSINE KINASE. J. H. McCarty and S. C. Feinstein*. Neuroscience Research Institute and Department of Molecular, Cellular and Developmental Biology, University of California, Santa Barbara, CA 93106.

The TrkB protein tyrosine kinase is a high affinity receptor for the neurotrophins brain-derived neurotrophic factor (BDNF) and neurotrophin-4/5 (NT-4/5). Neurotrophin binding leads to activation of the receptor's cytoplasmic tyrosine kinase domain, leading to the autophosphorylation on five intracellular TrkB tyrosines: Y484, Y670, Y674, Y675, and Y785. Phosphorylation of these residues initiates a series of poorly understood cytoplasmic and nuclear signal transduction events, which lead to differentiative or proliferative responses, depending on the cellular context.

To better understand the role of individual autophosphorylation sites in mediating BDNF and NT-4/5 action, we have generated a panel of stably transfected 3T3 and PC12 cells expressing trkB receptors containing a variety of tyrosine to phenylalanine substitutions. These mutant receptors have been assessed for their ability to engage in a number of wild type trkB activities, such as promoting cellular differentiation or proliferation, autophosphorylation, association with SHC, SYP, and PLC-γ and c-fos induction. A comparative analysis of the signaling pathways used in these two cellular contexts will be presented. Supported by American Heart Association #94-421 and PHS grant

Signal transduction of TrkB in septal neurons in primary culture. K. Wada, M. Ishikawa, N. Okada, Y. Iwasaki, and S. Koizumi* International Research Laboratories, Ciba-Geigy Japan Ltd., Takarazuka 665.

Brain-derived neurotrophic factor (BDNF), one of the neurotrophin, promote the survival and differentiation of neurons both in the PNS and CNS stimulates its receptor, TrkB, and the autophosphorylation of TrkB initiates the intracellular signal transduction.

In the present investigation, we have examined the presence of TrkB receptors in septal neurons by immunostaining and western blot analysis. In addition, the association and tyrosine phosphorylation of different intracellular signaling

molecules induced by TrkB stimulation have been studied in primary neurons.

Septal neurons were prepared from fetal rats (E17), plated at the initial cell. density of 1.0 x 10° / cm2 and maintained for 3 days. When the neurons were treated with BDNF, but not NGF, the tyrosine phosphorylation of a Trk family protein(s) was clearly stimulated. In addition, BDNF was more potent than NGF in promoting the survival of septal neurons. In the down stream signal transduction of the receptor, the tyrosine phosphorylation of SHC proteins, PLC and MAP kinase were stimulated with BDNF-treatment.

To confirm that the BDNF activity is mediated through TrkB activation in septal neurons, an immunohistochemical study was performed using specific antibody against the tyrosine kinase domain of TrkB. The staining result clearly demonstrated the presence of TrkB in most of the neuronal population. In conclution, our data supports the importance of TrkB in mediating the action of neurotrophin in septal neurons under this condition.

TRANSCRIPTIONAL REGULATION BY BDNF AND PACAP

INVOLVED IN THE CONTROL OF APOPTOSIS IN CEREBELLAR GRANULAR NEURONS.

Y. Larmet, P. Kienlen-Campard, C. Gaiddon, C. Crochemore, A.L. Boutillier*, J.P. Loeffler, URA 1446 CNRS, IPCB, Université Louis Pasteur, 21, rue René Descartes, 67084 Strasbourg Cedex, France.

The contribution of BDNF and PACAP as well as the transcriptional regulations involved in programmed cell death were investigated in primary cultures of cerebellar neurons. TUNEL histochemistry revealed that K+ deprivation induces extensive neuronal apoptosis, and BDNF or PACAP reverse this effect. Since apoptotic processes require de novo protein synthesis, the regulatory pathways controlling gene expression were investigated. We show that both PACAP and BDNF stimulates c-fos and c-jun mRNA accumulation in cerebellar neurons. Detailed promoter deletion analysis by gene transfer revealed that both ligands operate through the same cis-acting elements. Our results indicate that the SRE, FAP element and the CRE present in the c-fos promoter are able to respond independently to BDNF and PACAP. By using the Gal4-CREB fusion protein to specifically study CRE-driven transcription, we show that BDNF and PACAP stimulates CREB dependent transcription through phosphorylation of Serine 133. In addition, unlike the other activators of CREB in neurons, BDNF neither stimulates the cAMP/PKA pathway (e.g. PACAP, CRH etc...) nor induce detectable variation of intracellular free Calcium(e.g. K+, Glutamate, etc...).Collectively these data indicate that under specific experimental conditions, second messenger-coupled receptors (PACAP) and neurotrophins (BDNF) stimulate a common set of genes although they transduce through distinct regulatory pathways.

399.18

FUNCTION OF trkB NEUROTROPHIN RECEPTOR SPLICE VARIANTS. T. Saarelainen M. Mochniakow + M. Saarma + and E. Castrén . A.I. Virtanen Institute, University of Kuopio, P.O.Box 1627, 70211 Kuopio, Finland, +Institute of Biotechnology, University of Helsinki, 00014 Helsinki, Finland.

Alternative splicing of trkB mRNA generates different trkB isoforms, each possessing the same extracellular and transmembrane domains but differing in their intracellular regions. The full length trk-TK(+) form contains the catalytically active tyrosine kinase (TK) domain but the truncated trk-TK(-) forms lack this domain. Both variants bind BDNF, but only trkB-TK(+) activates intracellular signal transduction. Trk-TK(-) forms may prevent the trophic actions of BDNF by mediating internalization of BDNF into non-neuronal cells. In addition, if the two isoforms are expressed in the same

neurons. trkB-TK(-) may act as a dominant negative receptor.

We are investigating the ability of trk-TK(-) to act as a physiological dominant-negative isoform in neurons. We have created expression constructs of trkB splice variants under CMV or elongation factor 1 promoter. The constructs were mutated to contain an octapeptide tag sequence, which is recognized by a monoclonal antibody (IBI Flag®). These plasmids will be transiently transfected into cell lines and cultured primary hippocampal neurons and the ability of BDNF to induce signal transduction or support survival of transfected cells will be monitored

Supported by Sigrid Jusclius Foundation and the Academy of Finland.

EXPRESSION OF trkB AND trkC mRNAS BY DOPAMINERGIC NEURONS OF THE ADULT RAT VENTRAL MIDBRAIN S. Numan* and K.B. Seroogy. Department of Anatomy & Neurobiology, University of Kentucky, Lexington, KY 40536.

Brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) are two members of the neurotrophin family that have been shown to increase the survival and differentiation of ventral midbrain dopamine neurons in vitro. Since BDNF and NT-3 mRNAs are expressed by midbrain dopamine neurons, these neurons may be able to derive trophic support locally. In order to respond to BDNF or NT-3, the neurons must express the appropriate high-affinity receptors, the tyrosine kinase receptors trkB or trkC, respectively. Although both trkB and trkC mRNAs have been detected in the ventral midbrain, their precise distribution within this region remains to be determined. In the present study, adjacent sections through the adult rat mesencephalon were processed for the in situ hybridization localization of trkB and trkC mRNAs. Double-labeling in situ hybridization was also performed to determine the proportion of tyrosine hydroxylase (TH, a dopamine cell marker) mRNA-expressing cells that also express trkB or trkC mRNA. trkB cRNA-hybridizing cells were densely labeled medially in the substantia nigra pars lateralls, the substantia nigra pars reticulate and the ventral tegmental area. A more uniform and moderate expression of trkC mRNA was observed in all of the above nuclei. The double-labeling results demonstrated that virtually all of the TH mRNA-expressing cells in the ventral midbrain also expressed trkB or trkC mRNAs. In contrast, there were additional cells within the above nuclei that expressed the neurotrophin receptor mRNAs but were not dopaminergic. These results provide evidence that midbrain dopaminergic neurons may be able to derive trophic support in vivo via paracrine and/or autocrine interactions. Supported by NIMH fellowship MH10806 (SN) and the National Parkinson Foundation (KBS).

ACTIVATION OF SHP-2 BY NEUROTROPHIN B.A. Goldsmith*, K.

ACTIVATION OF SHP-2 BY NEUROTROPHIN B.A. Goldsmith*. K. Wada. N. Okada and S. Koizumi. Bio-organics Res. Dept., Int'l Research Laboratories, Ciba Geigy (Japan) Ltd., Takarazuka 665, Japan. Upon ligand binding, the Trk family of receptor tyrosine kinases become autophosphorylated leading to recuitment of proteins to the receptor via Src homology 2 domains (SH2) interactions. Protein tyrosine phosphatases (PTPases) with SH2 domains may play a role in regulating receptor tyrosine kinases. These phosphatases, SHP-1 and SHP-2, may bind to activated receptors or other phosphoproteins to dephosphorylate the targets. This localization may also activate the PTPases by phosphorylation and/or occupation of the SH2 domains. To examine the role of SHP-2 in neurotrophin signalling, we asked whether Trk activation regulates SHP-2 in cortical neurons and PC12 cells. We found that application of BDNF to cortical neurons caused a significant increase in PTPase activity in SHP-2 immunoprecipitates. In addition, BDNF induced the formation of a complex of SHP-2 with tyrosine phosphorylated proteins. In PC12 cells, application of NGF similarly stimulated PTPase activity in SHP-2 immunoprecipitates and induced a complex of tyrosine phosphorylated proteins with SHP-2. In cortical neurons and PC12 cells, Trk receptors activation also increased PTPase activity associated with the receptors. To further characterize the SHP-2/Trk interaction, we are now utilizing an in gel PTPase assay (Burridge and Nelson (1996) Anal. Biochem. 232, 56-64.) to assess whether SHP-2 associates with Trk and Trk-associated proteins.

These results show that Trk stimulation regulates SHP-2 activity and localization, suggesting that SHP-2 plays an important role in regulating the Trk signal. No tyrosine phosphorylation of SHP-2 was detected after neurotrophin treatment, suugesting that the enhancement of PTPase activity may be a result of occupation of SHP-2's SH2 domains by the correcipitated phosphoproteins.

Generation of various major and minor RPTP ζβ isoforms and regulation of their mRNA expression

J. Li*, S. E. Snyder, P. E. Schauwecker[#], T. H. McNeill[#] and S. R. J. Salton. Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, NY, 10029. [#]Andrus Gerentology Center, University of Southern California, Los Angeles, CA, 90089.

The receptor protein tyrosine phosphatase RPTP ζ/β is distributed throughout the rat nervous system, abundantly in the embryonic and early postnatal brain, primarily in astroglia, but also in certain neuronal populations. RPTPζ/β, expressed as chondroitin sulfate proteoglycans (CSPGs), binds to cell adhesion molecules and the extracellular matrix protein tenascin. Previously three major (e.g. phosphacan) and at least one minor isoform of rat RPTP ζ/β have been identified. In this study, we have used genomic southern analysis and genomic library screening to demonstrate that these various rat RPTP ζ/β isoforms are encoded by the same gene and are generated by alternative mRNA splicing. Genomic sequences around exon/intron splicing junctions of all the major $RPTP\zeta/\beta$ isoforms have also been determined. Furthermore, we have found that mRNA expression of these RPTP ζ/β isoforms is differentially regulated during neural development and is induced in regions of axonal sprouting and glial scarring in response to CNS lesions. Supported by grants from the NIH, Pew Foundation and American Paralysis Association.

CLONING AND CHARACTERIZATION OF A NOVEL RECEPTOR PROTEIN TYROSINE PHOSPHATASE EXPRESSED IN RAT BRAIN AND OLFACTORY TISSUE.

L. Rydelek Fitzgerald*, K.M. Walton^, and B.L. Largent, Dupont Merck Research Labs, CNS Molecular Biology Research, Wilmington, DE 19880 and Univ. of Maryland, Dept. of Anatomy,

Baltimore, MD 21201 ^Cephalon Inc., West Chester, PA, 19380. Protein Tyrosine Phosphatases (PTPs) regulate the level of tyrosine phosphorylation within a cell and as a result play an important role in phosphorylation within a cell and as a result play an important role in both neuronal function and development. Here we report the cloning of a novel protein tyrosine phosphatase expressed in rat brain and olfactory tissue. PCR was performed on cDNA from rat olfactory tissue using degenerate primers designed to the conserved catalytic regions of PTPs. A novel PCR fragment showed approximately 73% sequence homology with other PTPs. Northern blot analysis using this fragment as a probe showed expression of a 5.4 kb mRNA in rat brain and to a lesser extent in olfactory tissue. A 5.2 kb clone as well as several other overlapping clones were isolated by screening a rat whole brain cDNA library. Sequence analysis demonstrated that this clone encodes a receptor phosphatase and appears to be homologous to a newly developing subclass of receptor PTPs. Our clone, as well as other previously published clones, contains a single catalytic domain which diverges from the consensus sequence at a critical amino acid previously shown to be important for phosphatase activity on a variety of substrates. The role of this class of putative phosphatases in regulating tyrosine phophorylation has yet to be determined. (NIH Grant DC01946)

400 2

PROTEIN-TYROSINE-PHOSPHATASE 2C IS NECESSARY FOR MAXIMAL ACTIVATION OF THE MITOGEN ACTIVATED PROTEIN KINASE BY THE LEUKEMIA INHIBITORY FACTOR RECEPTOR AND GP130. <u>I.L. Bartoe, S.E. Hamilton*, and N.M. Nathanson.</u> Department of Pharmacology, Univ. of Washington, Seattle, WA 98195.

The neurokines ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF) initiate transmembrane signaling through heterodimerization of two shared receptor subunits, the low affinity LIF receptor α (LIFR α) and gp130 polypeptides. The protein-tyrosine-phosphatase 2C (PTP2C) has been shown to associate with gp130, and the domain necessary for binding of PTP2C by gp130 lies within a region recently identified by our lab as necessary f activation of mitogen activated protein kinase (MAPK). Using chimeric receptors composed of the extracellular domains of the granulocyte colony stimulating factor receptor (GR) and the granuocyte coonly stitutiating factor receptor (GR) and the cytoplasmic domains of either the LIFR α and gp130 (GR/LIFR α and GR/gp130), we have shown that PTP2C is necessary for maximal activation of MAPK by both the LIFR α and gp130 polypeptides. Overexpression of a dominant negative PTP2C construct reduces Overexpression of a dominant negative F1F2C construct reduces MAPK activation by GR/LIFR α and GR/gp130 by as much as 70%, while overexpression of a wild type PTP2C construct had no effect on MAPK activation. Our results suggest that both gp130 and the LIFR α can associate with and activate PTP2C, leading to the activation of MAPK. (Supported by the National Institutes of Health).

DISTRIBUTION OF RECEPTOR PROTEIN TYROSINE PHOSPHATASE KAPPA IN A TRANSGENIC MOUSE BRAIN. P. Shen, P. Canoll, J. Sap, G.I. Botchkina and J.M. Musacchio*

Sap. G.I. Botchkina and J.M. Musacchio*. Dept. of Pharmacology, NYU Medical Center, New York, NY 10016 RPTP-k is expressed at high levels in brain, kidney and liver, and contains an ectodomain that engages in homophilic cell-cell interactions (Sap et al., 1994, Mol. Cell. Biol., 14:1). In a transgenic mouse model, which has a LacZ insertion upstream of the phosphatase domains of the RPTP-k gene (Skarnes et al., 1995, PNAS, 92:6592), visualization of RPTP-k expression by 8-galactosidase activity revealed a widespread, but non-uniform, cellular distribution throughout the brain and spinal cord. The majority of labeled cells occurred in the superficial layers of the cerebral cortex. In the preoptic/hypothalamic area, the suprachiasmatic n., anterior medial preoptic n. and arcuate hypothalamic n. expressed RPTP-k. The medial amygdaloid n. was intensely labeled. Mesencephalic areas with prominent RPTP-k expression included the colliculi, central gray and raphe. RPTP-k was found in the spinal trigeminal n. and raphe. RPTP-k was found in the spinal trigeminal n. and nucleus of the solitary tract in the medulla. In the spinal cord, labeled cells appeared in the dorsal horn and area X. Labeled cells also were found in the trigeminal and dorsal root ganglia. Most labeled cells in the cerebellum occurred in the granule cell layer. Ependymal cells were labeled throughout the CNS. Because these data are consistent with the wildtype RPTP-k immunostaining pattern, this transgenic model may be useful in determining the role of tyrosine phosphatases in the brain.

Wesleyan Univ., Middletown, CT 06459.
Tyrosine phosphorylation appears to be an essential component of many
signal transduction pathways involved in neuronal development and
differentiation. Studies of protein tyrosine kinases and protein tyrosine
phosphatases (PTPs) in the CNS indicate that many members of these
classes of enzymes are likely to exist. We have previously identified and
characterized a family of brain-enriched PTPs designated STEP. Members
of this family of PTPs arise through alternative splicing, with the result that
cytosolic, transmembrane, and truncated forms are expressed in the
nervous system. Here we report findings concerning two novel members of
nervous system. nervous system. Here we report findings concerning two novel members of the STEP family, STEP₆₁ and STEP₃₈. Their NH₂-terminal regions contain several amino acid motifs not present in a cytosolic form, STEP₄₆. These several artiflio acid motifs not present in a cytosolic form, STEP46. These motifs include two putative transmembrane domains, two PEST sequences, and two polyproline-rich domains. Transfection experiments in fibroblasts, as well as subcellular fractionation, sucrose density gradient, immunofluorescence staining, and immunogold EM studies have shown that STEP61 and STEP38 are targeted to the endoplasmic reticulum. Enzymatic assays indicate that STEP61 has approximately 8-fold less phosphatase activity than STEP46. As STEP46 is contained in its entirety within STEP61, our data suggest that the NH2-terminus of STEP61 is responsible not only for targeting STEP isoforms, but also for routering responsible not only for targeting STEP isoforms, but also for regulating

LAR TRANSCRIPTS WITH A CAG-RICH ALTERNATIVE 3' UNTRANSLATED REGION RESULT FROM TRANS-SPLICING. C. Zhang', I.S. Zhang, I.A. Martignetti. S.M. Massa and F.M. Longo. Dept. of Neurology, UCSF/VAMC, San Francisco, CA 94121 and Dept. of Pediatrics, Mt. Sinai Med Ctr, NY, NY.

Trans-splicing of RNA transcripts derived from separate genes has been found in trypanosomes but its existence in mammalian cells is not widely established. The Leukocyte Common Antigen-Related (LAR) gene codes for a tyrosine-phosphatase receptor which may regulate mammalian neural development (Longo et al., JBC 1993). We isolated an LAR cDNA clone containing an alternative 3' untranslated region (3'UTR) with extensive tandem CAG repeats (JS Zhang and FM Longo, JCB 1995). RT-PCR of rat brain mRNA using primers flanking the junction between the known LAR sequence and the alternative sequence verified that these alternative transcripts exist in vivo. Northern analysis of rat cerebellum mRNA with probes corresponding to the constitutive and alternative 3'UTRs further confirmed their presence. Unexpectedly, Southern and PCR analysis of P1 genomic clones (> 80kb inserts) derived with either constitutive (2 P1 clones) or alternative (4 P1 clones) 3'UTR PCR primers showed no overlap. The absence of overlap suggested that the alternative 3'UTR exon was separated from the remainder of the LAR gene by an unconventionally large segment of genomic DNA. Fluorescent in-situ hybridization (FISH) with LAR P1 and alternative 3'UTR P1 probes demonstrated that these loci are in fact on different chromosomes. Thus, LAR transcripts with the alternative 3'UTR are derived by trans-splicing. The existance of trans-splicing in mammalian cells may have important implications for gene mapping and for defining the concept of a mammalian gene. Supported by the ACS (FL), NIA (FL) and VA (FL).

LAR RECEPTOR-DEFICIENT TRANSGENIC MICE: ALTERED EXPRESSION OF NEUROTROPHIN RECEPTORS. T. Yang. Y.M. Xie. T. T. Yeo, and F. M. Longo. Dept. of Neurology, UCSF/VAMC, San Francisco, CA 94121.

Francisco, CA 94121.

Developmentally regulated expression and alternative splicing of the Leukocyte Common Antigen-Related (LAR) tyrosine phosphatase receptor in mammalian neurons suggests a role in neural development (Longo et al., SNS Abst., 1991; Longo et al., JBC, 1993; Zhang and Longo, JCB, 1995). Our previous Northern analyses of LAR-deficient transgenic mice demonstrated decreased LAR transcripts in +/- mice (Yang et al. SNS Abst., 1995). In this study, Western analysis confirmed similar decrease in LAR protein. The tyrosine phosphatases regulating Trk receptor activity are unknown. To analyze potential functional interactions between LAR and neurotrophin receptors, mRNA and protein levels of TrkA, TrkB, TrkC and p75 were examined in LAR +/+, +/- and -/- mice using RT-PCR and Western blots. In -/- mice, there was a significant decrease of TrkA mRNA expression in whole brain at postnatal day 0 (PO) and in the adult hippocampus. TrkA mRNA expression was increased in the adult septum and spinal cord. TrkB mRNA was increased only in the adult hippocampus. No significant cortex and hippocampus and increased in septum. On the protein level, there was a marked reduction of TrkA in whole brain at PO. p75 protein level was unchanged in whole brain at PO but was significantly decreased in the adult. In all cases, intermediate levels of mRNA and protein were observed in +/- mice and in all cases (except expression of p75 protein in the adult) changes in mRNA and protein were correlated. Current experiments will confirm whether neurons derived from +/- and -/- mice have differential responses to neurotrophins. These observations support our hypothesis (Longo et al., JBC, 1993) that LAR-type tyrosine phosphatases regulate neurotrophin function through direct or indirect interaction with neurotrophin receptors. Supported by an AFAR Beeson Award (FL), NIA ROl (FL), VA (FL).

THE ROLE OF PROTEIN TYROSINE DEPHOSPHORYLATION IN ACTIVATION OF VOLUME-SENSITIVE CHLORIDE CHANNELS.

P. Doroshenko. Loeb Research Institute, Univ. of Ottawa, Ottawa, Ontario K1Y 4E9, Canada

Involvement of protein tyrosine kinases (PTK) and phosphatases (PTP) in activation of volume-sensitive CI channels (J. Physiol. 449: 197, 1992) has been studied in bovine chromaffin cells using wholecell patch clamp techniques. PTK inhibitor, tyrphostin B46 (5-20 µM), applied either extra- or intracellularly, did not prevent the current activation by GTPyS or cell swelling. However, sodium pervanadate, an inhibitor of PTP, effectively inhibited the current when added to the patch pipette solution (100-200 μM). To see whether stimulation of protein tyrosine dephosphorylation may result in activation of the Cl channels in the absence of other stimuli, we used a recombinant enzyme, a murine analog of the human T-cell protein tyrosine phosphatase (Mol. Biol. Cell 14: 3030,1994). In preliminary experiments, a slow developing inward current was observed in 13 out of 17 cells perfused with the GST-PTP fusion protein. The current reversed at close to E_{Cl} (0 mV). No current was observed in cells perfused with the PTP inactivated by boiling (4 cells) or by addition of 200 μM sodium pervanadate (4 cells). The 34-kDa catalytic subunit of PTP from Yersinia enterocolitica (Calbiochem) failed to elicit the current when applied in similar conditions. These findings suggest that protein tyrosine dephosphorylation may mediate activation of the volume-sensitive ion channels. Supported by the Loeb Research Institute.

LAR TYROSINE PHOSPHATASE RECEPTOR: EXPRESSION AND FUNCTION DURING SCIATIC NERVE REGENERATION. Youmei Xie*, Tao Yang, Tracy T. Yeo, Cheng Zhang and Frank M. Longo. Dept. of Neurology, UCSF/ VAMC, San Francisco, CA 94121.

Developmentally-regulated expression of the Leukocyte Common Antigen-Related (LAR) tyrosine phosphatase receptor and neuronpreferential alternative splicing suggested that LAR regulates mammalian neural development (Longo et al. SNS, 1991; Longo et al. JBC, 1993; Zhang and Longo, JCB, 1995). In previous studies we found aberrant cholinergic innervation of the dentate gyrus in LAR-deficient transgenic mice (Yang et al SNS 1995 and Yeo et al, submitted). Since LAR is expressed by spinal cord motor and dorsal root ganglia (DRG) sensory neurons (Zhang et al, SNS, 1995) we tested the hypothesis that LAR also functions during peripheral nerve regeneration. We evaluated alternative splicing of LAR in DRG and lumbar spinal cord in response to sciatic nerve transection. RT PCR demonstrated that following transection: i) the proportion of LAR transcripts containing LAR alternatively spliced element-a (LASE-a) decreased in spinal cord; ii) the proportion of LAR transcripts containing LASE-c decreased in spinal cord and increased in DRG; iii) LAR levels increased in spinal cord and DRG. LAR-deficient transgenic mice were used to evaluate neurite outgrowth by the pinch method (performed in a blinded manner) in sciatic nerves 14 days following crush injury. LAR +/- mice (n=5) demonstrated a 27% decrease in outgrowth distance compared to +/+ mice (n=6), (p= 0.001). These studies demonstrate the first peripheral nervous system phenotype for a tyrosine phosphatase transgenic mouse and introduce a major new gene family playing an important role in mammalian nerve regeneration. Supported by: NIA (FL) and VA (FL).

SPATIAL-TEMPORAL EXPRESSION PATTERNS OF THE PROTEIN TYROSINE PHOSPHATASE, PC12-PTP1, IN RAT BRAIN. <u>T.M. Perney* and E. Sharma</u>. Center for Molecular and Behavioral Neuroscience, Rutgers, Newark, NJ 07102.

In the nervous system, protein tyrosine phosphatases play important

In the nervous system, protein tyrosine phosphatases play important role in neuronal differentiation, axon guidance and signal transduction. Recently, a novel protein tyrosine phosphatase (PC12-PTP1) was isolated from nerve growth factor treated PC12 cells (JBC 270: 49-53, 1995). We have begun to examine the expression pattern of PC12-PTP1 mRNA in the rat brain. Two major transcripts of 2.6 and 3 kb are detected on Northern blots of total rat brain RNA (only the 3 kb transcript is present in PC12 cells). Regional analysis of PC12-PTP1 expression revealed that the 3 kB transcript is present in all brain regions, whereas the 2.6 kb transcript is detectable only in the cerebellum and brainstem. *In situ* hybridization histochemistry showed that the subpopulation of neurons with highest levels PC12-PTP1 message are the Purkinje cells of the cerebellum and granule cells of the dentate gyrus

The expression levels of the two transcripts were found to be differentially regulated during early postnatal development. The 3 kb transcript is detected as early as embryonic day 17 and expression levels decrease dramatically between PD14 and PD17. The expression of the 2.8 kb transcript, on the other hand, does not appear until approximately PD14 and is followed by a sharp increase in the expression level that is maintained into adulthood. The switch in the expression levels of the two transcripts occurs at a time when many neurons are becoming both morphologically and functionally mature. It is possible that PC12-PTP1 may play an important role in these developmental changes. (Supported by a Hoechst Celanese/Rutgers Innovative research award)

SOMATOSTATIN (SRIF) INHIBITION OF CELL PROLIFERATION IS IMPAIRED BY E1A ONCOGENE EXPRESSION VIA THE UNCOUPLING OF SRIF RECEPTORS TO PHOSPHOTYROSINE PHOSPHATASES T. Florio*, A. Scorziello and G. Schettini. Dept. Clinical and Experimental Oncology, Univ. of Genoa. IST. Unit of Neuroscience Advanced Biotechnology Center, Largo R.Benzi 10, 16132 Genova, Italy.

The effects of SRIF on the proliferation of PC Cl3 thyroid cell line, the intracellular mechanisms involved and the alterations induced by the malignant transformation of these cells, by means of stable expression of the E1A oncogene, are reported. In PC C13 SRIF inhibited insulin- and insulin+TSH-dependent cell proliferation, blocking the G1-S progression in the cell cycle. These effects were completely reverted by vanadate. suggesting that SRIF may modulate phosphotyrosine phosphatases (PTP) activity. Indeed, SRIF increased by 100% PTP activity. In the E1Atransformed cell line (PC E1A), SRIF was completely ineffective in inhibiting cell proliferation although SRIF receptors were regularly expressed and coupled to adenylyl cyclase activity. Conversely, in PC E1A cells, an alteration in the coupling of SRIF receptors to the phosphotyrosine phosphatase occurred. In conclusion, SRIF activates PTP in PC Cl3 thyroid cells to inhibit cell proliferation, and that the stable expression of E1A oncogene in these cells completely abolishes this antiproliferative effect. (AIRC 1994 to GS and CNR 95.02266 to TF).

EFFECTS OF p75NGFR ANTIBODY ON SURVIVAL OF CULTURED SYMPATHETIC NEURONS. M. Freidin* and M. V. Chao, Dept. Cell Biol and Anat., Cornell Univ. Coll. of Medicine., New York, NY 10021 Sympathetic neurons become dependent on different neurotrophins during

development in direct correlation with the expression of the corresponding high affinity Trk receptor. The low affinity p75NGFR, which binds all neurotrophins with similar affinity, is expressed at increasing levels across development. Neonatal rat sympathetic neurons are dependent on NGF for maturation and survival and express high levels of both Trk A and p75NGFR. To examine the role of p75NGFR on survival of these cells, we treated dissociated cultures of rat superior cervical ganglion cells (SCG) with an antibody to the extracellular domain of the rat p75NGFR (α -pREX). 36-48H cultures were treated with purified α -pREX in the presence of NGF (100ng/ml) and examined after 12-18H. Exposure to the antibody caused a significant decrease in cell survival. The effect was target specific, dose dependent and reversed by cycloheximide and ActinomycinC1. αpREX treatment affected both neurons and nonneuronal cells while withdrawl of NGF affected only neuronal survival. Antibody-mediated cell death was partially blocked by forskolin and unaffected by ceramide. By contrast, NGF withdrawl was partially reversed by ceramide. To examine the cellular mechanism of $\alpha\text{-pREX}$ nuclear extracts from cultured SCG were examined for NFkB and AP1 binding by EMSA. Changes in NFkB and AP1 binding were observed with time following treatment. These effects were attenuated by pretreatment with forskolin and dexamethasone. A different shift pattern and time course for NFkB binding were observed following treatment with TNFα. These results suggest α-pREX stimulates cell death in cultured Moreover, these observations sympathetic neurons through apoptosis suggest a role for p75NGFR in neuron survival

FEATURES OF RECEPTOR ULTRASTRUCTURE REQUIRED FOR NERVE

FEATURES OF RECEPTOR ULTRASTRUCTURE REQUIRED FOR NERVE GROWTH FACTOR SIGNALING. S. Maliartchouk, A. C. Cuello* and H. U. Saragovi. Dept of Pharmacology & Therapeutics, McGill Univ., Montréal, Québec, CANADA.

Nerve Growth Factor (NGF) actions are mediated via distinct TrkA and p75 receptors, but the structure of the functional receptor remains undefined. Although expression of TrkA alone is sufficient for cellular responses, studies have shown that p75 can regulate TrkA-NGF interaction and signal transduction.

Alternative models of functional NGF receptors propose either heteromeric, homodimeric or homooligomeric complexes of TrkA and p75. Models of monovalent, bi-valent, homodimeric and/or heteromeric binding of NGF receptors were experimentally tested using bivalent anti-TrkA or anti-p75 monoclonal antibodies, and their monovalent fragments as artificial ligands. Trophic effects upon neuronal and receptor transfected cell lines were studied after receptor ligation.

ligation.
Results demonstrate that (i) trophic signals mediated Results demonstrate that (i) trophic signals mediated by p75 require simultaneous expression and ligation of TrkA; (ii) p75 homodimerization is absolutely necessary for the trophic effect mediated by this receptor; (iii) TrkA homodimerization significantly enhances its biological activity, and also potentiates the effect of p75 ligation; (iv) TrkA homodimers and p75 homodimers produce more robust cellular responses than TrkA-p75 heterodimers. These data suggest that the functional NGF receptor consists of at least p75 and TrkA homodimers, or higher order oligomers of p75 and TrkA. This work is supported by the Medical Research Council

NEUROTROPHINS ACTIVATE JNK IN CELLS EXPRESSING THE NEUROTROPHINS ACTIVATE JNK IN CELLS EXPRESSING THE LOW AFFINITY RECEPTOR P75LNTR. Christian Lachance, Christine Zeindler, Philip A. Barker*. Center for Neuronal Survival. Montreal Neurological Institute. McGill University, Montreal, Quebec. H3A 2B4 p75LNTR was the first identified member of a superfamily of related receptors which includes CD27, CD30, CD40, 4-1BB, OX40, the fas antigen and the two tumor necrosis factor receptors (TNF-R1 and TNF-R2). The shared homelogy that defines this group resides in conserved. R2). The shared homology that defines this group resides in conserved protein modules, termed Cys repeats. In addition to this extracellular homology, the fas, TNF-R1 and p75LNTR receptors contain an intracellular domain, termed the "death domain", which, in the case of the TNF-R1 and fas, has been implicated in signal transduction events culminating in apoptosis. TNF-R1 signals in part by activating jink/sapk, possibly via a ceramide-dependent pathway, and this activation appears to play a key role in activating the cell death pathway. Using a fibroblast cortansformation paradigm, we have previously shown that p75LNTR overexpression may be linked to cell death. To test if p75LNTR ligation activates jnk, we measured neurotrophin-dependent changes in jnk activation and jun mRNA levels in cell lines. In fibroblasts expressing p75LNTR, NGF produces a modest increases in jnk activity and jun mRNA levels. Differentiated PC12 cells tested in a NGF-deprivation paradigm showed BDNF-mediated increases in jnk activity. To determine paradigm showed BDINT-interfact incleases in Jink activity. To determine the functional consequences of the neurotrophin-mediated activation observed in fibroblasts, MTT assays were performed to determine if neurotrophins affect cell viability. The results show that NGF at high concentrations causes a marked decrease in cell survival. Together, these results suggest that neurotrophins may activate the jnk pathway via p75LNTR and that such activation may affect cell survival. NGF-INSENSITIVE APOPTOSIS INDUCED BY NEXB INHIBITION IN PC12 CELLS, G.Taglialatela* & J.R.Perez-Polo, Dept. of HBC&G, UTMB

The mechanism(s) underlying NGF-mediated rescue of neurons from apoptosis is poorly understood. The report that the transfection of the lowaffinity NGF receptor (p75NGFR) induces apoptosis prompted us to analyze signal transduction in the modulation of apoptosis in PC12 cells. Since p75^{NGFR} and the tumor necrosis factor α (TNF α) receptor (TNFR) belong to the same receptor protein superfamily, the nuclear factor kappa B (NFkB) transcription factor mediating TNFα-induced apoptosis in lymphoid cells could also mediate p75^{NGFR} signal transduction. Here we report that inhibition of NFkB function by treatment with a proteasome inhibitor (PSI) or a mild freeradical scavenger (PDTC) results in apoptosis of rat PC12 cells. Furthermore, NGF did not protect PC12 cells from cell death induced by the inhibition of NFkB. These results indicate that NFkB function is essential to PC12 cell survival and to NGF rescue, consistent with the idea that p75NGFR- and TNFRmediated signal transductions are differentially regulated in apoptosis. In addition these data support the idea that NFkB may be a common downstream signaling element for both p75^{NGFR} and TrkA, the NGF tyrosine kinase receptor that is essential to mediate NGF effects

REGULATION OF P75 NGF RECEPTOR EXPRESSION IN BASAL FOREBRAIN NEURONS AND THEIR AFFERENT PROJECTIONS TO HIPPOCAMPUS AFTER KAINATE-INDUCED SEIZURES.

S. Koh, T. Torgerson and A. J. Cole*, Pediatric Neurology, New England Medical Center, Boston, MA and Epilepsy Research Laboratory, Neurology Service, Massachusetts General Hospital, Harvard Medical School, Boston, MA

Basal forebrain neurons express low affinity NGF receptors (p75NGFR), which interact with both BDNF and NGF, and are dependent on these neurotrophins for survival and differentiation. Systemic administration of kainate (KA) not only induces prolonged seizures, but causes a marked, transient increase in NGF and BDNF mRNAs in hippocampus. Using 192 IgG immunocytochemistry, we studied the changes in the expression of p^{25NGFR} in rats following KA (15mg/kg i.p.) induced seizures. Animals were perfused 12h, 24h, 48h, 72h and 10days after KA. Horizontal sections from control (n=3) and from different time points (n=4 each) were processed together for immunocytochemistry. Adjacent sections were stained with cresyl violet. Dramatic increases in immunoreactive neurons and in immunoreactivity of dendritic plexi are observed in basal forebrain nuclei 12 hr after KA. In addition, intensely immunoreactive axons are clearly visible as they course through fimbria/fornix to form diffusely laminated terminals in hippocampus. By 24-48h, profuse dendritic plexi or axon terminals are no longer visible, and immunoreactive soma appear shrunken, vacuolated and pyknotic. At 72h, remarkable recovery of basal forebrain cell integrity and neurite staining is observed along with reappearance of terminal staining in hippocampus. By 10 days, only a few atrophic, pyknotic immunoreactive profiles remain and severe neuronal loss is seen in CA1-CA3 pyramidal neurons. These studies shows biphasic regulation of P^{75NOFR} expression in basal forebrain projection neurons after KA, likely in response to activity dependent induction of neurotrophins at their terminals. This regulation may underlie synaptic reorganization after repeated seizures Support: Whitehall Foundation

DEVELOPMENTAL AND INJURY-INDUCED ALTERATIONS IN THE EXPRESSION OF THE LOW-AFFINITY NEUROTROPHIN
RECEPTOR (p75) IN THE THALAMIC VENTRAL BASAL COMPLEX (VB) IN RAT. D.P. Crockett*, E. Kim, L. Wang, R.X. Zhang and M.D. Egger. Dept. Neuroscience and Cell Biology, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854-5635

We report on the transient, patterned expression of p75 in the VB of the thalamus, the major thalamic relay for somatosensation. We immunostained the brains of neonates on postnatal days (pd) 0 - 3, 7 - 9 and 14 with an antibody against p75. To compare p75 expression with the developing synaptic organization within VB, we localized the synaptic-vesicle-associated protein, synaptophysin (SYN), on alternate sections. Dense uniform p75 immunoreactivity (IR) was observed on pd 0 - 3. On pd 7 - 9, p75 IR was patterned, reminiscent of cytochrome-oxidase-stained barreloids, a characteristic feature of the VB in rodents. By pd 14, p75 IR was not detectable in VB. Light, but clearly patterned SYN IR was first visible on pd 3, increasing in intensity with age and through pd 14. Infraorbital nerve sectioning on pd 0 disrupted patterned p75 and SYN IR within the ventroposterior medial nucleus in pd 7 - 8 neonates. Lesioning the somatosensory cortex on pd 0 resulted in a complete loss of p75 IR as well as a greatly reduced SYN IR within VB. Intense p75 IR observed in VB during the first two weeks postpartum suggests that p75 plays a significant role during periods of active synaptogenesis and pattern formation.

DEPENDENCE OF BASAL FOREBRAIN CHOLINERGIC INNERVATION OF THE LIMBIC SYSTEM ON THE p75 NGF RECEPTOR. T. T. Yeo*12, F. M. Longo¹, D. E. Bredesen³, L. L. Butcher². ¹Dept of Neurology, UCSF-VAMC, San Francisco, CA 94121; ²Dept of Psychology, UCLA, Los Angeles, CA 90024; ³Program on Aging, La Jolla Cancer Research Foundation, CA92037.

The role of p75 in the development of the basal forebrain cholinergic system was examined using transgenic mice carrying a non-functional p75 gene (p75-knockout mice; K-F Lee et al. 1992). Cholinergic innervation was revealed by use of AChE-histochemistry. Lack of p75 caused a reduction of AChE-positive fibers in several areas of the limbic telencephalon that are heavily innervated by p75-positive basal forebrain cholinergic neurons, including the hippocampus and retrosplenial cortex. In the hippocampus, the most prominent reduction of AChE-fibers was found in areas where cholinergic and p75-positive fibers are colocalized, including the suprapyramidal layer in all CA regions and the supragranular layer in the dentate gyrus. Reduction of AChE-fibers was also observed in cortical layers of the retrosplenial cortex, including layer 1, which is heavily innervated by p75-positive cholinergic fibers in normal animals, and to a lesser extent in layers 2/3 and 5. No apparent difference in the staining intensity of cholinergic cell bodies and patterns of AChE-fibers in the fimbria-formix was observed between wildtype and p75-knockout mice, indicating that the reduction of AChE-fibers in target areas is not due to defects in cholinergic phenotype or a generalized deficiency in neurite outgrowth, but rather a loss of innervation for specific cholinergic targets. These data suggest that p75 is crucial for basal forebrain cholinergic innervation of certain target areas of the limbic system. p75 NGF RECEPTOR BLOCKING PREVENTS DEVELOPMENTAL DEATH OF CHOLINERGIC BASAL FOREBRAIN NEURONS IN VIVO

C.E.E.M. Van der Zee*, G.M. Ross*, R.J. Riopelle*, T. Hagg

Dept. Anatomy & Neurobiology, Dalhousie Univ., Halifax, B3H 4H7, Canada; # Dept. Medicine (Neurology), Queen's University, Kingston, K7L 2V7 Canada

Nerve growth factor (NGF), through activation of TrkA receptor, promotes survival of neurons. Low-affinity NGF receptor (p75) binds all neurotrophins but its functions are just beginning to be identified. p75 can signal independent of TrkA by formation of ceramide and can cause apoptosis in vitro. Here we show in transgenic mice with a null mutation for p75 (p75-KO) that the same number of cholinergic medial septum neurons are present early postnatal and in adults. However, in control mice (wild type parental and two other strains), 25% of these neurons undergo cell death (apoptosis) between postnatal day 6 and 15, suggesting that p75 causes their death. At P6, all cholinergic septal neurons in control mice were p75 immunoreactive (anti-REX antibody) but only 75% had detectable levels of TrkA in control and p75-KO mice (both antibodies: gift from L.F. Reichardt). Beyond P6, the TrkA-positive number remained constant in control and p75-KO mice, suggesting that only neurons that lack TrkA (but with p75) undergo the developmental death, i.e., that p75 induces apoptosis in the absence of TrkA. We have synthesized a peptide, based on the putative p75-interacting NGF residues 28-36, which neurite outgrowth in vitro and inhibits binding and crosslinking of NGF to p75 receptor but not to TrkA. Systemic injection with p75-inhibiting peptide from P0 to P15 in control mice prevented the developmental death of cholinergic septal neurons. Thus, p75 plays a role in apoptosis of developing cholinergic basal forebrain neurons and its pharmacological manipulation can promote neuronal survival, Support: Network of Centres of Excellence, Canada,

401.8

ROLE OF p75 NGF RECEPTOR IN RETROGRADE TRANSPORT OF NEUROTROPHINS BY CHOLINERGIC SEPTOHIPPOCAMPAL NEURONS T. Hagg*, B.M.R. Kramer, C.E.E.M. Van der Zee

Dept. Anatomy & Neurobiology, Dalhousie Univ., Halifax, B3H 4H7, Canada.

The neurotrophins NGF (nerve growth factor), BDNF (brain-derived neurotrophic factor), NT-3 (neurotrophin-3) and NT-4/5 (neurotrophin-4/5) are retrogradely transported from their innervation territories to the neuronal cell bodies of the peripheral and central nervous system. All neurotrophins bind to the low-affinity NGF receptor (p75) whose functions are just beginning to be identified. Besides its role in receptor signaling, p75 appears to be involved in retrograde transport of BDNF and NT-4/5 (and to a lesser extent of NGF) to cell bodies of peripheral sensory neurons (Curtis, Neuron 14:1201). We have shown that adult transgenic mice with a null mutation for p75 have approximately 50% more septohippocampal neurons than control mice (C. Van der Zee, this Volume) and that they have an apparently normal cholinergic innervation pattern in the hippocampal formation. Thus, these p75-deficient transgenic mice provide an excellent opportunity to investigate the role of p75 in retrograde transport of neurotrophins in the central nervous system. The adult transgenic mice and their parental wild type controls (Jackson Labs) were injected into the right hippocampal formation with 0.6 μ l ¹²⁵l-labeled HPLC-purified mouse ß NGF (0.3 pmol; 7 ng; Cedar Lane Inc.). After 24 h, the animals were sacrificed and the percentages of cholinergic septohippocampal basal forebrain neurons that retrogradely transported 1251-labeled neurotrophin will be determined by combined ChAT-immunostaining and emulsion autoradiography. Similar experiments will be performed for recombinant human BDNF, NT-3 and NT-4/5 (a gift from Regeneron Pharmaceuticals Inc.).

The p75 and Trk Receptors Are Expressed in Reciprocal Patterns in a Wide Variety of Non-Neural Tissues During Rat Embryonic Development, Indicating Independent Receptor Functions. Wheeler, E.F.*#; Gong, H.#; Bothwell, M.* #The University of Texas at San Antonio, San Antonio, TX. *The University of Washington, Seattle, WA.

The p75 neurotrophin receptor has been detected in a number of non-neural tissues, especially during development. Reports of Trk receptor transcripts in non-neural tissues raises the possibility that the sites of p75 receptor expression may correlate with Trk receptor expression in developing non-neural tissues. Co-expression of p75 and the Trk receptors would indicate a cooperative function between the two receptor subclasses. To address these questions, the p75 receptor was localized relative to the three known trk receptors during the later stages of embryonic rat development when the highest levels of p75 receptor have been observed in the muscle, maxillary pad, kidney and lung. Using in situ hybridization and immunhistochemical analyses, we show here that the Trk receptors are expressed extensively in these and other non-neural tissues during cell differentiation and tissue morphogenesis but in patterns that are generally reciprocal to p75 receptor expression patterns. The results indicate that the p75 receptor most likely functions independently of the Trk receptors in most developing non-neural tissues. All of the neurotrophin receptors are expressed in patterns that suggest they cooperate in integrating innervation with the development of non-neural tissues. Supported by San Antonio Area Foundation, UTSA Faculty Research Awards, H. F. Kerr Foundation, NIH-MBRS-GM08194-16 and NIH-HL43397.

NERVE GROWTH FACTOR (NGF) INDUCES C-FOS PROTEIN IN TRKA IMMUNOREACTIVE DORSAL ROOT GANGLION CELLS *IN VIVO*. G.J. Michael*, R.K. Joshi, D.L.H. Bennett, S.B. McMahon and J.V. Priestley. UMDS, St. Thomas' Hospital, London, SEI 7EH, UK. Systemic injection of NGF elicits a delayed, but long lasting, centrally-mediated hyperalgesia which has been proposed to involve changes in the expression of

Systemic injection of NGF elicits a delayed, but long lasting, centrally-mediated hyperalgesia which has been proposed to involve changes in the expression of neurotransmitters or neuromodulators by dorsal root ganglion cells. Neuropeptide regulation by NGF has been well documented in a number of in viro and in vivo models. Immediate early genes, which may affect these later alterations in neuropeptide expression, are also known to be induced by NGF in vitro. Whether NGF has similar effects in vivo has not been established. In this study, we examine the effects of in vivo administration of NGF on the expression of the immediate early gene product, c-fos, in lumbar dorsal root ganglion cells. Anaesthetized, male Wistar rats were implanted with intrathecal cannulae which were inserted at the level of the L6 and S1 vertebrae and then advanced beneath the dura to the level of the lumbar enlargement. After recovery of three days, NGF (50 µg in 100 µl saline) or vehicle was administered intrathecally via the cannulae. Animals were sacrificed by perfusion and dorsal root ganglia were processed for c-fos immunohistochemisty. Three hours after NGF administration a dramatic induction of c-fos immunoreactivity was observed in ganglia extending from L1 to S1. Up to 40% of DRG cells showed c-fos immunoreactivity. Intrathecal administration of vehicle or BDNF using the samp protocol had little effect on c-fos immunoreactivity in DRG cells. Intraperitoneal injection of NGF (3mg/kg) elicited a similar c-fos expression pattern, however the staining was less intense. Using dual colour immunoreactivity in procession which might count for the trkA immunoreactivity. The confined exclusively to the trkA immunoreactivity in DRG cells. Threse results indicate that NGF is capable of activating c-fos via the trkA receptor in vivo. The induction of immediate early gene expression in dorsal root ganglia is hypothesized to mediate further alterations in gene expression in dorsal root ganglia is hypothesized to mediate further alterations i

DELINEATING THE MECHANISM OF ACTION OF RETINOIC ACID ON CNS NEURONAL DIFFERENTIATION. W. M. W. Cheung*, A. H. Chu, M. F. Leung and N. Y. Ip. Department of Biology, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong.

Retinoic acid (RA) induces human embryonal carcinoma cells (NT2/D1) to undergo terminal differentiation and become postmitotic CNS neurons The underlying molecular mechanism by which RA induces neuronal differentiation, however, is not known. As part of an effort to investigate the potential involvement of the neurotrophic factors in the actions of RA, we have examined the expression of the Trk receptors in NT2/D1 cells after RA treatment. Our findings demonstrated that the mRNA expression of all three human trk receptors (trkA, trkB and trkC) was upregulated by RA in NT2/D1 cells, raising the possibility that the coordinated upregulation of these receptors may be involved in the RAinduced differentiation of the neuronal progenitor cells into postmitotic human CN5 neurons. This is consistent with our finding that treatment of NT2/D1 cells with multiple neurotrophic factors was able to drive a proportion of these cells into differentiated CNS neurons, in a manner similar to that observed with RA, albeit with a faster time course. further elucidate the mechanism of action of retinoic acid, RNA fingerprinting by arbitrarily primed PCR was used to identify transcripts that are differentially expressed upon RA treatment. Our findings revealed that RA treatment of NT2/D1 cells induced the expression of clathrin as well as several novel genes. Similar studies with neurotrophic factors should provide insight into the molecular mechanism underlying the effects of RA on CNS neuronal differentiation.

A MUTANT V-CRK ADAPTOR PROTEIN DISSOCIATES NGF-INDUCED SIGNAL TRANSDUCTION FROM NEURITE ELONGATION IN PC12 CELLS. <u>J.C. Courtney¹, K.K. Teng², R.B. Birge³, <u>J.A. Wagner¹</u>, and <u>B.L. Hempstead^{1,2}</u>. Program in Neuroscience¹, Division of Hematology², Department of Molecular Oncology³, The Rockefeller College, and Department of Molecular Oncology³, The Rockefeller</u>

University, New York, NY 10021.

Ectopic expression of the adaptor protein v-Crk in PC12 cells augments NGF-induced neurite outgrowth while stable expression of a SH2 mutant v-Crk protein v-Crk(R273N) delays NGF-induced neuritogenesis. Although a sustained activation of NGF-induced signaling pathways correlates with augmented neuritogenesis in v-CrkPC12 cells, the inhibitory effect of the v-Crk(R273N) on neurite elongation does not result from impaired Trk A dependent signaling and gene induction; these responses to NGF are either prolonged or unchanged in the v-CrkPC12 or v-Crk(R273N)PC12 cells as compared to native PC12 cells. Immunofluorescence studies and Triton X-100 extraction experiments establish that v-Crk co-localizes with the cytoskeletal protein paxillin in the actin cytoskeleton whereas the v-Crk SH2 mutant v-Crk serves to uncouple signaling events from the cytoskeletal interactions necessary for neurite elongation. Furthermore, the neurotrophin receptor p75 in v-Crk PC12 cells displays enhanced localization to the cytoskeleton and these cells have an increased rate of NGF internalization, implicating a direct action of v-Crk on NGF receptor trafficking. Taken together, the data suggest that a major cellular target of v-Crk is the neuronal cytoskeleton and the v-Crk targets NGF-activated receptor signaling complexes to this subcellular compartment; thereby directly potentiating the neuritogenic action of NGF at the level of the growth cone. NGF/TRKA SIGNALING IN THE SN56 MURINE SEPTAL CELL LINE .

<u>B. Berse*</u>¹ and <u>J.K. Blusztajn</u>^{1,2}, Departments of ¹Pathology and ²Psychiatry, Boston University School of Medicine, Boston, MA 02118.

TrkA tyrosine kinase is the high affinity receptor for nerve growth factor (NGF), and is essential *in vivo* for the survival, differentiation, and growth of sympathetic neurons, subpopulations of neural crest-derived sensory neurons, and striatal and basal forebrain cholinergic neurons. However, the majority of the data on NGF/TrkA signal transduction *in vitro* have been obtained from a single model system, rat phaeochromocytoma PC12 cells. In order to study TrkA-mediated signaling in cholinergic cells, we transfected *trkA* cDNA, under the control of the murine sarcoma virus long terminal repeat promoter, into a mouse septal cholinergic cell line SN56. Immunobloting with an anti-TrkA antibody indicated that the transfected clones express varying amounts of TrkA protein. In one TrkA-positive clone, T17, NGF treatment (100 ng/ml) induced better attachment to the substratum and prominent neurite formation. The growth rate of two other clones was markedly increased in a medium containing NGF (200 ng/ml), whereas the growth rates of untransfected SN56 cells and a TrkA-negative transfectant, T1, were not affected by NGF. These data indicate that NGF and TrkA can modulate both cell growth and differentiation. On the molecular level, we showed that stimulation of the TrkA-positive transfectants with NGF induced a rapid increase in tyrosine phosphorylation of many protein species, including the adaptor protein SHC. We also assayed the effect of NGF on cytosolic free Ca³⁺ concentration ([Ca²⁺]) by Fura-2 fluorescence. Basal [Ca²⁺], in the trasfectants was approximately 100 nM. Application of NGF caused a small but sustained elevation of [Ca²⁺], in clone T22, whereas the response was transient in clone T17, which expresses a lower level of TrkA. The [Ca²⁺], response appears to be mediated by TrkA, as no measurable changes were observed in the TrkA-negative clone T1. Thus, both major signalling pathways initiated by NGF, one involving SHC, and one mediating the calcium response, are functional in SN56 cells ex

AG879 BLOCKS NGF MODULATION OF iCGRP RELEASE AND PHOSPHORYLATION OF trk A. WR Bowles*, RM DeCamp, CM Flores & KM Hargreaves. Dept Rest Sci, Univ of MN School of Dentistry, Minneanolis. MN.

NGF has been shown to involved in hyperalgesia (Lewin et al; J Neurosci. 13:2136, 1992; Kehl et al; IASP abst, 1996). NGF interaction with its high affinity receptor, trk A, is thought to initiate signal transduction through tyrosine phosphorylation (Kaplan et al, J. Neurobiol 25:1404, 1994). We have shown previously that high concentrations of NGF stimulate release of iCGRP from bovine dental pulp in an in vitro superfusion model. Pretreatment of tissue with the tyrphostin AG879 (which blocks autophosphorylation of trk A) inhibits this release by >90% of the control response (p< .01). To examine the phosphorylation event, NGF(7.4 nM), a combination of AG879(40µM) and NGF(7.4 nM), or Krebs buffer alone, were applied to bovine dental pulp during in vitro superfusion. Tissue was removed, homogenized, and proteins separated by SDS-PAGE and transferred to nitrocellulose. Blots were probed with anti-trk (Santa Cruz, CA) or anti-phosphotyrosine (UBI) and immunoreactivity visualized and quantitated using an imaging densitometer (BioRad). Anti-rrk A and anti-phosphotyrosine antibodies both identified a 140 kD band Administration of NGF to dental pulp evoked > 50% increase in the antiphosphotyrosine band density. Further, co-administration of AG879 and NGF to dental pulp blocked NGF effects on peptide release and phosphorylation of the 140 kD band. Collectively, these data indicate that autophosphorylation of trk A is necessary for modulation of neuropeptide secretion. Further, evaluation of trk A phosphorylation may be a useful method for determining activation of this pathway during tissue inflammation, injury, or development. Expression of Human trkA Receptors in trkA-deficient PC12/Endothelial Hybrid Cells (PC12EN) Results in Nerve Growth Factor (NGF)-induced DNA Synthesis. H. Jiang*, P. Lazarovici, V. Movsesyan, M. Fasler, M. Whalin, Y. Katagiri, M. Monshipouri, G. Dickens, P.J. Lelkesf. and G. Guroff, Section on Growth Factors, NICHD, NIH, Bethesda, MD 20892 and ¶ Laboratory of Cell Biology, Dept. of Medicine, Univ. of Wisconsin, Milwaukee, WI 53201-0342

NGF, an important neurotrophin, regulates proliferation, differentiation and survival in sympathetic and sensory neurons using trkA receptor tyrosine kinase activity. These different biological effects of NGF signalling depend on trkA substrates which probably differ between neurons. To better define trkA receptor substrates and NGF proliferative signalling, we have stably transfected PC12EN with an expression vector encoding the full-length human trkA cDNA. Two stably transfected clones overexpressing trkA with high affinity (PC12EN-trk3, K_d-57.4 pM, Bmax-9.7 fmole/mg) and low affinity (PC12ENtrk1, K_d-392.4 pM, Bmax-57, fmole/mg) binding were generated. RT-PCR and immunoblot analysis indicate the absence of trkA in parental cells and stable expression of trkA transcripts and protein in PC12EN transfectants. Radioreceptor assays indicate that transfected trkA receptors show slow dissociation kinetics, are resistant towards trypsin or Triton X-100 treatment and internalize or downregulate similarly to the native PC12 trkA receptors. Furthmore, in both clones, NGF stimulates trk and erk tyrosine phosphorylation in a dose- and time-dependent fashion, a process inhibited by 200-1000 nM K 252a (a selective trk inhibitor). NGF treatment in low serum media stimulated 1.3- and 2.3-fold increase of DNA synthesis measured by ³H-thymidine incorporation in PC12EN-trk1 and PC12EN-trk3, respectively. This effect is comparable to the mitogenic stimulation of bFGF and serum under identical conditions. These data emphasize the functionality of the transfected receptors and indicate these transfectant cells can serve as a novel cellular model to study the mitogenic properties of NGF and substrates of trkA receptors.

EXPRESSION, PURIFICATION, AND CHARACTERIZATION OF THE EXTRACELLULAR DOMAIN OF TRKA RECEPTOR. Sang B. Woo* and Kenneth E. Neet. Dept. of Biological Chemistry, Finch UHS/The Chicago Medical School, N. Chicago, IL 60064

The 373 amino acid extracellular domain of human TrkA receptor for nerve growth factor (NGF) was overexpressed in Sf21 insect cells and purified to homogeneity. NH2-terminal sequencing and analysis of the amino acid composition verified the authenticity of the recombinant TrkA-RED. TrkA-RED also inhibited the neuritogenic activity of NGF on PC12 cells. Reduction of the molecular weight on SDS-PAGE from 70 kDa to 52 kDa upon treatment with an endoglycosidase suggested a high degree of glycosylation of the polypeptide. *In vitro* binding assays were performed with NGF to confirm the receptor capability of TrkA-RED. The formation of the NGF-TrkA-RED complex was shown qualitatively by retarded migration of TrkA-RED complex was shown qualitatively by retarded migration of TrkA-RED on a native gel in the presence of NGF at neutral pH, crosslinking studies with 1251-labeled NGF to TrkA-RED with disuccinimidyl suberate (DSS), and Superose 12 FPLC gel filtration chromatography from a mixture of NGF and TrkA-RED. Quantitative kinetic analysis was conducted with the Pharmacia Bialite biosensor. When NGF was immobilized onto a carboxymethyl sensor chip and TrkA-RED was used as analyte, or vice versa, the association rate was determined to be 104 - 105 M-1s-1, while the dissociation rate was in the range of 10-2 - 10-3 s-1. These results suggest that the recombinant TrkA-RED adequately mimics TrkA receptor binding to NGF, but with a somewhat lower equilibrium association constant, and is an appropriate system in which to study the details of NGF-TrkA interactions. (Supported by NIH grant NS24380)

402.8

DIFFERENTIAL LOCALIZATION OF trkA & p75 NEUROTROPHIN RECEPTORS IN POSTNATAL & ADULT SYMPATHETIC NEURONS. J.Kohn*, J. Toma, G.A. Kuchel and F.D. Miller. Centre for Neuronal Survival, Montreal Neurological Institute, Montreal. PQ. Canada.

Biological responses of sympathetic neurons to NGF may be partially regulated by the spatial distribution of TrkA and p75 receptors along the neuronal surface. Previous work in our lab has shown that NGF-inducible gene expression (tyrosine hydroxylase and p75 mRNAs) in cultured postnatal sympathetic neurons is regulated as a function of the cellular localization of the activated ligand-receptor complex. To visualize distribution of trkA and p75 along the neuronal surface, we performed immunocytochemistry with antibodies against these receptors. Immunocytochemical analysis revealed very little trkA staining on neuritic processes, but a high relative density on cell bodies, while p75 density was similar on both neurites and cell bodies. To obtain a more quantitative measure of relative receptor levels on cell bodies versus neurites, results were analyzed densitometrically using confocal microscopy on neurons cultured in 20 ng/ml or 50 ng/ml NGF. Regardless of NGF concentration, there was 3-4 times more trkA and approximately 1.6-fold more p75 on cell bodies than on neurites. To confirm that distribution observed *in vitro* was representative in vivo distribution, immunocytochemistry with the same antibodies was also carried out on tissue sections of adult rat SCG and one of its targets, the pineal gland. TrkA and p75 were both distributed diffusely throughout the SCG. In the pineal gland, however, p75 antibody stained the entire axonal arbor, while trkA was distributed in a punctate pattern, suggestive of varicosities of nerve terminals. These data suggest that biological responses of sympathetic neurons to the trkA ligands NGF and NT-3 may be regulated as a function of the spatial source of the neurotrophin. TRKA IMMUNOREACTIVITY INCREASES IN THE DRG NEURONS AFTER PERIPHERAL NERVE INJURY IN THE RAT. H. Shen, K. Chung and J. M. Chung*. Marine Biomed. Inst., Depts. of Anat. & Neurosci. and Physiol. & Biophys., Univ. Texas Med. Br., Galveston, TX 77555.

A neurotrophic receptor trkA is responsible for signal transduction triggered by nerve growth factor, which is critical for the normal metabolism and survival of sensory neurons. There have been conflicting reports about the effects of peripheral nerve injury on trkA mRNA expression in dorsal root ganglion (DRG). The aim of the present study was to determine the trkA receptor regulation in the DRG after peripheral nerve injury in the rat.

Young adult male rats were subjected to a unilateral spinal nerve ligation. Rats were sacrificed by perfusion at various time points after the surgery. TrkA expression was identified by staining for immunoreactivity (IR) with polyclonal antibodies to trkA (Santa cruse, 1:1,000) by the ABC method.

Under normal conditions, some small sized neurons were labeled with trkA-IR. After spinal nerve ligation, the staining intensity and the number of neurons expressing trkA-IR were increased, suggesting an increase in the level of trkA receptor in the DRG after peripheral nerve injury. (Supported by NIH grants NS 31680 and NS 11255)

DEVELOPMENT AND CHARACTERIZATION OF NOVEL TRK-A SPECIFIC MONOCLONAL ANTIBODIES, <u>I.S. Hongo, D.L. Shelton*</u>, H. Phillips, L. O'Connell, R. Urfer, M. Sadick, A. <u>Galloway and B.M. Fendly</u>. Depts. of BioAnaltyical Technology, Neuroscience and Immunology, Genentech, Inc., South San Francisco, CA 175A

A panel of 5 murine monoclonal antibodies (MAbs) specific to the extracellular domain of the trkA receptor have been developed and characterized. Epitope mapping using domain deletion and trkC domain substituted mutants have revealed both unique and overlapping MAb epitope specificities. Two MAbs (1488 and 1503) bind a conformational epitope spanning domains 1-4 (cysteine rich I, leucine rich II, cysteine rich II, Immunoglobulin I domains); MAb 1486 binds an epitope formed by domains 4 and 5 (Immunoglobulin I and II domains); MAb 1487 shows domain 4 specificity (Immunoglobulin I domain), and MAb 1502 is domain 5 specific (Immunoglobulin II domain). Two of the MAbs (1488 and 1503) bind trkA in formalin-fixed chimpanzee, monkey and human tissue. Additionally, MAb 1503 is a potent inhibitor of trkA-NGF binding as determined by a kinase-induced-receptoractivation (KIRA) bioassay. MAb 1487, in conjunction with an anti-NGF specific MAb, has been used to develop a sensitive, quantitative ELISA for the analysis of trkA variants prepared by site-directed mutagenesis. Novel, specific MAbs with varying epitope specificities and functional characteristics should be valuable reagents for both in vitro and in vivo characterization of the trkA receptor and its relationship to NGF. (Genenctech, Inc.)

402.13

TrkA EXPRESSION LEVELS OF SYMPATHETIC NEURONS CORRELATE WITH NGF RESPONSIVENESS DURING DEVELOPMENT AND AFTER TREATMENT WITH RETINOIC ACID. A. von Holst*, F.B. Lefcort# and H. Rohrer, Max-Planck-Institute f Brain Research, Dept. Neurochem., 60528 Frankfurt, Germany; #Dept. Biol., Montana State Univ., Bozeman, MT 59717, USA.

Sympathetic neurons depend on the classical neurotrophin nerve growth factor (NGF) for survival by the time they innervate their targets, but not before. The acquisition of NGF responsiveness is thought to be controlled by environmental cues in sympathetic neurons. In cultures of immature chick sympathetic neurons, which do not respond to NGF in vitro, we only detected low mRNA expressionlevels for the NGF receptor trkA. Treatment with retinoic acid (RA) lead to a strong and selective increase in trkA mRNA levels and the induction of NGF-dependent survival. Concommitantly, trkA mRNA expressed at low levels in sympathetic ganglia at embryonic day 6.5 (E6.5) in vivo, increases more than 5-fold between E6.5 and E10 of chick embryo development. In parallel, the number of sympathetic neurons responding to NGF with survival in vitro increases from 0% at E6.5 to almost 100% at E10. A single systemic addition of RA into the egg at E6 lead to an increase in trkA mRNA levels at E6.5, showing that sympathetic neurons can also respond to RA in the in vivo situation. This increase however, is less strong (2-fold instead of 6-fold) and not sufficient to induce NGF-responsiveness in cultures of sympathetic neurons from treated embryos.

To study the developmental expression of trkA protein, immunohistochemical labelling of tissue sections and confocal microscopical analysis were carried out, using a polyclonal antibody specific for chick trkA. Interestingly, trkA immunoreactivity was detected as early as E4 (Hamburger Hamilton stage 23). Expression decreased to undetectable levels around stage 27 (E5) but reappeared at stage 29 (E6.5) and strongly increased up to E10. Thus, trkA expression increases between E6.5 and E10 both at the RNA and protein level. The role of trkA during the first expression phase is under investigation.

CHARACTERIZATION OF THE HUMAN TRKA PROMOTER IN NEUROBLASTOMA CELLS B. Chang. D. Martin-Zanca† D.L. Kilpatrick*, Worcester Foundation for Biomedical Research, 222 Maple Ave. Shrewsbury, MA 01545, USA and †Dept. of Microbiol. and Genetics, Univ. De Salamanca, Salamanca, Spain 37007

Up-regulation of the NGF receptor TrkA plays a critical role in peripheral sympathetic and sensory neuronal development and in regulating cholinergic neurons in the CNS. In addition, elevated TrkA expression is associated with a favorable prognosis for neuroblastoma. Investigating the mechanisms underlying TrkA gene regulation is thus of great importance in understanding nervous system development and in the possible management of neuroblastoma. To this end, we have analyzed the human TrkA promoter in neuroblastoma cell lines that express this protein. A 2.6 kb genomic fragment encompassing the TrkA promoter region was inserted into the pGL3 luciferase reporter and tested by transient transfection. After normalizing luciferase activities using CMV-Bgal, SMS-KCN cells (high TrkA expression) exhibited 5- to 10-fold higher luciferase activity than SH-SY5Y cells, which express TrkA at low to modest levels. Expression of the 2.6 kb promoter construct in TrkA-negative human kidney 293 cells was only 5-10% of that in SH-SY5Y cells. Analysis of a series of deleted reporter constructs in SH-SY5Y cells revealed that 130-bp surrounding the presumptive initiation region is sufficient for activity. Further analysis of the proximal promoter region in human neuroblastoma cells is now underway, including transfection and DNA mapping studies. This work should ultimately help to reveal the factors specifically mediating TrkA transcription in human neuroblastoma tumors. (This was supported by PHS Grant DK-36468)

402.12

NEUROTROPHIN-3 AND NGF DIRECTLY ACTIVATE TrkA BUT DIFFERENTIALLY MEDIATE BIOLOGICAL RESPONSES IN SYMPATHETIC NEURONS. D.J. Belliveau*, C.F. Ibanez and F.D. Miller. Centre for Neuronal Survival, Montreal Neurological Institute, Montreal, PQ, Canada, H3A 2B4.

We have been examining the role of NGF and NT-3 in mediating survival and neuritogenesis in cultured sympathetic neurons. Previous data from our lab has shown that NT-3 can mediate neuritogenesis of sympathetic neurons as well as NGF but cannot mediate survival. Biochemical investigations revealed that induction with NT-3 lead to the autophosphorylation of trkA in addition to trkC in these neurons. In the present experiments we examined whether other neurotrophins had similar effects in sympathetic neurons and, in addition, if NT-3 directly activated the trkA receptor. Cultures of sympathetic neurons induced for 10 minutes with various neurotrophins revealed that NGF, NT-3 and NT-4/5 resulted in the autophosphorylation of trkA, whereas BDNF had no effect. Survival assays for each of the neurotrophins demonstrated that although the degree of trkA phosphorylation was similar, NT-3 mediated 2-4 fold greater survival than NT-4/5. NGF, conversely, induced greater trkA autophosphorylation and survival than any other neurotrophin. In attempting to determine if NT-3 mediates its effects directly through trkA, we used a mutant NT-3 (Ryden and Ibanez, J. Biol. Chem. 271: 5623, 1996) which could bind only trkC, not trkA. Induction assays on trk-transfected fibroblasts and sympathetic neurons confirmed the effectiveness of the mutant NT-3. Survival assays with 50-100 ng/ml wild type NT-3 mediated the survival of 50-65% of sympathetic neurons respectively whereas the mutant NT-3 mediated less than 5% survival. These data provide strong evidence indicating that multiple neurotrophins may act through one receptor to mediate a variety of biological responses. THEORETICAL STUDIES ON THE BIOACTIVE CONFORMATION OF NERVE GROWTH FACTOR FOR TRKA ACTIVATION. I.L. Shamovsky, G.M.Ross, R.J.Riopelle and D.F.Weaver. Departments of Chemistry and Medicine, Queen's University, Kingston, Ontario, Canada K7L 3N6.

While the amino and carboxyl termini of NGF are endowed with trkA receptor activating properties, their conformations have not been resolved in X-ray studies. Monte Carlo simulated annealing algorithm is utilized to determine the most stable conformations of the termini of different NGF analogues in order to identify their bioactive conformation. Stereospecific interaction of the termini of dimeric (1-118)NGF results in the formation of two distinct moieties of the complex: a rigid region (residues 9-11 and 112'-118') and a flexible loop (residues 1-8), with residues 6-9 adopting a β pleated sheet motif. The geometry of the rigid region, which is mainly maintained by electrostatic interaction between Glu and Arg is conserved in active molecules only. Currently available experimental data on 21 molecules (117-, 118- and 120-residue NGF analogues and their deletion and point mutations) are interpreted using this structural model.

A p75NTR-trkA HETERODIMER IN PC12 CELLS IS AN NGE RECEPTOR COMPLEX WHICH DISSOCIATES IN THE PRESENCE OF LIGAND. G.M. Ross*, G. Lawrance, M. Solc, and R.J. Riopelle. Apps Research Centre, Queen's University, Kingston, Ontario, Canada K7L 2V7

The ability of the low affinity neurotrophin receptor p75NTR to influence a variety of high affinity trkA receptor mediated biochemical and biological outcomes has been well documented. In order to explain this phenomenon, several models have been proposed to suggest a mechanism whereby the low affinity receptor could alter the binding and signal transduction properties of the high affinity receptor. Fundamental differences between these models include the existence of a p75^{NTR}-trkA heterodimer (eg. a "conformation" model) versus an indirect interaction of these proteins (eg. a "presentation" model). We have used BDNF as a p75^{NTR} specific ligand to probe the effects of the low affinity receptor on trkA binding and phosphorylation. In the presence of saturating concentrations of BDNF, we demonstrate a significant reduction of trkA affinity for NGF as well as reduced trkA phosphorylation. These data are consistent with a direct interaction of the receptors, which has prompted us to develop an affinity crosslinking system to demonstrate directly a heterodimeric complex of trkA and p75NTR. The receptor complex is consistent with a high affinity binding species which appears to dissociate upon binding to ligand Supported by Allelix Biopharmaceuticals Inc.

CEREBRAL CORTEX AND LIMBIC SYSTEM

403.1

EARLY RESTRICTION OF DEVELOPMENTAL POTENTIAL AND LATER REGULATION OF DIFFERENTIATION IN CORTICAL PRECURSOR CELLS FOR NEURONAL EXPRESSION OF LATEXIN. Y. Arimatsu*, M. Ishida, K. Takiguchi-Hayashi, Y. Uratani, M-H, Jin and M. Sato. Mitsubishi Kasei Inst. Life Sci., Machida-shi, Tokyo 194, Japan.

Latexin is expressed in neurons in infragranular layers of lateral (L), but not dorsal (D), neocortex in the rat (PNAS 89,8879,1992). To understand the region-specific differentiation of latexin(+) neurons, we monitored latexin expression in fetal cortical cells in vitro. BrdU-labeled cells from a L or D portion of the cerebral wall of E13-20 rat fetuses were maintained in a reaggregated-cell culture with an excess of unlabeled cells from either L or D cortex of the same age. Substantial E13-20 Lcells, but far less D cells, became latexin(+) in vitro with either L or D cells. E13-18 L cells becoming latexin(+) were significantly fewer with D than L cells white E20 L cells becoming latexin(+) were almost the same with D and L cells. These results suggest 1) that E13-20 D cells are restricted in their ability to differentiate to latexin(+) neurons, 2) that E13-20 L cortex contains precursor cells with developmental potential to become latexin(+) neurons, 3) that the fate of L cells has not been determined ultimately at E18, and 4) that, at least until E18, there is a regional difference between D and L cortex in the ability to influence latexin expression in L cells. To address whether the apparent difference between the results with E13-18 cells and that with E20 cells were due to 1) completion of terminal differentiation of L cells at around E20, or due to 2) loss of regional difference at around E20 in the ability to influence cell differentiation, we performed a around E20 in the ability to influence cell differentiation, we performed a heterochronic mixed-region reaggregated-cell culture experiment. L cells, either from E18 or E20 rats, that became latexin(+) were fewer with E18 D cells than with E18 L cells, but were almost the same with E20 D and E20 L cells, showing that the second possibility is more conceivable. Taken together, we propose that the neocortical regional specificity represented by latexin(+) neurons is substantiated early by restriction of developmental potential in certain cortical progenitors but that terminal differentiation of competent precursors can be regulated by environmental cues even after their final mitosis. Supported by Mitsubishi Kasei Inst. Life Sci.

403.3

TARGETED MUTATION OF THE TBR-1 GENE CAUSES ABNORMAL DEVELOPMENT OF THE CEREBRAL CORTEX AND OLFACTORY BULB. R. F. Hevner*, S. Smiga, A. Bulfone, J. J. Meneses, R. A. Pedersen, and J. L. R. Rubenstein. Dept. of Psychiatry, Nina Ireland Lab., and Lab. of Radiobiol. and Environ. Health, UCSF, San Francisco, CA 94143-0984. The Tbr-1 gene encodes a putative transcription factor that is expressed in

postmitotic neurons of the cerebral cortex and clfactory bulb almost exclusively (Bulfone et al., Neuron 15:63-78). To investigate the role of Tbr-1 in brain development, we used gene targeting in ES cells to disrupt Tbr-1 and generate mutant mice. Animals heterozygous for the mutation are generate mutant mice. Animals heterozygous for the mutation are phenotypically normal. Homozygotes generally die on the first day of postnatal life, apparently due to poor feeding; with assisted feeding, some animals survive to adulthood. Mutant homozygotes have severely atrophic, disorganized olfactory bulbs with some well-formed glomeruli but no mitral cell layer. A few large neurons do persist in the bulbs, but it is unclear as yet whether they represent mitral or tufted cells. The lateral olfactory tracts and primary olfactory (piriform) cortex are severly atrophic or absent. The isocortex in neonatal animals is thin, lacks a well-formed subplate, and has few or no Cajal-Retzius neurons. The somatosensory barrels, which form characteristic modules in the normal isocortex, are not detectable by cytochrome oxidase histochemistry in adult homozygotes. Posterior cortical regions (including the occipital pole, entorhinal area, and subicular complex) contain abnormally large clusters of neurons. The hippocampus proper and dentate gyrus display a normal cytoarchitecture.

These findings indicate that Tbr-1 expression is essential for normal development of the olfactory bulb and cerebral cortex. Further studies are in progress to determine which steps in development (e.g., cell differentiation, migration, or survival) are disrupted by the mutation. Supported by grants from the March of Dimes, NARSAD, and NIMH (RO1 MH49428-01 and KO2 MH01046-01) to JLRR.

VENTRICULAR ZONE GENE-1 (VZG-1), EXPRESSED WITHIN THE EMBRYONIC VENTRICULAR ZONE OF THE CEREBRAL CORTEX, ENCODES A LYSOPHOSPHATIDIC ACID RECEPTOR. L. H. Hecht, J. A. Weiner, and J. Chun*. Dept. of Pharmacology and Program in Neurosciences,

School of Medicine, University of California, San Diego, La Jolla, CA 92093-0636.

Molecular studies of signaling pathways regulating cortical neurogenesis within the molecular studies of signature pathways regiming conteal neurogeness winning poliferative ventricular zone (vz) have implicated receptor tyrosine kinases (RTKs). However, properties of G-protein coupled receptors (GPCRs) suggest that they could also regulate cortical neurogenesis. This question was addressed by using a novel murine telencephalic cell line (line TSM, Chun and Jaenisch, Molecular and Cellular Neuroscience, in press) to isolate GPCRs via degenerate oligonucleotide PCR. One PCR product, which had homology to GPCRs and was expressed in the vz, was used reck product, within an internal monogy to offers and was expressed in the 22 was assist to isolate a novel GPCR, termed v.g.-1. Northern blot analysis with v.g.-1 detected a 3.8 kb transcript in the brain by embryonic day 13 (E13). In situ hybridization to E12 to E18 embryos demonstrated that v.g.-1 expression within the vz follows cortical neurogenesis. Transient overexpression of v.g.-1 in TSM cells induced scrumdependent neurite retraction and sustained cell rounding. Lysophosphatidic acid (LPA), a bioactive lipid present in high concentrations in serum, reproduced the effect (LPA), a movering upon present it ringit concentrations in settini, teproduced the effect of serum on transfected cells. Stable TSM transfectants overexpressing vzg-1 in the sense and antisense orientations were generated. Compared to controls, sense transfected lines had enhanced responses to LPA, and antisense lines had reduced responses. LPA, but not four related phospholipids, induced vzg-1 dependent ustained cell rounding. Ligand binding indicated sense overexpression was associated with an increase in specific LPA binding. Western analysis with anti-Vzg-1 antiserum detected a protein of 41-42 kDa, consistent with previous studies using photolabeling. The adult tissue distribution of vzg-1 is consistent with previous photoaceting. The adult tissue distribution of vzg-7 is consistent with previous studies of functional LPA receptors. In addition to describing the isolation of an LPA receptor, this study suggests that bioactive lipid signaling, mediated by pathways distinct from RTKs, may be an important regulator of cortical neurogenesis. FUNCTIONAL IPSILATERAL CORTICOSPINAL PROJECTIONS IN THE PRESENCE OF EITHER HOMOTOPIC OR HETEROTOPIC E17 CORTICAL TRANSPLANTS. S. Barbay* B. Shi & B. B. Stanfield. Lab. of Neurophysiology, NIMH, NIH Animal Ctr., Poolesville, MD 20837.

An E17 homotopic transplant placed into a lesion cavity in the rostral cortex of a

newborn rat has been shown to spare sensorimotor behaviors (vibrissae tactile placing and forelimb tactile placing) contralateral to the transplants. A similar lesion, but without a transplant, has been shown to induce an aberrant ipsilateral corticospinal projection from the intact hemisphere. This aberrant projection has been implicated in the sparing of vibrissae tactile placing found in these animals. To explore what role any aberrant ipsilateral corticospinal fibers may play in rat pups receiving transplants anatomical and behavioral experiments were used to test for the presence and function of these fibers following transplantation of fetal tissue in the rostral cortex of newborn rats. Homotopic or heterotopic (occipital) E17 or E15 fetal tissue was transplanted into a lesion cavity placed in the rostral cortex of newborn rats. Similar lesions were placed in control rats with no transplants. Five weeks later, biotinylated dextran was injected into the homotopic contralateral hemisphere of several of these rats and into an additional control group of normal rats. The several of these rats and into an additional control group of normal rats. The remaining rats from each group were assayed for tactile placing behaviors 41 days after birth. One week later the cortical origin of any ipsilateral corticospinal projections was destroyed. Behaviors were assayed again five days later. The results demonstrate that the aberrant ipsilateral projection fibers are present following E17 rostral or occipital transplants. Behavioral tests suggest that these fibers contribute to the vibrissae tactile placing, but not to forelimb tactile behavior seen after E17 homotopic transplants. Thus the behavior of these animals is influenced by both the transplanted tissue and the aberrant projection of the unlesioned hemisphere. The behavioral results from the E15 homotopic and heterotopic transplant groups were similar to the E17 homotopic group. Supported by NIMH.

EFFECTS OF INFRAORBITAL NERVE SECTION ON THE DEVELOPMENT OF INTRACORTICAL CONNECTIONS IN MOUSE BARREL CORTEX. N.M.J. Blake*, B. Miller and T.A. Woolsey. Department of Neurology and Neurosurgery, Washington University School of Medicine, St. Louis MO 63110.

Intracortical axons in rodent barrel cortex connect barrels in the same row and barrels of adjacent rows. Section of the infraorbital nerve (ION) at postnatal day 7 (P7) arrests development of the intracortical connections, resulting in few if any connections with adjacent barrels (PNAS 89: 1832). This pattern is reminiscent of the extent of axon growth in P7 brain (Soc. Neuro. Abs. 21: 44). We sought to examine the developmental window in which disruption of peripheral input affects the pattern of intracortical projections. The right ION was sectioned on P7 or P10, biotinylated dextran amine injected into barrel subfield on P30 and mice sacrificed days later. Tangential sections 40µm thick were processed using the ABC procedure with DAB and enhanced with silver/gold. The position of axons in the supragranular layers was plotted relative to the barrel pattern. Axonal projections were measured in the tangential plane as the average distance from the center of the injection. Labeled axons in the deafferented cortex of animals lesioned at P7 extended only to the limits of the barrel of origin. Axonal projections in animals with ION lesion at P10 however extended into adjacent barrels, a pattern similar to that observed in normal adults. This contrasts with the axonal projections in normal P10 pups, which extend approximately half the adult distance. Additionally, the projections in the P10 ION lesioned animals were significantly more abundant than in normal P10 pups, indicating that additional axon growth occurred in the lesioned animals. These results show that unlike ION section at P7, ION section at P10 does not grossly disrupt normal development of intracortical projections. Thus, after P10, intracortical connections continue to grow in the absence of peripheral input. NEONATAL INFRAORBITAL (IO) NERVE TRANSECTION RESULTS IN AN INCREASE IN THE NUMBER OF CORTICOTRIGEMINAL NEURONS WITH PROJECTIONS TO IPSILATERAL AND CONTRALATERAL BRAINSTEM. W.E. Renehan* and N. Hadzijahic. Lab. of Gastrointestinal, Gustatory and Somatic Sensation, Henry Ford Health Sciences Center, Detroit, MI 48202.

We have previously shown that neonatal IO transection results in an increase in the density of the cortical projection to the ipsilateral trigeminal brainstem nuclear complex (TBNC). In the present study, we sought to determine whether these ipsilateral corticotrigeminal (CT) axons are collaterals of the CT neurons that project to the contralateral TBNC. Fast Blue (FB) was injected into the right or left TBNC and fluorogold (FG) was injected into the contralateral brainstem of normal adult rats and adults that had sustained transection of the left IO nerve on the day of birth. In normal animals, an average of 1.04 % (SE = 0.12) of the labeled neurons in the left (ipsilateral) somatosensory cortex contained both FB and FG. In IOlesioned animals, however, 9.2 ± 3.0 % of the CT neurons in the left cortex were double-labeled. The difference between the number of double-labeled neurons in normal cortex and the number of double-labeled neurons ipsilateral to IO transection was statistically significant (t-test, p < 0.01). We suggest that the results provide evidence that the neonatal IO lesion has caused a significant number of CT neurons to retain a normally transient collateral to the ipsilateral TBNC. Supported by DE 07734.

SUBPLATE DELETION RESULTS IN ABNORMAL FORMATION OF LAYERS IN FERRET SOMATOSENSORY CORTEX. Sharon L. Juliano, Stephen C. Noctor, Sidney L. Palmer. Department of Anatomy & Cell Biology and Program in Neuroscience, USUHS, Bethesda, MD 20814.

The significance of the subplate as an important factor in development of the neocortex has emerged over the past few years. This early-generated cortical layer does not persist into maturity, but plays an important role in forming subsequent cortical architecture. In order to more clearly understand the effect of earlier born cortical layers on the maturation of cerebral cortex, we conducted experiments in which layers of the neocortex were deleted in utero. This was achieved by injections of methylazoxymethanol (MAM) at appropriate gestational ages into pregnant ferrets.

MAM prevents cells from dividing during a specific period of time, therefore blocks generation of a specific population of cells. When layer 3 or 4 of the somatosensory cortex was deleted by MAM injection at E34 or 35, most aspects of cortical organization were relatively normal in neonatal and adult ferrets, except for the absence of the target layer. When the subplate underlying the somatosensory cortex was deleted by MAM injection on E24 or E25, the resulting cortex was markedly disorganized. Although neurons continued to be born, and attempted to migrate, as evidenced by BRDU label, cortical layers did not form properly, a distinct laminar pattern was not seen, and the cortex was very thin (103 μm compared with 376 μm in normal neonatal somatosensory cortex). In normal P1 ferrets, injections of dextrans label precise radial columns consisting of radial glia and neurons migrating to the neocortex. In animals treated with MAM to delete the subplate, the normal radial columnar pattern after dextran injections is highly distorted. Immunoreactivity for antibodies directed against vimentin verify that the radial glia form fan-like arrays, rather than their normal spoke-like pattern. The appearance of the disrupted pattern of vimentin immunoreactivity suggests that the absence of the subplate may result in early differentiation of radial glia into astrocytes. THE DEVELOPMENT OF CORTICOTHALAMIC PROJECTIONS IN THE MOUSE SOMATOSENSORY SYSTEM. B. Miller* and T.A. Woolsey. Dept. of Neurosurgery, Washington University School of Medicine, St. Louis, MO 63110.

Reciprocal connections between the thalamus and cerebral cortex are

Reciprocal connections between the thalamus and cerebral cortex are topographically precise. In rodent barrel cortex, corticothalamic cells in layer 6 are aligned in barrel-associated clusters in register with thalamic arbors in layer 4, and project back to the homotopic barreloid in thalamus and to an arc of barreloids in other rows at the same row position (Hoogland et al. 1987, Exp. Brain Res., 68:73-87). In rodent visual system (Miller et al. 1993, J. Comp. Neurol., 335: 16-41) the arrival of corticothalamic axons is relatively late and immediately topographic. We investigated the development of somatosensory corticothalamic projections by placing crystals of the lipophilic tracer DiI in the ventrobasal (VB) thalamic complex of aldehyde fixed brain. Between postnatal days 2-4 (P2-4), the few DiI retrogradely labeled layer 6 cells in the cortex are widely dispersed and not associated with barrel columns, while thalamic arbors form clear barrel-like clusters in layer 4. In contrast, at P9 large numbers of layer 6 cells are retrogradely labeled and the position of these cells is in register with the columnar position of anterogradely labeled thalamic afferents. Thus, the major contingent of layer 6 corticothalamic projections arrives at the thalamus after thalamic afferents have entered and arborized in layer 4.

GRADIENTS AND TIMING OF THE ARRIVAL OF THALAMIC AXONS IN THE MOUSE NEOCORTEX. F. Polleux*, C. Dehay and H. Kennedy. INSERM U371.18 Av Doyen Lépine 69675 Cedex BRON (FRANCE).

Thalamic afferents (TA) are known to exert a major organizing influence on the developing cortex (Killackey, 1990). The stage of development at which the environmental influence begins is determined by the date of arrival of the TA in the vicinity of the cortex (Kennedy and Dehay, 1993). In this context we have investigated the date of arrival of TA in the vicinity of the developing cortical plate since numerous studies have shown that afferents axons can modulate the proliferative activity of target tissues. We have used multiple injections of the carbocyanine Dil in order to label virtually all the developing thalamic cells on paraformaldehyde fixed mouse embryos ranging from E14.5 to E18.5 (reference day of vaginal plug E1). Using this approach we have found a pronounced gradient in the date of arrival of TA. On E14.5 the first TA exit the thalamus and are located in the internal capsule. On E15.5, TA arrive at the most lateral part of the middle third of the cerebral cortex which roughly correspond to the future primary somato-sensory areas. At E16.5, TA in the middle third are mid-way to the medial wall. At the anterior and posterior thirds, TA have only just contacted the most lateral part of the neocortex. At E17.5, TA have fully innervated the most medial extent of the middle third and are midway to the medial wall in the anterior and posterior thirds. At E18.5 the anterior and posterior thirds of the cortex are fully innervated. This implies that cortical areas originating from the most rostral and caudal thirds of the developing telencephalon are contacted by thalamic afferents at least 24 hours later than the somatosensory field located at the middle third of the cortex.

TRANSPLANTATION OF VENTRICULAR ZONE CELLS INTO LAYER DELETED FERRET SOMATOSENSORY CORTEX. S.C. Noctor*, S.L. Palmer, S.L. Juliano. Neuroscience and Anatomy, USUHS, Bethesda, MD 20814
Our earlier studies determined that timed administration of the anti-mitotic

methylazoxymethanol (MAM) to pregnant ferrets effectively deletes a specific layer of the somatosensory cortex (SSC). After injections timed to delete layer 4, many properties of cortical maturation appear relatively normal, but layer 4 is absent. The current study investigates the possibility that appropriately timed migrating cells can repopulate a missing cortical layer when transplanted into hosts treated with MAM. To test this prospect, we injected MAM into pregnant ferrets at E34 or E36, which deletes layer 3 or 4 of the SSC. On P0 static interface organotypic cultures were prepared from the layer deleted or normal kits. After 1-2 days in culture (DIC), we prepared a cell suspension comprised of cells from the ventricular zone (VZ) underlying the SSC of E34 or P0 normal ferrets. The VZ cells obtained from P0 animals would normally be migrating to layer 2 of the SSC at the time of transplantation. The E34 VZ cells would not normally be migrating at the time of transplantation but would populate layer 4, the missing layer. The cell suspensions were labeled with fluorescent microspheres and transplanted into the ventricular zone or deep intermediate zone of the organotypic slices. Slices were removed from culture at regular intervals up to 7 DIC. Only about 15% of the transplanted cells migrated from the injection site. P0 VZ cell suspensions were more likely to migrate to upper cortical plate in layer-deleted host organotypic cultures. The suspensions prepared from the E34 VZ were more likely to migrate to lower layers in the layer-deleted hosts. The cells were less likely to migrate from the injection site in normal host cultures. These data suggest that layer-deleted host organotypic cultures are a more permissive substrate than normal host cortical cultures and that transplanted VZ cells tend to migrate close to cortical sites they would normally populate according to their date of birth. Supported by PHS RO1 NS24014.

THALAMOCORTICAL DEVELOPMENT IN ORGANOTYPIC COCULTURES OF NORMAL AND MAM-LESIONED FERRET SOMATOSENSORY CORTEX. S.L. Palmer*, S.C. Noctor, and S.L. Juliano. Anatomy and Cell Biology & Neuroscience, USUHS, Bethesda, MD 20814.

To understand factors involved in the growth of thalamic axons into somatoser cortex, we examined the effect of maintaining organotypic cultures of thalamus with either normal or layer-deleted cortical slices. Cortical layers were deleted by injections of methylazoxymethanol acetate (MAM) into pregnant ferrets on appropriate gestational days. In ferret, the thalamic recipient layers (3&4) of somatosensory cortex are deleted by in utero injections of MAM at E34 or E36. On PND 0, cortical slices prepared from normal and E34-36 MAM-treated ferrets were placed in an incubation chamber as static interface cultures. Thalamic slices obtained from PND 0 ferrets were added to the cortical slices after 0-3 days in culture. At various days of coculture (DCC), slices were removed and placed in an oxygenated chamber perfused with artificial CSF; injections of fluororuby were made into the thalamic pieces. In layerdeleted cortex after 3-8 DCC, thalamic fibers terminated in layers 5-6 of the cortex as well as subplate and white matter regions, but did not invade upper cortical plate. Later, at 8-10 DCC, thalamocortical fibers grew into the upper cortical plate. The cocultures of normal cortex and thalamus developed in a similar manner. Thalamic invasion of upper cortical layers in the normal cocultures occurs slightly earlier than in the MAM-lesioned slices however. Even after 3 DCC axons from thalamic cultures grew long distances to terminate near layer 1. In some cases, subplate cells in the cortical cultures established reciprocal connections with the thalamic pieces. Evidence from DiI injections into thalamus of layer 4 deleted brains also demonstrate that thalamic axons do not enter superficial cortical layers at early ages. As reported for in vivo thalamocortical development in the somatosensory system, permissive cues are present in lower layers prior to their appearance in the upper layers. The deletion of layers 3 or 4 delays the invasion of thalamocortical fibers into the cortical plate. Supported by PHS RO1NS24014.

Cortical Neurogenesis in the Tish Mutant Rat: Evidence for Dual Proliferative Zones. J.L. Collins and K.S. Lee*. Dept. of Neurological Surgery, Univ. of Virginia, Charlottesville, VA 22908.

The Tish rat is a neurological mutant exhibiting a bilateral cortical

heterotopia that resembles the human syndrome of double cortex. Previous findings indicate that cells comprising the normal and heterotopic cortices are generated over the entire period of normal neocortical neurogenesis (Collins et al., Soc. Neurosci. Abs., '95). However, the cells in the heterotopic cortex fail to exhibit typical lamination and orientation. The present study examined the birth sites and early migratory paths of cells in the developing cortex of the Tish mutant.

Brain cells undergoing DNA synthesis were labeled between embryonic days 13 and 20 by injecting pregnant Tish dams intraperitoneally with 5-Bromo-2'-deoxyuridine (Brdu). Pups were removed by hysterotomy and sacrificed at 2h, 8h, or 24h postinjection.

Brains from normal rats exhibited typical DNA synthesis near the ventricular zone followed by migration toward the pial surface. In contrast, brains from Tish animals exhibited dual proliferative zones. One zone was in the typical position while a second was displaced radially to a point between the ventricular and pial surfaces. These results indicate that some cortical heterotopias may derive from an early error in the formation of the germinal matrix, rather than resulting from a strict error in the process of post-mitotic neuronal migration. STEREOLOGICAL QUANTITATION OF THE CENTRAL NERVOUS SYSTEM. B. Pakkenberg*, M.J. Bundgaard, C. Fisher, L. Regeur, L. Korbo, B. Bo Andersen, M. West, S. Oster, J. Troncoso, G.B. Samuelsen, U.J. Weber, C.R. Cabello and H.J.G. Gundersen. Neurological Research Laboratory, Bartholin Institute, Kommunehospitalet, 1399 Copenhagen K, and Stereological Research Laboratory, Bartholin Building, University of Århus, 8000 Århus C, Denmark.

New stereological techniques, superior to conventional methods in quantitating macroscopic and microscopic structures in the central nervous system, have been developed within the last decade. Particles of any size and shape can only be sampled with equal probability by the use of a three-dimensional probe. With a combination of the disector and the Cavalieri method, it is possible to obtain an efficient and yet precise estimate of the total number of neurons in any specific region, where a delineation of the region can be made, and the cells identified. Using uniform sampling designs, the efficiency is highly increased: e.g. a subset of approximately 200 uniformly selected disectors from the human neocortex (taken with a known, fixed, but arbitrary probability) is sufficient for the estimation of the total number of nerve cells. The method has been applied to brains from controls, schizophrenics, Alzheimer and AIDS patients and to brains from chronic

TOPOGRAPHIC ORGANIZATION OF SOMATOSENSORY CONNECTIONS IN A NOVEL MUTANT RAT WITH A 'DOUBLE' CORTEX. F. Schottler*, A. Rao, D. Couture, H. Fabiato, and K.S. Lee. Dept. of Neurological Surgery, University of Virginia, Charlottesville, VA, 22908

The present study examined the topography of somatosensory connections in a novel mutant rat having what appears to be a 'double cortex' located below the cortical mantle. Injections of anterograde tracers (biotinylated dextran amine, or Phaseolus vulgaris leucoagglutinin) into the ventral posterolateral nucleus (VPL) resulted in terminal labeling in layers IV and VI of medial portions of the overlying somatosensory cortex (SSCtx) and columnar-like labeling in medial portions of the underlying Telencephalic Internal Structural Heterotopia (Tish). In contrast, injections into the ventral posteromedial nucleus (VPM) labeled barrellike clusters of terminals in layer IV of more lateral portions of SSCtx; patches of terminal labeling were observed in the Tish region of animals in which the structure extended laterally at the same level. Terminal labeling of SII was sparse following injections into VPL and VPM; caudal portions of SII were predominately labeled following injections into caudal portions of VPM/ posterior nucleus. These latter injections led to sparse labeling in the Tish region; the extent of labeling appeared to depend on the presence or absence of the Tish structure at caudolateral levels. A virtually identical topographic pattern of retrogradely labeled neurons was obtained following injections of fluorogold into various parts of the ventral basal complex. Labelled neurons were observed mainly in layer VI of medial and lateral portions of SSCtx and scattered neurons were observed dorsoventrally in the immediately underlying Tish region following injections into VPL and VPM, respectively. The present results demonstrate a topographic organization of reciprocal connections between specific thalamic somatosensory relay nuclei and both the overlying SSCtx and Tish region in these mutant animals. Supported by NS34124 to KSL

INITIAL TOPOLOGICAL ORDER OF THALAMOCORTICAL PROJECTIONS IN THE BARRELLESS MUTANT MOUSE

PROJECTIONS IN THE BARRELLESS MUTANT MOUSE Zoltán Molnári**, Gilles Bronchti²- Colin Blakemore¹, Egbert Welker² ¹University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, U.K. and ¹Institut d'anatomie, Université de Lausanne, Rue du Bugnon 9, 1005 Lausanne. Switzerland Barrelless (brl) mice lack the morphological whisker representation in SI cortex. Whisker-related patterns exist in brainstem nuclei, but are less clear in the ventrobasal nucleus of the thalamus (VB) than in normal mice (Welker et al. Science, 271: 1864, 1996). We tested the hypothesis that the cortical phenotype is due to disconting the large right president search in dayadorment.

disorganized thalamocortical projections early in development.

Single crystals of two carbocyanine dyes
(DiI and DiAsp) were placed 500 µm apart,
in both putative somatosensory and visual cortex of normal (Nor) and brl-mice fixed at postnatal day 2. Results were indistinguishable in the two phenotypes both in VB and LGN. In VB the cells back-Results labelled by the two different dyes formed two clear, just overlapping clusters. In LGN the number of labelled cells was 3-5 times lower and their scatter somewhat greater than in VB. In both phenotypes, and in both nuclei, very few cells were double-labelled (VB: Nor, 0.6%, brl, 0.7%; LGN: Nor, 0.5%, brl. 0.4%).

Anterograde labelling from the thalamus revealed similar laminar distributions of thalamic fibres in both groups of animals. A cortical defect of pattern formation after correct ingrowth of thalamic axons may cause the barrelless abnormality, rather than initial spatial disorganization of the thalamocortical projection (see figure). FORMATION AND FOLDING OF CEREBRAL AND CEREBELLAR CORTEX: A TENSION-BASED THEORY OF MORPHOGENESIS AND COMPACT WIRING. D. C. Van Essen# Anatomy and Neurobiology Dept., Washington Univ. Sch. of Med., St. Louis, MO, 63110.

Why is the cerebral cortex a thin sheet that in many species folds into characteristic convolutions? I propose that mechanical tension, acting upon anisotropically oriented and asymmetrically connected neuronal and glial processes, accounts for many aspects of cortical development. Neuronal processes in vitro generate substantial tension. Likewise, many CNS neurons and glia are likely to be under tension that counterbalances hydrostatic pressure generated across cell membranes and from elevated intraventricular pressure. During development, radially oriented neural and glial processes should be associated with greater compliance (lower stiffness) tangential to the surface, contributing to the sheet-like expansion of the embryonic neuroepithelium and cerebral cortex. Folding of the cortical surface can be explained by characteristic projection asymmetries. In general, tension along axons that enter and leave the cortex should tend to "shrink-wrap" the cortex around a compact subcortical interior, even when this necessitates folding. Tension along major pathways between neighboring cortical regions should tend to draw them together, leading to "outward folds" (crowns of gyri) such as those along the border between areas V1 and V2 in many species. "Inward folds" (fundi of sulci) should separate regions that are only weakly interconnected (e.g., areas 3 and 4 along the central sulcus).

Tension interacting with cellular architecture and connectivity patterns.

separate regions that are only weakly interconnected (e.g., areas 3 and 4 along the central sulcus).

Tension, interacting with cellular architecture and connectivity patterns characteristic of other structures, can also account for the distinctive structure of the hippocampus (including the perforant pathway), cerebellar cortex (with its highly anisotropic elongation), retina (including the foveal pit), and olfactory bulb (with its glomeruli). Altogether, tension-based morphogenesis provides an efficient developmental mechanism for achieving compact wiring of the adult CNS. Supported by NIH EY02091.

DIFFERENT ORIGINS AND DEVELOPMENTAL HISTORIES OF TRANSIENT NEURONS IN THE MARGINAL ZONE OF THE FETAL RAT CORTEX G. Meyer*1 and A. Fairén? 1Depto. Anatomía, Univ. La Laguna, Tenerife, 2Inst. Neurociencias Alicante, Spain

Several populations of transient neurons, here collectively referred to as Cajal-Retzius (CR) cells, lead an ephemeral life in the marginal zone (MZ) of the fetal rat cortex. We used Calbindin (CB), Calretinin (CalR), GABA and BrdU immunohistochemistry to assess their major developmental steps. (1) The primary CR cells appear at E11 in the outer aspect of the neuroepithelium of the ventrolateral telencephalic vesicle (TV), prior to the derivatives of the olfactory placode. At E12, pioneer cells in the ganglion terminale, closely apposed to the medioventral TV, innervate CR cells and ventricular zone (VZ) in the rostral TV, and also seem to enter the MZ. At E12.5, terminal mitoses in the MZ and at different levels of the VZ throughout the TV increase the number of the primary CR cells. A CR subset sends an axonal projection into the subplate. All primary CR cells disappear after E16. (2) From E12.5 to E14, the neuroepithelium of the retrobulbar TV generates huge numbers of small neurons, the secondary CR cells, possibly the rodent equivalent of the human subpial granular layer. They invade the MZ of the entire cortex in successive, neurochemically different waves through tangential, subpial migration. The first waves express CB and GABA, the later ones CalR. The secondary CR cells disappear from the MZ at different moments of pre and postnatal life

A DISTINCTIVE ACHE STAINING PATTERN IN THE RETROSPLENIAL

A DISTINCTIVE ACHE STAINING PATTERN IN THE RETROSPLENIAL CORTEX OF REELER MUTANT MICE. B. B. Stanfield* and J. M. Wyss².

Lab. of Neurophysiology, NIMH, NIH Animal Center, Poolesville, MD 20837 &

2Dept. of Cell Biology and Medicine, Univ. of Alabama, Birmingham, AL 35294.

Acetylcholinesterase (AChE) histochemistry reveals an elaborate staining pattern near the midline of the posterior cerebral cortex of weanling and mature reeler (rl/rl)
mice. This AChE staining pattern is obvious even at low levels of magnification and is characterized by a complex trabecular network of dense AChE staining that is largely surrounded by zones of very sparse AChE staining. Some patches of moderate staining, comparable to the levels seen in nearby cortical fields, are also present in this cortical field. Comparison with adjacent Nissl-stained sections present in this cortical field. Comparison with adjacent NissI-stained sections reveals that the dense AChE staining corresponds, at least in part, to clusters of neuronal cell bodies, while the zones of very low AChE staining contain relatively few neuronal somata. No similar configuration of AChE staining is seen in any other region of reeler cerebral cortex, or in any region of the cortex of phenotypically normal (rl/+ or +/+) littermates. This complex of AChE staining appears to be within the retrosplenial cortex. This is confirmed by retrograde and anterograde tracing experiments examining the thalamocortical projections to this cortex. Injections of the retrograde tracer Fast Blue into the region of reeler cortex that contains the elaborate AChE staining pattern label thalamocortical neurons primarily in the anterior thalamic nuclei. Injections of the anterograde tracer biotinylated dextran into the anterior thalamic nuclei of the reeler label individual thalamocortical axons and terminals that are within the region of cortex that contains the elaborate AChE staining pattern. These observations indicate that the elaborate and striking network of AChE staining in the posterior-medial cortex of reeler mice is contained within and confined to the retrosplenial cortex. The connectivity patterns presumably underlying this AChE staining pattern remain to be clarified. Further, these observations do not support a previous description of a similar AChE-staining pattern in the visual cortex of reeler mice.

PRENATAL DEVELOPMENT OF LAYER I IN THE HUMAN PREFRONTAL CORTEX. R. Spreafico*, P. Arcelli, M. Selvaggio, P. Canetti, G. Giaccone and C. Frassoni. Depts. Neurophysiology and Neuropathology, Ist. Naz. Neurologico C. Besta', via Celoria, 11, 20133 Milano, Italy.

Histochemical and immunocytochemical studies were performed on 13

brains from premature infants, ranging from 21 gestational weeks (GW) and 2 months postnatally, died for non neurological diseases. Autopsies were performed, according to the Italian law, after 24 hours from death. Brains were fixed by immersion in either 4% paraformaldehyde buffered solution or in Carnois. 5-10 mm thick slabs from the prefrontal cortex were embedded in paraffin, subsequently cut in 5-10 μm thick sections and processed for Thionine, Bodian stains and for immunocytochemistry (ICC) using antibodies against MAP₂ , GFAP, Vimentine (VIM) and Calretinine (CR). Some sections were also processed using Tunel method for the detection of apoptosis. Data obtained from histochemical study and from ICC using GFAP and MAP₂ were similar to those reported by Sims et al. (1988) and by Gadisseux et al (1992). In addition, CR ICC revealed that this calcium binding protein is already present in layer I (LI) as early as 21 GW in a large number of neurons. They decrease progressively so that by 34 GW only few large CR positive neurons, with a morphology similar to the Cajal-Retzius cells, are present. The progressive reduction of CR positive neurons during the second gestational semester does not seem to be due to cellular death. In fact, during this period, although some apoptotic nuclei are present in LI, their number is lower than the amount of the disappeared CR positive cells. The reduction of the CR positive neurons could be due to either a transient expression of CR during LI development or to an incorporation of some CR positive neurons in the superficial part of the cortical plate.

This work was supported by Mariani Foundation.

POSTNATAL DEVELOPMENT OF THE HUMAN ENTORHINAL CORTEX.L. Graterón, L.M. Gonzalo and R. Insausti*. Dept. Anatomy, Univ. Navarra, Apdo. 273, 31080 Pamplona, SPAIN

Studies on the development of the human cerebral cortex are increasingly important for the understanding of pathology such as schizophrenia. We present here a study based on 12 cases ranging in age from newborn to 5 years. Some preterm infant brains were also available for study. The brains were fixed by immersion in a solution of 4% paraformaldehyde and 0.02% picric acid, or 10% formalin. When possible, the brain was blocked orthogonal to the anterior-posterior commissures axis. Serial sections were obtained, and thionin- and myelin stained series were analyzed, focusing on the laminar and areal differentiation of the entorhinal cortex and comparing it to the adult pattern. Our results show that at the time of birth, the overall laminar structure of the entorhinal cortex is present. Compared to adults, the most relevant difference was in the upper layers (II-III), where dense clumps of small, immature cells were separated by acellular intervening spaces. These clumps (prospective cell islands of layer II) were fused with layer III at the time of birth. At 5 months postnatally, only a fraction of the cells in the clumps had the appearance of stellate cells, and the clumps were still separated by wide, acellular spaces. By one year of age, clearly defined cell islands of neurons resembling the morphology of stellate cells were present in layer II, and the spaces between clumps decreased in size. At 21/2 and 5 years the maturation affected mainly the morphology of the neurons. The deep layers display less variation than the upper layers

DEVELOPMENT OF VISUAL CORTEX I

CORTICAL SPECIFICATION: THALAMIC PROJECTIONS TO LAYER I DEVELOP WEEKS AHEAD OF PROJECTIONS TO & Cognitive Sciences, M.I.T., Cambridge, MA 02139 and Dept. of Morphology, Sch. of Med., Autónoma Univ., Madrid, SPAIN 28029.

We investigated the timing of thalamocortical axon ingrowth in the cerebral cortex

using the anterograde transport of Dil and the highly sensitive tracer Cholera Toxin B subunit (CTB). CTB was stereotaxically iontophoresized in discrete thalamic nuclei in living pups (n=19), subsequently perfused at 43 to 59 days postconception (PC). Dif-crystals were implanted the thalamus of fixed brains aged PC36-60 (n=31). We analyzed the cortical labeling using optical and confocal microscopy. That axons start branching in the subplate of the topographically appropriate cortical zone by PC36. Density of the subplate plexus peaks around PC42, remaining high for the rest of the period examined. Axons destined for layer I, which in the adult are known to arise from a subclass of small-sized thalamic relay neurons, grow though the cortical plate by PC40-42 but do not branch within the plate. CTB labeling demonstrates that upon arrival in the marginal zone (prospective layer I) thalamic axons give off a number of varieose branches which extend horizontally, rapidly establishing a dense number of varicose branches which extend horizontally, rapidly establishing a dense subpial plexus. This layer I projection is topographically precise, and by PC49-50 has reached adult-like density and complexity. At this same age, however, axons destined for layer IV, which in the adult arise from a different subclass of thalamic relay neurons, have not yet entered their target cortical layer. The ingrowth and branching of layer 4 axons begins after E50-51, and proceeds slowly, so that even by the last age examined with CTB (PC59), the layer IV plexus is still less dense than in the adult. As a whole, our data indicate that the layer I projecting thalamocortical system reacts to cortical cues regulating ingrowth and branching in a way completely different from As a whole, our data indicate that the layer 1 projecting that amocortical system reacts to cortical cues regulating ingrowth and branching in a way completely different from that of the axons projecting to layer IV. Furthermore, these findings raise the possibility that the early growing layer 1 projection system plays a role in the precise mapping of the later-developing layer IV projection.

HOMEOBOX GENE EXPRESSION DURING THE CRITICAL PERIOD OF THE DEVELOPING KITTEN VISUAL CORTEX, Sarven Sabunciyan* and Max Cynader, Dept. of Ophthalmology, UBC, Vancouver, BC, Canada, V5Z 3N9.

Homeobox genes are an extensively studied family of helix-turn-helix type transcription factors which function as developmental regulators. Although much of the published data about the homeobox genes suggest that their role during development is limited to embryonic stages, homeobox gene involvement in developmental events occurring postnatally has been reported. For example, homeobox genes have been discovered in the retinae of adult goldfish which maintain visual plasticity throughout life. In addition, experiments examining the role of homeobox genes in neuronal tissue suggest that they may act as neurotrophic factors and may also be involved in synapse formation. Furthermore, genes encoding glutamate receptors have homeobox-binding-domains in their promoter regions and thus, may be under the regulation of homeobox genes. Given this evidence, we believe that homeobox genes are likely to play a general role in the postnatal development of the brain and hence, we decided to investigate their potential expression in the developing visual cortex of the cat. Degenerate primers targeting the conserved homeodomain region of this gene family were designed and PCR was performed on 30 day old cat visual cortex (VC) cDNA. The PCR product was electrophoresed and the appropriate size band was excised from the gel and cloned. Since the degenerate primers had the potential to match and amplify all of the members of the homeobox gene family, the single excised band represented a heterogeneous population of homeobox genes and thus, the clones derived from this band contained different homeobox sequences. Hence, several clones were picked at random and sequenced. Database searches of these clones revealed that they had >90% homology to homeodomain sequences found in other species and furthermore, confirmed the existence of more than one type of homeobox gene in the 30 day old kitten visual cortex. At present, we are trying to determine the different types of homeobox genes expressed in the 30 day VC by sequencing more of these homeobox clones. We are also trying to determine the expression pattern of these genes throughout the critical period using *insitu* hybridization and quantitative PCR.

DEVELOPMENTAL STUDY OF CYCLIC NUCLEOTIDE -GATED CHANNELS IN RAT VISUAL CORTEX D. Samanta Roy*, P.A. Kingston, and C.J. Barnstable, Interdepartmental

D.Samanta Roy*, P.A. Kingston, and C.J. Barnstable. Interdepartmental Neuroscience Program, Dept. of Ophthalmology and Visual Sciences, Yale University School of Medicine, New Haven, CT 06510

To begin to study how cGMP might affect development and plasticity in mammalian visual cortex, we previously described the developmental expression of a series of molecules involved in cGMP metabolism and cGMP effector molecules (Soc. Neurosci. Abstr. 650.6, 1995). Using RT-PCR, we detected expression of the rod cGMP-gated channel, cGMP kinase, cGMP stimulated phosphodiesterase, and the 61 and 63 kD forms of the calcium-calmodulin dependent phosphodiesterase. Furthermore, each molecule had a unique pattern of expression during postnatal development.

These data led us to ask the question of whether the three known forms of the

during postnatal development.

These data led us to ask the question of whether the three known forms of the cyclic nucleotide-gated (CNG) channel- rod, olfactory, and cone/testis- may also be differentially expressed in rat visual cortex. Preliminary PCR data suggests that they do have different developmental time courses, with the rod and olfactory RNA levels peaking earlier in visual cortical development, and the cone/testis peaking later in development. In situ hybridization, using digoxigenin-labeled RNA probes specific to each form of CNG channel, was also carried out to determine the layerspecific pattern of each in the visual cortex.

In summary, we have found the three known forms of cyclic nucleotide-gated channel to be differentially expressed in developing rat visual cortex, and have found each to be localized to discrete layers of the visual cortex. These findings suggest that different forms of the CNG channel may play an important role at different stages of rat visual cortical development. Supported by grants from the NIH.

TRANSMITTERS USED BY SUBPLATE NEURONS WITH AXONAL PROJECTIONS INTO VISUAL CORTEX. E. M. Finney*,

J. R. Stone, and C. J. Shatz. Howard Hughes Medical Institute and Dept. of Molecular and Cell Biology, University of California, Berkeley, CA 94720 Subplate neurons send axonal projections into the cortical plate during development, and are involved in the formation of ocular dominance columns (ODC's) (Allendoerfer and Shatz, 1994). To understand further how subplate neurons interact with neurons of the cortical plate, we have begun to identify the neurotransmitters and peptides expressed by those subplate neurons that send axons into the overlying visual cortex during the time ODC's are forming in ferret. axons into the overlying visual cortex during the time ODC's are forming in ferret. Fluorescent latex microspheres were injected into the primary visual cortex (with the exception of layer 6) of postnatal day 28 ferrets (P28) in order to label subplate neurons retrogradely. Brains were processed for immunohistochemistry using antibodies raised against glutamate, gamma-aminobutyric acid (GABA), glutamic acid decarboxylase 67 (GAD-67), neuropeptide Y (NPY), somatostatin (SRIF), and nitric oxide synthase (NOS). Results indicate: (1) the majority of retrogradely labeled subplate neurons are located in the region of the subplate just below layer 6-in the upper subplate; (2) while many subplate neurons can be immunostained for GABA, GAD-67, NPY, SRIF, or NOS, few if any of the retrogradely labeled population are immunoreactive for these transmitters or enzymes; (3) in contrast, subplate neurons that project to cortex can be glutamatergic, since they can be both retrogradely labeled with microspheres and immunostained for glutamate; (4) as in cat, so too in ferret, the SRIF positive subplate neurons are located primarily in the upper subplate. These results indicate that only a subset of all subplate neurons-those located primarily in the upper subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAergic subplate neurons have cortical polate. The fact that very few GABAer is not likely to be directly inhibitory. Thus, subplate neurons may provide excitation required for the activity-dependent modification of synaptic connections during visual cortical development.

NMDA-R1 enriched neurons in layers 6B and the white matter of neonatal visual cortices: Are they the "peptidergic subplate neurons"? Chiye AOKI* and Alev ERIŞIR, Center for Neural Science, New York Univ., New York, NY 10003

In a previous study, we showed that the laminar and subcellular distributions of NMDA-R1 in the visual cortex of rats and cats undergo dramatic changes during early postnatal period (Aoki et al., J. Neurosci. 14: 5202). Most notably, we observed prominent immunolabeling of large multipolar neurons in the infragranular layers and of fusiform neurons in the white matter. Since these are detectable only during the earliest postnatal period, we thought that these might be the transiently present peptidergic "subplate" neurons reported to be involved in guiding the formation synaptic connections between the cerebral cortex and subcortical structures. Since many of the "subplate neurons" contain neuropeptide Y (NPY) and these, in turn, stain positively by the NADPH-diaphorase (NADPHd) histochemical procedure and nitric oxide synthase (NOS) immunocytochemistry, this hypothesis was tested by determining whether the intensely NMDA-R1-immunoreactive neurons label dually for NOS or NADPHd. Our results indicate that few, if any, of the NMDA-R1 enriched infragranular neurons at stages PND3, PND 12 or 25 in the kitten visual cortex are positive for NADPHd or NOS. These results indicate that neurons residing in the subplate consist of a heterogeneous population with distinct modes of neurotransmitter receptivity. Whether or not those neurons specialized for NMDAtype synaptic transmission undergo apoptosis as do the other subplate neurons or merely cease to express high levels of the receptor within matured cortices remains to be determined. Supported by NIH Grants EY08055 and NS30944 (Shannon Award), the NSF Presidential Faculty Fellowship RCD 92-53750 and the Human Frontiers Science Program RG-16/93 to C.A.

THE DEVELOPMENT OF TAURINE-LIKE IMMUNOREACTIVITY IN THE VISUAL CORTEX OF FERRETS. <u>K. Herrmann*</u>, Lab. Neurophysiol., NIMH, NIH Animal Center, Poolesville, MD 20837, USA.

NIMH, NIH Animal Center, Poolesville, MD 20837, USA.

The sulfur containing amino acid taurine is the second most abundant amino acid after glutamate in brain and can be found in millimolar concentrations throughout the CNS. Functions of taurine include osmoregulation, regulation of Ca⁺⁺ fluxes and regulation of protein phosphorylation. The role of taurine as a true neurotransmitter is still controversial, despite the fact that taurine interacts with both excitatory and inhibitory systems in the CNS. Nevertheless, during development taurine might play a crucial role, and is necessary for the development and survival of certain cell types. The present study employed immunohistochemical methods using an polyclonal antibody against taurine (a gift from Drs. D.V. Pow and D.I. Vaney, VTHRC, Brisbane, Australia), to determine the distribution of taurine-positive cells in the developing visual cortex of ferrets between postnatal day (P1) and Australia), to determine the distribution of taurine-positive cells in the developing visual cortex of ferrets between postnatal day (P)1 and adulthood. In the adult, taurine-positive neurons could be found in all cortical layers, but pyramidal cells in the upper cortical layers 2/3 showed the strongest immunoreactivity, while neurons in layers 1 and 5 contained only few taurine-positive neurons. At P1, only a small population of cells in the cortical plate was immunopositive for taurine, however, neuropil staining was obvious in the marginal zone, the subplate, the lower intermediate zone and the ventricular zone. Subplate cells were also immunoreactive. Over the course of the following three weeks, the number of taurine positive cells increased in the cortical plate. By postnatal day 42, the pattern of immunostaining was indistinguishable from that seen in adults. These data show that taurine is present during early cortical development, and needs therefore to be included among the several transmitter-like molecules that are candidate agents to influence cortical development. NMDAR-1 GENE EXPRESSION IN THE RAT VISUAL CORTEX DURING POSTNATAL DEVELOPMENT AND THE EFFECT OF DARK REARING. Z. Cao*, B. Gordon, M. E. Lickey, and M.H. Kim. Inst. of Neuroscience., Univ. of Oregon, Eugene, OR 97403

NMDA receptors may mediate activity dependent plasticity in the visual cortex during development (for review see Fox and Zahs, 1994). All functional NMDA receptors contain the NMDAR-1 subunit (Nakanishi, 1992). In rats, maximal visual plasticity probably occurs at approximately 24-34days of age (Fagiolini et al., 1994). To study the relationship between NMDA receptors and plasticity in the visual cortex of Long-Evans rats, we studied NMDAR-1 gene expression with in situ hybridization. For normally reared (NR) rats (P14, P22, P30, P45, and P90, n=5 per age), the level of NMDAR-1 mRNA was decreased gradually from P14 to P90. For dark-reared (DR) rats (P14, P22, P30, P45, and P90, n=2 per age), the message declined markedly from P14 to P22, and then remained approximately constant until P90. By P22 it was already substantially lower than it was at P14. In both NR and DR rats, the pattern of decline was similar in all cortical layers. The decline of NR1 mRNA reported here occurs distinctly earlier than the decline of plasticity reported by Fagiolini et al. Therefore the abundance of NMDAR-1 mRNA is probably not a limiting factor controlling visual plasticity. The next step in studying the role of NMDA receptors in plasticity is to examine other subunits. Supported by NEI grant EY04050 to Barbara Gordon.

NMDA AND AMPA RECEPTOR SUBUNIT EXPRESSION IN DEVELOPING FERRET PRIMARY VISUAL CORTEX. A.L.Smith*1.2, I.D.Thompson¹ and H.Monyer². ¹University Laboratory of Physiology, Parks Road, Oxford OX1 3PT,

U.K. ²ZMBH, Im Neuenheimer Feld 282, 69120 Heidelberg, Germany.
In the primary visual cortex of ferrets NMDA receptor protein levels increase by up to 9-fold during the first two postnatal months while AMPA receptor levels remain relatively constant. Here we examine the developmental patterns of gene expression for NMDA and AMPA receptor subunits in this region. Sequences spanning the TM1 to TM3 region of ferret NR2A-D and GluRA-D were obtained by RT-PCR and mRNA expression was measured by radioactive in situ hybridization using ³⁵S-labelled oligonucleotide probes. The NR2 subunits probably provide the basis for NMDA channel diversity and transcripts encoding each of the NR2 subunits in developing primary visual cortex exhibit different spatiotemporal patterns of expression. NR2A mRNA levels increase greatly throughout development and by adulthood are highest in layer IV and lowest in layers I and V. NR2B transcripts maintain a constant level during postnatal development and are highest in layers VI and II/III and lowest in layers I and V. NR2C and NR2D mRNAs are prominent at the superficial edge of the cortical plate at birth, but levels in cortex rapidly decrease from the first and second postnatal weeks respectively. Thus only the changes in the levels of second postnatal weeks respectively. This only the changes in the levels of transcripts for NR2A parallel the changes seen in NMDA receptor protein levels during postnatal development. While GluRD levels within cortex are negligible, the levels of mRNAs encoding GluRA-C are high at birth and exhibit little change during development. GluRA-C transcripts are most concentrated in layer VI and the superficial edge of the cortical plate, later to become layers II/III, and while GluRA and GluRB mRNA expression levels are equally low in layers IV and V, GluRC mRNA levels in layer V exceed those in layer IV. Supported by the EMBO and by The Wellcome Trust, UK.

Spontaneous neuronal coactivation correlates with dve coupling

Spontaneous neuronal coactivation correlates with dye coupling in developing neocortical slices A. Peinado* Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY, 10461. Injections of the gap junction tracer Neurobiotin into single neurons in developing neocortical slices result in labeling of many neurons in the immediate vicinity of the injected cell. Compared to the injected neuron most coupled cells are faintly stained, suggesting weak coupling. Occasionally, however, two or three neurons show strong dye-coupling. I combined calcium imaging and fluorescent dye-coupling techniques to directly test the prediction that strongly coupled neurons would exhibit highly correlated patterns of activity.

Transverse slices of neocortex were made from neonatal and early postnatal rat and mouse pups (P0-P7) and stained with Fura-2 AM. Neuronal activity, as reflected by changes in Fura-2 fluorescence, was monitored at a single excitation wavelength (380 nm) with a fast cooled integrating CCD camera. Post-aquisition image processing was used to

integrating CCD camera. Post-aquisition image processing was used to identify sets of neurons having correlated patterns of spontaneous activity among dozens of active neurons found within the imaged area (approx. 200 µm) in one plane of focus.

Several pairs of neurons were found whose activity showed a consistent pattern of correlation over successive 20-second recording episodes. In 5 such cases, one of the two neurons was subsequently targeted with a patch pipette containing a fluorescent gap junction tracer, a technique that is useful for revealing instances of strong coupling. In 4 of these, the dye

usern for revealing instances of strong coupling. In 4 of these, the dye spread to the other coactive neurons in the vicinity of the patched cell. In the fifth pair no dye coupling was detectable. These results are consistent with the idea that coupling in developing neocortex can synchronize electrical activity between neurons. Supported by grants from NIMH and NINDS.

MECHANISMS INVOLVED IN THE NORMAL AND ARNORMAL DEVELOPMENT OF GENICULO-CORTICAL TOPOGRAPHY IN THE SYRIAN HAMSTER. K.Krug and I.D.Thompson (SPON: Brain Research Association). Laboratory of Physiology, Parks Road, Oxford, OX1 3PT, UK.

Previous work has shown that adult geniculo-cortical topography is

sculpted postnatally from an initially unordered projection. In newborn hamsters, a discrete injection of a retrograde fluorescent tracer into area 17 fills cells throughout the lateral geniculate nucleus (LGN). A comparable adult injection labels a discrete column of cells. We were interested in the extent to which terminal reordering and cell death shape the geniculo-cortical map and what role neuronal activity might play in this process.

We have examined the contribution of selective cell death to emerging topography by heterochronic tracing techniques. A single injection at P2 results in a similar pattern of labelled geniculate cells after both long-term (4-10d) and short-term (24h) survival: more than 75% of the LGN is labelled in both cases and the numbers of filled cells are comparable. Superimposing a second injection at P6 or P12 - at a time when the projection is adult-like - gives a maximum 35% of double-labelled neurons. These results suggest terminal rearrangement rather than selective cell death as the mechanism underlying development of topography. Making paired injections at different ages and using different survival times we are also able to quantify changes in topographic order

Monocular enucleation at birth leaves an altered geniculo-cortical topography ipsilateral to the remaining eye. Preliminary results following intraocular injections of TTX into monocularly enucleated animals reveal no dramatic change on the side which retains the majority of its input, whereas topography appears grossly disturbed on the side ipsilateral to the remaining eye. This suggests a role for retinal activity in the reorganization of projections. This work was supported by the Wellcome Trust, UK.

LAMINAR REMODELLING OF CORTICO-CORTICAL PROJECTIONS IN THE CAT, A. Batardière*, P. Barone, C. Dehay, H. Kennedy, INSERM U371, 18 Ave du Doyen Lépine, 69675 BRON (France).

In the development of cortical pathways in the primate we have shown that there is a massive reduction of neurons in the supragranular layers which project back to area 17 (Kennedy et al 1989; Barone et al., 1995). This remodeling of connections is a major feature in the development of the primate where it occurs exclusively in the feedback pathways. We have investigated if a similar development of progress occurs in the set. Betreards tracer to the set of the primate where it occurs the progress of the set of the primate where it occurs the primate where it occu developmental process occurs in the cat. Retrograde tracers were injected separately into areas 17, 18 and 19 in kittens. For each case the laminar distribution of retrogradely labeled neurons was determined in extrastriate areas. These results showed that during development there was a small but significant reduction in the numbers of supragranular neurons projecting to striate cortex.

These results show that the laminar remodelling of the feedback

cortical pathways is very weak in the cat and that the extensive remodelling in the primate is a characteristic feature of this order. Bibliography: Kennedy et al., PNAS (1989) 86:8093-8097; Barone et al., Cerebral Cortex (1995) 5:22-38

DEVELOPMENT OF HORIZONTAL CONNECTIONS IN LAYER 2/3 OF TREE SHREW STRIATE CORTEX: RELATION TO MAPS OF ORIENTATION PREFERENCE. J. C. Crowley, W. H. Bosking, M. Foster, and D. Fitzpatrick*. Dept. Neurobiol., Duke Univ. Medical Center, Durham NC 27710

Neurons in layer 2/3 of tree shrew striate cortex give rise to horizontal connections that exhibit modular specificity, contacting other neurons with similar preferred orientations, and axial specificity, contacting other neurons whose receptive fields are aligned collinearly in visual space. We combined optical imaging techniques with injections of biocytin to explore the normal development of these connections and their relation to maps of orientation preference. Maps of orientation preference could be visualized within the first week following eye opening. The size, shape, and spacing of the orientation domains in these maps were similar to those found in the adult. Injections of biocytin made into layer 2/3 of animals with 1-3 weeks of visual experience revealed a patchy network of horizontal connections that extended up to 5 mm from the injection site. Comparisons of the labeled bouton distributions with maps of orientation preference revealed a modular and axial specificity similar to that seen in the adult. Injections of biocytin in other animals with as little as 2 days of visual experience also resulted in a patchy distribution of boutons that was aligned along an axis, consistent with the pattern seen in the older animals. These results suggest that a small amount of visual experience is sufficient for establishing the modular and axial specificity of horizontal connections, as well as the functional map of orientation preference. Supported by EY06821.

DEVELOPMENT OF HORIZONTAL AND VERTICAL MOTION SYMMETRIES IN MONKEYS: VEP ASSESSMENTS. A. Aiyer, J.R. Wilson, and R.G. Boothe*. Division of Visual Science, Yerkes Regional Primate Research Center, Emory University, Atlanta, GA 30322.

The present study compares the development of horizontal and vertical directions of motion symmetries in the rhesus macaque. Ten normal rhesus macaques, ages 6 mths to 5 yrs were tested. An additional 2 normals were tested biweekly for a period of six months. To facilitate testing, younger animals were given butorphanol. Older monkeys were given propofol. Stimulus generation and VEP response analysis were carried out using the sweep VEP system of Norcia et al. (IEEE. Vol. 4, 1985). For horizontal motion, stimuli consisted of vertical grating that was "jittered" horizontally in both directions on a video monitor. Two different spatial (0.25 and 1.0 cpd) and temporal (6 and 10 Hz.) frequencies were tested. For vertical motion, the stimulus monitor was rotated by ninety degrees. Horizontal and vertical motion data were obtained within a twoday span for each monkey. At birth, both directions of motion show a large asymmetry. By six months of age, animals exhibited motion symmetry for both horizontal and vertical motion at 6 Hz. but some residual asymmetry at 10 Hz. Horizontal and vertical asymmetries were found to be highly correlated. Results for development of horizontal symmetries are similar to those observed in human infants (Norcia et al. (IOVS Vol. 32, 1991). Higher spatial and temporal frequencies take longer to mature in comparison to lower frequencies. The fact that the response to vertical and horizontal motion systems show a similar developmental time course suggests that they share a common cortical mechanism. Supported by NIH grants RR00165 and EY05975.

EFFECTS OF EARLY PRENATAL ENUCLEATION ON CORTICAL CONNECTIVITY IN MONKEY. P. Barone*, A. Batardière, C. Dehay, M. Berland and H. Kennedy. INSERM U371, Cerveau et Vision, 69675 BRON, France.

In monkey, early prenatal enucleation induces a large reduction in the dimensions of the striate cortex, and the cortex which was destined to acquire area 17 features of the striate cortex, and the cortex which was destined to acquire area 17 features becomes indistinguishable from area 18. We refer to this as DEC (default extrastriate cortex, Dehay et al., J. Comp. Neurol. 367, 1996). A recent study in the visual cortex of blind humans showed an activation from other sensory modalities (Sadato et al. Nature 380,1996). We investigated if DEC could be invaded by projections from other sensory modalities. Bilateral enucleation was performed prenatally around ESS, At bifur extraored tracers was injusted in the partie betared part of the DEC. E58. At birth, retrograde tracers were injected in the ventro-lateral part of the DEC. The analysis of the distribution of retrogradely labeled cells shows that there are

no projections from auditory or somatosensory primary areas to DEC. Likewise, there are no retrogradely labeled neurons in thalamic nuclei other than those dealing there are no retrogradely labeled neurons in thalamic nuclei other than those dealing with visual inputs to the cortex. All the visual extrastriate areas that normally send feedback projections to area V1, are connected to DEC. Feedback projections arise mostly from infragranular neurons. This adult pattern emerges during development by the elimination of a large number of feedback projections from supragranular neurons (Barone et al Cerebral Cortex 4, 1994). We analysed the effect of the enucleation on this laminar remodelling of feedback projections that normally occurs during development. In the enucleate, the laminar distribution of labeled cells in the visual associative areas buried in the intraparietal and superior temporal sulci (IPS of STS) expresset, that it, both loci there is a greater reporting of labeled paragraphs.

visual associative areas buried in the intraparietal and superior temporal suici (IPS and STS) suggests that in both loci there is a greater proportion of labeled neurons located in the upper layers than it is the case in the normal neonate.

These results suggest that following prenatal enucleation, the areal pattern of feedback projections is unchanged. However, the lack of retinal inputs reduces the process of laminar reorganization that characterized the establishment of feedback pathways in the developing monkey. Supported by the FRM, HFSP# RG-55/94B, CEE #SCI*CT91-0622.

LOCAL LEARNING RULE FOR SELF-ORGANIZATION AND NON-PARAMETRIC MODELING. Marc M. Van Hulle Laboratorium voor Neuro- en Psychofysiologie, K.U.Leuven, Faculteit Geneeskunde, Campus Gasthuisberg, Herestraat 49, B-3000 Leuven, Belgium.

We show that topographic map formation can be achieved in a self-organizing

We show that topographic map formation can be achieved in a self-organizing manner, using a competitive learning rule which maximizes the information-theoretic entropy of the map's neural output. The key difference between this learning rule, called the Maximum Entropy learning Rule (MER), and the most widely-used rule, called the Self-Organizing (feature) Map (SOM) algorithm (Kohonen, Biol. Cybern., 1982), and the many variants of the latter (Kohonen, Self-organizing maps, Springer Verlag, 1995), can be summarized as follows. In the SOM algorithm non-overlapping receptive fields (RFs) are defined (Voronoi tessellation). Hence, in order to introduce neighborhood relationships, the weight update rule needs a neighborhood function. In MER, the RFs of neighboring neurons mutually overlaps so that, by the overlap, neighborhood relations are neurons mutually overlap so that, by the overlap, neighborhood relations are already present at the neural activation stage. Hence, no neighborhood function is required per se in our weight update rule: purely local weight updates suffice to achieve correct topographic maps.

We show that our local learning rule can be used for non-parametric modeling

in essentially two distinct ways: probability density estimation and regression. In the first case, we show that MER yields an optimal map in terms of resource usage and an areal magnification factor range in accordance with the biological evidence available for area V1 of primates (Wässle et al., Nature, 1989). Hence, entropy maximization is a plausible computational principle for topographic map formation, in the second case, we show that MER can be used for identifying unknown input functions and for unsupervised classification and pattern recognition purposes. Hence, entropy maximization is a viable default learning strategy for modeling the

input flow in a self-organizing way, using only locally-available information.

The author is a research associate of the National Fund for Scientific Research Belgium) and is supported by research grants received from the National Fund (G.0185.96) and the European Commission (ECVnet EP8212).

MONOCLONAL ANTIBODIES TO NGF AFFECT DEVELOPMENT OF VISUAL CORTICAL NEURONS FUNCTIONAL PROPERTIES IN RATS N. Berardi, R. Siciliano, M.C. Cenni, F. Ruberti, A. Cellerino, A. Cattaneo, L. Maffei and L. Domenici *. Istituto di Neurofisiologia del CNR, 1-56127 Pisa, Scuola Normale Superiore, Pisa, Dept. Physiol. Biochem., Pisa, and SISSA, Trieste (Italy)

Recent results suggest an important role for neurotrophins in visual cortex (VC) development and plasticity. In particular, we have shown that antagonizing endogenous NGF action by intraventricular (i.v.) implant of αD11 hybridoma cells secreting neutralizing antibodies (Mabs) to NGF at the beginning of the critical period (day P15) affects—ocular dominance distribution (ODD) of rat visual cortical (vc) neurons. We have now examined, by means of electrophysiological recordings, orientation selectivity and receptive field (RF) size of vc neurons in 5 rats i.v. implanted with αD11 (10⁶ cells) at P15 and recorded (urethane anaesthesia) at the end of the critical period (P45). Mabs titre in the CSF was assessed (ELISA). Five littermates implanted at P15 with parental myeloma cells and 5 normal P45 rats were recorded as controls. We confirm that in aD11 rats ODD was strongly shifted towards the contralateral eye dominance, with reduction of binocular cells (Binocular Index=0.28±0.08) with respect to controls (BI=0.5±0.1). RFs were larger in αD11 rats than in controls (mean size 21±4 and 9±4 deg, respectively) and the number of orientation sclective cells was reduced (50% vs 67%). None of these effects was present in a parallel group of P45 rats (N=5) deprived (by excitotoxic lesion) of the cholinergic input to VC at P15. This points out to a direct role of endogenous NGF in regulating development of vc neurons functional properties which is not ascribable to a possible cholinergic hypofunction brought about by anti-NGF

EFFECT OF NEONATAL CORTICAL INJECTION OF KAINIC ACID ON THE DEVELOPMENT OF FUNCTIONAL ARCHITECTURE OF THE VISUAL CORTEX. K. Imamura*1, T. Shiomitsu^{1,2}, Y. Yoshimura*, and Y. Watanabe^{1,2}, 'Dept. of Neurosci., Osaka Biosci. Inst., 'Subfemtomole Biorecognition Project, JRDC, Osaka 565, Japan.

Neuronal activity and function of subplate cells have been proposed to play important roles in development of the functional architecture of cat visual cortex. We have studied effects of a neurotoxin, kainic acid, injected locally into the visual cortex of newborn cats to destroy early generated neurons in deeper layers of the cortex. The affected neurons were evaluated by recording electrophysiological responses to kainic acid in slice Electrophysiological and immunohistochemical examinations showed that the synaptic connections for normal visuocortical function was prevented to develop by this pharmacological manipulation. The anterograde tracing experiments using PHA-L revealed that axons of the lateral genicualte (LGN) neurons extended to layer II-III, outside the normal termination layer IV in the visual cortex treated with kainic acid. This abnormal termination pattern of LGN axon is probably responsible for the lack of vigorous visual response in the cortex injected with kainic acid. We also examined the effects of kainic acid injection on the development of the visual callosal projection. Retrograde tracing experiments showed that the number of the callosal projection to the visual cortex injected with kainic acid was markedly reduced. These results for the first time demonstrated that cortical injection of kainic acid in the first week of age affected not only thalamocortical projection but also the callosal projection in kitten visual cortex. It is also suggested that interaction of axons with deep-layer cortical neurons, including subplate cells, plays an important role for establishing appropriate connections to the postsynaptic cells and maintaining them in the visual cortex

ROLE OF BDNF IN THE ACTIVITY-DEPENDENT REGULATION OF CORTICAL FIRING RATES AND GABA EXPRESSION. L. Rutherford, A. DeWan, and G.G. Turrigiano*, Dept. of Biology and Volen Center, Brandeis University, Waltham, MA 02254.

Maintaining the proper balance of excitation and inhibition is important

for normal cortical function. Here we show that activity regulates the firing rates of cultured cortical neurons, in part through the brain-derived neurotrophic factor (BDNF)-mediated regulation of GABA expression.

Whole-cell recordings were obtained from pyramidal neurons from cultures of P5-6 rat visual cortex after 7-9 DIV. Recordings were made from control cultures grown in normal medium or sister cultures treated for 48 hrs with TTX to block all spikes, then washed extensively prior to recordings. Pyramidal neurons from TTX treated cultures had 9-fold higher firing rates (20.7 \pm 7.8 spikes/min) than from control cultures (2.3 \pm 0.8 spikes/min , p < 0.05, Student's t test). Resting potentials and input resistances were not different. To determine whether a decrease in inhibition could contribute to such hyperexcitability, cultures were treated with TTX for 48 hrs, fixed, and labeled against GABA and the neuronal marker MAP2. TTX treated cultures had a lower percentage of GABA positive neurons than control cultures (20.2±1.6% and $28.2\pm1.0\%$, respectively; p < 0.01, Student's t test). Coapplication of BDNF prevented this decrease (28.4±4.0 %), and the trk receptor blocker K252a produced a decrease similar to that produced by TTX (18.0 \pm 1.9 %), suggesting that activity regulates GABA levels through a BDNF-dependent mechanism. These data indicate that activity can regulate cortical firing rates in culture, and part of this regulation may be through the expression of the inhibitory neurotransmitter GABA. ALPHA,-TUBULIN mRNA LEVELS ARE UNCHANGED BY PROXIMAL AXOTOMY IN MOUSE CORTICAL NEURONS.
E.J. Elliott*, D.A. Parks, P.S. Fishman. Research Service, VA Medical Center, Baltimore, MD 21201.

Our previous work with transcallosal cortical neurons in the mouse

Center, Baltimore, MD 21201. Our previous work with transcallosal cortical neurons in the mouse showed that proximal axotomy did not significantly alter their levels of GAP-43 mRNA, suggesting that the neurons failed to mount any regenerative response. The cytoskeletal protein α_i -tubulin, like GAP-43, is strongly upregulated in developing and regenerating neurons, but may be regulated independently from GAP-43. We have examined brain sections from the same animals used in the GAP-43 study, this time looking for changes in α_i -tubulin mRNA, to determine whether the response seen with GAP-43 (which was variable) would be reproduced with α_i -tubulin. In situ hybridization with a "P-labeled oligonucleotide probe for mouse α_i -tubulin showed no consistent changes in α_i -tubulin mRNA in axotomized cortical neurons at 1 day, 3 days or 7 days after injury. (This contrasted with regenerating spinal motor neuron controls, which showed a consistent large increase in α_i -tubulin expression.) Half the animals showed no significant differences in silver grain density over axotomized compared to unaxotomized cortical neurons. Four animals out of 17 showed small increases in grain density (35-63%) that were statistically significant, and 5 out of 17 showed decreases (26%-60%). However, of those animals which showed increases in α_i -tubulin, only one was an animal which had shown slight increases in GAP-43 mRNA. The other three had shown either no change, or a slight decrease in GAP-43 mRNA. The other three had shown either no change, or a slight decrease in α_i -tubulin had shown decreases in GAP-43, but rather had been unchanged, or shown either no change, or a slight decrease in GAP-43 mount and the property of the animals which showed decreases in α_i -tubulin had shown decreases in GAP-43, but rather had been unchanged, or shown shown decreases in GAP-43, but rather had been unchanged, or shown slight increases. These results confirm our earlier conclusions that transcallosal cortical neurons in the mouse give little regenerative response even to proximal axotomy. INDUCTION OF A PHOSPHORYLATED MAPIB IN TARGET-DEPRIVED AFFERENT FIBERS AFTER NEURODEGENERATION

DEPRIVED AFFERENT FIBERS AFTER NEURODEGENERATION PRODUCED LESION. S. Soares, I. Fischer¹, J.-D. Vincent and F. Nothias*, Inst. A. Fessard, CNRS, Gif-Sur-Yvette, France, I. Med. Coll. of Penn., Philadelphia, PA. 19129.

Microtubule associated protein IB (MAPIB) is the first MAP to be detected during the development of the CNS and becomes markedly down regulated postnatally. Its expression, particularly of its phosphorylated forms, is associated with axonal growth. We previously showed that a phosphorylated MAPIB (MAPIB-P) was restricted to axons, while total MAPIB was present in cell bodies and processes. In the adult MAPIB-P levels decreased dramatically and remained detectable in only a few areas that undergo morphological plasticity. To confirm these observations, the present study was undertaken to determine whether MAPIB-P expression is induced in axonal remodeling after neurodegenerative lesion. The right ventrobasal thalamus of adult rats was depleted of neurons by in situ injection of kainic acid. Rats were allowed to survive 4 days to 3 months. Somatosensory and cortical afferents were identified by anterograde tracing with dextran biotin injected in dorsal column nuclei, trigeminal nuclei, and somatosensory cortex.

MAP1B-P immunostaining is absent in the unlesioned control adult thalamus. Four days after kainic acid injection, MAP1B-P staining is thalamus. Four days after kainic acid injection. MAPIB-P staining is detected in the afferent fibers within the lesion, increased during the two following weeks and remained high for several weeks. The double staining showed that MAPIB-P is induced in both somatosensory and cortical afferents. Deprived of their specific neuron-target, these fibers undergo morphological changes that resemble regenerating growth cones and are able to regenerate synapses when new target is provided by neuronal transplant. neuronal transplant

TUBULIN ISOTYPE REGULATION IN INJURED, REGENERATING AND BDNF TREATED RETINAL GANGLION CELLS A.E. Fournier, L. McKerracher* Center for Research in Neuroscience, McGill University, Université de Montréal, Departement de pathologie, Québec, H3C 3J7.

Université de Montréal, Departement de pathologie, Québec, H3C 317. We are interested in the factors which regulate gene expression during axon regeneration in the CNS. Axon injury is known to affect the expression of tubulin, and here we investiage how growth permissive peripheral nerve (PN) grafts or the application of BDNF modulates the neuronal response to injury. Five tubulin isotypes in adult rat retinal ganglion cells (RGC) were examined after intraorbital axotomy, after applying a PN graft, and after RGC injury accompanied by an intraretinal injection of 5µg of BDNF. The mRNA levels were monitored by quantitative in situ hybridization with tubulin isotype-specific RNA probes. Treated and control sections were hybridized on the same slide and silver grains over individual RGCs were counted. RGCs with regenerated axons were detected by retrograde labelling from the graft. Following axotomy, mRNA levels for the BI, BII, BIII, and BIV B-tubulin isotypes and for the $T\alpha I$ α -tubulin isotype decreased to approximately 70% of control levels by two weeks. RGCs which regenerated their axons into PN grafts, showed dramatically enhanced mRNA levels for the BII, BIII and $T\alpha I$ isotypes (approximately 300%). This enhancement was specific for these isotypes whose expression levels were also enhanced during development, and was not observed for the BI, and BIV isotypes. A single injection of the neurotrophin BDNF, which is known to enhance survival of injured RGCs, had a specific effect on the BII isotype 3 days following treatment. The effect of BDNF on the BII isotype was modest, but significant, and was not observed for the BII (my graft suggest that multiple factors present in PN grafts help modulate tubulin expression. EXPRESSION OF c-JUN IN MATURE CNS AFTER SPINAL CORD INJURY E.Broude, M.McAtee, H.Bernstein-Goral*, B.S.Bregman, Georgetown University, Washington, DC 20007

Protein product of the immediate early gene c-jun is highly expressed in axotomized peripheral neurons during regeneration and in central neurons after cervical, but not thoracic spinal cord injury. Fetal spinal cord transplant induced and application of exogenous neurotrophic factors enhanced more growth of host axons in the adult rat after midthoracic overhemisection. The aim of this study was to determine if interventions shown to increase the amount of axonal growth after injury upregulate expression of c-Jun and alter the extent of neuronal atrophy and/or cell loss of the axotomized neurons. The following experimental interventions were used: hemisection only; hemisection plus transplant; hemisection plus neurotrophins (BDNF or NT-3) with or without transplant. Animals were sacrificed at 7 and 30days after surgery. By 7 days after lesion immunohistochemistry and quantitative image analysis showed increased c-Jun expression in axotomized red nucleus and locus coeruleus of animals from all experimental groups, as compared to normal and hemisected-only rats. Fetal spinal cord transplants, exogenous neurotrophins and the combination of both significantly affected axotomized neurons, inducing high expression of c-Jun protein. Both cell number and cell size were greater than in lesion only animals. We also compared expression of c-Jun in dorsal root ganglion neurons (DRG) after central or peripheral axotomy. The number of c-Jun-positive cells was increased when embryonic spinal cord transplant was present at the site of central dorsal root axotomy, as compared to central axotomy-only animals. Small and medium diameter DRG neurons were affected preferentially. Our results suggest that expression of c-Jun protein in axotomized mature CNS neurons is elicited by interventions which increase the extent of axonal growth after injury and plays an important role in induction of genes specific for growth of the mature CNS Supported by NIH NS 19259; neurotrophins generously provided by Regeneron.

REPRESSION OF GAP-43 EXPRESSION BY CYCLIC AMP IN THE CNS NEURONAL CELL LINE RN46A <u>D.J. Schreyer*1</u>, <u>P.L. Andersen</u>¹, and <u>S.R. Whittemore</u>² ¹Dept. Anatomy and Cell Biology, Univ. Saskatchewan School of Medicine, Saskatoon, SK, Canada S7K 0M7, and ²Dept. Neurological Surgery, Univ. Miami School of Medicine, Miami, FL 33136

Neurons of the adult mammalian central nervous system (CNS) display poor regenerative growth following axon injury. Regenerative failure has been attributed to growth inhibitors associated with CNS myelin. It is not known whether CNS myelin growth inhibitors act only at the level of the growth cone, or additionally influence neuronal gene expression which supports growth. Using a cell-ELISA assay, we show that expression of the growth-associated protein GAP-43 is normally detectable in cultured RN46A cells, a cell line derived from E13 rat raphe nucleus neurons. RN46A cell expression of GAP-43 is markedly suppressed by chronic exposure to cholera toxin, forskolin, cAMP analogues and phosphodiesterase inhibitors. DNA assays performed on sister cultures indicate that the changes in GAP-43 are not due to changes in cell survival. These findings suggest that extracellular influences may inhibit GAP-43 expression in CNS neurons via a G-protein linked receptor and adenyl cyclase. Supported by MRC Canada and NS26887.

CHONDROITIN SULFATE PROTEOGLYCAN EXPRESSION FOLLOWING SPINAL CORD INJURY

M.L. Lemons*, D.R. Howland and D.K. Anderson. VAMC and Dept. of Neuroscience, University of Florida, Gainesville, Fl 32610. Extrinsic factors appear to be primarily responsible for the lack of regeneration in the adult CNS. To ultimately enhance axonal growth, these factors must be more fully understood. We are examining in vivo, the role of an extracellular matrix molecule, chondroitin sulfate proteoglycan (CSPG), which inhibits neurite outgrowth in vitro. Our studies are designed to answer two main questions: 1) Does CSPG expression increase in vivo after spinal cord injury? and, if so, 2) can CSPG be enzymatically cleaved and its inhibitory function disrupted in vivo? Four groups of adult rats are being studied; normal, sham injured, spinal cord contused and contused + fetal spinal cord graft. CSPG immunocytochemical staining in shams is similar to normals. In cross-section it outlines axons in the white matter and shows a peri-neuronal pattern in the gray matter. By one week post injury, CSPG immunoreactivity is intensified around axons in the white matter and in the gray matter particularly at the lesion cavity edge. This host pattern persists for at least 30 days and is not altered by a fetal graft By 30 days, the graft also becomes CSPG positive. To disrupt this increase in CSPG expression, gelfoam soaked in chondroitinase ABC (chase) is laid on the dorsal spinal surface of sham and spinal cord injured rats. Chase is known to cleave and disrupt CSPG's inhibitory function in vitro. Within 4 days, chase cleaves CSPG in the superficial white matter. CSPG is not cleaved in a saline soaked gelfoam control group. These results suggest that a) CSPG increases after spinal cord contusion injury and correlates with the lack of axonal growth and b) chase can cleave CSPG in vivo Currently, CSPG expression is being characterized in other spinal cord lesion models and the application of chase is being modified to enhance its penetration and prolong its exposure to the site of injury as well as to intraspinal grafts. B-50/GAP-43 OVER-EXPRESSION IN TRANSGENIC MOUSE PURKINJE CELLS IS NOT SUFFICIENT TO INDUCE AXON REGENERATION A. Buffo¹, A.J.G.D. Holtmaal², T. Savio¹, B. Oestreicher², W.H. Gispen², J. Verhaagen², P. Strata * F. Rossi, ¹ Dept. Neurosci., Univ. of Turin, Turin, 1-10125; ²Neth. Inst. Brain Res., 1105 AZ Amsterdam., NL.

It has been shown that the growth permissive/promoting conditions created by grafts of embryonic nervous tissue and Schwann cell suspensions induce the regeneration of several populations of severed axons in the adult CNS. By contrast, Purkinje cell (PC) axons never regenerate into such grafts. The failure of PC axon regeneration may be due to their inability to express the gene programme necessary to sustain neurite outgrowth. Indeed, both intact and lesioned PCs never express B-50/GAP-43, a protein associated to axonal outgrowth during development and involved in neuronal response to axotomy and regeneration. According to this hypothesis, PC axon regeneration might be obtained by inducing the expression of growth associated genes in these neurones. We have investigated the regenerative capabilities of PC axons in a strain of mine carrying a transgene in which the rat coding sequence of B-50/GAP-43 was cloned downstream to the mouse L7 protein promoter to specifically direct the expression of B-50/GAP-43 in PCs. High levels of B-50/GAP-43 were expressed in all PC somata and axons from intact mice and this expression was maintained after axotomy obtained by passing a microscalpel through the cerebellar parenchyma. However, by anti-calbindin or anti-B-50/GAP-43 immunolabelling no PC axon regeneration was observed either after axotomy alone, or when embryonic cerebellar grafts or Schwann cell suspensions were placed into the lesion track. Thus, B-50/GAP-43 expression alone does not seem to be sufficient to obtain PC axon regeneration into growth permissive territories. Alternatively, it is possible that neurite outgrowth is prevented by the strong hypertrophic reaction which affects transected PC axons. (Supported by ALS M.)

ELEVATED LEVELS OF THE CELL ADHESION MOLECULE. LI. FOLLOWING SPINAL CORD INJURY IN THE ADULT RAT. C. Roonprapunt®. A. Hooper, W. Huang, D. Friedlander, M. Grumet and W. Young, Departs, of Physiology and Pharmacology, NYU Medical Center, New York, NY 10016.

Physiology and Pharmacology, NYU Medical Center, New York, NY 10016.

As a mediator of cell to cell interactions in the nervous system, L1 functions in cell adhesion, neuronal migration, and neurite outgrowth. In an effort to understand the effects of spinal cord injury on L1 expression, we conducted an immunohistochemical analysis of L1 at the site of injury. With the NYU weight drop device, spinal cord contusions were induced in made and female adult Long-tvan's hooded rats. A 10 gm rod was dropped from a height of 2.5 cm directly above the spinal cord exposed by laminectomy at T-10. The spinal cords were analyzed by immunostaining and quantitative Western blotting at one day, one week, and six weeks following impact.

Immunostaining of normal non-injured cords revealed weak L1 signal. In

Immunostaining of normal non-injured cords revealed weak L1 signal. In the white matter L1 was present on axonal fiber tracts seen on horizontal section, and in the gray matter there was some L1 primarily at the dorsal root entry zone seen in cross-section. At one week after injury, staining at the injury site appeared more intense when compared to age-matched, non-injured control animals. The results of the biochemical quantitation confirmed that the observed increase in L1 immunoreactivity represented actual increases in concentrations of the cell adhesion molecule, and not simply a staining artifact (eg. unmasking of antigenic components in uninjured spinal cords). By six weeks, the injury site had developed a post-traumatic cyst filled with a loose non-neuronal matrix of fibers. This new growth of neurofilament-positive fibers expressed intense L1 immunoreactivity. The origin of these regenerating fibers, peripheral or central, is currently under investigation. Supported by Accorda Therapeutics

EXPRESSION CHANGE OF F3/CONTACTIN IN GERBIL HIPPOCAMPUS AFTER TRANSIENT FOREBRAIN ISCHEMIA
K. Shimazaki* H. Cho¹, K. Takeuchi² and K. Watanabe³

¹Depts. Physiol. Neurosurg Jichi Medical School, Tochigi-ken 329-04,
Japan. ²Dept. of Bio. Sci. Nara Adv. Inst. Sci. Tech. Nara-ken 630-01,

Japan. ³Dept. Exp. Biol. Tokyo Metropolitan Inst. of Gerontology. Tokyo 173, Japan.

The neural cell specific adhesion molecule F3(contactin), a member of the immunoglobulin(Ig) superfamily, plays important roles of neurite outgrowth and axonal guidance during development. However, the role of F3 in adult brain has been poorly understood. We have studied changes in the expression in gerbil hippocampus after transient forebrain ischemia for 5 min. Immunoblotting study revealed that F3 expression decreased from 1 to 7 days after ischemia, while it increased later than 21 days after ischemia. By immunohistochemical study, biphasic change in F3 was seen selectively in CA1 sector. The initial decrease of F3 may reflect on going cell death of CA1 pyramidal neurons. Late increase in F3, which showed similar time course with increased immunoreactivity of 145 kDa neurofilament. That may be caused by sprouting of the neurites of the input fibers to CA1, since damage to CA3 neurons failed to increase in F3. Our results suggest that F3 plays an important role in regenerative processes after ischemic cell death, including sprouting of the Schaffer collateral/commissural axons in CA1 subfield. of the immunoglobulin(Ig) superfamily, plays important roles of neurite CA1 subfield.

VESTIBULAR NEURONS INCREASE EXPRESSION OF GAP-43 mRNA VESTIBULAR NEURONS INCREASE EXPRESSION OF GAP-43 mRNA AFTER CERVICAL SPINAL CORD HEMISECTION. B.C. Tryon-1_JL. Seeburger¹, T.M. Connors¹, A. Tessler^{1,2}, M. Murray¹, J.E. Springer² Dept. Neurobiology and Anatomy, Medical College of Pennsylvania Hahnemann University, Philadelphia, PA. 19129. ²The VA Medical Center, Philadelphia, PA. 19104 ³Dept. Anatomy and Neurobiology, University of Kentucky, Lexington, KY 40524, 2009. 40536-0084.

Because vestibular neurons play a critical role in maintaining balance and posture, promoting regeneration of vestibulospinal axons may improve functional outcome after spinal cord injury. To examine the capacity for regeneration of vestibulospinal neurons, we studied the expression of GAP-43 mRNA in axotomized neurons of the lateral vestibular and adjacent spinal vestibular nuclei. 24 adult female Sprague-Dawley rats underwent hemisection of the spinal cord at the C5 segment. At 3 days and at 1, 3, and 8 weeks postoperative (n=6, each group) brainstem tissue was processed for in situ hybridization using a full length antisense riboprobe for GAP-43 mRNA. Since the vestibulospinal tract is primarily an ipsilateral projection, the vestibular nuclei contralateral to the hemisection served as an internal control for GAP-43 mRNA expression. GAP-43 mRNA levels did not change from baseline in GAP-43 mRNA expression. GAP-43 mRNA levels did not change from baseline in lateral vestibular or adjacent spinal vestibular neurons 3 days following cervical hemisection, but were significantly increased in the nuclei ipsilateral to surgery at 1, 3 and 8 weeks postoperatively. This result suggests that lateral vestibular and adjacent spinal vestibular neurons retain the capacity for growth for at least 2 months following cervical spinal cord hemisection. This propensity may account for the regeneration of vestibulospinal axons into intraspinal grafts (Ye and Houle, '95; Xu et al., '95). Supported by grants from the Dept. of Veterans Affairs, NIH NS 24707, PVA, APA and International Research in Paraplegia.

IDENTIFICATION OF GROWTH-ASSOCIATED GENES IN RAT RETINAL GANGLION CELLS DURING REGENERATION AND EMBRYOGENESIS. C. V. Esguerra*^{1,2}, E. Guenther³, A. Cellerino³, E. Hoffmann^{1,2}, and M. Bähr^{1,2}. Max Planck Institute for Developmental

E. Hoftmann^{1-x}, and M. Bähr^{1-x}. ¹Max Planck Institute for Developmental Biology, ²Department of Neurology, University of Tübingen, and ³Research Center for Experimental Opthalmology, D-72076 Tübingen, Germany We recently devised an approach involving patch-clamp technology, global PCR amplification of mRNA from single cells, and subtractive hybridization for the rapid identification of genes potentially involved in the regeneration of adult retinal ganglion cell axons into a peripheral nerve graft after lesion. An efficient multiple-parameter selection strategy involving Boolean hybridization steps enabled us to significantly enrich for genes upregulated in both regenerating and embryonic retinal ganglion cells.

Initial screening of this library resulted in the isolation of a series of

upregulated in both regenerating and embryonic retinal ganglion cells. Initial screening of this library resulted in the isolation of a series of genes, both known and novel. Aside from highly enriching for and recovering the GAP-43 gene, we isolated genes that code for putative transcription factors (GATA-1 and a novel zinc finger protein), a growth factor and its corresponding receptor (a novel IGF-1 isolog and IGFIIR), signal transduction proteins (calmodulin and a novel G-protein), cytoskeletal proteins (α - and β -tubulin), axoplasmic transport proteins (myosin lightchain and dynein), an extracellular matrix glycoprotein (fibronectin), and a synaptogenesis protein (synaptotagmin IV). Initial characterization of the zinc finger gene, a novel member of the Krüppel family of transcription factors, revealed a significant upregulation of expression in embryonic and factors, revealed a significant upregulation of expression in embryonic and regenerating retinal ganglion cells in comparison with the levels of expression in normal adult and degenerating ganglion cells. Final results of the library screen will be presented, in addition to a thorough characterization

SEPTOHIPPOCAMPAL NEURONS TRANSIENTLY UP-REGULATE CNTF RECEPTOR α EXPRESSION FOLLOWING BILATERAL FIMBRIA-FORNIX TRANSECTION. T. Naumann*, Mun-Yong Lee, M. Kirsch, M. Frotscher and H.-D. Hofmann, Institute of Anatomy, University of Freiburg, P.O. Box 111, Germany.

Most cholinergic as well as parvalbumin-containing GABAergic septohippocampal neurons survive bilateral fimbria-fornix transection (ff-t). Moreover, they are able to

restore the synthesis of their marker proteins choline acetyltransferase and parvalbumin after transient downregulation following axotomy (Naumann et al., '94). It has been shown that exogenously applied ciliary neurotrophic factor (CNTF) can prevent degeneration and loss of most injured medial septum neurons whereas the effects of nerve growth factor are restricted to the cholinergic neurons (Hagg et al., 92). To investigate, if CNTF could act directly on septal neurons to influence their response to axotomy, we have studied the expression of CNTF receptor α in the medial

septum / diagonal band complex (MSDB) in normal and lesioned rats.

Adult Sprague-Dawley rats received bilateral ff-t and survived for 3, 7, 10 days and 3, 10, 30 weeks. In some of the animals septohippocampal projection neurons were prelabeled by intrahippocampal Fluoro-Gold injections prior to axotomy. Expression of CNTF receptor α mRNA was determined by in situ hybridization using a digoxigenin-labeled RNA probe.

CNTF receptor α mRNA was undetectable in the MSDB of unlesioned animals, but was upregulated following ff-t. Labeling of MSDB neurons was first observed at 7 days postlesion, reached a maximum after 10 days, and was close to normal levels after 3 weeks. CNTF receptor α -expressing septohippocampal neurons could be identified by the presence of Fluoro-Gold. The dramatic upregulation of the CNTF receptor α following ff-t suggests that locally supplied CNTF may contribute to the survival of axotomized MSDB neurons. DAIL, Lona Linda, CA, 92300.

DAII is a novel fatty acid lipid-binding protein isolated from a rat cDNA library made from dorsal root ganglia ipsilateral to a sciatic nerve crush. DAII mRNA and protein are induced in neurons in the DRG ipsilateral to a sciatic nerve cut as compared with contralateral and naive DRG (Molina et al., Soc Neurosci, Abstr 21:1073; De León et al., J. Neurosci Res., In press), and in neonatal brain tissue Express DA11 in the rat developing brain. In Soc Neurosci. Abstr 21:1073). The present study expands our earlier observations, and identifies which cell types express DA11 in the rat developing brain. In situ hybridization and immunocytochemical experiments showed that DA11 protein and mRNA were localized inhulmicytochedical experiments showed und DAT1 protein and introva were occurred in neurons. In the cerebral cortex, those neurons undergoing neurogenesis, migration, and differentiation exhibited higher levels of DA11 expression than differentiated cells. The cerebral cortex neurons expressing higher levels of DA11 mRNA and protein were part of the group of neurons forming the characteristic "column" structures throughout the brain cortex. The Purkinje cells in the cerebellum contained very high levels of DATI mRNA and protein. This expression was observed as early as E21, sustained during the first 10 days of postnatal development, and was significantly down-regulated during the first 10 days of postmatal development, and was significantly down-regulated in adult cells. Neurons in the hippocampus, brain stem, and spinal cord also exhibited a similar developmental pattern of DA11 expression to that observed in the Purkinje cells. High levels of DA11 were also found in the olfactory bulb and the retina. In the retina, DA11 was localized in bipolar and ganglion cell layers. In the olfactory bulb, DA11 was expressed in the mitral cell layer, but there was also a moderate level of expression in glomerular and granule cell layer. Our data show that the observed transient but significant induction of DA11 during early and postnatal development of CNS is associated with the process of neuronal cell differentiation. This work was CNS is associated with the process of neuronal cell differentiation. This work was supported by NIH grant HD3807-Supplement.

EXPRESSION OF GROWTH ASSOCIATED PROTEINS AFTER LESION AND DURING RETINAL AXON REGENERATION IN RATS. B. Petrausch¹, M. Jung¹, D. Karagogeos² and C.A.O. Stuermer¹*. ¹Faculty of Biology, University of Konstanz, D-78434 Konstanz, F.R.G., ²Dept. of Medical Science, University of Crete, Iraklion, 71110 Crete, Greece.

After optic nerve transection (ONS) and during axon regeneration in fish, all retinal ganglion cells (RGCs) re-express GAP-43 and cell adhesion molecules (CAM), which they originally displayed during axon outgrowth. In rats, RGCs express related proteins in the embryo. In adults, a limited number of rat RGCs reexpresses GAP-43 after ONS, as well as during axon regeneration, when a peripheral nerve graft (PN) is provided.

Using immunocytochemistry and in situ hybridisation, we examined in rats whether

regenerating axons in PN grafts carry the CAMs £587 antigen, L1/NILE, DM-GRASP/SC-1, TAG-1 and whether this correlates with mRNA upregulation in GRASP/SC-1, TAG-1 and whether this correlates with mkNA upregulation in RGCs. In embryos axons expressed all these proteins, and mRNA of GAP-43 and TAG-1 (those tested so far) were present in all RGCs. RGC axons in normal adults and upon ONS expressed all these proteins in their intraretinal path but lost TAG-1 some days after ONS. Accordingly, DM-GRASP/SC-1 and TAG-1 mRNAs were present in normal adult RGCs. Upon ONS, DM-GRASP/SC-1 mRNA remained in some RGCs but TAG-1 mRNA was lost. Regenerating axons in PN grafts carried GAP-43, £587 antigen, L1, DM-GRASP, but not TAG-1. Accordingly, DM-GRASP/SC-1 mRNA was present in some RGCs of PN grafted rats (much like GAP-43 mRNA), whereas TAG-1 mRNA never reappeared. Expression of L1/NILE and £587 antigen mRNAs is currently studied. Thus, axon regeneration is paralleled by re-expression of GAP-43 and upregulation of certain CAMs, but TAG-1 which interacts with other CAMs is lost and not re-expressed.

Probes were kindly provided by L.I. Benowitz, A.J.W. Furley, T.M. Jessell, G.E. Pollerberg, F.G. Rathjen, J.H.P. Skene and W.B. Stallcup. Supp. by BMBF, ISRT, and Dt. Stiflung Querschnittslåhmung.

gRICH68 AND gRICH70 ARE GOLDFISH 2',3'-CYCLIC-NUCLEOTIDE 3'-PHOSPHODIESTERASES UPREGULATED DURING OPTIC NERVE REGENERATION, R. P. Ballestero, G. R. Wilmot, B. W. Agranoff and M. D. Uhler*. Department of Biological Chemistry and Mental Health Research Institute, University of Michigan, MI48109.

The teleost optic nerve is a model system for the study of axonal regeneration in the CNS, p68/70 is a doublet of acidic proteins induced in retinal ganglion cells upon optic nerve crush. We previously reported the cloning of a cDNA encoding RICH, a protein homologous to mammalian CNPases (2',3'-cyclic nucleotide 3'-phosphodiesterases; 36.3% identical to human CNPase1) and with several characteristics that relate it to the p68/70 doublet (Proc. Natl. Acad. Sci. USA, 1995, Vol 92, pp 8621-8625). We have now isolated a cDNA encoding a second isoform of RICH. Using recombinant technology we have expressed the encoded proteins both in prokaryotic and eukaryotic systems. We have obtained additional support documenting their relation to the components of the p68/70 protein doublet, and thus we have renamed them gRICH68 and gRICH70. We have additionally found and characterized the enzymatic propertics of the bacterially expressed and purified gRICH proteins versus recombinant mCNP1, confirming that gRICH proteins are 2'.3'-cyclic-nucleotide 3'-phophodiesterases. The physiological role of these enzymes remains unknown, but the induction of these novel members of the family during goldfish optic nerve regeneration provides a new model to elucidate their biochemical role in nervous tissues.

the law date their biochemical role in nervous tissues.

IDENTIFICATION OF GENES DIFFERENTIALLY EXPRESSED AFTER OPTIC NERVE LESION IN ZEBRAFISH. P. Bormann, A. Bonnet and E. Reinhard*. Dept. Pharmacology, Biozentrum of the University of Basel, 4056 Basel, Switzerland.

Retinal ganglion cells (RGCs) in the adult zebrafish retina are easily accessible for studies of regeneration in the adult central nervous system. Following optic nervo lesion, RGCs re-express genes that were selectively silenced after neuronal development. Two well characterised genes, whose mRNA expression is strongly increased after lesion, are GAP-43 and α-tubulin. Comparison of their temporal expression pattern by in situ hybridization and RT-PCR studies revealed that both genes are induced at 24-48 hours after lesion and mRNA levels reach a maximum between 5 and 7 days after lesion. At 15 days after lesion, when abundant reinnervation of the optic tectum occurs, the GAP-43 mRNA level is drastically reduced. In contrast, α-tubulin declines more slowly and its mRNA level is still elevated 4 weeks after lesion. This indicates that a common pathway upregulates both genes, whereas distinct pathways are used in their downregulation. To learn more about the molecular requirements for regeneration, we started to identify additional genes that are regulated in response to nerve injury. To do this, we compared gene expression in regenerating and non-regenerating zebrafish retinas by differential display. We have so far isolated eleven partial cDNA clones, of which eight are upregulated and three are downregulated in response to lesion. One clone is homologous to the 60S ribosomal protein L24, another to the vesicular fusion protein NSF. All other clones, including a 2.2 kb clone isolated from a cDNA library made from regenerating retinas showed no homologies to sequences in GenEMBL. Isolation of full-length cDNA clones will allow study of the function of these potentially novel growth-associated genes during regeneration. Supported by a grant from the SNF # 31-45925.95.

CNS AXON REGENERATION IN VIVO AND IN VITRO IN TRANSGENC MICE EXPRESSING A PROTO-ONCOGENE BCL-2. Dong Feng Chenl-1.2; lean-Claude Martinou³, Gerald E. Schneider² & Susumu Tonegawa ^{1,2}. ¹Howard Hughes Med. Institute, Center for Cancer Research, ²Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139; ³Glaxo Institute for Molecular Biology, 14 Chemin des Aulx, plan-les-Ouates, 1228 Geneva, Switzerland.

Most neurons of mammalian central nervous system (CNS) lose the ability to regenerate severed axons after a certain point in development. This lose is controlled by a genetic program in the neurons of origin (Chen et al., PNAS, 1995). We have been studying the molecular mechanisms that underlie this process. We report here that the proto-oncogene bcl-2 is critical in this developmental switch. First, during development the level of expression of bcl-2 in retinal ganglion cells correlates well with their ability to regenerate axons. Second, neurons from mice genetically deficient in bcl-2 exhibit a great reduction in their ability to grow axons in embryo. Third, in mice that express transgenic bcl-2 constitutively, the ability of CNS neurons to regenerate their severed axons remains intact throughout life as demonstrated in our retinotectal explant coculture model. Finally, extensive nerve regeneration has been achieved in vivo in young transgenic mice after postnatal transection of the optic tract.

The axonal regeneration observed in bcl-2 transgenic mice does not seem to be an indirect consequence of the well known anti-apoptotic activity of bcl-2: Another anti-apoptotic agent -- ZVAD -- does not promote axonal regeneration; in addition, quantitative studies of ganglion cell survival and their axonal growth in our in vivo and in vitro experiments have shown a dissociation between these two properties. We conclude that bcl-2 plays a key role in regulating the growth ability of CNS axons during neuronal development and regeneration. (Supported by NIH Grants R35-CA53874 and EY00126).

ISOLATION OF A PARTIAL cDNA ENCODING THE ZEBRAFISH PROTEIN ZRICH AND ITS EXPRESSION AFTER OPTIC NERVE CRUSH. M. D. Uhler, R. P. Ballestero, J. A. Dybowski and B. W. Agranoft*. Department of Biological Chemistry and Mental Health Research Institute, University of Michigan, MI48109.

Health Research Institute, University of Michigan, MI48109.

Teleosts are used as models for nerve regeneration in the central nervous system. We have previously isolated cDNAs encoding gRICH, a protein induced during goldfish optic nerve regeneration that shows homology with mammalian CNPases (2',3'-cyclic nucleotide 3'-phosphodiesterases). We also showed the presence of cross-reacting proteins in other fish species including zebrafish by immunoblot analysis. Using goldfish-derived probes, we have isolated a cDNA clone from zebrafish that shows a partial ORF encoding zRICH. The zebrafish represents a model genetic system that offers experimental approaches not easily achieved in the goldfish. We are currently examining the expression of zRICH mRNA after optic nerve crush by in situ hybridization and RNase protection assays. The presence of a close homolog in this second species is suggestive of a conserved role for RICH in optic nerve regeneration. Studying the role of zRICH in nerve regeneration in zebrafish CNS is a starting point for the genetic and developmental study of as yet unidentified proteins related to this family from other organisms.

ELECTROPHORETIC ANALYSIS OF AXONALLY TRANSPORTED PROTEOGLYCANS OF REGENERATING GOLDFISH OPTIC NERVE, <u>I.S. Elam*</u> and <u>C.E. Hudson</u> Program in Neuroscience, Florida State University, Tallahassee, Florida 32306.

Our previous studies on proteoglycans in nerve regeneration have focused primarily on the characteristics of chondroitin 4 sulfate (C4S) and heparan sulfate (HS) that undergo 6-7 fold enhanced axonal transport in regenerating goldfish optic (Challacombe and Elam, Neurochem Res 20 253 (1995). We have extended these studies to the intact transported proteoglycans (PGs) that contain the HS and C4S chains. Control and 21 day regenerating optic tracts were isolated 10h after intraocular injection of ³⁵SO₄. Following homogenization and extraction with 1% Triton-IM NaCl, proteoglycans were purified by DEAE. Results show a regeneration related increase in the proportion of extracted $^{35}\mathrm{SO_4}$ eluting as proteoglycans (from 49% to 68%) and a corresponding increase in the amount of protein per tract in the proteoglycan fraction. Proteoglycan fractions were then subjected to electrophoresis on 6% SDS gels. Regions of the gel containing axonally transported chondroitin-4-sulfate proteoglycans (CSPGs) and heparan sulfate proteoglycans (HSPGs) were identified by treatment of proteoglycan samples with chondroitinase AC and heparitinase. Autoradiographic results from both control and regenerating tracts indicate that CSPGs are distributed in the size range of 120--260kDa. However, the greatest regeneration correlated increase was in molecules with apparent sizes of 150 and 180 kDa. Both control and regenerating tracts showed a size range of HSPGs ranging from 190-270 kDa. Labeling with 35S-methionine revealed the presence of core proteins of 65kDa and 59 kDa following treatment with chondroitinase and heparitinase respectively. These results support the conclusion that there is enhanced axonal transport of proteoglycans in regenerating nerve. The present results also indicate that the proportionately large regeneration related increase in transported C4S is concentrated in particular sized CSPGs. (Supported by NIH grant NS 20502)

ANTINOCICEPTIVE EFFECTS OF SPINALLY TRANSPLANTED SYNTHETIC FOAM SCAFFOLDS IMPREGNATED WITH BOVINE ADRENAL CHROMAFFIN CELLS IN THE RAT A5/C FOOT WITHDRAWAL TEST D.C. Yeomans, T. M. Sioussat', P. Michalewicz, Y. Lu and G. D. Pappas* Dept. of Anatomy and Cell Biology, University of Illinois at Chicago. Chicago, IL 60612; ¹Tissue Engineering, Inc., 451 D St., Boston, MA 02210.

The purpose of this study was to determine whether spinal transplantation of bovine chromaffin cells which had been seeded into NATPOL™ collagen foam cell scaffolds would attenuate Aδ or C fiber mediated nociception. Three different collagen foam preparations were seeded with freshly isolated chromaffin cells. After 48 hr in culture, the foams were transplanted onto the dorsal surface of the spinal cord of rats who were allowed 1 week to recover. Other animals received sham operations. After induction of light anesthesia with urethane, foot withdrawal latencies as evoked by high rate (Aδ nociceptor mediated) or low rate (C nociceptor mediated) skin heating were measured at 10 min intervals for 1 hr. Sham-operated rats demonstrated latencies similar to those measured previously for normal animals. Transplants of chromaffin cells in NATPOL™ foam scaffolds produced antinociception for both Aδ and C nociceptor-mediated responses. The antinociception varied in degree depending on the preparation of NATPOL™ used for the foam. These results contrast with results from non-scaffolded cells with which systemic administration of nicotine is critical to their antinociceptive function. These data, taken with light and electron microscopic findings indicating better uptake of cells in foams of certain types indicate that the preparation of scaffolding foam rnay play a role in determining the extent to which adrenal chromaffin cell transplants can inhibit nociceptive responsivity. In addition, these results may indicate that foam scaffolding upregulates secretion of antinociceptive effectors from chromaffin cells.

A MET-ENKEPHALIN PRODUCING PC12 CELL LINE AS AN ALTERNATIVE DONOR SOURCE FOR NEURAL TRANSPLANTS IN THE REDUCTION OF CHRONIC PAIN. P. H. Kim, X.-T. Wang*, A. F. Seasholtz, J. Sagen and J. R. Unnerstall Dept. of Anatomy and Cell Biology. University of Illinois-Chicago. Illinois 60612.

Many studies in our laboratory have demonstrated the efficacy of using adrenal medullary chromaffin cell transplants in the reduction of chronic pain. It is hypothesized that the production and release of catecholamines and opioid peptides (met-enkephalin) by adrenal medullary chromaffin cells seem be contribute to the mechanism of action for pain relief. Unfortunately, the ready availability and consistent preparation of these cells are some of the limiting factors in the clinical setting. The generation of a cell line that can produce both catecholamines and met-enkephalin may allow us to circumvent this obstacle of donor tissue availability and consistency. In this study, PC12 cells - a tumor cell derivative of rat adrenal medullary chromaffin cells - were transfected with a human proenkephalin gene to increase met-enkephalin production. Although these cells produce high levels of catecholamines, they only produce low levels of met-enkephalin. PC12 cells were co-transfected with two plasmids (pCON II and pRSVneo) using the calciumphosphate precipitation method. After transfection and selection, surviving colonies were transferred to separate plates and grown out for analysis. Radioimmunoassay revealed a four fold increase in both cellular content and release of met-enkephalin in compared to cells non-transfected Immunohisochemistry demonstrated the conservation of catecholamine production and morphological alterations resembling chormaffin cells following transfection. Due to the many similarities with chromaffin cells, these newly transfected PC12 cells may prove to be a viable alternative donor source for neural transplantation in chronic pain therapy. Supported by NS25054 and Campus Research Board of the University of Illinois-Chicago.

AXONAL REGROWTH INTO DISTAL HOST SPINAL CORD THROUGH A SCHWANN CELL BRIDGE IN A PARTIAL LESION MODEL IN THE ADULT RAT. S.X. Zhang, H. Li, N. Kabeer, and X. M.Xu*. Dept. Anat. & Neurobiol. Saint Louis Univ. Sch. of Med., St. Louis, MO 63104. We previously demonstrated that a mid-thoracic spinal cord hemisection and

We previously demonstrated that a mid-thoracic spinal cord hemisection and transplantation of a small diameter semipermeable channel (O.D.=1.25 mm) filled with Schwann cells (SCs) effectively promoted axonal regeneration in adult rats (Soc. Neurosci. Abstr., 21:820,1995). To study if axons that regenerated into the graft were able to reenter the host spinal cord through the distal graft-cord interface, an anterograde tracer, PHA-L, was employed. SCs were purified in culture from adult rat sciatic nerves, suspended in a 30:70 solution of Matrigel:DMEM, and seeded into channels (1.25 x 3 mm, MWCO=50K Da, 120 x 10° cells/ml). After the spinal cords of adult Fischer rats were hemisected at T8 on the right. SC-channels were introduced into the gaps with both ends of the channels contacting the adjacent cord stumps. Two months later, the intact left hemicords were completely transected to prevent axons from entering the distal cords via that route and PHA-L was injected iontophoretically into the rostral gray matter 6-9 mm from the grafts. After appropriate processing, PHA-L labeled axons from the rostral propriospinal neurons were observed in the graft and, more significantly, in the distal host spinal cord. These labeled axons exhibited terminal boutons, suggesting that they innervated the appropriate gray matter. In a second set of experiments, Fast Blue, a retrograde tracer, was injected into the middle of the graft 30 days after grafting. Labeled propriospinal neurons were found in both rostral and caudal cord segments. Surprisingly, a group of supraspinal nuclei were retrogradely labeled as well. Whether supraspinal axons are able to reenter the distal spinal cord through the graft remains to be determined. (Supported by Daniel Heumann Fund for Spinal Cord Research and Leda Sears Trust Fund)

OLFACTORY NEUROEPITHELIUM SPINAL CORD OVERLAYS. <u>U. Vaidya.*</u> <u>R.M. Galler, B.H. Hallas, and M.R. Wells</u>. New York College of Osteopathic Medicine, Dept. Of Neuroscience, Old Westbury, NY 11568-8000.

Olfactory neuroepithelium of young post natal rats was isolated, labeled with Dil, and overlaid onto the spinal cord of ten adult hosts (Vaidya and Wells, 1990). The sheets of neuroepithelium was dissected under high magnification, labelled with Dil for 30 mins, at 37°C, washed several times before the neuroepithelium was drawn into a needle for implantation. Using standard surgical technique and dissection, a lower thoracic laminectomy was performed and the spinal cord was exposed. The neuroepithelium was then placed under the dura onto the host spinal cord. Transplants were examined using standard histofluorescence techniques, and semithin plastic sections 14 and 30 days after implantation. All the transplants survived, grew and differentiated. In histological preparations, all transplants were seen to contain normal looking, well differentiated neurons, integrated with the host tissue. There was no excessive gap or sear between the grafts and host tissue surrounding them. Neither transplants nor the host spinal cord showed any pathological reaction or evidence of neoplastic growth. Olfactory neuroepithelium has the potential as a suitable donor material for neural grafting into the spinal cord. Supported by the New York College of Osteopathic Medicine

TRANSPLANTATION STRATEGIES TO REPLACE DEGENERATED SPINAL MOTONEURONS AND REINNERVATE MUSCLE S.M. Onifer 1.3, A.B. Cannon 1, L.A. White 1, M.B. Bunge 1.3, R.P. Bunge 1.3, S.R. Whittemore 1.3.4 The Miami Project to Cure Paralysis, Departments of 2 Cell Biology & Anatomy, 3 Neurological Surgery, and 4 Physiology & Biophysics, University of Miami School of Medicine, Miami, FL 33136.

Spinal motoneuron degeneration occurs in motoneuron diseases and after spinal cord injuy. Experimental evidence indicates that transplanted embryonic spinal motoneurons have the ability to replace degenerated motoneurons and reinnervate muscles. The therapeutic potential of this approach has been hindered by 1) limitations in obtaining sufficient numbers of embryonic motoneurons, 2) poor survival of transplanted motoneurons, and 3) the inability of transplanted motoneurons to extend axons out of the spinal cord via the ventral root to reinnervate muscles. It is possible to produce unlimited numbers of neurons for transplantation through the generation of non-tumorigenic neural cell lines. Schwann cells transplanted in a linear array in the CNS or PNS act as a bridge and provide a permissive substrate for axon elongation by CNS neurons, including adult motoneurons (I. Neurosci., 1992, 12: 3310-3320; J. Comp. Neurol., 1995, 351: 145-160). To enhance the therapeutic potential of motoneuron transplantation, the present study examines 1) various neuronal cell lines for replacing lost spinal motoneurons and 2) Schwann cells for enhancing axon elongation into the ventral root by co-transplanted embryonic spinal cord cells. The cell lines that are being investigated include: SC10, a conditionally immortalized neural cell line derived from embryonic rat spinal cord. and 46Ch1, a mutant of RN46A (I. Neurosci., 1994, 14: 6744-6753; Molec. Ccil. Neurosci., 1996, in press) stably transfected with the secreted-ciliary neurotrophic factor gene. Preliminary data suggests that Schwann cells transplanted into the ventral white matter of the motoneuron-depleted lumbar spinal cord promote axon elongation into the L4 and L5 ventral roots by co-transplanted embryonic spinal cord cells. Supported by The Miami Project, General Reinsurance, and NS26887.

AXONAL GROWTH AFTER CO-IMPLANTATION OF CARBON FILAMENTS AND FETAL TISSUE IN THE CONTUSED RAT SPINAL CORD. L. S. Liu* T. Khan, and S. Sayers Rehabilitation R & D Center, Hines VA Hospital, Hines, IL. 60141.

We have recendly reported that the co-implantation of carbon filaments and fetal

We have recently reported that the co-implantation of carbon filaments and fetal spinal cord tissue play an important role in promoting electrophysiological recovery after spinal cord injury (Neurosci. Lett. 200, 1996). This study was designed to determine whether culturing fetal spinal cord on carbon filaments, and then subsequently implanting these filaments into the injured spinal cord, would enhance axonal regrowth across the lesion site. The rats were divided into five groups: Group One consisted of normal rats (n=7), Group Two consisted of rats which sustained contusion injuries and the lesion sites were subsequently filled with a bundle of approximately 10,000 carbon filaments of 5um in diameter (AMOCO Thornel TM) cultured with 15 day old rat fetal spinal cord explants (n=5), Group Three consisted of rats which received fetal spinal cord tissue implants after contusion injury (n=4), and Group Five consisted of rats which sustained a contusion injury only (n=4), The implantation was performed one hour after the contusion injury. After a ten-week survival period, all animals received injections of Fast Blue in the lumbar spinal cord. The results showed more retrograde labelling across the lesion in the group which received carbon filament implants cultured with fetal spinal cord tissue as compared to the other three injury groups. Further studies are underway to determine the relation between the host and the grafted explant. Supported by Rehabilitation R&D Service (B742-RA), DVA.

SPONTANEOUS NEURAL ACTIVITIES RECORDED FROM REGENERATING AXONS IN PERIPHERAL NERVE AUTOGRAFTS INTO SPINAL DESCENDING PATHWAYS IN ADULT RATS. I. Kohama and M. Aoki*. Dept. of Physiology, Sch. of Med., Sapporo Medical Univ., Sapporo 060, Japan

We implanted autologous segments of the peroneal nerve into the upper cervical cord of adult rats to induce axonal regeneration from spinal descending pathways. The distal part of each graft was left unconnected. Five to 18 wk after implantation, we recorded the neural activities from regenerated fibers in the graft to examine if brainstem and upper cervical cord neurons regenerate their axons into the nerve graft. Spontaneous multi-unit discharges were present in all of 18 grafts examined. In 11 (61%) of these grafts, we found units with respiratoryrelated activity. In 7 other grafts (39%) we found units with nonrespiratory related activity. Respiratory discharge patterns were similar to those of intrinsic respiratory neurons in the normal rat. After the recordings were completed, we bathed the proximal end of each graft in HRP solution for 2 h to examine the location of neurons regenrating axons. Many HRP-labeled neurons were observed in the region of medullary ventral respiratory group (VRG), especially at the obex level. These results demonstrate that: (1) some spinal descending axons from brainstem respiratory and non-respiratory neurons regenerate into the peripheral nerve grafts, (2) normal respiratory discharge patterns are maintained in respiratory neurons with regenerating axons. A MOUSE SCHWANN CELL LINE INDUCES AXON GROWTH IN ADULT RAT BRAIN. A. Soekarno* and G. Raisman. Division of Neurobiology, NIMR, The Ridgeway, Mill Hill, London NW7 1AA, U.K.

We wanted to investigate the extent to which the IMS32 cell line (derived from spontaneously immortalized adult mouse Schwann cells; Watabe et 1995, J. Neurosci. Res., 41, 279-290) could be used to mimic the known axogenic effects of primary Schwann cells on cut CNS axons.

Cells were extrusion grafted as vertical columns through the thalamus and hippocampus of adult rat hosts. Primary Schwann cells from neonatal rat sciatic nerve and the immortalized cells formed similar elongated vertical columns that were maintained for up to at least 4 weeks. Neurofilament staining showed that both cell types were able to recruit comparable outgrowth of host axons. Although both cell types were of host axons. Although both cell types were \$100 positive, the immortalized cells were less intensely labelled neurotrophin receptor, p75.

CHARACTERIZATION OF HUMAN FETAL SPINAL CORD GRAFTS IN ACUTE AND CHRONIC INTRASPINAL LESIONS IN THE RAT.

M.A. Giovanini, T.A. Eskin, P.J. Reier, and D.K. Anderson*. Departments. of Neurosurgery, Neuropathology, and Neuroscience, Univsity of Florida College of Medicine. Gainesville FL 32610.

Previous reports of homotopic fetal intraspinal allografts in animal models of spinal cord injury have demonstrated graft survival, integration and degrees of improved functional recovery. The aim of this study is to evaluate the growth potential and integration of human fetal spinal cord (HFSC) grafts in acute and chronic lesions of the rat spinal cord using whole pieces or suspensions of dissociated tissue. Six to 9 week HFSC tissue was collected from elective abortions. Acute thoracic lesions were created by gentle aspiration of the intramedullary portion of the spinal cord. Chronic lesions were created by contusion of the thoracic cord with the NYU weight drop device followed by grafting 10-30 days after injury. The intraspinal xenografts were analyzed 2 months after grafting using either 2µ plastic sections or paraffin immunocytochemistry. Preliminary results show excellent survival of HFSC grafts in all lesion types. Intraspinal grafts (ISG) of whole pieces into both acute and chroni lesions show poor integration with large residual areas of cavitation. Suspension grafts show excellent integration with the host and typically fill the cavity. ISG in acute lesions are largely GFAP (glial fibillary acidic protein) positive and sparsely positive for NFP (neurofilament protein) and MAP2 (microtubule associated protein). In contrast ISG in chronic lesions show large areas of MAP2 and NFP positivity. The MAP2 shows a greater affinity for immature cells and, therefore, delineates the graft by robustly labeling graft but not host neurons. In addition, MAP2 positive neurons in host white matter suggest that grafted neurons can migrate from suspension grafts into the host spinal cord. Supported by the C.M. and K.E. SCHWANN CELLS GENETICALLY ENGINEERED TO PRODUCE BDNF PROMOTE AXONAL REGENERATION OF BRAINSTEM NEURONS ACROSS TRANSECTED ADULT RAT SPINAL CORD. P. Menei, C. Montero-Menei, S.R. Whittemore, M.B. Bunge*, R.P. Bunge. The Miami Project, University of Miami School of Medicine, Miami, FL 33136

The infusion of BDNF and NT-3 into Schwann cell (SC) grafts promotes regeneration of brainstem neurons into the grafts placed in adult rat spinal cord

transected at T8 (Exp. Neurol. 134:261-272, 1995). Here, we compared normal SCs with SCs genetically engineered to produce human BDNF, grafted as trails 5 mm with SCs genetically engineered to produce human BDNF, grafted as trails 5 mm long in the cord distal to a transection site and also deposited in the transection site, in their ability to stimulate supraspinal axonal regeneration beyond the injury. SCs purified from adult rat sciatic nerve were infected with the replication-deficient retroviral vector (pL(hBDNF)RNL encoding the human preproBDNF cDNA. The amount of BDNF secreted (ELISA) was 23 and 5 ng/ml/10⁶ cells/24h for infected and normal SCs, respectively. Activity of the secreted BDNF was confirmed by retinal ganglion cell bioassay. The spinal cord was transected at 78. The use of Hoechst prelabelled SCs demonstrated that trails were maintained for a month. In controls, no SCs were grafted. One month after grafting, axons were present in SC trails. More 5-HT-positive and some DBH-positive fibers were observed in the infected vs. normal SC trails. When Fast Blue was injected 5 mm below the transection site (at the end of the trail), an average of 57 retrogradely labelled neurons was found in the brainstem, mostly in the reticular and raphe nuclei (normal SCs, 10, mostly in vestibular nuclei). Numerous neurons were labelled in the ventral hypothalamus (normal, 0). A mean of 138 labelled cells was present in rostral dorsal root ganglia (normal, 46) and rostral spinal cord (39 vs. 32). No labelled neurons rostral to the transection were seen when SCs were not transplanted. Thus, the transplantation of SCs secreting increased amounts of BDNF led to the best regenerative response across a transection site in the thoracic cord. The regeneration we observe with infected SCs appears specific; the largest response was from neurons known to express trk\u00e48. (Supported by NIH NS28059, IRME, the Heumann and Rudin Foundations, and The Miami Project.)

COMPENSATORY EFFECT OF EMBRYONIC RAPHE NEURONS GRAFTING ON THE REGULATION OF THE GAD_{67} ISOFORM mRNA IN TRANSECTED ADULT RAT SPINAL CORD. A. Dumoulin, M. Giménez y Ribotta, M. Anoal, A. Privat and S. Feldblum*. INSERM U336, ENSCM 34053 Montpellier, France.

We have demonstrated in recent studies an activation of the GABAergic

spinal system following rat spinal cord injury. Since the graft of embryonic raphe neurons within the transected adult rat spinal cord is known to improve raphe neurons within the transected adult rat spinal cord is known to improve functional recovery, we studied the effect of such a graft onto the regulation of the GABAergic system. In a first group of animals the spinal cord was transected at thoracic level. In a second group the cord was similarly transected and a cell suspension of embryonic (E14) caudal raphe was injected at lumbar level, one week following the transection. Detection of GAD₆₅ and GAD₆₇ mRNAs was assessed by non-radioactive *in situ* hybridization, 21 and 42 days after lesion. In the grafted cords numerous cells containing GAD₆₅ and GAD₆₇ mRNAs were observed within the graft itself, indicating the expression of the GABAergic phenotype in vivo in the transplanted immature tissue. In transected and host cords minor modifications in the number of cells expressing GAD₆₅ mRNA were observed at either 21 or 42 days. The number of cells containing GAD₆₇ mRNA appeared to be 1.6 fold increased in sectioned cords at 21 days as compared to intact animals. In contrast, the number of GAD₆₇ mRNA positive compared to intact animals. In contrast, the number of GAD $_{67}$ mRNA positive cells in the grafted host cords at 21 days had returned close to the intact animals level. In conclusion, differential mRNA regulation of the two GADs is thus observed, suggesting that mainly ${\rm GAD}_{67}$ is involved in the restructuration of the adult lesioned cord. Moreover, since the graft is enriched in GABAergic cells, it may act as a GABA supplier for the host transperted cord. transected cord.

ASTROCYTIC CONNEXIN43 IN RAT BRAIN AFTER FOCAL ISCHEMIA. W.E.I. Li*¹, E.L. Hertzberg² and J.I. Nagy¹, Dept. of Physiol., Univ. of Manitoba, Winnipeg, MB R3E 0W3 Canada; ²Dept. of Neurosci., Albert Einstein College of Med., Bronx, NY10461.

In order to study the role of astrocytic gap junctions and Cx43 in CNS homeostasis, we utilized three anti-Cx43 antibodies (designated 18A-8, 16A-8 and 13-8300) to examine Cx43 responses in a rat cerebral focal ischemia model after different degrees of ischemic injury and after various survival times following reperfusion. After 15 min ischemia, a reduction of immunostaining was seen with 18A-8 and 16A-8 in hypothalamic preoptic areas at zero survival time, but no loss was evident at 7 days survival, suggesting a transient, reversible effect of mild ischemia on Cx43. After 1 hr ischemia with 3-48 hr survival, a near total loss of staining with 18A-8 at the ischemic center was surrounded by intense labeling, while increased labeling was seen with 16A-8 at the ischemic center. Under these conditions, a rim of intense labeling at the ischemic penumbra was seen with 13-8300. Similar results were obtained in striatum and cerebral cortex except that changes in labeling in these areas were delayed in a manner depending on ischemia severity. These results were reproduced in brain slices under in vitro conditions mimicking ischemia and this is expected to allow correlation of Cx43 detectability with the functional state of astrocytic gap junctions and with changes that occur in astrocytic intercellular communication during ischemic pathology. KINETICS OF CELL CYCLE INHIBITION IN PRIMARY ASTROCYTES AND GLIOMA CELLS. V. Li, R.C. Chou and T.J. Langan*. Depts. of Neurology and Neurosurg. Sch. of Medicne, SUNY at Buffalo, NY 14222

Mammalian astrocytes remain in a state of quiescence, but maintain the capacity to leave Go/G1 and enter S phase of the cell cycle in response to brain injuries/diseases or due to neoplastic transformation. The mechanisms involved in this activation process remain unknown, although the sterol synthetic pathway is believed to play a role. In the present study, the time courses of cell cycling in primary astrocytic and glioma cell cultures were compared. Primary astrocytes were harvested from Sprague Dawley rat pups of 0-48 hrs old, while C6 glioma cells were purchased from ATCC. These cell cultures were allowed to grow to 30-50% confluence in DMEM + 10% bovine calf serum (BCS), followed by serum deprivation in DMEM + 0.1% BCS for 48 hrs. The cell cultures were then incubated in DMEM + 10% BCS in the presence of two cell cycle phase-specific inhibitors, hydroxyurea and the HMG CoA reductase inhibitor mevinolin, which were added to the cell cultures at different time points of incubation. Rates of DNA synthesis were evaluated by measuring ³H-thymidine incorporation and total cellular protein content. Results reveal that C6 glioma cells entered S phase 3-4 h earlier than primary astrocytes after synchronization. Maximum inhibition of DNA synthesis in primary astrocytes by mevinolin occurred with exposure at 10-14 h post-synchronization. Similar inhibition by mevinolin occurred 4 h early in C6 glioma cells. The inhibitory effect of hydroxyurea on both primary astrocytes and C6 glioma cells increased with incubation time. Early withdrawal of hydroxyurea resulted in more complete recovery of cell cycling in the C6 glioma cells. (Supported by N.I.H. grant NS-30718 to T.J.L.)

IN VITRO EFFECTS OF CELL CYCLE INHIBITORS ON PRIMARY ASTROCYTES AND GLIOMA CELLS. R.C. Chou, V. Li, M. Wong, and T.J. Langan. Depts. of Neurology and Neurosurgery, State University of New York at Buffalo, Buffalo, NY 14222

Astrocytes remain in a state of quiescence in the mammalian central nervous system under normal circumstances, but enter the cell cycle during many pathological conditions, such as neoplasia. The sterol synthetic pathway is believed to play a role in regulating cell cycling. In the present study, we examined the effects upon astrocytic cell cultures of two cell cycle phase-specific inhibitors, hydroxyurea and the HMG CoA reductase inhibitor mevinolin. Primary astrocytes were obtained from neonatal Sprague Dawley rats pups. These cell cultures, as well as C6 glioma cells, were grown in DMEM + 10% bovine calf serum (BCS). After synchronization in DMEM + 0.1% BCS for 48 hours, they were incubated for different periods of time in DMEM + 10% BCS in the presence of graded concentrations of hydroxyurea and mevinolin. thymidine incorporation and protein content in cultures were measured. Rate of DNA synthesis at the S phase of the cell cycle is significantly higher in C6 glioma cells. Both hydroxyurea and mevinolin caused significant concentrationdependent inhibition of cell proliferation in primary astrocytes and C6 glioma cells. However, hydroxyurea and mevinolin appeared differentially synergistic in their inhibitory effects upon primary astrocytes and C6 glioma cells. Thus, not only do these results indicate the presence of different cell cycle regulatory mechanisms in the two types of cells, they also suggest possible interventions for selective targeting of neoplastic astroglia. (Supported by N.I.H. grant NS-30718 to T.J.L.)

DETECTION OF DEPHOSPHORYLATED Cx43 IN BRAIN, HEART AND IN SPINAL CORD AFTER NERVE STIMULATION. J.I. Nagy*1. W.E.I. Li¹, B.W. Doblel² S. Hochman¹, E.L. Hertzberg³ and E. Kardami^{1,2}. Dept. of Physiol¹ & Anat.², Univ. of Manitoba, Winnipeg, R3E 0W3 Canada, Dept. of Neurosci.³, Albert Einstein College of Med., Bronx, NY 10461.

Cells that express connexin43 (Cx43) contain various levels of phosphorylated or dephosphorylated forms of this protein. We have identified a monoclonal anti-Cx43 antibody (designated 13-8300; Zymed Laboratories Inc.) that appears to recognize specifically dephosphorylated form of Cx43. Immuno-histochemically, it did not detect Cx43 in heart, cultured cardiac myocytes or in brain, but produced staining in brain after Cx43 dephosphorylation. By Western blotting, only a 41 kDa form of Cx43 was detected in control brain and in homogenate from neonatal cardiac myocyte cultures after alkaline phosphatase treatment, while no bands were recognized in a gap junction-enriched membrane preparation from adult hearts. In contrast to intense staining seen in dorsal horn with other anti-Cx43 antibodies, only faint staining was seen with 13-8300. After nerve cut, intense labeling appeared in lateral regions of lamina I-III. After 1 hr sciatic nerve stimulation, it gave increased punctate labeling in the dorsal horn. These results suggest that neuronal activity increases Cx43 dephosphorylation, which may alter coupling efficiency of astrocytic gap junctions.

TUMOR NECROSIS FACTOR AND CELL CYCLING IN PRIMARY ASTROCYTES. L. Pleban*, R.C. Chou and T.J. Langan. Depts of Physiology and Neurology, State University of New York at Buffalo, Buffalo, NY 14214.

Astrocytes, normally in a state of quiescence in the cell cycle (arrested in phase G₀), are activated and re-enter the cell cycle during reactive gliosis that ensues in response to brain injury/disease. The proinflammatory mediator tumor necrosis factor (TNF) has also been implicated in several neurological disorders. Production of TNF by astrocytes, as well as possible feedback augmentation on astrocyte proliferation by TNF, was examined in the present study. were obtained from neonatal Sprague Dawley rat pups and cultured in DMEM + 10% bovine calf serum (BCS). Sychronization of astrocytes occurred through serum deprivation for 48 hours, followed by serum up-shift in DMEM + 10% BCS, allowing astrocytes to re-enter the G1 phase of the cell cycle. Kinetic studies of astrocyte proliferation were performed by measuring 3H-thymidine incorporation and total cellular protein content at different time points. TNF production by astrocytes, as well as cell proliferation upon stimulation by bacterial lipopolysaccharide (LPS) was also determined. Results of our studies demonstrate that both LPS and recombinant TNF enhance astrocyte proliferation in a concentration-dependent manner. Additionally, an increase in TNF concentration was found upon graded stimulation of astrocytes by LPS. TNF levels were undetectable in control culture supernatant. However, significant downregulation of astrocyte proliferation was found upon addition of a polyclonal anti-TNF antibody for different periods of time during the Go/G1 phase. These results suggest that TNF released from astrocytes has an autoregulatory effect upon their progression through the cell division cycle. (Supported by N.I.H. grant NS-30718 to T.J.L.)

ACTIVATED ASTROCYTES INDUCE NITRIC OXIDE SYNTHASE-2 EXPRESSION IN CEREBROVASCULAR ENDOTHELIAL CELLS. Pathology and Pharmacology, Univ. of Iowa, Iowa City, IA 52242, and Dept. Neuropharmacology, Scripps Research Inst., La Jolla, CA 92037.

Activation of astrocytes with cytokines promotes release of a transcriptionally-regulated factor which can

induce nitric oxide synthase (NOS)-2 mRNA and protein expression in cerebrovascular endothelial cells. To define the nature of this factor, RNA from activated astrocytes was subjected to ribonuclease protection assay astrocytes was subjected to ribonuclease protection assay with a panel of probes for cytokines and, based on this screening, TNF α and IL-6 were selected. TNF α alone or in combination with IL-6 will induce NOS-2 expression in endothelium. TNF α signals through the NF-KP pathway and we found translocation of the p65 subunit into nuclei of endothelial cells exposed to activated astrocytes. In addition, astrocyte induction of NOS-2 in endothelium could be blocked by N-acetylcysteine, an inhibitor of NF-2 activities. KB activation. These results suggest intercellular signalling mechanisms by which NOS-2 expression in the CNS may be amplified under pathological conditions. Supported by NS24621.

ASTROCYTE NITRIC OXIDE SYNTHASE-2 EXPRESSION IS BLOCKED BY DIVERSE FACTORS THAT INHIBIT NF- κ B BINDING TO DNA. S.K. Park*, H.L. Lin and S. Murphy. Dept. of Pharmacology, Univ. of Iowa College of Medicine, Iowa

S.K. Park*, H.L. Lin and S. Murphy. Dept. of Pharmacology, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

We have shown that prior exposure of astrocytes to a diversity of factors blocks subsequent activation of the nitric oxide synthase (NOS)-2 gene by cytokines. The purpose of this study was to reveal whether a single or multiple mechanisms of action are involved. Exogenous NO did not block cytokine-evoked translocation of the p50 or p65 subunits of NF-KB into the nucleus. Gel shift assay revealed that the NF-KB complexes which bind to the promoter response element are composed mainly of p50 homodimers. This binding of p50 to DNA was inhibited by NO in a redox-sensitive and reversible manner. The formation of other transcription factor complexes with DNA (IRF-1, STAT 1) was little affected by NO. Gel shift assay also showed diminished p50/DNA binding in cytokine-activated astrocytes pretreated with ATP and glutamate. but cytokine activation of NF-KB (deduced from p65 translocation) was unaffected. These results suggest that diverse factors can block activation of the NOS-2 gene at a common site, namely at NF-KB response elements in the promoter. Such regulation may explain the spatial and temporal pattern of NOS-2 expression associated with particular neuropathologies such as stroke and trauma. particular neuropathologies such as stroke and trauma. OPPOSITE EFFECTS OF ADENOSINE A3 RECEPTOR AGONISTS ON ASTROCYTES: CELL PROTECTION AT LOW AND INDUCTION OF CELL DEATH AT HIGH CONCENTRATIONS. M.P. Abbracchio 1*, S. Ceruti 1. R. Brambilla¹, D. Barbieri², C. Franceschi², A.M. Giammarioli³, G. Rainaldi³, W. Malorni², DKJE von Lubitz⁴, K.A. Jacobson⁴, F. Cattabeni¹. ¹Inst. Pharmacol. Sci., Milan, Italy; ²Inst Gen Pathol., 41100 Modena, Italy; ³Ist. Sup. Sanita, 00100 Rome, Italy; 4Mol. Recogn. Sect., Lab. Bioorg. Chem., NIDDK/NIH, Bethesda, MD 20892, USA

Acute or chronic treatment with the adenosine A3 selective agonist N⁶-(3-iodobenzyl)adenosine-5'-N-methyluronamide (IB-MECA) prior to ischemia in gerbils has been shown, respectively, to worsen or ameliorate survival rate and hippocampal cell death (von Lubitz et al., Eur. J. Pharm. 263:59, 1994). To investigate the role of astroglial cells in these effects, we exposed both rat brain primary astrocytes and ADF cells (a human astroglioma cell line) to either IB-MECA or its 2-chloro-derivative (Cl-IB-MECA) (0.01 nM-60 µM). In both systems, morphological and flow cytometric analysis of propidium iodide-stained nuclei revealed apoptosis at 30-60 μ M agonist concentrations. At 10-100 nM concentrations, neither compound induced apoptosis, but instead a marked reduction of the number of spontaneously detached apoptotic cells was observed. These effects were also accompanied by profound morphological changes such as increased cell protusions, increased staining of microfilament markers and modified cell adhesion patterns. A3 agonists therefore induce biphasic and concentration-dependent changes of astrocytes, resulting in cell protection at nM and in apoptosis at μ M concentrations. These effects may be related to the opposing actions of IB-MECA on ischemia-associated cell death after <u>in vivo</u> administration.

SCHWANN CELL APOPTOSIS IN DEVELOPING PERIPHERAL NERVE AND ITS REGULATION BY NEUREGULIN Judith B. Grinspan*, Mark A. Marchionni, Matthew Reeves, Markella Coulaloglou, and Steven S. Scherer, Children's Hospital of Philadelphia and University of Pennsylvania, Phila, PA 19104 and Cambridge Neuroscience, Cambridge, MA 02139

In the developing nervous system, the differentiation of neurons and disadents like the second system.

oligodendroglia is accompanied by a large amount of programmed cell death resulting from competition for limited amounts of growth factors. We have now demonstrated that Schwann cells are also subject to programmed cell death via apoptosis modulated by Schwann cell:axon interactions. Apoptotic Schwann cells expressing the \$100 antigen can be detected during the first two weeks after birth in the rat and constitute up to two percent of the Schwann cells. Axotomy increases the amount of apoptosis ten fold, but only during this post-natal period. Apoptotic Schwann cells express the low-affinity nerve growth factor receptor and erbB2/neu, but not myelin-related proteins such as periaxin, suggesting that only the pre-myelinating Schwann cells are susceptible to apoptosis. Schwann cell death following axotomy can be completely inhibited by administration of neuregulin, a growth factor which stimulates Schwann cells in vitro. Neuregulin administration also lowers the endogenous rate of apoptosis during early development. Developing Schwann cells express a neuregulin receptor composed of erbB2 and erbB3 which are phosphorylated in vivo in neonatal but not adult nerves. These data indicate that axon-Schwann cell interactions regulate the number of premyelinating Schwann cells in developing nerves, at least in part, through the actions of neuregulins. SOLUBLE TNF-RECEPTOR INHIBITS IL-12 PRODUCTION BY STIMULATED HUMAN ADULT MICROGLIAL CELLS. B. Becher, V. Dodelet, V. Fedorowicz and J. P. Antel*, Department of Neurology and Neurosurgery, Neuroimmunology Unit, McGill University, Montreal, QC, H3A 2B4, Canada.

Il-12 is a cytokine which is detected in active lesions in multiple sclerosis (MS) and which promotes the acquisition of a Th1 cytokine profile by CD4 T cells. Autoreactive T cells recovered from the CNS of animals with experimental autoimmune encephalomyelitis (EAE), a disease model for MS, display this phenotype. demonstrate that human CNS-derived microglia, but not astroglia can produce IL-12 in vitro. Under basal culture conditions, human adult microglia do not express detectable levels of IL-12, although these cells show some degree of activation as assessed by expression of immuno-regulatory surface molecules, such as HLA-DR and B7-1/2, and low levels of TNF-α mRNA. Following activation with LPS, IL-12 p40 mRNA and p70 Protein can be readily detected. IL-12 p70 production is preceded by TNF-α production and is inhibited by recombinant soluble human TNF receptor (II)-IgG1 fusion protein (shu-TNF-R). These data indicate regulation of IL-12 by an autocrine TNF-α dependent feedback loop, providing an additional mechanism whereby shu-TNF-R, now used in clinical trials in MS, may be exerting its effect. CHARACTERIZATION OF ASTROCYTES AND PROGENITOR CELLS PROLIFERATING IN RESPONSE TO EXCITOTOXIC INJURY <u>E.M. Welter</u>, S.D. Collins, and D.M.D. Landis* Dept. Neurology, Case Western Reserve University, Cleveland, Ohio 44106

We have distinguished two populations of cells that proliferate in response to a kainic acid-induced lesion in the adult rat caudatoputamen, using retrovirus-mediated transfer of the β -galactosidase gene and BrdU labelling. In ν ivo, β -gal-IR cells were clustered near the lesion site and adjacent to the needle tract. Very few β -gal-IR cells were positive for GFAP or vimentin through 30 days after injury. These cells did not express microglial markers (Ox42, ED1), immature oligodendrocyte markers (O4,

A2B5), or nestin, an intermediate filament protein found in neuroepithelial cells during development, or in astrocytes following injury.

In contrast, in cultures obtained from dissociated injury sites, many of the 8-gal-IR cells were positive for GFAP or A2B5/GalC, depending on the culture conditions.

cells were positive for GFAP or A2B5/GalC, depending on the culture conditions. This pattern of differentiation is characteristic of 0-2A progenitor cells.

When BrdU was injected systemically in addition to the retrovirus, we found that a large proportion of the BrdU-IR cells near the lesion were GFAP-IR or nestin-IR, but only rare 6-gal-IR cells were also BrdU-IR.

These results suggest that GFAP-IR cells and glial progenitor cells proliferate in response to injury. In vivo, the 6-gal-IR progenitor cells fail to express nestin and do not differentiate into GFAP-IR cells, but in viro they behave as O-2A progenitor cells. These may be properties of the labelled cell population, or differentiation in vivo may be altered by the viral genome. The low frequency of colabelling for BrdU. vivo may be altered by the viral genome. The low frequency of co-labelling for BrdU and β-galactosidase may reflect cumulative toxicity.

This study was supported by grant NS22614 from the National Institutes of Health to D.M.D. Landis.

Ceramide-dependent cell death in cultured cortical, oligodendrocytes. P.Casaccia-Bonnefil L. Aibel, M. V. Chao. Department of Cell Biology and Anatomy, Cornell University Medical College, NY, NY 10021.

Ceramide is a lipid second messenger implicated in the mechanism of apoptotic cell death. The effect of the cell permeable ceramide analogue C2 has been tested on primary cortical cultures of oligodendrocytes, neurons, and astrocytes. C2-ceramide, but not the inactive analogue dihydro-C2-ceramide, induced a dose-dependent dihydro-C2-ceramide, induced a dose-dependent cell death in primary oligodendrocytes that correlated with the activation of jun kinase. Committment of oligodendrocytes to cell death occurred within the first 6 hours of treatment. In contrast, ceramide treatment of primary astrocytic cortical cultures had no effect on cell survival and did not activate jun kinase. Furthermore, bipotential progenitors that were differentiated towards astrocytes, also became resistant to ceramide treatment as they acquired a mature astrocytic phenotype.

These experiments suggest that cell type specific factors are required for ceramidemediated cell death in the nervous system. Support by grants from NIH/NRSA and Shearson Lehman.

REDOX REGULATION OF C-JUN N-TERMINAL KINASE / STRESS-ACTIVATED PROTEIN KINASE IN GLIAH IMPLICATIONS FOR A CYTO-PROTECTIVE RESPONSE AGAINST OXIDATIVE STRESS, N.R. Bhat*. Neurology Dept, Med Univ SC, Charleston, SC 29425

The c-Jun N-terminal kinases(JNKs)/stress-activated protein kinases (SAPKs) are activated by pro-inflammatory cytokines and a variety of other stress inducers. This study examines the relationship between oxidative stress and JNK/SAPK activation in primary cultures of rat brain glial cells. Treatment of cultured astrocytes and oligodendrocytes with the cytokine $TNF\sigma$ resulted in a rapid activation of JNK/SAPK (determined by a solid-phase "kinase capture" assay) which could be blocked by oxidants, such as H₂O₂, diamide and diethyl maleate, but enhanced by the antioxidant, N-acetylcysteine (NAC). In contrast, oxidative stress induced by homocysteate (HCA), an inhibitor of cystine transport, and buthionine sulfoximine (BSO), an inhibitor of glutathione biosynthesis, resulted in a delayed but sustained activation of JNK/SAPK. conditions also induced cell death as determined by a cell viability assay using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazoliumbromide (MTT, a chromogenic compound cleaved by active mitochondria). Co-treatment with NAC inhibited oxidative stress-induced cytotoxicity at the same time potentiating JNK/SAPK activation. Gel mobility shift assay using AP-1 consensus sequences demonstrated changes in AP-1 DNA binding activity parallel to JNK activation/inhibition. These results suggest a complex regulation of JNK/SAPK by cellular redox state and implicate JNK/SAPK activation (and possibly AP-1 mediated gene regulation) in a protective response of glial cells to oxidative damage. Supported in part by NMSS grants RG2481 and RG2474.

THE EFFECT OF A FREE RADICAL GENERATOR ON MYELINATED RAT SPINAL CORD AGGREGATE CULTURES B.L. Bartnik and R.M. Devon.* Department of Anatomy and Cell Biology, University of Saskatchewan, Saskatoon. SK. S7N-5E5 Canada

Recent in vitro experiments suggest that, compared to astrocytes, oligodendrocytes and their precursors have reduced abilities to scavenge free radicals due to lower levels of glutathione and increased iron content. The following study was performed to determine the effect of free radicals on both myelin and oligodendrocyte mophology. Myelinating E15 rat spinal cord aggregate cultures were established and used as an in vitro model of CNS myelination. Aggregate cultures were maintained for 4 weeks in DMEM/F12 supplemented with 10% FBS and 1% glucose until adequately myelinated. Aggregates were then treatred with 3-morpholinosyndnonamine (SIN-1). myelinated. Aggregates were then treatred with 3-morpholinosyndnonamine (SIN-1), an 0°_2 and NO' generator, in concentrations ranging from 1mM through to $0.01\mu M$ and sampled at 24.48 and 96 hours. Treating the cultures with 1mM, 100 μM and $10~\mu M$ for 24 hours resulted in a dramatic loss of neuropil in the aggregate accompanied by widespread non-specific cell death. By 48 hours the sampled aggregates were almost completely devoid of cellular detail and by 96 hours all cells were killed. Subsequent experiments using concentrations of $1\mu M$, $0.1\mu M$ and $0.01\mu M$ demonstrated that the SIN-1 had little effect on aggregate structure at 24 hours. However when sampled at 48 hours the aggregates showed a significant increase in damage to both the cells and myelin. This damage was both time and concentration dependent as determined by cell viability assays using Mitotracker as a viability probe. Alterations to the myelin structure in the form of delamination and demyelination of axons were determined by electron microscopy. Stereological analysis of cells in the aggregates indicate that at $1~\mu M$ SIN-1, there was a significant decrease in the cell number and nuclear volume fraction of oligodendrocytes by 48 hours and a concomitant increase in the nuclear volume fraction of astrocytes decrease in the cell number and nuclear volume fraction of oligonendrocytes by 46 hours and a concomitant increase in the nuclear volume fraction of astrocytes compared to the control aggregates. Taken together, these results suggest that oligodendrocytes appear to sustain free radical damage and that astrocytes may become reactive in response to the SIN-1 treatment.

INTERFERONβ-1b CAN COUNTERACT THE INCREASED MIGRATION RATE OF HUMAN T LYMPHOCYTES INDUCED BY CHEMOKINES. S.S. Jung*, O. Stüve, V.W. Yong. Montreal Neurological Institute, Department of Neuroimmunology, McGill University, Montreal, Canada, H3A 2B4.

Interferon B-1b (IFN B-1b) has been shown to be effective in decreasing the number of relapses in relapsing-remitting multiple sclerosis (MS); magnetic resonance imaging studies indicate that the number of CNS lesions is also reduced by IFNβ-1b. The mechanism of action of IFNβ-1b remains unclear. Evidence suggests that MS is a predominantly T lymphocyte-mediated disorder, and that the migration of systemic T cells into the cerebral parenchyma, towards a gradient of chemokines, constitutes a key event in its pathogenesis. Using a Boyden chamber assay, we investigated whether T lymphocyte migration towards chemokines could be influenced by IFN β -1b. We observed an anticipated increase in the migration rate of human T cells after exposure to the β chemokines MIP-1 α , MCP-1 and RANTES. Pretreatment of these cells with IFN\$\beta\$-1b reduced the migration rate to control levels. The mechanism of action of IFNB-1b is currently being investigated. Our findings suggest that a potential mechanism of IFNβ-1b in MS is the reduction in migration of T lymphocytes into the central nervous system.

A novel mechanism of antibody mediated oligodendrocyte cell death. Lixin Zhou* and Robert H. Miller, Dept. of Neurosci., Case Western Reserve Univ. School of Medicine, Cleveland, OH 44106. We have described a mouse monoclonal antibody (Mab) termed 2B10 which identifies a novel protein expressed on cell surface of oligodendrocytes and mediates myelin disruption in adult rat CNS. To investigate the effect of Mab 2B10 on oligodendrocyte development and survival, affinity purified Mab 2B10 was added to dissociated neonatal rat whole spinal cord cultures. Two days later significant cell death was observed. Immunofluorescent studies indicated that the number of O1' oligodendrocytes was reduced by more than 80%. By contrast, the number of astrocytes in these cultures were not affected. Mab 2B10 did not affect proliferation and differentiation of A2B5/O4. contrast, the number of astrocytes in these cultures were not affected. Mab 2B 10 did not affect proliferation and differentiation of A2B5'/O4 oligodendrocyte precursors. The specific removal of O1' oligodendrocytes was independent of complement, but required environmental signals. In immunopanned purified oligodendrocyte cultures, binding of the antibody to the oligodendrocyte cell surface did not result in cell death. Transwell co-culture and conditioned medium experiments indicated that soluble signals alone were not adequate for the antibody killing. However, Mab 2B10 induced cell death was reconstituted in cultures where purified oligodendrocytes were grown on top of astrocyte monolayer, suggesting that a contact dependent signal from astrocytes is required. Such antibody mediated oligodendrocyte cell death may in part explain the loss of oligodendrocytes and myelin in such demyelination diseases as Multiple Sclerosis. (supported by NIH grant 30800)

CHARACTERIZATION OF PHOSPHODIESTERASE I EXPRESSION IN THE CNS OF NORMAL, MUTANT AND EAE MICE. B. Fuss^{1*}, H. Baba², T. Phan¹, P. A. Dore-Duffy³, V.K.Tuohy and W. B. Macklin ¹ 'Cleveland Clinic Foundation, Cleveland, Ohio 44195, USA. ²Nat. Inst. for Physiol. Sci., Okazaki, Aichi 444, Japan. ³Wayne State Univ Sch Med, Detroit, MI 48201, USA

The cDNA clone p421.HB/phosphodiesterase I was isolated by differential and subtractive screening techniques in order to identify new proteins expressed in oligodendrocytes. Sequence analysis revealed that it represents an alternatively spliced isoform of rat brain-specific phosphodiesterase I/pyrophosphatase and a species homolog of the human cytokine autotaxin. In situ hybridization of rat brain sections revealed positive staining in cells of the choroid plexus and white matter tracts. During development, expression in white matter tracts peaks around postnatal day 20, whereas it continues to increase with age in the choroid plexus. Upon further analysis, we found that the longer alternatively spliced form of p421.HB/phosphodiesterase I is brain-specific, while the shorter isoform is expressed ubiquitously. In order to study possible functional roles of p421.HB/phosphodiesterase I we characterized its expression in the mouse dysmyelinating mutant shiverer and in murine EAE (experimental autoimmune encephalomyelitis). The time course of its expression in wild type oligodendrocytes and lower levels of expression at p26 in shiverer mutant brains suggest an association of p421.HB/phosphodiesterase I with molecular events involved in myelin sheath formation. In the adult, p421.HB/ phosphodiesterase I expression seems restricted to cells of the choroid plexus and possibly microvessels (shown by RT-PCR of isolated microvessels). Therefore, initial experiments, in which p421.HB/phosphodiesterase expression appears to be downregulated in EAE brains, may suggest a possible functional role in the maintenance of body fluid - brain barriers. Supported by the National Multiple Sclerosis Society.

CHARACTERIZATION OF EXPRESSION PATTERNS OF MEMBERS OF THE CIC CHLORIDE CHANNEL FAMILY. J.L. Kugler*†, C.E. Sedwick†, and D.J. Nelson†§ Depts. of §Neurology and †Pharmacology and Physiology, University of Chicago, Chicago, IL 60637.

Sedwick†, and D.J. Nelson† & Depts. of & Neurology and †Pharmacology and Physiology, University of Chicago, Chicago, IL 60637.
Chloride currents are known to play important roles in such diverse activities as synaptic transmission, volume regulation, and morphological changes in microglia. Some have been well characterized at the molecular level, particularly CFTR and the GABA, and glycine receptor-ionophores. A new family of Cl channels has recently been identified by sequence homology to the voltage-gated Torpedo Cl channel, ClC-0. One obstacle to characterization of ClC family members has been an inability to obtain reliable functional electrophysiological expression of many of these channels in either *Xenopus* coocyte* or mammalian expression systems. We have used heteroplex PCR techniques in an attempt to identify the molecular basis for a nearly ubiquitously expressed calcium-activated Cl conductance which we believe to be a member of the ClC family. By this assay, human monocytes and macrophages express ClC-3 but not ClC-4, while 1774.1 cells (a murine monocyte-derived cell line) express ClC-4, clC-5 and ClC-7, but not ClC-3 or ClC-6. Neither human macrophages nor 1774.1 cells appear to express ClC-1 or ClC-2. Partial sequencing of the human isoform of rat ClC-3 has demonstrated strong homology with the rat isoform at the amino acid level with considerable divergence at the nucleotide level. Electrophysiological studies of rat ClC-3 transiently expressed in human macrophages and murine 1774.1 cells has identified a Ca²-calmodulin dependent kinase II- (CaMK-II)-activated, nonselective ion conductance which, once activated, leads to cell death by osmotic swelling. Based on these observations, we conclude that neither ClC-1, ClC-2, ClC-3 nor ClC-4 is responsible for the ubiquitous calcium-activated Cl conductance. This current may be carried by another previously identified ClC family member, or perhaps a novel channel.

THE CI CURRENT ACTIVATED BY ALPHAXALONE IN EMBRYONIC HUMAN DRG CELLS A.Y. Valeyev*, J.C. Hackman*, P.M. Wood* and R.A. Davidoff* Neurophysiology Laboratory, Veteran*s Administration Medical Center*, Department of Neurology and Miami Project*, University of Miami, School of Medicine, Miami, Florida 33101

Whole-cell voltage clamp recordings with Cl-filled pipettes were performed at room temperature on cells cultured from embryonic (8-10 week) human dorsal root ganglia (DRG). Neurons were grown for 5 or more days in serum-supplemented medium. In the majority of cells recorded in 1 μM TTX and 10 mM MgCl₂ the baseline current signal fluctuated at all potentials except 0 mV. All cells responded to micromolar concentrations of GABA, pentobarbital, or alphaxalone (3α-hydroxy-5α-pregnane-11,20-dion) but not muscimol, baclofen or CACA (cis-4-aminocrotonic acid). With equal intra- and extracellular Cl concentrations, the reversal potential for alphaxalone-activated current was set near 0 mV which corresponds to E_{Cl}- calculated from the Nernst equation and suggests a dominant role for Cl ions in the response. GABA receptor agonists and modulators were applied by pressure pulses from closely positioned pipettes. The current activated by alphaxalone was linear at negative holding potentials, but displayed strong rectification at positive holding membrane potentials. The Cl current activated by alphaxalone was not blocked by bicuculline, picrotoxin or TBPS. Single-channel recording show unique properties of the alphaxalone-activated current. IDENTIFICATION OF CA2*-DEPENDENT CI*-CONDUCTANCE IN NEONATAL RAT PHRENIC MOTONEURONS, C.K. Su* & J.L. Feldman. Depts. of Physiol. Sci. and Neurobiol., UCLA, LA, CA 90095-1527

J.L. Feldman. Depts. of Physiol. Sci. and Neurobiol., UCLA, LA, CA 90095-1527

To understand the postinspiratory changes of membrane excitability induced by inspiratory drive, ionic conductances were measured in neonatal rat phrenic motoneurons (PMNs) following long depolarizing pulses. We focused on Ca³-dependent conductances, especially the Ca³-dependent Cl conductance. Experiments were performed after blockade of synaptic transmission by TTX. To eliminate the confounding effects of K⁻ currents, PMNs were loaded with high Cs¹ under whole-cell patch-clamp conditions. The Cl equilibrium potential (E_{Cl}) was raised to about -35 mV by increasing intracellular Cl concentration. A two-pulse paradigm was used: a depolarizing pulse (-60 to -10 mV, 100-400 ms) was followed by a step pulse to different levels (-120 to -50 mV, 10 mV/step, 900-600 ms). With a low Ca³- buffer pipette solution (0.1 mM BAPTA), a long tail inward current was elicited by the depolarizing pulse. Extrapolation of the I-V curve indicated the tail current reversed close to E_{Cl}. Such tail currents were abolished by 50 µM Cd³- or high Ca³- buffer pipette solution (10 mM BAPTA). Activation (at -10 mV) and inactivation (at -80 mV) of this conductance were also time-dependent, with a 50% ratio at about 90 and 140 ms, respectively. Our data suggest that a Ca³--dependent Cl conductance underlies the tail responses induced by inspiratory drive. This conductance may facilitate membrane repolarization toward resting levels under normal physiological conditions and may stabilize PMN membrane potential during strong inspiratory drives. A MULTI-LEVEL HIGH CONDUCTANCE CHLORIDE CHANNEL IN PC12 CELLS. R.J. Pearce* and Z. Galdzicki. LNS, NIA, NIH, Bethesda, MD 20892.

A chloride channel which reaches the upper limits of single channel conductance values has been observed in a number of cell types, including skeletal muscle, neurons and epithelia. We have now identified a similar channel in undifferentiated PC12 cells. Using the single channel patch-clamp technique we have recorded from PC12 cells (2-3 days in culture) in both the cell-attached and the excised-patch mode. Single channel activity was observed in 40% (n=27) of cell-attached patches. For excised patches, 70-90% showed activity depending on the recording solution (n=118). In general, activity was not seen immediately on patch excision, but started within a couple of minutes. In excised patches, under conditions of symmetrical 120 mM choline chloride, 10 mM CaCl₂, 10 mM TEA and 10 mM 4-AP, two correlated single channel levels were most frequently elicited: the first one corresponded to a maximum conductance level of 360 ± 55 pS (n=4) and the second (a substate) corresponded to a lower conductance of 142 ± 13 pS (n=4). We also observed other levels with lower probabilities of opening indicating the existence of numerous sub-levels. Replacing the major cation with either Na (120 mM) or Cs (120 mM) had no significant effect on the reversal potential for either conductance level (n=3-5). However, replacing 120 mM of the total 154 mM chloride with acetate resulted in a significant shift in the reversal potential at both conductance levels (n=3), confirming chloride as the major charge carrier for this channel. In no instance did the reversal potential of the two main conductance level differ significantly. Single channel activity was observed in the presence of CaCl₂ at 10 mM, 2 mM and nominal (µM) levels. Removing calcium with EGTA did not significantly alter the reversal potential or slope conductance of either the high or low conductance. In 120 mM symmetrical choline chloride and 10 mM EGTA only 42% of patches (n=12) showed activity, comparable with the activity of cell-attached patches, but lower than the activity observed in excised patches in Ca-containing solutions. This raises the possibility that while the channel is not calcium-dependent it may be calcium modulated.

SINGLE CHANNEL RECORDINGS OF THE INWARD RECTIFIER CURRENT I_H FROM HUMAN SURAL NERVE AXONS <u>S. Quasthoff, J. Großkreutz, M. Kühn, Ch. Alzheimer and P. Grafe*.</u> Dept. of Neurology (S.Q., J.G., M.K.), Technical Univ. and Dept. of Physiology, Univ. of Munich, Munich, Germany. A time-dependent inward rectification has been demonstrated in myelinated axons of mammalian peripheral nervous system (Baker, Bostock, Grafe & Martius 1987 J.Physiol. 383:45-67). The functional role of the hyperpolarization-induced current (IH) may be to maintain membrane potential at appropriate levels during highfrequency firing. After the patch-clamp technique was applied to the myelinated axon many different ion channels have been described. However, up to now single channel recordings of the ion channel responsible for this delayed inward rectification current (IH) are absent. We applied the patch-clamp technique to enzymatically dissociated and para- and/or internodally demyelinated axons from human sural nerve biopsies. The following solutions were used to registrate the unspecific cation current: (mM) NaCl, 70; KCl, 70; CaCl2, 1.8; MgCl2, 1; BaCl2, 1; MnCl2, 2; and Hepes-NaOH, 5; (for electrodes) and potassium aspartate, 130; NaCl, 10; CaCl2, 2; EGTA, 5; and Hepes-KOH, 10 (for bath). A hyperpolarizing current pulse protocol (0.5-1 sec. duration) from a holding potential of 0 mV was applied to the inside-out membrane patches. In the presence of 10-100 μ M c-AMP in the bath solution hyperpolarization in a range of -60 to -140 mV resulted in delayed activation of up to three single channel levels. Latency from the pulse start to the first opening of the channels ranged between 50 to 100 ms. No channel inactivation was observed during long lasting current pulses. The calculated slope conductance of the I/V curve was about 0.96 pS. The channel share many common characteristics with the (I_f) channel in cardiac pacemaker sino-atrial node cells described by DiFrancessco and Mangoni (J. Physiol. 1994 474: 473-482). In summary, we describe single channel recordings of the delayed inward rectifying channel ($l_{\rm H}$) from human sural nerve axons. Channel activity seems to be directly dependent on long lasting hyperpolarization and on the presence of c-AMP. Supported by the W. Sander Stiftung (S.Q., M.K.) and the DFG.

MOLECULAR AND PHARMACOLOGICAL CHARACTERISATION OF THE HYPERPOLARISATION ACTIVATED CHLORIDE CURRENT IN DISSOCIATED RAT SCG NEURONS. Samannha Clark, Maureen Docherty and Alistair Mathie*. Department of Pharmacology, Royal Free Hospital School of Medicine, Rowland Hill St., London NW3 2PF, UK.

We have shown that neurons isolated from the superior cervical ganglion (SCG) of 7-8 day old rats possess a hyperpolarisation-activated inwardly-rectifying chloride current $I_{\rm CISCG)}$ (Clark & Mathie, J. Physiol. 485 48-49P, 1995). Of the chloride channels cloned to date, the functional properties of this current have most in common with ClC-2, however, a complete functional characterisation of both $I_{\rm CISCG)}$ and ClC-2 is lacking and it is not known whether ClC-2 is expressed in SCGs.

In this study, we have used RT-PCR and Southern blotting of PCR products to show that mRNA for CIC-2 is present in dissociated rat SCGs. In contrast, rat cerebellar granule neurons, which do not possess a hyperpolarisation activated chloride current, do not appear to have mRNA for CIC-2. We have further characterised the properties of $I_{CI(SCG)}$ by examining the effects of five organic chloride channel blockers on the current using whole-cell patch-clamp recording. At -90 mV, DIDS (1 mM) blocked $I_{CI(SCG)}$ by 35 ±6% (n=3), 9AC (1 mM) inhibited the current by 34 ± 7% (n=5) and NPPB (200 μ M) inhibited it by 59 ±2% (n=7). In contrast SITS (1 mM, n=7) and niflumic acid (100 μ M, n=3) had little effect on $I_{CI(SCG)}$. Interestingly, the block produced by each of the three effective inhibitors was voltage-dependent with DIDS and NPPB producing a greater inhibition at depolarised potentials while 9AC was more effective at hyperpolarised potentials.

more effective at hyperpolarised potentials. Thus we have shown that CIC-2 is expressed in SCG neurons and we have provided a description of the action of a number of chloride channel blockers on $I_{\text{CI(SCG)}}$ which will aid future characterisation of this current. Supported by the MRC.

HYPERPOLARIZATION-ACTIVATED CURRENT (I_h) IN LAYER II CELLS OF THE MEDIAL ENTORHINAL CORTEX (MEC). <u>C.T. Dickson and A. Alonso.</u> Montreal Neurological Inst. and McGill University, Montreal, Que. Canada.

Stellate cells in MEC layer II display prominent time dependent inward rectification in current clamp recordings with sharp electrodes. Using the infrared guidance technique we have now performed whole cell patch-clamp recordings of MEC layer II neurons from adult rat brain slices and characterized under voltage clamp conditions the hyperpolarization activated current (I $_{\rm h}$) underlying inward rectification. In response to hyperpolarizing voltage-clamp steps I $_{\rm h}$ activated slowly and showed no inactivation. The activation time course of I $_{\rm h}$ was well fitted by a double exponential and the time constant of both the fast and slow current components ($\tau_{\rm f}$ and $\tau_{\rm S}$) decreased with hyperpolarization. The mean values of $\tau_{\rm f}$ and $\tau_{\rm S}$) decreased with hyperpolarization. The mean values of $\tau_{\rm f}$ and $\tau_{\rm S}$) at 30 me 175ms and 500ms, respectively. I $_{\rm h}$ activated over the range -55 to -120mV with half activation at -85mV. The reversal potential of I $_{\rm h}$ was estimated by extrapolation of the instantaneous (chord) conductance computed from II/P plots at different holding potentials and was, on average, -30 mV. Over the entire range of voltage potential steps, raising [K $^{+}$] $_{\rm o}$ or [Na $^{+}$] $_{\rm o}$ was found to decrease the amplitude of the current while lowering [K $^{+}$] $_{\rm o}$ or [Na $^{+}$] $_{\rm o}$ was found to decrease the amplitude of I $_{\rm h}$. Similarly to inward rectification in current clamp, I $_{\rm h}$ was blocked by perfusion with 2mM Cs $^{+}$ but not 2mM Ba2 $^{+}$. Blockade of I $_{\rm h}$ with Cs $^{+}$ decreased the rhythmicity and lowered the frequency of the subthreshold membrane potential oscillations typical of the stellate cells. Thus, it appears that this current plays a significant but not determinant role in pacing the active subthreshold membrane voltage behavior of the stellate cells. Thus was supported by the MRC, the FRSQ and an NSERC fellowship to C.T.D.

PACAP ACTIVATES A NOVEL NON-SELECTIVE CATION CHANNEL IN RAT PINEAL CELLS N. Darvish, B. H. Nguyen, E. Neale and J. T. Russell LCMN, NICHD, NIH.

Analysis of membrane currents using patch clamp techniques in cultured rat pineal cells revealed a novel class of non selective cation channels activated by pituitary adenylate cyclase activating polypeptide (PACAP) and its second messenger cAMP. Channel activity was observed in 30% of the patches having a unitary conductance of 150±2pS (n=25). The open probability (P_O) measured in the on-cell and in the inside-out modes increased at depolarizing voltage commands. Bath application of PACAP (1µM) in the cell attached mode increased P_O from 0.0027±0.001 to 0.26± 0.1 (n=12) suggesting a second messenger mediated mechanism. In the resting cell, the channel was found to carry only outward current (n=25). Upon PACAP application, however, inward current was detectable through the same channel (n=10) in the patch, suggesting a PACAP induced change in channel rectification properties. In the cell attached mode, 8-Br-cAMP (2mM) activated the channel within 3-8 min (n=5) while, the Rp isomer of cAMP did not, raising the possibility of a cAMP mediated phosphorylation step for channel activation (n=4). The permeability ratio (PK+/PNa+) of the channel activation (n=4). The permeability ratio (PK+/PNa+) of the channel activation mediated phosphorylation step for channel activation (n=4). The permeability ratio (PK+/PNa+) of the channel rectification properties by 10 mediated phosphorylation step for channel activation (n=4). The permeability ratio (PK+/PNa+) of the channel rectification properties by 10 mediated phosphorylation step for channel rectification properties by 10 mediated phosphorylation step for channel activation (n=4). The permeability ratio (pK+/PNa+) of the channel activation concentration to 110-8 M had no effect on channel Po (n=6) and CSCI (10mM) applied to the inner mouth of the channel blocked all channel activity. Under the current clamp condition, PACAP application resulted in depolarization of resting membrane potential by 12±2MV which is in agreement with

A HYPERPOLARIZATION-ACTIVATED CURRENT CARRIED BY SODIUM AND POTASSIUM (Ih) IN PITUITARY CELLS. S.M. Simasko* and S. Sankaranarayanan. Dept. of VCAPP, College of Veterinary Medicine, Washington State Univ., Pullman, WA 99164. The ionic mechanisms that underlie spontaneous electrical activity in

The ionic mechanisms that underlie spontaneous electrical activity in lactotrophs and somatotrophs have yet to be fully elucidated. In this study we have investigated the possibility that an Ih- or If-like current could participate in maintaining spontaneous electrical activity as it does in cells of the SA-node in the heart. In the clonal pituitary cell line GH₃, which secrete both prolactin and growth hormone, a slow activating, sustained inward current was observed when cells were held at -60 mV and pulsed to -120 mV (1 sec to half maximal activation; -16.4 ± 1.5 pA in physiological solutions, n=71). The current was 50% activated at -99 mV, unaffected by 10 mM tetraethylammonium, 10 mM 4-aminopyridine, or 1 mM Ba²+, but completely blocked by 3 mM Cs+. Reversal potential measurements demonstrated a 3-fold selectivity for potassium over sodium. A similar but smaller Cs+-blocked current was found in somatotrophs identified by reverse-hemolytic plaque assay (-2.4 ± 0.4 pA in physiological solutions, n=15) but not in plaque-identified lactotrophs. Exposing spontaneously spiking GH₃ cells to 3 mM Cs+ either had no effect or increased spike frequency. This latter result suggests that spontaneously spiking pituitary cells probably rest too far depolarized for this current to have any role in mediating spontaneous depolarizations. However, the possibility remains that this current, at least in somatotrophs, could be important in depolarizing the cell when the cell recovers from somatostatin-induced hyperpolarization.

A SLOW NONSELECTIVE CATION CONDUCTANCE ACTIVATED BY NEUROTENSIN IN MIDBRAIN DOPAMINERGIC NEURONS. P.-Y. Chien^{*1}, R. H. Farkas¹, S. Nakajima² and Y. Nakajima¹. Dept. of Anat. and Cell Biol. ¹, and Dept. of Pharmacol. ², Univ. of Illinois, College of Med., Chicago, IL 60612.

We previosly showed that in cultured dopaminergic neurons from the ventral tegmental area, neurotensin (NT) induces a conductance permeable to Na $^{+}$ and Cs $^{+}$, but not to Cl $^{-}$. We used whole-cell recording to further characterize this NT-induced nonselective cation conductance. The relative permeability of K $^{+}$ to Na $^{+}$ was calculated from the shift of reversal potential of the NT response in individual cells upon switching from Na $^{+}$ - to K $^{+}$ -containing external solution. The average shift of reversal potential was only -0.1±1.9 mV (n = 9). Thus, the permeability of K $^{+}$ to Na $^{+}$ (P_K / P_{Na}) was about 1. These results indicated that the current induced by NT was indeed a nonselective cation current. The latency of the NT response was long (\geq 185 msec, average 406 msec at 30 °C), suggesting that NT did not induce the conductance through a ligand-gated channel. The NT response was unaffected by loading the neurons with 1 mM cyclic GMP or cyclic AMP (each with the phosphodiesterase inhibitor IBMX, 100 μ M). Loading the neurons with either the Ca $^{2+}$ chelator BAPTA (20 mM) or with 1 mM Ca $^{2+}$ did not affect the size of the NT response. Therefore, the NT-induced nonselective cation conductance was neither activated by cyclic nucleotides nor by internal Ca $^{2+}$. Supported by NSF grant IBN 9319456 and F30MH10167.

CONCENTRATION DEPENDENCE OF CATION PERMEATION THROUGH CYCLIC AMP-GATED CHANNELS IN MAMMALIAN OLFACTORY RECEPTOR NEURONS

P. H. Barry, S. Balasubramanian, J. W. Lynch, and A. M. Cunningham, School of Physiology and Pharmacology. University of New South Wales, Sydney 2052 and Neurobiology Division, Garvan Institute of Medical Research, Darlinghurst, NSW 2010. Australia.

We have already investigated the permeation and selectivity properties of the adenosine 3', 5'-cyclic monophosphate (cAMP)-gated channel in excised insidebut patches from the dendritic knobs of dissociated adult rat olfactory neurons and shown (1) that these cyclic nucleotide-gated (CNG) channels are permeable to large organic cations, having minimum pore dimensions of about 6.5 x 6.5 Å, and (2) that they do not exhibit anomalous mole fraction effects. We have now investigated the concentration dependence of the current-voltage relations of these channels. In symmetrical NaCl solutions without added divalent ions, the current-voltage curve was linear, reversing close to 0 mV. Varying internal [NaCl], from 25 to 300 mmol/l NaCl (osmotically balanced with sucrose) with external [NaCl], sept constant at 150 mmol/l, the reversal potential closely followed the Na' equilibrium potential, implying that $P_{\rm Cy}/P_{\rm Na} \equiv 0$. Na' currents through the channels did not obey the independence principle, with inward currents being much more strongly dependent on internal [Na] at negative potentials than would be predicted by equations such as the Goldman-Hodgkin-Katz equation. The patch currents exhibited saturation kinetics as internal [Na] increased, with an apparent dissociation constant of about 125 \pm 1 mmol/l, at both positive and negative potentials. These results suggest multiple binding sites within the channel, presumably with sites located close to each end of the channel.

Supported by the Australian Research Council.

SODIUM-ACTIVATED CATION CHANNEL FROM LOBSTER OLFACTORY RECEPTOR CELLS: GATING AND CONDUCTION PROPERTIES. A. B. Zhainazarov and B. W. Ache. Whitney Lab. and Depts. Zoology & Neurosci., Univ. of Florida, St. Augustine, FL 32086

We further characterized a novel Na+activated channel in excised patches from lobster olfactory receptor cells (J. Neurophys. 73: 1774, 1995). The open probability vs [Na⁺] relationship could be fit by the Hill equation with a coefficient of 3.1. At 210 mM (saturating) Na*, the open probability was 0.5±0.1(S.D.) (n=5; -60 mV). At 30 mM Na+, channel openings were infrequent and bursty. Increasing [Na+] increased the frequency of transitions until at 180 mM Na* one observed long, continuous flickering transitions. At 30 mM Na⁺, the closed time distribution could be fit by the sum of four exponential components with mean time constants of 0.2±0.1, 7.8±2.0, 80±10, and 896±23 ms. At 210 mM Na+, the closed time distribution could still be fit by a four exponential function, but the longer tree components shortened considerably. The open time distributions could be fit by a single-exponential function [4.6±0.1] (S.E.M.) ms, 30 mM Na⁺] that was not affected by [Na⁺]. Permeability ratios calculated from the reversal potentials for monovalent and divalent cations in biionic conditions were Li(1.1)>Na(1.0)>K(0.5)>Rb (0.4)>Cs(0.2) and Ca(35)>Mg(30)>Mn(13)>Ba(11)>Na(1). The channel could be localized this channel to the outer dendrites, the site of odor transduction in these cells, but its role in transduction, if any, remains to be determined. FUNCTIONAL COUPLING OF CAPACITATIVE CALCIUM ENTRY AND SECRETION IN PC12 CELLS. S. Koizumi* and K. Inoue. Div. Pharmacol., Natl. Inst. Health Sci., Kamiyoga, Setagaya, Tokyo 158,

The caffeine-evoked rise in intracellular Ca²⁺ concentration ([Ca]i) and release of dopamine in rat pheochromocytoma PC12 cells were investigated. Caffeine produced a transient rise in [Ca]i followed by a sustained elevation in [Ca]i in the cells. When extracellular Ca²⁺ was sustained elevation in [Ca] in the cens. When extracellular Ca²⁺ was removed, the sustained [Ca]i rise was disappeared whereas the transient one was unaffected, showing that the sustained [Ca]i rise results from Ca²⁺ influx from extracellular spaces. Pretreatment of cells with cyclopiazonic acid, an inhibitor of Ca²⁺ATPase of endoplasmic reticulum, abolished the Ca²⁺ responses to caffeine, which suggests that both of the transient and the sustained [Ca]i rises depend on intracellular ${\rm Ca^{2+}}$ stores. Caffeine evoked the release of dopamine in the cells, which was totally dependent on extracellular ${\rm Ca^{2+}}$. The effects of ${\rm Zn^{2+}}$, ${\rm Cd^{2+}}$ La³⁺ and nicardipine on the caffeine-evoked responses were examined. Both the caffeine-evoked dopamine release and the sustained rise in [Ca]i Both the caffeine-evoked dopamine release and the sustained rise in [Ca]i were inhibited by Zn^{2+} (30 μ M) but not by Cd^{2+} (100 μ M), La^{3+} (100 μ M) or nicardipine (30 μ M). The transient rise in [Ca]i induced by caffeine was not affected by Zn^{2+} . Taken together, we demonstrated that caffeine stimulates not only Ca^{2+} mobilization but also Ca^{2+} influx via a pathway which is highly sensitive to Zn^{2+} and that the sustained Zn^{2+} influx is essential for the release of dopamine from PC12 cells. It is strongly suggested that the sustained Ca2+ influx evoked by caffeine appears to be so-called "capacitative Ca²⁺ entry" and that one of the physiological significance of the Ca²⁺ entry is secretion in the cells.

AUS.14

NEURONAL AND NON-NEURONAL CELLS. S. DasGupta, F. Qian, R.J. Miller and L.H. Philipson'. Depts. of Pharmacol. and Physiol. Sci. and Medicine'. University of Chicago, Chicago, IL 60637.

In many cells, production of IP₃ releases intracellular calcium, resulting in a biphasic calcium signal; the first from a transient rise in the cytosolic calcium concentration, followed by calcium influx across the plasma membrane. Proteins homologous to the Drosophila photoreceptor transient receptor potential (tpp), have been suggested to be involved in voltage independent calcium entry while trp1-related proteins may encode an IP₃-activated nonselective cation current. We have recently cloned mtrpb-1, a mammalian trp and trp1 homologue from mouse BTC3 cells an IP₃-activated nonselective cation current. We have recently cloned mtrpb-1, a mammalian *trp* and *trpl* homologue from mouse BTC3 cells and have now employed a reverse-transcription polymerase chain reaction method to determine the presence of mtrpb-1 mRNA in a variety of tissues, cells and cells lines. Using oligonucleotide primers flanking regions encoding the sixth and eighth transmembrane domains in the mtrpb-1 cDNA, we found mtrpb-1 to be expressed in the mouse and rat brain, mouse pituitary tumor AtT20 cells, insulin secreting BTC3 and NIT cells. While present in astrocytes and CG-4 glial precursor cells but absent in a oligodendrocyte derived cell line, mtrpb-1 message was not detected in PC12, F11 and IMR32 cell lines. Primary cultures of rat cerebellar neurons showed barely detectable levels of mtrpb-1. In conclusion, we find mtrpb-1 mRNA to be present in excitable as well as non-excitable cells. Detailed knowledge of expression of the family of mammalian *trp* and *trp1* related genes will aid in understanding the role of these gene products in regulating intracellular calcium-associated signalling pathways. nathways

THE LARGEST MAMMALIAN GAP JUNCTION CHANNEL (FORMED OF RAT CX37 IN TRANSFECTED N2A CELLS) EXHIBITS SATURATION AND CATIONIC SELECTIVITY. M. Tao, M. Waltzmann and

D.C. Spray, Dept. Neuroscience, Albert Einstein Coll. Med., Bronx, NY.
We stably transfected N2A neuroblastoma cells with a vector containing cDNA encoding rat Cx37, the gap junction channels formed displayed the highest unitary conductances of the gap junction channels that have been characterized (as high as 300 pS). Sensitivity of steady state macroscopic conductances to tais light as 300 ps). Setsitively is starting to start as start intransjunctional voltage (V_1) was strong $(V_0 \pm 29 \text{ mV}, g_{min}/g_{max} \sim 0.18 \text{ and n},$ equivalent gating charge about 2.25). In addition, instantaneous junctional conductance declined as command pulses exceeded $\pm 20 \text{ mV}$. Recordings of unitary junctional currents showed a mainstate and substate conductance. Mainstate conductance declined with voltage, apparently accounting for the changes in instantaneous macroscopic conductance; mainstate open time decreased with increasing V_j, apparently accounting for the behavior of steady state macroscopic conductance. When ionic strength was reduced by isosmotic substitution of CsCl with mannitol, channels saturated at about 50 mM salt. To quantitate selectivity, unitary conductances and macroscopic voltage sensitivity were assessed in symmetric 150 mM solutions of CsCl, Choline (Ch)Cl, tetramethylammonium (TMA)Cl and tetraethylammonium (TEA) Cl and under asymmetric conditions, where one electrode contained CsCl and the other ChCl, TMACl or TEACl. Under symmetric conditions, relative permeabilities for the cations were Cs:Ch:TMA:TEA:1:0.4:0.2:0.1 and permeabilities of Cl was estimated to be no more than 10% that of Cs. In asymmetric solutions, reversal potentials revealed relative permeability ratios of 0.5:0.5: 0.3 for Ch:TMA:TEA vs Cs. We conclude that Cx37 gap junction channels saturate at modest $V_{\rm j}$ and at physiological salt concentrations, and that Cx37 is a remarkably cation-selective gap junction channel that passes even large cations rather well.

THE CAPSAICIN RECEPTOR - TARGET FOR A NOVEL ACTION OF ASPIRIN-LIKE DRUGS? Kress M.*, Vyklicky L.§ and Reeh P.W., Dept. Physiol. & Exp. Pathophysiol., Universitätsstr. 17, D-91054 Erlangen, Germany; § Academy of Science, Dept. Physiol., Prague, Czech Rep.

Capsaicin (CAPS) has long been known as an algogenic substance selectively exciting and sensitizing nociceptors. As a possible mechanism of action, an excitatory non-selective cation current has been identified in a subpopulation of adult dorsal root ganglion (DRG) neurons in culture. Aspirin on the other hand is an analgesic acting peripherally by inhibition of prostaglandin synthesis, as generally assumed.

In the present study we tested if aspirin-like drugs could counteract the excitatory effect of CAPS by performing whole cell patch-clamp recordings from acutely dissociated rat DRG neurons using a 12 channel computer controlled system for fast drug application. At -80 mV holding potential, CAPS $(3~\mu\text{M})$ induced an inward current in 80 % of small DRG neurones that showed little inactivation within 40 s. The current was inhibited by acetylsalicylic acid, salicylic acid (SA) and diclofenac in concentrations below those needed for inhibition of prostaglandin formation. Half-maximal inhibition of the current by could be overcome by increasing the CAPS concentration to $6\ \mu\text{M}$ which may suggest competition of the drug at the binding site of the putative CAPS receptor-channel complex. The inhibition was also present at +40 mV holding potential though higher drug concentrations were needed.

The present results demonstrate an inhibition of the capsaicin-induced

current by aspirin-like drugs in adult rat DRG neurons. Since the sensitivity to CAPS is specific for nociceptors this inhibitory action may represent a new and potentially important mechanism of the analgesic action of aspirin-like drugs though an endogenous ligand of the CAPS receptor has not been identified so

CHARACTERIZATION OF ION CHANNELS PRODUCED BY BOTULINUM TOXINS IN PC12 CELLS. R. E. Sheridan.* Neurotoxicology Branch, USAMRICD, Aberdeen Proving Ground, MD 21010-5425.

Neurotoxicology Branch, USAMRICD, Aberdeen Proving Ground, MD 21010-5425.

Botulinum neurotoxin (BoNT) is known to produce large conductance cationic channels in artificial bilayers. The purpose of this study was to examine these ion channels in membrane patches excised from transformed PC12 cells and to compare the properties of these ion channels produced by different serotypes of botulinum toxin. PC12 cells were grown in RPMI-1640 media supplemented with 10% horse serum, 5% fetal bovine serum and 50-100 ng/ml of nerve growth factor (NGF, 2.5S) on a polylysine coated glass substrate. After a minimum of 4 days, the cells were transferred to a bath containing either 200 mM CsCl or 200 mM RbCl, 5 mM Na*HEPES (pH 7.0) and 1 mM dithiothreitol (DTT) at 21°C. Patch pipettes were prepared with a matching salt solution but buffered to pH 5.0 with 5 mM Na*acetate and containing 2-10 μg/ml BoNT serotypes A or E. Patches of membrane were excised in the inside—out configuration and membrane currents were monitored over time. After a delay of 5-20 minutes, large conductance ion channel openings were observed. Unlike single channel currents endogenous to the membrane, which were predominantly K*-channels, the toxin-induced channels were most active with a positive potential applied to the same side as the toxin (cis) and showed an increased mean open time and a decreased closed time. These ion channels started as a single conductance level but typically increased in equal steps up to 5 times the original channel conductance, with full openings and closings of even the largest channels observed as common events. There were no significant differences between BoNT/A and BoNT/E in ionic conductance or the voltage-dependence of channel gating. Supported by the DoD. gating. Supported by the DoD.

PROPERTIES OF A NOVEL SYNAPTIC CAN CURRENT ACTIVATED BY mGluRs IN CA1 HIPPOCAMPAL NEURONS

P. Congar, V. Crépel, A. Böhme - and Y. Ben-Ari - INSERM U29, 123 Bld de Port-Royal, 75674 Paris cedex 14 (France).

The currents evoked in CA1 pyramidal neurons by the selective metabotropic glutamate receptor agonist 15,3R-ACPD were studied in whole-cell patch-clamp configuration (Cs-gluconate 125 mM) in the presence of TTX (1µM), kynurenate (1 mM) and bicuculline (10 µM) and K-channel blockers (6 mM Cs+, 5 mM 4-AP and 10 mM TEA). As previously shown, bath application of 15,3R-ACPD (100-200 µM, 2-3 min) induced a Ca²+-activated nonspecific cationic current (CAN) sensible to external divalent cations (Crépel et al., *J. Neurophysiol.* 72: 1561-69, 1994; Congar et al. Soc. Neurosci. Abstr., 32: 10, 1995). In the present work, we have investigated the role of G proteins in the induction of CAN current, its pharmacological features and its synaptic expression.

We now report that: (i) CAN current is mediated exclusively through a G protein-dependent process; it becomes irreversible in the presence of intracellular GTPγS and it is blocked by GDPβS. (ii) It is activated by selective agonists of at least two types of metabotropic receptors linked to IP3 pathway: the group I mGluRs and the muscarinic receptors. (iii) It is not activated through cAMP pathway, since it is neither antagonized by forskoline (50 μM), nor evoked by selective agonists of group II and group III mGluRs (linked to cAMP pathway). (iv) CAN current can be synaptically evoked by high-frequency stimulation in the lacunosum-moleculare. Furthermore, this synaptic CAN current is considerably increased in duration and amplitude in presence of intracellular GTPγS. The mGluR CAN current may play an important role in the long lasting synaptic modulations of cell excitability.

FAST AND SLOW ADPS IN CORTICAL NEURONS AND THEIR REGULATION BY MUSCARINIC RECEPTORS. <u>S. Hai-Dahmane* and R. Andrade</u> Dept. of Psychiatry and Behavioral Neurosciences, Wayne State Univ. School of Med. Detroit, MI 48201.

Aftercurrents play an important role in controlling neuronal firing pattern. We have previously shown that muscarinic stimulation in rat prefrontal cortex elicits a slow afterdepolarization (sADP) mediated by a calcium activated cation nonselective current. In the present study, we describe the presence of an additional fast afterdepolarising potential (fADP) which is also modulated by muscarinic stimulation.

Whole cell recordings are obtained from rat prefrontal cortex layer V pyramidal neurons in vitro. In cesium loaded cells a calcium spike in the presence of TTX (1 μ M) induces a fast inward aftercurrent which decays completely in about 200 ms in neurons clamped at their resting membrane potential (~ -70 mV). Blocking the calcium influx using cadmium or buffering the intracellular calcium with 10 mM BAPTA strongly reduces the amplitude of the fast inward aftercurrent. Ion substitution experiments reveal that the fast inward aftercurrent is dependent on the extracellular concentration of sodium.This indicates that fADP is also mediated by a calcium activated cation nonselective current. Bath administration of carbachol (30 μ M) enhances the fast component and activates a much slower inward aftercurrent which decays incompletely over a period of several seconds.

These results indicate that pyramidal neurons of rat prefrontal cortex have a constitutively fast depolarizing afterpotential. Stimulation of muscarinic receptors enhance this fADP and results in the appearance of a sADP.

"CHANNEL NOISE" MAY INFLUENCE THE FIRING PROPERTIES OF NEURONS IN THE MEDIAL ENTORHINAL CORTEX J.A. White", R. Klink², A. Alonso², and A.R. Kay³, ¹Dept. of Biomed. Engr., Boston Univ. Boston, MA 02215; ²Montreal Neurol. Inst., Montreal, PQ H3A 2B4 CANADA; ³Dept. of Biol. Sci., Univ. of Iowa, Iowa City, IA 52242.

The theta rhythm, generated by partially synchronous neuronal activity at frequencies of 4-12 Hz in the hippocampus and associated areas, plays an important role in spatial learning. Neurons of layer 2 of medial entorhinal cortex, which deliver neocortical input to the hippocampus, exhibit slow subthreshold oscillations under current clamp. These intrinsic oscillations, driven by a persistent Na* current and a slow outward current, may help generate the theta rhythm.

The number of persistent Na $^{\circ}$ channels underlying this phenomenon is relatively small (< 10 $^{\circ}$). Here, we examined the effects of this finite number of channels using stochastic simulation techniques. The probabilistic nature of the Na $^{\circ}$ channels can account for the noise in current-clamp records; this added noise makes oscillatory behavior less sensitive to changes in parameter values than in deterministic models. Preliminary results indicate that stochastic simulations may replicate higher order interspike interval statistics seen in vitro. Channel noise may shape cellular responses in vivo as well: the stochastic system has enhanced sensitivity to small periodic stimuli, in a form of stochastic resonance, and diminished sensitivity to large periodic stimuli.

INTERACTIVE MODELLING OF HIPPOCAMPAL NEURONS

R.C. Cannon, R.J. Holland, C.Bernard¹ and H.V. Wheal.*

Neuroscience Research Group, University of Southampton, SO16 7PX, UK.

¹ INSERM U29, Höpital de Port Royal, Paris, France.

Interactions between excitatory and inhibitory synaptic circuitry in the CA1 region of the hippocampus play a crucial role in the control of cell excitability and consequently in the generation of epileptiform activity.

In order to explore this behaviour we have constructed multicompartmental models of CA1 pyramidal cells and inhibitory interneurons. These models follow a modified Hodgkin-Huxley formalism and have been derived from our own experimental data by an incremental fitting algorithm, constrained by published channel kineties and synaptic properties.

Our connectivity database (Bernard and Wheal, 1994, Hippocampus 4, 497-529) is being extended to include detailed cellular morphology and physiology in order to build realistic local networks.

We have developed a graphical interface in java for interactive examination of the biophysical behaviour of the single cell models. It may be used across the web at http://www.neuro.soton.ac.uk/ca1_neurons.html.

ACETYLCHOLINE: STRUCTURE/FUNCTION I

410.1

HUMAN CHOLINE ACETYLTRANSFERASE mRNAS WITH DIFFERENT 5'-REGION PRODUCE A 69-kDa MAJOR TRANSLATION PRODUCT. H. Misawa*, J. Matsuura, Y. Oda, R. Takahashi and T. Deguchi. Dept. of Neurol., Tokyo Metropolitan Inst. for Neurosci., Tokyo 183, Japan. *Dept of Pathol., Kanazawa Univ., Sch. of Med., Ishikawa 920, Japan.

Previously unknown types of human choline acetyltransferase (ChAT) cDNAs (N1- and N2-types) were cloned and their translation products were analyzed. In four species of ChAT mRNAs (R-, N1-, N2- and M-types), the ATG initiation codon in the rat, mouse and pig was replaced by ACG, which does not serve as an initiation codon for translation. In vitro translation and mammalian expression analyses revealed that N1-, N2- and R-type mRNAs give rise to a single 69 kDa enzyme, while M-type mRNA produces both 82 and 69 kDa enzymes. The translation efficiency of M-type mRNA was lower than that of the other mRNA species. Moreover the translation efficiency of human ChAT mRNAs was considerably lower than that of rat ChAT mRNA, suggesting that the ATG codons for human ChAT mRNAs are unfavorable for translation initiation. These results provide rational explanations for the previous reports that human ChAT protein purified from the brain and placenta had 66-70 kDa molecular mass, and that ChAT activity in a single motor neuron of human was far lower than that of other vertebrates. Furthermore sequencing of monkey ChAT gene showed that the initiation ATG in rodent ChAT was also replaced by ACA in the monkey. ANTISENSE OLIGODEOXYNUCLEOTIDE TO THE MUSCARINIC M2 RECEPTOR SUPPORTS ITS ROLE AS A NEGATIVE AUTORECEPTOR REGULATING ACETYLCHOLINE RELEASE. K. Kitaichi, A. I. Hersi, J. W. Richard, T. West*, L. K. Srivastava, R. Quirion. Douglas Hospital Research Centre, Dept. of Psychiatry, Faculty of Medicine, McGill University, Verdun, Quebec, Canada H4H 1R3.

At least five (m₁ to m₅) distinct muscarinic receptors have been cloned thus far. However, it is difficult to ascertain their respective physiological roles due to the lack of highly selective agonists and antagonists for a given subtype. For example, the pharmacologically defined muscarinic M₂ class consists of two subtypes (m2 and m4 receptors), both having high affinity for the AF-DX series of antagonists. Recently, much interest has focused on the M2-like receptor family on the basis of its possible role as negative autoreceptor modulating acetylcholine (ACh) release in the brain. However, it is unclear if these autoreceptors belong to cloned m₂ or m₄ (or both) subtype(s). To address this issue, we utilized a antisense oligodeoxynucleotide-in vivo dialysis Phosphorothioate-modified antisense oligodeoxynucleotides targeted to subtype specific sequences at the 5' region were continuously infused (1 µg/µL/hr for 3 days) into the third ventricle of adult male Sprague-Dawley rats. These animals were then used in in vivo dialysis to monitor ACh release as recently described (Hersi et al., J. Neurosci, 15; 7150, 1995). The m_2 antisense treatment reduced AF-DX 384 (0.1 μ M)-induced hippocampal ACh release whereas a random sequence oligodeoxynucleotide did not. It thus appears that the molecularly defined m2 receptors are involved in the regulation of ACh release in the rat hippocampus. This work was supported by the MRCC.

A ROLE FOR DOPAMINE D5 RECEPTORS IN THE MODULATION OF HIPPOCAMPAL ACETYLCHOLINE RELEASE REVEALED BY ANTISENSE OLIGONUCLEOTIDES A. I. Hersi, L. K. Srivastava, P. Gaudreau and R. Quirion. Depts. of Neurology/Neurosurgery and Psychiatry McGill University, Montreal, Quebec, Canada and Douglas Hospital Research Center, Verdun, Quebec, Canada H4H 1R3. Neuroendocrinology Lab., Hopital Notre Dame, Université de Montreal, Montreal, Quebec, Canada.

Lately, D1-like (D1 and D5) receptors and their possible involvement in cognition

have generated considerable interest. However, due to the lack of selective ligands, it has not been possible to ascertain which of these receptors is(are) involved in these processes. We and others have recently shown that D1-like receptors modulate hippocampal acetylcholine (ACh) release (Day and Fibiger, 1994; Hersi et al., 1995; Imperato et al., 1993). In the present study, the receptor subtype(s) responsible for this effect was investigated using a combined antisense in vivo dialysis approach. Phosphorothioate modified antisense oligodeoxynucleotides, targeted against specific regions of the D1 or D5 receptors were continuously infused into the third ventricle of Sprague Dawley rats (250-350g) for three days at a dose of lug/hr Both antisense oligos reduced hippocampal-formation D1-like/[3H] SCH 23390 binding sites to similar extents. However, only the antisense directed against the D5 receptor was able to block the increase in hippocampal ACh induced by the D1-like receptor agonist, SKF 38393 (100μM). Administration of a random-sequence anti-D5 oligonucleotide failed to either decrease D1-like receptors or block the SKF 38393 induced increase in ACh release. Taken together, these findings suggest that the receptor subtype involved in the dopaminergic regulation of hippocampal ACh release is of the D5 subtype. To our knowledge, this is the first evidence of a physiological function for the D5 receptor in the mammalian brain. Supported by the MRCC and FRSQ.

EFFECTS OF REPEATED IONTOPHORETIC ADMINISTRATION OF ACETYLCHOLINE ON THE RESPONSIVENESS OF RAT SOMATOSENSORY CORTICAL NEURONS BEFORE AND AFTER SYSTEMIC DFP TREATMENT. A.A. Myasnikov*, G. Testylier, M. Maalouf, A.E. Butt & R.W. Dykes. Département de Physiologie, Université de Montréal, Québec, Canada H3C 3J7.

We describe the evolution of the responsiveness of single units in the awake (24 cells) or urethane-anesthetized (37 cells) rat somatosensory cortex subjected to repeated (20-200 pulses) iontophoretic administration of acetylcholine (ACh; 1.0 s duration, 80 nA pulses), before and after systemic treatment with the irreversible acetylcholinesterase pulses, before an after systemic treatment with the inversions acceptationnesserace. (AChE) inhibitor disopropyllluorophosphate (DFP, 0.3-0.5 LD₅₀). The responses to ACh varied among cortical neurons and fluctuated across time. There were monophasic excitatory (E) or inhibitory (I) responses to ACh in some cells (n = 20), and biphasic (E-I, I-E, E-E, and I-I) or triphasic (E-E-I, I-I-E, and I-E-I) responses in others (n = 41). Although the direction and complexity of these responses remained consistent, the magnitude of the response to ACh fluctuated across time; most cells exhibited either an initial increase or decrease in responsiveness followed by fluctuations that diminished across time, such that the response magnitude eventually returned to initial levels. DFP treatment given 1 hr after beginning ACh administration resulted in a re-emergence of the increase or decrease in responsiveness followed by fluctuations in the response similar to those seen during the first part of the experiment. Results suggest the existence of dynamic, homeostatic mechanisms controlling the balance between excitatory and inhibitory influences within the cortical circuitry; these mechanisms are engaged by the prolonged increase in extracellular ACh levels caused either by repeated intophoretic ACh administration or by AChE inhibition by DFP. The ability of the cholinergic system to rapidly adjust to changes in tonic levels of extracellular ACh raises questions about the potential efficacy of therapeutic treatments in Alzheimer's disease designed to increase ACh activity. PONTINE MICROINJECTION OF 4-AMINOBENZOVESAMICOL (ABV) BLOCKS CHOLINERGIC RAPID EYE MOVEMENT (REM) SLEEP ENHANCEMENT. R. Lydic* M.L. Capece, and S.M.N. Efange. Department of Anesthesia, Pennsylvania State University, College of Medicine, Hershey, PA 17033.

Pontine microinjection of the acetylcholinesterase inhibitor neostigmine produces a REM sleep-like state (REM-Neo), presumably by increasing the amount of acetylcholine (ACh) available to activate postsynaptic receptors (J. Pharmacol. Exp. Ther. 231:173, 1984). Recent studies revealed inhibition of REM sleep generation when vesicle uptake of ACh was blocked by intracerebroventricular administration of vesamicol (Psychopham 121:485, 1995). ABV is a selective blocker of presynaptic ACh vesicular storage and an inhibitor of ACh release (J. Med. Chem. 32:1217, 1989). The present study is testing the hypothesis that ABV can decrease neostigmine-induced REM sleep when microinjected into the medial pontine reticular formation (mPRF) of intact, unanesthetized cat. To date, 3 cats have received unilateral mPRF microinjections (n) of saline (n=7), neostigmine (n=9), ABV (n=6), and ABV as a 15 min pretreatment to neostigmine (n=9), ABV (n=6), and ABV as a 15 min pretreatment to neostigmine (n=0), ABV (n=6), and ABV as a 15 min pretreatment to neostigmine (n=0), Tolygraphic recordings were made for 2 hr after each injection to quantify percent time in sleep and wakefulness. Mean REM sleep time (16.3%, saline control) was decreased (-47.8%) by ABV (8.5% REM sleep). The REM sleep-like state elicited by neostigmine (61.2%) was significantly decreased (-36.1%) by pontine administration of ABV (39.1% REM-Neo). The finding that neostigmine-induced REM sleep enhancement can be blocked by decreasing presynaptic ACh release within the mPRF provides new support for the importance of pontine cholinergic neurotransmission in REM sleep generation. HISTOCHEMICAL CHARACTERIZATION OF MATURE AND AGED RATS FOLLOWING INTRASEPTAL INJECTION OF 192-IgG-SAPORIN. G.R. Stevens^{1*}, W.L. Klein¹, P. Curzon², M.W. Decker² and A.W. Bannon².

Northwestern Univ., Dept. Neurobiol. and Physiol., Evanston, IL 60208; ²Abbott Laboratories, Neuroscience Research, D-47W, AP-

9A, Abbott Park, IL 60064-3500 192-IgG-saporin is an immunotoxin that selectively targets basal forebrain cholinergic neurons that express nerve growth factor receptors (NGFr). Previously, we found subtle behavioral effects in aged, but not mature Long-Evans rats following intraseptal injection of 192-IgG-saporin into the medial septum (Brain Res., in press). However, depletion of choline acetyltransferase (ChAT) activity in However, depletion of choline acetyltransferase (ChA1) activity in hippocampus and cingulate cortex was the same in both mature and aged rats. In this study, parvalbumin, ChAT, NGFr and alpha bungarotoxin (α BgT) staining were examined in mature and aged rats following intraseptal injection of 192-IgG-saporin. Consistent with other reports, 192-IgG-saporin treatment appears reduce NGFr and ChAT staining while sparing parvalbumin staining. Interestingly, loss of α BgT staining coincided with loss of NGFr and ChAT staining in the medial septum. These early data support the specificity of 192-IgG-saporin as a selective cholinergic toxin, and suggest the existance of α BgT binding sites on basal forebrain cholinergic neurons existance of aBgT binding sites on basal forebrain cholinergic neurons in the medial septum. NEURONAL AND GLIAL S-100 IMMUNOREACTIVE CELLS IN THE AVIAN BRAIN.

E.Garcia-Ojeda, A. Garzino, G.C.Panzica*. *Dept. Anatomy, Pharmacology, & Forensic Medicine, Univ. Torino, I- 10126 Torino, Italy.

S-100 is a calcium-binding dimeric protein that has been classically regarded as a specific marker of central and peripheral glial cells. Recent studies had, however, demonstrated a wide population of S-100 positive neurons in the rat brain, as well as in some nuclei of other vertebrate species. In the present study we analyzed by immunocytochemistry the distribution of S-100 immunoreactivity (IR) in a well-studied avian species, the Japanese quait. Two different antisera raised against the whole molecule (polyclonal) or against its B-subunit (BS-100, monoclonal) were used. Both glial and neuronal cells were recognized by both antibodies, and the used. Both gran and helicition certs were recognized by both anionodies, and instaining was more pronounced in the brainstem than in the forebrain. Immunostained glial elements were radial glia and tanycytes (stained with the ßS-100 only), or astrocytes (stained with both sera). A wide population of neurons, identified by morphological criteria, was stained with both antibodies. Their degree of staining morphological criteria, was stained with both antibodies. Their degree of staining varied from weak to strong according to their location. In the prosencephalon, scattered S-100 positive neurons were observed in the striatal complex, in the nucleus paraventricularis thalami, nucleus rotundus, and nucleus geniculatus lateralis. In the brainstem a rich S-100 neuronal population was detected in several discrete structures, including motor and sensitive nuclei of cranial nerves (3rd, 4th,Vth,VIIth, VIIIth). The pattern of distribution of neuronal S-100 IR in quail is highly comparable to that previously reported for the rat brain. Some of these locations (motor nuclei) of cranial nerves striatal complex) have also high leads of locations (motor nuclei of cranial nerves, striatal complex) have also high levels of IR for cholineacetyltransferase, suggesting hence a possible co-existence of S-100 IR in a portion of the cholinergic system. The present results confirm previous scattered reports for different vertebrates and represent the first detailed map of distribution of neuronal S-100 IR in a non mammalian vertebrate. Moreover they demonstrate that the neuronal distribution pattern of this calcium binding protein is highly conserved throughout phylogeny. Work supported by grants from CNR, MURST and EU.

CONTRIBUTION OF α_2 -ADRENERGIC AUTO- AND HETERO-RECEPTORS IN MODULATING CORTICAL ACETYLCHOLINE (ACh) RELEASE *IN VIVO*. S. Tellez, F. Colpaert and M. Marien*, Pierre Fabre Res. Ctr., Castres, France.

Cortical ACh release in vivo can be modulated by a2-adrenoceptor agonists and antagonists. The systemic administration of α_2 -antagonists including (+)efaroxan (EFX) increase, while α_2 -adrenoceptor agonists such as UK-14304 (UK) decrease the release of ACh in the medial prefrontal cortex (mPFC) of conscious rats as measured by microdialysis (Tellez et al, 1995, Soc. Neurosci. Abstr. 21, 2138). To evaluate the contribution of α_2 -adrenergic autoreceptors in mediating these drug effects, we re-examined the drug-induced changes in ACh release in rats which had previously undergone noradrenergic deafferent-ation procedures. Male SD rats were pretreated with the noradrenergic neurotoxin DSP-4 (40 mg/kg i,p.), or prepared with bilateral 6-OHDA-induced lesions of the locus coeruleus (LC). At 3 and 7 days following these respective restors of the locus coefficients (LC). At 3 and 7 days following fress respective prefreatments, microdialysis of the mPFC was performed. No significant difference in basal ACh outflow was observed in either the DSP-4 or LC-lesioned rats when compared to their control (vehicle or LC-sham) counterparts. In the control rats, ACh outflow was increased to 250% of baseline values by EFX (0.63 mg/kg i.p.), and decreased to 40% of baseline by UK (2.5 mg/kg i.p.), confirming our previous findings. In the DSP-4 pretreated rats, the inhibitory effect of UK on ACh outflow was preserved, while the ability of EFX to increase outflow was essentially eliminated. In LC-lesioned rats, EFX still significantly increased ACh outflow, but only to 170% of baseline values. Postmortem tissue concentrations of noradrenaline in the cortex were reduced by 81 \pm 6% and 61 \pm 6% in the DSP-4 and LC-lesion groups, respectively, as compared to controls. Results suggest that $\alpha_2\text{-}adrenoceptors$ both on noradrenergic neurons (autoreceptors) and on non-noradrenergic elements (heteroreceptors) can participate in modulating cortical ACh release in vivo. The ACh release-enhancing effect of EFX appears to be dependent on at least a partially intact noradrenergic innervation.

DIAGONAL BAND (NDB) STIMULATION INCREASES THE SPONTANEOUS ACTIVITY OF CELLS IN THE PIRIFORM CORTEX (PC) IN VIVO. L.A. Zimmer*, M. Ennis, and M.T. Shipley, Dept. Anatomy, Univ. Maryland School of Medicine, Baltimore, MD 21201 Electrical stimulation of NDB, the sole source of cholinergic input to PC, rapidly (<45

Electrical stimulation of NDB, the sole source of cholinergic input to PC, rapidly (~45 min) increases Fos protein expression in PC neurons. NDB-evoked Fos expression is prevented by muscarinic receptor antagonists. In vitro, high doses of cholinergic agonists in PC increases the excitability of pyramidal cells to afferent stimulation of the lateral olfactory tract (LOT). Taken together, these results suggest that activation of NDB cholinergic neurons should increase the activity of PC neurons. To test this hypothesis, extracellular single unit and field potential responses were recorded in PC before and during electrical activation of NDB neurons in anesthetized rats. Recordings were made from PC neurons (n=23) that exhibited stable spontaneous activity and a short-latency excitatory response to LOT stimulation (0.2 Hz; 100-500 μ A). NDB stimulation (4 pulses, 100 Hz, 400 μ A, n=7) increased the spontaneous discharge rate of PC cells from 4.9±1.6 to 7.3±1.4 spikes/s (49% increase, p ≤0.05).

LOT-evoked field potentials in PC consisted of an initial (A1; afferent mediated)

LOT-evoked field potentials in PC consisted of an initial (A1; afferent mediated) negative wave (onset=6.0±0.7ms; slope=-2.1±0.3mV/ms; mag=5.0±0.9mV) followed by a second (B1; associational mediated) negative wave (onset 12 ms), and a positive (P2) wave (onset=26.6±1.4ms; slope=0.6±0.06mV/ms; mag=5.8±0.4mV); P2 has been associated with LOT-evoked inhibition of PC pyramidal cells. NDB stimulation produced no field potentials in PC. Following paired electrical stimulation of NDB and LOT (n=8; LOT pulse occurring at the 4th NDB pulse), the A1 and B1 waves were unchanged. However, the magnitude of P2 decreased 37% to 2.4±0.4mV ($p \le 0.05$); the slope was unchanged. Electrical activation of NDB increases the spontaneous activity of PC neurons. This may result from inhibition of LOT-evoked activation of GABAergic interneurons or inhibition of associational synapses onto GABAergic interneurons. ACTIVATION OF CHOLINE ACETYLTRANSFERASE BY CALPAIN D.H. Wu*, Y. Gu, W. Lian, L.B. Hersh, and J. Elce' Department of Biochemistry, University of Kentucky, Lexington, KY 40536-0084; 'Department of Biochemistry, Queen's University, Kingston, Canada

Choline acetyltransferase (ChAT, E.C. 2.3.1.6), catalyzes the biosynthesis of the neurotransmitter acetylcholine (ACh). Regulation of ChAT activity could be an important determinant in the generation and maintenance of the terminal concentration of the neurotransmitter ACh. In this study, we examine the possible regulatory effects of Ca²- on the activity of ChAT. In particular, we report that the Ca²- dependent neutral proteinase (calpain) increases ChAT activity in a well defined in vitro system. Using recombinant calpain I and its inactive mutant (Cys105Ser), the effects of proteolysis of this Ca²- dependent neutral proteinase on ChAT activity were measured. We found that incubation with calpain I but not its inactive mutant increases ChAT activity 2 to 3 fold. However, prolonged digestion resulted inactivation of ChAT. This observation could provide a potential mechanism for the regulation of neurotransmitter synthesis in response to synaptic activity and possibly a mechanism of ChAT turnover.

THE ACETYLCHOLINE CONCENTRATION IN POA-AHA PRESENTS ASYMMETRIC VARIATIONS DURING THE ESTROUS CYCLE OF THE RAT. P.R. Arteaga and M.E. Cruz*. UIBR FES- Zaragoza, UNAM. México.

There is evidence that the cholinergic system of POA-AHA plays a stimulatory

There is evidence that the cholinergic system of POA-AHA plays a stimulatory role on the regulation of gonadotropine secretion and ovulation. By the analysis of the effects of unilateral implants of atropine and the cholinoacetiltransferase (ChAT) activity, we have shown asymmetry in the activity of the cholinergic system in right and left side of POA-AHA during the estrous cycle. In present study, the concentration of acetylcholine (Ach) in the left and right side of POA-AHA at 13:00 hours of each day of the estrous cycle was cuantificated.

The figure shows the changes in the concentration of the Ach in the left anf right side of POA-AHA during the estrous cycle.

The differences in the Ach concentration in POA-AHA during the cycle could reflect the differences and asymmetry observed in the ChAT activity during the estrous cycle. (NeuroReport 5:433; 1994). Supported by DGAPA:IN204693, PUIS.

EFFECT OF DNA α-POLYMERASE INHIBITION ON THE CHOLINERGIC PROPERTIES OF A NEUROBLASTOMA CELL LINE (SN-56). Malik¹, S. Muntasser¹, J.K. Blusztajn² and C.E. Greenwood¹-∗. ¹Dept. Nutritional Sciences, Univ. of Toronto, Toronto, Ontario, Canada MSS 3E2 and ²Dept. Pathology, Boston Univ. School of Medicine, Boston, MA.

The use of agents which inhibit cell proliferation provide a useful tool to study the relationship between neuronal proliferation and differentiation. Aphidicolin, a DNA α-polymerase inhibitor, has been successfully used to study this relationship in the catecholaminergic neuroblastoma cell line, SH-SY5Y (LoPresti et al, 1992). Inhibition of proliferation was accompanied by morphologic differentiation including neurite extension. Our objectives were first to determine if comparable effects of aphidicolin on morphologic differentiation could be seen in the cholinergic neuroblastoma cell line SN56.B5.G4 and second to examine whether biochemical differentiation (acetylcholine (Ach) production) accompanied these changes. To assess the magnitude of response to aphidicolin, the changes in Ach production were compared to those previously reported for the neurotrophic agent, retinoic acid. Various aphidicolin concentrations (0.01 to 1.0 µM) were tested, cells were harvested and DNA and protein analyses were performed after 48 hrs. Treatment of SN-56 cells with 0.5 μM aphidicolin stopped cell proliferation with the least amount of cell death amongst the doses tested. Associated with this decrease in cell proliferation was an increase in neurite extension and intracellular Ach levels (measured by HPLC). The magnitude of increase in Ach levels was comparable to. or even greater than, the observed increase with saturating concentrations of all-trans retinoic acid (1 µM). No further increase in Ach levels were observed with a longer aphidicolin treatment period (4 days). These results indicate that treatment of cells with an optimal dose of aphidicolin results in a morphological change that is accompanied by an increased expression of its neurotransmitter, Ach. (NSERC).

PHARMACOLOGICAL REGULATION OF SENSORY STIMULATION-EVOKED INCREASES IN CORTICAL ACETYLCHOLINE RELEASE <u>E. ACQUAS*, H.C. FIBIGER</u> Division of Neurological Sciences, Department of Psychiatry, University of British Columbia, Vancouver, B.C., V6T 1Z3 Canada Recent reports have indicated that sensory stimuli increase the release of

acetylcholine (ACh) in rat frontal cortex. The aim of the present study was to elucidate the neurochemical regulation of basal forebrain cholinergic neurons. To this end the effects of systemic administration of agonists and antagonists of various neurotransmitter receptors were studied on tactile stimulation (TS) evoked increases in frontal cortical ACh release. TS, produced by gently stroking the rat's neck with a nylon brush for 20 min., significantly increased frontal cortical ACh release by 116%above baseline. Administration of the benzodiazepine agonist diazepam (5 mg/kg) significantly reduced basal and TS-evoked cortical ACh release. Similarly, administration of the noradrenergic α_1 antagonist prazosin (1 mg/kg) or the α_2 agonist clonidine (0.1 or 0.2 mg/kg) significantly reduced the increases in ACh release produced by TS. The dopaminergic D_1 and D_2 receptor antagonists, SCH 23390 (0.15 mg/kg) and raclopride (1 mg/kg) failed to significantly reduce TS-induced increases in cortical ACh release. However, co-administration of SCH 23390 and raclopride significantly reduced the increases in cortical ACh release evoked by TS. These results confirm that cortically projecting cholinergic neurons are activated by unconditioned sensory stimuli, and indicate that the increases in cortical ACh release produced by TS are inhibited by enhanced GABAergic transmission, by stimulation of α_2 , and by blockade of α_1 noradrenergic receptors. In addition, these findings indicate that concurrent blockade of D_1 and D_2 receptors is necessary to achieve a significant reduction of sensory stimulation-evoked ACh release in the frontal cortex. These results are consistent with a role for basal forebrain cholinergic neurons in the regulation of arousal/attention. REGIONAL DIFFERENCES IN THE EFFECTS OF PERINATAL LEAD EXPOSURE ON ChAT ACTIVITY IN THE CNS OF THE POSTNATAL RAT. X. Tian*, and J. B. Suszkiw. Dept. of Molecular & Cellular Physiology, University of Cincinnati, Cincinnati, OH 45267-0576.

We have previously reported that lead (Pb) exerts cholinotoxic effects in the septum of developing rat. In order to determine if developmental cholinotoxicity of Pb is region-specific, we compared the effects of low-level Pb exposure on the cholinergic marker enzyme, cholineacetyltransferase (ChAT) activity in the septum, striatum, brainstem and spinal cord. Rat pups were exposed to lead from gestational day 16 via administration of 0.2% lead acetate in drinking water to the dams. ChAT activity was assayed on postnatal (PN) days 7 and 14. The ChAT activities (in nmol/mg P/min) in control PN7 and PN14 animals were respectively, 0.32 and 0.92 in the septum, 0.65 and 1.12 in the striatum, 0.66 and 1.04 in the brainstem, and 0.94 and 1.44 in the spinal cord. Lead exposure resulted in a 63% and 37% reduction of septal ChAT, and a 38% and 34% reduction of striatal ChAT activity levels at PN7 and PN14, respectively. In contrast, Pb exposure had no significant effect on ChAT activities in the brainstem or spinal cord. These results suggest that developmental Pb exposure causes a reduction of ChAT activity in the forebrain cholinergic neurons without affecting the expression of ChAT activity in the cholinergic cells in the brainstem and spinal cord. This work was supported by NIEHS grant ES06365.

REGULATION OF CHOLINERGIC GENE EXPRESSION IN C. REGULATION OF CHOLINERGIC GENE EARRESSION IN C.

ELEGANS. D. Frisby, J. McManus, J. Duerr, and J. Rand*. Program in Molecular and Cell Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK 73104.

The genomic organization of the *cha-1* and *unc-17* genes in

Caenorhabditis elegans, encoding choline acetyltransferase (ChAT) and a vesicular acetylcholine transporter (VAChT) respectively, resembles that of an "operon." The unc-17 coding sequence is completely nested within the first intron of cha-1, and both genes appear to be expressed in a common transcription unit that is alternatively spliced to give rise to each mRNA. A similar genomic arrangement of these genes is conserved from nematodes to vertebrates, suggesting that coordinated regulation is important. Our data indicate that the all of the important upstream regulatory loci reside within 3.1 kb of exon-1. Comparison of the nucleotide sequence of the DNA upstream of cha-1/unc-17 with the C. briggsae homologue revealed several highly-conserved regions which may be important for regulation. Deletion analysis has confirmed the existence of at least two important upstream regulatory loci. The first is located within a 747 bp region about 2.4 kb upstream, and is is located within a 747 bp region about 2.4 kb upstream, and is necessary for expression in most of the body cholinergic neurons. A previously identified point mutation, called β, located within this 747 bp region has a similar phenotype. The second is located within an 824 bp region located about 1.3 kb upstream of exon-1. Deletion of this region, which contains three conserved sequences, results in reduced expression in the dorsal and ventral sublateral nerve cords. Supported by grants from NIH and OCAST

EXPRESSION OF PRESENILIN-1 AND -2 mRNAs IN THE HIPPOCAMPUS AND CEREBELLUM IN ALZHEIMER DISEASE

HIPPOCAMPUS AND CEREBELLOW IN ALZHEIMER DISEASE.
K. Terai, K. Takami, D. G. Walker, A. Matsuo, A. Jakubovic* and P. L.
McGeer, Kinsmen Laboratory of Neurological Research. University of British
Columbia, 2255 Wesbrook Mall, Vancouver. B.C.. V6T 1Z3, Canada
Recently, new genetic linkages have been identified for early onset
familial Alzheimer disease (AD) in the presentlin (PS)-1 (S182) gene on
chromosome 14 and the PS-2 (STMZ/E5-a) gene on chromosome 1. The genes are 67% homologous. In order to understand their role in AD, it is important to identify their expression in brain. We investigated the localization of the mRNAs for PS-1 and PS-2 in the hippocampus and cerezation of the mRNAs for PS-1 and PS-2 in the hippocampus and cerebellum from 4 AD cases and 4 controls by in situ hybridization. Oligonucleotide probes from the 5'-region, which has the lowest homology between the two PSs, were synthesized and labeled at the 3'-end with 35S-4ATP. The sequences corresponded to nucleotide bp 200-244 and 353-397 of mouse PS-1, bp 261-305 and 414-458 of human PS-1 and bp 380-424 and 503-547 of human PS-2. PS-1 mRNA expression was seen in hippocampal pyramidal and dentate granule neurons, as well as cerebellar Purkinje and granule neurons of both AD and control cases. The distribution of PS-2 mRNA expression cells was similar. The expression distribution of PS-2 mRNA expressing cells was similar. The expression of both mRNAs in hippocampal neurons was decreased in comparison to cerebellar neurons in the AD but not the control cases. However, PS-2 but not PS-1 expressing astrocytic-like cells were seen in AD hippocampus. The present data indicate that the PSs may play important roles in specific neurons in normal brain, and that a decrease of PS-1 and PS-2 expressing neurons may occur in affected areas of AD brain. STRUCTURE AND REGULATION OF CHOLINE ACETYLTRANSFERASE AND VESICULAR ACETYLCHOLINE TRANSPORTER GENES IN DROSOPHILA. T. Kitamoto*, W. Wang, B. Sun and P. M. Salvaterra. Div Neuroscience, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

Functional cholinergic neurons require coordinated expression of two cholinergic macromolecules: choline acetyltransferase (ChAT; the biosynthetic enzyme for acetylcholine) and vesicular acetylcholine transporter (VAChT; the proton exchanger that packages acetylcholine into synaptic vesicles). We are using Drosophila as a model system to understand the mechanism and physiological significance of regulation of these two genes. In the present study we have isolated cDNA and genomic DNA clones for *Drosophila* VAChT. The *Drosophila* VAChT gene shares the 1st exon with ChAT and the rest is nested within an intron of the ChAT gene. RNase protection analyses reveal that all VAChT mRNA contains the shared 1st exon, indicating that cholinergic neuron-specific transcription of the ChAT and VAChT genes is mediated by the common regulatory region. The ratios of ChAT and VAChT mRNAs, however, differ in different tissues and in Cha temperature-sensitive mutants. This suggests the levels of ChAT and VAChT mRNAs can be independently regulated by post-transcriptional mechanisms. The *Drosophila* VAChT cDNA is 7.1 kb long and has unusually long 5' and 3' untranslated regions (UTR). The VAChT 5' UTR contains the GTG codon for ChAT translational initiation and three ATG codons, which are followed by a number of termination codons in all reading frames. These features of the VAChT 5'-UTR suggest that VAChT translational initiation is mediated by internal riboson binding. (Supported by NIH-NINDS and the French foundation.)

ACETYLCHOLINE RECEPTORS: NICOTINIC-REGULATION OF GENE EXPRESSION

411.1

DIFFERENTIAL REGULATION OF NEURONAL NICOTINIC RECEPTOR SUBTYPES FOLLOWING CHRONIC NICOTINE TREATMENT IN RATS. M.I. Dávila-García², Y.M. Ulrich¹ and K.J. Kellar². ¹Department of Restorative Sciences, University of Minnesota, Minneapolis, MN 55455 and 2Department of Pharmacology, Georgetown University, Washington, D.C. 20007. Chronic nicotine administration to rats leads to an increase in neuronal nicotinic receptor binding sites throughout the central nervous system. Moreover, the increased

sites that are labeled by ³H-cytisine in cerebral cortex are composed exclusively of α 4 and $\beta 2$ subunits. Although it is unknown whether other potential subtypes that do not bind 3H -cytisine with high affinity (e.g. $\alpha 3\beta 4$) are also increased following chronic nicotine treatment, the recent availability of 3H -epibatidine has made possible the detection of several different receptor subtypes in nervous tissue and in transfected cell lines. In the present studies, we tested the hypothesis that chronic nicotine administration differentially regulates neuronal nicotinic receptor subtypes in rat nervous tissues. Thus, in rats receiving twice daily injections of nicotine (2mg/kg s.c.) or saline vehicle, we compared the binding of ³H-cytisine and ³H-epibatidine to neuronal nicotinic receptors in brain, spinal cord and trigeminal ganglion. In each of these, chronic nicotine treatment led to an increase in binding sites labeled with ³Hcytisine as well as with ³H-epibatidine; however, the magnitude of the increase in the ³H-cytisine binding was always greater than that for ³H-epibatidine binding. In fact, the entire extent of nicotine-induced increases in binding sites could be accounted for by an increase in the fraction of receptors bound by ³H-cytisine. In contrast, no by an increase in 3H -epibatidine binding was seen in the adrenal gland, which is thought to express a receptor subtype that is composed of $\alpha 3$ but not $\alpha 4$ subunits and does not bind 3H -cytisine with high affinity. These data indicate that, under these conditions, chronic nicotine administration leads to a preferential increase in the $\alpha4\beta2$ but not non- $\alpha4\beta2$ subtypes of neuronal nicotinic receptor. This differential effect may be related to the differing affinities of these subtypes for nicotine and suggests that the expression of receptor subtypes is subject to distinct regulatory mechanisms. Supported by Smokeless Tobacco Research Council (490 and NIH DA06486.

VALIDATION OF A CHRONIC INFUSION MODEL FOR PRODUCING NICOTINE-INDUCED INCREASES IN NEURONAL NICOTINIC RECEPTORS IN RATS. Y.M. Ulrich*, K.M. Hargreaves and C.M. Flores.

Department of Restorative Sciences, University of Minnesota, Mpls, MN 55455.

Chronic nicotine exposure in rats produces a characteristic increase in neuronal nicotinic binding sites in many brain regions and spinal cord. The classical paradigm for inducing such increases consists of a twice daily injection regimen. This schedule was initially developed for its convenience and typically utilizes a near maximal, sub-convulsive dose of nicotine (e.g. 2 mg/kg of the bitartrate dihydrate salt). An alternative to this paradigm involves the chronic infusion of drug using an osmotic mini-pump. Although well characterized in mice, to our knowledge the use of osmotic mini-pumps in rats to produce chronic nicotine-mediated receptor increases has yet to be validated. To determine whether the use of osmotic mini-pumps could serve as a viable alternative to twice daily injections, we chronically (i.e. 10 days) exposed separate groups (n=8) of adult, male Sprague-Dawley rats to saline vehicle or nicotine bilartrate via either injections (2 mg/kg s.c., twice daily) or osmotic pumps (1 mg/kg/hr). This infusion dose, which represents a 6-fold greater overall daily dose compared to injections, was chosen to maximize the probability that steady state nicotine levels would be of sufficient magnitude to produce receptor changes. Radioreceptor binding analyses were performed in cortex, thalamus and dorsal and ventral lumbar spinal cord from each group of animals using [³H]-epibatidine under saturating concentrations and 300 μM nicotine to define non-specific binding. In all regions examined, compared with saline treated controls, neuronal nicotinic receptor levels were significantly increased (p < 0.05) in the nicotine treated animals in both the injection and infusion paradigms. Interestingly, the magnitude of the increase in each region was approximately four times greater in the pump animals vs the injection animals. These data demonstrate the efficacy of osmotic mini-pumps for producing nicotine-induced receptor changes in rats and indicate that, under these conditions, the magnitude of the increases obtained by chronic infusion can exceed those achieved using the classical injection paradigm.

TRANSCRIPTION OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR α -3, β -4 AND α -5 SUBUNIT GENES BY THYMOCYTES AND THYMIC EPITHELIAL CELLS. DOWN REGULATION DURING THE PROCESS OF IMMUNOCYTE MATURATION. Mirta Mihovilovic*. Stephen Benning*, Yun Mai*, Leona Whichward*, Dhaval Patel*, and Allen D. Roses!*

Department of Medicine, Division of Neurology, *Department of Cardiology, Duke University Medical Center, Durham, NC 27710.

Thymic tissues express transcripts encoding for the α -3, α -5 and β -4 subunits of nicotinic neuronal acetylcholine receptors (AcChRs). This pattern of transcriptional expression suggests that neuronal AcChRs similar to those expressed in ganglia are expressed in the thymus and that these receptors may be of importance in transducing signals delivered to the thymus through the autonomic nervous system or be responsive to local production of AcCh.

To determine the cell type responsible for thymic transcription we used freshly purified thymocyte preparations and cultured thymic epithelial cells as osurce of RNA. Our results indicate that thymocytes express transcripts at levels comparable to those of the thymic tissue as a whole. When compared to thymocytes, epithelial cells express 100 fold less of the α -3, and β -4 transcripts in immature CD4+8+ show higher levels of the α -5 and β -4 AcChR subunit transcripts. Transcriptional analyses of thymocyte subsets characterized as CD4+8-, CD4-8+ and CD4+8+ show higher levels of the α -5 and β -4 transcripts in immature CD4+8+ show higher levels of the α -5 and β -4 transcription, however, appears to be constant in all thymocytes subsets tested.

Overall our results indicate that neuronal nicotinic AcChR transcripts are expressed in both lymphoid and non-lymphoid thymic cells. In addition, the observation that peripheral lymphocytes do not express neuronal α -3 and β -4 AcChR transcripts and low levels of α -5 transcripts suggest that during the process of thymocyte maturation there is transcriptional regulation of neuronal AcChR su

PURIFICATION OF A DNA-BINDING ACTIVITY THAT SPECIFICALLY INTERACTS WITH A NICOTINIC ACETYLCHOLINE RECEPTOR GENE PROMOTER. Q. Du, S.G. Britt* and P.D. Gardner. Center for Molecular Medicine, Institute of Biotechnology, University of Texas Health Science Center, San Antonio, TX 78245.

Nicotinic acetylcholine receptors constitute a multigene family (α2 -

Nicotinic acetylcholine receptors constitute a multigene tamily (α2 - α9, β2 - β4) expressed in discrete temporal and spatial patterns within the nervous system. The receptors are critical for proper signal transmission between neurons and their targets. The molecular mechanisms underlying receptor gene expression have not been completely elucidated but clearly involve regulation at the level of transcription. We previously identified a novel 19-bp transcriptional regulatory element in the promoter region of the rat β4 subunit gene. The 19-bp element specifically interacts with DNA-binding proteins enriched in nuclear extracts prepared from adult rat brain. We have begun the biochemical purification of these nuclear proteins. In vitro begun the biochemical purification of these nuclear proteins. In vitro binding assays indicated that the proteins are conserved between rat and bovine and therefore, bovine brain was used as a source of starting material. Using a combination of cation exchange (cellulose phosphate) chromatography and sequence-specific affinity chromatography, we purified the 19-bp element-binding activity approximately 20,000-fold. SDS-PAGE revealed the presence of four bands in the final product, ranging in molecular weight between 43 kDa and 100 kDa. Denaturation/renaturation studies are underway. Supported by The National Institutes of Health, The Council for Tobacco Research and The Smokeless Tobacco Research Council.

IDENTIFICATION OF A NEURAL-SPECIFIC ENHANCER IN THE 3'-UNTRANSLATED EXON OF THE β4 NICOTINIC RECEPTOR GENE. J. A. McDonough* and E. Deneris. Department of Neuroscience, School of Medicine, Case Western Reserve University, Cleveland, OH 44106.

The transcriptional mechanisms that generate complex patterns of neuronal nAChR subunit gene expression are not understood. We have identified an enhancer which activates transcription of both $\alpha 3$ and $\beta 4$ nAChR promoters in PC12 cells. This enhancer, designated $\beta 43$ ', is composed of two 37bp direct repeats separated by 6bp and is located within the 3' untranslated region of repeats separated by bop and is located within the 3 unitalisated region. The β 4 gene, about 3kb upstream of the α 3 transcription start site region. The enhancer activates transcription from reporters in the PC12 neuroendocrine cell line, but not in cell lines derived from rat fibroblasts, liver, pancreas, or from a human carcinoma cell line. It is weakly active in the C6 glial and from a human carcinoma cell line. It is weakly active in the Co gilai and C1300 neuroblastoma cell lines. Thus $\beta 43^{\circ}$ activity is restricted among neural lines. To characterize nuclear proteins that interact with $\beta 43^{\circ}$, an oligonucleotide bearing the first repeat of the enhancer was used as a probe in electrophoretic mobility shifts. Two protein/DNA complexes, RBP1 and RBP2, were formed with nuclear extracts from PC12 cells. In nuclear extracts from non-neural lines and the C6 line, a complex that co-migrated with RBP2 but not RBP1 was detected. An RBP2 co-migrating complex and a trace of complex co-migrating with RBP1 were detected in the C1300 line. \$43' is the first example of a neural cell-type specific enhancer controlling neuronal nAchR genes. Its cell-type restricted activity makes it an attractive candidate for a component of the cis-regulatory information that restricts expression of clustered neuronal nAChR genes to specific populations of neurons. We are currently making mutations through the repeat region to identify cis elements necessary for enhancer activity.

THE TRANSCRIPTIONAL ACTIVATOR SPI BINDS TO A PROMOTER ELEMENT WITHIN THE NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR β4 GENE. C.B. Bigger and P.D. Gardner*. Center for Molecular Medicine, Institute of Biotechnology, University of Texas Health Science Center, San Antonio, TX 78245.

To date, eleven members ($\alpha 2 \cdot \alpha 9$ and $\beta 2 \cdot \beta 4$) of the neuronal, nicotinic acetylcholine receptor (nAChR) gene family have been identified. These subunits have been demonstrated to form a variety of distinct receptors with different pharmacological and physiological profiles and are expressed in cell-restricted patterns within the CNS and PNS. Distinct transcriptional mechanisms probably direct this segregation in nAChR gene expression, although evidence identifying transcriptional control elements and their cognate DNA-binding proteins is minimal. control elements and their cognate DNA-binding proteins is minimal. Efforts to characterize β4 subunit gene expression have revealed the presence of several sequence motifs within the proximal promoter that are required for gene expression. Among these include a previously identified C/T-rich, 19bp sequence shown to be required for expression of β4 promoter-reporter gene constructs. Here we report the identification (by site-directed mutagenesis) of a CACCC motif that is required for β4 gene expression. This element was shown to interact with Sp1-like proteins based upon mobility shift competition assays and DNaseI footprinting experiments. Mobility supershift assays using specific antiserum to Sp1 confirmed the identification of the CACCC binding activity as Sp1. Investigations into the possible interaction between Sp1 and proteins binding to the adjacent 19bp sequence are in progress. Supported by The National Institutes of Health and The Council for Tobacco Research.

EFFECTS OF CHRONIC NICOTINE ON THE PHARMACOLOGY AND FUNCTION OF NEURONAL NICOTINIC RECEPTOR SUBTYPES. E. L. Mever*, Y. Xiao, M. I. Dávila-García, and K. J. Kellar. Dept. of Pharmacology, Georgetown Univ. Sch. of Med., Washington D. C. 20007.

Neuronal nicotinic acetylcholine receptors comprise a diverse group of ligand gated ion channels differing in subunit composition and biophysical and pharmacological properties. These receptors are thought to be pentamers, assembled from two kinds of subunits, termed α and β . At least eight different genes encoding α subunits (α 2- α 9) and three different genes encoding β subunits (β 2- β 4) have been identified in vertebrate brain. It is believed that two α subunits and three β subunits combine to form neuronal nicotinic receptors which function as ion channels permeable to Na*, K* and in some cases Ca**. Chronic administration of nicotine to rats or mice, and smoking in humans increases the density of nicotinic receptor binding sites in brain. Brain may contain several different subtypes of nicotinic receptors; as a result, it is difficult to study the effects of chronic nicotine on any one particular subtype. Therefore, we have generated a library of transfected HEK 293 (human embryonal kidney) cell lines, each stably expressing one subtype of neuronal nicotinic receptor. These cell lines, in conjunction with tumor cell lines, provide models for studying nicotinic receptor subtypes. In this study, we compared the effects of chronic nicotine treatment on agonist stimulated ⁸⁶Rb* efflux and on [3H]epibatidine ([3H]EB) binding sites in cells transfected with α2 and β4 nicotinic receptor subunits (KXα2β4R1 cells) and in IMR-32 cells, a human neuroblastoma receptor subunits (KACL2P4R1 Cens) and in Inter-2 cens, a number of each line which expresses $\alpha 3$, $\alpha 5$, $\alpha 7$, $\beta 2$, and $\beta 4$ subunits. In IMR-32 cells treated with 100 μ M nicotine for eight days, nicotinic receptors labeled by [³H]EB are increased by $\approx 100\%$. However, these cells show an $\approx 50\%$ decrease in function measured by ⁸⁶Rb⁺ efflux. A six day treatment of KX $\alpha 2\beta 4R$ 1 cells with 100 μ M nicotine resulted in a four fold increase in [³H]EB binding sites with little or no change in nicotinic receptor function measured by ⁸⁶Rb⁺ efflux. (NIH grant DA06486)

411.8

NEURONAL NICOTINIC RECEPTOR mRNA EXPRESSION PATTERNS IN DEVELOPING POSTNATAL RAT BRAIN. J. J. Shacka* and S. E. Robinson. Department of Pharmacology & Toxicology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0613. The purpose of this study was to determine postnatal development patterns of neuronal nicotinic receptor (nNR) subunit mRNA in Sprague Dawley rat brain. Total RNA from male and female postnatal days (PJ), 7, 14 and 28 rat hippocampus (hippocampus +septum) and cortex was size-fractionated and transferred to nylon. Northern hybridization was performed using α -32p (CTP-labelled 216 and 339 bn CDNA probes targeting the respective α 7 and transferred to nylon. Northern hybridization was performed using $\alpha.^{32}P$ dCTP-labelled 216 and 339 bp cDNA probes targeting the respective $\alpha 7$ and $\beta 2$ nNRs' putative non-conserved 3' intracellular loops. $\gamma.^{32}P$ -labelled 28S rRNA served to normalize for gel loading. All data were quantified using a Molecular Dynamics. PhosphorImager and expressed as the ratio of transcript nRNA to 28S rRNA. These studies identified four transcripts (3.7, 5.0, 7.5 and 10.0 kb) homologous to β cDNA, and a single 5.7 kb transcript homologous to α cDNA. Among the four β transcripts, the 5.0 kb transcript was consistently the most intense. All transcripts were present at each time point tested. ANOVA indicated no sex differences for each transcript at any time point, and that cortical α 7 transcript levels peaked at P7 (p<.005, as compared to P1 and P28). Hippocampuls/septal α 7 transcript levels appeared higher at P7 as compared to P1. β 2 transcript levels appeared greater in P14 hippocampuls/septum and cortex as compared to P1 and P3. Tissue distribution patterns correlated well with previously published reports in adult Sprague hippocampus/septum and cortex as compared to P1 and P7. Tissue distribution patterns correlated well with previously published reports in adult Sprague Dawley rats. At all time points, $\alpha 7$ transcript levels appeared higher in the hippocampus/septum than in the cortex. However, hippocampal/septal versus cortical levels of all four $\beta 2$ transcripts were similar; this may be due in part to $\beta 2$'s putative association with numerous alpha and beta subunits. The existence of multiple $\beta 2$ transcripts may be the result of post transcriptional modification events, or evidence of still uncloned nNR subunits. [Supported in part by DA 07027]

COEXPRESSION OF RAPSYN SLOWS THE TURNOVER OF THE NICOTINIC ACETYLCHOLINE RECEPTOR (AChR) IN COS CELLS. Z.-Z. Wang* and Z. W. Hall. Laboratory of Cell Biology, National Institute of Mental Health, National Institutes of Health, Bethesda, MD20892.

Development of the neuromuscular junction is characterized by clustering of AChRs in the postsynaptic membrane as well as a marked increase in their metabolic stability. Rapsyn, a 43 kDa protein which is closely associated with the AChR, is critical for the redistribution of the receptor in the muscle membrane during synaptogenesis. We examine here whether association of rapsyn with AChRs also affects the turnover rate of the receptor protein. Coexpression of rapsyn with AChR in COS cells significantly reduced the degradation rate of surface AChRs labeled by ¹²⁵I-α-bungarotoxin (10 hours in control vs. >24 hours with rapsyn). The effect was more prominent with increased amounts of rapsyn cDNA cotransfected, and was seen for both embryonic $(\alpha_2\beta\delta\gamma)$ and adult $(\alpha_2\beta\delta\epsilon)$ AChRs, as well as for an AChR whose β subunit lacks the putative tyrosine phosphorylation site in the cytoplasmic loop. Rapsyn mutants lacking the myristylation signal, those with N-terminal residues 16-254 deleted, and those with deletion of C-terminal region containing the zinc-finger domain and PKA phosphorylation site, all failed to cluster the AChR and to slow down its turnover. These data suggest that rapsyn may contribute to the metabolic stabilization of AChR in mature neuromuscular junctions. MANIPULATING ALPHA-3 NEURONAL NICOTINIC ACETYLCHOLINE RECEPTOR SUBUNIT EXPRESSION IN CULTURED NEONATAL RAT SYMPATHETIC NEURONS USING ADENOVIRUS-MEDIATED GENE TRANSFER. Madelaine Rosenberg* and Ellis Cooper. Dept. of Physiology, McGill University, Montréal, Québec, Canada, H3G 1Y6.

University, Montreal, Quebec, Canada, H3G 176. We have previously shown that neonatal rat sympathetic neurons express five nicotinic acetylcholine receptor (nAChR) subunit genes: $\alpha 3$, $\alpha 5$, $\alpha 7$, $\beta 2$ and $\beta 4$. During early postnatal development, and in culture, the mRNA levels of $\alpha 5$, $\beta 2$ and $\beta 4$ remain constant, whereas $\alpha 3$ mRNA levels increase and correlate closely with increases in ACh-evoked current densities on these neurons. These results indicate that changes in $\alpha 3$ expression influence the number of functional nAChRs on neonatal sympathetic neurons. To explore further the relationship between $\alpha 3$ mRNA levels and functional

To explore further the relationship between $\alpha 3$ mRNA levels and functional nAChRs, we have constructed a replication-deficient (E1 deleted) adenovirus vector containing the rat $\alpha 3$ cDNA under the control of the HCMV promoter. This vector was produced in HEK 293 cells by homologous recombination of a shuttle plasmid containing the full length $\alpha 3$ cDNA and a portion of the left end of the Ad 5 genome, and a second plasmid (pJM17) containing overlapping left end Ad 5 regions and the remainder of the Ad 5 genome. In addition, we have inserted the sequence coding for the epitope FLAG at the 3' end of the $\alpha 3$ cDNA to localize the expressed proteins in infected cells. We have co-expressed the $\alpha 3$ -shuttle plasmid with $\beta 4$ cDNA in *Xenopus* cocytes to ensure that the modified $\alpha 3$ -FLAG subunit can co-assemble with β subunits into functional receptors. Our preliminary data indicate that neurons infected with $\alpha 3$ -FLAG-containing adenovirus express mRNA for $\alpha 3$ -FLAG and immunostain for $\alpha 3$ -FLAG proteins. We are now examining infected neurons electrophysiologically to quantify changes in ACh-evoked current densities. (Supported by CHSF and MRC of Canada.)

CNS SITES AFFECTING NICOTINE-INDUCED NOREPINEPHRINE SECRETION IN THE PARAVENTRICULAR NUCLEUS (PVN). Y Fu*, S Matta, J Valentine and B Sharp. Endocrine Neuroscience Laboratory, Minneapolis Med Res Fndn and Depts of Medicine, Hennepin County Medical Center and University of Minnesota, Minneapolis MN 55404.

Brainstem noradrenergic projections to the hypothalamic PVN are involved in nicotine-induced ACTH secretion from the pituitary. To determine whether iv nicotine affects norepinephrine (NE) terminals within the PVN in addition to NE neurons within the brainstem, in vivo PVN microdialysis studies were conducted and mecamylamine (Mec), a nicotinic antagonist, was administered into the PVN or the fourth ventricle. A concentric microdialysis probe was inserted via chronic guide cannula into the PVN of freely moving rats (male Holtzman) during their active (dark) phase and perfused at a rate of ¹µl/min. Studies showed that both baseline and peak NE responses were similar when dialysis was performed on 3 alternate days (d¹, d³, d⁵) in each rat. Nicotine (0.045 mg/kg per 30 s for 30, 60 or 90 s.) dose-dependently increased NE secretion with an ED₅₀ of 0.09 mg/kg. In subsequent experiments, Mec was infused via the PVN microdialysis probe (0.4 - 2.0 μg/μl/min for 40 min prior to nicotine 0.09 mg/kg iv) or microinjected into the fourth ventricle (0.4 - 4.8 μg/0.5 μl, 5 min prior to iv nicotine). Infusion of Mec into the PVN blocked nicotine stimulated NE secretion by 40%. In contrast, Mec delivered into the 4th ventricle (ED₅₀ of 0.4 μg) inhibited at least 85% of the PVN NE response to nicotine. These results indicate that nicotine dose-dependently stimulated NE secretion in the PVN through nicotinic receptors located adjacent to the 4th ventricle and, to a lesser extent, through receptors located in the PVN. THE EFFECTS OF ENUCLEATION ON THE DEVELOPMENTAL EXPRESSION OF NEURONAL NICOTINIC RECEPTOR SUBUNIT mRNA IN PRIMARY VISUAL CORTEX. B.S. Stoveken. * R. T. Robertson. and F.M. Leslie Depts of Pharmacology and Anatomy and Neurobiology, University of California, Irvine Irvine, CA 92717

University of California, Irvine Irvine, CA 92717 Studies have shown that during the second week of postnatal rat development acetylcholinesterase (AChE) (R.T. Robertson et al 1985 Dev. Brain Res 21: 203-214, R.T. Robertson et al 1987 Dev. Brain Res 33: 185-197), and [3H]nicotine binding (Prusky et al 1988 Brain Res, 467: 154-159) are transiently upregulated in layer IV of the primary visual cortex (V1). With binocular enucleation at birth, this transient [3H]nicotine binding and AChE staining are lost (Prusky et al 1988 Brain Res, 467: 154-159). We have previously shown the mRNA expression of the neuronal nicotinic acetylcholine receptor (nAChR) subunits $\alpha 3$ and $\beta 4$ exhibit a transient expression in V1 with a spatial and temporal pattern similar to AChE staining and [3H]nicotine binding. The present study was therefore undertaken to determine whether removal of peripheral sensory input influences the expression of $\alpha 3$ and $\beta 4$ mRNA transcripts in developing V1. Unilateral and bilateral enucleations were done at P0 and litter mates served as controls. Coronal sections from pups sacrificed on P7, P13, and P17 were processed for in situ hybridization using $[^{35}S]$ -labelled riboprobes. Data were analyzed using computer assisted quantitation of the resulting autoradiograms. $\beta 4$ mRNA expression in V1 layer IV was found to be high at P7 and to have declined to the adult level by P17. This decline was not correlated with eye-opening since decreased expression of $\beta 4$ mRNA was already evident at P13 prior to eye-opening. Enucleation did not significantly affect either $\beta 4$ or $\alpha 3$ mRNA expression at any time point examined. This finding suggest that while both $\alpha 3$ and $\beta 4$ nAChR mRNA show increased expression during early postnatal development this expression is not regulated by sensory input form the periphery. Consequently if either or both of these mRNA's contribute to transient expression of $[^3H]$ nicotine binding in layer IV of V1 during the second postnatal week, then regulation is at

STABLE EXPRESSION OF RAT NICOTINIC ACETYLCHOLINE RECEPTOR SUBTYPES IN MAMMALIAN CELLS. Y. Xiao*, E. L. Meyer, R. A. Houghtling, J. M. Thompson and K. J. Kellar. Dept. of Pharmacology, Georgetown Univ. Sch. of Med., Washington, D.C. 20007

Neuronal nicotinicacetylcholine receptors (nAChRs) are ligand-gated ion channels composed of α and β subunits. At least eight α and three β subunits of neuronal nAChRs have been identified. We have transfected human embryonal kidney cells (HEK 293 cell line) with six rat nAChR subunit genes. Cell lines stably expressing the putative nAChR subtypes $\alpha 2/\beta 2$ (KX $\alpha 2\beta 2$ R1), $\alpha 2/\beta 4$ (KX $\alpha 2\beta 4$ R1), ad $\alpha 4/\beta 2$ (KX $\alpha 4\beta 2$ R1), as well as cell lines stably expressing a single α or β subunit, have been established. [PH]Epibatidine (PH]EB) binds with high affinity in membranes of cells that express each of these nAChR subtypes but not in membranes of cells that express only a single subunit gene. The K_a values of [PH]EB binding in these cell lines range from 15 pM (KX $\alpha 2\beta 2$ R1) to 130 pM (KX $\alpha 2\beta 4$ R1). Interestingly, the K_a value of [PH]EB binding in KX $\alpha 4\beta 2$ R1 cells (20 pM) appears to be slightly lower than in rat forebrain (45 pM). Cytisine, nicotine, carbachol, DH βE , curare and ACh compete for all of the binding sites labeled by [PH]EB in each cell line, but with different rank orders of potency. The cell line KX $\alpha 2\beta 4$ R1 has a very high density of [PH]EB binding sites ($R_{max} \approx 800$ fmol/mg protein) and preliminary studies indicate most of these sites are on the cell surface. Nicotine stimulates 16 Rb + efflux in KX $\alpha 2\beta 4$ R1 and KX $\alpha 3\beta 4$ R1 cells, but not in cells expressing a single subunit gene. Chronic exposure of cells expressing nAChR subtypes to 100 μ M nicotine results in a marked increase in the Bmx values of [PH]EB binding. These results show that functional rat nAChR subtypes can be stably expressed in HEK 293 cells. A library of such cell lines expressing different subunit combinations should be very useful for studying the pharmacological properties and regulation of nAChR subtypes and the contributions to these characteristics imparted by each α and β subunit. This study was supported by NIH grant DAO6486.

COMPARATIVE EXPRESSION OF IMMEDIATE EARLY GENES IN BRAINSTEM AND PARAVENTRICULAR NUCLEUS (PVN) IN RESPONSE TO NICOTINE. SG Matta*, JD Valentine, JT Hokanson and BM Sharp. Minneapolis Medical Research Foundation and Departments of Medicine, Hennepin County Medical Center and University of Minnesota, Minneapolis, MN 55404

cFos has been used in this laboratory as an anatomical marker to correlate activation of PVN neurons with phenotypically identified (and unidentified) neurons in catecholaminergic regions of the brainstem. cFos also is important for transcriptional regulation of other genes in nicotine-responsive neurons. The present studies were conducted to determine whether immediate early genes related to cFos, involved in formation of AP-1 complexes or otherwise involved in transcriptional regulation were responsive to nicotine. Rats were cardiac perfused 1, 6 or 24 h after receiving saline or nicotine (0.09 mg/kg over 60 sec) iv and brains were processed for immunocytochemistry for cFos, FosB, FRA1, FRA2, junB, junD or KROX24. As expected, cFos was activated in parvocellular PVN (pcPVN) and NTS-A2 and -C2 catecholaminergic regions; only A2 was still elevated at 6 h. FosB expression was increased at 1 h and peaked at 6 h in pcPVN. FRA1 and FRA2 were unaffected by nicotine. JunB was induced within 1 h in pcPVN and A2, remaining elevated at 6 h. In contrast, junD was expressed in magnocellular PVN at 1h, but not pcPVN. Expression of KROX24 was seen at 1 h in pcPVN and A2. These studies demonstrate that nicotine selectively increased the number of cells positive for KROX24 and for transcription factors involved in the formation of AP-1 complexes. DYSTROPHIN AFFECTS ACETYLCHOLINE RECEPTOR (ACHR) DEGRADATION Rufeng Xu* and Miriam M. Salpeter. Neurobiology and Behavior, Cornell University, Ithaca NY 14853

DEGRADATION Rufeng Xu* and Miriam M. Salpeter. Neurobiology and Behavior, Cornell University, thbaca NY 14853

Neural regulation of acetylcholine receptor (AChR) turnover is well established but not well understood. In addition the possible role played by muscle cytoskeletal elements or other potential anchoring molecules remains elusive. The present study reports that the absence of dystrophin, an integral cytoskeletal element, affects the degradation rate of the Rs but not that of the Rr AChRs. Rs and Rr AChRs are two populations of receptors expressed at the neuromuscular junction (nmj) dependent on the state of muscle innervation. The Rs is synthesized in innervated muscles and has a degradation 11/2 of about 8-10 days. When the muscle is denervated the Rs degradation accelerates to a 11/2 of about 3 days but can be restabilized to adult values by reinnervation or elevation of intracellular cAMP. The Rr, on the other hand, is synthesized in denervated muscles, has a degradation 11/2 of ~ 1-2 d, like that of embryonic AChRs, and is not stabilized to adult values by reinnervation. In early post denervation periods before all the Rs has degradat and been replaced by Rr, both AChR populations are interspersed at the top of the junctional folds at a total site density as seen in adult muscle.

To ask whether cytoskeletal integrity plays a role in the regulation of AChR turnover, we examined AChR degradation in the mutant mdx mouse known to be devoid of dystrophin. We found no difference in the degradation rates of Rr AChRs between mdx and control muscles from same strain of mice. This was true for the degradation of material may be a supplied to the degradation rate of Rs AChRs between mdx and control muscles from same strain of mice. This was true for the degradation of diaphragm) in vivo, the degradation accelerated Rs (11/2 ~3-5 days) seen in control mice. Denervating these mdx muscles did not further accelerate their Rs degradation of the AChRs normally seen in innervated muscles. Supported by NIH NS09315 an

EXCITATORY AMINO ACIDS: PHARMACOLOGY-METABOTROPIC RECEPTORS

SUPERSENSITIVITY OF METABOTROPIC GLUTAMATE RECEPTORS IN 6-HYDROXYDOPAMINE (6-OHDA) LESIONED HEMIPARKINSON RATS. K.A. Serpa* and L.T. Meltzer, Parke-Davis Pharmaceutical Research, Division of Warner Lambert Company, Ann Arbor, MI 48105

Recent findings have indicated that interactions between the dopaminergic (DA) and

glutamatergic (GLU) systems in the basal ganglia may play a role in the symptomology of Parkinson's disease (PD). We examined the behavioral effects of stimulation of the metabotropic subtype of the GLU receptor (mGluR) in the caudate of both normal rats and rats made hemiparkinson by injection of 6-OHDA into the right medial forebrain

Normal or lesioned rats were implanted with a chronic guide cannula in the right caudate nucleus. At least 8 days post-surgery, rats were injected with the mGluR agonist (1S,3R)-1-aminocyclopentane-1,3-dicarboxylic acid (ACPD) into the caudate and rotational activity monitored for 6 h. In normal rats, ACPD 1 µmol produced a low level of predominantly contraversive turning (mean 43 ± 21 turns/6h, n=11). In lesioned animals, injection of ACPD 1 μ mol into the denervated caudate produced more robust contraversive turning than that seen in normal rats (468 ± 70 turns/6h, n=19). Most (>90%) of the turning was observed in the first 2 hours post injection. Injection of ACPD 0.1 \(\alpha\) mol resulted in a similar total number of turns/6h (454 + 186 \, n=6) but the turning occurred at a lower rate and occurred over more than 4h. The turning induced by ACPD 1,4mol in lesioned rats was not antagonized by pretreatment with SCH 23390 $30~\mu g/kg$ SC + haloperidol 0.3 mg/kg IP, indicating that ACPD is acting independent of DA mechanisms. The mGluR1/2 receptor antagonist, α -methyl-4-carboxyphenylglycine 1 μ mol, co-injected with ACPD 1 μ mol, did not reduce the number of turns/6h (471 \pm 82, =4), but reduced the rate and increased the duration of the response to that seen following ACPD 0.1 µmol. Thus, 6-OHDA lesioned rats appear to have functionally supersensitive mGluRs. (Supported by Warner-Lambert.)

PHARMACOLOGICAL ACTIVITIES OF FLUORID CCG DERIVATIVES: DISCOVERY OF A NOVEL AGONIST FOR METABOTROPIC GLUTAMATE H. Shinozaki1*, M. Ishida1, T. Saitoh1, Y. Uyama1 and T. Taguchi². The Tokyo Met. Inst. Med. Sci., Tokyo 113 and ²Tokyo College Pharmacy, Tokyo 192-03, Japan

Derivatives of 2-(carboxycyclopropyl)glycine (CCG), a conformationally restricted glutamate analogue with an extended and folded form, are proving useful in determining the active conformation of glutamate at various receptors We have already found that the extended CCG derivatives, L-CCG-I, DCG-IV and cis- and trans-MCG-I, are potent agonists for metabotropic glutamate receptors (mGluR), but are weak agonists of ionotropic glutamate receptors (iGluRs), suggesting that mGluRs are activated by extended conformation of Lglutamate, while iGluRs are activated by a folded form. Fluoridation of the 3'-carbon of CCG compounds would be expected to further restrict their conformational freedom. In the present paper, we compared the pharmacological actions of eight isomers of 3',3'-difluoro-CCG (3'-F2CCG) with those of CCG in the isolated spinal cord of newborn rats. L-3'-F2CCG-I (extended form, corresponding to L-CCG-I) was respectively about 3 and 1.5 times a more potent agonist of Group I and Group II mGluRs than L-CCG-I. L-CCG-III is a potent uptake inhibitor for L-glutamate, but L-3'-F2CCG-III (folded form, corresponding to L-CCG-III) did not enhance glutamate-induced depolarization, suggesting no Other fluoro-CCG inhibitory action on the L-glutamate uptake system. compounds did not show large differences from CCG, although were generally less active than the corresponding CCGs. In addition to potent activation of mGluRs, L-3'-F2CCG-I demonstrated novel pharmacological features, suggesting that L-3'-F2CCG-I may be a useful probe for elucidating the physiological roles of mGluRs

18,3R-ACPD-INDUCED INCREASES OF CAMP IN THE NEONATAL RAT HIPPOCAMPUS ARE MEDIATED BY A SYNERGISTIC INTERACTION BETWEEN PHOSPHOINOSITIDE HYDROLYSIS- AND INHIBITORY cAMP-COUPLED mGluRs B. G. Johnson* D. D. Schoepp, and J. A. Monn Central Nervous System Research Eli Lilly and Company, Lilly Research Laboratories, Indianapolis, Indiana 46285.

Research Laboratories, Indianapolis, Indiana 46285.

A pharmacological approach was used to investigate the cellular mechanism and subtypes of metabotropic glutamate receptors (mGluRs) that mediate stimulation of basal cAMP formation in slices of the neonatal rat hippocampus. 15,3R-ACPD, an agonist for phosphoinositide-coupled and inhibitory-coupled cAMP-linked mGluRs in cloned and in situ preparations, produced prominant stimulations of basal cAMP. However, the agonists DHPG and 2R,4R-APDC, that selectively, act on phosphoinositide-coupled and inhibitory cAMP-coupled mGluRs, respectively, only weakly increased cAMP. When these two mGluRs subtype selective agonists were added in combination, increases in cAMP similar to those observed for 15,3R-ACPD, were found. Stimulations of cAMP evoked by 15,3R-ACPD and combined additions of DHPG + 2R,4R-APDC occurred at concentrations of these agents which directly couple to APDC occured at concentrations of these agents which directly couple to other mGluR second messenger responses. However, these stimulatory cAMP responses were prevented by the presence of adenosine deaminase, and 8-para-sulfophenyltheophylline (an adenosine receptor antagonist), as well as (+)-MCPG (an mGluR receptor antagonist). Thus, 1\$3R-ACPD-induced increases in CAMP formation in the neonatal rat hippocampus are mediated by a synergistic interaction between phosphoinositide- (group 1) and inhibitory cAMP-coupled (group 2) mGluRs, which are indirectly expressed by potentiation of cAMP responses to other agonists (in this case endogenous adenosine).

GTP'S BINDING AS A TOOL TO CHARACTERIZE METABOTROPIC GLUTAMATE RECEPTOR (mGluR) AGONISTS IN CHO CELLS EXPRESSING SUBTYPES 2 AND 6. C. J. Spencer*, C. B. Nelson and R. D. Schwarz. Parke-Davis Pharmaceutical Res., Div. of Warner Lambert Co., Ann Arbor, MI 48105

mGluRS belong to the superfamily of G-protein coupled receptors. In the resting state, GDP is bound to the associated heterotrimeric G proteins; upon agonist activation, GTP exchanges with the GDP. By using [35S]GTPγS, agonist stimulated GDP-GTP exchange can be assessed by standard binding techniques. This method was applied to subtypes 2 and 6 expressed in CHO cells. Membrane preparations were incubated at 30° C in a pH 7.4 buffer containing NaCl, MgCl₂. and GDP at optimal concentrations for each subtype. Agonists and radioligand were added for 30 min. Bound ligand was separated from free by rapid filtration. Agonists examined were (2S,1'S,2'S)-2-(carboxycyclopropyl)glycine (CCG), (S)-4carboxy-3-hydroxyphenyl-glycine (4C3HPG), O-phospho-L-serine (SOP) and the acids L-glutamic (glu), L-quisqualic (quis), ibotenic (ibo), (1S,3R)-1-aminocyclopentane-1,3-dicarboxylic (ACPD) and L(+)-2-amino-4-phosphonobutyric (AP4). EC₅₀ values were determined and compared to EC₅₀ values for the same compounds' ability to reverse forskolin stimulated cAMP accumulation. In mGluR2 membranes, the rank order of potency for [35S]GTPγS binding was CCG>glu>ACPD=4C3HPG>ibo>>quis=AP4=SOP; the rank order for cAMP was CCG>glu>ACPD>4C3HPG>>ibo=quis=AP4. For mGluR6, the [35S]GTPyS order was AP4≈SOP>glu>ACPD; others were inactive. The cAMP rank was similar. These results show good correlation between the two methods. [35 S]GTPyS binding has major advantages over other second messenger assays since GDP-GTP exchange is common to all the subtypes regardless of the subsequent pathways and thus can be used to directly compare agonist activity between subtypes. (Supported by Warner-Lambert.)

GLUTAMATE METABOTROPIC RECEPTORS: ANTICONVULSANT AND CONVULSANT EFFECTS OF GROUP II AGONISTS AND ANTAGONISTS B.S. Meldrum 1 , M. Ghauri 1 , E. Tang 1 , P.K. Yip 1 , D.E. Jane 2 , J.C. Watkins 2 and A.G. Chapman $^{1\,\star}$. 1 Dept. of Neurol, Inst. of Psychiatry, London, SE5 8AF, U.K., 2 Dept. of Pharmacol., School of Med. Sci., Bristol BS8 1TD, U.K.

Metabotropic glutamate receptors are classified into three groups on the basis of their sequence homology, pharmacology and signal transduction mechanism. Groups II and III are negatively coupled to adenylate cyclase and act presynaptically to depress the release of glutamate and GABA. We have examined proconvulsant action of group II selective compounds in non-epilentic Swiss-Webster (SW) and epilentic DBA/2 strains of mice, and anticonvulsant action against sound-induced (95-110dB; 12-16 KHz) seizures in DBA/2 mice. Groups of mice were observed for 30 min for clonic and tonic seizures and/or response to sound-exposure at 5, 15 or 30 min following intracerebroventricular (icv) 10µl injections. The non-selective metabotropic agonists (1S,3R)-1-aminocyclopentane-1,3-dicarboxylate (1S,3R-ACPD; 500-700 nmol) and (2S,1'S,2'S)-2-(2-Carboxycyclopropyl) glycine (L-CCG-I) at low doses (20-50 nmol) suppressed sound-induced clonic seizures in DBA/2 mice at 5 and 15 min. The selective group II agonist (1S,3S)-1-amino-cyclopentane-1,3-dicarboxylate (1S,3S-ACPD; 50-500 nmol), in contrast, was convulsant in both SW and DBA/2 mice. The potent, selective group II antagonist α -ethylglutamate (EGLU; 3-7 μ mol) was also convulsant in both strains of mice. The anticonvulsant effects of the group II agonists are consistent with those reported by Dalby and Thomsen (JPET, 276; 516-522; 1996); the proconvulsant effects of both agonists and antagonists of group II match those previously reported by us for group III agonists and antagonists (Ghauri et al., Neuroreport, in press).

4C3HPG ACTIVATES PHOSPHATIDYL INOSITOL (PI)-LINKED METABOTROPIC GLUTAMATE RECEPTORS (mGLURs): DIFFERENTIAL FFFECTS IN NEONATAL RAT BRAIN REGIONS. E. M. Santori* A. I. Sacaan, T. S. Rao, M. A. Varney, E. C. Johnson, G. Velicelebi, and G. K. Lloyd, SIBIA Neurosciences Inc., La Jolla, CA 92037. To characterize the native mGluRs expressed in different brain regions, the efficacy and

To characterize the native mGluRs expressed in different brain regions, the efficacy and potency of several mGluR agonists and antagonists were compared using Pl hydrolysis in neonatal rat striatal, hippocampus and cortex, all agonists tested were equiefficacious (normalized to 10 μM Quis) with rank order of potency of Quis>(RS)-3.5.DHPG>1S.3R-ACPD>>Glu. Interestingly, 4C3HPG, a putative class 1 mGluR antagonist, also displayed full agonist activity with a potency similar to that of Glu in the striatum, hippocampus and cortex, and this effect was significantly blocked by (S)-4CPG. In the cerebellum however, 4C3HPG as a very weak agonist (37% of that of 10 μM Quis). The stimulatory effects of 4C3HPG are in contrast with its antagonistic properties shown in studies on recombinant receptors (Neuropharmacol. 34: 887-94 and 895-903, 1995). 4C3HPG did not show any agonistic activity in cell lines stably expressing hmGluRI bot 5a, and selectively antagonized Quis response in hmGluRI bot unot 5a cell lines. The effect of the mGluR antagonists (+)-MCPG, (S)-4CPG, and UPF523 on a class I selective mGluR agonist, 3.5-DiHPG (10 μM)-stimulated Pl hydrolysis was evaluated. Results are summarized below:

Antagonist	K _b (μM)			
	Cerebellum	Striatum	Hippocampus	Cortex
(+)-MCPG	59	78	80	87
(S)-4CPG	238	208	115	159
UPF523	648	484	493	not tested

The similar K_b values observed for these antagonists in the different brain regions contrasts with the differential distribution of mGluR subtypes in these regions as demonstrated by insitu hybridization and immunohistochemistry studies. These results suggest that the pharmacology of these compounds on native mGluR receptors substantially differ from their pharmacology on recombinant class 1 mGluRs. Furthermore, stimulatory effects of 4C3HPG observed in this study may reflect activity at a novel P1-linked mGluR subtype.

412.9

IN VITRO CHARACTERIZATION OF LY354740 MONOHYDRATE: A HIGHLY POTENT AND SELECTIVE AGONIST FOR GROUP 2 METABOTROPIC GLUTAMATE RECEPTORS. J. A. Monn, M. J. Valli, R. A. Wright*, B. G. Johnson, C. R. Salhoff, J. P. Burnett, N. G. Mayne, R. Belagaje, S. Wu and D. D. Schoepp Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, 46285, and Greenfield, IN, 46140, USA

Metabotropic glutamate receptors (mGluRs) are a heterogenous family of G-protein coupled receptors that are linked to multiple second messenger systems. We report here that the conformationally constrained analog of glutamic acid, 1S,2S,5R,6S-2-aminobicyclo[3.1.0]hexane-2,6-dicarboxylate monohydrate (LY354740 monohydrate) binds with high affinity to mGluRs in rat forebrain homogenates (ACPD-sensitive $^3\mathrm{H}$ -glutamate binding IC $_{50}=180$ ± 52 nM) and is a highly potent agonist at group 2 mGluRs, both in the adult rat hippocampus (EC $_{50}=22\pm3$ nM) and in cells expressing recombinant human group 2 mGluRs (mGluR2 EC $_{50}=5.1\pm0.3$ nM; mGluR3 EC $_{50}=24.3\pm0.5$ nM). Unlike other selective group 2 mGluR agonists, LY354740 does not produce group 1 mGluR agonist or antagonist effects (up to 100,000 nM) either in the rat hippocampus or in cells expressing human group 1 mGluRs (mGluR1 or mGluR5). In addition, this compound is

(mGluH1 or mGluH5). In addition, this compound is not active as an agonist or antagonist (up to 10,000 nM) at recombinant human group 3 mGluRs (mGluR4 or mGluR7) and shows no measurable ionotropic glutamate receptor affinity up to 100,000 nM. Thus, LY354740 monohydrate is a useful pharmacological agent for exploring the functional consequences of group 2 mGluR activation in vivo (see Helton et al., Kallman et al. and Tizzano et al., this meeting).

EFFECT OF THE NOVEL ANTAGONIST MPPG ON ADENYLATE CYCLASE-LINKED GLUTAMATE RECEPTORS IN MESENCEPHALIC AND STRIATAL NEURONS IN VITRO. L. Bresciani, F. Fidone, N. Brunello^{A*} G. Racagni and A. Ambrosini. Center of Neuropharmacology, Univ. of Milan, and *Dept. Pharmaceutical Sciences, Univ. of Modena -(I).

New selective agonists enabled us to characterise the activity of metabotropic glutamate receptors (mGluRs) of class I, that trigger the phosphoinositide (PI) hydrolysis, and classes II or III, that modulate cAMP levels, in mesencephalic (Mol. Pharmacol. 47, 1057, 1995) and in striatal neurons. In both neuronal systems, the agonist (RS)-3,5dihydroxyphenylglycine (DHPG) was more potent on PI hydrolysis stimulation than on the modulation of cAMP levels, a difference that was more evident in striatal neurons, in which the EC50 values on the two pathways were 3 µM and 25 µM, respectively. On the contrary, (2S,3S,4S)alpha-(carboxycyclopropyl)glycine (CCGI) inhibited cAMP formation at lower concentrations than those required to activate PI turnover. In striatal neurons, its EC50 values were 50 μM on the PI system and 0.8 μM on cAMP modulation. Aminophosphonobutyrate (AP4) and serine-O-phosphate (SOP) also inhibited adenylate cyclase activity both in mesencephalic and in striatal neurons. The effect of the novel antagonist (RS)-alpha-methyl-4-phosphonophenylglycine (MPPG), proposed as selective for class III mGluRs, was then tested. MPPG (10 µM) did not affect basal cAMP values, but effectively blocked the response to AP4, SOP and CCGI, confirming its pure antagonist action at mGluRs that inhibit adenylate cyclase, although selectivity between class II and III was not evident. The pharmacological distinction of the mGluR effects may help to clarify their role in the basal ganglia. Study partially supported by Pharmacia-Upjohn

412.8

THE METABOTROPIC GLUTAMATE RECEPTOR AGONIST LY354740 ATTENUATES INCREASES IN SENSORIMOTOR REACTIVITY RESULTING FROM WITHDRAWAL OF CHRONIC NICOTINE

D.R. Helton* J.P. Tizzano, J.A. Monn, D.D. Schoepp and M.J. Kallman Lilly Research Laboratories, Greenfield Laboratories, Eli Lilly and Company, Greenfield, IN 46140, USA

LY354740 monohydrate is a highly selective metabotropic glutamate receptor agonist (Group 2: mGluR₂/mGluR₃) which has been shown to be efficacious in animal models of anxiety and benzodiazepine withdrawal (see Monn et al. and Kallman et al., this meeting). To explore the potential clinical efficacy of LY354740 for the alleviation of nicotine withdrawal symptoms or as an aid in smoking cessation, the auditory startle reflex was examined in rats undergoing withdrawal from chronic administration of nicotine. We have previously described a model for evaluation of nicotine withdrawal using the acoustic startle reflex in rats (Helton et al., Psychopharmacology, 113:205-212;1993). Animals were exposed to nicotine continuously for 12 days (6 mg/kg/day, subcutaneous) via osmotic minipumps. After 12 days the pumps were removed and the animals were allowed to go through spontaneous withdrawal. The acoustic startle reflex was significantly increased on days 1, 2, 3, and 4 following nicotine withdrawal. Withdrawal-evoked increases in startle responding were suppressed by readministration of nicotine or treatment with the anxiolytic, diazepam. Treatment with LY354740 (0.03 to 3 mg/kg, oral) produced a dose-dependent suppression of the enhanced auditory startle responding following nicotine withdrawal (ED₅₀ = 0.7 mg/kg). LY354740 did not alter baseline startle responding at doses which suppressed nicotine withdrawal. The (-)-enantioner of LY354740, LY366563, which is inactive as a Group 2 mGluR agonist, had no effect on nicotine withdrawal at an oral dose of 10 mg/kg. Thus, the Group 2 mGluR agonist LY354740 may be an effective treatment for nicotine withdrawal and/or smoking cessation in man

412.10

LY354740: IN VIVO PROPERTIES OF A NOVEL METABOTROPIC GLUTAMATE RECEPTOR GROUP 2 AGONIST FOR THE POTENTIAL TREATMENT OF ANXIETY M.J. Kallman*, J.P. Tizzano, J.A. Monn, D.D. Schoepp and D.R. Helton Lilly Research Laboratories, Greenfield Laboratories, Eli Lilly and Company, Greenfield, IN 46140, USA

LY354740 monohydrate is a conformationally constrained analog of glutamate with highly selective nanomolar agonist affinity for Group 2 cAMP coupled metabotropic glutamate receptors (mGluR₂ and mGluR₃). The discovery of this novel pharmacological agent has allowed the exploration of the functional consequences of activating Group 2 mGluRs in vivo (see Helton et al., and Tizzano et al., this meeting). In an effort to evaluate the clinical utility of LY354740 as an anxiolytic, we examined its effects in the fear potentiated startle and elevated plus maze models of anxiety (0.1 to 10 mg/kg, oral) and compared the results with the clinically prescribed anxiolytics diazepam (ip) and buspirone (ip). In the fear potentiated startle and elevated plus maze models, LY354740, diazepam and 0.6 mg/kg for fear potentiated startle and 0.2, 0.5, and 0.2 mg/kg for the elevated plus maze, respectively). The duration of pharmacological effect for LY354740 in the efficacy models was 4 to 6 hours following administration. The effects observed were stereoselective since the (-)-enantiomer of LY354740, LY366563, was without effect in these models. In contrast to diazepam, acute administration of LY354740 did not produce sedation, cause deficits in neuromuscular coordination, interact with CNS depressants, produce memory impairment, or change convulsive thresholds at doses 100 to 1000 fold the efficacious doses in animals. Thus, LY354740 has atypical anxiolytic activity in animals comparable to diazepam. More importantly, at maximally effective doses in these models, LY354740 produced none of the unwanted secondary pharmacology associated with other currently prescribed benzodiazepines.

THE NOVEL METABOTROPIC GLUTAMATE RECEPTOR AGONIST LY354740 BLOCKS THE EFFECTS OF DIAZEPAM WITHDRAWAL ON AUDITORY STARTLE RESPONDING J.P. Tizzano*, M.J. Kallman, J.A. Monn, D.D. Schoepp and D.R. Helton Lilly Research Laboratories, Greenfield Laboratories, Eti Lilly and Company, Greenfield, IN 46140, USA

In humans, withdrawal from the chronic administration of benzodiazepines can result in a variety of undestrable side-effects, including anxiety. Previously, we have shown that benzodiazepine withdrawal produces anxiogenic effects in rats as indicated by enhanced auditory startle response (NeuroReport, 5:154-156;1993). To investigate the potential clinical utility of mGluR agonists for the treatment of benzodiazepine withdrawal symptoms, we examined the effects of the selective mGluR Group 2 (mGluR₂/mGluR₃) agonist, LY354740 monohydrate on the chronic administration of diazepam. Furthermore, the potential for LY354740 to produce benzodiazepine-like signs of withdrawal was evaluated under the similar experimental conditions as diazepam. Rats were exposed to diazepam (10 mg/kg/day) or LY354740 (1, 3, 10 mg/kg/day) continuously for 12 days via osmotic minipumps (sc). After 12 days the pumps were removed and the animals were allowed to go through spontaneous withdrawal. Significant increases in sensorimotor reactivity were observed on days 1, 2, 3, and 4 following cessation of diazepam. Unlike diazepam, removal of LY354740 following chronic administration did not produce signs of withdrawal. Acute treatment with either diazepam (3 to 30 mg/kg, ip) or LY354740 (0.01 to 0.3 mg/kg, po) dose-dependently blocked withdrawal-induced increases in the auditory startle response following cessation of diazepam. Thus, in addition to the anxiolytic potential of LY354740, these data suggest that LY354740 may be beneficial in the treatment of benzodiazepine withdrawal or as an intermediate drug treatment when shifting individuals from typical to atypical anxiolytics.

EXCITATORY AMINO ACID RECEPTORS: STRUCTURE, FUNCTION, AND EXPRESSION-METABOTROPIC GLUTAMATE RECEPTORS

PROTEIN KINASE C-MEDIATED DESENSITIZATION OF mGluR5 IN XENOPUS OOCYTES. R.W. Gereau IV* and S.F. Heinemann. Molecular Neurobiology Laboratory. The Salk Institute for Biological Studies, La Jolla, CA 92037.

Much evidence from studies using cultured neurons and brain slices indicates that metabotropic glutamate receptors (mGluRs) coupled to phosphoinositide hydrolysis desensitize in response to prolonged or repeated agonist exposure, and that this desensitization is mediated by a mechanism involving activation of protein kinase C (PKC). The present studies were undertaken to determine if this desensitization could be mediated by direct PKC-mediated phosphorylation of mGluR5.

When expressed in *Xenopus* oocytes, both mGluR5a and mGluR5b showed pronounced desensitization which recovered slowly over 30min following a 1min exposure to 100µM Glu. The extent and timecourse of desensitization were very similar for mGluR5a and mGluR5b. This desensitization was mimicked by direct activation of PKC and was blocked by selective PKC inhibition. Furthermore, the recovery from the desensitized state was prevented by phosphatase inhibitors. These data suggest that PKC-mediated phosphorylation is involved in the desensitization of mGluR5a-mediated responses observed in this system.

By constructing point mutants to knock out various PKC consensus phosphorylation sites, we provide evidence that this desensitization is likely mediated by direct PKC-mediated phosphorylation of mGluR5. Supported by grants from the NIH and the McKnight Foundation to SFH and an NIH postdoctoral NRSA to RWG.

REDUCED HIPPOCAMPAL LTP AND IMPAIRED SPATIAL AND CONTEXTUAL LEARNING IN MICE LACKING mGluR5. Z. Jia¹, Y.M. Lu², J.M. Wojtowicz², W. Abramow-Newerly¹, J. Henderson *¹, F. Taverna¹, R. Gerlai¹, C. Janus¹ and J. Roder¹. Samuel Lunenfeld Research Inst., Mt. Sinai Hospital¹, and Dept. of Physiology², University of Toronto, Toronto, Ont. Canada M5S 1A8.

Metabotropic glutamate receptors (mGluR) have been implicated in a variety of physiological phenomena including synaptic plasticity, for example, long-term potentiation (LTP) and learning and memory. While it has been clearly shown that mGluR1, a member of group I mGluRs coupled with G-protein linked to PI pathway, is important in cerebellar long-term depression and motor coordination, the role of mGluR5, the other known member of group I mGluRs, remains obscure. Since there is no available agonist and antagonist specific to mGluR5, and since it is highly expressed in hippocampus suggesting its role in hippocampal dependent functions, we have used gene targeting techniques to make transgenic mice lacking mGluR5. This allows us to investigate the roles of mGluR5 specifically in synaptic physiology and behaviour. We show here that the mGluR5 mutant mice exhibit substantially reduced LTP in both CA1 region and dentate gyrus of hippocampal slices, whereas synaptic responses, the paired-pulse facilitation, and LTP in the CA3 region of the hippocampus are normal, mGluR5 mutant mice also showed impaired learning in both spatial and contextual performance, whereas other activities including motor coordination were normal. Our data suggests crucial roles of mGluR5 in regulating NMDA-dependent LTP and in learning and memory. Details of synaptic responses and behaviour of mGluR5 mutant mice will be discussed. Also, see accompanying abstract by Y. Lu et al. Supported by MRC and NCE of Canada.

413.2

SYNAPTIC TRANSMISSION AND PLASTICITY IN MICE LACKING MGIURS. Y.M. Lu*1, Z. Jia², J. Roder², J.M. Wojtowicz¹. Dept. of Physiol.¹, Samuel Lunenfeld Res. Inst.², Univ. of Toronto, Toronto, Ont, Canada M5S 1A8. mGluR5 is highly expressed in the hippocampus but its function remains unknown due to lack of selective pharmacological blockers. We used gene targeting techniques to delete mGluR5 in mice and measured synaptic transmission in hippocampal slices prepared from knockout (KO) animals and control littermates. Gross anatomical features and organization of synaptic pathways appeared normal in KO animals. Field responses in stratum radiatum or whole-cell recordings were used to measure synaptic functions. The basal level of synaptic transmission and the magnitude of the paired-pulse facilitation did not differ in the two groups, suggesting normal level of transmitter release in the KO animals. However, KO mice showed learning deficits and reduced long-term potentiation in the hippocampus (see accompanying abstract by Z. Jia et al.). To explore possible causes of these deficits we applied a metabotropic glutamate receptor agonist, 1S,3R ACPD (ACPD), which inhibited the evoked fEPSPs at 10-100 μ M in control mice with EC₅₀ = 40 μ M. In conrast, in KO mice EC₅₀ for ACPD was increased to 300 μ M indicating less effective inhibition. effect was receptor specific since similar inhibition caused by a cholinergic agonist carbachol (EC $_{50} = 5\mu M$) was not affected. Whole-cell current clamp recordings from CA1 pyramidal neurons showed decrease of evoked EPSPs and membrane depolarization during applications of 50 μM ACPD in control but not in KO mice. Evoked population spike in stratum pyramidale was enhanced by 50 μ M ACPD in the control but not in KO mice. We conclude that mGluR5 may be involved in modulation of neuronal excitability and long-term potentiation in the hippocampus. Supported by MRC and NCE of Canada

CLONING AND FUNCTIONAL CHARACTERIZATION OF DROSOPHILA METABOTROPIC GLUTAMATE RECEPTORS. M. L. Parmentier, V. Brand, J. P. Pin, J. Bockaert* and Y. Grau. UPR 9023, C.C.I.P.E. Montpellier, FRANCE.

The excitatory neurotransmitter glutamate plays very important roles in the mammalian brain. To mediate its effects, glutamate activates two types of receptors, ligand-gated channels and metabotropic receptors coupled to G-proteins (mGluRs). Both families of glutamate receptors share no sequence homology and possess original structural features compared to other ligand-gated channels and G-protein coupled receptors respectively. Glutamate-gated receptor-channel subunits have already been characterized in invertebrates. Here, we report the cloning of two cDNAs coding for proteins homologous to metabotropic glutamate receptors in *Drosophila melanogaster*; DmGluRA and DmGluRB. DmGluRA proteic sequence is 43% and 45% identical to its mammalian homologues mGluR2 and mGluR3 respectively. When expressed in Human Embryonic Kidney 293 cells, it displays a very similar pharmacology and transduction mechanism than mGluR2 and 3. In situ hybridization data show that DmGluRA RNAs are expressed in the central nervous system of the late embryo. These results indicate that the original structural and functional features of all glutamate receptors types are conserved from insects to mammals and suggest that such receptors trigger fundamental functions highly conserved during evolution.

This work was supported by grants from the CNRS, CEE (BIO2-CT93-0243 and PL95-0228), the french ministry of Education, Research and Professional Insertion (ACC-SV5, n°9505077) and Bayer company (Wupertal; Germany).

MOLECULAR CLONING AND FUNCTIONAL EXPRESSION OF A NOVEL HUMAN METABOTROPIC GLUTAMATE RECEPTOR, mGluR8. R.T. Simin¹, L.G. Hammerland¹, D. Riccardi², K.J. Krapcho¹, F. Fuller¹, S.C. Hebert² and T.M. Stormann*¹. ¹NPS Pharmaceuticals, Inc., Salt Lake City, UT 84108 and ²Renal Division, Department of Medicine, Brigham and Women's Hospital, Boston, MA

The metabotropic glutamate receptors (mGluRs) and calcium receptors (CaRs) make up a family of G-protein-coupled receptors with unique structural features. In an effort to identify novel mGluR/CaR sequences, degenerate PCR primers were designed against regions that are highly conserved between mGluRs and CaRs. These primers against regions that are highly conserved between mGluRs and CaRs. These primers were used to amplify from human genomic DNA, and PCR products within an expected size range were cloned. Sequence analysis of these clones resulted in the identification of a novel mGluR sequence. Northern blot analysis revealed that a hybridizing 3.8 Kb mRNA was expressed at low to moderate levels throughout the human brain. The highest levels of expression were detected in subthalamic nucleus and cerebral cortex. A full length, 3.8 Kb DDNA clone was isolated from a human cerebral cortex cDNA library and subsequently identified as the human homologue of mouse mGluRs (Duvoisin et al., J. Neuroscience 15:3075, 1995). Both mouse and human mGluR8 cDNAs encode 908 amino acid proteins that share an amino acid identity of 97.5% up to residue 894, at which point the sequences diverge for the remaining 15 amino acids. PCR experiments indicate that this divergence is the result of alternative splicing and that two splice variants are expressed in human retina, subthalamic nucleus and cerebral cortex. Functional activity of the human mGluR8 cDNA was assessed in *Xenopus* oocytes. Application of L-glutamate or (S)-2-amino-4-phosphonobutyric acid (L-AP4) evoked inwardly-rectifying potassium (3)-2-animo-t-pinospinoloudiyi acid (L-Ar-)-evoked inwaduy-tectivity polassium currents in oocytes co-injected with cRNAs for human mGluR8 and the rat GIRK/CIR potassium channel subunits. Oocytes injected with the GIRK/CIR cRNAs alone did not respond to these agonists. Further pharmacological characterization of human mGluR8 is currently underway. Overlapping cDNA fragments isolated from human retinal cDNA libraries were used to construct a full-length hmGluR6 cDNA. The deduced amino acid sequences of the hmGluR6 cDNA. The deduced amino acid sequences of the hmGluR6 receptor is 877 residues which is 6 amino acids longer than the rat mGluR6. Comparison of the amino acid sequences of human and rat mGluR6 revealed an overall divergence of 5.7%. In rat retina, mGluR6 has been shown to be exclusively expressed in ON-bipolar cells.

The cDNA encoding hmGluR6 and an 8-amino acid antibody epitope (1D4) was transiently transfected in COS-7 cells were used in an in vitro transducin assay. Transducin is the rod photoreceptor specific G-protein. Activation of transducin was observed by transducin-dependentGTPgammaS binding assay. The activation by 1 mM Glutamate was comparable to light-activated wild-type rhodopsin at a similar concentration of receptor.

Our results demonstrate that hmGluR6 can couple to transducin. The rat homolog of mGluR6 has been shown to be expressed exclusively in retinal on-bipolar cells. Thus, these results support the hypothesis that the transduction machinery in on-bipolar cells is similar to that in photoreceptors. Furthermore, since mGluR6 is a G-protein coupled receptor that does not have substantial sequence homology to opsin, our results suggest a novel coupling of a non-rhodopsin G-protein coupled receptor to transducin. Previous studies indicated that neurectomy (NCT) increases the susceptibility of medoneuros (MD) to glutamate indiced neurosciptions (MD) and hydrogen neurosciptions.

motoneurons (MN) to glutamate induced neurotoxicity and downregulates NMDAR1 receptor mRNA. To characterize the involvement of metabotropic glutamate receptors we have monitored the distribution of mGluR (1-5,7) mRNA in MN following 1,2,3 and 4 weeks (w) of sciatic nerve transsection in adult rats. The spinal cord lumbar enlargements (N=4 each group) were processed with specific oligonucleotides for the detection of mGluR 1-5,7 mRNA with in situ hybridization techniques. From emulsion dipped slices (14 µm) silver grain densities over neuron profiles in the sciatic nerve alpha-motoneuron (MN) pool were counted, averaged (N=40 MN per animal and oligonucleotide) and compared to control animals and contralateral values of NCT animals. MN in control animals expressed mGluR 1,4 and 7 mRNA, NCT did not change the overall number of MN on the ipsi- or contralateral side. In ipsilateral MN, a transient swelling with a maximum after 1w and a return to normal cell size after 4w was observed. The mGluR1 mRNA signal was step-wise reduced to 55±8% of control levels after 1w NCT and 26±4% after 4w NCT. Following 1w of NCT the mGluR4 signal showed a initial decline to 22±3% with no apparent further decrease. During the whole observation period of NCT the mGluR7 mRNA was not significantly altered. An en passant observation concerned stable expression of all mGluR subunits in the dorsal horn of the spinal cord. The differential regulation of mGluR subtypes may be part of an adaptive cell program that helps to rescue adult motoneurons from excitotoxic cell death during the stress of peripheral deafferentation. (Supported by SFB 391).

ANATOMICAL DISTRIBUTION OF METABOTROPIC GLUTAMATE RECEPTOR MGLUR8 EXPRESSION AND ITS PHYSIOLOGICAL REGULATION IN THE OLFACTORY BULB. N. Min*, H. Baker and B. M. Duvoisin, Margaret M. Dyson Vision Res. Inst. and Burke Med. Res. Inst., Cornell University Medical College, New York, NY.

Eight metabotropic glutamate receptors have been identified, including mGluR8 (Duvoisin et al., 1995), whose function remains unknown. First, an in-situ hydridization study was performed to determine the anatomical distribution of mGluR8 gene expression in the rodent brain. Strong expression was found in the olfactory bulb, and widespread expression was detected in many parts of the brain. For a more detailed mapping of mGluR8 expression, a polyclonal antibody was raised against a bacterial fusion protein, and comparisons between the distribution of mGluR8 message and protein were performed. Since there is a strong expression of mGluR8 in the olfactory bulb, its regulation was studied in a sensory deprivation paradigm. Unilateral naris closure causes odor deprivation, and as a result it induces several biochemical changes, for instance a profound down-regulation of tyrosine hydroxylase expression in the glomerular layer of the olfactory bulb. Since glutamate is the neurotransmitter used by the olfactory epithelium, we are investigating whether glutamate receptor levels are also affected. Preliminary results indicate an alteration of mGluR8 expression. The understanding of the functional roles of the mGluR8 expression. The understanding of the functional roles of the mGluR8 expression. The understanding of the functional roles of the mGluR8 will further our knowledge of glutamate neurotransmission in physiological and pathological conditions.

Metabotropic glutamate receptors (mGluR) play a role in the development of spinal hyperexcitability in inflammation. For further characterisation of the particular subtypes involved, we have monitored the distribution of mGluR1-5 and 7 in the rat spinal cord during the development of inflammatory hyperalgesia.

Lumbar segments of the spinal cord were removed from age matched control and UV treated Sprague-Dawley rat pups (postnatal day 11, 12 and 13). Bilateral mechanical hyperalgesia was induced on day 9 by exposure of the glabrous surface of the left hindpaw to a UVA light source for 90 secs in two sessions within an 18 hour interval. Pups were sacrificed one, two or three days later. In situ hybridisation with specific oligonuceotide probes was used to localise mGluR mRNA in the spinal cord. Silver grain density from emulsion-dipped sections was analysed using a computer-assisted image analyser. mGluR mRNA was seen in all areas of the spinal cord with distribution being specific for each subtype. No changes have been seen in the levels of expression of mGluR1, 2, 4, 5 and 7 in spinal cords taken from hyperalgesic animals. However, a significant increase in the expression of mGluR3 mRNA in large neurones in the superficial dorsal laminae and in interneurones in the deep dorsal horn was seen one day after the onset of inflammation on both sides. The increase was most pronounced in laminae III and IV but was transient and had disappeared by the third day after the onset of inflammation. These observations suggest that under conditions of inflammation, the expression of mGluR3 is enhanced and that these receptors may participate in the development or regulation of plastic changes within the spinal cord.

EXPRESSION OF METABOTROPIC GLUTAMATE RECEPTOR SUBTYPE EXPRESSION OF METABOTROPIC GLUTAMATE RECEPTOR SUBTYPE MESSENGER RNA IN THE HUMAN CEREBRALA AND CEREBELLAR CORTEX. A. Berthele**, S. Platzer*, D.J. Laurie*, B. Sommer*, T. Arzberger*, A. Weindl*, B. Conrad*, W. Zieglänsberger*, T.R. Tölle*-b. *Max-Planck-Institute of Psychiatry, Clinical Institute, 80804 Munich, Germany; bept. of Neurology, Technical University, 81675 Munich, Germany; Sandoz Pharma AG, 4002 Basle, Switzerleich

Glutamate mediates excitatory neurotransmission by activating ionotropic receptor channels as well as G protein coupled metabotropic receptors. Currently, eight subtypes of the metabotropic glutamate receptor family (mGluR) have been characterized in rodents and corresponding sequences for the human mGluR1 to 5 subtypes (hmGluR1-5) have recently been described. Here we report the expression patterns of mRNAs encoding hmGluR1 to 5 subtypes in the human cerebral and cerebellar cortex as examined by in situ hybridization with specific oligonucleotide probes. Human brain tissues (N=5) were obtained at autopsy from patients with no history of neurological or psychiatric disease. In frontal cortex, considerable amounts of hmGluR1, 2, 3 and 5 mRNA were expressed, whereas hmGluR4 mRNA was not detectable. Cellular resolution revealed a differential distribution of these hmGluR mRNAs in different cortical laminae with overall levels of hmGluR1 and 2 transcripts being much lower than those of hmGluR3 and 5. In cerebellar cortex, hmGluR1 and 4 mRNA expression was most abundant with high amounts of mRNA detectable in Purkinje and granule cells; mRNA encoding the hmGluR4 subtype was additionally expressed in Bergmann glia cells. hmGluR2 transcripts were exclusively detected in Golgi cells, whereas hmGluR3 mRNA expression was prominent in Golgi cells as well as in Bergmann glia. The hmGluR5 signal was moderate in Bergmann glia and low in Purkinje cells.

The present data show that hmGluR mRNA is differentially distributed in human

brain. However, expression patterns of mGluR mRNA are highly conserved between corresponding structures of human and rodent CNS. (Supported by SFB 391).

DEPLETION OF GLUTAMATERGIC PRIMARY INPUT TO RAT OLFACTORY BULB MODULATES THE EXPRESSION OF c-fos AND mGluR1a mRNAs. P.Bovolin*, N. Ferraris, S. De Marchis, I. Perroteau, A. Fasolo. Dept. Animal Biology, Univ. of Torino, 10123 Torino, Italy. Glutamatergic primary olfactory neurons located in the nasal mucosa send their axons to the glomerular layer of the olfactory bulb (OB) where they make synapses with relay neurons mixed and third (MIT) calle, and with periodergales (PG).

axons to the gonetic and agree of the original and tufted (M/T) cells, and with periglomenular (PG) interneurons. We have previously demonstrated that deafferentation by nasal irrigation with 0.17 M ZnSO₄ produces a 50%-60% reduction in TH mRNA, expressed by PG neurons, accompanied by a 40% decrease of the γ2 GABA_A receptor subunit mRNA, expressed by M/T cells. On the opposite, the mRNA expression of the ionotropic glutamate receptor subunit GluR1 and NMDAR1 remains unaltered In the present work we examined 1) the possible involvement of c-fos in the neuronal plasticity mechanisms occurring in response to glutamatergic input loss, and 2) the mRNA content of two different splicing forms of the metabotropic glutamate receptor 1 expressed by M/T cells, mGluR1a and mGluR1b. Control and ZnSO₄ bilaterally irrigated rats were sacrificed 2 and 16 days after the lesion. Both morphological analysis and quantitative RT-PCR have been performed on olfactory mucosae and OB. First we measured the expression of the Olfactory Marker Protein (OMP), which is exclusively expressed by mature olfactory neurons and whose mRNA is transported along the axonal processes to the OB. OMP mRNA quantitation showed a 60% decrease in the lesioned mucosae and 70-90% decrease in the correspondent OBs. c-fos mRNA in the OB was 30% lower at 2 days and 60 % higher at 16 days post-lesion. The mRNA for mGluR1a form was 40% reduced in lesioned rats, while the b form did not show any significant change. In conclusion, the long-term up-regulation of c-fos mRNA and the expression regulation of selected neurotransmitter receptors following glutamatergic deafferentation suggest an ongoing circuitry adaptation of the OB directed by modulatory events at the transcriptional level. (Supported by grants from Italian MURST).

GROUP-I METABOTROPIC GLUTAMATE RECEPTORS (mGluRs) AND APOPTOSIS BY TROPHIC DEPRIVATION IN CULTURED CEREBELLAR GRANULE CELLS. F. Nicoletti 1.2*, A. Copani³, G. Casabona^{2,3}, V. Bruno^{2,3}, A. Caruso⁴, D.F. Condorelli⁴, R. Kuhn⁵ and T. Knöpfel 1. Institutes of Pharmacology, 1School of Pharmacy or ³Medicine, and ⁴Biochemistry, Catania University, Italy; ²I.M.N. "Neuromed", Pozzilli, Italy; 5CIBA-GEIGY, Basel, Switzerland.

Cultured cerebellar granule cells grown in "low-K+" (10 mM) containing medium undergo apoptotis after 4 DIV and express high levels of mGluR5, which appears early in the development. Expression of mGluR1a is instead observed at later stages of maturation and predominates in cultures grown in 25 mM K⁺. In cultures grown in 10 mM K^+ at 4 DIV, mGluR5 expression was restricted to the population of viable cells and was not observed in cells which had already entered the executive phase of apoptosis. In contrast, at this age, mGluR1a was exclusively present in apoptotic cells. Enzymatic depletion of extracellular glutamate or addition of the mGluR antagonist, MCPG, increased the percentage of apoptotic neurons in cultures grown in 10 mM K⁺. NMDA receptor antagonists, as well as preferential antagonists of group II or -III mGluRs were ineffective. We speculate that activation of mGluR5 protects granule cells against apoptosis by trophic deprivation during the first 4 DIV in cultures. Transfection with antisense oligonucleotides or mGluR5 cDNA is currently carried out to verify this hypothesis.

413.15

CHANGES IN mRNA FOR METABOTROPIC GLUTAMATE RECEPTORS AFTER IN UTERO HYPOXIA-ISCHEMIA. A. Simonyi, H.C. Scott and G.Y. Sun Dept. Biochem. and Pathology, Univ. Missouri, Columbia, MO, 65212

The expression of the metabotropic glutamate receptor 1 (mGluR1) and 5 (mGluR5) mRNA was studied by in situ hybridization in the developing rat hippocampus after in utero hypoxic-ischemic insult. Both receptors are coupled to the phosphoinositide (PI) signaling pathway and appear to be particularly active during long term processing of neuronal plasticity and neurodegeneration. In utero hypoxia-ischemia was induced by clamping the uterine blood vessels of near-term fetuses for 10 min. Fetuses were delivered surgically, resuscitated and raised by foster mothers until 7 (P7) or 14 (P14) days. Results from in situ hybridization indicated a decrease in the level of mGluR1 mRNA in the dentate gyrus of the 7 day-old animals. From P7 until P14, the mGluR1 mRNA expression was increased and similar levels were attained by both the control and the ischemic groups by 14 days. During the same period of time, mGluR5 mRNA showed a constant high expression in the CA1 region of the control animals and a significant increase of mRNA levels in the ischemic group. Since long-term potentiation (LTP) activity is substantially increased between P7 and P15, our results suggest that in utero hypoxia-ischemia can alter the temporal expression pattern of the metabotropic glutamate receptors during postnatal hippocampal development (supported in part by the Children's Miracle Network Telethon Research Fund, University of

413 12

DIFFERENTIAL LOCALIZATION OF METABOTROPIC GLUTAMATE RECEPTORS IN CULTURED HIPPOCAMPAL NEURONS J.N. Stowell*, M.E. McGrath and A.M. Craig. Dept. of Cell and Structural Biology, University of Illinois, Urbana, IL 61801.

Metabotropic glutamate receptors (mGluRs) can be functionally and

pharmacologically divided into three groups; group I is positively coupled to phospholipase C, while groups II and III are negatively coupled to adenylyl cyclase. Some function as autoreceptors presynaptically while others act at postsynaptic sites along with ionotropic receptors. To study the subcellular targeting of mGluRs, wild-type or epitope-tagged cDNAs of mGluR1 α (group I), mGluR2 (group II), and mGluR7 (group III) were expressed from defective herpes simplex virus vectors in cultured embryonic rat hippocampal neurons. mGluR1α exhibited a marked colocalization with the endogenous AMPA-selective ionotropic receptor GluR1. Dendritic spines that were immunopositive for $mGluR1\alpha$ were also immunopositive for GluR1, and there was a correlation in the relative intensities of immunofluorescence at individual synapses(r=0.72,n=339). These results suggest that the colocalization of these unrelated glutamate receptors may be regulated by similar mechanisms, with the consequence that their coactivation may contribute to many forms of synaptic plasticity. mGluR1α was targeted to the somatodendritic domain but excluded from axons of mature neurons. Myc-tagged mGluR2 exhibited a similar distribution to mGR1 α . In contrast, myc-tagged mGluR7 was present throughout the neuron, in the axon as well as the dendrites, suggesting a presynaptic function. Analysis of chimeric proteins may lead to the identification of subcellular localization signals.

EXPRESSION AND COUPLING TO PHOSPHOINOSITIDE (PI) HYDROLYSIS OF GROUP-I METABOTROPIC GLUTAMATE RECEPTORS (mGluRs) IN EARLY POSTNATAL AND ADULT RAT BRAIN. G. Casabona 1.2 R. Parenti M.V. Catania 4* R. Kuhn⁵, T. Knöpfel⁶, F. Gasparini⁵, F. Cicirata³, and F. Nicoletti², 6. Institutes of Pharmacology, ¹School of Medicine or ⁶Pharmacy, and ³Physiology, Catania University, Italy; ²I.M.N. "Neuromed", Pozzilli, Italy; 4I.B.F.S.N.C., CNR, Catania, Italy; 5CIBA-GEIGY, Basel, Switzerland

We have studied the expression of group-I mGluR subtypes by Western blot analysis in different brain regions of both adult and 9 day-old (PND9) rats. A high level of expression of mGluR5 protein was found in all the brain regions examined at PND9, mGluR5 expression was reduced in adult tissue, and this reduction was more prominent in was reduced in adult issue, and this reduction was into profilment in the cerebral cortex, corpus striatum, olfactory bulb and hippocampus. mGluR1a showed a different pattern of expression and, at least in the cerebellum, substantially increased with age. mGluR5 expression was well correlated with the extent of the PI response to mGluR agonists in brain slices, which was uniformely high at PND9 and was negligible in the adult hypothalamus and cerebellum. Cyclopropan [b]chromen-la-carboxylic acid, at concentrations which antagonized mGluR1- but not mGluR5-mediated responses in recombinant cells, did not affect the stimulation of PI hydrolysis by quisqualate or 1_S,3_R-ACPD in brain slices from PND9 or adult rats. We conclude that it is mGluR5 which mediates the PI response to mGluR agonists in brain tissue

APOPTOTIC DEATH IN CHO CELLS EXPRESSING METABOTROPIC GLUTAMATE RECEPTORS COUPLED WITH PHOSPHOLIPASE C.

S. Pshenichkin*, A. Surin, E. Surina and J.T. Wroblewski, Department of Pharmacology, Georgetown Univ. Sch. of Med., Washington, D.C. 20007

Metabotropic glutamate receptors (mGluRs) coupled to the activation of phospholipase C and to subsequent release of calcium from intracellular stores (group 1) were reported to contribute to glutamate neurotoxicity. We examined the viability of Chinese Hamster Ovary (CHO) cell lines stably transfected with DNA encoding for mGluR1a and mGluR5a receptors. The expression of the respective receptors in CHO cells was established by PCR, immunoblotting and functional measurements of phosphoinostide hydrolysis and intracellular calcium release. The agonist selectivity of the transfected receptors was similar to that reported for mGluR1a and mGluR5 in other studies. Cell viability was assessed by MTT reduction and by fluorescent staining. Cells transfected with mGluR1a showed a decreased life span after reaching confluency in contrast to cells expressing mGluR5a and to untransfected cells. Cells transfected with mGluR1a showed a decreased rate of protein biosynthesis as assessed by ³H-arginine incorporation, as compared to untransfected and mGluR5a-transfected cells. DNA analysis performed by agarose gel electrophoresis and ethidium bromide staining revealed a pattern of fragmentation typical of apoptosis in mGluR1a-transfected cells but not in cells expressing mGluR5a. Cell cultures expressing mGluR5a. However, cells expressing mGluR5a also showed increased accumulation of lactate in the medium accompanied by decreased pH, suggesting a profound alteration of oxidative metabolism. The addition of glutamate (1 mMy) to the medium was strongly toxic to cells expressing mGluR5a. Bos showed increased accumulation of lactate in the medium accompanied by decreased pH, suggesting a profound alteration of oxidative metabolism. The addition of glutamate (1 mMy) to the medium was strongl

MODULATION OF INTRACELLULAR CALCIUM SIGNALS EVOKED BY PHOSPHOLIPASE C-COUPLED AND CHIMERIC METABOTROPIC GLUTAMATE RECEPTORS EXPRESSED IN HEK-293 CELLS.

A. Surin*, S. Pshenichkin, E. Surina and J.T. Wroblewski. Department of Pharmacology, Georgetown Univ. Sch. of Med. Washington, D.C. 20007

Metabotropic glutamate receptors mGluR1 and mGluR5 stimulate phospholipase C leading to an increase of IP3, level and to Ca²+ release from intracellular stores. The specific roles of mGluR1 and mGluR5 in intracellular ca²+ homeostasis are poorly understood. Using Fura-2 fluorescence imaging, we examined the increases of intracellular free Ca²+ concentrations ([Ca²+]) induced by mGluR agonists in HEK-293 cells transiently transfected with rat mGluR1a, and mGluR5a receptors. We also constructed two chimeric receptors in which the N-terminal domains of either mGluR2 (mGluR2/1a chimera) or mGluR3 (mGluR3/1a chimera). These receptors, expressed in HEK293 cells conserved the coupling characteristic for mGluR1 and induced [Ca²+], increases while their pharmacology was similar to that reported for unmodified mGluR2 and mGluR3 receptors. The time patterns of Ca² mobilization induced by glutamate, quisqualate and transACPD were different in cells transfected with mGluR1a and mGluR5a. Activation of mGluR2-increases while mGluR1a and mGluR5a. Activation of mGluR2-increases acused transient [Ca²+], increases. Activation of mGluR2/1a and mGluR3/1a chimeras caused transient [Ca²+], increases induced by mGluR1a cyclothiazide (CTZ), known as a blocker of AMPA receptor desensitization, inhibited transACPD-induced elevation of [Ca²+], in cells transfected with mGluR1a but not with mGluR1a, while only slightly increased the period of [Ca²+] in cells transfected with mGluR1a but not with mGluR5a, and was without effect on cAMP-coupled mGluR2 receptor. In contrast, CTZ inhibited [Ca²+], increases induced by mGluR2/1a and mGluR3/1a chimeras. These results suggest that the modulatory effect of CTZ is not determined by interactions with the N-termi

DEVELOPMENT OF MONOCLONAL ANTIBODIES TO THE mGLUR1 ALPHA RECEPTOR. S. Singh*1, C.Wu¹, L. Shi¹, J. Wei¹, P. Dias¹, R.S. Petralia², Y.-X. Wang², and R.J. Wenthold². ¹PharMingen, 10975 Torreyana Road, San Diego, CA 92121; ²NIDCD/NIH, 36 Convent Drive, Bethesda, MD 20892-4162.

Molecular cloning and pharmacological studies have identified eight metabotropic glutamate receptor (mGluR) subtypes, mGluR18. mGluR1, consists of three splice variants, mGluR1a, mGluR1b, and mGluR1c, differing at the carboxy terminus. Monoclonal antibodies were generated against C-terminus domain (aa 842-1200) of human mGluR1a receptor protein. Several clones which specifically reacted in wetsern blot with mGluR1a protein in rat brain synaptic plasma membrane and transfected mammalian cells brain synaptic plasma membrane and transfected mammalian cells were tested for reactivity in immunocytochemistry using rat brain sections. Overall distribution of mGluR1 immunostaining using one of these clone, G209-1590, was similar to that described using polyclonal C-terminus antibodies (Martin et al., Neuron 9, 259, 1992; Baude et al., Neuron 11, 771, 1993); e.g., abundant staining was found in the olfactory bulb, globus pallidus, thalamus, and Purkinje and Golgi cells of the cerebellum. Ultrastructural studies of the hippocampus showed that immunostaining was prevalent in the postsynaptic portion of synapses, but was absent from the synaptic the hippocampus showed that immunostating was prevalent in the postsynaptic portion of synapses, but was absent from the synaptic cleft and presynaptic terminal. Stained synapses were found on dendrite shafts and occasionally on dendrite spines. Staining was found in patches throughout the cytoplasm of neuron somas, as described with other glutamate receptor antibodies, and was particularly prevalent in portions of the endoplasmic reticulum.

REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS II

DISTRIBUTION OF ρ_1 and ρ_2 GABA RECEPTOR SUBUNIT TRANSCRIPTS IN THE RAT BRAIN

K. Wegelius', M. Reeben', M. Saarma', K. Kaila'* and M.Pasternack'

Dept. of Biosciences, Div. of Animal Physiology, P.O.Box 17 and 2Institute of Biotechnology P.O.Box 56, FIN-00014 University of Helsinki, Finland.

The ρ_1 and ρ_2 GABA receptor subunits form pharmacologically distinct GABA receptors with properties similar the so-called GABA_C receptors observed in vertebrate retinal interneurons. So far the physiological significance of these receptors is poorly

We have cloned the full cDNA of the rat ρ_1 subunit and a 750 bp segment of the rat ρ_2 subunit, and studied the expression of the transcripts of these subunits in different areas of the rat CNS using in situ hybridization, Northern blotting, and RT-PCR

techniques. ρ , mRNA was detected with Northern blotting exclusively in the retina, whereas a 2.0 kb and a 2.3 kb ρ_2 mRNA was found in retina, hippocampus and superior colliculus (SC). In cortex only a 2.0 kB ρ_2 mRNA could be detected. In situ hybridization showed a high level of ρ_2 expression in the retinal inner nuclear and external plexiform layers. Interestingly a relatively high level of ρ_2 expression was seen in a limited subset of cells in the dorsal lateral geniculate nucleus (DLG) and in the superficial gray layer of the SC. ρ_2 mRNA was also detected in area CA1 of the hippocampus and at a low level in the layer 6 of the visual cortex. RT-PCR combined with Southern blotting revealed n the layer of the Visual criter. NETFOR Conformed with Southern footing preference, mRNA expression in hippocampus, cortex, brain stem, thalamus, SC and dorsal root ganglia. Our preliminary findings also indicate higher expression of p, mRNA in the 8-day old rat hippocampus as compared to the adult. The RT-PCR results were normalized with light neurofilament PCR results obtained from the same specimen.

Our results show that ρ_1 and ρ_2 subunits are expressed in the retina, hippocampus and in formations pertaining to the visual pathway. These findings may be of importance in elucidating the functional role of the GABA receptors formed from ρ_1 and o. subunits

NEUROCHEMICAL DIFFERENTIATION OF GABAERGIC AMACRINE CELLS IN THE FISH RETINA. H.-J. Wagner, B. Nordmann and U. D. Behrens*.

Anatomisches Institut, Universität Tübingen, D-72074 Tübingen, Germany
GABA is the dominant neurotransmitter of the inner plexiform layer, used by 30-

50% of the amacrine cells (ACs). In view of the morphological diversity of this class of retinal cells, we used the pattern of colocalisation with various neuropeptides to study the heterogeneity of GABAergic ACs.

Immunohistochemical localisation of GABA was performed on cryostat sections of cyprinid retinae using a polyclonal antiserum (guinea pig) which was visualised with DTAF. The same sections were then incubated with one of the following polyclonal antisera (rabbit): SP, NPY, CGRP, met-ENK, VIP, and SST, and visualised with Texas Red. Colocalisation of a peptide and GABA was detected with a Zeiss LSM 410 and an image analysis feature detecting overlap of the two spectral channels. For a quantitative evaluation, a minimum of 1,000 GABA-ir perikarya (for each of the peptides) were counted in radial sections of various retinal locations and

Between 3% (CGRP) and 1% (VIP NPY met-ENK SST) of all GABAergic cells are colocalised with the respective neuropeptide. Conversely, about 80% of the peptidergic cells are immunoreactive for GABA. The ramification pattern and fine structure specific for each neuropeptide allowed a further differentiation of the GABAergic ACs. The double immunoreactive ACs ramify most strongly in sublayers 1, 3 and 5, with CGRP-and SP-ir cells being monostratified (sl3), and ENK-, SST-, VIP-, and NPY-ir cells trilaminar. In addition, the individual peptidergic cells are characterised by the calibre of their processes and the density and size of varicosities

These investigations provide an approach to further analyse the "GABAergic system" of the retina. They clearly demonstrate that this "system" is morphologically highly differentiated and suggest that this is reflected on the functional level. IMMUNOCYTOCHEMICAL LOCALIZATION OF TAGLUTAMATE IN THE PERIPHERAL OLFACTORY SYSTEM. TAURINE

A Didner* (1), O.P. Otterson (2), E. Mosse (1), F. Jourdan (1) and J. Storm-Mathisen (2), (1) Physiologic Neurosensorielle, CNRS-ERS 5643, Université Claude Bernard, F-69622, Villeurbanne, France and (2) Anatomical Institute, University of Oslo, PO Box 1105, Blindern, N-0317, Oslo, Norway, We have previously shown that taurine and glutamate are co-localized in the

terminals of primary olfactory neurons in the olfactory bulb (OB), with a subcellular distribution supporting a transmitter role for glutamate in these neurons (Didier et al., Neuroreport 6.145-148, 1994). Here, we further describe the cellular localization of these two amino acids in the other cell types of the OB and of the olfactory epithelium (OE). Immunocytochemistry of taurine and glutamate was performed by using fully characterized antibodies raised in rabbits against glutaraldehyde conjugates of taurine and glutamate. At the light microscopic level on semi-thin sections of the OB, glutamate is found in primary olfactory terminals, in mitral cells and in cell bodies of the external plexiform layer. Taurine is present in the primary olfactory terminals, in cell bodies of the periglomerular area and of the granular layer. In the OE, a semiquantitative study at the electron microscopic level using colloidal gold-coupled second antibody, reveals that the density of particles (particles/µm) reflecting the level of fixed taurine is higher in olfactory neurons (100.8±43.0, mean ± SD, n=9) and horizontal basal cells (78.2±15.5, n=5) than in globose basal cells (35.6±16.3, n=13). In contrast, glutamate distribution among the different cell types of the OE is homogeneous (25.26±11.54, n=7, 28.4±17.7 n=5, 18.4±9.1, n=8 for densities of particles in primary neurons, horizontal and globose basal cells respectively). Our data suggest neuromodulatory actions for both amino acids in different neuronal types of the OB. In the OE, the functional implication of the non homogeneous distribution of taurine requires further investigations.

LOCALIZATION OF GLUTAMATE RECEPTOR SUBUNITS OF -AMINO-3-HYDROXY-5-METHYL-4-ISOXAZOLEPROPIONATE (AMPA) TYPE IN THE PANCREAS OF NEWBORN GUINEA PIG. H.P. LIU, S.S.W. TAY* and S.K. LEONG. Department of Anatomy, National University of Singapore, Singapore

Glutamate and related molecules are excitatory neurotransmitters in the central nervous system, but little is known about them in the peripheral nervous system. The present study investigated the glutamate receptor subunits of AMPA type (GluRl, GluR2-3, and GluR4) in the pancreas of newborn guinea-pigs. With double labelling method of immunofluorescence and immuno-DAB-reaction, GluRl and GluR4 were localized in the insulin-secreting islet cells, and GluR2-3 in the non-insulin secreting islet cells. With double labelling method employing immunofluorescence and NADPH-d histochemistry, GluR2-3 and GluR4 immunoreactivities were localized in most of the NADPH-d positive pancreatic ganglion cells. GluRl immunoreactivity was undetected in the pancreatic ganglion cells. These results suggest that glutamate receptor of AMPA type may play an important role in the regulation of hormone secretion in the pancreas, and its neural effects may be mediated by the novel neurotransmitter, nitric oxide.

LOCALIZATION OF GLYCINE RECEPTORS ON THE MEMBRANE OF RAT ABDUCENS MOTONEURONES INTRACELLULARLY LABELLED WITH ABDUCENS MOTONEURONES INTRACELLECTART LEADLED WITH NEUROBIOTINE. A CONFOCAL AND ULTRASTRUCTURAL ANALYSIS. H. Bras* and A. Barbe Unité de Neurocyernétique cellulaire, CNRS UPR 9041, 280 Bd Ste Marguerite, 13009 Marseille, France We have recently shown that GABA and glycine, which are the major inhibitory neurotransmitters in the central nervous system, are colocalized in

miniotory neurotransmitters in the central nervous system, are coloranzed in 9% of the axon terminals apposed on the membrane of the soma and proximal dendrites of rat abducens motoneurones. The analysis of the organisation of the post synaptic membrane, ie the visualisation of glycine and/or GABAA receptors constitute the present aim of our study. Wistar rats were deeply anaesthetized with pentobarbitol. Abducens motoneurones were identified by their antidromic responses to the stimulation of the ipsilateral muscle rectus lateralis, and intracellularly injected with neurobiotine. After muscle rectus alterans, and intracentiary injected with neurosotine. After tanscardiac perfusion with 4 % paraformaldehyde, the brainstem was sectionned with a vibratome and the sections were processed for immunocytochemistry using a monoclonal antibody to glycine receptors (Boehringer). The neurobiotine was coupled to a rhodamin-avidin while the receptors were labelled with a fluorescein FITC-conjugated specific antibody. A confocal microscope (CM) analysis revealed the presence of glycine receptors on the membrane of the soma and the dendendrites of the aducens motoneurones. Special attention was paid to local geometrical features such as branching points and dendritic spines. The abducens motoneurones were reconstructed in 3 dimensions using a software program motoncurones were reconstructed in 3 amenisons using a software program for reconstruction of single neurones, to obtain a quantitative description of the geometry of the arborization. This software allowed to calculate the path distance from the soma of any local dendritic parts observed in CM. The vibratome sections were serially ultrathin sectionned and an electron microscopic was performed. These observations were compared to the data of the confocal microscopic analysis.

TRKA IMMUNOREACTIVE NEURONS IN THE RAT BASAL FOREBRAIN: RELATIONSHIP WITH GALANIN AND NITRIC OXIDE SYNTHASE. T.Sobreviela*, S. Jaffar and E.J. Mufson. Dept. of Neurol. Sci.2, Rush Med. Ctr., Chicago, IL 60612.

Cholinergic basal forebrain (BF) neurons express the high affinity trkA receptor for NGF, the neuromodualator galanin (GAL) and nitric oxide synthase (NOS), a marker for the neurotransmitter nitric oxide. We defined the expression of these markers within the medial septal/vertical limb of the diagonal band (MS/VDB), horizontal limb of the diagonal band (HDB) and nucleus basalis (NB) using colchicine pretreated rat tissue. TrkA positive neurons were seen throughout all BF subfields. In contrast, NOS and GAL neurons were mainly distributed within the MS/DB complex. Colocalization experiments revealed that virtually all NOS neurons (visualized by NADPH-d histochemistry) also contained trkA (>90%), whereas, only 25% of trkA neurons contained NADPH-d within the MS/VDB. Within the HDB NADPH-d neurons expressed trkA (75-85%), whereas, only a few trk-A neurons expressed NADPH-d (-15%). Within the NB very few neurons were NADPH-d reactive, although most contained trk-A. Only an occasional trk-A neuron (2-5%) expressed NADPH-d. Colocalization revealed that 10-25% neurons expressed NADPH-d, whereas, 20-30% of NADPH-d cells displayed GAL within the MS/DB complex. No colocalization occurred within the NB. Adjacent sections stained for GAL and trkA revealed twice as many trkA as GAL neurons within MS/DB complex. Within the NB there were ten times as many trkA as GAL neurons. These findings suggest that NGF via trkA modulates select BF neurons containing NOS and GAL. Support: AG10668, AG10161, AG09466 and IDPH

DIFFERENTIAL LOCALIZATION OF TWO METABOTROPIC GLUTAMATE RECEPTOR SUBTYPES IN SOMATOSENSORY THALAMUS OF THE RAT. X. B. Liu*, R.M. Mansour and E. G. Jones. Department of Anatomy and Neurobiology, University of California, Irvine, Irvine, CA92717.

Recent neuropharmacological studies have demonstrated that metabotropic glutamate receptors (mGluRs) play important roles in regulating excitatory and inhibitory neurotransmission in the thalamus. In situ hybridization data have confirmed that mGluR mRNAs are expressed in varying patterns in the thalamus. However, little is known about the localization of mGluR proteins in somatosensory thalamus (VP nucleus). Information regarding distribution patterns of different mGluR subtypes and their relationships with identified thalamic synapses is lacking. The aims of the present study are (1) To reveal the cellular distributions of mGluR1α and mGluR2/3 and correlate with the localization of α-calcium/calmodulin protein kinase (CAM II kinase-α). (2) To visualize the subcellular distribution patterns of mGluR1α and mGluR2/3 and their relationships with specific thalamic synapses. At the light microscopic level, large numbers of mGluR1α mmunostained neuronal processes and punctate structures were found in VP. The thalamic reticular nucleus (RTN) was devoid of immunostaining which is identical to the CAM II kinase-α immunostaining pattern. In contrast, mGluR2/3 showed less dense but fairly even labelling in VB and RTN, but most of the neurons lacked mGluR2/3 immunostaining. At the subcellular level, mGluR1α immunoreactivity was primarily confined in postsynaptic densities associated with RS type (corticothalamic) terminals, distal dendritic profiles and small appendages presumably deriving from relay cells. mGluR2/3 immunoreactivity was mainly localized within astroglial processes which were frequently found to wrap the RS terminals and some of the F type or RL type terminals. Neither mGluR1α nor mGluR2/3 was found in presynaptic terminals. The findings indicate that the two mGlu

GLYCINE, GLYCINE-RECEPTORS AND GLYCINE-TRANSPORTERS IN THE RAT PARABRACHIAL COMPLEX. H. Herbert A. Guthmann O.P. Ottersen A. Guthmann Dept. Animal Physiol., Univ. Tübingen, Germany Anatom. Inst., Univ. Oslo, Norway "Centro de Biol. Molec., Univ. Madrid, Spain. In the present study we sought to investigate whether the inhibitory amino

In the present study we sought to investigate whether the inhibitory amino acid glycine might play a role in signal transduction within the Parabrachial (PB) and Kölliker-Fuse nuclei (KF). Glycine (Gly) immunoreactivity (ir) was demonstrated on semithin plastic sections using a polyclonal rabbit anti-Gly antiserum and the PAP-technique. Glycine-Receptor (GlyR)-ir was demonstrated on cryostal sections by using a monoclonal mouse anti-GlyR antibody (mAb 2b, courtesy of H. Betz, MPI Frankfurt) and the indirect immunofluorescence technique. Glycine-Transporter (GlyT)-ir was demonstrated on vibratome sections monoclonic transporter (GlyT)-ir was demonstrated on vibratome sections. employing two different polyclonal rabbit anti-GlyT antisera (Ab#176: GlyT₁ and Ab#218: GlyT₂) and the PAP-technique. Sections were analyzed by light and fluorescence microscopy and by confocal laser-scanning microscopy.

Our results show that Gly-ir varicose fibers, GlyR-ir, and GlyT₂-ir are all co-

Our results show that Orly rearries needs, Orly it, and Orly 12-11 are an internal lateral (ii) PB and the lateral crescent of the PB, and in the KF. Gly-ir neurons were only occasionally seen in the PBil and the KF. In contrast, the external, central, and orsal lateral PB were totally devoid of these immunoreactivities. Furthermore, we observed that the pattern of GlyT₁-ir in the PB/KF is different from the GlyT₂-ir distribution. This indicates that the GlyT₁ is not necessarily associated with the strychnine-sensitive inhibitory glycinergic neurotransmission. From previous tracing experiments we know that the PBil, which is rich in Gly-ir fibers, GlyR-ir, and GlyT₂-ir, receives a prominent and exclusive input from spinal neurons located in the lateral reticulated area of lamina V. Thus, it is conceivable that the inhibitory amino acid glycine is used in this presumed somatosensory spino-parabrachial pathway. Furthermore, our data indicate that the respiratory related neurons in the KF are also under inhibitory control. However, the origin of the glycinergic input in the KF is not yet known. Supported by DFG He 1842:6-1

NITRIC OXIDE SYNTHASE (NOS)-IMMUNOREACTIVE NEURONS IN THE RAT HIPPOCAMPUS AND DENTATE GYRUS ARE CHEMICALLY HETEROGENEOUS. C.E. Adams* and R. Freedman. Department of Psychiatry, University of Colorado Health Sciences Center, Denver, CO 80262

Non-principle neurons within the rat hippocampus and dentate gyrus can be subdivided based upon whether they contain peptides, calcium binding proteins or nitric oxide synthase. The degree of overlap between these chemically-defined groups of neurons has not been completely characterized. The wide-spread distribution of neurons containing nitric oxide synthase within the rat hippocampus and dentate gyrus suggests that NOS-positive neurons might overlap to some degree with both the peptide and calcium binding protein subgroups. As an initial examination of this possibility, immunocytochemical staining of NOS was compared to that of somatostatin, cholecystokinin, parvalbumin, calbindin or calretinin in the same tissue sections. Our preliminary results indicate that subpopulations of NOS-immunoreactive neurons also contain somatostatin, parvalbumin, cholecystokinin and calretinin, but not calbindin. Thus, neurons containing nitric oxide synthase within the rat hippocampus and dentate gyrus overlap, in part, with both the peptide and calcium binding protein subgroups of non-principle cells [This research was supported by USPHS Grant MH44212]

LATERAL PARIETAL AND TEMPORAL NEOCORTEX OF THE OPOSSUM HAVE A REMARKABLE CONCENTRATION OF DIAPHORASE-POSITIVE NEURONS. J.G. Franca, R.L.S. Oliveira and E. Volchan. Lab. of Neurobiology II, Institute of Biophysics Carlos Chagas Filho, Federal University of Rio de Janeiro, Rio de Janeiro, 21949-900, Brazil.

Many authors utilize NADPH diaphorase histochemistry as a means to label

nitric oxide synthase-positive (NOS+) neurons and study their morphology. There are though few studies devoted to quantify their distribution in neocortex. Four adult opossums (Didelphis marsupialis aurita) were used. Three hemispheres were flattened and tangential sectioned. The fourth was cut coronal. All 60µm-thick-sections were incubated in a solution for 'indirect' NADPH diaphorase histochemistry. Analysis of labeled cells was performed in medial x lateral portions in both coronal and tangential sections. In the latter, three other sectors were also analyzed: anterior x intermediate x posterior. In all hemispheres, posterior parts show very low labeled cell densities. The intermediate part is the most crowded region, followed closely by the anterior one. The opossum neocortex shows much higher labeled cell densities in lateral than in medial half. In one of the tangential cut hemispheres, medial x lateral distribution was compared in the 3 antero-posterior sectors. Densities in each lateral half were two-fold that of the corresponding medial one. Supragranular layers have very few cells. Laminar densities increase dorso-ventrally reaching their highest values in infragranular layers. The results suggest that visual areas in this species are rather deprived of NOS+ neurons. On the other hand, the lateral parietal cortex has a high density of these cells. This region might correspond to the somatosensory representation of the snout. Auditory temporal cortex has also a high concentration of NOS-+ neurons. Functional significance of this heterogeneous distribution is still unknown. Funding Sources: CNPq, FINEP, CEPG.

REGIONAL AND SUBCELLULAR DISTRIBUTION OF PDE4 SUBTYPES IN RAT BRAIN. Y. Ye, J. Chandler, J. M. O'Donnell*, LSU Medical Center, Shreveport, LA 71130.

Immunoblot analysis revealed that in rat cerebral Immunoblot analysis revealed that in rat cerebral cortex there are four specific proteins reacting to K116, an antibody generated against rolipram-sensitive, high affinity, cyclic AMP phosphodiesterase (PDE4). These four proteins have molecular masses of 109, 102, 98, and 91 KDa. Using subtype-specific PDE4 antibodies, we identified 109 KDa protein as PDE4A and 91 KDa as PDE4D; the other proteins remain to be identified. Comparison among the regions showed that pituitary and pineal gland have only 102 and 98 KDa bands, whereas the other regions have all four bands which vary in intensity. Brain stem is low in all four bands; cerebellum is high in 109 and 102 KDa PDE4, but low in the other two bands; cerebral cortex, hippocampus, and striatum have similar patterns for the four bands. Subcellular fractionation indicated that the 102 KDa PDE4 exists exclusively in the P2 fraction and the 98 and 91 KDa PDE4s are concentrated in the S2 fraction, except for the pineal gland. Studies using primary cultures showed that pinear grand. Studies using primary cuttures showed that all four bands are present in neurons, while only 102 and 98 KDa PDE4s are seen in astroglia. The findings are consistent with the complex nature of PDE4 and support the notion that PDE4 subtypes may be differentially involved in signal transdution systems underlying different physiological processes.

IMMUNOHISTOCHEMICAL LOCALIZATION AND QUANTIFICATION OF GTP CYCLOHYDROLASE I (GTPCH), THE GENE DEFECTIVE IN HEREDITARY PROGRESSIVE DYSTONIA (HPD), WITHIN RAT BRAIN MONOAMINE (MA) NEURONS K. Hirayama*, R. Shen, M. Khalil and G. Kapatos Cellular and Clinical Neurobiology Program, Department of Psychiatry and Behavioral Neurosciences, Wayne State University School of Medicine, Detroit, MI 48201.

GTPCH is the first and rate-limiting enzyme in the biosynthesis of

tetrahydrobiopterin (BH4), the obligatory cofactor for tyrosine and tryptophan hydroxylases. Intracellular levels of BH4 are believed to be subsaturating with respect to these enzymes. Using *In situ* hybridization, we have localized GTPCH mRNA to MA neurons in rat brain. There is significant heterogeneity in the abundance of this transcript in different MA cell populations, with the highest levels of expression in 5-HT and the lowest in DA neurons. In order to determine whether heterogeneity in GTPCH mRNA levels are reflected in GTPCH protein, we have raised an antibody directed against the N-terminal 12-36 amino acids of GTPCH. GTPCH immunoreactivity was detected within MA neurons throughout the rat brain and was eliminated by absorption with the peptide antigen. Through the use of 35 S-labeled secondary antibody and autoradiographic emulsion detection, GTPCH protein levels were quantitated within individual MA neurons known to express different levels of GTPCH mRNA. These studies indicate that heterogeneity in GTPCH protein levels is expressed to an even greater degree than previously observed for GTPCH mRNA. This heterogeneity presumably underlies cell-specific differences in the intracellular concentration of BH4 and, therefore, the capacity to synthesize MA. Very low levels of GTPCH protein were found within A9 DA neurons. This may help to explain why A9 DA neurons are more sensitive than other MA neurons to the mutations in GTPCH that affect individuals with HPD, a movement disorder characterized by a selective inability to synthesize DA within the basal ganglia. DISTRIBUTION OF NADPH-DIAPHORASE IN THE FOREBRAIN OF THE SNAKES Thamnophis sirtalis AND Lamprophis fulginosis. Halpern*, Dept. of Anatomy and Cell Biology, Health Science Center at Brooklyn, SUNY, Brooklyn, NY 11203

The distribution pattern of NADPH-diaphorase (NADPH-d) activity in the prosencephalon of the snakes *Thannophis sirialis* and *Lamprophis fulginosis* exhibit some important interspecific differences. In the telencephalon of both species NADPH-d reactive neurons were numerous in the retrobulbar formation, olfactory tubercle, striatum, amygdala and dorsal ventricular ridge. A moderate number of stained neurons were present in the septum, medial, dorsal and lateral cortices. Areas stained neurons were present in the septum, medial, dorsal and lateral cornices. Areas of staining (probably terminal) were observed in the glomeruli of the main and accessory olfactory bulbs, nucleus accumbens, striatum, dorsolateral septum, hilus of the nucleus sphericus and lateral amygdala. The glomeruli of the accessory olfactory bulb showed the strongest NADPH-d reactivity of the entire brain. In L. fulginosis, but not in T. sirtalis, labeled neurons were present in the ventral amygdala, and a NADPH-d reactive ventral amygdalofugal tract was observed.

In the thalamus, labeled neurons and fibers were observed in the lateral geniculate complex westerled test believes the section of the lateral geniculate.

complex, ventrolateral thalamus, nucleus rotundus and nucleus lentiformis thalamu. Labeled neurons, but not fibers, were present in the nucleus ovalis and the medial thalamic nucleus. The neuropil of the lateral habenula was NADPH-d positive. In the thalamic nucleus. The neuropil of the lateral habenula was NADPH-d positive. In the hypothalamus of both species labeled neurons were present in the anterior hypothalamus and periventricular organ. The ventromedial edge of the optic tract showed a bundle of positive fibers. In the hypothalamus of *L. fulginosis*, but not in *T. sirtalis*, a number of labeled neurons were seen in the lateral hypothalamic area, and the ventromedial hypothalamic neuropil was NADPH-d reactive.

In contrast with our results, the NADPH-diaphorase activity in the brain of the snake, *Trimesurus flavoviridis* (Jiang et al., 1996; Brain Res. 713:168-177), was almost absent in the forebrain.

almost absent in the forebrain.

GTP_{[1}³⁵S] AUTORADIOGRAPHY ALLOWS REGION-SPECIFIC DETECTION OF G PROTEIN ACTIVATION IN THE CHICK OPTIC TECTUM. K. Kurkinen^{1,2*}, M. Jokinen¹, J.M. Saavedra³ and J.T. Laitinen¹. 1)Department of Physiology and 2) A.I.Virtanen Institute, University of Kuopio, P.O.B. 1627, FIN-70211 Kuopio and 3) Section of Pharmacology, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD, USA. A recently introduced technique of GTP [58] autoradiography was used to

visualize agonist-dependent activation of G proteins in tissue sections of chick optic tectum, a brain region with relatively high expression of G protein-coupled receptors (GPCRs) for the neurotransmitter acetylcholine and pineal hormone melatonin. Quantitative comparison of GTP₁(3^SS] binding responses normone melatonin. Quantitative comparison of C177~5] binding responses between tectal sections and membrane preparations revealed a close match between the two tissue preparations for the response elicited by the cholinergic agonist carbachol (CCh), its dose-dependent blockade with the muscarinic antagonist atropine, its 100-fold selectivity towards blockade with M1-type (pirenzepine) over M2-type (gallamine) muscarinic antagonist, as well as absolute requirement for micromolar concentrations of GDP (EC₅₀ 10 µM) for the agonist-dependent GTP [35S] response. By using spesific antisera against the C-terminus of G protein α subunits, we found that the pirenzepine-sensitive muscarinic receptors efficiently interacted with $\alpha_{i1/2}$ providing first functional muscarinic receptors enticiently interacted with $\Omega_{1/2}$ providing first functional data on chick tectal mAChRs. However, we failed to detect any melatonin receptor-mediated GTP $\{^{15}S\}$ response in conditions where CCh, somatostatin and 5-HT all elicited region-spesific increases in GTP $\{^{15}S\}$ binding. As already demonstrated for the rat brain, GTP $\{^{15}S\}$ autoradiography represents a promising tool for functional neuroanatomical studies on G protein activation by several (but perhaps not all) GPCRs. GTP\(^3\frac{1}{5}\frac{1}{5}\) autoradiography should greatly facilitate studies on endogenous G protein-coupling specificity of various receptor subtypes in situ at physiological expression levels of the signaling components.

AGONIST-INDUCED INTERNALIZATION OF THE HUMAN P2Y2 PURINERGIC RECEPTOR. S.M. Sromek* and T.K. Harden#. Curr. in Neurobiology and Dept. of Pharmacology#, Univ. of North Carolina, Chapel Hill NC 27599.

The human P2Y2 purinergic receptor (P2Y2-R) is a 377 amino acid G protein-coupled receptor that is activated by ATP and UTP and stimulates phospholipase C (PLC). P2Y2-R undergo agonist-induced desensitization as demonstrated by a reduced capacity of P2Y2-R agonists to activate PLC. This desensitization is reversible upon agonist removal (resensitization). Agonist-induced receptor internalization has been observed for many G protein-coupled receptors. Recycling of internalized receptors back to the plasma membrane has been suggested to be a mechanism underlying receptor resensitization. To study whether internalization plays a role in P2Y2-R agonist-induced desensitization and/or resensitization, an epitope-tagged P2Y2-R was constructed by addition of the hemagluttinin A (HA) tag to the amino terminus (P2Y2-HA-R). When expressed in 1321N1 human astrocytoma cells, P2Y2-HA-R exhibited a similar pharmacological selectivity and a similar desensitization profile to that of wild-type P2Y2-R. ELISA-based assays demonstrated that cell surface P2Y2-HA-R immunoreactivity was decreased within 15 min of agonist treatment. The methodology for viewing cell-surface distribution of P2Y2-HA-R by indirect immunofluorescence (IIF) has been established. IIF microscopy and ELISA-based assays are currently being utilized to study agonist-induced redistribution of P2Y2-R. This project is supported by USPHS grant HL34322.

ROLE OF ADENOSINE IN PRODUCING CHANNEL ARREST IN THE ANOXIC TURTLE BRAIN. M.Pek, P.L.Lutz* Dept.of Biology, Florida Atlantic University, Boca Raton, FL 33431.

The turtle brain's remarkable ability to survive anoxia is mainly based upon the flexible regulation of energy demand and energy production. Earlier studies indicate that extracellular adenosine is involved in reducing the brain's energy demand and increasing the cerebral blood flow. We tested the involvement of adenosine in the reduction of potassium flux(channel arrest)that occurs in the anoxic turtle brain. Changes in extracellular K+ in the in situ brain of the turtle Trachemys scripta were monitored following inhibition of the Na-K ATP-ase with ouabain. The consequentincrease of extracellular K+ was substantially(3-fold)slower in the anoxic brain compared to normoxic controls. Superfusing the brain before and during anoxia with theophylline, or the specific adenosine Al receptor blocker 8-cyclopenthyltheophylline(CPT), resulted in a significant increase in potassium efflux in the anoxic brain, and the lowering of the depolarization K+ inflexion point. This is the first demonstration of the involvement of the adenosine Al recep tors in the reduction of ion flux in the anoxic brain, and the inflexion point change under anoxia. ACTIVATION OF ADENOSINE A3 RECEPTORS REDUCES THE SENSITIVITY OF RAT HIPPOCAMPAL A1 RECEPTORS, L.H. Diao*, T.V. Dunwiddie, H.O. Kim, K.A. Jacobson. Depts. of Pharmacol. and Neurosci., Univ. Col. Hlth. Sci. Ctr., VA Med. Ctr.. Denver, CO 80262, Molecular Recognition Section, Lab. of Bioorganic Chemistry, NIDDK, NIH, Bethesda, MD 20892

The adenosine A3 receptor is expressed in rat brain, including the hippocampal formation. However, the effects of activation of this receptor on electrophysiological activity are unknown. To address this issue, the effects of a highly selective adenosine A3 receptor agonist, 2-chloro-N⁶-(3-iodobenzyl)-adenosine-5'-N-methyluron-amide (Cl-IB-MECA) were determined in the CA1 area of rat hippocampal slices. Superfusion with Cl-IB-MECA (0.1-1µM) had no direct effects on fEPSPs, population spikes, long-term potentiation, or paired-pulse facilitation. However, the A1 receptor-mediated inhibition of excitatory neurotransmission was significantly antagonized by CI-IB-MECA in a concentration-dependent fashion, but not by the selective A2a receptor agonist, CGS 21680. The presynaptic inhibitory effects of baclofen and carbachol were unaffected by CI-IB-MECA. The maximal response to adenosine was unchanged, suggesting that the primary effect of CI-IB-MECA was to reduce the affinity of adenosine for the A1 receptor, rather than to uncouple it. The actions of CI-IB-MECA were partially antagonized by chelerythrine, an inhibitor of protein kinase C, suggesting that presynaptic A3 receptors might be coupled to activation of phospholipase C Supported by NS 29173 and the VA Medical Research Service

EXPRESSION AND PARASYMPATHETIC TRANS-SYNAPTIC REGULATION OF $P_{\rm 2x}$ PURINOCEPTORS IN RAT PAROTID

REGULATION OF Pax PURINOCEPTORS IN RAI PAROTII
ACINAR CELLS Barbara Talamo and Lalitha Tenneti
of Neuroscience, Tufts U. Medical School, Boston, MA
ATP activates P_{2x} and P_{2x} (through ATP⁺) -type purinoceptors in
rat parotid acinar cells to gate non-selective cation currents.
Cytosolic calcium (Ca_i) is regulated through Ca²⁺ influx gated by
these receptors as well as through intracellular Ca²⁺ release activated these receptors as well as through intracellular Ca* release activated by muscarinic, \(\alpha\)-adrenergic and substance P receptors coupled through G proteins to phospholipase C. Fluorimetric ratio imaging of Cai in single dissociated cells labeled with fura-2AM showed that most cells are responsive to ACh, Substance P and ATP\(^4\). However, MgATP-activated Ca\(^2\) influx was observed in only 20\(^6\) of the cells, with a pharmacology similar to that of the recently cloned P2x4 receptor. RT-PCR showed abundant mRNA for this receptor in parotid tissue. Following postganglionic parasympathetic depervation all of these recentor-mediated Ca. responses became denervation, all of these receptor-mediated Ca_i responses became more sensitive to activation. The fraction of cells responding to MgATP tripled and the fraction of cells "supersensitive" to ATP increased 7-fold. Analysis of Ca; responses in single cells showed that sensitivity to muscarinic activation and to MgATP activation is distributed across different subsets of cells and appears to depend on different mechanisms and be regulated independently. Previous data suggested that muscarinic responses are regulated downstream from the receptor. We hypothesize that parasympathetic signals regulate P_{2x4} receptors trans-synaptically. A1 ADENOSINE RECEPTOR REGULATION IN CEREBELLAR GRANULE CELLS . B.D. Hettinger-Smith*, M. Leid and T.F. Murray. College of Pharmacy, Oregon State University, Corvallis,

Adenosine is a ubiquitous physiological regulator and neuromodulator acting at A1, A2a, A2b and A3 adenosine receptors neuromodulator acting at A1, A2a, A2b and A3 agenosine receptors all of which are coupled to G-proteins. A1 adenosine receptors (A1AR) are coupled to the inhibition of adenylyl cyclase and regulation of these receptors provides a means for cells to adapt to chronic agonist or antagonist exposure. Primary cultures of cerebellar granule cells from 8 day old Sprague Dawley rat pups were established and used to study A1AR regulation in response to chronic exposure to agonists, antagonists and forskolin. A 48 hour exposure to the A1AR agonist, cyclopentyladenosine (CPA) effected a decrease in receptor density, impaired AIAR coupling to G-proteins and a blunted adenylyl cyclase response to AIAR agonists. Agonist exposure also increases the fraction of sequestered AIAR. Agonist exposure also increases the raction of sequesceted ATAL. In order to assess the role of cAMP in receptor regulation, cells were treated with forskolin. Forskolin exposure did not affect A1AR density or affinity indicating that intracellular cAMP does not modulate the expression of A1AR. Alterations in A1AR density due nodulate the expression of ATAK. Attraction in ATAK exclusing the chronic agonist and/or antagonist exposure are not paralleled by substantive changes in receptor mRNA as measured by RNAse protection assay. These results indicate that down- or upregulation of A1AR levels are not mediated by transcriptional regulation. (Supported by NIDA grant F31 DA05631 to BHS).

EFFECTS OF THE ADENOSINE BINDING ENHANCER, PD 81723, ON ELECTROPHYSIOLOGY & NEUROTRANSMITTER RELEASE IN THE HIPPOCAMPAL SLICE. G. Wang¹, R. F. Berman^{1*} & R. M. Broad², ¹Wayne State

University, Detroit, Michigan and ²Karolinska Institute, Stockholm, Sweden. Adenosine is an important inhibitory neuromodulator in the central nervous system. Adenosine depresses spontaneous neuronal firing in the mammalian CNS and inhibits

Adenosine depresses spontaneous neuronal firing in the mammalian CNS and inhibits evoked synaptic activity in the *in vitro* hippocampal slice. The adenosine receptor binding enhancer, PD 81723, enhances these inhibitory effects of adenosine *in vitro*. In the present study the effects of PD81723 alone, or in combination with 2-chloroadenosine on *in vitro* hippocampal synaptic activity were examined. Superfused hippocampal slices were prepared from Long-Evans rats. Schaffer collateral's were stimulated at 1 Hz and evoked field potentials were recorded.

As expected, the addition of 200 nM 2-chloroadenosine alone depressed population spike amplitude by approximately 43%. Subsequent addition of 10 uM PD 81723 produced a further 33% depression of synaptic activity. This enhancement of the effects of 2-chloroadenosine is consistent with our previously reported effects with this compound. The effects of 10 uM PD 81723 when added to 400 nM 2-chloroadenosine were similar, but the magnitude of the enhancement was greater (i.e., 73%). In contrast, addition of 50 uM PD 81723 partially reversed the 2-chloroadenosine-mediated depression of synaptic activity, again consistent with previous reports of antagonist-like effects of higher concentrations of PD 81723. The addition of 10 uM PD 81723 alone to the superfusion media produced a small but significant decrease in the population spike amplitude, and this effect was reversed when the concentration of PD 81723 was amplitude, and this effect was reversed when the concentration of PD 81723 was increased to 50 uM. These results were compared to the effects of PD 81723 on 2 chloroadenosine-mediated inhibition of evoked [3H]-norepinephrine and [14C]acetylcholine release from perfused hippocampal slices. In contrast to the electrophysiological findings, PD 81723 had only limited effects on the ability of 2 chloroadenosine to affect neurotransmitter release from hippocampal slices. These results extend our previous findings that PD 81723 enhances adenosine activity, to the stable adenosine analog 2-chloroadenosine. (Supported by NIDRR H133A20016)

MODULATION OF GABA RELEASE IN RAT BASAL GANGLIA:

MODULATION OF GABA RELEASE IN RAT BASAL GANGLIA: ANTAGONISTIC ADENOSINE A1/DOPAMINE D1 RECEPTOR INTERACTION?

R.D. Mayfield*. H.A. Miller, and N.R. Zahniser. Dept. Pharmacol., Univ. Colorado Hith. Sci. Ctr., Denver, CO 80262.

Behavioral and biochemical studies suggest that a negative interaction exists between adenosine (ADO) A1 and dopamine (DA) D1 receptors in the brain, which may contribute to the motor depressant effects of ADO agonists and the motor stimulating effects of ADO antagonists. We examined the functional significance of A1 and D1 receptor subtypes in modulating electrically-evoked endogenous GABA release from tissue slices of rat basal ganglia (striatum, globus pallidus, striatum containing globus pallidus, and substantia nigra reticulata) in the presence of a GABA uptake blocker. Selective stimulation of A1 receptors with R-PIA (1-100 nM) resulted in a concentration dependent decrease in GABA release from globus pallidus and striatum containing globus pallidus. Maximum inhibition of release was approximately 40% in the presence of 100 nM R-PIA. NECA (10 nM) inhibited GABA release to the same extent. The selective A1 antagonist DPCPX (10-100 nM) increased GABA 100 nM R-PIA. NECA (10 nM) inhibited GABA release to the same extent. The selective A₁ antagonist DPCPX (10-100 nM) increased GABA release suggesting that endogenous ADO tonically inhibits GABA release. In contrast, consistent DA D₁ receptor modulation of GABA release was not observed in any brain region using a number of D₁ agonists (SKF-38938), fenoldopam, CY-208-243, and SKF-82958) or the D₁ antagonist SCH-23390. Finally, co-stimulation of A₁ and D₁ receptors in striatum containing globus pallidus with R-PIA (10 nM) and SKF-82958 (1 μ M) resulted in a decrease in GABA release that was similar to that observed for R-PIA alone, thus, confirming the lack of D₁ receptor modulation under these conditions. These results do not support a role for an antagonistic A₁D₁ receptor interaction in modulating electrically-evoked GABA release; however, the possibility exists that this interaction might be observed in the absence of a GABA uptake blocker. (Support: NS 26851)

DIFFERENTIAL FEFECTS OF CLOZAPINE AND HALOPERIDOL ON DOPAMINE RECEPTOR mRNA EXPRESSION IN RAT STRIATUM AND CORTEX. S. P. Damask and J. H. Meador-Woodruff*. Mental Health Research Institute and Department of Psychiatry, University of Michigan Medical Center, Ann Arbor, MI 48109-0720

The regulation of the dopamine (DA) receptors is of considerable interest, in part because treatment with antipsychotic drugs is known to upregulate striatal D₂-like receptors. While previous studies have focused on the regulation of striatal DA receptors, less is known about the pharmacological regulation of cortical DA receptors. The purpose of this study was to examine the regulation of DA mRNA receptors. The purpose of this study was to examine the regulation of DA mRNA receptor expression in the cortex compared to the striatum following treatment with antipsychotic agents. Adult male Sprague-Dawley rats were injected daily with haloperidol (2 mg/kg/day), clozapine (20 mg/kg/day) or a control vehicle for a period of 14 days. Following treatment, brains were subjected to in situ hybridization for the mRNAs encoding the five dopamine receptors; only D₁, D₂, and D₃ receptor mRNAs were detected in these regions. Haloperidol tended to either modestly upregulate or have no effect on dopamine receptor mRNAs detected in striatal structures, while clozapine generally downregulated these mRNAs. On the other hand, in the cortex, both drugs had striking effects on D₁ and D₂ mRNA levels. Cortical D₁ mRNA was upregulated by haloperidol, but this effect was primarily restricted to cingulate cortex; clozapine also upregulated D₁ mRNA, but primarily in parietal regions. Haloperidol downregulated D₂ mRNA in the majority of cortical regions, but most dramatically in downregulated D_2 mRNA in the majority of cortical regions, but most dramatically in frontal and cingulate regions; clozapine typically upregulated this mRNA, but primarily in regions other than frontal and eingulate oriex. These results indicate that clozapine and haloperidol each have regionally-specific effects, and differentially regulate dopamine receptor mRNA expression in striatal and cortical regions of the rat brain. This work was supported by a grant to Dr. Meador-Woodruff from NIMH (MHS3327). This project was also supported by the Mental Health Research Institute and the Department of Psychiatry at the University of Michigan.

MUTATION OF SERINE 167 OF THE D2L RECEPTOR MODULATES RECEPTOR REGULATION. S. Starr*, V. J. Watts, M. N. Vu, and K.A. Neve Oregon Health Sciences University and VA Medical Center, Portland OR, 97201

Molecular modeling studies of the D2L dopamine receptor have suggested that residues phenylalanine 110 and serine 167 are important for ligand binding and activation. These residues are found in transmembrane domains 3 and 4 respectively. Mutant D2L cDNA was generated in which phenylalanine 110 and serine 167 were changed to alanine (F110A) and (S167A) respectively, using the method of trans-PCR. HEK293 cells were stably transfected with D2L, F110A or S167A cDNAs. Saturation analysis using [3H]spiperone determined that receptor densities ranged from 300 to 3,000 fmol/mg protein for both D2L and mutant receptors. Ability to inhibit forskolin-stimulated adenylate cyclase activity was assessed using dopamine, (+)-3-PPP, and quinpirole. All three agonists were efficacious at both D2L and mutant receptors. However the EC50s for F110A and S167A were shifted slightly to the right, indicating decreased potency for the mutant receptors. Additional studies were carried out to examine agonist-induced regulation of D2L receptor density. Following an 18-fir treatment with agonist, there were modest changes in receptor density for D2L or F110A receptor. However the density of receptors was increased 4-5 fold for S167A, from 300 fmol/mg to 1580 and 1410 fmol/mg by treatment with NPA and quinpirole, respectively. Similar results were found with a second \$167A clone. Apparent affinities for the these clones were somewhat decreased which may be the result of some residual drug. Further analysis of this mutant may provide insight into the mechanisms of agonist induced up-regulation of D2 receptors observed in some other cell lines. Supported by MH45372 and VA Merit Review Program.

COCAINE WITHDRAWAL DOES NOT ALTER D1 RECEPTORS IN THE RAT BRAIN. C. M. Ohuoha*, M. H. Baumann, B. Emilien, R. B. Rothman, Clinical Psychopharmacology Section, CPB/DIR/NIDA, Baltimore MD

The role of dopamine (DA) receptor subtypes in drug abuse have been studied extensively with much of the investigation centered on the role of D2 receptors. D1 receptors are functionally and anatomically segregated from D2 receptors in the neostriatum. Unlike D2 receptor subtypes which occur as postsynaptic receptors or presynaptic autoreceptors, D1 subtypes are concentrated on postsynaptic sites in the nigrostriatal dopamine system. The measurement of D1 receptor density with the anatomical resolution of autoradiography may provide information regarding the effects of chronic cocaine on D1 receptors in cocaine withdrawal. In this study rats received 15mg/kg of cocaine or saline two times per day for seven days. A 42 hour withdrawal period was allowed prior to sacrifice and harvesting of the brains. Brains were stored immediately in -70°C until processed 14µm thick coronal sections through the striatum were mounted on acid-cleaned, gel coated slides. Tissue sections were preincubated in buffer (50mM Tris HCl, 120mM NaCl, 1mM MgCl₂, 5mM KCl and 2mM CaCl₂, pH 7.4) for 5 minutes at room temperature. Total binding was determined in buffer solution containing 2nM [3H]SCH 23390 (44.2Ci/mmole NEN, Boston MA) and 20nM mianserin to block 5HT₂ receptors. Non-specific binding was assessed using 10μM (+)-butaclamol. Analysis of the autoradiograms did not show any significant difference in D1 receptor density in the two groups studied in the frontal cortex, striatum, substantial nigra, hippocampus and dentate gyrus. These results indicate that D1 receptors are unaltered during early cocaine withdrawal and are in contrast to some earlier studies in the striatum. (Work was supported by DIR/NIDA, NIH)

NEONATAL RAT MEDIAL PREFRONTAL CORTEX LESION: DOPAMINE AND LOCOMOTION G. Flores, G.K. Wood, J.J. Liang, R. Quirion, & L.K. Srivastava* Douglas Hospital Research Centre, McGill University, Montreal, Quebec, Canada, H4H 1R3.

Adult rats with lesions to the medial prefrontal cortex (MPFC) demonstrate increased behavioral response to stressful stimuli and altered mesolimbic/nigrostriatal dopamine (DA) levels (Jaskiw et al., Brain Res. 534, 263). While this lesion relates to the MPFC pathology and presumed DAergic alterations seen in schizophrenia, it does not address the developmental aspect of this disease, namely, insult to the pre/neonatal brain causing postpubertal behavioral changes. Therefore, in order to determine if MPFC damage in a developmental period will manifest behavioral and DAergic enhancements postpubertally, neonatal (PD7) ibotenic acid lesions of the rat MPFC were performed and compared to adult MPFC lesions. Neonatal lesions to the rat MPFC caused increased novelty and amphetamineinduced locomotion postpubertally (PD56; postoperative week 7) but not prepubertally (PD35). Adult lesions to the rat MPFC produced significantly increased amphetamine-induced locomotion on postoperative week 7, but not to the extent of neonatal MPFC lesion. Autoradiographic and in situ measurement of DA receptor subtypes revealed a significant increase in D2 receptors in the shell of the accumbens and dorsal striatum in postpubertal rats neonatally lesioned in the MPFC. These results suggest that neonatal lesions to the MPFC can cause delayed onset of behavioral hyperactivity and concurrent increased mesolimbic/nigrostriatal DA D2 receptor density. (Supported by the FRSQ).

LONG LASTING CHANGES IN CORTICAL EXCITATORY AMINO ACID RECEPTOR LEVELS AND DOPAMINE-INDUCED BEHAVIOR AFTER NEONATAL EXCITOTOXIC LESION OF THE VENTRAL HIPPOCAMPUS IN RATS Z. Albo*, G. Flores, R. Quirion and L.K. Srivastava. Douglas Hospital Research Center, Departments of Psychiatry and Pharmacology and Therapeutics, McGill University, Montreal, Quebec, Canada H4H 1R3

Bilateral excitotoxic lesions of the ventral hippocampus in neonatal rats result in

hyperlocomotor behaviors induced by dopamine agonists, and hyperresponsiveness to stress induced behavior in postpuberal animals (Lipska et al., Neuropsychopharm. 9:67, 1993). A cortical maldevelopment has also been suggested to explain the behavioral changes observed but direct evidence is lacking to support this assumption (Weinberger and Lipska, Schizophr Res.16:87,1995). We have reported that the levels of cortical N-methyl-D-aspartate (NMDA) receptors increased in postpuberal (PD56) but not prepuberal (PD35) rats after neonatal excitotoxic lesion of the ventral hippocampus (Albo et al, Soc Neurosc. Abst. 21:1145, 1995). Now, we have compared the levels of NMDA receptors in cortical areas of 6 month-old rats that underwent either bilateral ibotenic acid lesions or sham-lesion of the ventral hippocampus at postnatal day 7 (PD7). Neonatally hippocampal-lesioned 6 month-old rats showed increased locomotor activities induced by D-amphetamine (Img/kg). The density of NMDA receptors as measured by ligand autoradiography using [¹²⁵1] MK-801 (200pM) was found to be significantly increased in the frontal and cingulate cortices in the 6 month-old neonatally hippocampal-lesioned group. Other brain areas studied showed no significant change in [1251] MK-801 binding. Taken together our results suggest that cortical glutamate abnormalities observed in hippocampal-lesioned rats are of enduring nature and may underlie some of the behavioral changes observed in these animals. (Supported by FRSQ).

PRE- AND POST- SYNAPTIC DOPAMINERGIC GENE EXPRESSION AFTER NMDA RECEPTOR BLOCKADE. Andrea de Bartolomeis*. Luigi Aloj, Carlo Contaldi, David Pickar, Giovanni Muscettola and Alan Breier Section of Psychiatry, Department of Neuroscience. Univ. School of Medicine Federico II, Via Pansini 5, 80131 Napoli Italy; ETB NIMH, NIH, Bethesda MD, USA; Nuclear Medicine. NIH. Bethesda. MD. USA.

Combined dysfunction of dopaminergic and glutamatergic systems and NMDA hypofunction has been suggested to be involved in pathophysiology of schizophrenia and has been investigated in humans with sub-anesthetic doses of ketamine a dissociative agent and NMDA non competitive antagonist. The effects of sub-anesthetic doses of ketamine on presynaptic and postsynaptic dopaminergic gene expression as well as enkephalin gene expression were studied in an animal model by means of quantitative in situ hybridization. Male Sprague Dawley rats were treated with NaCl 0.9%, or 12 mg/kg or 50 mg/kg ketamine-HCl i.p. Brain sections were hybridized with ³⁵S radiolabeled synthetic oligonucleotides for dopamine receptors D₁ and D₂, dopamine transporter (DAT), and preproenkephalin. The computer assisted analysis of the autoradiograms showed increased DAT mRNA in ventral tegmental area (p= 0.019) and modulation of enkephalin gene expression in sub-regions of striatum in rats treated with ketamine compared to controls. These results suggest a potential regulation of dopamine transporter and enkephalin mRNA after NMDA blockade by subanesthetic doses of ketamine. FIS -IRGASD grant to A.d.B. and G.M.

THE ROLE OF G-PROTEINS IN MEDIATING DOPAMINE RECEPTOR SUPERSENSITIVITY: THE USE OF IN VIVO ANTISENSE OLIGONUCLEOTIDES. E.R. Marcotte* and R.K. Mishra. Depts. of Psychiatry and Biomedical Sciences, McMaster University, Hamilton, Ontario, L8N 375 Canada

Previously, studies of receptor supersensitivity have focused largely on changes in receptor density and ligand affinity. Although receptor upregulation provides an obvious and direct mechanism by which supersensitivity could occur, it has proven insufficient in explaining many aspects of dopamine receptor supersensitivity. Gproteins, as the next step in receptor-mediated signal transduction and amplification, provide a logical focus for further research. We have previously shown that the striatal stimulatory G-proteins Gs and Golf are elevated in an animal model of Parkinson's disease, the 6-hydroxydopamine lesioned rat. We now report direct evidence for the role of Golf in mediating dopamine receptor supersensitivity using in vivo Golf antisense oligonucleotides. Golf antisense infusion virtually abolished apomorphine-induced rotation in this animal model. Correspondingly, Golf levels were specifically reduced by antisense infusion. In the MPTP mouse model, a differential regulation of stimulatory G-protein levels by MPTP treatment was observed. We found an acute reduction in Gs and Golf shortly after the lesion, followed by a delayed increase in stimulatory G-proteins during recovery. This is in stark contrast to the consistent upregulation seen in 6-hydroxydopamine lesioned rats, and presumably reflects differences in the regulation of dopamine receptor supersensitivity in these two animal models of Parkinson's disease. Further study with in vivo antisense agents may help to resolve these issues. Funded by the Parkinson's Foundation of Canada, and the NIH

MODULATORY EFFECTS OF THE NEUROSTEROID DEHYDROEPIANDROSTERONE (DHEA) ON NEUROTRANSMITTERS MEMBRANE RECEPTORS IN THE MALE RAT BRAIN. S. Lee Mei Si and T. Di Paolo*. School of Pharmacy, Laval University and Dept. of Molecular Endocrinology, C.H.U.Q. Research Center, Quebec, Que., Canada, G1V 4G2.

DHEA is a precursor of sex steroids and has been shown to decline in the

DHEA is a precursor of sex steroids and has been shown to decline in the blood of aging men and women. DHEA is considered as a neurosteroid and its neuromodulatory activity includes interactions with a variety of membrane receptors. The present study investigated the role of DHEA in male rats on the balance of numerous neurotransmitters receptors in the brain which are involved in central nervous system disorders. 30 animals were divided into 3 distinct groups: (1) Intact, (2) orchidectomized, (3) orchidectomized + DHEA. Castration was used as a model of decreasing gonadal function such as in aging. DHEA treatment consisted of a 15 mg subcutaneous injection, b.i.d for 2 weeks. D2 dopamine receptors in the striatum (D2Rs) and 5-HT2A serotonin receptors in the frontal cortex (5-HT2ARcf) were determined by saturation experiments on appropriate tissue, using [3H]Spiperone and [3H]Ketanserin respectively. [3H]Flunitrazepam ([3H]Flu) binding to the GABAA receptor complex in the substantia nigra pars reticulata was measured by quantitative autoradiography. Orchidectomy decreased 5-HT2Acf levels (p<0.05) and improved the affinity for its ligand (p<0.05). Those changes were not corrected with DHEA treatment. Gonadal steroid withdrawal did not alter D2Rs or [3H]Flu binding properties. Supplementation with DHEA decreased D2R density by 23.6% (p<0.01) and enhanced [3H]Flu binding by 29 % (p<0.01). Affinity was not affected by castration nor DHEA replacement therapy. DHEA could exert its action by itself or via its transformation into estradiol or testosterone. However, the different response of D2 and GABAA, receptors to DHEA as compared to our previous data with estradiol suggest that DHEA activity is more likely androgenic. Our study provides evidence of DHEA influence on aminergic and gabaergic neurotransmission in the male rat brain. Supported by the MRC of Canada.

IDENTIFICATION OF PROTEIN KINASE C ISOENZYMES IN ADRENAL MEDULLA AND SYMPATHETIC GANGLIA OF RAT A. R. Wakade* Y. Watanabe & H. Hidaka Dept. of Pharmacology, Wayne State Univ. School of Medicine, Detroit and Nagoya University School of Medicine, Nagoya, Japan.

Protein kinase C (PKC) plays an important role in exocytosis and neuronal differentiation in adrenal medulla (AM) and sympathetic neurons. Using mono-and poly-clonal antibodies we have identified various PKC isoenzymes in adrenal medulla (AM) and superior cervical ganglia (SCG) of rat. Among cPKC, gamma was absent in AM and SCG. Beta form was sparsely detectable in AM but was abundant in cytosol fraction of SCG. Alpha was present in cytosol fractions of both tissues but was higher in SCG. nPKC isoforms, delta and epsilon were also detected in AM and SCG. Delta was weak but epsilon was high in SCG. aPKC zeta form was most abundant of all forms in SCG and AM cytosol fractions. Alpha PKC was translocated to AM membrane fraction by stimulation with excess K+, muscarine (MUS), and pituitary adenylate cyclase activating polypeptide (PACAP). PACAP and MUS also translocated zeta form. In contrast, all the three agonists translocated beta isoform in SCG membranes. Zeta form was unaffected by these agents and phorbol 12, 13- dibutyrate. Excess K+ and muscarine translocated alpha cPKC and epsilon nPKC, respectively in SCG membranes. We conclude that alpha and beta cPKC are the major isoforms of PKC involved in signal transduction mechanisms in AM and SCG, respectively and the role of other isoenzymes remains unclear at this time

MONOAMINE SYNTHESIZING ENZYMES WITHIN CARDIAC GANGLIA OF THE ADULT HUMAN HEART. S. Singh*, P. I. Johnson, A. Javed, T. S. Gray, and R. D. Wurster. Anatomy, Physiology, Pharmacology and Center, Maywood, Illinois 60153-3500.

Classically, cardiac ganglia were thought to contain cholinergic neurons relaying information from preganglionic neurons in the brainstem to the heart's muscle and nodal tissue. More recently evidence suggests that cardiac ganglia contain a heterogeneous population of neurons capable of synthesizing several neurotransmitters and containing various neuropeptides. However, reports regarding catecholamine and indoleamine synthesizing enzymes within these ganglia are limited and conflicting. In addition, studies examining all of these enzymes in the human cardiac ganglia do not exist. Therefore, the purpose of this study was to determine if monoamine synthesizing enzymes are present within neurons of the human cardiac ganglia. Human heart tissue from near the sino-atrial and atrio-ventricular nodes was obtained from heart transplants and autopsies. Polyclonal antibodies previously shown to be specific for tyrosine hydroxylase (TH), aromatic amino-acid decarboxylase (AADC), dopamine β-hydroxylase (TpH) and choline acetyltransferase (ChAT) were used to detect these enzymes within the cardiac ganglia. Primary antibodies were omitted from the incubation solution as negative controls while sympathetic nerve fibers and small intensely fluorescent cells, known to contain monoamine synthesizing enzymes, served as positive internal controls. Our results indicate that many neurons within the cardiac ganglia are immunoreactive for TH, AADC, DBH, PNMT, TryH and ChAT. To the best of our knowledge, this is the first demonstration of PNMT and TryH within neurons of any mammalian cardiac ganglia. These findings suggest that dopamine, norepineprine, epinephrine, servotonin and acetylcholine can all be synthesized by neurons within the human cardiac ganglia. Furthermore, since most neurons are also immunoreactive for ChAT, a subpopulation of neurons within the cardiac ganglia expresses the enzymes needed to synthesize multiple neurotransmitters. Supported by NIH Grant HL 27595

NITRIC OXIDE AND CARBON MONOXIDE SYNTHESIZING ENZYMES WITHIN CARDIAC GANGLIA OF THE ADULT HUMAN HEART. C. L. Webber. Jr.* S. Singh. P. I. Johnson. R. D. Wurster. Neuroscience Program and Departments of Physiology, Pharmacology and Neurosurgery, Loyola University Medical Center, Maywood, Illinois 60153-3500.

Nitric oxide and carbon monoxide are diffusible gases that can activate soluble guanylyl cyclase and act as neuromodulators within the central and peripheral nervous systems. In addition, nitric oxide and carbon monoxide have been linked with a variety of physiological and pathophysiological cardiovascular functions. Neuronal nitric oxide synthase (6NOS), which synthesizes nitric oxide, has been demonstrated in the cardiac ganglia of several mammalian species but has not been demonstrated in the human cardiac ganglia. Heme-oxygenase 2 (HO-2), which synthesizes carbon monoxide, has been demonstrated within certain autonomic ganglia but never within cardiac ganglia of any mammalian species. The purpose of this study was to determine if the enzymes involved with generation of nitric oxide and carbon monoxide are present within the human cardiac ganglia. Human heart transplants and autopsies. Polyclonal antibodies previously shown to be specific for DNOS, HO-2 and choline acetyltransferase (ChAT) were used to detect these enzymes within the cardiac ganglia. Primary antibodies were omitted from the incubation solution as negative controls, while brain regions previously shown to express bNOS. HO-2 and ChAT were used as positive controls. NADPH-diaphorase histochemistry, which detects bNOS, was also used to confirm the immunohistochemical findings. Our results indicate that many neurons within the human cardiac ganglia are immunoreactive for bNOS and HO-2. Given that most of the neurons within the cardiac ganglia were also immunoreactive for ChAT, the data suggest that a subpopulation of neurons expresses the enzymes needed to synthesize nitric oxide or carbon monoxide along with acetylcholine. Furthermore, these observations suggest a possible role for nitric oxide and carbon monoxide in the integration of cardiac ganglian furnic function and cardiovascular regulation. LOCALIZATION OF NEURONS IN PREVERTEBRAL GANGLIA THAT INNERVATE INFERIOR MESENTERIC ARTERY AND VEIN. <u>D.L. Kreulen* Z. L. Zheng.</u> and <u>R. A. Travagli</u>. Dept. of Physiology, Sch. of Med., West Virginia Univ. Morgantown. WY 26506-9229

Prevertebral ganglia (Celiac, CG, and Inferior Mesenteric, IMG) innervate the intestine and the mesenteric blood vessels in guinea pig. Electrical stimulation of IMG evokes different response in mesenteric arteries (IMA) and veins (IMV), thus, suggested the probability of a diversified neuronal population providing innervation to the vasculature. The aims of this study are: 1) to determine whether sympathetic neurons in IMG that innervate the IMA comprise a separate population from those that innervate IMV. 2) to investigate if the IMG innervating the IMA and/or IMV Retrograde neuronal tracing in combination immunohistochemistry were applied to an *in vitro* preparation. Rhodamine beads and Fluoro-Gold were injected into the lumen of IMA or IMV, respectively. After fixation 16 µm thick sections of IMG were stained FITC-labeled NPY and analyzed for fluorescence. Neurons, filled with rhodamine beads, were located in central areas of IMG while the neurons providing venous innervation stained with Fluoro-Gold were distributed more laterally in the IMG. Neurons containing NPY were occasionally colocalized with rhodamine beads. Double labeling of rhodamine beads and Fluoro-Gold was not observed. The NPY-labeled nerve fibers were more prominent in IMV than IMA. The results provide evidence that there are neurochemically and functionally distinct subpopulations of neurons in guinea pig IMG that innervate IMA and IMV.

ADRENOCORTICAL CELLS AND GROWTH FACTORS AFFECT SYMPATHETIC NEURON GROWTH IN CULTURE. Ching-H Wu* and M. A. Holzwarth. Dept. of Molecular and Integrative Physiology and Neuroscience Program, Univ. of Illinois, Urbana, IL 61801.

In the process of establishing co-cultures of sympathetic neurons and adrenocortical cells to study sympatho-adrenal interactions, factors which affect the growth and differentiation of the sympathetic neurons have been identified. These include the presence of adrenocortical cells as target cells as well as growth factors. Sympathetic neurons from superior cervical and chain ganglia of 5-7 day old rat pups were dispersed and grown in supplemented DME/F12 media on poly-D-lysine- and laminin-coated glass coverslips in the absence or presence of adrenocortical cells. Sympathetic ganglion cells were cultured with 10ng/ml nerve growth factor (NGF), 10ng/ml basic fibroblast growth factor (bFGF), 10 M IL-1B, 5-10% fetal bovine serum (FBS) or media alone. Neuronal growth and differentiation were evaluated using ICC localization of neurofilament protein (2H3), tyrosine hydroxylase (TOH), bFGF, vasoactive intestinal peptide (VIP) and synaptophysin Identification of adrenocortical cells was verified by 3-Bhydroxysteroid dehydrogenase (3-B-HSD) histochemistry and ICC. The presence of NGF, bFGF, IL-1 enhanced the expression of NOS, TOH, bFGF and also stimulated neurite outgrowth. The presence of adrenocortical cells, also enhanced neurite outgrowth, expression of synaptophysin bFGF, VIP and TOH. When adrenocortical cells were separated from the sympathetic neurons by plating in transwell, the effects of adrenocortical cells were less evident. These findings suggest that both the physical proximity of the adrenocortical cells as well as secreted factors contribute to the diffentiation and development of sympathetic neurons. (Supported by NSF Grant IBN-9310866)

416.4

LOCALIZATION OF NITRIC OXIDE SYNTHASE IN SENSORY FIBERS AND EFFECTS OF NITRIC OXIDE IN CULTURED PREVERTEBRAL SYMPATHETIC GANGLIA NEURONS. Z. L. Zheng, D. L. Kreulen, and R. A. Travagli*. Dept. of Physiology, Sch. of Med., West Virginia Univ. Morgantown, WV 26506-9229

Sympathetic neurons in prevertebral ganglia (Celiac ganglion, CG, and Inferior Mesenteric Ganglion, IMG) innervate the mesenteric vasculature and regulate intestinal blood flow. Mesenteric vessels are also innervated by capsaicin-sensitive primary sensory neurons which can evoke a nitric oxide mediated vasodilatation in mesenteric artery. The purpose of this project was: 1) to determine if NOS-containing fibers in the prevertebral ganglia originated in primary sensory neurons, 2) to study the effects of nitric oxide on neurons in prevertebral ganglia. Using primary anti-neuronal NOS (1:100) and anti-SP (1:200) antibodies, NOS was colocalized with SP in cell bodies of DRG and in fibers in the CG and IMG (n=3). Pretreatment with capsaicin (50, 100, or 350 mg/kg injected over 1, 2 and 3 days, N=5), a toxin known to induce a selective degeneration of sensory nerves, abolished all the SP immunoreactivity and significantly decreased the NOS immunoreactivity in fibers in the prevertebral ganglia. To investigate the actions of nitric oxide on sympathetic neurons, cultured CG cells were used for patch clamp studies. The NOgenerating compound L-nitrosocysteine (100 µM-1 mM, LNC) depolarized >70% of CG neurons in a concentration-related fashion. LNC also reduced the amplitude of the afterhyperpolarization that follows the action potential. In voltage clamp, 300 μM LNC induced an inward current (-85±31 pA, N=4) which was accompanied by an increase in input resistance ($\pm 2.0\pm 1196$); these effects were antagonized by pretreatment with the NO scavenger, hemoglobin ($10\mu M$, N=3). In conclusion, the present study provides evidence that sensory nerves from DRG are a source of NO to sympathetic ganglia, NO also modulates sympathetic neuron activity in preverteberal sympathetic ganglion neurons in vitro.

416.6

THE EFFECTS OF DEPOLARIZATION ON FROG CHROMAFFIN AND ADRENOCORTICAL CELLS IN CO-CULTURE. S.P. Shepherd* and M.A. Holzwarth. Neuroscience Program and Dept of Molecular and Integrative Physiology, Univ. of Illinois, Urbana IL 61801.

Based on previous morphological and physiological evidence of adrenal medullary modulation of adrenocortical function, we have developed co-cultures of amphibian (Rana pipiens) chromaffin and adrenocortical cells to study directly the cellular interactions. Many characteristics are retained in our co-cultures, including the expression and release of neurotransmitters by chromaffin cells and steroidogenesis by adrenocortical cells. Furthermore, chromaffin cells extend processes that project toward or onto adrenocortical cells, thereby providing the substrate for direct autonomic regulation of adrenocortical function and also mimicking the organization in vivo. In the process of investigating the effect of chromaffin cell activation on adrenocortical function, we have observed concomitant morphological changes in the chromaffin cells. Thirty-six hour chromaffin cell depolarization with veratridine (50 μM), a sodium ionophore, was followed by fixation on day 7 in vitro and identification of the chromaffin cells by immunocytochemistry of the neuronal marker for tau (linc). Chromaffin cell depolarization results in increased mean neurite length (70 μm to 150 μm, p<.001), increased mean number of neurites per cell (1.5 to 2.5, p<.001), and increased mean number of branches per neurite (0 to 1.5, p<.005). Time lapse microscopy confirms that veratridine increases neurite outgrowth and thus is likely to enhance cell-cell interactions in our co-cultures Importantly, the veratridine-induced chromaffin cell depolarization activates adrenocortical cells as shown by increased Fos expression and increased steroidogenesis. These findings indicate that depolarization can affect neuronal morphology and provide further evidence that chromaffin cell activity modulates adrenocortical function. (Supported by NIH HD07333 and NSF IBN-9310866).

PLASTICITY OF AUTONOMIC NERVES IN THE ADRENAL CORTEX. M.A. Holzwarth*¹,G. Wendelschafer-Crabb², W.R. Kennedy² and W.C. Engeland³¹Dept. of Molecular and Integrative Physiology, Univ. of Illinois, Urbana IL 61801; PDept. of Neurology and ³Dept. Surgery, Univ. of Minnesota, Minneapolis MN 55455, USA

Autonomic innervation of the adrenal cortex includes fine plexuses of nerve fibers expressing catecholamines and a variety of neuropeptides. These nerves, hypothesized to participate in the regulation of adrenal blood flow, steroidogenesis and proliferation, are distributed primarily in the capsule and outer zona glomerulosa suggesting cell-specific functions. Since growth and secretory function of the zona glomerulosa are stimulated in rats on a low Na+ diet, we investigated whether adrenal innervation changes when the glomerulosa is expanded. Adrenals were collected at 1, 2 and 3 weeks from male rats maintained on low (0.04%) or normal (0.4%) Na+ diets. Adrenals were fixed, cryosectioned at 100 um and immunostained for nerve fibers using antibodies against calcitonin gene-related peptide (CGRP), vasoactive peptide (VIP) and the pan-neuronal marker, protein gene product (PGP). With normal diet, the VIP(+) nerves show a more extensive distribution in the capsule and among outer cortical cells compared to the CGRP(+) nerves. The distribution of the nerve fibers was greatly expanded commensurate with the expanded glomerulosa in the low Na+ group. The nerve fibers appeared to loop inward within the glomerulosa and back out to the subcapsular region. Growth of nerve fibers was already evident after one week of low Na+ diet but was most prominent after 3 weeks. These findings demonstrate that the adrenal autonomic nerves show plasticity with their distribution being associated with the glomerulosa cell phenotype (Supported by NSF IBN-9310866 and IBN-9319097 and funds from the Minn. Med. Found.).

ENDOTOXIN INDUCES NEURONAL NITRIC OXIDE SYNTHASE IN THE ADRENAL IN AN AGE-DEPENDENT MANNER. <u>I.R. Tobin*</u>, <u>L.C. Moore</u>. Dept. of Anesthesia, Bowman Gray School of Medicine, Winston-Salem, NC 27157-1009.

Anesthesia, Bowman Gray School of Medicine, Winston-Salem, NC. 27137-1009.

Nitric oxide (NO) is recognized as an important neurotransmitter and second messenger. Endotoxin (ENDO) elicits large increases in inducible (Type II) nitric oxide synthase (NOS) in many organs. This NOS isoform has a different molecular weight than neuronal NOS, and its activity is independent of Ca*. Dexamethasone (DEX) inhibits inducible isoform expression. NOS in the adrenal inhibits steroidogenesis and has biphasic action on catecholamine secretion. Adrenal NOS increases following ENDO exposure. This study examines age-related chapses in NOS and isoform expression in the adrenal.

catecholamine secretion. Adrenal NOS increases following ENDO exposure.¹ This study examines age-related changes in NOS and isoform expression in the adrenal. WKY rats of 5 age groups were studied (<48 hrs. 1, 2, 4, and 12 wks of age [n=8/group]). Animals were anesthetized and adrenals harvested. In a second experiment, ENDO (1 mg/kg ip), DEX 2 mg/kg + ENDO, or saline was administered to 1, 2, 4 and 12-wk-old rats (n=8/group) 4 hr prior to adrenal harvest. NOS activity was assayed by conversion of [¹*C]-arginine to [¹*C]-citrulline.² NOS activity was assayed for Ca** dependency, and isoform analysis was performed by Western blotting, and immunocytochemistry. Data analysis was performed by ANOVA (**p>c.0.05).

conversion of [\frac{1}^4C]-arginine to [\frac{1}^4C]-citrulline.\frac{2}{1} NOS activity was assayed for Ca** dependency, and isoform analysis was performed by MOVA (*p>0.05).

Adrenal NOS is age-dependent with highest levels seen in young animals. ENDO elicits a significant increase in NOS at 2 and 4 wks of age (23±1 to 29.5±2.6* and 7.2±0.3 to 18±2* pmol/mg prot/min, respectively), but not 1 wk or 12 wk of age (7.5±0.6* to 7.8±0.3 and 3±0.3 to 3.2±0.3, respectively). DEX inhibits the increase in expression of NOS (4 wk control 7.2±0.3, DEX+ENDO 9.7±1.2, ENDO 18±2). Increased NOS activity by ENDO was Ca-dependent (activity without Ca=<1 pmol/mg prot/min) and Western blotting revealed increased neuronal isoform but minimal expression of Type II NOS. Immuno-cytochemical localization demonstrated heterogeneous staining of chromaffin and non-chromaffin cells. We noted age-related differences in NOS expression and age-related ENDO induced increases. These findings contrast with ENDO induced NOS expression primarily of Type II isoform in other tissues. Age-specific adrenal NOS responses to endotoxin may contribute to altered adrenal physiology.

endotoxin may contribute to altered adrenal physiology.

AGMATINE IS AN ENDOGENOUS MODULATOR OF NORADRENERGIC SYMPATHETIC NEUROTRANSMISSION IN BLOOD VESSELS. <u>C. González</u>, <u>S. Ragunathan</u>[#], <u>D.J. Reis</u>[#] and <u>C. Estrada</u>. Dpto. de Fisiología, Facultad de Medicina, UAM, Madrid, Spain, and #Div. of Neurobiology, Dep. of Neurology and Neuroscience, Cornell Univ. Med. Coll., New York, N.Y. We investigated the vascular effects of agmatine (decarboxylated arginine), an endogenous ligand for α₂-adrenoreceptors and non-modular effects of the control of

We investigated the vascular effects of agmatine (decarboxylated arginine), an endogenous ligand for α_2 -adrenoreceptors and non-adrenergic imidazoline (I-) receptors, present in endothelium, smooth muscle and plasma, using the rat tail artery as a model. Isometric tension recordings were performed in isolated vascular rings maintained in an oxigenated physiological solution at 37°C and exposed to transmural nerve stimulation (TNS, 200 mA, 0.2 ms, 1 Hz. 10 s) and/or different drugs. By itself, agmatine (10 nM-1 mM) was without effect on isolated arterial rings, although at the highest concentration used (1 mM) it increased EC50 for contractions ellcited respectively by the α_1 - and α_2 -adrenoreceptor agonists metoxamine and clonidine. Agmatine (0.03-1 mM) had a biphasic effect on contractions induced by TNS: an immediate reduction followed after ~10 min by a delayed facilitation. These effects were not replicated by agmatine on contractions induced by noradrenaline administration. The inhibition by agmatine of TNS-induced contractions was abolished by rawolscine or idazoxan, while the delayed facilitation was prevented by cocaine. Agmatine can regulate vascular function by actions at sympathetic nerve terminals wherein it acts as a prejunctional α_2 -adrenoreceptor agonist and also by antagonizing noradrenergic transporter function. The results reveal the existence of a novel endogenous amine modulating noradrenaline release and re-uptake in the perivascular sympathetic terminals. Supported by grants 94/0388, and 95/1422 FIS, Spain.

GANGLION NEURONS ASSOCIATED WITH THE CAT LINGUAL NERVE AND ITS BRANCHES: DISTRIBUTION AND PARASYMPATHETIC SUPPLY TO THE ORO-MANDIBULAR REGION S. Kuchiiwal* and T. Kuchiiwa² Dept. Anat., Fac. Med., Kagoshima Univ., Kagoshima 890, Japan²; Dept. Life Science, Kagoshima Immaculate Heart College, Kagoshima 890, Japan² Whole mount acetylthiocholinesterase (WATChE) histochemistry was performed to detect the localization of ganglion neurons associated with the

Whole mount acetythiocholinesterase (WATChE) histochemistry was performed to detect the localization of ganglion neurons associated with the cat lingual nerve and its branches with the aid of a dissection microscope. Besides the submandibular, sublingual and lingual ganglia, many WATChE-positive ganglia were found in the mandibular regions. Particularly constant were a single irregularly shaped prominent ganglion (oromandibular ganglion) and a few small ganglia (perliingual ganglia) in the mucous membrane of the oral cavity medial to the body of the mandibular ganglion consisted of two ganglion cell populations, large elliptical neurons which resembled the submandibular and sublingual ganglion neurons, and small irregularly shaped cells with an eccentric nucleus which were nearly comparable to the lingual ganglion neurons. The penilingual ganglia consisted of small cells similar to the lingual ganglion neurons in the nicotinamide adenine dinucleotide phosphate: (NADPH-) diaphorase histochemistry, virtually all neurons in the oromandibular penilingual and lingual ganglia were intensely stained, while the submandibular ganglion consisted of clusters of NADPH-diaphorase intensively labeled neurons and non-labeled neurons. In the animals which had received injections of WGA-HRP into the rostral half of the tongue in which no exocrine glands existed, retrogradely labeled neurons were observed in the lingual, perilingual and oromandibular ganglia. When the tracer was injected into the submandibular ganglion, labeled cells were found in the oromandibular ganglion. These findings suggest that the oromandibular ganglion plays a role in the vasomotor and secretomotor functions of the oro-mandibular region, and that the perilingual ganglia play some part in the vasomotor function of the tongue.

NONEXOCYTOTIC NORADRENALINE RELEASE FROM RAT CARDIAC SYNAPTOSOMES. M. Dumont and S. Lemaire. Department of Pharmacology, University of Ottawa, Ottawa Ontario CANADA K1H 8M5.

Nonexocytotic noradrenaline (NA) release was examined in preparations of cardiac synaptosomes from male Wistar rats. Synaptosomes were prepared from rat hearts and labelled with [³H]NA (300 nM; 1 hr at 37°C). Ischemic conditions (1 mM iodoacetate + 2 mM NaCN; 15 min at 37°C) caused a release of [³H]NA from cardiac synaptosomes which represented 33.4% of total synaptosomal content. The [³H]NA release was not diminished in the absence of extracellular Ca²+ or Na+ but it was inhibited by preincubation of the loaded synaptosomes with the uptake, inhibitors, nisoxetine (10⁴M) and desipramine (10⁴M). Tyramine (10⁶-10³M) were also able to evoke the release of [³H]NA from cardiac synaptosomes in the absence of extracellular Ca²+. Among various drugs tested, dextrorphan (10⁴M) blocked the release of [³H]NA induced by ischemic conditions and tyramine (10⁴M). These data suggest that in all four experimental conditions, [³H]NA release occurs via a nonexocytotic process involving most likely the reversal of the uptake, mechanism for ischemic conditions and tyramine and some other efflux mechanism for phencyclidine and rimcazole. Supported by the HSFO.

EFFECT OF IRON (II) ON THE GENERATION OF HYDROXYL FREE RADICALS IN RAT MYOCARDIUM. T. Obata* and Y. Yamanaka. Dept. of Pharmacol. Oita Medical Univ., Hasama-machi, Oita 879-55, Japan

Using microdialysis technique, we examined the effect of iron (II) on the generation of hydroxyl free radicals (•OH) in the extracellular fluid of rat myocardium. Salicylic acid in Ringer's solution (0.5 nmol·µl-1·min-1) was directly infused through a microdialysis probe to detect the generation of •OH as reflected by the formation of dihydroxybenzoic acid (DHBA) in the myocardium of anesthetized rats. Cardiac dialysate was assayed for 2,3- and 2,5-DHBA by a high performance liquid chromatograph with an electrochemical (HPLC-EC) procedure. The average relative recovery of 2,3- and 2,5-DHBA by this system, tested *in vitro*, was 10.1±0.8 % and 10.5±0.9 %, respectively. Iron clealy produced a dose-dependent increase in the •OH formation. A positive linear correlation between the iron (II) and the formation of 2,3-DHBA (R²=0.970) or 2.5-DHBA (R²=0.983) was observed. However, when desferrioxamine (DES) was infused through dialysis probe, a marked increase in the DHBA formation was obtained

SYMPATHETIC NERVES CONTROL CEREBRAL VESSELS OPPOSITELY TO SYSTEMIC VESSELS. M. Maeda*, M. Inoue, H. Hirakawa, Y. Ikegami and Y. Hayashida. Dept. of Systems Physiology, Univ. of Occupational and Environmental Health, Kitakyushu 807, Japan

During an acute development of hypertension, cerebral vessels are constricted to maintain cerebral blood flow constant (autoregulation), on the other hand systemic vessels are dilated by a baroreflex. Denervation of the sympathetic nerves to control cerebral vessels impairs cerebral autoregulation. We, therefore, had a hypothesis that the sympathetic nerve activities (SNA) to control cerebral vessels may increase during hypertension in the opposite direction of the SNA to control systemic vessels. In order to test the hypothesis, we monitored the vertebral nerve activities, which are thought to be pure SNA to control cerebral vessels, during hypertension in anesthetized male rats. During hypertension by intravenous injection of phenylephrine (2 μ g), the vertebral sympatetic nerve activities (VSNA) increased on the other hand the renal sympatetic nerve activities (RSNA) decreased. During hypotension by controlled hemorrhage, the VSNA decreased on the other hand the RSNA increased. The VSNA was completely undetectable after hexamethonium (4 mg) was intravenously injected, indicating this nerve activities were post ganglionic. The characteristics of the SNA, which are thought to be decreased and increase during baroreflex activation and inhibition, may have to be changed.

THE ROLE OF THE SYMPATHETIC INNERVATION IN THE REGULATION OF THE EYE BLOOD VESSELS IN FELINE. M.Razumovskij*, N.Balashov and A.Grigorian. Lab. of Vision Physiol., Inst. of Occup.Guidance and Decease, St.Petersburg, 195096, Russia.

The functional significance of the sympathetic innervation in regulation of the arterial blood vessels tone in the eye bulb connective as well as in retina is still sufficiently far from clear understanding. With this aim in our experiments on adult male cats the diameter of fine vessels of the bulb connective and of eye retina was studied by means of special microsphere, the level of outflow intraocular liquid and contents of noradrenaline in arterial blood in iris membrane and ciliar body before and after desympathyzation were also determined. For control of the chronic desympathyzation a hystochemical method was used. It was shown that in the microcirculatory blood network of the feline eye there is a heterogenity of sensitivity to sympathetic influences. The vessels of the eye bulb connective as well as of episclera exist under predominantly tonic sympathetic influences. Meanwhile sympathetic denervation had no effect on the diameter of the arteriols of the central part of retina. The increase of the intraocular pressure was accompanied by vasoconstriction of the arterioles of the retina in desympathetized eye. In summary, the obtained data suggest, that in contrast to eye bulbar connective and episclera, the autoregulatory mechanism for vessels exists only in the arterial network of the retina.

416.17

INCREASED EXPRESSION OF SP mRNA IN DORSAL ROOT GANGLIA NEURONS OF THE TWO KIDNEY-ONE CLIP OVARIECTOMIZED FEMALE RAT. L. P. Solano-Flores* M. P. Rosas-Arellano and J. Ciriello, Department of Physiology, University of Western Ontario, London, ON, Canada, N6A 5C1.

Physiology, University of Western Ontario, London, ON, Canada, N6A 5C1.

It has been suggested that afferent renal nerves are involved in both the development and maintenance of the elevated arterial pressure in the two kidney, one clip (2K1C) model of experimental hypertension. However, the receptors and the neurotransmitters associated with the afferent fibers from these receptors involved in this hypertensive process are not known. Recently, we have shown that renal artery occlusion results in the induction of c-fos in dorsal root ganglion neurons that contain substance-P (SP). In this study, the possibility was examined that SP may be the putative neurotransmitter in afferent renal nerves activated during the development of 2K1C hypertension. Experiments were done in female ovariectomized rats. The left renal artery was clipped or sham-clipped. After arterial pressure had increased approximately 15-20 mmHg above sham-clipped control animals in the 2K1C animals, all animals were sacrificed and the dorsal root ganglia from T8 - L1 of both the clipped or sham-clipped side and the contralateral side were removed. The ganglia were processed for in situ hybridization using an oligonucleotide probe for SP mRNA labelled using terminal deoxynucleotide transferase and alpha-^{3S}S dATP. Autoradiograms were exposed for 4 weeks and analyzed using light microscopy. A large number of neurons in the dorsal root ganglia from levels T11 - T13 on the side ipsilateral to the clipped renal artery expressed SP mRNA. On the other hand, few, if any neurons in dorsal root ganglia from the contralateral side or in sham-clipped animals at the same spinal levels expressed SP mRNA. These data suggest that SP may be one of the neurotransmitters involved in mediating renal sensory information during the establishment of 2K1C hypertension. (Supported by Heart and Stroke Foundation of Ontario).

SEGMENTAL ORGANIZATION OF NERVE INNERVATING THE VERTEBRO-BASILAR ARTERIAL SYSTEM IN CATS. J. C. Liu, L. C. Lu., S. D. Wang and C. L. Cheng*. Depts. of Biology & Anatomy, and Surgery, National Defense Medical Center, Taipei, Taiwan, ROC.

In mammal, intracranial and extracranial blood vessels receive extensive afferent and efferent innervation that plays a very important role for physiological function. Only a few studies examined the origin of the vertebro-basilar arterial system. The present experiment is designed to extensive study the localization of the vertebro-basilar arterial system in cats by using retrograde HRP tracing method. HRP was applied on the initial segment, C2-C3 level and intracranial segment of the vertebral artery (VA). and basilar artery. HRP labeled cell bodies are existed in bilateral middle cervical and stellate ganglia, and ipsilateral C8-T3 dorsal root ganglia from the initial segment of VA. HRP labeled cell bodies are presented in bilateral superior cervical ganglia and ipsilateral C2-C3 dorsal ganglia from the C2-C3 level of VA. HRP labeled cell bodies are identified in bilateral superior cervical and ophthalmic branch of trigeminal ganglia and C1 dorsal root ganglia from intracranial segment of VA. HRP labeled cell bodies are existed in bilateral superior cervical and ophthalmic branch of trigeminal ganglia. The labeled neurons are identified more on extracranial arteries than intracranial arteries with ipsilateral predominance. There is no HRP labeled neuron in the ciliary, pterygopalatine, otic and nodose ganglia. These results suggest that segmental organization of nerve innervation is noted at the vertebro-basilar arterial system. (Suported by NSC-85-2331-B016-095, ROC)

DO IDENTIFIED CARDIAC SYMPATHETIC AFFERENT NEURONS EXHIBIT AN INCREASED SENSITIVITY TO [pH],? J.H. Schild* Oregon Health Sciences University, Portland OR. (jhs@rice.edu)

Cardiac sympathetic afferent (CSA) fibers with cell bodies in the thoracic spinal ganglia are markedly activated during acute myocardial ischemia (MI) and are believed to be involved in cardiac related pain. One of the many consequences of MI is a decrease in extracellular pH ($\{[pH]_o\}$) which can contribute to the activation of CSA fibers. Objectives: Is it possible to label CSA fibers in a manner that enables identification of CSA neurons from annong a general population of isolated sensory neurons? Do CSA neurons from annong a general population of isolated sensory neurons? Do CSA neurons from annong a general population of isolated sensory neurons? Procedure: The fluorescent probe rhodamine was injected into the pericardial sac of 3-4 day old rat pups. After 3-7 days the rats were euthanized and the left T_3 ganglia was removed. The neurons were enzymatically dispersed in the conventional manner and prepared for patch clamp recording. Rhodamine labeling identified the functionally specific CSA neurons. A multibarrel pipette provided rapid exchange of perfusates which were closely matched in chemical composition, osmolarity and temperature but differed in pH (6.5-7.4). Results: A rather modest 0.4 $[[pH]_o$ from a background $[pH]_o$ of 7.4 elicited a large inward current. The time course of the response was similar to that reported in the literature for an unspecified population of sensory neurons (both transient and sustained components, $V_{hold} = -80 \text{mV}$) but CSA neurons appeared to have an increased sensitivity to $[pH]_o$

Conclusion: It is technically feasible to fluorescently label CSA fibers and study identified CSA neurons in isolation. These preliminary data support the intriguing possibility that, consistent with their physiological role, CSA neurons exhibit an elevated sensitivity to [[pH]]. (support: NIH HL09242)

INDUCTION OF C-FOS IN DORSAL ROOT GANGLION NEURONS CONTAINING NEUROPEPTIDE IMMUNOREACTIVITY AFTER ACTIVATION OF THE RENAL MECHANO-OR CHEMO-RECEPTORS . M. P. Rosas-Arellano. Flores and J. Ciriello, Department of Physiology, University of Western Ontario, London, ON, Canada, N6A 5C1.

Although a variety of putative neurotransmitters have been identified in afferent renal nerves (ARN), it is not known whether ARN mediating certain functional information contain specific neurotransmitters. The region of the kidney where renal mechano- (MR) and chemo- (CR) receptors are found is innervated by nerve fibers that contain substance-P (SP) and calcitonin gene-related peptide (CGRP). The present study was done to determine whether MR and/or CR afferent fibers contain SP and/or CGRP and to identify the distribution of c-fos immunoreactive neurons in relation to SP and CGRP terminal fields in the spinal cord after MR or CR activation. The left renal vein was occluded (VO) to activate MC, and left renal artery occlusion (AO) was used to activate CR in the Inactin anesthetized rat. C-fos labelled neurons were found in the ipsilateral dorsal root ganglia (DRG) extending from T9 - L1, with most within the T11 -113 DRG after either activation of MR or CR. None were found in the contralateral DRG or DRG from the same spinal levels of sham-occluded animals. After AO, most c-Fos labelled neurons in DRG were found to be immunoreactive to SP and a small number to CGRP. In contrast, in DRG of rats with VO, a few c-fos labelled neurons contained CGRP and a smaller number contained SP. Within the ipsilateral dorsal horn of the spinal cord, c-fos labelled neurons were found throughout laminae I-III in rats with VO, and predominantly along the medial edge of lamina III in AO rats. These c-fos labelled neurons were surrounded by SP and CGRP immunoreactive fibers. No c-fos labelled neurons were found in the contralateral dorsal horn or in the dorsal horn of the sham-occluded animals. These data suggest that specific neurotransmitters may be used by functionally different ARN. (Supported by Heart and Stroke Foundation of Ontario)

INWARD RECTIFIER POTASSIUM CHANNELS (K_{ir}'s) IN THE RAT MIDDLE CEREBRAL ARTERY (MCA). <u>T.D. Johnson</u>, <u>M.L. Steenberg</u>, <u>R.G. Grossman*, and R.M. Bryan</u>, <u>Jr.</u> Dept. of Anesthesiology, Baylor College of Medicine, Houston, TX 77030

 K_{ir} 's are voltage dependent channels (closed by depolarization) whose open state probability increases with increased extracellular K^{+} . We asked three questions: (1) Are K_{ir} 's present in the proximal portion of the rat MCA? (2) Do K_{ir} 's contribute to the resting tone of the MCA? (3) Are K_{ir} 's involved in the myogenic response in the MCA? Rat MCAs were isolated, cannulated at each end with a glass micropipet, and pressurized to 40, 85, or 100 mm Hg. The MCAs were immersed in a bath (37° C) containing physiological saline solution. Resting diameters for the MCAs at 40, 85, and 100 mm Hg were 209 ± 8 , 198 ± 6 , and 189 ± 6 µm (n=7) for each) respectively. Abluminal administration of 15 mM KCl produced a dilation of 18 ± 2 , 19 ± 2 , and 21 ± 4 % at 40, 85, and 100 mm Hg respectively. At a concentration of BaCl₂ (75 μM) specific for K_{ir} inhibition, the dilation to KCl was completely blocked at all three pressures. The dilations elicited by 15 mM KCl were not affected by TEA (1 mM), Glibenclamide (10 μ M), or 4-aminopyridine (1 mM) indicating the dilation did not involve other types of K channels. The addition of BaCl2 decreased the resting diameter by approximately 8% at all pressures. Upon increasing the pressure from 40 mm Hg to 85 and 100 mm Hg, MCAs demonstrated a myogenic response by significantly constricting 5 ± 1 and 10 ± 1 % respectively (p<0.0001). Blocking the K_{ir}'s with BaCl₂ did not affect the myogenic response. We conclude that (1) K_{ir}'s are present in the proximal portion of the rat MCA; (2) Some, but not all, of the Kir's are open during the resting conditions and are responsible for dilating the MCAs by 8%; and (3) The K_{π} 's are not involved in the myogenic response. (PHS grant PO1 NS 27616)

HYPERPOLARIZATION-ACTIVATED CATION CURRENT (I_H) IN NODOSE SENSORY NEURONS. <u>T. N. Doan, P. J. Reynolds, M. C. Andresen, and D. L. Kunze*</u> Baylor College of Med., Houston, TX 77030;Oregon Health Sciences Univ., Portland, OR 97201;Rammelkamp Research Center, Cleveland, OH 44109.

The role of I_H at the peripheral terminal of the baroreceptor neuron is unknown. When capsaicin-insensitive fibers of the aortic depressor nerve (ADN) were perfused with CsCl (a blocker of IH) during a slow pressure ramp, there was a decrease in the threshold pressure (95.2%±2.1; means±SE) and a decrease in threshold frequency (79.4%±20.8) relative to control without any significant changes in the slope, saturation pressure, and saturation frequency (n=7). An ADN fiber that was capsaicin-sensitive (previously shown not to have I_H) was not affected by CsCl. To further investigate the effects of CsCl, isolated rat nodose sensory neurons were studied with the nystatin-perforated patch during current clamp. When neurons were given hyperpolarizing current injections, a time-dependent rectification occurred due to the slow activation of the non-inactivating inward current IH. When CsCl was superfused, the time-dependent rectification was abolished, resulting in greater hyperpolarization. The input resistance of the neuron at membrane potentials more negative than -70mV was increased from 0.40 \pm 0.09 G Ω to 1.15 \pm 0.15 G Ω in the presence of CsCl (n=9; p<0.001). Unexpectedly, when depolarizing current ramps from the resting membrane potential (-60mV) were used to simulate pressure changes at the peripheral terminals, CsCl did not affect the interspike interval or the profile of the action potential (n=3; p>0.05). However, block of I_H with CsCl at hyperpolarized membrane potentials (-100mV) enabled nodose neurons to spike during subsequent depolarizing current injection to potentials at which there was no discharge in the absence of CsCl (n=3). The contribution of I_H to this response is currently under investigation. (Supported by HL36840, HL41119.)

416.22

THE EFFECT OF THE ANTICHOLINESTERASE EDROPHONIUM ON AUTONOMIC CHOLINERGIC TRANSMISSION. RD Stein*, C Polosa and SB Backman, Dept. Anaesthesia, Royal Victoria Hospital & Dept. Physiology, McGill University Montreal Ouebec H74 A 14

University, Montreal, Quebec H3A 1A1.

In the absence of preganglionic input, the anticholinesterase edrophonium (EDRO) can produce autonomic responses. For example, in vagotomized, beta-blocked cats EDRO produces a dose-dependent bradycardia which is highly correlated to its inhibition of cholinesterase (Can J Anaesth 1996, 43 in press). Presumably, the bradycardia results from an anticholinesterase action, preventing the hydrolysis of ACh spontaneously released from pre- and postganglionic neurons. The present study examined the effect of EDRO on autonomic responses in the presence of preganglionic input. Cats were anaesthetized, mechanically respired, bilaterally vagotomized and beta-blocked. Continuous right vagus nerve stimulation decreased baseline heart rate from 162 ± 11 bpm to 101 ± 6 bpm (38 ± 1% decrease, n=8). EDRO produced a dose-dependent bradycardia with a max decrease to 81.4 ± 4.0 bpm (78.9 ± 2.6 % baseline) at a dose of 0.8 ± 0.2 mg.kg°. Unexpectedly, at doses greater than 1.5 mg.kg° EDRO produced a dose-dependent tachycardia to a max of 147.3 ± 9.2 bpm (131 ± 3 % baseline) at a dose of 20 mg.kg°. The possibility that EDRO in higher doses interferes with cholinergic ganglionic transmission was investigated in an invitro rat cervical sympathetic ganglion preparation. In the presence of muscarinic and partial nicotinic block, EDRO produced a dose-dependent reduction in the compound action potential recorded from postganglionic axons to preganglionic extensions to migration of ACh (100 µg) into the cervical sympathetic ganglion (n=4). These observations suggest that EDRO, in higher doses, may interfere with nicotinic receptor activation and thereby block autonomic ganglionic

EVIDENCE FOR LOCAL EFFECTOR ACTION OF VAGAL AFFERENT INTRAGANGLIONIC LAMINAR ENDINGS (IGLEs) IN RAT GASTRIC MYENTERIC PLEXUS. H.-R. Berthoud*, A. Lauve, K.A. Sharkey and L.M. Patterson. Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA 70808, USA, and Univ. of Calgary, Canada.

Intraganglionic laminar endings (IGLEs) are found throughout the myenteric plexus of esophagus and gastrointestinal tract, but no specific receptive function has been conclusively associated with this most prominent type of vagal afferent terminal. Since ultrastructural studies have shown the presence of numerous mitochondria and small clear vesicles in WGA-HRP labeled IGLEs of rat esophagus, it has been suggested that these terminals can release neurotransmitters or modulators to affect myenteric plexus neurons (Neuhuber et al., 1991), and the aim of the present experiment was, therefore, to provide functional evidence for such effector action.

to provide functional evidence for such effector action. Left supranodose vagotomy was performed in male SD rats to let vagal preganglionic fibers degenerate but leave vagal afferent fibers intact. Ten to 30 days later animals were anesthetized, and the peripheral end of the left cervical vagus was re-exposed and electrically stimulated for 30 min (16 Hz, 1 mA, 0.5 ms, 10s on, 10s off), or sham-stimulated (no current). One hour after termination of stimulation the rats were perfused and c-fos immunocyto-chemistry was performed on sections of the gastric corpus. On the ipsilateral (ventral) corpus, c-fos was expressed in 1.60±0.48% of myenteric plexus neurons, while in sham-stimulated animals 0.08±0.04%, and in animals with efferent vagal stimulation 27% of the neurons were activated.

The results support the hypothesis that vagal afferent IGLEs can act as effectors to execute local axon reflexes. However, only a fraction of the neurons anatomically associated with the IGLEs seems to be activated, and an additional sensory function as mechano- or chemoreceptors cannot be ruled out. Supported by NIH grant DK 47348.

LOCALIZATION AND CHEMICAL CODING OF NK3 RECEPTOR-IMMUNOREACTIVE ENTERIC NEURONS IN RAT GASTROINTESTINAL TRACT. A.M. Yunker^{†*}, V.V. Karpitskiy^{*}, K.A. Roth[†], and J.E. Krause[‡]. Depts. of *Pathology and *Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Tachykinins (TKs) bind and activate three distinct neurokinin (NK) receptors (NKrs) in gastrointestinal (GI) tissues, resulting in altered motility, secretion, and absorption. Although distribution of NK1rs has been elucidated, the cellular Therefore, polyclonal antiserum and localization of NK3rs is unclear. monoclonal antibodies generated against NK3rs were used on longitudinal sections and whole mount preparations of rat GI tract. Immunoreactive myenteric somata with Dogiel type I morphology and numerous varicose nerve fibers were observed in preparations of glandular stomach, small and large intestines. and caecum. Although NK3r-ir nerve fibers associated with arterioles, GI smooth muscle, and lamina propria, the density of innervation was not uniform, as more NK3r-ir nerves associated with circular muscle in stomach and caecum, whereas more NK3r-ir nerves associated with lamina propria in colon. NK3r-ir was not detected in epithelial, endothelial or smooth muscle cells, or in interstitial cells of Cajal. In preparations of small intestine, many submucosal and myenteric NK3rir nerve fibers contained vasoactive intestinal polypeptide (VIP)-ir or nitric oxide synthase (NOS)-ir, although some VIP-ir and NOS-ir nerves did not contain detectable NK3r-ir. Subpopulations of submucosal and myenteric TK-ir nerves also contained NK3r-ir, although TK-ir and VIP-ir were not co-localized. Finally, most NK3r-ir somata did not contain NK1r-ir. Taken together, these results suggest that NK3rs are distributed throughout the gut, and are likely found on both inhibitory and excitatory nerves. CHOLECYSTOKININ SYNERGISTICALLY INTERACTS WITH LEPTIN TO ACTIVATE RAT GASTRIC VAGAL AFFERENT TERMINALS. Yu Hua Wang, Y Taché, AB Scheibel', VLW Go and Jen Yu Wei. Dept. of Med., CURE Digest. Dis. Res. Cent. and BRI, UCLA Sch. of Med., Los Angeles, CA 90095.

Leptin and cholecystokinin (CCK) administered peripherally reduced food intake in rodents. CCK action is mediated via activation of gastric vagal afferent (GVA) terminals. We investigate the influence of leptin on GVA discharges and modulation of leptin action by CCK. Experiments were conducted on in vitro gastric vagus-stomach preparation (Gastroenterology 100:A507, 1991). The left gastric artery was cannulated for CCK and leptin intra-arterial injection (ia). The GVA unit activities were recorded from thin strands isolated from the gastric branch of the vagus. Three multi-units and 9 single units were analyzed from 3 experiments. Five of the 9 units displayed continue irregular ongoing activity (median 0.22 spike/sec), 3 with rhythmic and 1 intermittent activity. The mechanoreceptive fields were located at pylorus-antrum (n=5) and fundus-corpus (n=4) regions. The response magnitude of CCK-8 ia (100 pmol n=3, 10 pmol n=9) were 5 to 10 times greater than those of leptin ia (5, 10, 50 μg). Most of the response durations of CCK-8 ia were > 30 min. Data indicate that prior CCK-8 ia enhances the leptin sensitivity of GVAs. For a confirmation, comparisons between the GVAs response to leptin before and after CCK-8 10 pmol ia were made by dividing the leptin-induced average spike count/bin (5 sec) after CCK-8 ia by that before ia. A quotient >1 indicates that the leptin sensitivity of GVAs increased. Six units have been analyzed from 2 experiments, and of those, three were tested with 5 and 10 μ g leptin ia and the other with 50 μ g. Seven quotients of the 9 trials were >1 (a range of 7.94 - 1.15 with median of 1.38), whereas the other 2 were 0.93. A similar enhancement effect of prior leptin ia on CCK-8 ia has also been noticed. (We thank Amgen Inc. for providing the leptin, Supported by NIH Grants NS 28433 & DK30110)

METABOTROPIC GLUTAMATE RECEPTORS IN THE ENTERIC NERVOUS SYSTEM (ENS) AND PANCREAS. A. Kirchgessner* and M.-T. Liu. Dept. of Anat.& Cell Biol., Columbia Univ., NY, NY 10032.

Glutamate appears to be an excitatory neurotransmitter in the ENS and pancreas. Prior studies have demonstrated NMDA and AMPA receptor subtypes in enteric and pancreatic ganglia. The present study was carried out (i) to determine whether metabotropic glutamate receptors (mGluRs) are involved in enteric glutamatergic neurotransmission, and (ii) to locate mGluRs in the gut and pancreas. Microejection of the mGluR agonist, 1S,3R-ACPD, induced a slow depolarization in a subset of myenteric AH/type 2 neurons. The slow response was associated with an increase in input resistance, inhibition of the afterhyperpolarization and an increase in the excitability of the cells. Immunocytochemistry, using antibodies (from Dr. R.J. Wenthold) which recognize mGluR1\u03e1 and mGluR2/3 subtypes, was employed to identify the neurons on which these receptors are located. mGluR1α and mGluR2/3 immunoreactivities (ir) were found in the perikarya of subsets of submucosal and myenteric neurons in all regions of the rat and guinea pig bowel. In both plexuses, all mGluR2/3-ir neurons contained ChAT, and a subset were co-stained with antibodies to calbindin (marks AH/type 2 neurons). mGluR1α-ir neurons were rare in the guinea pig myenteric plexus; however, in the submucosal plexus, 5.0 ± 0.5 neurons/ganglion were mGluR1 α -ir. In addition, mGluR1 α -ir fibers were abundant in the circular muscle. In the pancreas, a subset of neurons and insulin-ir islet cells were mGluR2/3-ir. Moreover, mGluR2/3-ir was found on ductal epithelial cells and goblet cells in mucosal crypts and villi. These observations are consistent with the idea that mGluRs play a role in the function of the gut and pancreas. Supported by NIH grants NS01582, NS27645 and the American Diabetes Association.

ANALYSIS OF PURINERGIC PATHWAYS IN MYENTERIC PLEXUS OF THE GUINEA PIG ILEUM. K. J. LePard* and J. J. Galligan, Dept. of Pharmacology/Toxicology and Neuroscience Program, Michigan State University, E. Lansing, MI 48824.

ATP mediates fast excitatory postsynaptic potentials (IEPSPs) in the myenteric plexus $via\ P_{2x}$ receptors. These studies examine axonal length and polarity of projection of via P_{2x} receptors. These studies examine axonal length and polarity of projection of purinergic neurons. Under ketamine/xylazine anesthesia, either extrinsic nerves were crushed (extrinsic denervation) or long myenteric pathways were interrupted (myotomy, single or double). Each treatment group consisted of 4 animals except sham (2). Effectiveness of surgical treatments was confirmed by histochemical methods. After severed axons degenerated (4-5 days), the relative proportion of purely cholinergic fEPSPs (blocked ≥83% by hexamethonium, 100 μM) vs. cholinergic/purinergic fi:PSPs (noncholinergic fEPSP blocked ≥20% by pyridoxal phosphate-6-azophenyl-2',4'-disulphonic acid, PPADS, 10 μM) at the operated site was determined using conventional electrophysiology methods. Noncholinergic fi:PSPs unaffected by PPADS were classified 'other'. Table lists percentage of each type fi:PSP observed in operated tissues for each surgical treatment. (Kruskal-Wallis' *9-0.05 as compared to sham.) surgical

surgical	#	mixed cholinergic/	cholinergic	mixed cholinergic/
treatment	neurons	purinergic fEPSP	fEPSP .	other fEPSP
sham	16	75%	19%	6%
extrinsic denervation	23	61%	17%	22%
double myotomy* single myotomy	27	30%	48%	22%
oral side*	14	21%	79%	0%
anal side	15	53%	47%	0%

anal side 15 35% 47% 0% 0%
The proportion of mixed cholinergic/purinergic fEPSPs was reduced in the isolated segment of myenteric plexus created by the double myotomy. A similar reduction was observed in recordings from the oral side of a single myotomy. These data suggest that most purinergic pathways are long and orally directed while a smaller proportion come from shorter local projections. (Supported by DK40210, NS01738 NS33289, NS07279.)

417.7

LOCALIZATION AND FUNCTION OF GLUTAMATE TRANSPORTERS IN THE ENTERIC NERVOUS SYSTEM (ENS) AND PANCREAS. M.-T. Liu*, J. D. Rothstein and A.Kirchgessner. Dept. of Anat.& Cell Biol., Columbia Univ., NY 10032, Dept. of Neuro., Johns Hopkins Univ., MD.

Glutamate (Glu) mediates excitatory neurotransmission in the ENS and pancreas. In the CNS, Glu is inactivated by diffusion and uptake. The present study was carried out (i) to locate Glu transporters in the gut and pancreas, and (ii) to determine whether Glu transport is important in enteric glutamatergic transmission. Immunocytochemistry, using antibodies to the Glu transporters, EAAC1, GLT-1, and GLAST, was employed to identify the structures on which these transporters are located. All Glu-immunoreactive (ir) neurons in both plexuses of the rat and guinea pig gut and in the pancreas were EAAC1-ir; however, EAAC1-ir was also observed in non-glutamatergic neurons including myenteric calbindin-ir neurons (marks AH/type 2 neurons). GLT-1-ir was observed in varicose nerve fibers in both enteric plexuses, and in the circular muscle layer. Both EAAC1- and GLT-1-ir were found in 5-HT-ir enterochromaffin cells. GLAST-ir was found in interstitial cells of Cajal. In the pancreas, EAAC1- and GLAST-ir were found on insulin-If the EAAC1 transporter is important in glutamatergic transmission then its inhibition would be predicted to potentiate responses to Glu. In the presence of THA (200 μ M), a blocker of Glu transport, depolarizing responses to Glu and Glu-mediated fast EPSPs were enhanced in myenteric AH/type 2 neurons. These observations are consistent with the idea that Glu transporters play a role in enteric glutamatergic transmission. The postsynaptic expression of EAAC1 supports its function to clear Glu; its presence in non-glutamatergic neurons could serve to provide neurons with Glu as a precursor of GABA and/or an energy source. Supported by NS01582, NS27645 and the American Diabetes Association.

INTRACELLULAR RECORDING FROM NEURONS OF THE HUMAN GALLBLADDER, K. Hillsley, L. J. Jennings*, S. B. Backman† and G. M. Mawe. Dept. Anatomy and Neurobiology, University of Vermont, Burlington, VT, 05405 & †Dept of Anaesthesia, Royal Victoria Hospital, Montreal, H3A 1A1 Canada Gallbladder neurons are important governors of gallbladder function. In animal models, gallbladder ganglia are regulated both by neural inputs from sympathetic fibres, vagal efferent fibres and sensory axon reflexes, and by hormonal input from

cholecystokinin. The purpose of this study was to demonstrate feasibility of obtaining recordings from intact human gallbladder neurons.

Human gallbladders were obtained from liver transplant donors (n=3) and routine cholecystectomies (n=2). Preparations were bathed in oxygenated Krebs (37 °C) containing the vital fluorescent stain 4-(4-diethylaminostyryl)-N-methyl-pyridinium iodide to aid in localization of the ganglia. Cells were characterized using conventional intracellular recording techniques. A total of 8 cells, from both normal (n=5) and diseased (n=3) gallbladders which exhibited overshoot action potentials

The mean resting membrane potential of human gallbladder neurons was -52.3±2 mV (range=-45 to -59 mV; n=8). Depolarizing current pulses (≥ 250 ms) elicited only 1-3 spikes regardless of the amplitude or duration of the current pulse. Afterspike hyperpolarizations had a mean duration of 114±6 ms (range=77-181 ms; n=7) and an amplitude of 10.1±2.2 mV (range=4-15.9 mV; n=7). Anodal break excitation was recorded in 2/8 neurons in response to 0.2 nA negative current pulses. Spontaneous

recorded in 2/8 neurons in response to 0.2 nA negative current pulses. Spontaneous activity was recorded in 3 neurons, all from the same normal gallbladder. In 5 cells, fibre tract stimulation elicited fast EPSPs, resulting in spikes in 3 neurons. There was no detectable difference between neurons from healthy and diseased gallbladders. These preliminary results are the first report of intracellular recordings of human gallbladder neurons. It appears from these results that human and guinea pig (Mawe; J. Physiol., 1990, 429, 323-38) gallbladder neurons have similar electrical properties and that electrophysiological studies of intact human gallbladder neurons are feasible. (Supported by NIH grants DK45410 & NS 26995).

ELECTROPHYSIOLOGICAL AND MORPHOLOGICAL INVESTIGATION OF LONGITUDINAL MUSCLE MOTOR NEURONS IN THE GUINEA-PIG ILEUM T.K. Smith and C.W.R. Shuttleworth*. Department of Physiology and Cell Biology, University of Nevada School of Medicine, Reno, NV, 895570-0046

During the peristaltic reflex, contraction of the longitudinal muscle layer precedes contractile activity of the underlying circular muscle layer

The mechanisms underlying increased sensitivity of the longitudinal muscle are not understood. We have tested the hypothesis that this phenomenon is due to increased excitability of longitudinal muscle motor neurons (LMMNs)

Standard intracellular microelectrodes (containing 2% neurobiotin in 2M KCl) were used to impale myenteric neurons in isolated segments of guinea-pig ileum. Impaled neurons were subsequently visualized by confocal microscopy, after processing to couple FITC-streptavidin to injected neurobiotin.

LMMNs were small neurons (10 - 15 µm) whose axon formed a number of varicose collaterals that contributed to the tertiary plexus supplying the longitudinal muscle. LMMNs were either at the entrance of internodal strands or in microganglia. These cells formed a distinct electrophysiological class of neuron, having 1) low resting membrane potential (-47 \pm 5 mV), 2) high input resistance (475 \pm 50 M Ω), 3)an "off spike" following the termination of hyperolarizing voltage response 4) low threshold for action potential generation (0.02-0.04nA) and responded either tonically or phasically with a short burst of action potentials (1 to 8). 20% (n=58) of LMMN neurons fired action potentials spontaneously. Nerve stimulation produced fast and slow excitatory synaptic potentials. Inhibitory postsynaptic potentials were seen in some neurons

In conclusion, these results suggest that LMMNs have a characteristic topagraphy within ganglia and distinctive electrophysiological characteristics. Their high excitability suggests that they may be activated before other muscle motor neurons during the peristaltic reflex. Support: NIH DK 45713 and DK 41315

LOWER ESOPHAGEAL DISTENSION ALTERS THE SENSITIVITY OF CHOLECYSTOKININ RESPONSIVE GASTRIC VAGAL AFFERENTS: AN IN VITRO STUDY. Jen Yu Wei* and Yu Hua Wang. Dept. of Med., CURE Digest.

Dis. Res. Cent. and BRI, UCLA Sch. of Med., Los Angeles, CA 90095.

Esophageal distension (ED) induces gastric relaxation through vagal dependent pathways (Dig Dis Sci 34:873, 1989). We reported that >40% of the relaxation response can be preserved after the central and enteric nervous system connection were interrupted while the vagal link between the lower esophagus and stomach was kept intact. This result suggests the possible involvement of a peripheral collateral reflex action (Neurosci Abst 21:1632, 1995; J Auton Nerv Syst, 52:83-97, 1995). CCK iv decreases intragastric pressure (Am J Physiol, 253:G165, 1987) and activates gastric vagal afferents (GVAs) which has been implicated in mediating CCK's satiety action. Using an <u>in vitro</u> gastric vagusstomach preparation (Gastroent 100:A507, 1991), we investigate the influence of ED on the responsive of GVAs to CCK-8 ia (via a left gastric artery cannula). A ligature was made at the gastroesophageal junction, which keeps both gastric vagal nerves intact. The GVA unit activities were recorded from ventral vagus nerve strands at the lower thoracic level. A thin latex balloon was introduced into subdiaphragmatic esophagus for ED. Comparisons between the GVAs response to subgraphragmant esophagus for ED. Comparisons between the GVAs response to CCK-8 ia with vs without prior ED (0.1 ml saline) were made by dividing the CCK-induced average spike count/bin (5 sec) with prior ED by that without ED. A quotient >1 indicates that the CCK-8 sensitivity of GVAs increased. Three multi- and 6 single units were analyzed from 3 experiments, and of those, 2 multi-and 4 single units were tested with 5 pmol CCK-8 and the other with 10 pmol. Three quotients of multi units were 1.09, 1.48, 0.98, respectively. The quotients of 5 of the 6 single units were >1, with a range of 1.86-1.05 and a median of 1.47, the other one is < 1 (0.75). These results suggest that ED enhances the sensitivity of GVAs to CCK-8 ia. (Supported by NIH Grant NS 28433)

IDENTIFICATION OF THE CHOLINERGIC NEURONS IN GUINEA PIG SPHINCTER OF ODDI (SO) GANGLIA. E.K. Talmage, K. Hillsley, A.L. Krystofolski, and G.M. Mawe*. Dept. Anatomy and Neurobiology, University of Vermont, Burlington, VT,

Neurons in guinea pig SO ganglia can be divided into two populations on the basis of transmitter phenotype. The majority of cells express substance P (SP) and/or enkephalin and are presumed to be excitatory neurons. A distinct group of cells express nitric oxide synthase (NOS) plus vasoactive intestinal peptide or neuropeptide Y, and are presumed to be inhibitory neurons. The purpose of this study was to identify the neurons in these ganglia express choline acetyltransferase (ChAT) immunoreactivity (IR).

SO whole mount preparations were fixed 2-12 hr in 2% formaldeyde/ 0.2% picric acid in phosphate buffer, and immunostained for expression of putative neurotransmitters and related synthetic enzymes. expression of putative neurotransmitters and related synthetic enzymes. Similar results were obtained with and without colchicine pretreatment. ChAT-IR was present in 70-80% of the neurons in the SO. Many, but not all, ChAT-IR neurons expressed SP-IR, while all SP-IR neurons expressed ChAT-IR. ChAT and NOS were not coexpressed; nor were ChAT-IR and NADPH-diaphorase activity. Together, the ChAT and NOS positive populations of cells accounted for all of the detectable SO neurons

These data indicate that a large proportion of SO neurons are able to synthesize acetylcholine. Furthermore, these findings are consistent with the concept that the ganglia of the SO consist of two general populations of neurons, one excitatory and the other inhibitory. (Supported by NIH grants DK45410 & NS 26995).

INNERVATION OF THE SMALL AND LARGE INTESTINES BY PREVERTEBRAL AND PELVIC GANGLIA. G.B. Luckensmeyer and J.R. Keast* Dept. Physiol. & Pharmacol., Uni. Qld., 4072, Australia.

Our studies investigate the effects of sympathetic nerve stimulation on different regions of intestine. The ileum, proximal and distal colon and rectum with associated prevertebral and pelvic ganglia were removed from anaesthetised male Wistar rats and placed in an organ bath. The effects of sympathetic nerve stimulation on longitudinal (LM) and circular muscle (CM) were observed. Nerve stimulation caused frequency-dependent inhibition in the ileum, while in all regions of the large intestine a mixture of excitation (α-adrenergic, and non-adrenergic, non-cholinergic) and inhibition (mediated by all three types of β-adrenoceptors) was observed. In the LM this excitation was the dominant response for low frequency stimulation (0.1-2Hz), while the inhibitory response was dominant at 5-30Hz. In the CM the excitatory response was more prevalent (0.5-20Hz). The sympathetic innervation of the lower bowel by the pelvic ganglia differed slightly to that by the prevertebral ganglia, with a weaker and less complex response in both LM and CM. Stimulation of the cavernous nerve (CN; connecting the pelvic ganglia with the caudal rectum) resulted in excitation of both LM and CM, most of which was atropine sensitive. An anatomical visualisation of the CN projections to the rectum was also carried out by anterograde labelling. These studies show that the sympathetic innervation of the large intestine differs to that of the rest of the bowel by predominantly causing excitation rather than inhibition (with implications for the effect of viscerofugal reflexes in the colon). There are subtle different ganglia. Finally, a functional connection with the rectum via the CN has now been demonstrated. Work supported by NHMRC Australia.

SENSORY TRANSDUCTION STUDIED WITH A CLONAL STRAIN OF SEROTONERGIC EPITHELIAL CELL. P.R. Wade* and M.D. Gershon, Dept of Anatomy & Cell Biology, College of Physicians & Surgeons, Columbia University. New York, NY 10032.

Enterochromaffin (EC) cells are enteric epithelial cells that secrete 5-HT, which initiates peristaltic and secretory reflexes by stimulating intrinsic sensory nerves. To study stimulus-secretion coupling, we developed, by serial dilution, a clonal cell strain that synthesizes, stores, and secretes 5-HT. This strain was derived from a heterogeneous parent cell line (BON [from a human carcinoid tumor]; donated by Dr. C. Townsend, Jr.). The BON cells were selected for uniformity in 5-HT immunoreactivity and the resultant clonal strain resembled EC cells in their basal accumulation of secretory granules and apical microvilli. Coincident expression of neurotensin, substance P. and/or CRF immunoreactivities was also observed. Secretion of 5-HT was evoked by ACh (10.0 μM). The effect of EC cell secretagogues on [Ca²+], was investigated in individual cells by imaging Fura-2 fluorescence. Agonists that raised [Ca²+], included ACh. isoproterenol (10 nM), and 5-HT (1-10 μM), but not KCl (50 mM). Differences between individual cells were detected in the magnitude of responses to ACh and 5-HT and the rates at which ACh receptors desensitized. Responses to 5-HT were not mimicked by the 5-HT_{1P}, agonist, 6-hydroxyindalpine (10 μM), or by the 5-HT_{3A} antagonist, tropisetron (1 μM); thus, responses to 5-HT were not mediated by receptors that stimulate enteric neurons. The similarity between the cloned strain and EC cells in agonist responses suggests that the cloned cells are useful for studies of enteric sensory transduction. Supported by NIH grant NS12969.

EFFECT OF COELIAC GANGLIONECTOMY IN THE LEVEL OF NGF OF THE RAT INTESTINE. M.Iwashita, K.Koyama, A.Miura* and M.Kawatani. Depts. of Surgery and Physiology, Akita Univ. Sch. of Med., Akita 010, Japan.

Nerve growth factor (NGF) is one of trophic factors for

innervation of peripheral tissue. In contrast to well-investigated NGF release and it's receptors in somatic sensory systems, a little information was available for NGF in intestine. Coeliac and superior mesenteric ganglionectomy was performed on adult rats, after 24-h fast. The rats were sacrificed at 12h, 1, 2, 3, 4, 5 and 7days after ganglionectomy under deep anesthesia with Nembutal. Tissue specimens were excised from the small intestine: the jejunum 4 cm aborad to the ligament of Treitz. NGF content of each specimen was measured by ELISA. In control animals NGF measured and the average of contents was 10.8±3.5 pg/mg protein. A significant increase in NGF content in the jejunum occurred at 12h to 5days after ganglionectomy, as compared with the contents of control rats (p<0.05). The maximal increases occurred at 2 days after denervation (59.9±12.9 pg/mg protein; 555±119% of control, p<0.001). At 7 days after ganglionectomy the content of NGF returned to no significant level (25.7±5.8 pg/mg protein, p>0.05). These results suggest that NGF might play a role for maintaining innervation in the digestive tract following peripheral nerve damage.

ACTION OF NITRIC OXIDE ON NEUROMUSCULAR TRANSMISSION IN MOUSE CRURAL DIAPHRAGM J. Liu, C.C. Cheng, E.H. Middlekauff, C. Joo, P.L. Stevenson, T.J. O'Shaughnessy, Y. Yamamoto, R.K. Mittal and Y.I. Kim. Departments of Biomedical Engineering & Neurology and Division of Gastroenterology & Hepatology, University of Virginia School of Medicine, Charlottesville, VA 22908.

The gastroesophageal junction pressure is maintained by two components: the lower esophageal sphincter smooth muscle and the crural diaphragm (CD) striated muscle. Both muscles relax during esophageal peristalsis. The mechanism for relaxation of the CD is not well understood. Peristaltic muscle relaxation of the CD can be blocked by a nitric oxide (NO) antagonist. The role of NO in neuromuscular transmission of the skeletal muscle is not known. In order to characterize the neuromuscular junction activities of the CD and to determine if NO plays a local inhibitory role at the neuromuscular junctions of the CD, intracellular microelectrode recording techniques were used to record spontaneous miniature end-plate potentials (MEPPs), neurally-evoked end-plate potentials (EPPs) and muscle action potentials (MAPs) from 20 intact phrenic nerve/CD preparations obtained from mice. MAPs with a mean peak-to-peak amplitude of 70.5 mV (n=10 fibers) were recorded from the CD. These MAPs were not significantly different in amplitude, duration or maximum dv/dt compared to those of the costal diaphragm. Spontaneous MEPPs exhibited a mean amplitude of 0.74 mV (n=33) and frequency of 1.27 Hz. Application of 10 mM sodium nitroprusside (NP, NO donor) did not alter these MEPP parameters. When measured in 1.2 mM Ca²+/10 mM Mg² solution, the quantal content of EPPs (m) was 0.81 (n=35), which declined to 0.46 in the presence of 10 mM NP. This effect was significant (p<0.001) and found to be due to presynaptic inhibitory action of the drug. These findings indicate that NO causes inhibition of neuromuscular transmission in the CD, reducing the neurally-evoked release of ACh. (Supported by NIH and MDA).

PENILE PATHWAYS IN THE CNS REVEALED BY THE TRANSSYNAPTIC TRACING WITH PSEUDORABIES VIRUS (PRV) IN THE CAT. V. Erickson, C. Tai, A.M. Booth, P. Card, W.C. de Groat and J.R. Roppolo* Dept. of Pharmacology, Univ. of Pgh. School of Medicine, Pittsburgh. PA 15261

The distribution of spinal efferent neurons and interneurons which control the penis, was examined using PRV. PRV (Becker strain) was injected bilaterally into the cavernous sinus of the cat penis under halothane anesthesia. Animals were perfused 60-98 hours later and the tissue processed with an antibody to the virus. Cholinergic preganglionic neurons were distinguished from PRV labeled (PL) interneurons by treating alternate sections, with an antibody to choline acetyltransferase (ChAT) which also delineated the sacral parasympathetic nucleus (SPN). PL neurons were identified in the S_1 - S_3 and L_1 - L_4 segments of the spinal cord with the majority of the PL neurons in the S_3 - rostral S_2 and L_3 segments. PL neurons were found in the sacral parasympathetic nucleus (SPN), the sacral dorsal commissure (DC) and the ventral horn. In the SPN both preganglionic neurons and small interneurons were distinguished by comparing the size, shape and location of ChAT labeled and PL cells in adjacent sections. Processes from PL SPN neurons projected medially to the DC and ventrally along the lateral edge of the ventral hom. PL neurons in the lumbar cord were primarily in the intermediolateral cell column but a few cells were seen in the lumbar DC. Sacral and lumbar dorsal root ganglion cells were also labeled. Following longer survival times (>90 hrs) PL neurons were seen in the brainstem in the dorsolateral pontine tegmentum just medial to the brachium conjunctivum and locus coeruleus. These data taken together with previous tracing studies which identified bladder and external urethral sphincter (EUS) efferents and interneurons suggest that the penile preganglionic neurons are adjacent to, but somewhat rostral (mostly in S1) to bladder preganglionic neurons (mostly in S2) while EUS motoneurons are largely in S₁ at the base of the ventral horn in Onuf's nucleus. There was considerable overlap of penile, bladder and EUS interneurons in the DC.(Supported by NO1-NS-5-2332)

IDENTIFICATION OF RAT SPINAL NEURONS THAT INNERVATE THE PROSTATE: COMPARISON OF HYPOGASTRIC AND PELVIC INPUTS USING TRANSNEURONAL TRACING WITH PSEUDORABIES VIRUS <u>L. Marson.* and R. Orr.</u> Department of Surgery/Urology, University of North Carolina School of Medicine, Chapel Hill, NC 27599

The rat prostate is innervated by the hypogastric and pelvic nerves. Previous research has focused on the sympathetic system (primarily hypogastric nerve), however, the parasympathetic system (pelvic nerve) may also be important. McVary and colleagues have shown that unilateral pelvic nerve cuts increased prostate weight of the intact side, whereas, unilateral hypogastric denervation decreased prostate weight of the lesioned side. In this study, transneuronal tracing was used to identify the spinal inputs of a single nerve to the ventral prostate. Rats received either bilateral pelvic and unilateral hypogastric nerve cuts or bilateral hypogastric and unilateral pelvic nerve cuts. Bartha's K strain of PRV was injected into one side of the ventral prostate (2-3 µl, 10° ph/ml, Lynn Enquist). Therefore, PRV was transported through only the ipsilateral hypogastric or the pelvic nerve. In addition, a group of rats were left intact, such that both nerve inputs were traced. Rats were perfused 65-72 hrs after their injections.

Spinal preganglionic neurons and interneurons were labelled in all groups (n=21). In intact rats, the majority of PRV neurons were found in the medial gray of L1-L6. Many cells were also labelled in the lateral gray of ipsilateral T12-L1 and L6, and contralateral L1 and L6. In rats with one hypogastric nerve intact, PRV cells were found primarily in the medial grey of L1-L4 and L6. In contrast, the majority of PRV cells in rats that had one pelvic nerve intact were in the medial and ipsilateral grey of L6. Thus, selective denervation results in differential labelling of spinal circuits that innervate the prostate. (Supported by NIH grants NS29420, DK49503 and Edwin Beer Award of the NYAM).

PERIPHERAL PATHWAYS OF THE SYMPATHETIC INNERVATION OF THE PENIS. V. Barba, R. Galindo, L. D. Partridge* and W. G. Dail. Dept. of Anatomy, Univ. of New Mexico, Sch. of Med., Albuquerque, NM 87131.

Previous functional studies suggest that branches of the pudendal nerve are the major route of sympathetic fibers to the penis but some contribution may be made by the cavernous nerves. The present study has used image analysis of catecholamine histofluorescence to further define sources of sympathetic innervation to rat erectile tissue. Interruption of the sensory branch of the pudendal nerve (SPN) in the gluteal area resulted in a severe loss (up to 90%) of adrenergic fibers of the intrinsic muscle of the penile crura. Some fibers remained on the helicine arteries (HA) but none were present on the deep penile artery (DPA). In the penile shaft, there were no adrenergic fibers to the intrinsic muscle near the cavernous vein or to the dorsal artery on the side of the lesion. Loss of adrenergic fibers from interruption of the motor branch of the pudendal (MPN) was more variable (5-30%). The DPA, HA and intrinsic muscle were still heavily innervated after this procedure. A near total reduction (to about 5% of control) in crural innervation was obtained when the SPN and MPN were cut and the pudendal artery and veins were treated with phenol. These results suggest that the SPN conveys the majority of adrenergic fibers to the penis while some fibers travel in the MPN and along penile vessels. By inference, the penis may not be a target of the adrenergic fibers in the rat cavernous nerves. Supported by NIH RO119839-13

HYPOGASTRIC NERVE-INDUCED PENILE VASODILATION FOLLOWING PARASYMPATHETIC DENERVATION: CHARACTERIZATION AND INVOLVEMENT OF NITRIC OXIDE. J. Gonzales, F. Harji, and W. G. Dail*. Dept. of Anatomy, Univ. of New Mexico Sch. Med., Albuquerque, NM 87131.

Stimulation of the hypogastric nerve (HN) in the rat increases vasodilation in the corpora cavernosa penis (CCP) after chronic interruption of the pelvic nerve (PN). We further characterized this response by: (1) examining its stimulus characteristics, (2) determining whether it involves nitric oxide, and (3) asking if it also involves the corpus cavernosa urethra (CCU). Stimulation of the ipsilateral HN two weeks after unilateral interruption of the PN consistently resulted in penile vasodilation. This response was always greater on the injured side (26 \pm 13 mmHg vs. 8 \pm 7 mmHg) and showed graded characteristics with changing frequency and voltage. The enhanced HN vasodilation in the CCP was inhibited by systemic infusion of Nw-Nitro-L-Arginine (ave 57% of control after 45 min. with 50 μg L-NNA/min./kg). Two weeks after cutting the pelvic nerve, ipsilateral HN stimulation also increased CCU pressure, while the contralateral HN provoked minor changes (24 mmHg vs. 6 mmHg). These results show that the HN mediates a weak and inconstant vasodilation of the CCP and CCU. Responses in both tissues are markedly strengthened after cutting the PN. Evidence suggests that with regard to NO, mediators of penile erection remain the same in the enhanced response. Supported by NIH R0119839-13

ENKEPHALIN-IMMUNOREACTIVE AFFERENTS ARE SEXUALLY DIMORPHIC IN RAT LUMBOSACRAL AUTONOMIC REGIONS. B.W. Newton* and W.A. Tate. Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205

The distribution of enkephalin-immunoreactivity (Enk-IR) has been described in the autonomic regions of the rat spinal cord, where a distinct "ladder-like" pattern was observed (Romagnano, et al., JCN, 266:319,87). However, former studies have not examined this Enk-IR pattern with regard to potential sex differences. This study used 12 male and 12 female, adult (P90-120), Sprague-Dawley rats (Sasco, Omaha, NE). The rats were anesthetized and perfused for IHC. The entire spinal cord was sectioned. The Enk antibody (IncStar, Corp., Stillwater, MN) recognizes m-Enk (>99%) and I-Enk (<1%). Determination of sexual dimorphisms were made by observers who were "blind" as to the sex of the rat. These data indicate that, by far, the most pronounced sexual dimorphism for Enk-IR occurs in laminae VII and X of the lumbosacral spinal cord: a region which provides the autonomic control of the pelvic viscera. Enk-IR afferents are found in greater numbers surrounding male lumbosacral autonomic neurons than females. The sexual dimorphism is most pronounced in the lumbar region, and is less pronounced in the sacral region. One of the functions of Enk is to decrease sensitivity to pain. The increased amounts of Enk in male rats provides anatomical evidence supporting data which indicates that male rats have a higher tolerance for pain than females (c.f., K.J. Berkley, Behav. Brain Sci., In press, Nov. '96). Furthermore, the lesser amounts of Enk in the female rat may "sensitize" the spinal cord to sensory input from the cervix which is necessary for induced ovulation to occur. Supported by NSF Grant IBN-9211368 to B.W.N.

MODULATION OF CAVERNOUS SINUS PRESSURE (CSP) BY MICROSTIMULATION OF THE SACRAL SPINAL CORD. C. Tai*, A.M. Booth, W.C. de Groat and J.R. Roppolo. Dept. of Pharmacology, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261

The purpose of the present study was to determine the stimulation parameters and the location of sites within the sacral spinal cord where focal electrical stimulation produced penile erection in the cat. Since electrically evoked penile protrusion correlated well with increased CSP, pressure recordings from the cavernous sinus (CS) were used as a quantitative measure of penile tumescence or erection. Adult male cats anesthetized with pentobarbital (20-25 mg/kg IV) were used in this study. CSP was recorded via a 22 gauge intracath placed in the CS through a small incision at the tip of the penis. Each sacral ventral root (S₁-S₃) was stimulated with a hook electrode to determine the spinal segment which produced the largest amplitude CSP response. In most cases (5 of 6 animals) the S₁ root produced the largest CS response (100-160 cm H₂O peak pressure), while in one animal the S₂ root was more effective. The S₂ root, however, usually produced the largest bladder response. The segment which produced the largest CSP change was probed with fine tipped (200-400 μ^2 surface) activated iridium microelectrodes advanced from the dorsal surface of the spinal cord in 200μ increments. Stimulation sites which produced the largest CS responses were in the middle of the ventral horn, 1.6-2.0 mm from the surface of the S₁ sacral segment and midway between the midline and the lateral edge of the grey matter. The area was 200-400 $\!\mu$ wide (medial to lateral) and extended 1-2 mm in the rostrocaudal direction. The response evoked with spinal stimulation occurred at a latency of 8-40 seconds and had an amplitude ranging from 20-120 cm H₂O. The duration and frequency of stimulation was important to produce a maximal response. The stimulus was presented for 1-1.5 minutes. The optimal frequency was between 25-35 Hz using 0.2 msec pulses at an intensity of 50-150μA. These studies suggest that focal microstimulation of the sacral spinal cord may be a useful technique for producing penile erection. (Supported by NO1-NS-5-2332)

POOR SPERM MOTILITY IN SPINAL CORD INJURED (SCI) MEN IS RELATED TO FACTORS IN THEIR SEMINAL PLASMA N.L. Brackett*, S.M. Ferrell, T.C. Aballa, and C.M. Lynne. The Miami Project to Cure Paralysis and Department of Urology, University of Miami School of Medicine, Miami, FL 33136

Introduction: SCI men have sperm of normal concentration but below normal motility. Lifestyle factors alone (scrotal hyperthermia, infrequent ejaculations, bladder management) do not seem to account for this condition. We have recently shown that seminal plasma of SCI men inhibits sperm motility of normal men, indicating that factors within the seminal plasma of SCI men contribute to their poor sperm motility. (Brackett et al., J Urol (1996) 155:1632-1635). Objective: The present study investigated if the degree of inhibition was related to the starting sperm motility of SCI men. Method: Identical aliquots of sperm from normal men (n=19) were mixed with seminal plasma originating from each of two groups of SCI men: those with "low (<10%) or "high" (>20%) sperm motility. The resulting motility of the normal men's sperm was analyzed 5 minutes after mixing with seminal plasma. Results: Motility of sperm from normal men showed significantly less inhibition if mixed with seminal plasma originating from SCI men with high compared to low sperm motility. Conclusions: The below normal sperm motility observed in SCI men is related in a dose-dependent manner to factors within their seminal plasma.

Support was provided by The Miami Project to Cure Paralysis, and State of Florida Specific Appropriations.

HISTOAUTORADIOGRAPHICAL EVIDENCE FOR OXYTOCINERGIC (OT) RECEPTORS IN THE LUMBOSACRAL SPINAL CORD OF THE MALE RAT. F. Véronneau-Longueville, F. Giuliano*, O. Rampin, M-J. Freund-Mercier and A. Calas. Dept. Urology and Lab. Exp. Surgery., Fac. Méd. Paris-Sud. F-94270 Bicètre: Lab. Neurobio Fonctions Végétatives. INRA, F-78352 Jouy-en-Josas. CNRS URA 1446, ULP. F-67000 Strasbourg: CNRS URA 1488. Univ. Paris 6, F-75005 Paris.

In the rat, the sacral parasympathetic nucleus (SPN) located in the intermediolateral gray matter of the L6-S1 spinal cord, contains proerectile parasympathetic preganglionic neurons. Reflexive erections are elicited by activation of dorsal penile nerve (afferent limb) and proerectile SPN neurons (efferent limb). This reflex response is organized at the L6-S1 spinal cord and likely involves interneurons. OT is a candidate for the spinal regulation of reflexive erections. Aim of our study was to search for OT binding sites in the SPN. Four adult male SD rats (250g) were anesthetized, decapitated, and the spinal cords were removed and frozen. Serial transverse sections (16μm) of the L6-S1 spinal cord were treated with highly specific radioonidated OT anagonist (d(CH₂)₃[Tyr(Me)²,Thr⁴,Tyr-NH₂⁹[OVT) for 24 hours, processed for autoradiography for 4-5 days, then for histoautoradiography for 20 days. Non specific binding was assessed by treating adjacent sections with an excess of OT. Histoautoradiography permitted light microscope detection of OT binding sites. They were found in layers I-II and the inner edge of the dorsal horn, the dorsal gray commissure, the intermediate gray matter and the SPN at the L6-S1 levels. No labeling occurred in adjacent control sections. We previously described synaptic contacts between OT fibers and SPN preganglionic neurons. The present study provides further evidence for the supraspinal regulation of parasympathetic efferent activity by OT either directly or via interneurons.

EFFECTS OF THE NMDA GLUTAMATERGIC RECEPTOR ANTAGONIST MK-801 ON REFLEXIVE ERECTIONS IN THE RAT. O. Rampin* J. Bernabé and J.P. Rousseau. Lab. Neurobio. Fonctions Végétatives. I.N.R.A., F-78352 Jouy-en-Josas.

Electrical stimulation of the dorsal penile nerve elicits an increase of the intracavernous pressure (ICP) in the anesthetized spinalized rat (Pescatori et al. J. Urol. 1993; Rampin et al. Neurosci. Lett.. 1994). The role of glutamatergic transmission was evaluated in this model by determining the effects of the glutamate antagonist MK-801 on the ICP increase and the cavernous and motor pudendal nerves responses elicited by dorsal penile nerve stimulations (5V, 5Hz. 0.1ms, 30s). The non-competitive NMDA antagonist MK-801 dose-dependently (0.1-3 mg/kg i.v.) increased the latency of ICP increase by 61-108%, decreased its maximal value by 24-65% and lowered the filling rate of the corpora by 31-78% (n=4). In contrast MK-801 dn to affect ICP increases elicited by pelvic nerve stimulation (n=4). MK-801 produced a dose-dependant (0.1-3mg/kg) inhibition of the complex evoked potentials recorded on the cavernous nerve; their amplitude and surface were decreased by 21-63% and 17-87%, respectively (n=5). Reflex potentials recorded on the motor pudendal nerve were decreased by 28-70% in amplitude and 23-38% in surface following injections of 0.1-10mg/kg MK-801 (n=5). The data suggest that glutamate acting at NMDA receptors, may play a role in the regulation of reflexive erections in the anesthetized, spinalized rat. Because MK-801 has no peripheral action, glutamate appears to mediate the response at the spinal cord level. Both autonomic and somatic reflex responses were affected by MK-801. It suggests that glutamate is present either in dorsal penile nerve afferents or in interneurons projecting onto parasympathetic preganglionic neurons and pudendal motoneurons

ESTROGEN RECEPTOR IMMUNOREACTIVITY IN THE LUMBOSACRAL SPINAL CORDS OF INTACT, OVARIECTOMIZED, AND PREGNANT RATS. <u>S.J. Williams* and R.E. Papka</u>. Department of Anatomical Sciences, University of Oklahoma HSC, Oklahoma City, OK 73190.

Throughout the reproductive cycle the uterus is influenced by estrogen. Little is known about the effects of estrogen on spinal cord neurons which might be involved in neural mechanisms conveying sensory and autonomic information regarding pregnancy, parturition, pain, and genital stimulation. We identified estrogen receptor (ER) containing neurons by immunostaining and determined if the mean number of ER neurons varied with serum estradiol (SE2) levels which occur at different reproductive states. Intact, ovariectomized, and pregnant rats were perfusion fixed, and sections of the lumbosacral cords were immunostained for ER using H222 antibody. SE2 levels were determined using radioimmunoassay. ER containing neurons were present in the dorsal half of the spinal cord. The mean number of ER neurons/section was significantly higher in ovariectomized rats. The ovariectomized rats had a mean of 15.15 \pm 0.8 with SE2 levels ranging from <5 - 12 pg/ml. During estrus, metestrus, and diestrus, the mean number of ER neurons/section and SE2 levels were respectively 12.47 \pm 3.9 and 24 pg/ml, 7.46 \pm 2.4 and 31 pg/ml, and 6.94 \pm 2.2 and 45 pg/ml. During proestrus a.m. the mean number of ER neurons/section was 6.35 \pm 2.0 and significantly higher mean of ER neurons/section at 6.5 \pm 0.8 with SE2 levels of 31 pg/ml than did the 20d (4.6 \pm 0.3 and 75 pg/ml) or 22d (3.0 \pm 0.2 and 80 pg/ml) pregnant rat had a significantly higher mean of ER neurons/section at 6.5 \pm 0.8 with SE2 levels of 8mp/ml pregnant rats. Our studies show that there is a significant change between ER neurons/section and SE2 levels of female rats in different reproductive states. (Supported in by NiH NS22526 & Presby. Health Fnd.)

EFFECTS OF SUBSTANCE P (SP) AND SP ANALOGS [Sar⁹,Met(0₂)¹¹]-SP, [Cys^{3,6},Tyr⁸,Pro¹⁰]-SP AND [D-Pro⁴,D-Trp^{7,2}]-SP ON RAT UTERINE ACTIVITY IN VITRO. R.L. Shew*, R.E. Papka, R.H. Goertz and C.W. Gatto. Department of Cell Biology & Neuroanatomy, University of Minnesota and Children's Health Care-St. Paul, Minneapolis, MN 55455 and St. Paul, MN 55102 and Department of Anatomical Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Substance P and related tachykinins have been localized in nerves in the uterus and stimulate uterine contraction in a dose-related manner. SP has been reported to bind preferentially to the NKI receptor in peripheral tissues. Highly selective agonists and antagonists for NK-1 receptors have been developed. Thus, we investigated the effect of various analogs of SP ([Sar²,Mct(0₂)¹¹]-SP, [Cys³.^T,yr³,Pro¹¹]-SP and [D-Pro⁴,D-Trp²,¹]-SP) on rat uterine tissue in vitro. Mature Sprague-Dawley rats (200-225 g) were treated with diethylstilbestrol and uterine horns removed 14+16 hours later and examined using an in vitro uterine assay. SP (10°-10° M), [Sar²,Mct(0₂)¹¹]-SP, and [Cys³.^T,Yr³,Pro¹¹]-SP, (10°-10° M) stimulated uterine contraction in a dose-related manner. Contractile responses ranged from 0-4 grams (n= 3-10). However, [D-Pro⁴,D-Trp²]-SP, a SP antagonist in the guinea pig ileum and rabbit mesenteric vein assay, demonstrated weak agonist activity at high concentrations (10° M, n=5, 1.1 ± 0.18 grams). These data demonstrate that, in our uterine assay, the SP analogs [Sar²,Met(0₂)¹¹]-SP and [Cys³.^T,Yr³,Pro¹¹]-SP, stimulate uterine contraction in a dose-related manner similar to SP and these analogs are probably acting through a NK-1 receptor. (Supported in part by NiH grant 1RO1HD30817)

418.10

THE DISTRIBUTION OF CHOLECYSTOKININ-8 AFFERENTS SURROUNDING LUMBOSACRAL AUTONOMIC NEURONS IS SEXUALLY DIMORPHIC AND ALTERED BY LACK OF ANDROGEN RECEPTORS. D.C. Phan* and B.W. Newton. University of Arkansas for Medical Sciences, Little Rock, AR 72205

The distribution of cholecystokinin-8 immunoreactivity (CCK-IR) has been previously described in the rat lumbosacral (L-S) spinal cord (Schrøder, JCN, 217:176, 83). While L-S autonomic neurons innervate the sexually dimorphic pelvic viscera, the potential sexually dimorphic distribution of this peptide has not been examined. Other studies have shown that CCK in lumbar motoneurons is regulated by testosterone (T) Sitewith that absence of T causes a decrease in CCK mRNA (Popper & Micevych, Neurosci., 50:87,92) This study used 6 male and 6 female, adult, Sprague-Dawley/King-Holtzman rats, as well as SD/KH Testicular feminization mutation (Tfm) rats. After anesthesia, the rats were perfused for IHC. The CCK-8 antiserum was purchased from IncStar (Stillwater, MN). The results indicate that there is a pronounced sexually dimorphic distribution of CCK-IR afferents surrounding L-S autonomic neurons: males have greater numbers of CCK-IR fibers than females. In male Tfm rats (which produce T, but lack androgen receptors), the levels of CCK-IR in the L-S spinal cord is dramatically reduced and presents with a distinctly female-like CCK-IR pattern. These results suggest that CCK plays a variable role in modulating autonomic neurons which innervate the pelvic viscera in males vs. females. In addition, CCK-IR within afferent fibers responds in a similar fashion to decreased T as has been demonstrated for CCK mRNA in sexually dimorphic motoneurons. Supported, in part, by NSF Grant IBN-9211368 to B.W.N.

ARE NEUROGENIC INFLAMMATORY PROCESSES INVOLVED IN CERVICAL RIPENING PRIOR TO PARTURITION? R.E. Papka*, K.E. Miller and B. Srinivasan. Department of Anatomical Sciences, University of Oklahoma HSC, Oklahoma City, OK, 73190
Mechanisms for initiating "ripening" of the uterine cervix at parturition are not known. However, they likely involve multifactorial processes and a variety of agents such as: hormones, eicosanoids, cytokines, and cervical neurogenic

Mechanisms for initiating "ripening" of the uterine cervix at parturition are not known. However, they likely involve multifactorial processes and a variety of agents such as: hormones, eicosanoids, cytokines, and cervical neurogenic inflammatory responses. The idea of a localized inflammatory response has received support but little research attention. Primary afferent nerves can release transmitters from their peripheral terminals which help orchestrate local inflammatory responses including vasodilation, increase of vascular permeability with tissue edema & protein extravasation, and activation and migration of inflammatory immune cells. Intense stimulus of uterine cervical primary afferents at term could lead to release of such neuropeptides as substance P (SP). SP, working through NK1 receptors, could be a component of neurogenic inflammation. Our preliminary studies sought to determine if uterine neurons influence cervical ripening near parturition through release of transmitters that contribute to neurogenic inflammation. We employed immunohistochemistry to study innervation of cervical venules in pregnancy and at parturition, the presence of NK1 receptors, and changes in extravascular inflammatory cells. Preliminary results suggest that all of the elements for neurogenic inflammation are present in the cervix of pregnant and parturient rats. The cervix from these rats show the hallmark signs of an inflammatory reaction including inflammatory (reflected in increased spaces in the connective tissues), and dilated vascuature. Primary afferent nerves containing tachykinins innervating venules and NK1 receptors (for SP and eurorkinin A) are apparent in endothelial cells of venules in cervixes from parturient rats (Supported by Presbyterian Health Frd. and NiH NS-22526).

NITRIC OXIDE SYNTHASE LEVELS IN CHRONIC DIABETIC RATS. R.E. Brannigan, K.T. McVary and K.E. McKenna* Depts. Physiology and Urology, Northwestern Med. School, Chicago, IL 60611

Nitric Oxide (NO) is the nonadrenergic, noncholinergic mediator of penile erection, and it is produced by the conversion of L-Arginine to L-Citrulline by Nitric Oxide Synthase (NOS). In the penis, release of NO results in penile smooth muscle relaxation, corpora cavernosal engorgement, and erection.

engorgement, and erection.

In humans, diabetic males have a high incidence of erectile dysfunction. Our previous studies of chronic diabetic BB/Wor rats revealed profound deficits in the sexual behavior of diabetic rats as well as deficits in sexual reflexes and penile erections. These results suggested the possibility of concurrent CNS dysfunction and peripheral neuropathic processes.

We undertook this study to semi-quantitatively evaluate NOS isoforms in the penile and spinal cord tissue of chronic diabetic BB/Wor rats. Tissue was harvested from both chronic diabetic and diabetes resistant (control) rats. The lumbosacral spinal cord and penises were homogenized, and Western blots were performed. NOS I and NOS III isoforms were identified with specific antibodies (Transduction Laboratories, Lexington, KY). Subsequently, semi-quantitative densitometry was used to evaluate our results. In the penis, NOS III staining was significantly reduced in the diabetic rats to approximately 40% of the controls. NOS I levels in the spinal cord were reduced by about 20%, but did not reach statistical significance.

Our results suggest that diabetic impotence may be related to NOS deficits in the penis and the central nervous system.

EXPANSION OF CORTICAL CONNECTIVITY IN THE BARREL FIELD FOLLOWING PARTIAL VIBRISSECTOMY IN ADULT MICE. M. Kossut* and S.L. Juliano. Nencki Institute, Warsaw, Poland and Anatomy and Cell Biology, Neuroscience, USUHS Bethesda, MD 20814.

A vibrissectomy that spares row C in adult mice results in changes in the areal extent of the cortical representation of the spared row. The anatomical substrate of the changes in cortical functional response observed after peripheral denervation in adult animals is not well documented. In the visual cortex of adult cats, partial denervation triggers growth of layer III axons into the denervated area. We examined changes in cortical connectivity in the barrel field 6-8 weeks after a vibrissectomy in young adult mice, sparing row C on both sides of the snout. We traced connections between the spared and denervated rows of the barrels in living cortical slices, 300 μ m thick, cut in a plane perpendicular to the rows of barrels. Small volumes of dextrans conjugated to either fluorescein or rhodamine were injected into visually identified barrels in transilluminated slices. Injections were also placed in layers II/III and V, over or under selected barrels. After 6 hours of incubation in a slice chamber the slices were fixed, cryoprotected and resectioned at 40 μm since chamber the sinces were fixed, cryoprotected and resectioned at 40 µm thickness. The fluorescent label was examined using a confocal microscope. The injection sites ranged from 120 to 180 µm diameter. The extent of resulting label was estimated in vibrissectomized and control animals. The distribution of labeled cell bodies and the fibers was more widespread when the injections were centered on the barrel of the spared row C (mean diameter $1000~\mu m$) than in the control animals (mean diameter 650 µm). This occurred after both the supragranular and granular layer injections, but not for those located in layer V. Counts of dendritic spines revealed a 30% increase of spine density on neurons in the spared vibrissal column compared to control mice.

VIBRATION-INDUCED ACTIVATION OF THE PRIMARY SOMATOSENSORY CORTEX AND SEVERE PERIPHERAL DEAFFERERNATION OF THE LEMNISCAL SYSTEM. CONTRIBUTION OF A SINGLE-CASE PET ACTIVATION STUDY. P. Remy*. P.F. Pradat. P. Belin, B. Aymard., M. Zitbovicius, E. Fournier, L. Naccache, T. Maisonobe, I.C. Willer, Y. Samson. SHFJ-CEA, Orsay and La Salpêtrière, Paris, France. PET activation studies show that high-frequency vibration (>100 Hz) induces a marked rCBF increase in the corresponding contralateral primary sensorimotor cortex (SM1). It remains however unknown if the extra-lemniscal system participates to this SM1 activation. We have previously reported a patient having a spinal cord section (T3 level) sparing only a part of the left anterolateral quadrant and in whom left foot vibration, although not perceived, still activated the right foot SM1. Here, we report a PET activation study in a 35-y.o. patient with a rare hereditary ganglionopathy with a selective disappearance of the large-diameter somatosensory fibers as demonstrated by neuromuscular biopsy. This patient had a marked deficit of discriminative touch and proprioception senses. rCBF measurements were performed using a high-resolution tomograph during rest; right had vibration; and right foot vibration (vibratior: 130 Hz. 2-tmm amplitude). Regions-of-interests (ROIs) were defined in hand and foot SM1 on the coregistered MRI. In these ROIs, the rCBF variations were compared to those obtained in 9 healthy volunteers (28. 3± 10.4 y.o., mean ± sd) using the same methods. In the patient, right foot vibration which was not perceived induced a +5.8 % rCBF increase in contralateral hond SM1 (controls: +15.8 ± 9.6%). The right hand vibration of the patient induced a slight feeling of touch and was associated with a +7.7% rCBF increase in the contralateral hand SM1 (controls: +10.9 ± 3.2 %). Thus the extra-lemniscal system may participate to the activation of SM1 induced by vibration. This result also show that conscious perception of a sensory stimulus may disappear despite

CHARACTERISTICS OF NEURONAL ACTIVITY IN THE REGION OF THE THALAMIC NUCLEUS VC IN PATIENTS WITH AMPUTATIONS.
A. Zirh, F.A. Lenz, I.M. Garonzik, R.T. Richardson, M. Ringkamp*, L.H. Rowland, P.M. Doughetty, Dept. Neurosurg., Johns Hopkins University, Baltimore MD 21287.

Thalamic activity was studied during the physiologic exploration which precedes stereotactic surgical procedures for stump pain (3 patients) and movement disorders. One patient exhibited an enlarged thalamic representation of the stump covering an area of approximately 7mm². The stump representation in the 15mm lateral plane was adjacent to the perioral representation which is usually found next to the thumb representation. Consistent results were found in two other patients suggesting that there has been reorganization of somatosensory thalamus.

The mean interspike intervals (ISI) was significantly shorter in the representation of the stump than in Vc region of movement disorder patients (control) or in the non-stump representations in the amputation patients (stump control, P< 0.01, Dunn multiple comparison test). Cells firing with a bursting pattern were much more common in stump control (41%) and stump areas (33%) than in control areas (15% - chi square tests, P<0.00001). Recent studies have demonstrated the presence of an area posterior to Vc with activity related to pain. In the stump and stump control areas there were large differences in the number of bursting cells by location in anterior (29%) or posterior (55%) regions (Chi square, P<0.002). Bursting cells were found to have patterns consistent with low threshold calcium spikes (LTS). LTS bursting occurred more commonly for cells in the stump region with RFs than for cells of any other type. Therefore stump pain may be related to LTS bursting in cells with receptive fields in the posterior zone of patients with amputations. Supported by grants to FAL from the NIH (NS28598, K08 NS01384, P01 NS32386-Proj. 1).

FIBROBLAST TRANSPLANTS GENETICALLY ENGINEERED TO SECRETE NGF RESTORE FUNCTIONAL ACTIVITY IN BARREL CORTEX OF BASAL FOREBRAIN LESIONED RATS. O. Rahimi, G. Hill III, O. Olaghere, J. Coulombe and S.L. Juliano. Anatomy, USUHS, Bethesda, MD 20814

Stimulus-evoked 2-deoxyglucose (2-DG) uptake is reduced in barrel cortex of rats after basal forebrain (BF) lesions that deplete the neocortex of acetylcholine (ACh). We previously showed that intraventricular injections of NGF restore stimulusevoked 2DG activity toward normal, despite sustained ACh depletion. To more clearly understand the site of NGF action, we used a more easily located form of NGF delivery consisting of fibroblasts genetically engineered to secrete NGF (NGF+). Since the most likely sites of NGF action include cerebral cortex or BF, NGF+ fibroblasts were transplanted in both places (in different rats receiving unilateral BF lesions). After survival times of 1-4 weeks, rats received 2DG injections during bilateral whisker stimulation. Controls included transplants of fibroblasts without the NGF gene (NGF-) into BF or cerebral cortex. NGF+ fibroblasts transplanted into the somatosensory cortex of BF-lesioned rats resulted in increased 2DG uptake in response to whisker stimulation, 36% above that evoked in the opposite control hemisphere. NGF+ transplants into the BF, or NGF- in either site, resulted in decreased (46%) 2DG uptake compared to opposite control hemisphere, similar to animals with BF lesions alone. These results support the notion that NGF is an important factor in mediating neocortical plasticity and suggest that NGF acts directly in the cerebral cortex, since transplants of NGF+ cells into BF had little effect. The mechanism of action used by NGF however, is unclear. Since recent studies indicate that NGF can increase expression of Bcl-2 protein and overexpression of Bcl-2 can rescue neurotrophin-deprived neurons in vitro, we assessed the immunoreactivity of Bcl-2 in normal and NGF-treated brains. Our results indicate increased Bcl-2 protein in the site of NGF treated cortex. Support: Alzheimer's Association and USUHS RO7064.

AN ANATOMICAL ISOMORPH OF THE HAND IN SOMATOSENSORY CORTEX OF OWL MONKEYS AND ITS IMMUTABILITY FOLLOWING PERIPHERAL DEAFFERENTATION. N. Jain*, K. C. Catania and J. H. Kaas. Department of Psychology, Vanderbilt University, Nashville, TN 37240.

We have observed a pattern of myelin dense ovals separated by myelin light septa in brain sections cut parallel to the surface in area 3b of owl monkeys (Aotus trivirgatus). Using microelectrode recordings to identify the zones of activation within the pattern, we determined that each of a lateromedial ovals in the rostral row corresponded to a specific digit of the hand, D1-D5. More caudal ovals represented specific pads of the palm. Thus there was a complete correspondence between the morphological and physiological maps. Furthermore, the components of morphological maps, which could be precisely measured, varied little across cases. Nevertheless, the physiological maps, as previously shown, could be modified by peripheral deafferentation. In two monkeys that had accidentally lost one or two digits, the morphological maps were completely normal, but neurons in ovals corresponding to the missing digits were activated from the remaining inputs from digits or palm. Likewise, the morphological map was normal in a monkey with long standing dorsal column section at the C3/C4 level even though this led to a profound reorganization of the physiological map of the hand. Thus an anatomical substrate for the hand representation is immutable in adult monkeys while the evoked activity pattern is plastic. Supported by NINDS NS-16445.

REORGANIZATION OF INTRACORTICAL PROJECTIONS TO SOMATOSENSORY CORTEX AFTER NEONATAL THALAMIC ABLATION IN THE HAMSTER. M. A. Kingsbury *, N. A. Lettman, B. Miller, and B. L. Finlay. Developmental Neuroscience Group, Cornell University, Ithaca, New York, 14853.

Thalamic afferents arrive at the cortex prior to the establishment of mature cortical projection systems. These axons may be important in directing the development of specific connections between cortical areas in the visual system. Previously, the removal of thalamic input to visual cortex resulted in an increase in the callosal and intracortical projections to the deafferented cortex. This expansion was manifested as a substantial increase in the number and tangential distribution of labeled cells. Here, we examine the organization of intracortical connections to somatosensory cortex that has been denervated of thalamic input.

Hamster pups were given unilateral electrolytic ablations of somatosensory thalamic nuclei on the day of birth. To visualize intracortical connections, thirty day old hamsters were given an injection of HRP into somatosensory cortex ipsilateral to the thalamic ablation. The distribution of retrogradely labeled intracortical cells was plotted. The experimental animals were compared to a control matched for placement of injection site. Animals with ablations displayed an increase in the number of labeled intracortical cells in temporal and visual cortices (T1, T3, V1 and V2) relative to the control. In addition, the horizontal connections within primary somatosensory cortex (target of VB afferents) increased after thalamic ablation. The normal projection has a comparable number of labeled cells in the supragranular and infragranular layers. In contrast, the increase in cells in experimental animals is manifested as an increase in the number of infragranular cells.

These results demonstrate that the development of normal intracortical projections depends upon the presence of thalamic afferents, which may provide genetic instruction or organizing activity to cortical areas. Supported by NIH R01 NS 19245.

A PRIMATE GENESIS MODEL OF FOCAL DYSTONIA AND REPETITIVE STRAIN INJURY: II. THE EFFECT OF MOVEMENT STRATEGY ON THE DE-DIFFERENTIATION OF THE HAND REPRESENTATION IN THE PRIMARY SOMATOSENSORY CORTEX IN OWL MONKEYS N.N. Byl*, M.M. Merzenich, S. Cheung, P. Bedenbaugh, S.S. Nagaraian, W.M. Jenkins, Keck Center for Integrative Neurosciences, Sch of Med, Grad Prog in Physical Therapy, Depts. of Otolaryngology and Physiology, Univ of California San Francisco, SF, CA 94143-0736

Otolaryngology and Physiology, Univ of California San Francisco, SF, CA 94143-0736

The purpose of this study was to document the neural consequences of an active, repetitive handclosing/opening behavioral paradigm using two Owl monkeys, one of whom trained once a day using an articulated hand squeezing strategy (A) and the other who trained twice a day using a proximal arm pulling strategy (B). After 20 weeks of training, the investigators analyzed motor control and then generated an electrophysiologic map of the hand representation within the primary somatosensory (SI area 3b) cortical zone. Monkey A showed statistically significant motor deterioration and degradation of the normally sharply segregated areas of the hand representation in the primary somatosensory cortex (3b) while Monkey B did not exhibit motor dysfunction and the hand representation was only mildly dedifferentiated. Degraded representational features included: 1) unusually large receptive fields (RFs) on the skin of the hand; 2) emergence of RFs covering the entire glabrous surface of an individual digit: 3) multiple RFs including the surfaces of two or more digits; 4) multiple RF's extending to the glabrous and the dorsal skin; and 5) signs of degradation of the hand representation on the untrained hemisphere. Highly stereotypical, repetitive, articulated hand squeezing was associated with learned, cortical changes with measureable loss of motor control, but proximally controlled hand closing was associated with only a mild degradation of the hand representation without loss of motor control. Treatment of RSI must restore the normal cortical sensory representation of the hand and patients must adapt a stress normal cortical sensory representation of the hand and patients must adapt a stress free, proximally controlled hand strategy to perform repetitive work without injury.

FIRING CHARACTERISTICS OF NEURONS IN THE FOREPAW BARREL SUBFIELD (FBS) CORTEX IN ADULT RAT: AN IN-VIVO INTRACELLULAR RECORDING AND LABELING STUDY. C.X. Li*, R.S. Waters. Dept. of Anatomy and Neurobiology, UT, Memphis, Col. of Medicine, Memphis, TN 38163. The intrinsic firing pattern of somatosensory (SI) cortical neurons has been

characterized in the in-vitro slice preparation. In rat, three classes of cortical spiking neurons have been identified: regular spiking (RS), intrinsic bursting (IB), and fast spiking (RFS). The laminar location(s) of each class and cell morphology have been described. Recently, Zarzecki and colleagues reported similar classes of spiking neurons in raccoon SI cortex using an in-vivo preparation; however, differences in

laminar location and mode of thalamic input were observed between the preparations.

As part of our ongoing studies of synaptic input in the forepaw barrel subfield (FBS), we describe the firing properties of SI neurons (n=39) in rat FBS using an invivo intracellular recording and labeling technique. Adult rats were anesthetized with Nembutal, the head was placed in a stereotaxic apparatus, and the SI cortex was exposed. The digit representation was mapped using a carbon-fiber extracellular electrode. Following mapping, an intracellular electrode containing 2M K acetate and 1% biocytin was used to impale neurons within the FBS forepaw representation. Mechanical and electrical stimulation applied to the digit was used to activate SI neurons. Latency to fire and intrinsic firing properties were measured using standard techniques, and when possible (n=20), the cell was labeled with biocytin. Our results:

- 1. Neurons in laminae II-V were activated by mechanical/electrical stimulation
- 2. Latency differences were observed for cells in each lamina; shortest latencies (6-7 ms) were always observed for neurons in layer IV.
- 3. Three firing patterns were observed: RS (51%), IB (41%), FS (7%); subclasses of RS and IB were also seen. RS and IB neurons were found in cortical layers II-V.
- 4. Multiple patterns of discharge were observed in RS and IB neurons as a function of membrane potential. (Supported by NSF Grant IBN-9400318)

EFFECTS OF MEDIAN NERVE CUT, REPAIR AND REGENERATION IN INFANT MACAQUE MONKEYS.

II. CORTICOCORTICAL CONNECTIONS. S.L. Florence* & J.H.

Kaas, Dept. Psychology, Vanderbilt Univ. Nashville, TN 37240.

The basis for recovery of tactile sensation in children with nerve cut

and surgical repair presumably involves structural or functional reorganization within the ascending somatosensory pathway. In an ongoing effort to establish how and where this recovery occurs, we studied the pattern of corticocortical connections in macaque monkey (Macaca mulatra) that had median nerve cut and repair soon after birth. At 12 - 18 months of age, each monkey received an injection of 2% WGA-HRP into the median nerve representation of cortical area 1, using AAALAC-approved surgical procedures. Approximately twenty hours later, the monkeys were sacrificed and sections through cortex were processed to visualize the injected tracer. The present report focuses on the distribution of label in area 3b. The results indicate that after early postnatal nerve cut, repair and regeneration, corticocortical connections are widespread and virtually non-topographic. For example, a single injection spanning the representations of D2 and D3 in area 1 labeled the entire hand representation of area 3b. Thus, there appears to have been extensive growth of cortical connections or retention of an immature widespread distribution. We suggest that such disperse connections allow greater potential for synapse selection so that nearly normal receptive fields can be generated through usedependent processes. Presumably, this is one of the major mechanisms of recovery after nerve injury early in life. Supported by NIH grants NS16446 and NICHDHD15052.

EFFECTS OF LARGE-SCALE LIMB DEAFFERENTATIONS ON THE MORPHOLOGICAL AND PHYSIOLOGICAL ORGANIZATION OF RAT FOREPAW BARREL SUBFIELD (FBS) ARE DEPENDENT ON THE TIME OF DEAFFERENTATION. P.P. Pearson , C.X. Li, E.J. Johnson, and R.S. Waters* Dept. Anatomy and Neurobiology, UT, Memphis, Col. of Medicine, Memphis, TN 38163.

We and others have described the organization/reorganization of barrels and barrel-like structures in layer IV of rat somatosensory cortex associated with the representation of the forelimb/forepaw. Pons et.al, (1991) reported the physiological results of largescale limb deafferentations in monkeys physiologically mapped more than twelve years later and reported that cortical regions formally served by the deafferented limb were subsequently responsive to new inputs from the face. The face representation in the intact monkey is represented many millimeters away from the forepaw representation and their findings reflect wide scale cortical reorganization

As part of our ongoing work on mechanisms of cortical reorganization we reexamined the consequences of large-scale deafferentations using the rat barrel-field model system. Deafferentations were made in one group of rats on post-natal day 3 (PND-3); prior to the end of the critical period for development of the forelimb barrels (PND-5), while a second group of rats was deafferented in adulthood. One month after deafferentation we mapped the body representation in the deafferented animals using extracellular recording methods. Following mapping, the barrel field cortex was examined using cytochrome oxidase, and the following results were noted:

- 1. Morphological and physiological maps of controls were aligned with one another.
- Adult deafferents had normal morphological maps, but the shoulder and trunk representations expanded into the FBS as revealed by physiological mapping.
 Deafferented neonates had altered morphological maps as well as an expanded
- representation of the shoulder and trunk in the FBS.
- Large-scale and restricted deafferentations reflect different mechanisms of reorganization. (Supported by NSF Grant IBN-9400318 to R.S.W.)

TIME COURSE OF USE-DEPENDENT DIFFERENTIAL. REORGANIZATION OF CORTICAL AND THALAMIC HINDPAW REPRESENTATIONS BY MODIFICATION OF WALKING IN ADULT RATS. R.F. Zepka, M. Jürgens and H.R. Dinse (SPON: Europ. Neurosci, Assoc). Institut für Neuroinformatik, Theoret. Biol., Ruhr Univ. Bochum, 44780 Bochum, Germany

Numerous studies have revealed that subject-environment interactions have significant impact on the reshaping of the cutaneous representation of somatosensory cortex (SI). We have recently demonstrated that also age-related modifications of the walking patterns that are paralleled by changes of sensory inputs, in turn affect the hindpaw representations in the ventral posterolateral nucleus (VPL) of the thalamus

and in the somatosensory cortex (Spengler, Godde, Dinse 1995 Neuroreport 6: 469).

Here we report experiments designed to evaluate the influence of systematic modification of walking behavior of the hindlegs on the timecourse of reorganization of the cutaneous hindpaw map in the SI-cortex and thalamus by unilateral cutting the tendon plantaris in adult rats. Receptive field (RF) measurements were performed starting a few days up to several months after the surgery. Thalamic and cortical RFs were derived from the contra- and ipsilateral hemisphere, the latter serving as intra-individual control. Significant enlargement of the RF-size in the contralateral hemisphere (impaired limb) compared to the ipsilateral control was found in SI as well as in VPL. However, there were significant differences in the onset and in the degree of RF-size changes. The reorganizations recorded in VPL of thalamus were tengtee of Kr-size changes. The feotganizations recorded in VI2 of thatamas were smaller and began substantially later than those found in cortex. The results indicate that modifications in the patterns of the sensory stimulation on the paws induced by tendon plantaris cutting, which lead to an impaired locomotion similar to that described for old rats, influence within a few days the representations of the cutaneous cortical and thalamic maps. The clear temporal delay in the thalamic reorganizations provides further evidence for a predominant cortical role in

representational postontogenetic plasticity.

EFFECTS OF MEDIAN NERVE CUT, REPAIR AND REGENERATION IN INFANT MACAQUE MONKEYS.
I. THALAMOCORTICAL CONNECTIONS. Taub. H.B., S.L. Florence, & J.H. Kaas*, Dept. Psychology, Vanderbilt Univ. Nashville, TN 37240.

Recovery of tactile sensation is much better in children with nerve cut and surgical repair than in adults, and the basis for this recover presumably involves structural or functional reorganization within the presumably involves structural or functional reorganization within the ascending somatosensory pathway. In an effort to establish how and where this recovery occurs, we studied thalamocortical connections in macaque monkeys (*Macaca mulatta*) that had median nerve cut and repair soon after birth. At 12 - 18 months of age, monkeys received an injection of 2% WGA-HRP into the median nerve representation of cortical area 1, using AAALAC-approved surgical procedures. Later, the monkeys were sacrificed and sections through cortex and thalamus were processed to visualize the injected tracer. The early sensory deprivation had little effect on the ambitectural appearance of the deprivation had little effect on the architectural appearance of the ventroposterior nucleus (VP), although cytochrome oxidase staining revealed an apparent reduction of metabolic activity in the region where the digit representations are located. Plots of the label in VP demonstrated a remarkably normal distribution despite the deprivation. Both labeled cell bodies and axon terminals were confined to a narrow dorsoventral column lateral to the cell free zone separating the face and hand representations, with an occasional labeled neuron just medial to this border. These findings suggest that reorganization of thalamocortical connections does not significantly contribute to the recovery after nerve injury early in life. Supported by NIH grants NS16446 and NICHDHD15052.

CHANGES OF RESPONSIVENESS OF VPL THALAMIC NEURONS DEAFFERENTATION TEMPORARY IPSILATERAL HOMOLOGOUS RECEPTIVE FIELD (RF) S.H. Park1, J.H. Sohn¹, I. Yi¹, C.K. Won², B.K. Kim², B.R. Park³*, J.W. Leem⁴, H.C. Shin², Dept. Physiol.², Hallym Univ., Chunchon, Dept. Psychology¹, Chungnam Nat'l Univ. Taejeon, Dept. Physiol.³, Wonkwang Univ., Dept. Physiol.⁴, Yonsei Univ., Korea

Peripheral sensory deafferentation induces immediate unmasking of new RFs at multiple levels of the somatosensory system of adult animals. It has also been reported that plasticity induced in one cortex is immediately mirrored in the other hemisphere (Calford and Tweedale, 1990). In this study, we tested the possible presence of interhemispheric transfer of the plasticity in the VPL thalamus of rats after peripheral deafferentation. After determining the stability of RF for 30 min of control period, denervation of an ipsilateral digit, which is the counterpart of the contralateral digit RF, were performed by subcutaneous injection of lidocaine (2%, 0.03 ml) to the ipsilateral digit. Afferent sensory transmissions from the contralateral RF were significantly facilitated ($25.66\pm10.7\%$, 15-20 min, p < 0.01) during 5-25 min following temporary deafferentation of ipsilateral homologus RF. This result suggests that plasticity-induced in one hemisphere by temporary sensory deprivation may immediately induce plastic chnages in thalamus of other hemisphere (supported by the 95' Basic Medical Science Grant from the KME to HCShin and in part by the 93' Nondirected Research Fund from the KRF to JHSohn).

SEGREGATED THALAMIC LABELING AFTER TRACER INJECTIONS INTO SOMATOSENSORY CORTEX OF MACAQUES. <u>E.R. Ergenzinger*</u> K.A. Findlay, M.M. Glasier, V.J. O'Boyle Jr., and T.P. Pons. Department of Neurosurgery, Bowman Gray School of Medicine, Winston-Salem, NC 27157-1029.

While large-scale reorganization of anterior parietal cortex (APC) has been demonstrated in macaques following long-standing dorsal rhizotomies (Pons et al., Science, 1991) the mechanism which explains the extent of this reorganization is unknown. Two possible mechanisms have been proposed: 1) that the reorganization occurs along pre-existing connections that are normally silent, or 2) that new connections are formed at some point along the ascending somatosensory pathway. Lund et al. (Science, 1994) proposed that thalamic input to the occiput/neck/shoulder region of APC, which is located medial to the upper limb representation, and input to the lateral face representation, might overlap across the entire upper limb representation. To directly test this possibility, we injected the fluorescent representation. To directly test this possibility, we injected the Indoceschi tracers diamidino yellow (DY), fluoro ruby (FR), and fast blue (FB) into electrophysiologically defined face, hand, and occiput/neck/shoulder regions of APC, respectively, and looked for overlap of label or double-labeled cells in the ventroposterior lateral and medial (VPL and VPM) nuclei of the thalamus. FB and FR labeled cells were observed in non-overlapping portions of VPL and DY labeled cells were observed in VPM. Virtually no overlap of label was observed, nor were there double-labeled cells in VPL or VPM resulting from any of the injected zones. Our results demonstrate that overlap of thalamocortical arbors is insufficient to account for the extent of the reorganization we previously reported after dorsal rhizotomies. Supported by NIMH RO1 MH53369-01. T.P. Pons was an Alfred P. Sloan

EVIDENCE FOR HETEROSYNAPTIC DEPRESSION IN THE RAT BARREL CORTEX Fox, K*and Glazewski, S. Molecular and Medical Bioscience, U. of W., Cardiff, U.K. and Washington University School of Medicine, St. Louis MO

Vibrissae deprivation not only causes potentiation of spared vibrissae responses but also depression of deprived vibrissae responses. In a deprived barrel-column, depression is greater for neurons located close to an active barrel-column. One possible explanation is that the spared vibrissa produces heterosynaptic depression of the principal vibrissa response [Glazewski and Fox, J. Neurophysiol., 75:1714]. To test this idea further, we compared the effect of depriving all vibrissae (11 rats) with depriving one single vibrissa (10 rats). Vibrissae were removed without injury unilaterally for 7 days and regrew for 6 to 8 days before recording single unit responses to standard vibrissae deflections. Animals were 28-35 days old. The

positions of all recording penetrations were recovered within the barrel field. Vibrissae responses were quantified using post-stimulus time histogram analysis. In animals deprived of all vibrissae, principal vibrissae responses were depressed to 38% of control levels in layers II/III (deprived 167, control 46 cells) and 78% in layer IV (deprived 89, control 40 cells). Depression was significant for cells in layers II/III (0.46±0.06 spikes per stimulus vs 1.22±0.12 for undeprived controls [p<0.005; df=13; t-test]) but not for those in layer IV (0.98±0.18 sp/stim vs 1.25±0.15 [p>0.1, df=13]). This indicates that a component of vibrissae response depression is homosynaptic in layers II/III.

However, depression was far greater if animals were only deprived of a single vibrissa. In the deprived barrel-column, principal vibrissa responses were depressed to 16% of control in layers II/III (100 cells) and 41% in layer IV (48 cells). Deprived vibrissa responses were significantly smaller for the "single-deprived vibrissa" paradigm than for the "all-deprived" cases for both layer II/III (0.2±0.06 sp/stim [p<0.01; df=19; 2-tail t-test]) and IV cells (0.51±0.14 sp/stim [p=0.05, df=19]). This indicates that a component of vibrissae response depression is heterosynaptic in origin. Supported by NIH NS27759 to KF.

DIVERGENCE OF CONNECTIONS FROM SECONDARY SOMATOSENSORY (SII) AND INSULAR CORTEX TO ANTERIOR PARIETAL CORTEX (APC) IN MACAQUES. M.M. Glasier*, E.R. Ergenzinger, K.A. Findlay, V.J. O'Boyle Jr. & T.P. Pons, Department of Neurosurgery, Bowman Gray School of Medicine, Winston-Salem, NC

27157.

APC cortex in macaques contains topographic representations of the contralateral body surface. The goal of this study was to determine the degree of divergence of projections from SII and insular cortex onto body representations in APC. Retrograde tracing techniques were used in combination with microelectrode mapping procedures to determine the regions of efferent neuronal connections to APC from SII and insular cortex. Injections of different tracers were made into three separate regions of APC, corresponding to face, hand and occiput/neck/shoulder representations, using diamidino yellow, fluororuby and fast blue dyes, respectively. In the granular insular cortex, neurons labeled by different dyes were observed in Layers V and VI. In SII, labeled neurons were seen in supragranular and infragranular layers, forming two bands that dyes were observed in Layers V and VI. In SII, labeled neurons were seen in supragranular and infragranular layers, forming two bands that followed the contours of the lateral fissure. Some of the labeling in SII and the insula was discrete, where neurons labeled with different dyes occupied separate zones, indicating independent regions give rise to projections to APC. In other portions of SII or the insula, the location of labeled neurons overlapped, indicating a divergence of projections onto different body part representations in APC. The pattern of projections from SII and the insula to APC could form the anatomical substrate for the expansion of the chin and jaw representation seen in APC after dorsal rhizotomies, via utilization of existing neuronal connections.

SHORT-TERM VIBRISSA DEPRIVATION IN JUVENILE RATS DOES NOT ALTER RESPONSIVITY OF VIBRISSA PRIMARY AFFERENTS. S. Glazewski*, K. Fox, J.A. DeMaro & M.F. Jacquin. Neurology & Center for the Study of Nervous System Injury, Washington Univ. Sch. Med., St. Louis, MO 63110; Molecular & Medical Biosci., Univ. Wales, Cardiff, UK.

An accompanying paper (Fox & Glazewski) describes the effects of daily removal of all of the whiskers on the responses of supragranular barrel cortex neurons to deflections of the regrown whiskers. As a first step in identifying a possible subcortical source(s) for the observed suppression of cortical responses, identical single unit recording and electromechanical whisker deflection methods were applied to trigeminal ganglion cells after an identical deprivation regimen. Tungsten microelectrodes and urethane anesthesia were used to record responses from 335 ganglion cells in 12 age-matched control rats and 155 cells in 7 cases whose whiskers were plucked daily for 1 week 4-7 days prior to the recording experiment. For all cells, stimuli were 50 vertical whisker deflections of 1° amplitude and 10 msec duration delivered at 1 Hz. Responses in the 0-50 msec post-stimulus interval were analyzed. All cells had single-whisker receptive fields and they rarely displayed spontaneous activity. Nonparametric ANOVA indicated that deprived and control groups did not differ (p = 0.09) in their total numbers of responses to single stimuli (mean of animal means \pm SD: 2.6 ± 0.7 , 4.0 ± 1.9 , respectively), whereas deprived cells had significantly (p = 0.03) longer latencies to first response (3.6 \pm 1.1 msec) than control cells (2.5 \pm 1.0). Posthoc comparisons of those cells displaying only an "on" response or only an "off" response or both are in progress to determine the cell type(s) responsible for this latency effect. These data suggest that deprivation-induced reductions in the numbers of cortical unit responses to whisker deflection are not due to altered primary afferent responses. GENE EXPRESSION IN SOMATOSENSORY CORTEX OF MONKEYS WITH LESIONS OF VENTROBASAL THALAMUS. T.M. Woods, P.R. Manger, E. Rausell*, K.Trinh & E.G. Jones. Dept. Anatomy and Neurobiology, Univ. California Irvine, Irvine, CA 92717-1280.

Thalamocortical projections from the ventrobasal nuclear complex (VB) of the thalamus to the somatosensory cortex of the postcentral gyrus in monkeys exhibit substantial divergence and overlap. This property of thalamocortical divergence may be one basis of somatosensory cortical plasticity. This study addresses the question of the extent to which this divergence can maintain a normal pattern of gene expression for molecules that may be involved in plasticity of 3b representational maps in the presence of diminishing VB input. Lesions of varying size were made in VB as defined by extracellular multi-unit mapping either electrolytically or with kainic acid. After one to five weeks recovery, the thalamus and somatosensory cortex were sectioned and stained for Nissl, cytochrome oxidase (CO), immunocytochemically for gamma-aminobutyric acid (GABA), NMDA receptor 1 (NR1), type II calcium/calmodulin dependent protein kinase α (CAMIIK α), parvalbumin, $\beta 2/\beta 3$ GABA, receptor subunits, and glutamate receptor 2/3 (GluR2/3), or hybridized with radioactive cRNA probes for glutamic acid decarboxylase (GAD), CAMIIKa, NR1, NR2a, NR2b, NR 2d receptors, the $\alpha 1$, $\beta 2$ and $\gamma 2$ subunits of the GABA_A receptor and the GluR2 receptor. Both electrolytic and kainic acid lesions produced a complete loss of VB neurons within the area of the lesion. Regions of decreased CO staining and neurotransmitter related molecule staining and hybridization in area 3b were dependent on the magnitude of the lesion and could only be detected with lesions that caused loss of VB neurons beyond a critical level of approximately 10% of the population

EFFECTS OF SENSORY DEPRIVATION ON GLIAL FIBRILLARY ACIDIC PROTEIN IN THE RAT BARREL CORTEX. . I. Tzimou and D. A. Weldon.* Dept. of Psychology, Hamilton College, Clinton, NY 13323.

The rodent barrel cortex shows plasticity in neuronal receptive fields and cell chemistry following alterations of sensory input from the whiskers. In the present study we investigated whether tactile deprivation from removal of whiskers would affect barrel cortex glial cells. Anesthetized rats had vibrissae on one side of the face removed with forceps. One week later, tangential sections were taken through the somatosensory cortex. Adjacent sections were stained with cresyl violet and processed for glial fibrillary acidic protein (GFAP) using immunocytochemistry. After identifying the barrel cortex location in the nissl-stained sections, we examined the GFAP-containing cells in the equivalent location of the immunocytochemically processed tissues. Cells contralateral to the intact vibrissae showed heavier and less patchy GFAP immunoreactivity than the cells located in the barrel cortex receiving information from the side of the face in which the whiskers had been removed. The results suggest that changes in glial cell chemistry can reflect neuronal plasticity in the barrel cortex.

L CORTEX WIDESPREAD 2DG LABELING IN BARREL CORTEX FOLLOWING REPEATED WHISKER TRIMMING IN ADULT HAMSTERS- A 2DG/IMMUNOSTAINING STUDY. <u>D.L. Maier and J.S.</u> FOLLOWING McCasland*. Dept. of Anatomy, SUNY HSC at Syracuse, Syracuse, NY 13210.

We have previously demonstrated a widespread, whisker-dependent activation of the entire barrel field in adults subject to ablation of most whisker follicles at postnatal day 7 (P7), after the fate of the barrel map is set (Soc. Neurosci. Abstr. 21: 124). Such strong activation of all large-whisker-related columns by as few as two whiskers is never observed in acutely-trimmed adults. Acute removal of the spared whiskers greatly reduces the intensity of metabolic labeling in all barrels, indicating that their presence was indeed responsible for the widespread labeling observed in the two-whisker animals. We interpret these data to mean that a large-scale synaptic reorganization of barrel cortex in hamsters occurs in response to P7 follicle ablation.

Physiological studies have shown plasticity in single-unit responses to whiskers "paired" for several days in adults (Diamond et al., Science '94). We tested for similar plasticity in our 2DG/immunostained materials following repeated trimming of most whiskers. Beginning around P40, animals had all whiskers except Row C trimmed on alternating days for periods ranging from 1 day to 2 weeks, after which they were administered ³H 2DG IP and allowed to explore a fresh empty cage.

Autoradiograms from these animals showed a clear expansion in the zone of heavy 2DG labeling with continued whisker trimming. Hamsters with Row C spared overnight showed markedly higher labeling in the Row C barrels as expected. After 2 weeks of repeated trimming, the pattern of 2DG labeling in the barrel field varied among the 4 cases we have examined, ranging from complete activation of all large-whisker columns reminiscent of that seen following follicle ablation, down to a more localized activation of Rows B, C, and D. More subtle effects were observed after six or seven days of trimming.

Our data suggest that a large-scale synaptic reorganization occurs in both neonatally- and adult-deprived barrel fields. The results provide a convenient model system for testing plasticity mechanisms operative in development, in adults, or in both. Supported by NIH grant NS31829.

GLOBAL TRAVELING WAVE AND LOCALIZED OSCILLATIONS IN NEOCORTICAL SLICE J.Y. Wu*, L.Guan, and Y. Tsau Department of Neurology and Institute for Cognitive and Computational Sciences, Georgetown University Medical Center, Washington DC, 20007

Coherent activity in neocortex may be important in information processing and storage. Here we report that localized oscillations were triggered by an initial traveling wave in neocortical slices. Spontaneous epoch oscillations in neocortical slices in a nominally zero magnesium medium (Silva et. al. Science 251:432, 1991) were examined by voltage sensitive dye (RH 479) imaging and electrode array (field potential). Each epoch of spontaneous oscillations was composed of a global initial traveling wave followed by localized loci of oscillation. The initial wave spread over the entire preparation (coronal slice of half hemisphere between Bregma -3 to -7 mm, from 20 to 30 day old SD rat). Its propagation velocity (40-120 mm/sec) appeared to vary significantly from epoch to epoch but complicated traveling patterns revealed by optical recordings suggesting that the velocity difference may due to multiple initiation sites or variations in the pathway. After each initial wave, oscillations emerged from different loci. At 27°C, each locus oscillated for 2 to 20 cycles at 2 to 8 hz. Optical imaging showed that some loci were highly localized, covering a narrow strip (0.2 to 1 mm) of the cortical section but encompassing all cortical layers. Overlap of activity from different loci was observed optically but the activity from different loci appeared independent or only weakly coupled. These segregated loci of oscillations may represent modular neural assemblies or oscillation attractors formed by local synaptic interactions (Supported by NIH NS 31425).

IONIC MECHANISMS GENERATING THE REFRACTORY PERIOD IN THALAMIC SYNCHRONIZED OSCILLATIONS. A. Lüthi* and D.A. McCormick. Section of Neurobiology, Yale University School of Medicine, New Haven, CT 06510.

Recent studies have shown that spindle wave oscillations in the ferret lateral geniculate nucleus are followed by a refractory period associated with a slowly decaying afterdepolarization (ADP) that involves the activation and subsequent deactivation of the inwardly rectifying cation current Ih. Here we examined the physiological factors contributing to this persistent activation of Ih. The intracellular injection of rhythmic short duration hyperpolarizing current pulses (5-20 pulses, 200-400 pA, 120 ms, 4 Hz), mimicking the arrival of IPSPs during synchronized oscillations, was associated with the generation of an ADP whose amplitude was larger than that following a single, long-duration hyperpolarizing pulse. This result suggests that the rebound Ca²⁺ spikes that occur during repetitive hyperpolarization may contribute to enhanced activation of I_b. Indeed, reduction of Ca²⁺ bursts with local application of Ni²⁺ ions resulted in a substantial reduction of the ADP. We suggest that both voltage-dependent cumulative activation of I_{h} and Ca2+ influx contribute to the development of the ADP and the generation of the refractory period. It remains to be investigated whether or not Ca2+ modulates Ih with respect to voltage-dependence, kinetics and/or maximal conductance. Sponsored by NIH and the Swiss National Science Foundation.

DYNAMIC REORGANIZATION IN RAT NEOCORTICAL SLICE. Y. Tsau*, L. Guan, and J.-Y. Wu. Georgetown Institute for Cognitive and Computational Sciences, Georgetown University Medical Center, Washington

Neurons in the neocortical slice tend to oscillate under conditions of zero Mg2+. We report that these oscillations underwent dynamic reorganization over time and was distributed unevenly over the neocortical slice. Experiments were carried out on SD rat coronal neocortical slices using electrode array and optical recording with voltage-sensitive dye (RH479). Spontaneous coherent rhythmicity was recorded electrically and optically, composed of a global initiation wave followed by localized oscillations. The initiation waves originated in temporal cortex area and propagated to parietal cortex when they started spontaneously 40 min to 1 hour after the slice was bathed in zero Mg medium. After 2 to 4 hours in zero Mg2+, the propagation velocity gradually increased from 44 mm/sec up to 110 mm/sec. After then the time delay between two recording sites became random in both sign and value, suggesting that the site of initiation waves became variable. The propagation velocity of an initiation wave also depended on time interval following the previous wave. The evoked initiation waves by electrical stimuli propagated at 57 mm/sec 20 sec after the previous waves and at 28 mm/sec 2.5 sec after. Simultaneous recordings of localized oscillations from different sites appeared similar but the oscillations were actually coincident. However, the oscillation patterns and locations seemed unchanged over time. The data suggest that the system is reorganized for generating initiation waves but the local circuit for oscillations remains stable after the medium changes. (Supported by NIH NS 31425)

RELATION BETWEEN OPTICAL IMAGING MAPS AND SPIKING AND NON-SPIKING POINT-SPREAD FUNCTIONS RECORDED IN SUPRAGRANULAR AND GRANULAR LAMINAE IN RAT SOMATOSENSORY CORTEX. T. Hilger, T. Berkefeld, B. Godde, K. Behrend* and H.R. Dinse. Institut für Neuroinformatik, Theoret. Biology. Ruhr-Univ. Bochum RUB, Bochum, Germany We investigated the relationship between optical imaging data and the width and the

slope of cortical spiking and non-spiking point-spread functions (PSFs) recorded in the supragranular and granular layers of the hind- and forepaw representations of the somatosensory cortex of urethane anaesthetized rats. As a rule, all different types of maps were always recorded for each animal. Spiking PSFs were obtained by measuring representational maps based on cutaneous receptive field (RF) mapping. Non-spiking PSFs were obtained by recording local field potential (LFP) maps. Each individual electrophysiological map was reconstructed from 60 to 80 electrode penetrations. Optical maps were obtained by means of optical recording of reflectance changes of intrinsic signals (LaVision Lightstar II imaging and acquisition system) using a 546 nm light source. Optical imaging maps and LFP maps were separately calculated for 25, 50 and 75 % of their maximal amplitudes.

We found a close correspondence between the size and the slope of the optical maps and the non-spiking PSFs recorded in layers IV. While the slopes of the non-spiking PSFs recorded in layers (II/III) were also comparable to the optical imaging data, the size of the layer II/III non-spiking PSF was significantly smaller than the optical maps and the layer IV LFP maps. Spiking PSFs based on RF measurements revealed a considerable resemblance with the optical and LFP maps calculated for the 50 % amplitude level. Combined, the data demonstrate that in rat somatosensory cortex optical imaging using a 546 nm light source reveals activity distributions that are in close correspondence with electrophysiologically obtained maps. The correspondence of optical imaging maps with layer IV PSFs suggest a substantial contribution of layer

DUAL WAVELENGTH OPTICAL IMAGING OF INTRINSIC SIGNALS IN RAT CORTICAL ACTIVITIES. M. NAKASHIMA*1, M. YANAURA1, S. YAMADA1, S. SHIONO and M. TANIFUJI Advanced Technology R&D Center, Mitsubishi Electric Corp., Hyogo 661, Japan and PRESTO2, JRDC, Tokyo 100, Japan

Simultaneous optical imaging with two wavelengths has the potential advantage of allowing efficient noise reduction and selective signal amplification, and achieving real-time imaging of cortical activities. One wavelength was set to be more sensitive to the cortical activities than the other, but both recorded the noise associated with cortical movement. In the optical system, two CCD cameras were used to visualize the same cortical surface. The combination of 570 and 600 nm band-pass filters was chosen to detect intrinsic hemoglobin signals relating to the cortical activities.

A SD strain rat was anesthetized with urethane and kept at the level of surgical anesthesia. The animal was placed in a non-traumatic head holder, and its somatosensory or gustatory cortex was exposed with the dura intact. To evoke the cortical response, a single whisker, and tongue region were stimulated by mechanical touch, and by taste solutions (sucrose, NaCl, HCl), respectively

We obtained the optical signals responding to the contra-lateral whisker stimulation. The significant optical changes were observed mainly at a time of 2-5s after the stimulus onset, and their extent was localized at about 1x 1mm2 area of somatosensory cortex. The responding area to the whisker stimulation was topologically correlated, depending on the whisker location. On the other hand, significant optical signals of gustatory cortex were observed at the area of about 4mm x 3mm dorsal to rhinalis sulcus, approximately at the level of crossing with the middle cerebral artery.

OPTICAL IMAGING OF NEURONAL ACTIVITY AND COUPLED METABOLIC ACTIVITY IN RAT BARREL CORTEX. I. TAKASHIMA* and T. IIJIMA Electrotechnical Laboratory, 1-1-4, Umezono, Tsukuba, Ibaraki, 305, Japan.

We studied the relationship between the functional map of whisker barrel field of the rat obtained with extrinsic optical signal recordings using a voltage-sensitive dye and the map obtained with intrinsic optical signal recordings with near infrared light. The functional map was very similar in the both recordings, if we compared the intrinsic signal map at the initial phase (600 ms) with the extrinsic signal map at the maximal response. However, the functional map at the maximal response of each signals were significantly different. The maximal "hot area" detected with intrinsic signals occupied twice as large area as the maximal "hot area" detected with extrinsic signals. The domain of the intrinsic signals finally moved to the superior cerebral veins. The intrinsic signals were recorded at the wavelength of 570, 580 and 610 nm. respectively. The changes in regional cerebral blood volume (rCBV) and hemoglobin oxidation-reduction state were thought to be involved in the intrinsic signal as the major source at these wavelength. Indeed, the optical signal changed in size and polarity according to the wavelength used, reflecting their origin of signal source. We tried to separate these two components based on the wavelength-absorption characteristic of oxy-deoxy hemoglobin. The results showed that the oxygen consumption of neurons preceded 200-400 ms to the increase of rCBV, and that the functional map obtained with this component, not the rCBV, was almost identical to the map obtained with the extrinsic signal recordings

IN VIVO OPTICAL IMAGING OF DENDRITIC CALCIUM DYNAMICS IN NEOCORTICAL NEURONS UNDER SENSORY STIMULATION. K. Syoboda, W. Denk, D. Kleinfeld, D.W. Tank. Bell Laboratories, Lucent Technologies, Murray Hill, NJ 07974.

We used the high resolution provided by two-photon laser scanning microscopy (see accompanying abstract) to measure spatio-temporal dendritic calcium dynamics in rat barrel cortex pyramidal neurons. Experiments were performed on 4-6 week old rats under urethane anesthesia (2mg/g). Neurons in layers 2 & 3 were impaled with beveled sharp microelectrodes containing 3 mM Calcium Green I and 400 mM K-Acetate (resistance ~ 60 - 120 MΩ). Periodic Calcium Green 1 and 400 mM K-Acetate (resistance ~ 60 - 120 Mt2). Periodic mechanical whisker deflections (5 Hz) produced two types of short latency (~ 15 ms) response; i) Unitary 'slow' membrane potential transients (width ~ 40 ms), typically at the beginning of stimulus trains, which produced bursts containing 1-3 Na* action potentials; ii) Sub-threshold slow transients with highly variable amplitudes. Sensory stimulation evoked rapid calcium transients (rise time < 10 ms) in the apical dendrite, synchronous with electrically recorded Na⁺ spikes. Calcium transients produced by two spikes were twice as large as those produced by one spike. The fractional change in fluorescence first increased with distance from the soma (up to 40 - 200 μ m) and then decreased, vanishing in the distal apical tuft in layer 1. Calcium transients were not observed during sub-threshold slow potentials. Hyperpolarization eliminated both Na' spikes and sub-threshold slow potentials. Hyperpolarization eliminated both Na* spikes and calcium transients but increased stimulus-induced slow potentials. Intracellular QX-314 (30 mM in the electrode) blocked Na* spikes but produced spontaneous regenerative potentials that could also be evoked with depolarizing current injections, consistent with increased calcium electrogenesis. Only under these conditions did sensory stimulation evoke calcium transients in the apical dendrite in the absence of Na* spikes. Under normal conditions apical dendritic calcium transients are always associated with Na* action potential invasion of the dendrite. (Supported by Bell Laboratories)

420.6

STIMULUS-EVOKED LOW FREQUENCY MAGNETIC FIELD OSCILLATIONS IN SOMATOSENSORY CORTEX OF AWAKE HUMANS D. Poeppel* S.S. Nagarajan, H.W. Mahncke, T.P.L. Roberts, H.A. Rowley, and M.M. Merzenich, University of California, San Francisco, CA 94143-0732.

Low-frequency oscillations (8-12Hz) have been observed in several regions of sensorimotor cortex in awake humans. However, the role of these oscillations in sensory processing remains unclear. Studies in anesthetized animals show that sensory processing remains unclear. Studies in anesthetized animals show that stimulus-evoked oscillations of local field potentials and multi-unit activity in this frequency range clearly affect the response to subsequent stimuli (Sameshima et al., Soc. Neurosc. Abst., 644.4, 1993). The purpose of this study was (1) to characterize oscillations evoked by a single somatosensory stimulus in awake humans, and (2) to determine the effect of such oscillations on responses to stimuli occurring at various delays after the first stimulus.

We recorded evoked magnetic fields (37-channel biomagnetometer, Magnes, Biomagnetic Technologies Inc., San Diego, CA) from somatosensory cortex in 5 human subjects passively attending to suprathreshold stimuli delivered to the distal tip of the index finger. Stimuli were single or paired air-puffs (25 PSI) separated by 50-250ms. The frequency spectrum, amplitude, and total power of the response elicited by each stimulus were measured.

We observed (1) oscillations that lasted between 200 and 400ms in the range of 8-12 Hz in response to single air-puffs. (2) The amplitude and total power of the

8-12 Hz in response to single air-puffs. (2) The amplitude and total power of the response depended on the position in time of the second stimulus relative to the response depended on the position in time of the second stimitus relative to the phase of the ongoing oscillation evoked by the first stimulus. Both the amplitude and total power plotted as a function of the inter-stimulus delay appear to be oscillatory in the frequency range of 8-12Hz. This is inconsistent with monotonic recovery from inhibition. The data suggest that these oscillations play a role in the processing of time-varying stimuli in the range of hundreds of milliseconds. [Supported by HHMI, the Charles A. Dana Foundation, and Biomagnetic Technologies Inc.)

HIGH RESOLUTION IMAGING OF RAT NEOCORTICAL NEURONS IN

HIGH RESOLUTION IMAGING OF RAT NEOCONTICAL NEURONS IV VIVO USING TWO-PHOTON EXCITATION LASER SCANNING MICROSCOPY. D. W. Tank', K. Svoboda, R. A. Stepnoski, D. Kleinfeld, W. Denk. Bell Laboratories, Lucent Technologies, Murray Hill, NJ 07974. Severe scattering of visible light by neural tissue has precluded high resolution optical imaging of neurons by conventional methods in intact nervous systems. The infrared wavelengths used to excite visible fluorophores by twophoton excitation penetrate much deeper into brain tissue. In addition, light absorption in Two Photon Laser Scanning Microscopy (TPLSM) occurs only in the focal volume, eliminating out-of-focus photobleaching and photodamage, while providing optical sectioning. Fluorescence light can be collected with high efficiency due to the absence of a confocal pinhole, reducing photodamage in the focal plane. These features suggest that TPLSM offers significant advantages in high-resolution imaging of neurons in the mammalian neocortex in vivo. To test this idea, we filled neurons in the somatosensory cortex of anesthetized rats with fluorescent calcium indicators and imaged them using a custom-made twophoton excitation laser scanning microscope. The excitation source was a pulsed Ti:sapphire laser (λ = 850 nm; 250 mW; 100 fs; 82 MHz). A skull-mounted chamber over a cranial window allowed simultaneous optical (40x 0.75 NA water immersion objective) and microelectrode access. Individual cortical neurons were filled iontophoretically with Calcium Green 1 using sharp microelectrodes. Dendritic processes were resolved with single spine resolution down to 500 µm below the pial surface. The complete 3D dendritic morphology could be reconstructed from stacks of optical sections. Dendritic calcium transients evoked reconstructed from stacks of optical sections. Denoritic calcium transients evoked by sensory stimulation or current injection through the recording electrode were repeatedly (> 100 times) measured with high temporal (up to 1 ms in line scan mode) and spatial (< lµm) resolution. Our results demonstrate that TPLSM offers a new way to probe the dynamics and structure of neocortical neurons in vivo. (Supported by Bell Laboratories)

WHAT IS THE NEURAL CORRELATE OF THE OPTICAL IMAGING SIGNAL? INTRACELLULAR RECEPTIVE FIELD MAPS AND OPTICAL IMAGING IN

RAT BARREL CORTEX C. I. Moore*, B. R. Sheth, A. Basu, S. Nelson & M. Sur Dept. of Brain & Cog. Sci., M.I.T., Cambridge, MA 02139
Changes in metabolic activity are co-opted in several techniques (fMRI, PET) to examine the organization of sensory cortex. Intrinsic signal optical imaging similarly relies on changes in the oxygenation state (and subsequent changes in the reflectance) of hemoglobin to provide a measure of activity in neuronal populations. The electrophysiological correlate of this metabolic signal is still being determined; either action potential firing or subthreshold neuronal activity is the more accurate correlate of the optical signal.

of the optical signal.

We examined this issue directly, with *in vivo* intracellular rf mapping in supragranular (SG) neurons (Moore and Nelson, 1994) and intrinsic signal optical imaging in the rat barrel cortex (Masino et al., 1992). We found a close correlation between the amplitude of subthreshold-EPSPs evoked by vibrissae that are 1- or 2-vibrissae away from the principle vibrissa of an SG neuron (78% and 52% of the optimal input, respectively), and the amplitude of the optical signal evoked by vibrissae 1- or 2-away from the principle vibrissa for a cortical activation zone (rad. 178m: 68% and 53% of the optimal input, respectively). Work in our laboratory and from others (Armstrong-James et al., 1992) demonstrates a much sharper fall off in the amplitude of SG extracellular receptive fields (i.e. 1-away).

extracellular receptive fields (i.e., 1-away inputs drive a neuron with <= 50% the efficacy of the principle vibrissa). We conclude that subthreshold inputs provide an accurate correlate of the optical signal generated in somatosensory neocortex. Support: EY07023.

TOPOGRAPHIC PATTERNS OF V1 AND V2 CORTICAL AND SUBCORTICAL CONNECTIONS IN TREE SHREWS. D.C. Lyon*, N. Jain, and J.H. Kaas Dept of Psychology, Vanderbilt University, Nashville, TN, 37240.

V2 connections were used to define and characterize extrastriate visual areas in tree shrews (Tupaia belangeri). Tree shrews are of special interest because they are highly visual, and they are closely related to primates. Injections of distinguishable fluorochromes were placed in different visuotopic locations along the length of V2. For comparison, WGA-HRP was injected into primary visual cortex. The results indicate that at least four extrastriate areas have topographic patterns of connections with V2. Three of these areas have been previously identified along the lateral border of V2 as the temporal anterior (TA), temporal dorsal (TD), and temporal posterior (TP) areas, since they also have inputs from V1 (Sesma et al., JCN, <u>230</u>: 337, 1984). A small oval of cortex lateral to TA and TD has less dense V2 connections. Both V1 and V2 have inputs from the lateral geniculate nucleus and pulvinar. We conclude that tree shrews have several areas, TA, TD, TP, rather than a single area, V3, along the lateral border of V2, and they have at least one further visual area in temporal cortex. Because these close relatives of primates do not have a V3, we question the premise that V3 is a valid visual area in primates. Supported by NEI grant EY-02686.

NEUROFILAMENT AND CALCIUM-BINDING PROTEINS DEFINE VISUAL CORTICAL AREAS IN HUMAN. M.M. Adams¹, L.G. Ungerleider^{*1}, G. Eden¹, C. Bouras², G. Bertini¹, J.H. Morrison³ and P.R. Hof³. ¹Lab. Psychol. Psychopath., NIMH, NIH, Bethesda, MD 20892; ²IUPG Belle-Idée, Univ. of Geneva, Switzerland; ³Dept. of Neurobiol., Mt. Sinai Sch. Med., New York, NY 10029.

Visual cortex in the macaque monky consists of at least 30 areas that can be distinguished on the basis of differential cytoarchitecture, patterns of connectivity, visual topography, and physiological properties. It has also been shown that many of these functional cortical regions can be delineated using neurochemical markers. In visual topography, and physiological properties. It has also been shown that many of these functional cortical regions can be delineated using neurochemical markers. In particular, nonphosphorylated neurofilament protein (NFP) has specific regional and laminar distributions in each visual area. To investigate the chemoarchitectonic organization of visual areas in the human, we used antibodies to NFP, which is found in a subset of pyramidal cells, and to the calcium-binding proteins (CaBP) calbindin, parvalbumin, and calretinin, which occur in subsets of GABAergic neurons. Immunohistochemistry revealed labeling patterns that defined at least six distinct visual areas which we have identified as homologues of monkey areas V1. V2, VP (V3v), V3d, V4, and MT. In area V1, strongly labeled NFP-positive neurons were found in layers IVA, IVB, and VI. Area V2 had more prominently labeled NFP-positive neurons in layers III, V, and VI. In contrast, area V4 had light NFP label in layers II, III, V, and VI. Area V3d displayed strong NFP label in layers II and III, with a few neurons in layer V extending their apical dendrite up to layer III. The most easily distinguishable area was MT, which had dense NFP label in layers III. V, and VI. Differences between visual areas were also observed using CaBP immunohistochemistry; however, the borders between these areas were not as clearly defined as those seen with NFP. These results show that, as in the macaque monkey, the human visual cortex can be subdivided into distinct areas on the basis of specific neurochemical characteristics. RETINOTOPIC ORGANIZATION BEYOND THE EARLY VISUAL AREAS IN HUMANS. M.K.Hasnain, M.Woldorff*, P.T.Fox. Research Imaging Center, UTHSCSA, San Antonio, TX 78284-6240 Evidence was found for retinotopic organization extending well

beyond the early visual areas in the human visual cortex. A retinotopic organization existing in the cerebellum was also identified. Striate and extrastriate areas were functionally mapped with PET (H₂O¹⁵). Bowextrastrate areas were functionary mapped with PET (n₃O). Bow-tie-shaped random dot patterns, changing at 8 Hz were presented with a centrally placed fixation point, oriented along the horizontal meridian in one task condition and along the vertical meridian in another. In the control condition the fixation point was presented without any surrounding patterns. Each condition was performed three times, for a total of nine scans. PET images within each task were averaged and averaged control images were subtracted from each of the averaged task images. Z-statistics were performed on the subtraction images and the significantly activated regions were overlaid onto a 3-D surface model of the occipital lobe generated from co-registered MRI images of the same subject. Significant activations were observed from the calcarine sulcus outward along the cortical surface, alternating between those caused by the horizontal meridian stimulus and those caused by the vertical meridian stimulus. Based on the alternating pattern of the activation sites, up to four extrastriate regions were discernible on the activation sites, up to four extrastriate regions were discernible on the medial occipital lobe and up to five extrastriate regions were discernible on the lateral aspect of the occipital lobe. The study identifies at least three more retinotopically organized areas than have currently been reported in the occipital lobe. In addition, the horizontal and vertical meridian stimuli produced different activation sites in the inferior temporal lobe and in the cerebellum.

CONNECTIONS OF VISUAL CORTICAL AREA 18 (V2) IN FLATTENED CORTEX OF GALAGOS. M.W. Pospichal* and J.H. Kaas. Department of Psychology, Vanderbilt University, Nashville, TN 37240.

Connections of the second visual area, V2 or area 18, of adult galagos were investigated by injecting different fluorochromes and WGA-HRP into the field. Later, the cortex was separated from deep structures, manually flattened, and cut parallel to the surface. Some sections were reacted for cytochrome oxidase or myelin, and areas V1, V2, and MT were identified. Results show that injections in V2 labeled neurons and terminations in V2, V1, the middle temporal area (MT) and regions of cortex presumed to contain dorsolateral (DL), dorsomedial (DM), and middle superior temporal (MST) visual areas, as well as inferotemporal cortex (IT). The largest zones of V2 inputs arose from V1 and from cortex rostral and adjacent to V2 (proposed DM and DL). V2 connections with MST and IT were relatively sparse and inputs from MT and intrinsic connections of V2 were intermediate in density. Separate injections in V2 led to partially overlapping regions of label in areas outside V2 that decreased with more widely spaced pairs of injections. The results support the conclusion that major cortical connections of V2 in prosimian primates closely resemble those of simian primates. (Supported by EY-02686 and EY-07135)

PARCELLATION OF VISUAL CORTICAL AREAS IN THE CHIMPANZEE USING NEUROFILAMENT AND CALCIUM-BINDING PROTEINS. R. Gattass. 1, M.M. Adams. 2, B.R. Hof³, and L.G. Ungerleider. 2 Inst. Carlos Chagas Filho, Univ. Fed., RJ, Brazil; 2 Lab. Psychol. Psychopath., NIMH, NIH, Bethesda, MD 20892; 3 Dept. Neurobiol., Mt. Sinai Sch. Med., New York, NY 10029.

Over 30 distinct visual areas have been described in the macaque cortex based on abridokrida properties and natures of competitivity. Many of these regions have also

physiological properties and patterns of connectivity. Many of these regions have also been distinguished on the basis of neurochemical characteristics. Functional imaging and lesion studies have demonstrated that the human visual cortex displays comparable, functionally specialized regions. Preliminary results have shown that these visual areas in the human exhibit neurochemical specialization patterns similar to those in the monkey. To investigate whether the chimpanzee visual system exhibits comparable organization, we used antibodies to neurofilament protein (NFP) and to the calcium-binding proteins (CaBP) calbindin, parvalbumin, and calretinin. We found at least 8 visual areas based on different patterns of immunostaining, which we regard as homologues of monkey areas V1, V2, V3, V4, MT, TEO, LIP, and VIP regard as homologues of monkey areas VI, V2, V3, V4, MT, TEO, LIP, and VIP. Area V1, V2, and MT were comparable in appearance in the monkey, chimpanzee, and human. In V1, darkly stained large pyramidal neurons were found in layers IVA, IVB, and VI. Area V2 had stongly labeled NFP-positive neurons in the superficial layers. Area MT was easily distinguishable by the intensely stained NFP labeled neurons in layers III, V, and VI. Areas V3, V4, LIP, and VIP were more similar to the monkey. Area V3 and V4 were characterized by many neurons in the superficial portion of layer III. TEO had many darkly labeled neurons in layers II and III, and an occasional large pyramidal neuron in layer V. Areas LIP and VIP displayed intensely stained neurons in layer III and occasional large pyramidal cells in VA. CaBP also showed regional differences but the borders between areas were more subtle than those defined by NFP. Those results indicate that, the chimpanzee visual cortex exhibits a comparable These results indicate that the chimpanzee visual cortex exhibits a comparable organization scheme to that of both monkeys and humans, although the location of organization scrime to that o'out monkeys and relations, divocation of the visual areas in relation to the sulci pattern in the chimpanzee is more similar to humans. The chimpanzee brain was donated by the Yerkes Regional Primate Center. Supported by CAPES, CNPq¹ and NIMH-IRP².

VISUAL PROCESSING MEMORIES OF HUMAN CEREBRAL CORTEX. M. A. Uusitalo^{a*}, S. J. Williamson^b, ^aBrain Research Unit, Low Temperature Laboratory, Helsinki University of

Technology, FIN-02150 Espoo, Finland. Department of Physics, New York University, New York City, NY 10003-1113.

Magnetic source images (MSIs) obtained with an array of 122 planar sensors revealed 12 cortical areas that responded within 0.5 s to a brief (70 ms) presentation of a checkerboard stimulus. The response amplitude of each source, modeled as a current dipole, could be characterized as a function of interstimulus interval (ISI) by the expression A(1-e^[ISI/tau]), where A is the saturated response amplitude for long ISI, and tau describes the shape of this "ISI curve" The parameter tau can be interpreted as the lifetime for the neural activation trace. These results provide evidence that every responding cortical region supports a memory function, for which we use the term "processing memory". The responding cortical areas fell into two groups: the earliest in occipital lobes with lifetimes ranging from 0.2 to 0.6 s and the later ones in temporal, parietal, and frontal lobes with lifetimes ranging from 7 to 30 s

These data suggest that the participation of local memories is an essential component of visual information processing.

OXIDATIVE METABOLISM IN HUMAN VISUAL CORTEX DURING PHYSIOLOGICAL ACTIVATION STUDIED BY PET. M. Vafaee, S. Marrett, T. Paus, A. Gjedde¹, A.C. Evans, A. Ptito^{*}, and E. Meyer.

McConnell Brain Imaging Centre, Montreal Neurological Institute, Montreal,
Canada H3A 2B4, ¹Aarhus, Denmark.

For the purpose of studying oxidative metabolism in individual human subjects, we tested a previously developed activation paradigm that was shown to increase brain oxidative metabolism in a group of normal controls (Marrett et al.; 1993). We used positron emission tomography (PET) to measure cerebral metabolic rate of oxygen (CMR_{O2}) during visual stimulation. Six healthy normal volunteers (age 19-33) were studied with the Scanditronix PC-2048 15B PET scanner. A yellow and blue checker board (50-200 of visual angle), reversing at a frequency of 8 Hz, was presented for a total of 7 min (starting 4 min before the onset of a 3-min scan). In the baseline condition, subjects began fixating a cross-hair 30 s before the scan and continued throughout the 3-min scan. Baseline and activation scans were repeated (n=12) for better statistics. CMR_{O_2} was measured using the two-compartment, weighted integration method of Ohta et al. (1992). Individual PET images were co-registered with the corresponding MRI scans. We found consistent foci in V1/2. V4 and parieto-occipital areas of visual cortex. CMR_{O_2} significantly increased in V1/2 and parieto-occipital areas (t>4.0) in both the averaged and in all individual images. We conclude that this particular visual stimulus not only increases CMR_{O2} in the striate cortex but also consistently elevates CMR_{O_2} in the extra-striate cortex. Moreover, this paradigm could be used to evaluate CMR_{O_2} in visual cortex in individual patients suffering from defects in oxidative metabolism such as mitochondrial

THE TIME-RESOLVED CODE BEHIND IMAGES FROM CORTICAL ISO-ORIENTATION MAPS.

G.Bernroider*, Institute of Zoology, University of Salzburg, Austria

Intrinsic optophysiological images from cat Area 18 of visual cortex can reproduce conditions of orientation specific, moving gratings in terms of light reflections within a given wavelength and exposed cortical patch (Bonhoeffer, et al, J. Neurosci., 13, 4157-4180, 1993). Traditionally, these 'maps' are combined and analyzed post hoc by correlating gray-level coded ensemble activities with specific sensory stimuli. However, revealing the neural code underlaying sensory configurations requires approaches from the opposite perspective: reconstructing unique stimulus conditions from the spatially resolved layout of activity maps. Here I propose a computational approach that uniquely deduces a time-advanced population code from the space-time layout of neural ensemble activities obtained from single-condition, isoorientation maps. Computations are based on the description of neuronal charge propagation and link the spatio-temporal organization of post-synaptic charges along dendritic trees to an action-potential phase-time code. The composition of these signals applied to isoorientation maps shows, that 'orientation' can become coded by the temporal evolution of population signals.

SURFACE-BASED COORDINATE SYSTEM FOR A CANONICAL HUMAN NEOCORTEX. M.J. Sereno*, A.M. Dale, A. Liu, and R.B.H. Tootell. Cognitive Science Department 0515, University of California at San Diego, La Jolla, CA 92093-0515 and MGH NMR Center, Charlestown, MA 02129.

MA 02129.

The cerebral cortex makes up the largest part of the human brain. It has the topology of a folded, 2-D sheet. Nevertheless, most approaches to analyzing and displaying human brain imaging data have relied upon a 3-D coordinate system. To allow surface-based techniques to be applied routinely, our cortical surface reconstruction process has been further automated. The method devised several years ago for recovering and unfolding the complete cortical surface of each hemisphere from high resolution MRI images can now be applied in a turnkey fashion to a single 5 minute scan. fashion to a single 5 minute scan.

hemisphere from high resolution MRI images can now be applied in a turnkey fashion to a single 5 minute scan.

To make it possible to average data in a surface-based format, however, we need to make a "canonical" cortical surface. This is done by averaging 2-D surfaces rather than 3-D volumes. The brains are first individually unfolded ("inflated") to remove minor and major sulci. This reconstruction and unfolding process has now been applied to a large number (-100) hemispheres. The brains are then morphed into each other, pair by pair, using a "shrink-wrapping" algorithm similar to that used for surface refinement and unfolding. A single, unfolded, curvature-marked (sulcus/gyrus) brain surface is obtained with a binary tree, and then completely flattened (or conversely, re-folded). Each point of this surface accesses a unique surface point on each of the hemispheres in the database and, hence, any of their associated functional (fMRI/EEG/MEG) data (see http://cogsci.ucsd.edu/-sereno).

A 2-D coordinate system is needed to refer sensibly to locations on the unfolded cortex. The obvious choice is latitude and longitude (two angles measured from a center point), applied after deforming the average cortical surface into an exact ellipsoid. This parameterization of the unfolded cortex has the attractive property that points with similar coordinates will refer to nearby points on the cortical map—nort generally true of a 3-D coordinate system. Nevertheless, the 3-D (Talairach) coordinates of every 2-D surface point can be easily obtained. VISUAL CORTEX: EXTRASTRIATE—FUNCTIONAL ORGANIZATION II

422.1

SPATIOTEMPORAL PATTERNS OF SYNAPTIC ACTIVATION EVOKED IN CORTICAL PYRAMIDAL CELLS BY DIFFUSE STROBOSCOPIC VISUAL STIMULI

David M. Senseman*

Div of Life Sciences, Univ. of Texas at San Antonio, San Antonio, TX 78249

Voltage-sensitive dye (VSD) signals recorded from the turtle visual cortex, in vitro, have waveforms that are similar to the complex polysynaptic potentials recorded concurrently in spiny pyramidal cells with intracellular microelectrodes (Senseman, Vis. Neurosci., in press). In the current series of experiments, I characterized the time-course of cortical VSD signals in order to better understand the spatiotemporal patterns in which local populations of pyramidal cells are activated by diffuse visual stimuli. Each element in a 464 element silicon photodiode array monitored activity in a 150 µm x 150 µm cortical area with near millisecond temporal resolution. Diffuse stroboscopic visual stimulation of the attached eye initiated a cortical response that appeared at the junction between the lateral and medial visual cortical subregions in a small area rostral to the eminence of Fowler. Onset latency ranged from 100 ms to more than 300 ms depending on the intensity of the visual stimulus. With monochromatic light at either 450nm or 650 nm, the relationship between stimulus intensity and onset latency followed a power function. From its site of initiation, the cortical response spread in rostral, caudal and dorsomedial directions with the greatest spread caudally. Velocity of the caudal propagation ranged between 0.02 and 0.04 m/s. Larger cortical responses evoked by more intense light flashes generated cortical waves with faster propagation velocities. Since cortical activity evoked by focal electrical stimulation propagates at ~ 0.1 m/s, it seems unlikely that the slow rate of cortical spread can be explained simply by the conduction velocity of the intrinsic cortical fibers. A more likely possibility is that the rate of spread reflects the balance of excitatory and inhibitory interactions between local populations of cortical pyramidal cells. Efforts are underway to examine this idea with a medium scale neuronal model.

BEHAVIOURAL VISUAL ACUITY OF WILD-TYPE AND BCL-2 TRANSGENIC MOUSE. L.Gianfranceschi¹, A. Fiorentini², L.Maffei^{1,2}, V.Porciatti². (1)Scuola Normale Superiore, (2)Istituto di Neurofisiologia CNR, Via S.Zeno 51; Pisa, ITALY. (SPON: European Brain and Behaviour Society).

Since the advent of gene manipulating techniques the mouse has become the favourite experimental subject for studying functional neural development. The bcl-2 gene has a powerful inhibitory action on naturally occurring cell death. In consequence of that the brain of a transgenic mouse overexpressing bcl-2 only in neurons is 1.5 times bigger than the brain of a wild type (wt) mouse (Martinou et al., 1994), and its retina has more than twice as many ganglion cells than normal. This fact opens the question of evaluating the possible functional differences between the nervous systems of wt and bcl-2 mice. Behavioural visual acuity was evaluated by a two-alternative, forced choice procedure on hybrid mice derived from breeding the C57BL/6J strain with the transgenic line NSE73a. The presence of the transgene was assessed by PCR. Mice were trained in an apparatus modified from the Wiesenfeld and Branchek maze (1976) and containing a start box, a choice area with swinging doors, and two parallel alleys 30 cm long, at the end of which stimulus cards were placed. The task consisted of discriminating between pairs of high-contrast vertical and horizontal gratings of the same spatial frequency. The correct choice (vertical) was rewarded by 15 mg of powdered mice pellets. Following the wrong choice (horizontal) the food reward was omitted and the animal was put back into the start box. Visual acuity was then measured with a staircase procedure in which blocks of four forced-choice trials for each spatial frequency were run. Spatial frequency was increased if more than two correct choices per block were made and decreased otherwise. Daily estimates of visual acuity were obtained from at least two oscillations in the staircase and found comparable with the 70% correct level of choice in frequency-of-seeing curves. Visual acuity was found to be of the same order (about 0.7 c/deg) in the 3 wt and the 2 bcl-2 mice tested so far. (Supported by Institute for Paraplegia).

SPATIOTEMPORAL STRUCTURE OF STIMULUS INDUCED ELECTRICAL ACTIVITY IN TURTLE VISUAL CORTEX. JC Prechtl* 1.2 L.B. Cohen 1.3 P.P. Mitra*, & D. Kleinfield¹*. (1) Marine Biological Laboratory, Woods Hole, MA 02543; (2) University of California San Diego, La Jolla, CA 92093; (3) Yale University School of Medicine, New Haven CT 06520; (4) Bell Laboratories, Murray Hill, NJ 07974.

In turtles, visual stimuli induce oscillations in the local field potential (LFP) in dorsal cortical areas D1 and D2 (Prechtl 1994). High resolution electrical recordings with linear arrays of electrodes showed that these responses include systematic (LFP) in dorsal cortical areas D1 and D2 (Prechtl 1994). High resolution electrical recordings with linear arrays of electrodes showed that these responses include systematic phase differences. Here we examine the spatial structure of the fast electrical activity (DC to 50 Hz) across D1 and D2 cortical areas in response to a behaviorally relevant visual stimulus, a looming object, or to a simple step change in diffuse illumination.

To probe the large-scale structure of the response in greater detail, we used widefield fluorescence microscopy (24 by 24 pixels at 1000 frames/s) in conjunction with voltage sensitive dyes (VSDs) to image the electrical activity from a roughly 3x3 mm region of visual cortex that was stained with the VSD RH795. To eliminate movement and blood flow artifacts, the spinal cord and cranial nerves IV-XII were sectioned and the animal was perfused with CSF+O². The LFP near the surface of D1 was measured concomitantly with the optical measurements. All results are based on single trials.

The optical response began as a spread of depolarization in geniculocortical visual area D2 and was followed by undulations of depolarization in peniculocortical visual areas D2 and D1. The spatiotemporal structures of the responses were complex, but support several conclusions: (1) The frequency spectrum of the temporal response has a ~11/° character, suggesting the involvement of

DIVERSITY OF THE W-CELL SYSTEM IN THE GENICULO-CORTICAL PROJECTIONS REVEALED BY A WGA-HRP ANTEROGRADE TRACING STUDY IN THE CAT.

PROJECTIONS REVEALED BY A WGA-RRY ANTEROGRADE TRACING STUDY IN THE CAT.

I. Kawano¹, M. Kudo*¹ and S. Kawamura². ¹Dept. of Anatomy, Sch. of Medicine, Kanazawa Univ., Kanazawa 920, JAPAN & ²Div. of Morphological Neural Science, Kumamnoto Univ., Graduate Sch. of Medical Sciences, Dept. of Neuroscience and Immunology, Kumamoto 860, JAPAN.

To examine the central visual pathways of the W-cell system, of which precise organization is as yet unknown, injections of WGA-HRP were placed in the parvocellular laminae C (Cparv) of the dorsal lateral geniculate nucleus in the cat, since the Cparv in this species is said to exclusively receive W-cell information from the retina, the superior colliculus, and the parabigeminal nucleus.

The results show that the cortical targets of the Cparv are areas 17, 18, 19, 20a, and 21a and the posteromedial (PMLS) and ventral (VLS) lateral suprasylvian areas. In area 17, the projection fibers terminate in the superficial half of layer I, the lower two-thirds of layer III - the upper quarter of layer IVa, and the lower quarter of layer IVb - layer Va, forming triple bands. The projection terminals in layer I are continuous, while those in layers III, IV, and Va distribute periodically, exhibiting patchy appearance. In areas 18 and 19, the projection fibers terminate in the superficial half of layer I and the full portions of layers III - IV, forming double bands. In these areas, the projection terminals in layer I are continuous, while those in layers III is a layer I are continuous, while those in layers III is IV distribute periodically, exhibiting patchy appearance. In areas 20a. to layer III - IV distribute periodically, exhibiting patchy appearance. In areas 20a. 21a, PMLS, and VLS, projection fibers terminate in the superficial part of layer II, a part of layer III - the full portion of layer IV, although they are much fewer than those seen in areas 17, 18, and 19.

Thus, the present results document the existence of localized projections from the Thus, the present results document the extraction of occarized projections from a Cparv to various cortical areas. Those projection fibers may constitute a W-cell system of pathways in the visual thalamocortical organization in a fashion comparable to the X-cell and Y-cell systems. The multiplicity of the projections may further imply functional divergence of the W-cell system.

INTRINSIC CONNECTIONS OF THE LATERAL SUPRASYLVIAN CORTEX (LS) IN THE CAT. M. Kase, K. Hoshino and M. Norita.* Dept.

Neurobiology and Anatomy, Niigata Univ. Sch. Med., Niigata, 951, Japan. LS is known to have numerous interconnections with visual cortical areas as well as with subcortical structures implicated in visually-guided behaviors. In contrast, little data is available regarding connections within LS itself. To gain information about intrinsic connections, an anterograde tracer (biocytin or biotinylated dextran amine) was deposited within various cortical laminae along the medial and lateral banks of LS of the cats. Injections in all laminae produced label contained within the respective bank that extended up to 8-10 mm rostrally or caudally from the injection site. Following medial bank injections, considerable label was distributed throughout the fundus and, to a lesser extent, in the lateral bank. In contrast, no label could be detected in the medial bank after lateral bank injections, and, although label was observed in the fundus, it was restricted to the most lateral aspects. However, the lack of medial bank label that was evident following centrally placed lateral bank injections was not evident in the most rostrally or caudally placed lateral bank injections. In these cases, moderate label could be observed in the medial aspect of the fundus as well as in the medial bank. Following an injection into the fundus, anterograde label was distributed in both rostral and caudal directions and into both banks as well. Injections in the supragranular laminae (I-III) yielded patchy label mainly within the supragranular laminae whereas injections in the infragranular laminae (IV-VI) gave rise to patchy label largely in laminae III-IV. The size of the patches varied, ranging from 0.2-0.5 mm. Supported by a Grant-in-Aid (06680731) from the Japanese Ministry of Education, Science and Culture and NISSAN SCIENCE FOUNDATION.

CENTER AND SURROUND RESPONSES IN EXTRASTRIATE AREAS L AND ML IN THE CALIFORNIA GROUND SQUIRREL. M. Paolini* and Ml. Serena. Cognitive Science Department, University of California San Diego, La Jolla, CA 92093-0515.

The classical excitatory center and non-classical surround of direction selective units have often been demonstrated to have an antagonistic relationship. The response to motion in the classical receptive field (RF) in a cell's preferred direction

units have often been demonstrated to have an antagonistic relationship. The response to motion in the classical receptive field (RF) in a cell's preferred direction (PD) has often been shown to be depressed by similar motion in the surround and enhanced by dissimilar surround motion. We analyzed the local direction selectivity to translational motion at many locations in and around the classical RF to more quantitatively determine how direction-selective RFs are organized. We previously reported (Paolini and Sereno, 1995) that extrastrate areas L and ML (lateral and middle lateral) in ground squirrels contain many strongly direction-selective units. We studied the responses in the center and surround of 140 cells in areas L and ML, during acute extracellular recording sessions. Excitatory RFs were mapped on the display monitor, using moderately fast (3-6/s) sequences of stationary flashing squares presented at 100 locations in the visual field in and beyond the hand-mapped RF. Then, small moving stimuli (high-contrast 2D textured shapes; random dot patterns moving through a fixed aperture) were presented to the same cells at the same rate at 36 or 100 visual field locations to characterize local translational direction selectivity. The location of the flashed receptive field, the area spanned by the path of individual stimuli, and local direction selectivity in the center and in the surround of the receptive field. In most of the cells (59%), the PD of the flashed-defined surround was the same as that of the center (37%) or changed smoothly across space from that of the center (a7%) or changed smoothly across space from that of the center (a7%) or changed smoothly across space from that of the center (a7%) or changed smoothly across space from that of the center (a7%). Responses to motion in an aperture were similar. Thes data show that when the center and the surround are separately stimulated, in most cases, the PD in the surround is not markedly different from the PD of the center. Supported by MH4H47035, O

422.6

RESPONSES OF CELLS IN EXTRASTRIATE CORTEX OF CATS AND MONKEYS TO BOUNDARIES INDUCED BY DIFFERENT CUES. Y-C. Wang^{1*}, M.T. Schmolesky¹, T-D. Shou² and A. G. Leventhal¹. ¹Dept. of Neurobiology and Anatomy, University of Utah, Salt Lake City, UT 84132. ²Dept. of Biology, USTC, Hefei 230027, P.R.China.

Some cells in monkey area V2 and cat area 18 respond selectively to boundaries induced by a variety of cues such as luminance (LIBs), motion (MIBs), texture (TIBs), gratings (GIBs) and illusory contours (ICs). We refer to these cells as cue-invariant (CI). In this study we compared the responses of CI cortical cells to boundaries induced by different cues.

CI cortical cells exhibit length summation when tested with light bars (LIBs). In contrast, the responses of these cells to TiBs, GIBs and ICs vary as a function of the number of elements inducing the boundary. Thus, a short GIB containing many inducing elements evokes a greater response from a CI cell than does a long GIB containing fewer inducing elements. The velocity tuning of CI cells varies depending upon the cue inducing the boundary employed as a stimulus. CI cells respond to rapidly moving LIBs, but not to rapidly moving MIBs, TIBs, GIBs and ICs. Some CI cells respond selectively to the orientation of flashing boundaries induced by various cues. The latency of visual response to flashing LIBs is almost 15 ms shorter than is the latency of response to flashing TIBs and GIBs.

The responses of CI cortical cells are consistent with a number of psychophysical phenomena indicating that 1) the detection of GIBs and ICs is dependent upon the number of inducing cycles defining the stimulus, and 2) rapidly moving GIBs and ICs are difficult to detect. The present results suggest that different connections mediate the responses of CI cells to LIBs and equiluminant boundaries (GIBs, TIBs and ICs). Supported by EY04951 to A.G.L.

COMPENSATION OF DIRECTION AND ORIENTATION SENSITIVITY IN CAT POSTEROMEDIAL LATERAL SUPRASYLVIAN (PMLS) EXTRASTRIATE CORTEX AFTER NEONATAL VISUAL CORTEX DAMAGE. Y.P. DANILOV*, V.R. KING, A. AHMAD, K.R. ILLIG and P. D. SPEAR. Dept. Psychology and Ctr Neuroscience, Univ. Wisconsin, Madison, WI 53706, USA.

Purpose, Damage to areas 17 and 18 (visual cortex, VC) in adult cats produces a

loss of orientation (OS) and direction (DS) sensitivity among PMLS neurons. In contrast, qualitative studies suggest that functional compensation occurs following neonatal VC damage so that there is no loss of DS among PMLS neurons. The present experiment used quantitative methods to re-examine the effects of neonatal VC damage on DS and to examine the effects on OS. Methods. Single-unit recordings were made in the PMLS cortex of anesthetized and paralyzed normal cats (n=4), cats that received VC damage on the day of birth and survived to adulthood (n=4), and cats that received VC damage as adults (n=4). Stimuli were moving or flashing sine-wave gratings (20°) at the optimal spatial frequency for each cell. Results. Adult VC graining (20) a the opininal spatial frequency for each cell. Accounts Adult VC damage caused a significant decrease of both OS and DS among PMLS cells compared to normal adult cats. Specifically, 85% of 108 PMLS cells in normal adult cats showed DS, compared with only 32% of 69 PMLS cells in cats that received VC damage during adulthood. Similarly, 79% of PMLS neurons in normal adult cats showed OS, compared with only 12% in cats that received VC damage during adulthood. In contrast, among PMLS neurons recorded in cats that received VC damage on the day of birth (n=88), 67% showed OS and 76% showed DS, which is not significantly different from normal. Conclusions. These results demonstrate that there is functional compensation for both DS and OS among PMLS neurons following neonatal VC damage

PROPERTIES OF NEURONS IN THE CAT'S PMLS CORTEX: RESPONSES TO MOVING TEXTURE PATTERNS. K. Minville*, L. Merabet, A. Desautels and C. Casanova. École d'Optométrie et Centre de Recherche en Sciences Neurologiques, Université de Montréal; Montréal, Québec, Canada.

Neurons in the posteromedial lateral suprasylvian cortex (PMLS) of the cat are sensitive to moving stimuli and the vast majority of these cells are highly direction selective. Previous studies (e.g., von Grünau and Frost, E.B.R.: 49, 1983) have reported that cells in PMLS do not respond to fine textured patterns (visual noise) despite evidence that response properties can be influenced by the presence of a visual noise outside the classical receptive field. Our group among others have previously demonstrated that area 17 and the striate recipient zone of the LP-pulvinar complex both respond to the motion of a fine texture field. Given that both these regions project to the PMLS, we reinvestigated the response properties of this cortical area with noise stimuli as used to characterize area 17 and LP-pulvinar. Experiments were performed with anesthetized normal adult cats. Receptive fields of PMLS units were first characterized using 60% contrast drifting sine-wave gratings then with moving visual noise presented at different directions and velocities (minimum texture element size: 0.07°). To date, 96 units have been recorded in PMLS and the large majority (77 cells, 80.2 %) responded to a varying extent to visual noise. For 75% of these cells, the responses to drifting gratings were more vigorous than those evoked by the motion of noise (dot index; mean=0.66±0.43, median=0.53). The preferred directions for noise of PMLS cells were distributed evenly across 360° (X*=8.9, p=0.6, df=11). Generally, the optimal direction for noise was similar to that of gratings but the noise tuning function was broader (mean: 62.6*±4 do fro noise vs 40.4*±22.7 for gratings). Of the texture sensitive cells, 76% were band pass tuned to noise velocity (mean bandwidth of 2.4 oct

AUDITORY SENSORY RESPONSES IN AREA LIP?

J.F. Linden*, A. Grunewald and R.A. Andersen, Division of Biology, California Institute of Technology 216-76, Pasadena, CA 91125.

Neurons in the macaque lateral intraparietal area (LIP), long considered a visual area, respond during delayed saccades to remembered auditory targets (Mazzoni et al., 1996). During the stimulus period of the auditory delayed-saccade task, when the monkey is required to maintain fixation through presentation of an auditory target, 36% of LIP neurons respond. Are these responses dependent on the performance of the auditory saccade task? To answer this question we trained a monkey to maintain fixation during presentation of behaviorally irrelevant visual and auditory stimuli. Of 78 LIP neurons tested, 37 (47%) responded to localized presentation of visual stimuli, while only 3 (4%) responded to auditory stimulation (ANOVA, p < 0.05). The proportion of cells with auditory responses in this task was therefore significantly less than the previously reported proportion of cells responding during the auditory stimulus period of a delayed-saccade task. Two possible explanations for this task dependence are being investigated. First, training the monkey to perform an auditory delayed-saccade task may introduce long-term changes in the responses of area LIP neurons to auditory stimuli. Alternatively, auditory signals may be gated into LIP only when they are behaviorally relevant, e.g. when they serve as targets for saccadic eye movements

AUDITORY TAKE OVER OF EXTRASTRIATE VISUAL AREAS IN EARLY BINOCULARLY DEPRIVED CATS: PHYSIOLOGICAL EVIDENCE R. Yaka 1.2 , U. Yinon 2 and Z. Wollberg 1 Dept. Zool. 1, George S. Wise, Fac. Life Sci., and Physiol. Lab 2. Goldschleger Eye Res. Inst., Fac. Med., Sheba Med. Ctr., Tel - Aviv. University, Tel - Aviv., 69978, Israel. Visual and auditory activity in non-primary anterolateral - and anteromedial - lateralsuprasylvian cortices (ALLS & AMLS, respectively) have been studied in eight normal and six neonatally visually deprived cats. Our working assumption was that an early loss of sight would induce a takeover of visual areas by the auditory system. Three of the deprived cats were binocularly enucleated (BE), and in the other three both eyelids were sutured (BD). About a year later single unit activity was extracellulary recorded. The major findings, regarding the changes in the responsiveness to various visual and auditory stimuli, in our cats, are summarized in the following table:

	% out of total cells							
group	ALLS			AMLS				
	auditory	bimodal	visual	auditory	bimodal	visual		
NORMAL	13.5	1.5	58.0	1.5	26.0	20.0		
BD	38.5	15.5	0.0	32.0	2.0	18.0		
BE	65.0	-	-	not tested				

In the ALLS of the deprived cats, as deprivation became more severe, there was a remarkable increase in the proportion of auditory cells. In the BD cats, a similar trend was found in the proportion of bimodal cells. Intriguingly, while bimodal cells were found in the BD cats, visual cells were not found in this group. In the AMLS of the BD cats there was a marked increase in the proportion of auditory cells. However, the proportion of bimodal cells dropped significantly, with no change in the proportion of visual cells. It is evident that in visually deprived cats there is a take over of visual areas by auditory input, and that the degree of take over depends on the severeness of deprivation. Supported by M. Waldman Ph.D. Fellowship and by the Israeli Ministry of Health (Grant no. 2397).

CONVERGENCE OF Y AND NON-Y INFORMATION CHANNELS ONTO SINGLE NEURONS IN THE ECTOSYLVIAN VISUAL CORTEX OF THE CAT. B. Dreher¹, M. Piito*², C. Wang ¹, N. Assaad¹ and W. Burke ¹. Institute for Biomedical Research¹, The University of Sydney, N. S.W. 2006, Australia and Groupe de Recherche en Neuropsychologie Expérimentale², Université de Montréal, Montréal, QC H3C 317, Canada.

The ectosylvian visual area (EVA) is a "higher-order" motion cortical area which receives its principal visual inputs via cortical motion areas located within the lateral suprasylvian region. EVA neurons respond optimally at very high stimulus velocities (200-9900/s) and tend to be strongly direction-selective. Furthermore, EVA is reciprocally connected with the "frontal eye field" and the "premotor" cortex. In the present study we have examined the visual receptive field properties of single neurons recorded from EVA of normal cats and cats with selective pressure-blocked Y-information channel. As in the normal cats, in the cats in which the Y-channel in one optic nerve has been selectively blocked, virtually all EVA neurons could be activated by photic stimuli presented via either eye. Thus, virtually all EVA neurons receive excitatory inputs from both Y and non-Y channels. Furthermore, discharge field sizes and direction selectivity indices of EVA neurons were not significantly affected by selective blockade of the Y-channel. These results challenge the idea of strictly selective excitatory links between the large-fibre channel (Y-channel) in the mammalian retinogeniculo-cortical pathway and the motion-processing stream in the visual cortex. On the other hand, the Y-channel clearly provides the principal excitatory drive to EVA, since the responses of EVA neurons to photic stimuli presented via the Yblocked eye were usually substantially weaker (mean peak discharge rate: 18.5 spikes/s) than those to the stimuli presented via the normal eye (mean peak discharge rate: 41.5 spikes/s). Furthermore, the excitatory input from the Y-channel underlies the responsiveness of EVA neurons to high stimulus velocities (above 2000/s). EFFECTS OF LIPOPHILIC IONS ON OUTER HAIR CELL VOLTAGE-DEPENDENT CAPACITANCE AND MOTILITY Min Wu*, J. Santos-Sacchi. Sections Otolaryngology and Neurobiology, Yale Medical School, New Haven, CT 06510

The outer hair cell (OHC) from the mammalian organ of Corti possesses a bellshaped voltage-dependent capacitance function. The ratio of peak voltage-dependent capacitance to linear capacitance ranges from about 1 to 2 depending upon cell length. The nonlinear capacitance reflects the activity of membrane bound voltage sensors associated with membrane motors which control OHC length. We have studied the effects of the lipophilic ions, tetraphenylborate (TPB') and tetraphenylphosphonium (TPP*), on OHC capacitance and motility. Effects on supporting cells were also investigated. Capacitance and motility were evaluated under whole cell voltage clamp using a Windows based program, jClamp. See Kakehata and Santos-Sacchi (Biophys J, 68, 2190-2197, 1995) for experimental details. TPB produced an increase in the OHC peak capacitance (Cm_{jk}) and shifted the voltage at peak capacitance (V_{jkcm}) to hyperpolarized levels. Washout reversed the effects Perfusion of 1 μ M TPB for two minutes caused an average increase in Cm_{jk} of 20.8 pF and V_{jkcm} shift of -9.3 mV (n= 17-22). With salicylate intracellularly (10 mM) to block OHC nonlinear capacitance, TPB treatment caused an increase in Cm _{pk} of 36.8 pF (n=16). This may indicate that either TPB reversed the effects of salicylate block or is more effective under these conditions. Preliminary results of mechanical response studies indicate little effect of TPB on OHC motility. TPB induced a voltage dependent capacitance in supporting cells whose characterisetics were similar to those of the OHC, but no indication of mechanical responses were noted. TPP* similar of tools of the OFC, but no indication of international responses were noted. Fig. (0.5-3 mM) did not change $Cm_{\rm piv}$ but did shift $V_{\rm picm}$ to depolarized levels. The average shift was 34.7 mV (n=13). Preliminary mechanical response studies indicate that TPP enhanced OHC motility and shifted its voltage dependence. These results indicate that OHC mechanical responses are not simply related to quantity of nonlinear charge moved

ROLE OF ION CHANNEL PHOSPHORYLATION IN OUTER HAIR CELL FUNCTION. <u>D.J. Jagger and J.F.Ashmore</u>*.Dept. of Physiology, School of Medical Sciences, University Walk, Bristol, BS8 1TD, UK.

Voltage-dependent ion channels play a significant role in the generation of the outer hair cell (OHC) motility which is believed to power the cochlear amplifier. Such channels determine the receptor potential and the cell resting potential and consequently set the contribution of OHCs to cochlear mechanics. We have been investigating long term channel regulation using whole-cell patch clamp recordings from isolated OHCs from the guinea-pig cochlea and in particular the hypothesis that channel phosphorylation can modulate whole cell currents in OHC's.

Bath application of 10 µM okadaic acid (OA) reversibly enhanced (by up to 40%) an outward K+ current (measured at 0 mV) and an inward current (measured at -120 mV) suggesting that the underlying currents are regulated by a protein phosphatase. 10 nM OA gave similar results. This identifies phosphatase 2A as one enzyme involved (Biochem. J. 256:283-290, 1988). These effects of OA were also observed when pipette K+ was replaced by Cs+ suggesting that one target current is I_{Kn} , a low voltage-activating potassium current (J.Physiol. 448, 73-98 1992). In order to reduce K^+ currents further the cells were dialysed with a Na $^+$ based pipette solution. In 4 out of 10 cells exposure to OA reduced the amplitude of the residual inward current (at -60 to -80mV), suggesting that the OHC cation current is downregulated by phosphorylation.

The data show that OA has distinct effects on the different ionic currents present in OHCs and that the channel phosphorylation state may have a significant influence on OHC force generating mechanisms.

THE VOLTAGE-DEPENDENT CAPACITANCE FUNCTION OF THE OUTER HAIR CELL HAS MEMORY J. Santos-Sacchi*, Seiji Kakehata and Shin Takahashi. Sections of Otolaryngology and Neurobiology, Yale Medical School, New Haven. CT 06510.

The outer hair cell (OHC) from the mammalian organ of Corti possesses a bell-shaped voltage-dependent capacitance function., which reflects the activity of membrane bound voltage sensors associated with membrane motors that control OHC length. The voltage at peak capacitance (V_{pkcm}) which corresponds to the voltage at maximal mechanical gain of the OHC is affected by a variety of treatments, including membrane stress and lanthanides. Here we report that initial voltage conditions affect pkem. OHC capacitance or nonlinear gating charge movement was evaluated under whole cell voltage clamp, after blocking ionic conductances (see Kakehata and Santos-Sacchi, Biophys J, 68, 2190-2197, 1995 for experimental details). In the present experiments, capacitance or gating charge was evaluated following prepulses of variable duration and/or magnitude. Prepluses to negative voltages shift V_{pkcm} to depolarized levels. The change in V_{pkcm} across the prepulse (1 sec duration) range of -150 to 50 mV is sigmoidal, with the magnitude of V_{pkcm} shift being about 10-15 mV (n=4). The greatest rate of shift is near the OHC's normal resting potential of -70 mV. The effect depends on the duration of prepulse, and is essentially absent below 30 ms duration. Recovery from prepulse effects appears on the same time scale as onset. We are currently working on determining the mechanism of this phenomenon. Nevertheless, these results indicate that the motility of the OHC may be dynamically modulated by factors which affect the resting potential in vivo. For example, the slow time course of efferent activation of the OHC would cause not only a hyperpolarization of the OHC, but a depolarizing shift of the motility function. The consequences of both actions would tend to reduce the gain of the cochlear amplifier. (Supported by NIDCD grant # DC00273 to JSS)

COCHLEAR DOPAMINE RECEPTORS: cDNA QUANTITATION AND IMMUNOHISTOCHEMISTRY. A.A. Karadaghy¹, M.J. Drescher¹*, J.S. Hatfield³ and D.G. Drescher^{1,2}. Lab. of Bio-otology, Depts. of ¹Otolaryng. and ²Biochem., Wayne State Univ. Sch. of Med., Detroit, MI 48201; and ³Veterans Admin. Med. Center, Allen Park, MI 48101.

Previous investigations have demonstrated that dopamine is present in the cochlea where it may function as an efferent neurotransmitter (Jones et al., Hearing Res. 30: 33-38, 1987; Gil-Loyzaga and Pares-Herbute, Devel. Brain Res. 48: 157-160, 1989; Drescher et al., Soc. Neurosci. Abstr. 20: 972, 1994). In the current study, expression of dopamine receptor isoforms was examined in the mouse cochlea and brain by RT-PCR analysis and nucleotide sequencing, utilizing specific primers. Cochlear cDNA corresponding to dopamine $D_{2(long)}$ and D_3 receptors was amplified, whereas cDNA for D_{1A} , D_{1B} , $D_{2(short)}$, and D_4 receptors was not detected. Utilizing quantitative competitive PCR analysis, the relative levels of dopamine receptor transcripts (per total RNA) were found to be 0.002, 0.014, 0.016, and 1.000 for $D_{2(long)}$ cochlea, D_3 cochlea, D_3 brain, and $D_{2(long)}$ brain, respectively. Localization studies of D_2 receptor-like immunoreactivity in rat cochleas were performed utilizing a rabbit polyclonal antibody to a rat D_2 receptor peptide (Chemicon). Fixed cochleas were decalcified, embedded in parafffin, and the deparaffinized sections were blocked, reacted with primary antibody, and visualized with biotinylated secondary antibody and streptavidin-peroxidase-diaminobenzidine (Vectastain). Reaction product was found in a discrete region below the inner hair cells. Taken together, these results are consistent with the presence of dopaminergic lateral cochlear efferents targeting cochlear receptors of the D_2 subfamily, and provide key evidence necessary to establish that dopamine is a neurotransmitter in the auditory inner ear. MEASURING MECHANICALLY AND ELECTRICALLY EVOKED RESPONSES IN THE ORGAN OF CORTI. D.C. Mountain¹¹, K.D. Karavitaki¹, R.C. Naidu¹ and A.R. Cody² Boston University¹, Hearing Research Center, Boston, MA 02215, The University of Queensland², St. Lucia, 4072 QLD, Australia.

The electromechanical characteristics of outer hair cells (OHC) are believed to significantly enhance hearing sensitivity in the mammalian cochlea. We address this issue by studying the motion of the organ of Corti (OC) in the excised gerbil cochlea in response to mechanical and electrical stimuli.

Point stiffness of the cochlear partition was determined by measuring the restoring force generated in response to a sinusoidal displacement. The measurements were performed using a piezoelectric force probe. The preparation was mounted on the stage of an inverted microscope so that the measurement location could be simultaneously viewed from the opposite side using a CCD camera. Images from the camera were processed off-line to study OC deformation. Data obtained from the top and bottom sides of the OC indicate that the stiffness of the pillar cell region is significantly greater than that of the OHC region.

Electrically-evoked micromechanical movements of the OC were elicited by delivering AC current near the scala vestibuli of the cochlear turn of interest using a low impedence glass electrode. The return electrode was placed toward the modiolus near scala tympani of the following turn. Motion synchronized to the stimulus frequency was captured using stroboscopic illumination. Images at specific stimulus phases for all frequencies were collected using a CCD camera and digitized. Animations of the observed motion were created for each stimulus frequency. Fourier analysis was used to estimate the magnitude and phase of motion at each frequency. The magnitude of the electrically stimulated motion was greater in the OHC region reaching up to 1.4 um peak-to-peak OHC length change in the apical turn.

Based on the data from both experiments we conclude that the pillar cells mechanically isolate the IHC from the OHC. This work was supported by NIDCD.

HYPERPOLARIZATION-ACTIVATED CURRENT IN GUINEA PIG SPIRAL GANGLION NEURONS. Chu Chen*, Kresge Hearing Research Lab., Dept. Of Otorhinolaryngology, LSU Medical Center, New Orleans, LA 70112.

The ionic mechanisms underlying relaying and encoding of auditory signals in primary afferent nerve fibers are not clear. In heart, a cationic inward current activated upon hyperpolarization (L), called the pacemaker current, plays a dominant role in diastolic depolarization that elicits the spontaneous firing in sinoatrial node cells and Purkinje fibers. In the central neurons, I, is believed to provide the pacemaker depolarization during spontaneous rhythmic firing. The purpose of the present study was to determine whether such an anomalous rectification is present in mammalian spiral ganglion neurons (SGNs). The experiments were performed in SGNs acutely isolated from adult guinea pig cochlea using the whole-cell patch-clamp technique. A large inward current was seen in response to hyperpolarizing steps negative to the resting membrane potential. The current activation and deactivation showed voltage-and time-dependence. The activation curve derived from tail currents was fitted to the Boltzmann equation. The current demonstrated no inactivation and was reversibly blocked by 1 mM Cs. Results suggest a hyperpolarization-activated inward current exists in SGNs. This current may contribute to the membrane depolarization during firing of the afferent nerve fibers.

4-AMINOPYRIDINE EFFECTS ON COCHLEAR SUMMATING POTENTIALS IN THE GUINEA PIG. M. G. van Emst*, S. F. L. Klis and G. F. Smoorenburg. Lab. of Exp. Audiology, Utrecht University, Utrecht 3584 CX, The Netherlands.

Sound-evoked DC receptor potentials in cochlear hair cells, and the associated extracellular DC potential known as summating potential (SP), are due to nonlinearities in the mechanoelectrical transduction chain. Voltage- and timedependent K+ channels sensitive to 4-aminopyridine (4-AP), which have been found in the basolateral membrane of both inner hair cells (IHC) and outer hair cells (OHC), might contribute to these nonlinearities. We perfused the perilymphatic spaces of the guinea pig cochlea with the K+ channel blocker 4aminopyridine (4-AP). Sound-evoked (2-12 kHz) intracochlear potentials were recorded from the basal turn of both scala vestibuli and scala tympani. Bidirectional frequency- and level-dependent effects of 4-AP on the magnitude of the SP were found. In both scalae a decrease in SP was found for low and moderate levels of 8 and 12 kHz stimuli where the SP presumably depends mainly on contributions from basal turn IHCs. The decrease in SP in both scalae indicates that 4-AP prevented the 4-AP sensitive K+ channels in the IHC membrane from increasing their conductance, which normally could serve to prevent excessive depolarizations of the membrane during stimulation and quicken repolarization after stimulation. In both scalae an increase in SP was found for high levels of 8 and 12 kHz stimuli and all levels of 2 and 4 kHz stimuli where the SP is assumed to depend mainly on contributions from basal turn OHCs. Blocking the 4-AP sensitive K+ channels in the OHC may lead to an increase in SP because of membrane depolarization and subsequent mechanical alterations

REGENERATION OF HAIR-CELL TIP LINKS FOLLOWING CALCIUM-CHELATOR RUPTURE IN THE CHICKEN BASILAR PAPILLA. Y.-D. Zhao, E.N. Yamoah, and P.G. Gillespie.* Dept. Physiology, Johns Hopkins School of Medicine, Baltimore, MD 21205. Tip links are 5×150 -nm extracellular filaments that run from the tip of

Tip links are 5×150 -nm extracellular filaments that run from the tip of a stereocilium to its tallest neighbor's side, and are thought to be the gating springs that open and close transduction channels. Although previous experiments showed that tip links can be broken by calcium chelators (Assad *et al. Neuron* 7, 985-994; 1991), regeneration of tip links has not been investigated previously.

We broke tip links of newborn chicken basilar papillae with the calcium chelator BAPTA, cultured the papillae in serum-free M199 for 0-24 hours, then observed tip links using scanning electron microscopy. We took topview photomicrographs of hair bundles, and four individuals blindly counted tip links in normal and angled (60° from the mirror-symmetry axis) positions. Although BAPTA treatment climinated tip links, their numbers returned to control by 24 hours. The recovery curve was fit well by [A+B*(exp(1-t/t)^n)]. With n=1, the time constant for recovery was ~7 hours; fits were better with n=2 or 3, suggesting that two or three identical subunits may come together to form a tip link. After BAPTA treatment, angled tip links increased dramatically at 2 hours, then fell to 2-to 3-fold higher than control. Although cycloheximide did not block tip-link regeneration, indicating new protein synthesis is not required, the calcium ionophore ionomycin effectively blocked regeneration.

BAPTA treatment fully abolished mechanoelectrical transduction, yet

BAPTA treatment fully abolished mechanoelectrical transduction, yet transduction currents recovered after 24 hours in culture. Adaptation was nearly absent. These results show that tip links are dynamic structures. (Supported by the NIH and the Pew Foundation.)

POSTNATAL DEVELOPMENT OF VOLTAGE-GATED CONDUCTANCES IN TYPE I AND TYPE II HAIR CELLS OF THE MOUSE UTRICLE. A. Rusch and R.A. Eatock*. Otolaryngology, Baylor College of Medicine, Houston, TX 77030.

The mature vestibular organs of amniotes have two types of hair cell, I and II, which have different complements of voltage-gated channels. We report that in mouse utricles these differences arise during the first postnatal week. Whole-cell currents were recorded from 360 hair cells in utricular epithelia that were excised and either put into denervated organotypic culture or studied acutely between the day after birth, postnatal day (PD) 1, and maturity

on PD 1-3, all hair cells expressed a delayed rectifier, $g_{DR,II}$, and a fast inward rectifier, $g_{DR,II}$ had a mean half-maximal activation voltage (V_{half}) of -30 ± 2.7 mV (SD, n=35) and a mean maximal value (g_{max}) of 42 ± 24 nS. For g_{K1} , g_{max} was 4 ± 1.7 nS (n = 107) and V_{half} was -88 ± 5.3 mV (n = 5). 42% of hair cells also expressed a voltage-gated Na+ conductance, g_{Na}. Between PD 4 and 8, an increasing percentage of cells expressed a large delayed rectifier conductance, $g_{K,L}$ ($g_{max} = 73\pm42$ nS, n = 57), with a very negative and variable range of activation (V_{half} between -88 and -62 mV). $g_{K,L}$ is typical of mature type I, but not type II, hair cells. From PD 8 on, $g_{K,L}$ was $g_{K,L}$ is typical of mature type L, but not type Π , hair cells. From PD 8 on, $g_{K,L}$ was present in 65% of cells. $g_{K,L}$ and g_{Na} were not found in cells with $g_{K,L}$, implying that these conductances were lost as $g_{K,L}$ was acquired. Cells with $g_{K,L}$, also had a large delayed rectifier, $g_{DR,L}$ ($g_{max}=114\pm61$ nS, n=42), that resembled $g_{DR,H}$ but was less sensitive to external Ba^{ab} and 4-AP. Also beginning on PD 4, an increasing percentage of cells expressed a slow inward rectifier, g_h ($g_{max}=1\pm0.9$ nS, n=79, $V_{haif}=-101\pm5$ mV). By PD 8, 88% of cells without $g_{K,L}$ and 34% of cells with $g_{K,L}$ expressed g_{h} . Thus, hair cells in the neonatal mouse utricle express $g_{DR,H}$, $g_{K,L}$ and of the $g_{N,L}$ and of the $g_{N,L}$ and one time $g_{N,L}$ and a sometimes $g_{N,L}$ and sometimes $g_{N,L}$ and a sometimes $g_{N,L}$. These

 $g_{DR,l}$ and sometimes g_h , and the other with $g_{DR,l}$, g_h , g_h and sometimes g_{Na} . These developmental changes affect the cells' voltage responses to injected current. Supported by NIDCD grant DC02290.

CALCIUM TRANSIENTS IN HAIR CELLS: MATHEMATICAL MODELING OF CONFOCAL MICROSCOPY OBSERVATIONS Jaramillo*, S. Betarbet and J. D. Hall. Dept. of Physiology. Emory Univ. Sch. of Med., Atlanta, GA 30322

Emory Univ. Sch. of Med., Atlanta, GA 30322.

Hair cell synapses in the auditory and vestibular systems faithfully relay sensory information to the CNS. These synapses respond to graded receptor potentials by admitting Ca++ into the hair cell's basal pole, where most synaptic active zones are located. The purpose of this study was to develop a model for the dynamics of Ca++ inside the hair cell, following a depolarizing stimulus. We monitored the activity of Ca++ with the help of the Ca-sensitive dye Fluo-3. The dye was introduced into the cell either through the whole cell recording pipette or by using the membrane permeant form. introduced into the cell either through the whole cell recording pipette or by using the membrane permeant form, and fluorescence was recorded with a confocal microscope in the line-scan mode. To model the dynamics of intracellular Ca++ near an active zone we consider the phenomenon as a diffusion-reaction of Ca++ from 80 point sources into the cell. Three species diffuse and react concurrently, Ca++, a buffer and a Ca-buffer complex. Cellular volume is divided into "cells" of a given size. The cells at the membrane surface which surround the point sources are allowed to integrate the incoming current and thus develop an elevated Ca++
concentration when the channels are open. A three
dimensional solution of this problem accounts for the
observed Fluorescence vs. Ca++ current relationship, as well as for the fluorescence rise-time, time course, decay-time, and relative intensity. Supported by NIDCD Grant DC02235.

FINITE ELEMENT MODEL OF UTRICULAR CILIARY BUNDLES IN A TURTLE, Trachemys (Pseudemys) scripta. <u>I.R. Cotton¹, I.W. Grant¹, and E.H. Peterson². ¹Dept. Engineering Science & Mechanics, Virginia Polytechnic Inst., Blacksburg, VA 24061, ²Neurobiology Program,</u> Ohio U., Athens, OH 45701.

Ciliary bundles in the turtle utricle exhibit orderly differences in structure. We are using finite element analysis (FEA) to explore how these structural differences may affect the hair cells' mechanical characteristics. This report describes a 3-dimensional model of type II hair cells on the medial (neural) side of the striola. These mechanoreceptors have 4-6 columns of cilia with 9-13 cilia per column. Maximum ciliary heights are short (2-4 μ m) relative to the kinocilium (\leq 10 μ m). Ciliary heights increase systematically with nearness to the striola.

We took dimensions and geometry of ciliary bundles from light (DIC) and electron micrographs of turtle utricle, and we estimated material properties of stereocilia, kinocilium, and connecting links from the literature. Stereocilia were modeled as transversely isotropic using Timoshenko (shear deformable) beam theory so that during bundle deflection their internal structure exhibits significant shear as described experimentally (Tilney et al., 1983). Force was applied to the tip of the 9 µm kinocilium.

The stiffness of a representative ciliary bundle (see figure) was 1.4 X 10⁻⁴ N/ m, which is within the range of stiffness values observed experimentally (Szymko et al., 1992)

POSTNATAL MORPHOLOGICAL DIFFERENTIATION OF TYPE I AND TYPE II HAIR CELLS OF THE MOUSE UTRICLE. A. Lysakowskit*, A. Rüscht and R.A. Eatockt. Anatomy & Cell Biology, University of Illinois, Chicago, IL 60612† and Otolaryngology, Baylor College of Medicine, Houston, TX 77030 ‡

The mature vestibular organs of amniotes have two types of hair cell, I and II, upon which afferent neurons make calvx and bouton terminals, respectively. Although the afferent terminal has been the primary criterion for classifying cell type, the two types also differ in secondary attributes. We have developed criteria, which include stereociliary and mitochondrial diameters, nuclear location and heterochromatin pattern, for classifying cell type in developing mouse utricles before calyx formation is complete Utricular epithelia were fixed *in situ* on postnatal day (PD) 0 (birth), 4, 7, 10 and 28. We studied one sample each from 2-3 animals at each age; each sample comprised 32 consecutive ultrathin sections cut from the center of the epithelium. We classified each cell in a sample as a supporting cell or one of the following kinds of hair cell: type I, type II, immature or undefined, and counted all cells in each class

At PD 0, cell division is almost complete (Ruben, Acta Otolaryngol. Suppl. 220, 1967). 17% of hair cells were immature, with features that appeared transitional between supporting and hair cells. 16% were type II. 33% were type I: two-thirds of these bore immature, partial calvees and the remainder were identified by secondary attributes. 34% of hair cells were not clearly in one of the other classes (undefined). The striolar region was more advanced than the extrastriolar region. By PD 4, 36% of hair cells bore partial or full calvees, and only 2% had type I secondary attributes but no calvx. Complex calvees were first seen after PD 4. By PD 28,90% of hair cells could be typed as I (63%) or II (27%). 1% were immature and 9% were undefined

Some utricles were put into denervated organotypic culture on PD 1 and fixed 3, 6 and 9 days afterwards. As there were no calvees, we used the secondary attributes to classify cell type. Similar cell types were present and differentiation followed a similar time course to that in vivo. (Supported by NIDCD grants DC02290 and DC02521.)

PLASMA-MEMBRANE CALCIUM ATPASE MAINTAINS A VERY LOW STEREOCILIARY CALCIUM CONCENTRATION. R.A. Dumont, E.N. Yamoah, E.A. Lumpkin[†], A.J. Hudspeth^{†*}, and P.G. Gillespie. Dept. Physiology, Johns Hopkins School of Medicine, Baltimore, MD 21205; [†]Rockefeller Univ., New York, NY 10021.

Ca²⁺ entering stereocilia through open transduction channels imposes a significant load on hair-bundle Ca²⁺-control mechanisms. Previous results demonstrated expression of the plasma-membrane Ca²⁺-ATPase (PMCA) by cochlear hair cells (Crouch & Schulte, *Hearing Res.* 92, 112; 1995). Using the 5F10 antibody, we find that bulfrog saccular stereocilia also possess large amounts of PMCA, some concentrated at stereociliary tips. Triton X-100-soluble, calmodulin-binding bundle proteins of 145 and 170 kD are precipitated with 5F10; their abundance suggests that PMCA is present at a density of ~2000 μm⁻².

Measurements with a vibrating Ca²⁺-selective electrode show that hair bundles, but not cell bodies, extrude substantial amounts of Ca²⁺ at rest. From hair cells clamped at -80 mV and dialyzed with Cs⁺ and with Cl⁻ at a concentration similar to that externally, we observe a transduction-activated outward current of ~10 pA. This current disappears when extracellular Ca²⁺ is replaced with Sr²⁺ or when cells are dialyzed with vanadate. These data suggest that the outward current originates from electrogenic PMCA pumps, whose density is ~1600 μm⁻².

Vanadate and ADPβS, inhibitors of PMCA, increase the resting Ca²⁺ elevation, modulations of Ca²⁺ concentration due to influx through open transduction channels can no longer be visualized. These results indicate that PMCA plays a major role in maintaining low bundle Ca²⁺ levels

transduction channels can no longer be visualized. These results indicate that PMCA plays a major role in maintaining low bundle Ca²⁺ levels. (Supported by the NIH, HHMI[†], and the Pew Foundation.)

VOLTAGE-GATED CURRENTS IN HAIR CELLS OF THE TURTLE POSTERIOR CRISTA. A. M. Brichta†*, A. Aubert ‡, J. M. Goldberg and R.A. Eatock‡ Otolaryngology† and Pharm. Physiol. Sci.§. Univ. of Chicago, Chicago, IL 60637 and Otolaryngology, Baylor Coll. Med., Houston, TX 77030‡.

The voltage-gated currents of hair cells isolated from the turtle posterior crista were studied with the whole-cell tight-seal method. Most hair cells were classified as type I or type II by their morphology. The goals were to determine if type I hair cells have a distinctive outwardly rectifying current, I_{K,L}, and to compare the electrophysiology of type II hair cells from the central zone and from the parts of the peripheral zone near the torus and near the planum. The last comparison is of interest as afferents innervating the two parts of the peripheral zone differ in their discharge properties.

IKL is recognized as an instantaneous current that is evoked by voltage steps from a holding potential of -65 mV and that deactivates negative to -100 mV. Cells without $I_{K,I}$ had outward rectifiers that activated only above -55 mV. $I_{K,I}$ was present in >75% of type I hair cells, but in <20% of type II hair cells. $I_{K,I}$ activated above -75 mV and was almost fully activated by -50 mV. Activation was sigmoidal and slow. The mean reversal potential was -81 mV, close to E_K. Maximal conductances were large, averaging 40 nS. A second outward rectifier was also present in type I hair cells. Like $I_{K,L}$ it had slow activation kinetics and large maximal conductances. Unlike $I_{K,L}$, it activated only above -55 mV. In these respects, type I hair cells from the turtle posterior crista resemble those from other vestibular organs

Type II hair cells had outwardly rectifying currents activating positive to -55 mV and two inward rectifiers (I_h and I_{K1}). Type II hair cells from different regions differed in three ways: 1) Activation of outward rectifiers was slower for central than for peripheral hair ceils. 2) Inactivation of outward rectifiers was fastest near the planum. 3) IKI was largest near the torus. The differences in voltage-gated currents from the planum and torus were too small, however, to explain the large differences in discharge properties of afferent fibers innervating the two regions. (NIDCD grant DC 02058)

MODELING OF SYNAPTIC VESICLE CAPTURE BY THE SYNAPTIC BODY IN FROG SACCULAR HAIR CELLS. <u>D. Lenzi*</u>, and <u>W.M. Roberts</u>. Institute of Neuroscience, University of Oregon, Eugene OR 97403-1254.

Afferent synapses in hair cells from the sacculus of Rana pipiens belong to the class of ribbon synapses. They feature a 400 nm spherical synaptic body that hovers above the active zone, covered by a shell of 40 nm vesicles. Since the synaptic body is of unknown function, we tested the idea that it increases the surface area with which the synapse captures vesicles from the cytoplasm. We compared the steady-state rate at which vesicles could reach the active zone, with and without a 400 nm synaptic body, assuming that diffusion to the active zone or synaptic body was rate-limiting, and that the entire surface of the active zone or synaptic body was absorbent. We modeled a 7 μm radius hemisphere of hair cell cytoplasm, bordered by the plasma membrane, and centered over a 300 nm active zone. The concentration at the active zone or synaptic body was set to zero, and that at the far boundary-to a constant. The cytoplasm was parsed into 50 nm x 1 degree compartments (polar coordinates), and the steady-state concentration of vesicles in each compartment calculated by iteration. The computation was checked against the analytical solution (without the synaptic body), and converged independently of the starting concentrations. The rate of vesicle absorption by the active zone or synaptic body was computed from the concentrations in the adjacent compartments, and was found to be four fold greater with the synaptic body present, showing that the synaptic body can improve vesicle capture. Although this ratio is independent of a vesicle's diffusion coefficient, it is smaller than the 10 fold ratio in surface areas available for vesicle binding. However, the diffusionlimited rates far exceeded the maximal rate of vesicles release observed in physiological experiments, suggesting additional roles for the synaptic body Supported by NIH grant NS27142 to WMR, and a DRF grant and MDA postdoctoral fellowship to DL.

NON-L-TYPE ALPHA-1 CALCIUM CHANNEL SUBUNIT IN A VERTEBRATE HAIR CELL SHEET. S.A. Sheikhali¹, A.A. Karadaghy¹, G.E. Green¹ and D.G. <u>Drescher ^{1,2}*</u>, Lab. of Bio-otology, Depts. of ¹Otolaryng. and ²Biochem., Wayne State Univ. Sch. of Med., Detroit, MI 48201.

We have previously presented evidence for the expression in teleost saccular hair cells of both an α_{1D} -like (L-type) voltage-gated calcium channel subunit message and a non-L-type α_{1} message, the latter with similarities to both α_{1A} (P-type) and α_{1B} (N-type) sequences (Green et al., Assoc. Res. Otolaryngol Abstr. 19: 151, 1996). Bullfrog saccular hair cells have been reported to utilize L-type and non-L-type calcium channels as well (Su et al., Hearing Res. 87: 62-68, 1995). To further elucidate the genotype of the α_{1} pore-forming subunit of the non-L-type calcium channel in the teleost saccular hair cell, we have utilized RT-PCR and nucleotide sequencing.

Saccules from rainbow trout were rapidly removed and placed in saline at 2 °C. Under magnification, hair cells were dissected as an intact sheet and homogenized in 4M guanidinium thiocyanate solution. Total RNA was obtained by phenol-chloroform extraction and treated with DNase prior to reverse transcription. Resulting cDNA was amplified by PCR employing primers designed to the doe–4 α_1 sequence of the marine ray (Horne et al., Proc. Natl. Acad. Sci USA 90: 3787–3791, 1993), a homolog of the mammalian α_{1B} calcium channel subunit gene. A targeted 3.0-kb product was obtained which was partially sequenced. A sequence representing the intracellular loop between domains II and III of the voltage–gated calcium channel α_1 subunit was found to be most homologous to the α_{1B} (N–type) gene sequence. The above results confirm that the teleost saccular hair cell expresses calcium channel mRNA corresponding to a non–L–type α_1 subunit, and suggest that this form is an N–type homolog. (Supported by NIH Grant RO1 DC00156 and T32 DC00026.)

IONIC MECHANISMS ASSOCIATED WITH THE DISCHARGE REGULARITY OF VESTIBULAR AFFERENTS NEURONS. A.Flores, J.Cebada and E.Soto*. Dept. de Fisiol, Biofis. y Neurosc. CINVESTAV-IPN, Mexico, D.F. Facultad de Medicina e Instituto de Fisiología. BUAP, Puebla, México.

Vestibular afferent neurons differ in their discharge regularity, which is determined by the coefficient of variation (CV) of interspike intervals. It was found (Manjarrez and Soto, unpublished results) that the correlation between the slope of action potential repolarization and CV was positive (r=+0.75) for the most irregular afferents (CV>1) and negative (r=-0.30) for the intermediate afferents (0.5<CV<1). In order to explain which are the ionic mechanisms involved in these correlations, we have examined the effects of 4AP and TEA on the slope of repolarization and CV, and studied the outward ionic currents present in these neurons. Two methods of conventional recording in an in vitro preparation of the semicircular canal ampullae of axolotl (Ambystoma tigrinum) were employed: 1) intra-axonal recording of basal spike discharge of the afferent fibers, and 2) patch-clamp (whole-cell recording) in dissociated afferent neurons (Scarpa's ganglion). Using intra-axonal recordings (n=8) we have found that 4AP (0.1mM) or TEA (3mM) decreased the slope of repolarization in all the tested fibers. In the 4AP experiments the CV increased (0.65 to 1.30) and in TEA experiments decreased (0.94 to 0.42). These results suggests that the slope of repolarization is causally related to discharge regularity (CV) rather than merely correlated with it. Patch-clamp recordings of vestibular afferent neurons (n=9) indicated that there are two types of outward currents: 1) I_A (transient potassium current) and 2) I_K (delayed rectifier), which suggests that these currents possibly have an important role in determining the discharge regularity in vestibular neurons. Supported by CONACyT fellows 88420 (AF) and 91894 (JC) and grant 2133-N (ES).

Modulation of calcium and potassium channels in the mechanosensory hair cells from the statocyst of the Octopus, *Eledone cirrhosa* A. Chrachir⁴ and R. Williamson^{1,2} ¹MBA, Cliadel Hill, Plymouth, PL1 2PB, UK & ²Department of Biological Sciences, Univ. of Plymouth, Drake Circus, Plymouth, PL4 8AA, UK.

Cephalopods, such as sepia, squid and octopus, show a well developed and sophisticated control of balance, particularly during prey capture and escape behaviours. This control is mediated by mechanosensory hair cells in their statocysts. This equilibrium system receives a large efferent innervation that can depress or enhance the statocyst output and that has been shown to contain acetylcholine (Auerbach & Budelmann, Cell Tissue Res. 243, 429-436), noradrenaline (NA) and/or dopamine (DA) (Budelmann & Bonn, Cell Tissue Res. 227, 475-483). The aim of this study is to determine whether ACh and DA modulate the calcium currents (I_{ax}) and potassium currents (I_{Ax}, I_x).

Using whole cell patch clamp technique, Williamson (*J. Comp. Physiol. A* 177, 261-271, 1995) identified an inward calcium current, a transient outward current resembling the A-current (I_A) and a sustained outward current resembling the delayed rectifier (I_K) in statocyst sensory hair cells.

We now show that bath application of ACh reduces both the voltage-dependent, inward calcium current and the outward potassium currents in a dose dependent manner. Bath application DA increases the calcium current in a dose dependent manner and decreases the potassium currents in a dose dependent manner. No change in the time course of the currents was observed during these applications.

ACh and DA have been shown previously to modulate electrical coupling between some groups of statocyst hair cells, with ACh decreasing the coupling and DA increasing coupling. The observations reported here are consistent with the view that intracellular calcium levels act to modulate the electrical coupling and hence alter the sensitivity of the cells to mechanical stimulation. AUDITORY SYSTEMS: CENTRAL PHYSIOLOGY-FOREBRAIN

424.1

EFFECTS OF CENTRAL MUSCARINIC BLOCKADE AND INTERSTIMULUS INTERVAL ON HIPPOCAMPAL AUDITORY EVOKED POTENTIALS IN THE RAT. T.R. Gregg* and K.A. Campbell. Dept. of Psychology, Univ. of Delaware, Newark, DE 19716.

The auditory evoked field potential (AEP) recorded from microelectrodes targeted to dentate gyrus (DG) in 8 awake freely-moving rats displayed a sharp negativity (N1) at 34 ms after onset of a 1-s, 80-dB, 10-kHz tone. Interstimulus intervals of 1 s or less suppressed N1 amplitude.

Scopolamine (0.5, 1.0, 2.0, and 5.0 mg/kg, subcutaneous) suppressed N1 peak amplitude in the first hour after injection, in a non-dose-dependent manner. However, the time required for N1 amplitude to recover to control levels after injection was dose-dependent: at 3 h, recovery was complete at 0.5 mg/kg but still suppressed at 5.0 mg/kg. Control injections of methscopolamine did not affect N1; thus central, not peripheral, muscarinic blockade suppressed N1 amplitude.

Motor activity temporarily increased after scopolamine but not after methscopolamine. Motor activity can suppress AEPs, so scopolamine may have suppressed NI indirectly through the increase in motor activity. To test this possibility, AEPs were recorded in 4 anesthetized, isothermic, acutely-prepared rats. Preliminary data indicate that NI declined after scopolamine, suggesting that scopolamine's effect on NI may be due to a direct effect of scopolamine on auditory input to the hippocampus. THE EFFECT OF BRAINSTEM STIMULATION ON NEURONS OF RAT AUDITORY THALAMUS IN VITRO. <u>D. M. Mooney* and B. Hu</u>. Loeb Research Institute, Ottawa Civic Hospital, Ottawa, Ontario, Canada K1Y 4E9.

Non-auditory input from the midbrain reticular formation (MRF) to the medial geniculate body (MGB) mediates behavioural state-dependent changes in sensory signal processing and is believed to be mostly cholinergic. To examine the synaptic influence of MRF input on MGB neurons, brain slices preserving the MGB and efferent tracts of the MRF were employed. 50 µM of picrotoxin was continuously present in the bathing medium. Repetitive electrical stimulation of putative MRF efferents produced a slow afterdepolarization or sADP in 35 of 53 responding MGB cells. The sADP was associated with an increase in membrane conductance (3/4) by an average of 160%. The sADP was abolished by tetrodotoxin (4/4). It was not, however, blocked by a CNQX/(±)-AP-5 mixture (5 μM/50-200 μM) or by the metabotropic GluR blocker (S)4CPG (100-200 µM). Neither was it blocked by methylscopolamine (5-50 μM) or hexamethonium (500 μM), suggesting a noncholinergic, nonglutamatergic mechanism. In another 13 of the responding MGB cells, MRF efferent stimulation elicited a slow afterhyperpolarization (sAHP). The remaining 5 cells had mixed or varying responses. The neurotransmitters underlying the sADP and the mechanisms of the other responses remain to be defined. These data suggest that MRF efferents provide a noncholinergic, nonglutamatergic input to the rat MGB. Supported by grants from MRC of Canada and the Ontario Graduate Scholarship Program.

DISTRIBUTION OF NADPH-DIAPHORASE AND CYTOCHROME OXIDASE IN RELATIONSHIP TO FUNCTIONAL ORGANIZATION OF THE MEDIAL GENICULATE BODY IN GUINEA PIG. J. Syka, R. Druga, J. Popelár, E. Kvasnák, D. Suta (SPON: European Neuroscience Association) Institute of Experimental Medicine, Academy of Sciences, 142 20 Prague, Czech Republic

The detailed functional organization of the medial geniculate body (MGB) was

The detailed functional organization of the medial geniculate body (MGB) was studied in guinea pigs with morphological and electrophysiological methods. Animals anaesthetized with pentobarbital were perfused with aldehyde fixation, and sections through the hemispheres and brainstem were cut on a freezing microtome and processed for NADPH-diaphorase (NADPH-d) according to Scherer-Singler et al. (J. Neurosci. Meth., 9: 229, 1983) and for cytochrome oxidase (CyOx) according to Wong-Riley (Brain Res., 171: 11, 1979). In another group of guinea pigs anaesthetized with ketamine, the MGB was penetrated with a microelectrode and parameters of neuronal response to acoustical stimuli, such as the characteristic frequency (CF), Q₁₀ and latency were evaluated. The MGB in the enginee pig (e.g. in atherwise). and latency, were evaluated. The MGB in the guinea pig (as in other mammalian species) can be divided into primary ventral division and secondary divisions such as dorsal, medial and suprageniculate division. The histochemical staining for CyOx was most pronounced in the ventral division of the MGB (mainly in its basal part), while weaker CyOx activity was present in the secondary divisions of the MGB. Intensely suprageniculate divisions. The ventral division is tonotopically organized. During penetration of the electrode in the dorso-ventral direction, the characteristic frequencies of recorded neurons increased from low to high CF. The tonotopy of other divisions of the MGB is more complex and less expressed. The majority of neurons in the ventral division have narrow tuning curves, whereas many neurons in other MGB divisions are broadly tuned or respond with multiple frequency ranges. The onset type of response is present about twice as frequently in the ventral division as in secondary divisions. Several units localized throughout the MGB respond with two or three reverberating discharges with a period of 150-250 ms. Supported by grant 309/940/0735 of the Grant Agency of the Czech Republic.

EFFECTS OF TETRODOTOXIN ON AUDITORY AND VISUAL EVOKED POTENTIALS IN THE RAT. E.L. Moore*, D.J. Carter, and C.E. Kling. Neurotoxicology Branch, Pathophysiology Division,

U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010-5425

The consumption of puffer fish is the leading cause of tetrodotoxin poisoning and represents a significant public health threat in many parts of the world. Tetrodotoxin is a potent neurotoxin, which is known to block voltage-activated Na* channels, resulting in a reduction in action potential initiation. The present study was designed to examine possible central actions of sublethal doses of TTX using auditory and visual evoked potentials recorded from rats. Male, Long-Evans rats (250-350 grams) were anesthetized with sodium pentobarbital (42 mg/kg; i.p.) and implanted with recording electrodes. Electrodes were secured to the skull with dental acrylic. Animals were allowed to recover from surgery for approximately one week. Rats were restrained and placed in a sound attenuating chamber for recording brainstem auditory evoked potentials (BAEPs) or in front of a screen for pattern reversal visual evoked potentials (PREPs). All evoked of a screen for patient reversal visual evoked potentials (PAEE). All evoked potentials were recorded before and after injection of TTX (2, 4, or 8 µg/kg; i.p.). TTX decreased the amplitude and increased the latency of BAEP peak III (representing superior olivary complex activity). This is strong evidence of a specific central effect of the toxin, since peak I (representing the peripheral component of the BAEP corresponding to auditory nerve input) was unaffected. Significant increases in latency and changes in PREP peak amplitudes were found of the TTX vectors. New hopeage very found in BAEPs or DEPS print to TTX. after TTX exposure. No changes were found in BAEPs or PREPs prior to TTX administration or with saline controls. These results suggest that TTX, given at sublethal doses, impairs auditory and visual processing in a selective manner. In summary, auditory and visual evoked potentials appear to be sensitive tools for assessing central nervous system effects of TTX and may have possible diagnostic applications

424.7

TEMPORAL PROPERTIES OF STIMULI DETERMINE THE RATE OF RECOVERY FROM ADAPTATION IN THE AUDITORY CORTEX, H.W. Mahncke*. C.E. Schreiner, and M.M. Merzenich. Keck Center for Integrative Neuroscience, University of California, San Francisco, SF, CA 94143-0732 Most auditory cortical neurons respond to the onset of a stimulus with a burst of activity that subsides to substantially lower levels during the remainder of the stimulus. Recovery from this form of adaptation has not been closely examined to date; it bears important implications for the processing of temporally complex stimuli by the cortex. The goals of this experiment were (1) to measure the time course of recovery from adaptation in auditory cortical field A1, and (2) to determine if the recovery of excitability is dependent on the temporal structure of the conditioning stimulus.

course of recovery from adaptation in auditory cortical field A1, and (2) to determine if the recovery of excitability is dependent on the temporal structure of the conditioning stimulus.

We recorded multiple-unit activity from the auditory cortex of nembutal anesthetized rats and presented click trains of positive-going 250µs square waves at frequencies between 125pps and 500pps. Click trains of equal duration were interrupted by variable duration silent gaps. The onset response to the second click train was used as a measure of recovery from adaptation to the first train. At each recording site, responses to single and paired click trains at 125pps and none other frequency were recorded. Responses to the 125pps click trains were used to normalize across different recording sites and different animals.

We found that (1) a 100ms long 125pps click train required, on average, a 49±10ms (s.d.,n=43) silent gap for a subsequent click train to evoke 50% of the activity generated by the first train. (2) The recovery time from adaptation was dependent on the frequency of the click train; click trains of higher frequency yielded shorter recovery times. The recovery time relative to the 125pps case was a linear function of the inter-click interval of the conditioning click train with a slope of 4.3ms/ms. Control experiments demonstrated that the difference in recovery times between click trains of different frequencies could not be attributed to the differing number of clicks in either the conditioning or probe click trains. These effects may be related to a form of auditory psychophysical adaptation observed by Hafter and colleagues (Hafter and Buell, 1990) and suggest specific physiological mechanisms by which sequentially occurring stimuli can be segregated and integrated in auditory cortex. 424.4

THE SPATIO-TEMPORAL RESPONSES TO TWO-TONE STIMULATION IN GUINEA PIG AUDITORY CORTEX

K.Fukunishi*, R.Tokioka, N. Murai and T.Miyashita. Advanced Research Lab., Hitachi, Ltd., Hatoyama, Saitama 350-03 Japan

Spatio-temporal neural activities in response to tones as the simplest sound and vocalizations as complex sounds in the auditory cortex (field A) of guinea pig observed by optical imaging with dye have revealed a neural encoding structure that the coding of the complex sounds in the cortex temporally correlates to the dominant spectrum at each time of the onset phase. Here, neural responses to a sound synthesized from tone bursts are observed optically in the guinea pig auditory cortex and discussed

An optical recording system of 12 by 12 photo-diode array with voltage sensitive dye (RH795) and a high N/A and low noise microscope were used for measuring spatiotemporal neural response in the auditory cortex (field A) of anaesthetized animals. measured area was 3 mm in diameter with a spatial resolution of 0.05 mm². Simple sounds synthesized from tone bursts (rising time: 10 ms, plateau: 30 ms, falling slope: 10 ms) of, for example, 2 kHz and 9 kHz. Sound pressure levels were just above response thresholds. The responses in the cortex to the synthesized sound and each tone are compared. The tonotopical areas for 2 kHz are suited rostrally and caudally for 9 kHz as previously recorded. The response amplitudes for 2 kHz were larger than those for 9 kHz and the latency is shorter for lower frequencies than for higher ones. The response area for the synthesized sound covered over both tonotopical areas and the latency was entrained by the response to the lower frequency. The response area of the responses to the synthesized sound subtracted by the responses to either tone almost overlaps to the response area to another tone. The results that the tonotopical area is linearly additive to the tone stimulus supports the previous experiment regarding to the coding of the complex sound temporally by its spectral characteristics.

424.6

THE EFFECTS OF SUBCORTICAL LESIONS ON EVOKED POTENTIALS AND SPONTANEOUS HIGH FREQUENCY (GAMMA-BAND) OSCILLATING POTENTIALS IN RAT AUDITORY CORTEX, B. Brett* and D.S. Barth. Department of Psychology, University of Colorado, Boulder, CO 80309-0345.

Functional subdivisions of auditory cortex in the rat were identified based on the distribution of temporal components of the mid-latency auditory evoked potential (MAEP) recorded with a multichannel epipial electrode array. Spontaneous data collected from the same location exhibited spindle-shaped bursts of oscillations in the gamma-Spontaneous data collected from the same band (20-40 Hz) whose location and spatial distribution were similar to that of the MAEP complex in that the bursts were localized to primary and secondary auditory cortex, the principle targets of primary and secondary auditory cortes, the principles in thalamocortical projections. This suggested that the neural generators the secondary auditory cortes, the principles in the principles of these electrophysiological events may be similar. However, ablation of the medial geniculate nucleus (MG) of the thalamus revealed that while this nucleus is required for the generation of MAEPs, it is not required for the generation of spontaneous gamma-band oscillations. Ablation of subcortical cholinergic nuclei revealed that cholinergic input via the thalamus or the basal forebrain is not necessary for the generation of either MAEPs or spontaneous gammaband oscillations recorded in this study. These results indicated that there may be networks of cells in sensory cortical areas endowed with an intrinsic capacity to oscillate independently of sensory or cholinergic input, but that may be modulated by this input.

ANATOMY AND PHYSIOLOGY OF IDENTIFIED RAT AUDITORY CORTICAL NEURONS. B. J. Hefti* and P.H. Smith, Neuroscience Training Program and Dept. of Anatomy, University of Wisconsin, Madison, WI 53706

Cortical neurons have been classified based on anatomical and physiological features in rodent somatosensory, visual, and motor cortices, but the rat auditory cortex remains largely uncharacterized. We have begun to characterize neurons according to existing classifications primarily based on intrinsic firing patterns and responses to synaptic stimulation, and to correlate these properties with anatomical features. Using neurobiotin-filled sharp microelectrodes, we record intracellularly from neurons in an *in vitro* slice preparation. Auditory cortical cells respond to current injection in the three basic patterns described by Agmon and Connors (1992) for somatosensory cortex. Layer II-VI pyramidal cells can show regular spiking (RS) behaviour with little (RS1) or significant (RS2) spike frequency adaptation. Supragranular cells show predominantly RS1 responses, infragranular can be either. Lowering Ca++ has little effect on the initial rapid spike rate of RS1 or RS2 responses but eliminates the buildup of adaptation in RS2 units. Other pyramidal cells in layer V and deep layer IV show intrinsic burst (IB) responses with an intial rapid burst of 3 to 4 spikes followed by single spikes at regular intervals. In low Ca⁺⁺ the later single spikes were converted to multispike bursts. Cell bodies of IB cells tend to be larger than RS cells in these layers with thicker apical dendrites which extend to layer I, where they branch profusely. Fast spiking (FS) cells are rarely seen, scattered through the layers. In RS units, white matter (wm) shock stimulation could usually elicit an early epsp, a subsequent higher threshold depolarizing GABAA ipsp (at rest), followed by a long duration GABAB ipsp. For two RS cells, theta burst restly, intowed by a long database space for the stimulation of wm inputs elicited pathway-specific LTP. Layer I shock stimulation typically evoked a longer latency epsp and was less likely to activate inhibition. IB units could show large suprathreshold responses to either wm or layer 1 simulatio with little sign of inhibition. Supported by PHS grant RO1 DC-01999

MULTIPLE AUDITORY CORTICAL FIELDS IN THE RAT. N. Doron, J.E. Ledoux and M.N. Semple*. University, New York, NY 10003. Center for Neural Science, New York

Previous anatomical studies have shown that rat auditory cortex is composed of a central core and a diffuse surrounding belt. The core is innervated heavily by the primary thalamic relay (the ventral medial geniculate) and the belt receives its predominant subcortical input from non-primary auditory areas. Physiological studies have demonstrated a single tonotopic field identified as primary auditory cortex (AI), but it is unclear whether additional tonotopic fields are contained within the core. Nothing is known about the functional properties of the belt. We studied responses of single neurons recorded extracellularly throughout core and belt areas of auditory cortex in the anesthetized Sprague-Dawley rat. Acoustic stimuli (tones, noise, and temporal modulations) were delivered dichotically via sealed systems. Consistent with previous findings, AI was characterized by an anterior to posterior tonotopic progression from high (>40 kHz) to low (<1 kHz) frequencies. A frequency reversal at the posterior border of AI marked entry into a second core tonotopic region (field P) with progressively higher frequencies encountered further posteriorly. Frequency tuning was relatively sharp in both fields. In contrast, responses in the ventral belt were often broadly tuned or unresponsive to tones, with no clear indication of tonotopic order. Broadband noise was an effective stimulus throughout rat auditory cortex, but bandpass noise was often even more effective in belt regions. Although a few neurons in AI responded to stimulus offset, discharge patterns in all cortical areas were more typically transient at stimulus onset, with shortest minimum latencies in AI. In all areas, response magnitude was most commonly a monotonic function of stimulus level, and most neurons were binaurally influenced. The discovery of multiple auditory cortical fields in the rat is consistent with auditory cortical organization in other mammals. Supported by a grant from the W. M. Keck Foundation. and by PHS grants R37MH38774. K02MH00956 & R01MH46516.

THE EFFECT OF PRIMARY AND SECONDARY AUDITORY CORTICAL LESION ON TEMPORAL AUDITORY PROCESSING IN RATS. M.G. Clark, Y.H. Liu, and T.M. Perney, P. Tallal, R.H. Fitch*. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102.

Functional localization of complex auditory processing to primary and secondary auditory cortices of the human brain is well established. Damage to these regions is known to produce severe deficits in speech perception and, to a lesser extent, non-linguistic auditory temporal processing. Moreover, in cats and monkeys it has been demonstrated that unilateral and bilateral ablation of auditory cortex produces severe impairments in certain aspects of auditory discrimination, including the ability to discriminate temporally patterned stimuli. Additionally, monkeys with auditory cortical ablation exhibit deficits in discriminating both human speech sounds and species-specific vocalizations. In contrast, little data exists regarding functional deficits following auditory cortical ablation in a rodent model. Most studies of which we are aware employed relatively low-level tasks (e.g., sound localization). It has been hypothesized (Kelly, 1990) that a temporally complex auditory task would elicit a deficit following such lesions. We trained adult male rats in an operant conditioning paradigm to discriminate between temporally patterned tone sequences, e.g. high-low vs. high-high, low-low, and low-high. The rats were randomly assigned to one of four lesion treatment groups: left (n=5), right (n=5), bilateral assigned to one of four tesion treatment groups: left (n=3), fight (n=3), olateral (n=4) and sham (n=5). Following aspiration lesion surgery and recovery, the rats were retested. Prior to surgery, all animals were able to discriminate the temporally patterned stimuli (p<.05). Post-surgically there was no significant change in the discrimination abilities of the shams, but lesion subjects performed near significantly worse than shams (p=.054). Furthermore, shams showed significant discrimination post-surgically (p<.05), while lesion subjects did not. These results confirm that the auditory cortex of the rat is functionally specialized for complex temporal auditory

SPATIO-TEMPORAL PATTERNS OF EVOKED POTENTIALS IN FERRET PRIMARY AUDITORY CORTEX. <u>A.L. Owens</u>, <u>H.</u>

FERRET PRIMARY AUDITORY CORTEX. A.L. Owens, H. Versnel*, S.A. Shamma. Institute for Systems Research, University of Maryland, College Park, MD 20742.

The work presented here is motivated by the question of how the topographic distribution of activity in primary auditory cortex (AI) varies temporally during presentations of non-stationary sounds. To did togst this group auditory corted a patroity. (Fig.) and varies temporally during presentations of non-stationary sounds. To address this question auditory evoked potentials (EPs) are measured at the surface of AI in barbiturate-anaesthetized ferrets with a flexible electrode array. The array consists, of 25 recording electrodes arranged in a square grid with 200 micron spacing between sites (Owens, A. et al, Journal of Neuroscience Methods, (58) 209-220, 1995). EPs are recorded in response to tones, clicks and frequency-modulated (FM) sweeps. Responses to pure tones determine the range of frequencies represented within the recording area. FM sweeps are generated by sweeping a tone frequency across area. FM sweeps are generated by sweeping a tone frequency across this range of frequencies. The frequency is swept both upwards and downwards at rates ranging from 30 octaves/s to 300 octaves/s. Spatial maps presented in video format are generated at 1-2 ms intervals during the sound presentation. The results indicate a temporal progression of evoked activity along both the tonotopic and isofrequency axes which depends on sweep rate and direction.

RESPONSES TO SOUND MOTION OF SINGLE NEURONS IN THE RAT PRIMARY AUDITORY CORTEX, D. E. Doan and J. C. Saunders*. Departments of Bioengineering and Otorhinolaryngology: Head and Neck Surgery, University of Pennsylvania, Philadelphia, PA 19104.

Single-unit recordings were made from the left primary auditory cortex of Long Evans rats. Computer synthesized sounds were generated by dynamically manipulating doppler shifts and interaural phase and intensity differences. Each sound mimicked motion of a sound source along one of 4 radial or 3 circumferential sound source trajectories in the front contralateral quadrant of the horizontal plane. In addition, simulated motion along each trajectory was presented at one of two speeds, and either in forward or reverse direction. Sounds were presented bilaterally via hollow ear bars and the total battery of 28 different waveforms (7 trajectories x 2 speeds x 2 directions) was repeated five times for each cell at its characteristic frequency. The activity of the cell was recorded throughout.

Preliminary results from 10 animals indicate that about 20% of all cells encountered showed a statistically significant increase in activity for one of the 28 conditions. This suggests that some cells within the rat primary auditory cortex respond not only to a preferred auditory spatial location, but that they also respond preferentially to a particular direction and speed of motion within that spatial extent.

EFFECTS OF DIFFERENT ANESTHETICS ON THE RESPONSES TO BROADBAND SOUNDS IN THE FERRET PRIMARY AUDITORY CORTEX AND BAIND SOURDS IN THE PERKET FRIMMALT ADDITION TO GREAT AND INFERIOR COLLICULUS. AZ.Kohn. D.A.Depireux and S.A.Shamma*.

Institute for Systems Research, University of Maryland, College Park, MD 20742.

We have previously shown that neuronal responses in Primary Auditory Cortex

(Al) of barbiturate-anesthetized Ferret to broad-band sounds are fully characterized by their responses to ripples, i.e. sounds whose spectral envelope is a sinusoid on a by their responses to rippies, i.e. sounds whose spectral enveripe is a situation of log frequency axis. This is analogous to the local spatial frequency analysis used in visual cortex, with ripple spectrum, stationary or moving, corresponding to visual gratings. We have also previously presented Inferior Colliculus (IC) recordings in the Pentobarbitol anesthetized Ferret. To understand the effects of anesthetics on the Pentobarbitol anesthetized Ferret. To understand the effects of anesthetics on the response characteristics, we have repeated our experiments using Ketamine and Xylazine as anesthetics. Our results show that, in AI, neurons respond essentially as before, i.e., maximally to ripples of specific ripple frequency, specific phase for stationary ripples, and specific ripple velocity for moving ripples. Some of the tuning characteristics are slightly different under Ketamine; e.g., ripple frequency tuning tends to be lower in the Ketamine preparation, possibly corresponding to a less effective inhibition of the inhibitory sidebands of the response area. Also, whereas under barbiturates, IC cells tend to be tuned to ripples with the lowest ripple frequency we used, or about .2 cycles per octave, under Ketamine we see more of a variety of tunings to higher ripple frequencies. Other response characteristics, including temporal properties of cells, will be presented.

Single units also exhibit periodicities in their responses that did not correspond to the spectral envelope of the stimulus, but rather to interactions between component tones present within the response area of the cell. While this substructure is common in IC recordings, it is uncommon in cortical ones for the barbiturate preparation, and present in 50% of recordings in the Ketamine preparation

INHIBITION AND DISINHIBITION OF AUDITORY CORTEX UNIT RESPONSES BY FORWARD MASKERS. L.M. Kitzes* Dept. of Anatomy & Neurobiology, University of California Irvine, Irvine, Ca 92717

Acoustic stimuli commonly occur in quick succession, providing both synchronous input to the two ears and sequential stimulation of each ear. Relative to stimulation of one ear, interactions between the activity evoked by synchronous stimulation of the two ears can result in facilitation, suppression or in a response when stimulation of either ear alone is totally ineffective. The response to a given stimulus can suppress the response to a subsequent stimulus. Such forward masking of unit responses in auditory cortex has been studied using only monaural stimuli. The present study assessed reciprocal influences between binaural interactions and forward masking on unit responses in primary auditory cortex of pentobarbital anesthetized cats. Stimuli consisted of two pairs of 50-ms duration binaural tonal stimuli, at the CF of the unit, separated by a 50-ms interval.

For units excited by stimulation of either ear, increasing levels of the first stimulus to the more effective ear increased the masking of the response to the second pair of stimuli, i.e., decreased the response to the second stimulus pair. This was true also for units excited by stimulation of one ear and inhibited by stimulation of the other ear. For these units, increasing levels of the first stimulus to the inhibitory ear increased, i.e., disinhibited, responses to the second pair of stimuli. The binaural interaction of the initial stimulus pair always preceded the forward masking

EFFECTS OF BACKGROUND NOISE ON NEURAL RESPONSES TO CONSONANT-VOWEL (CV) STIMULI IN THE PRIMARY AUDITORY CORTEX OF THE CAT. S.W. Wong* and C.E. Schreiner. Coleman Laboratory, W.M. Keck Center for Integrative Neuroscience. University of California, San Francisco, CA 94143.

The representation of speech at the level of the primary auditory cortex challenges our understanding of how complex sounds are encoded in the central auditory nervous system. Our understanding of the functional organization of A1 for basic receptive field properties, such as intensity and bandwidth, to simple stimuli may provide a framework whereby spatial-temporal patterns of distributed neural activity to complex sounds spatial-temporal patterns of distributed neural activity to complex sounds such as speech may be classified. In studies on anesthetized cats, multi-unit neural tuning from a low-frequency patch of AI was mapped and neural spike train responses to binaurally presented CV syllables were recorded. Responses were recorded for a repertoire of CV stimuli in a quiet background and in backgrounds of continuous noise at several levels. Data obtained in the quiet listening condition revealed a double-on response similar to that reported by Eggermont (JASA, 1995 Aug 98 (2 Pt.1): 911-920) for CV stimuli with unvoiced consonants. In addition, AI topography of spike responses depicted spatially selective temporal activity patterns in accordance with slight spectral-temporal differences in the stimuli. The addition of continuous background noise exerted differential effects upon the spike response topography of AI neurons along the dimensions of noise level and CV stimulus type. Suppressive effects of the noise were manifest along both spatial and temporal domains. Findings in this study further emphasize the prominent effects of background noise on the representation of complex sounds in the primary auditory cortex. primary auditory cortex.

LONG-LATENT NEURONS IN THE CAT DORSAL AUDITORY CORTEX IN RELATION TO TEMPORAL INTEGRATION J. He*, T. Hashikawa & Y. Kinouchi, Laboratory for Neural Systems, Frontier Research Program, RIKEN, Saitama, and Department of Electrical and Electronic Engineering, The University of Tokushima, Tokushima, Japan The present study examined the response dependency of cortical neurons on the duration length of noise burst. We recorded 150 neurons with latenay leaves they always the surface of the sea dispose unit in the search leaves they are additionally additional to the search of the sea dispose and the search of the sear

with latency longer than 30 ms to auditory stimuli in the cat dorsal auditory cortex. 78 out of 150 neurons were classified to temporal summation neurons which showed increasing responses to noise bursts of longer duration (type I neuron), and 72 neurons showed temporal suppression processing in one or two phases of the stimulus time domain, and were classified to temporal suppression neurons (type II neurons). Of 78 type I neurons, 30 showed no response to noise burst of duration shorter than a threshold, and showed increasing responses only when we prolonged the duration longer than the threshold and shorter than their latency. Each of these neurons seemed to have an integrating period and remained their maximum responses when the duration of noise burst were longer than their integrating periods. Of 72 type II neurons, 41 showed good responses to noise burst of short duration, but poor responses to that of longer duration, their responses were induced by the beginning period of the noise burst, but were suppressed by the later coming period of the noise burst. 13 type II neurons showed maximum responses to noise bursts of a certain duration and were classified to duration-tuned neurons, as which have been previously found in the frog and the bat.

These results suggest that the long-latent neurons are related to temporal integration on the time domain before their responses. This integration includes temporal summation and temporal suppression.

OPTICAL IMAGING OF TOPOGRAPHY OF FREQUENCY AND INTENSITY ORGANIZATION OF CAT AUDITORY CORTEX USING INTRINSIC SIGNALS H.R. Dinse, B. Godde, T. Hilger and C.E. Schreiner*, Institut für Neuroinformatik, Theoret. Biol. Ruhr-Univ. Bochum RUB, D-44780 Bochum, Germany and Keck Center for Integrative Neuroscience., Univ. California, San Francisco, CA 94143

We studied the functional organization of cat auditory cortex (AI) by means of

optical imaging of reflectance changes of intrinsic signals (LaVision Lightstar II) using a 546 nm light source.

using a 546 nm light source.

We were able to measure up to 70 different maps for a variety of stimulus conditions in one individual animal. Following tone burst stimulation at various stimulus intensities we found topographically restricted response areas. However, these areas were large and highly overlapping, which is in accordance with results recently obtained in somatosensory cortex (Godde et al. 1995. Neuroreport 7: 24-28). Variation of the stimulation frequencies between 0.5 and 28 kHz revealed a systematic and corresponding shift of the response areas revealing an overall tonotopic frequency cranitation. Two one presentations, revealed severe suppressive and excitatory. organization. Two-tone presentations revealed severe suppressive and excitatory interactions involving large portion of AI. Systematic variation of the sound level over a range of 50 dB evoked different spatial patterns of reflectance changes that appeared

a range of 50 dB evoked different spatial patterns of reflectance changes that appeared patchy. Increasingly higher levels recruited increasingly larger response areas resulting in a decreasing spatial selectivity. This was paralleled by positional shifts of activity zones indicating that increasing intensity involves the additional engagement of previously unresponsive areas and the retreat from previously activated zones. The results suggest that optical imaging intrinsic signals which corresponds to the measurement of the cortical point spread function reveals a profound tonotopic organization compatible with single cell data. On the other hand new aspects such as the substantial overlap between isofrequency domains could be visualized that bears important implications for stimulus interactions and plastic reorganizations. Changes in other signal dimensions, such as azimuthal location or fundamental frequency, also resulted in distinct spatial patterns of activation that may hold important information regarding the functional organization of primary auditory cortex.

INFORMATION-BEARING ELEMENTS OF SPIKE TRAINS IN THE CAT'S AUDITORY CORTEX. J.C. Middlebrooks* and L. Xu. Kresge Hearing Research Institute, University. of Michigan, Ann Arbor, MI 48109-

We have shown previously that the temporal firing patterns of cortical units carry substantially more information about sound-source location than is carried by spike counts alone (Science 264:842-844). In the current study, we have begun to identify specific elements of the spike patterns that carry information. We represent averaged spike patterns as weighted sums of principal components. For 114 of 118 single units, the spike count correlates closely (r>0.8) with the weight on the first principal component (PC1). This means that, given only one number with which to represent a firing pattern, spike count usually is the best to choose. Nevertheless, PC1 accounts for an average of only 55.4% of the variance across all the spike patterns of each unit. We evaluated mean post-stimulus-times (PST's) and a measure of the temporal dispersion of spikes as possible contributors to the additional variance. For some units, those variables correlated with spike counts and, thus, contributed little additional information. For the majority of units, however, mean PST and temporal dispersion were practically independent of spike count. Among those units, mean PST correlated with the weight on PC2 or PC3 in the majority of cases, and temporal dispersion often correlated with the weight on PC3. We now are testing the extent to which mean PST and temporal dispersion carry information specifically about sound-source azimuth, elevation, and SPL. (supported by NIDCD)

INTRA-CORTICAL INHIBITORY CONNECTIONS REFINE SPECIFICITY OF CAT AI NEURON RESPONSIVITY. S. Ta Bonham*, S. W. Wong, and C. Schreiner. Neuroscience, UCSF, San Francisco, CA 94143. Keck Center for Integrative

In the mammalian auditory system, ascending auditory information passes from the medial geniculate nucleus (MGN) of the thalamus to the primary auditory the medial geniculate nucleus (MGN) of the thalamus to the primary auditory cortex (A1) as well as associated auditory fields. In this ascending circuit, while the broad organization of tonotopy is maintained, individual neuronal response properties are considerably altered. The degree to which these differences can be ascribed to ascending thalamic projections or to intra-cortical connections is largely unknown. Using the GABA, inhibitor bicuculline, we investigated the contribution of the intra-cortical inhibitory connections in shaping cortical neuron frequency response areas (FRAs) and modulation transfer functions (MTFs).

frequency response areas (FRAs) and modulation transfer functions (MTFs). Multi-unit extracellular recordings were made in A1 of the cat; using tone burst and wide-band click stimuli, tuning curves and MTFs for all units were derived before and after bicuculline application. Five microliters of bicuculline were applied directly to the exposed surface of the brain at a concentration of 1 mM. Bicuculline consistently altered three aspects of unit responses. 1) Loss of GABA, inhibition expanded tuning curves to include both higher and lower frequency regions, leaving the best frequency for the unit unchanged. 2) The threshold of the best frequency response was reduced; neurons became more sensitive to low intensity stimuli. 3) Bicuculline addition increased the threshold of the best frequency response was reduced; neurons became more sensitive to low intensity stimuli.

3) Bicuculline addition increased the monotonicity of firing in response to increasing sound intensity. Initially nonmonotonic units responded monotonically after bicuculline addition. Comparison of MTFs before and after bicuculline application did not indicate a consistent change in the phase-locking ability of recorded cells. These results suggest that inhibitory sidebands created in the cortex via lateral inhibitory connections play a significant role in shaping the spectral but not the temporal response properties of cortical neurons. EFFECTS OF ELECTRICAL STIMULATION OF A MULTI-CHANNEL COCHLEAR IMPLANT ON CAT AUDITORY CORTICAL ORGANIZATION REVEALED BY OPTICAL IMAGING. B. Godde*, G. Reuter, T. Hilger, S.M. Cords, T. Lenarz and H.R. Dinse. Institut für Neuroinformatik, Theoret. Biol. Ruhr-

Univ. Bochum RUB, Bochum and Med. Hochschule, Exp. HNO, Hannover, Germany
We measured reflectance changes by means of optical imaging (LaVision, Lightstar
II imaging and acquisition system) of intrinsic signals to study the effects of acute
electrical cochlear stimulation on the topography of the cat auditory cortex.
Multichannel implant electrodes consisting of several pairs of platinum-iridium balls
were inserted into the scala tympani. The total length of the inserted electrode portion

were inserted into the scala tympani. The total length of the inserted electrode portion was about 8 mm. the mean distance between electrode sites was about 1.8 mm. Following single pulse electrical stimulation at selected sites of a multichannel implant device, we found topographically restricted response areas representing mainly the high frequency ranges of the primary auditory cortex (AI) and of the anterior auditory field (AAF). Systematic variation of the stimulation pairs and thus of the cochlear frequency sites revealed a systematic and corresponding shift of the response areas that matched the underlying frequency organization. Based on estimates on average sizes of the organ of corti and the corresponding frequency localization, the stimulating electrode sites were likely to cover a frequency range of 6 to maximal 50 kHz. Intensity functions were usually very steep. Increasingly higher stimulation currents evoked increasingly larger response areas resulting in decreasing spatial, cochleotopic selectivity. Using high frequency periodic stimulation between spatial, cochleotopic selectivity. Using high frequency periodic stimulation between 100 and 5000 Hz evoked similar spatial patterns as did single pulse stimulation.

The results suggest that the method of optical imaging intrinsic signals can be used to map response areas evoked by electrical cochlear stimulation and that the electrical stimulation in fact produces a profound cochleotopic selectivity. The implications of these findings are discussed in respect to underlying mechanisms of sound sensation mediated by cochlear implants and in respect to the information processing of normal acoustic signals

THE GABAergic ORGANIZATION OF THE CAT MEDIAL GENICULATE BODY. C.L. Huang*, D.M. Huchton, D.T. Larue, and J.A. Winer. Department of

Molecular and Cell Biology, University of California, Berkeley, California 94720. We studied the GABAergic cells and axon terminals (puncta) in the MGB with antisera to GABA or GAD. Neurons were classified in 50 µm-thick sections, and 1 µm-thick sections were used for quantitative purposes. We found that (1) each division had a different concentration of GABAergic neurons. The ventral division (V) had 34%, the dorsal division (D) 26%, and the medial division (M) 21%. (2) In V and M, GABAergic cells had a drumstick shaped perikaryon (~12-14 μ m in diameter) and sparse dendrites. D had small (10-12 μ m × 15-18 μ m) and large (12-15 μ m) μ m × 18-21 μ m) cells, the former with a flask-shape perikaryon, the latter with a triangular or ovoid soma; each had a stellate or radiate dendritic branching pattern. (3) There were caudal-to-rostral spatial gradients in the proportion of these cells: V ranged from 29% (caudally) to 38% (rostrally), D from 32% to 16%, and M from 9% to 39%. Others (Rouiller et al., *Hearing Res.*, 1990, **49**:249-258) found the opposite gradient in V. (4) The form of puncta were unique to each division. V neuropil had many globular, grape-like clusters; D puncta were denser and more variable in shape: M had small, flattened puncta and some large and prominent axosomatic endings. Thick axons (3-4 µm in diameter) in the brachial neuropil may arise from the IC (J.A. Winer et al., Proc. Natl. Acad. Sci. U.S.A., 1996, 93: in press). (5) GAD+ somata received few endings, while most GAD-cells had many axosomatic puncta.

Each division shares a similar distribution of axosomatic puncta, and each has more than 20% GABAergic cells. Divisional differences in their proportion, qualitative differences in puncta, and the two GABAergic cell types in D suggest that each division also has unique inhibitory features.

GABA AND GLYCINE IN THE AUDITORY THALAMUS AND MIDBRAIN OF THE BARN OWL (Tyto alba). LA. Winer* and D.T. Lange. Department of Molecular and Cell Biology, University of California, Berkeley, California 94720. We surveyed the distribution of GABA, GAD, and glycine (Gly) in the owl's auditory thalamus (nucleus ovoidalis; Ov) and midbrain (nucleus mesencephalicus

lateralis, pars dorsalis; MLD). Neurons and axon terminals (puncta) were analyzed in 50 µm thick sections (GABA and Gly), 25 µm sections (GAD), and in postembedded

material 0.5-2 μm thick (GABA and Gly).

In Ov, the presumptive homologue of the mammalian MGB, GABAergic neurons were rare (<1%) and these were concentrated in the rostral pole. Both features are characteristic of the GABAergic organization of the mustache bat's MGB. There were many GABAergic puncta in the neuropil, on GABA-negative perikarya, and many preterminal axons in the fiber tract beneath Ov. The Gly arrangement in Ov was entirely different, with a sparse, widespread network of fine preterminal axons and puncta, including axosomatic endings.

and puncta, including axosomatic endings.

In MLD, there were many GABAergic neurons and numerous puncta. A few Gly neurons were immunostained, and Gly puncta were plentiful. Glycinergic cells are entirely absent in the IC of the bat, rat, and cat.

A third finding was the apparent absence of brain stem glycinergic centers in the owl that correspond to the medial nucleus of the trapezoid body. Perhaps the neurons that represent this nucleus do not form a discrete group.

Despite global parallels between avian and mammalian auditory system

Despite global paralest severed avial and infilmment adultory system organization, there are substantial differences in chemical architecture that may reflect species differences in sound processing or phylogenetic distance between orders. We thank Dr. Catherine E. Carr for kindly providing the owls, and we are grateful to her and to Dr. E.I. Knudsen and Dr. L.E. Proctor for helpful advice. Supported by

United States Public Health Service grant R01 DC02319-16

Selective labelling of GABAergic inputs to the central nucleus of the inferior colliculus using retrograde transport of γ-vinyl GABA. M.W. Spitzer*, M.B. Calford, D.V. Pow. Department of Physiology and Pharmacology, Univ. of Queensland, Brisbane, QLD, 4072, Australia.

Previous investigations have demonstrated selective uptake of vinyl GABA by GABAergic neurons in the retina. We investigated the potential use of y-vinyl GABA as a neurotransmitter-specific retrograde tracer in the central nervous system. Pressure injections of y-vinyl GABA (4 mM in saline) were placed in the central nucleus of the inferior colliculus (IC) of adult pigmented guinea pigs anesthetized with ketamine/sylazine. Following a 48 hour recovery period animals were sacrificed and perfused with glutaraldehyde. befride animals were sacrificed and perfused with glutanutrylucture. Labelled neurons were visualized immunocytochemically using a polyclonal primary antibody raised against glutaraldehyde conjugates of y-vinyl GABA. Immuno-positive cell bodies, axons and terminals were always present within the injected IC. Immunocytochemical labelling of alternate series of semithin sections demonstrated that all series (GABA immunococitive neurons were also immunocactive labelling of alternate series of semithin sections demonstrated that all γ -vinyl GABA immuno-positive neurons were also immunoreactive for GABA. but only a fraction of all GABA-immunoreactive neurons were labelled with γ -vinyl GABA. Following some injections labelled neurons were also located in the dorsal nuclei of the lateral lemniscus, bilaterally, but not in other auditory brainstem nuclei. These results suggest that uptake and retrograde transport of γ -vinyl GABA is specific for GABAergic neurons. Supported by NHMRC (Australia), ARC and The University of Oueensland.

Queensland.

425.2

GABAergic ORGANIZATION OF THE MAMMALIAN MEDIAL GENICULATE BODY: A COMPARATIVE STUDY. D.T. Larue* and J.A. Winer. Department of Molecular and Cell Biology, University of California, Berkeley, California 94720. GABAergic neurons and axon terminals (puncta) were studied in the medial

geniculate body (MGB) of mustache bats, albino rats, cats and monkeys. Antisera to GABA were used on thick Vibratomed (50 µm) or semithin (0.5-2 µm) sections while frozen sections 25 µm thick were immunostained with antisera to GAD. The results were the same for each method.

The proportion of GABAergic neurons ranged from <1% in the bat and rat to 25% or more in the cat and monkey. In all species, the chief type of MGB GABAergic neuron had a flask-shaped soma ~10 µm in diameter, thin dendrites, and a fine axon. In the cat and monkey a second, larger and rarer GABAergic cell was also seen. While the proportion of GABAergic MGB cells varied, their number in the inferior colliculus and auditory cortex was ~15-20% in all species.

In the bat, these cells were most numerous in the dorsal division, and rare or absent in the medial division. In the rat, they were concentrated in the ventral and dorsal divisions. In the cat and monkey, each division had many.

All four species had many GABAergic puncta that arise from the thalamic reticular nucleus and intrinsic sources. A third origin in the cat is the inferior colliculus (J.A. Winer et al., *Proc. Natl. Acad. Sci. U.S.A.*, 1996, **93**: in press).

Dendrodendritic glomerular arrangements common in the cat (and perhaps in the monkey) should be rarer in the bat and rat. The number of MGB GABAergic cells is similar to that in the ventrobasal complex, while the proportion of GABAergic cells in the lateral geniculate body is largely conserved. Perhaps the number of MGB GABAergic neurons relates to the forebrain's role in vocalization and speech-like

425.4

CONTRASTING AUDITORY CORTICOFUGAL PROJECTIONS TO THE INFERIOR COLLICULUS AND THE MEDIAL GENICULATE BODY.

J.J. Diehl* and J.A. Winer. Department of Molecular and Cell Biology, University of California, Berkeley, California 94720.

We compared the corticocollicular (CC) projections to the cat inferior colliculus (IC) with the corticothalamic (CT) input to the medial geniculate body (MGB). Axoplasmic transport (WGA) and axonal bulk filling (BDA) methods were used. 1. Divergence. All 10 fields are part of the CT system, while three nonprimary ones had no CC input. Tonotopic areas had more limited MGB targets than nontonotopic areas; in the IC, input from tonotopic fields dominated.

2. Convergence. Single MGB nuclei received input from 3-10 areas; IC nuclei were

- the target of 2-7 areas. The central nucleus of the IC received only sparse input. 3. *Topography*. All projections were focal and clustered. The input from nontonotopic fields was as orderly as that from tonotopic areas.
- 4. Axonal structure. CC axons had a narrow size range (0.3-2 μm in diameter), a simple terminal architecture, and strong similarities despite their many areal origins. CT axons spanned a wider size spectrum (0.3-4 µm), and had diverse terminals ranging from simple configurations to massive (~5 µm) endings that can form clusters of several hundred terminals in the dorsal division of the MGB.

Our main conclusions are:

- . The CC system has more limited origins and targets than the CT projection, and fewer types of axons. Perhaps it has a more specific functional role.

 Cortical input to the MGB reaches both auditory and polysensory nuclei
- · Association and limbic-related areas have the most widespread input to the MGB,

425.6

NEURONS OF THE RAT INFERIOR COLLICULUS WITH GABA-LIKE IMMUNOREACTIVITY CAN PROJECT TO THE MEDIAL GENICULATE BODY. D. Peruzzi* and D.L. Oliver. Department of Anatomy, University of Connecticut Health Center, Farmington, CT 06030.

To determine if neurons that contain GABA in rat inferior colliculus also project to the medial geniculate body, two techniques were combined. Projection neurons from the inferior colliculus were retrogradely labeled by making injections of red latex microshperes (Lumifluor) into the medial geniculate body. After two to four days survival, 50 µm thick slices were taken through the inferior colliculus. The presence of GABA was assessed by immunostaining these slices with a monoclonal antibody to GABA (Sigma) and an FITC labeled secondary. Data were collected from four rats.

Roughly one-quarter to one-half of neurons that project from the ipsilateral inferior colliculus to the medial geniculate body displayed GABA-like immunoreactivity. When the inferior colliculus was parcelled into the subdivisions of central nucleus, dorsal cortex, and lateral cortex, regional differences were noted. For instance, the percentage of GABA-positive projection neurons in the central nucleus was usually higher than that of those neurons in the dorsal cortex

The presence of GABA-positive projection neurons suggests that neurons in the inferior colliculus may participate in GABAergic synapses in the medial geniculate body. Thus, ascending projections from the inferior colliculus may produce inhibitory potentials in thalamic neurons as well as excitatory potentials. Supported by NIH grant DC00189.

COMPARATIVE ANALYSIS OF CALCIUM-BINDING PROTEIN-POSITIVE NEURONAL POPULATIONS IN VISUAL AND AUDITORY SYSTEMS OF CETACEAN, UNGULATE, CARNIVORE AND PRIMATE BRAINS <u>Ilya I.</u> Glezer*¹, Patrick R. Hof ², Gundela Meyer ³, and Peter J. Morgane ⁴, ¹Dept. Cell Bio. & Anat Sci. CUNY Med. Sch.NY, NY 10031, ²Dept. of Neurobiol., Mount Sinai Sch. Med. NY, NY 10029, 3Dept. of Anat., Univ. La Laguna Sch. Med., Tenerife,

Spain and 'Dept. Pharmacol. Univ. New Engl., Biddeford, ME 04005.

Immunocytochemical analysis, combined with computerized imaging, revealed that in the visual and auditory systems (V1, A1 of cortex, LGN, MGN, superior and inferior colliculi of tectum) of odontocete whales calretinin (CR) and calbindin (CB) are the major calcium-binding proteins (CaBP), whereas parvalbumin (PV) is present in significantly fewer neurons. The prevalence of CR and CB-positive neurons is especially prominent in the auditory system of cetaceans. Among studied species of terrestrial mammals only in ungulates this cetacean-like pattern of distribution of CaBP is found. In ungulates CR-positive neurons are found, not only in cortical layers II and IIIa, but also in layer I. In auditory and visual systems of Old in cortical layers II and IIIa, but also in layer I. In auditory and visual systems of Old World monkeys and carnivores CR and CB-positive neurons are either equal in numbers or significantly fewer than PV-positive neurons. The prevalence of PV-positive, over CR- and CB-positive neurons is particularly obvious in visual system of primates. Thus, the dominant sensory systems in both aquatic and terrestrial mammals are enriched with a specific phenotypes of calcium-binding protein-positive neurons. The similarity between cetacean and ungulate cortex in ratios of different populations of CaBP neurons within specific neocortical areas correlates with paleontological and genetic data showing evolutionary linkage of these mammalian orders (McKenna, 1975, Eisenberg, 1981). Significant differences between cetaceans, on the one hand, and primates and carnivores on the other in ratios of CaBP neuronal populations may indicate different directions in biochemical evolution of sensory systems in totally aquatic (cetaceans) and terrestrial (primates, carnivores) mammals. ACTIVATION OF HUMAN AUDITORY CORTEX DURING PASSIVE LISTENING TO FM TONES DEMONSTRATED WITH FUNCTIONAL MRL \underline{J}_-

LISTENING TO FM TONES DEMONSTRATED WITH FUNCTIONAL MIR. J. Wang*, M.S. Cohen S.Y. Bookheimer and M. Dapretto, Div. of Brain Mapping, UCLA School of Medicine, Los Angeles, CA 90095-1769.

The invasiveness of many brain mapping techniques has prevented the study of the function of human auditory cortex. A number of previous studies have used PET or functional MRI to measure responses in human auditory cortex to acoustic stimuli. However, most of these studies made use of acoustic stimuli of either language or musical context, or the subjects when were required to make discriminations. The present orthe investigated activities of human auditory cortex in subjects when were passively

study investigated activation of human auditory cortex in subjects who were passively listening to frequency-modulated tones with functional MRI.

Adult human volunteers with normal hearing were used as subjects. Sound stimuli were 500-ms FM tones, with 5 Hz modulation rate and deviation of 1/5 of the center frequency. FM tones were produced by a Macintosh software (SoundEdit 16, 8 bit, 22.05 kH sampling rate). Tones were presented to the subjects through tightly sealed earphones at a rate of 1 Hz. Five FM tones (at center frequencies of 250 Hz, 500 Hz. 1 earphones at a rate of 1 Hz. Five FW tonics are center frequencies of 20 Hz. 500 Hz. 4 kHz. 2 kHz and 4 kHz) were used in this study. The experimental series began with a rest block (no sound presentation) followed by alternating blocks of passive listening (presentation of FM tones at one of the five center frequencies). Each block lasted 25 seconds. Multi-slice functional images were acquired on a GE 3 Tesla scanner using EPI (Advanced NMR). A total of 110 images at each slice location were collected in a 4:35 time period (2.5 secs/image). The functional data were analyzed using within-subject Student's t-test of pixel intensity during lateralization vs. that during rest (not subject students - test of pixel mensity during lateralization ss. that during rest uniculating the initial rest period). The functional data were analyzed using within-subject Student's t-test of pixel intensity during each passive listening period vs. rest period. Maps of pixels of t-statistic (t>2.66, df-68) were produced and superimposed onto the corresponding flow-enhanced image for localization of the auditory cortex.

Activation by FM tones of all the five center frequencies were demonstrated in all the subjects tested. Areas that showed significant signal increase also included superior temporal gyrus and association auditory cortex (posterior transverse temporal gyrus) in addition to the primary auditory cortex (anterior transverse temporal gyrus).

CLAUSTRAL NEURONS PROJECTING TO AUDITORY CORTEX ARE ARRANGED TOPOGRAPHICALLY. M. Beneyto*, J.J. Prieto, M.L. Picó, M.L. Sala, and J.A. Winer. Department of Histology, University of Alicante, 03080-Alicante, Spain (MB, JJP MLP, MLS) and Department of Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA 94720-3200 (JAW).

The claustral neurons projecting to the limbic (Witter et al., 1988, Neuroscience

24: 519-539), prefrontal and motor cortex (Clascá et al., 1992, J. Comp. Neurol. 326: 402-422) are arranged topographically with regard to their cortical targets along the dorsoventral axis. We wondered if input to auditory cortex obeyed this principle. Auditory areas AI, AAF, PAF, VPAF, AII, SF/daz, EPD, EPI, TE and INS were injected with WGA-HRP. Three days later the animal was perfused, and frozen sections were reacted for TMB.

There was a rostrocaudal segregation of the claustrocortical neurons. Afferents to AAF were in the rostral claustrum, those innervating AI occupied the middle sections, and those projecting to PAF were caudalmost in the nucleus. There was also a dorsoventral segregation from injections in SF/daz (dorsally), through AI, EPD, AII, INS to TE (ventrally). Areas at similar dorsoventral levels, such as AAF, AI, and PAF, on one hand, and AII and EPD, on the other, preserved this dorsoventral topography within the claustrum.

We conclude that claustrocortical neurons are segregated spatially within the nucleus. This pattern precisely recapitulates, in two dimensions, the location of every cortical area on the hemisphere. Some overlap among these projections suggests that the segregation is not absolute. The claustrocortical system therefore follows similar principles in its affiliations with limbic, motor, and sensory fields and may play

analogous functional roles in each.

CORRELATIVE IMMUNOCYTOCHEMICAL AND ELECTRO-PHYSIOLOGICAL STUDIES ON JAPANESE MONKEY AUDITORY CORTEX H.Kosaki^{-1,2} T.Hashikawa¹ J.He¹ & E.G.Jones^{1,3} Univ.Tokyo, Tokyo, Japan 3; Dept. Anatomy & Neurobiology, Univ.California, Irvine, CA

The superior temporal plane of Japanese monkeys (*Macaca fuscata*) was

studied to confirm the location and subdivision of the auditory cortex by immunocytochemical staining for the calcium binding protein parvalbumin coupled with single unit recording. Anesthetized monkeys were exposed to white noise bursts and pure tone bursts for stimuli.

In parvalbumin staining, an intense staining area, which appears to be primary auditory cortex, is surrounded by a rather-weak staining zone. In the primary auditory cortex, is surrounded by a rather-weak staining zone. In the intensely stained central area neurons showed sharp tuning curves for pure tone bursts and were arranged in order of best frequency. The best frequency varied along the rostrocaudal axis. This axis was divided in two part : in the rostral parts, the best frequency of the most rostral site was the highest, then decreased caudally, but further caudally the best frequencies increased gradually again. Neurons of the surrounding zone also showed responses to acoustic stimuli, but sharp tuning curves were not observed. This surrounding zone is thus likely to be a non-primary auditory area. The lateral part of this surrounding area showed some degrees of tonotopicity. The axis of this was parallel to that of primary cortex. The neurons of other parts of the surrounding area responded poorly to pure tone stimuli.

These results suggest that the density of parvalbumin staining is coincident with electrophysiological features that delineate different functional areas of auditory cortex. And the neurons of non-primary areas which showed poorer responses to the simple pure tone stimuli than those of primary areas were expected to integrate information over a large range.

TONOTOPIC ORGANIZATION OF HUMAN AUDITORY CORTEX WITH BOLD FUNCTIONAL RESONANCE IMAGING C.L. Kussmaul^{1/2} C.M.Wessinger^{1/5} M.H. Buonocore⁴ G.R. Mangun^{1/3} Center for Neuroscience, Depts ²Computer Science, ³Psychology, Univ of Calif, Davis CA 95616: ⁴Dept of Radiology, UC Davis Medical Center, Sacramento, CA 95817; 'Georgetown Institute for Cognitive and Computational Sciences, Washington, DC 20007

Tonotopic organization refers to a systematic mapping of frequency within the auditory system, and can be observed beginning in the cochlea and continuing in various structures of the ascending auditory pathway to include the cortex. In the macaque monkey, microelectrode recordings have shown tonotopy in auditory cortex. Previous investigations of tonotopy in humans have used positron emission tomography and inverse dipole modeling of electric and magnetic field potentials recorded at the scalp. The present study investigated tonotopic organization in human auditory cortex using functional magnetic resonance imaging (fMRI) Functional MRI permits the direct visualization of human cortical organization without the necessity of either intersubject averaging or inverse modeling. Despite potential masking effects from the auditory environment inherent to the blood oxygenation level dependent (BOLD) technique we used, whole brain volume imaging demonstrated bilateral functional activity in individual subjects (N= 7) Furthermore, there was a tendency for high-frequency tones to produce activation more posterior and medial than low-frequency tones, especially in the left hemisphere. This is consistent with descriptions of tonotopy obtained with other methodologies. This research was supported by funding from NIMH, NINDS and the McDonnell-Pew Foundation

DISTRIBUTION OF THE NEURONES PROJECTING FROM THE VENTRAL DIVISION OF THE MEDIAL GENICULATE BODY TO AUDITORY CORTEX IN THE RAT. F.Collia*, J.L. Lanciego, M.A. Pérez de la Cruz, J.A. Aboy, and J.A., García-Méndez, Dpto Anat. e Histol. Hum. Fac. Med. Univ. Sal. Salamanca 37007. España

The organization of the thalamo-cortical projections of the rat auditory cortex, mainly studied with degeneration or HRP techniques, has afforded information about the cortical targets of the medial geniculate body (MGB). However, data concerning the numerical proportions and distribution of neurons projecting to the different areas of the auditory cortex are lacking.

In this study, 20% HRP was injected iontophoretically into

different areas of the left temporal cortex of 50 Wistar rats. After 48 hours the animals were perfused and the brain was removed and processed to visualize the neurones labeled in the MGB. The localization and extent of the areas of injection were mapped, as were the thalamic neurones projecting to the temporal cortex. Subsequent countings render the numerical distribution of labeled neurons in different territories of the ventral division of the MGB

Our results show that neurones of the ventral division of the MGB project to the three areas of the temporal cortex(Te1.Te2 and Te3). The central area of Te1 and the rostroventral portion of Te2 receive projections from the largest number of neurons. An axial correspondence (rostro-caudal and ventro-dorsal) can be established between areas of the MGB, and the cortical divisions (Te1,Te2, and Te3)receiving projections these areas.Our results also confirm the "banded" model proposed by Cipolloni and Peters(1979) to interpret the auditory geniculo-cortical projections in

ANATOMICAL CONNECTIVITY OF THE AUDITORY FOREBRAIN IN THE BARN OWL. Y.E. Cohen and E.I. Knudsen. Dept. Neurobiology,

Stanford Univ. School of Med. Stanford, CA 94305.

The contribution of the forebrain to sound localization has been well documented in the barn owl and other mammalian species. In this study, we used retrograde and anterograde pathway tracing techniques to identify a forebrain pathway in the barn owl that is involved in sound localization and gaze control

The results of this study indicated that auditory thalamic nucleus ovoidalis efferents terminate in a cytologically-distinct region of the primary auditory field (PAF) that corresponds to Field L of Rose. This region of the PAF, in turn, projects to adjacent regions of the PAF, located dorsally and ventrally. turn, projects to adjacent regions of the PAF, located dorsainy and verification. PAF efferents terminate in a variety of telencephalic structures, including the caudal neostriatum, the corpus striatum, and the archistriatal gaze fields (AGF). The AGF also receives input from other regions of the lateral neostriatum. Feedback from the AGF to the PAF is provided through a direct projection and an indirect projection via midline septal nuclei and the lobus parolfactorius. The AGF, in turn, projects to the optic tectum and tegmental structures involved in gaze control

These results indicate that auditory spatial information is mediated, at least in part, by a direct and indirect projection from the PAF, a general processor auditory information, to the AGF, a structure that plays a critical role in sound localization and gaze control. A comparison of the binaural sensitivity of PAF and AGF sites suggests that AGF sites are more selective for binaural cue values than PAF sites. This transformation of spatial information appears to be comparable to the transformation that occurs in the midbrain sound localization pathway.

THALAMIC CONNECTIONS OF THE AUDITORY PARABELT REGION IN MACAQUE MONKEYS. T. Hackett*, I. Stepniewska and J.H. Kaas. Dept of Psychology, Vanderbilt University, Nashville, TN 37240.

As the result of previous studies, we have divided auditory cortex of macaques (*Macaca*) into a core of three primary-like areas, a narrow belt of surrounding areas, and a lateral parabelt of cortex along the upper half of the superior temporal gyrus. The purpose of present study was to determine the pattern of thalamic connections of the auditory parabelt region. Multiple injections of up to six different tracers (fluorescent dyes and WGA-HRP) were placed in the parabelt cortex in 4 monkeys. After 7-12 days survival, the brains were fixed and frozen, and thalamic tissue was cut into 40-50 mm sections. Patterns of label were related to architectonic subdivisions delineated in adjacent sections stained for Nissel cytochome svidase acetylcholinesterase. sections stained for Nissl, cytochrome oxidase, acetylcholinesterase, calbindin, and parvalbumin.

Patterns of dense label were found with the medial geniculate complex (MGC) and medial pulvinar (PM). The dorsal and magnocellular MGC nuclei projected most heavily to the auditory parabelt, whereas the ventral nucleus was almost free of label. Caudorostral rows of injections in the parabelt labeled rostral ventrolateral to caudal dorsomedial locations in MGNm and MGNd, and ventrolateral to caudal dorsomedial locations in MGNm and MGNd, and lateral to medial locations in PM. Foci of sparser label were found in the suprageniculate and limitans nuclei, as well as the peripeduncular, intralaminar nuclei, and the posterolateral part of the mediodorsal nucleus. The present results indicate that a third level of auditory percessing in the auditory belt can be importantly influenced by widely projecting divisions of the auditory thalamus and the medial pulvinar. DII TRACING OF CENTRAL AUDITORY PATHWAYS IN THE BULLFROG. V.Kumaresan, M.Molina and A.Megela Simmons.*
Department of Neuroscience, Brown University, Providence, RI 02912.

Dil has been used to trace central auditory pathways in Rana catesbeiand Adults, recently postmetamorphic juveniles (snout-vent length 2.5-4cm) and tadpoles (Gosner stages 28-43) were used. In ranids, metamorphosis involves loss of the lateral line system and acquisition of the ability to perceive airborne sounds. We have re-examined the reorganization of octavo-lateralis pathways that accompanies this change in sensory modality and have examined the presence of synaptic domains within the inferior colliculus, an area of multisensory integration Small crystals of Dil were placed in tissue that was fixed in methanol-free, 10% formalin. Tissue was incubated at room temperature in the dark. At the end of five weeks, 50 um thick sections were obtained using a vibratome, and viewed with an Olympus epifluorescence microscope equipped with a rhodamine filter. The transport pattern obtained using Dil is consistent with previous reports that have used horseradish peroxidase as the tracer. Some transneuronal dye transfer occurs in tadpoles. Placement of dye in the auditory nerve branchlets innervating inner ear sensory epithelia in tadpoles (Gosner stage 28-31) results in labeling of the lateral group of presumptive acoustic nucleus (AcN) cells in the medulla. In the midbrain, the caudal torus superior to the nucleus isthmi is labeled. In tadpoles (Gosner stage 38-43) however, there is a reduction of labeling in the caudal midbrain along with an increase of label within the principal nucleus. Initially, the central region of the principal nucleus, a low frequency sensitive region is labeled. Increased labeling of the central principal nucleus occurs concurrent with increase in label of the ventral area of the dorsally located AcN of the medulla. This suggests that there may be a changes in the projection to the midbrain concurrent with the development of an AcN that is typical to the adult structure.

THALAMOCORTICAL AXONS OF LORENTE DE NO: A DESCRIPTION OF AFFERENT AXONS FROM THE MGV TO LAYER I WITH DESCENDING PROJECTIONS TO LAYERS III/IV. J. S. Cetas, R.K. de Venecia and N.T. McMullen.* Dept. of Cell Biology and Anatomy, Univ. of Arizona College of Medicine, Tucson, AZ 85724.

In his seminal description of the "acoustic cortex" of the mouse in 1922 (transl by Fairen et al, 1992, Somatosens. Motor Res., 9:3-36), Lorente de No described at least three types of cortical afferent fibers that could be traced from the internal capsule and were thought to originate from the thalamus. The first two types constitute the classic categories of "specific" and "nonspecific" cortical afferents introduced in his famous chapter in Fulton's Physiology of the Nervous System (1938). A third type of afferent axon (not fully described in 1938) was unusual because it ascended unbranched to layer I and then descended to terminate within the glomerular afferent plexuses in layer IV. It was thought by Lorente de No to represent a separate route for "specific sensory impressions" to neocortex. We describe similar axons arising from the ventral division of the medial geniculate body (MGV). Focal injections of the anterograde tracers biocytin or biotinylated dextran amine (BDA) were made into the MGV of young adult rabbits. In addition to thalamocortical patches of "specific" axons in layers III/IV and tangential axons in layer I, these injections labeled a third class of axon that were reconstructed from 100 um thick serial sections. This class of thalamocortical axon ascends relatively unbranched to layer I where it turns and becomes a tangential fiber. After a variable distance in layer I, they descend into the supragranular layers, begin to branch and terminate within the "specific" thalamocortical patches in III/IV. Their morphology is remarkably similar to axons illustrated in Lorente de No's original article (Fig. 25, axon b; Fig 26, axons e and f). The significance of these axons as a parallel thalamocortical pathway for sensory information will be discussed. (Supported by NIH/NIDCD Grant 02410)

NUCLEUS SAGULUM: A POSSIBLE SUBSTRATE FOR CORTICAL CONTROL OF THE AUDITORY MIDBRAIN. J.J. Prieto*, M. Beneyto, M.L. Picó, J.A. Merchán, and J.A. Winer. Department of Histology, University of Alicante, 03080-Alicante, Spain (JJP, MB, ML, JAM) and Department of Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA 94720-3200 (JAW)

The sagulum is affiliated with many auditory centers, including the DNLL, IC. and MGB. However, the nature of its input from the auditory cortex is unknown We mapped the distribution of corticofugal axons from areas AI, AAF, PAF, VPAF, AII, EPD, EPI, TE and INS. We injected WGA-HRP, and processed frozen sections with TMB as the chromogen

Al and All project throughout the rostrocaudal axis of the sagulum. Al labeling was moderate and concentrated in the central region of the nucleus, while the AII input was heavier and located laterally. SF/daz labeling was light, especially in caudal sections, and like the AI projection, chiefly in the central sagulum. The EPD projection was comparatively stronger and in the dorsolateral part of the nucleus. EPI had a light input situated dorsally. Finally, TE projected to the most lateral sagulum, spanning the entire dorsoventral region, while INS axons ended diffusely in the dorsolateral part.

This suggests that the secondary auditory and polymodal association areas provide the dominant cortical input to the sagulum. The sagulum may be part a hub through which the cortex propagates inhibitory influence to the IC and MGB. Such projections are independent of, yet parallel to, those from auditory cortex to

REPRESENTATION OF ODORANT INFORMATION BY SPATIAL AFFERENT ACTIVITY PATTERNS IN THE ZEBRAFISH OLFACTORY BULB. R. W. <u>Friedrich and S. I. Korsching La.</u> Max-Planck-Inst. für Entwicklungs-bio., Spemannstr. 35/I, D-72076 Tübingen, Germany. Present address: ¹Inst. für Genetik der Univ. Köln, Zülpicherstr. 47, D-50674 Köln, Germany.

To examine how odorant stimuli are represented within the olfactory bulb (OB) we traced olfactory receptor neuron (ORN) axons of the zebrafish *in vivo* with voltage-or calcium-sensitive dyes, thereby labeling afferent axons and glomeruli in the olfactory bulb. Neuronal activity in the olfactory bulb was then imaged with a CCD camera in a tissue explant. Experiments with voltage-sensitive dyes revealed that different classes of natural odorants elicit signals in different regions of the OB: amino acids (AAs) in a lateral neuropil region that is not parcellated into distinct glomeruli, bile acids in medial and ventral regions. Calcium-sensitive dye signals from nerve terminals were used to examine activity patterns induced by AAs in detail. Each of 17 L-amino acids tested (at 100 μM) elicits a unique pattern of foci of activity. The total number of distinguishable foci is usually >40 per fish. The degree of similarity between activity patterns correlates with the similarity in chemical structures of the odorants. Interindividually, patterns obtained with the same AA are similar. Individual foci of activity often have different response spectra and doseresponse characteristics. No signal is elicited by D-Ala and Pro, indicating a high selectivity and stereospecificity of the underlying odorant receptor molecules.

These data show that olfactory stimuli are encoded within the OB by spatial activity patterns in a combinatorial fashion. A molecular and anatomical basis for this coding strategy could be the convergence of ORNs expressing the same odorant receptors onto common glomeruli in the olfactory bulb (Ressler et al., Cell 79, 1994; Vassar et al., Cell 79, 1994). This work was supported by the Max-Planck-Gesellschaft. R.W.F. was supported

This work was supported by the Max-Planck-Gesellschaft. R.W.F. was supported by fellowships from the Bochringer Ingelheim Fonds and the Studienstiftung des deutschen Volkes. H. Baier was involved in an early phase of the experiments with calcium-sensitive dyes.

426.3

OCCURRENCE AND VOLUMETRIC PLASTICITY OF DISTINCT OLFACTORY AFFERENT FIELDS IN THE SALMON BULB. <u>H.E. Jarrard*B.B. Kang, & T.T. Takahashi</u>, Inst. of Neurosci., Univ. of Oregon, Eugene. OR 97403.

In the adult trout, differential binding of the lectin pokeweed agglutinin (PWA) reveals nine biochemically and anatomically distinct projection fields in the glomerular layer of the olfactory bulb (Riddle et al. [1993] J. Neurosci. 13:3018). Using a double-labeling technique with PWA and anti-keyhole limpet hemocyanin (see Riddle & Oakley [1992] JCN 324:575), we have replicated this result in the coho salmon (Oncorhynchus kisutch), identifying nine regions that also differ distinctly in their PWA-binding capabilities and cytoarchitecture. In addition, we have compared the individual volumes of these fields, relative to that of the olfactory bulb (% OB), during juvenile life (1,3,9,12, and 14 months of age; n=3 at each). In preliminary results, two fields show a clear increase in % OB across these ages: anterior medial (AM) increases from a mean of 13.5 % OB (S.E. .3 %) to 22.1 % OB (.4 %) between 1 and 14 months of age, and dorsal lateral (DL) also increases from 4.1 % OB (.4 %) to 6.9 % OB (.2 %) across this period. In contrast, posterior lateral (PL) decreases in % OB from .88 % (.1 %) to .27 % (.009 %) between 1 and 14 months. The remaining fields, while identifiable, did not show a consistent trend. While the functional significance of specialization in these fields remains to be determined, they may represent segregation in the processing of olfactory information. Plasticity in projection field relative volume in juvenile salmon may reflect changes in the processing capabilities of the bulb, and have important behavioral implications in the phenomenon of olfactory imprinting. (Support: NIH GM07257, NSF IBN-9410637).

ALTERED TRANSCRIPTION FACTOR EXPRESSION IN OLFACTORY BULB AFTER UNILATERAL NARIS CLOSURE IN ADULT MICE. E. Cigola, B.K. Jin, L. Franzen, C. Tinti, B. Conti, T. H. Joh and H. Baker*. Cornell Univ. Med. Coll. at Burke Med. Res. Inst., White Plains, NY 10605.

Sensory deprivation, produced by two months of unilateral naris closure in adult mice, resulted in a profound reduction in tyrosine hydroxylase (TH) expression in periglomerular (PG) dopamine neurons in the ipsilateral olfactory bulb. The upstream region of the TH gene contains consensus sequences for two cis-acting elements, CRE and AP-1, known to regulate TH expression in vitro. Previous studies demonstrated that expression of cFos, an immediate early gene which binds to the AP1 site, decreased in parallel with TH in PG neurons in the sensory-deprived olfactory bulb. The current experiments investigate regulation of transcription factor expression in the olfactory bulb in vivo using immunocytochemical and gel shift analyses. Two different antisera confirmed the previously reported extensive decrease in cFos expression in PG cells ipsilateral to the closure. Sensory deprivation, also produced a small decrease in FosB-positive PG cells. In the absence of novel odor stimuli, cFos and FosB exhibited differential distribution. cFos stained only PG cells while FosB labeled both granule and PG cells. Little or no change occurred in PG cell staining with antisera to CREB, phosphoCREB, CREM, cJun, JunD, FRA1 and SP4. Gel shift analysis showed that sensory deprivation did not alter the binding patterns of nuclear proteins to either AP-1 or CRE consensus sites. However, odor deprivation reduced AP-1 binding activity, as predicted by the change in cFos immunoractivity, while protein binding to the CRE site increased. These data suggest that CRE and AP-1 sites may participate in the regulation of TH expression in the olfactory bulb. (Supported by AG09686)

OLFACTORY RECEPTOR CELL MORPHOLOGY CORRELATES WITH SITE OF AXON TERMINATION IN THE OLFACTORY BULB. Y. Morita and T.E. Finger. Rocky Mountain Taste & Smell Ctr., Dept. Cellular & Structural Biology, U. Colorado Med. Sch., Denver, CO 80262.

Olfactory receptor cells are bipolar neurons situated in the pseudostratified nasal epithelium. Thus, the nucleus of a receptor cell may lie nearer or farther from the basal lamina although the cell is thought to extend the full height of the epithelium. Our recent studies using dil as a postmortem retrograde tracer from injections into different sites in the olfactory bulb of catfish reveal that olfactory receptor cells do not have a uniform morphology but vary from short, superficially-situated cells to tall, slender bipolar cells more typical of classical descriptions. Further, a class of short microvillar receptor cell projects preferentially to the dorsal posterior bulb while tall ciliated receptors connect preferentially to the ventral posterior bulb. In the current experiments, dve applications to two more sites have revealed additional morphological classes of receptor cells. Following dil application to the rostral, ventral olfactory bulb, a unique class of short receptor cell is labeled. These short receptors have a distinctive apical specialization appearing as a bright elongate fluorescence perpendicular to the epithelial surface but contained within the apical part of the cell. Another unique receptor cell type was found after dil application directly to the olfactory tracts. The resulting retrogradely-filled receptor cells presumably give rise to the extra-bulbar olfactory pathway (EPOB) described by others. These EPOB receptors are broad, tall receptor cells not observed following dye application to the olfactory bulb proper. In addition, numerous labeled pseudounipolar and bipolar neurons are scattered along the olfactory nerve from the rostral tip of the epithelium up to the rostral end of the olfactory bulb. The peripheral processes of these cells enter the olfactory rosette, but the site and mode of termination could not be determined

MORPHOLOGICAL CHANGES OF RECIPROCAL SYNAPSES INDUCED BY URINARY STIMULATION IN THE HAMSTER ACCESSORY OLFACTORY BULB. M. Matsuoka^{1,2}, Y. Mori², and M. Ichikawa*¹ ¹Tokyo Metoropoli. Inst. for Neurosci., Fuchu, Tokyo 183. Janan. ²Univ. of Tokyo, Bunkyo-ku, Tokyo 113. Janan

M. Ichikawa*¹ ¹ ¹Tokyo Metoropoli. Inst. for Neurosci., Fuchu, Tokyo 183, Japan, ²Univ. of Tokyo, Bunkyo-ku, Tokyo 113, Japan.

The dendrodendritic reciprocal synapses in the accessory olfactory bulb may have important functions in the processing of pheromonal information. The effects of urine stimuli were studied on the reciprocal synapses in the accessory olfactory bulb of adult male hamsters by examining two different synaptic complexes; asymmetrical synapses, characterized by a marked postsynaptic thickening, are oriented in the polarity from mitral/tufted to granule cells, and symmetrical synapses, characterized by symmetrical pre- and postsynaptic thickenings, show the polarity from granule to mitral/tufted cells. Thirty-day old male hamsters were divided into five groups and exposed to one of following five materials: distilled water, female hamster urine, ovariectomized hamster urine, female rat urine, and male hamster urine. Each material was renewed daily. After fifteen days, the length of synaptic active zone, was characterized by the postsynaptic thickening, was measured as an indicator of synaptic size in both asymmetrical and symmetrical synapses by electron microscopy. The exposure to female hamster urine induced a reduction in the size of asymmetrical synapses, whereas that to ovariectomized hamster urine induced an increment in the size of symmetrical synapses. On the other hand, female rat urine and male hamster urine had no effect. These differential morphological changes in the reciprocal synapses can be ascribed to differing pheromonal components contained in each urine preparation.

APOLIPOPROTEIN E IN OLFACTORY BULB. <u>R.G. Struble*</u>, <u>Z. Nie, V. Ramkumar</u>, Alzheimer Center and Department of Pharmacology. Southern Illinois University School of Medicine, Springfield, IL 62794.

A possible function of apolipoprotein E (APOE) in the central nervous system is binding lipoproteins for processing either during degeneration or regeneration. The ability of the olfactory nerve to regenerate following an acute lesion presents an *in vivo* system for examining both of these processes. To evaluate the role of APOE in degeneration and regeneration, we initially determined the distribution and cellular locatization of APOE-like immunoreactivity in both human and rat olfactory bulb.

In human olfactory bulb APOE immunoreactivity was consistently found in processes surrounding the olfactory nerve and glomeruli. Only seldomly were somata stained, but when they were, their location was consistent with ensheathing glia. A slightly different pattern was seen in rats. APOE immunoreactivity was found both in ensheathing glia processes and also in somata of astroglia of the external plexiform layer. In normal animals, somata within glomeruli were not stained. The granule cell layer displayed little or no immunoreactivity.

To examine degeneration, we injected diethyldithiocarbamate in rats, which lesions the olfactory epithelium. In this preliminary study, APOE immunoreactivity substantially increased throughout the olfactory bulb three days after injection during olfactory nerve degeneration. Immunoreactive somata were clearly visible throughout the bulb and particularly apparent surrounding glomeruli. These observations suggest that APOE is substantially upregulated during degenerative changes following lesion of the olfactory nerve. We hypothesize that APOE is present in the olfactory bulb to support the continued degeneration and regeneration that occurs in this structure. Supported by a SIU-CRC grant to RGS.

IN VITRO MAGNETIC RESONANCE MICROIMAGING ALLOWS DETAILED RESOLUTION OF OLFACTORY BULB MICROSTRUCTURE IN ADULT AND DEVELOPING RATS. Saied Agahi*, Essie Meisami and Paul C. Lauterbur (Dept. Molecular and Integrative Physiology & Biomedical Magnetic Resonance Laboratory, University of Illinois, Urbana, II. 61801).

We have recently reported that application of in vivo magnetic resonance imaging (MRI), utilizing a SISCO 4.7T/33 cm bore imaging spectrometer, permits a fair degree of visualization of rat olfactory bulb (OB) structure (Agahi et al, Soc. Neurosci. Abst. 20, 328, 1994 & ibid, Soc. Neurosci. Abst. 21, 1185, 1995). To further improve resolution, we used, in the present study, an in vitro microimaging approach, utilizing a Varian NMR spectrometer system (11.7T/50 mm vertical bore) with a Doty microimaging probe. This method allows microimaging of a single detached rat OB (<5 mm in each dimension) with a high resolution of 35-50 µm compared to 300 µm in the in vivo microimaging of a single detached rat OB (<5 mm in each dimension) with a high resolution of 35-50 µm compared to 300 µm in the *in vivo* images. The results revealed a high definition of OB's laminar organization: the mitral cell layer and some glomeruli were clearly visible, in contrast to the *in vivo* images; also the accessory olfactory bulb and its laminae were visualized. We have begun to microimage the OBs of newborn and developing postnatal rats to visualize, using this method, the changes taking place in the OB's cytoarchitecture during development, a feat which was not possible with the *in vivo* MR-imaging. In *in vitro* microimaging, the higher magnetic field and the smaller more efficient radiofrequency coil, provide a higher signal-toimaging. In *in vitro* microimaging, the higher magnetic field and the smaller, more efficient radiofrequency coil, provide a higher signal-to-noise ratio than in *in vivo* studies, permitting smaller volume elements (voxel) and higher resolution for better visualization of OB's laminar structure. *Supp:* NSF DIR 89-20133- COOP, NIH PHS 5 P41 RR05964, Servants United Foundation, UIUC Research Funds.

STRUCTURAL FEATURES OF INTERNEURONS IN THE GLOMERULAR LAYER OF THE RAT MAIN OLFACTORY BULB: I. CALBINDIN D28K-CONTAINING NEURONS.

K. Toida*. K. Kosaka and T. Kosaka. Department of Anatomy and Neurobiology, Kyushu

University Faculty of Medicine, Higashiku, Fukuoka, 812-82, Japan.

Our recent studies have revealed chemically defined subpopulations of interneurons in the Our recent studies have reveated chemically defined subpopulations of interneurons in the glomerular layer of the rat main olfactory bulb and their heterogeneity in intraglomerular dendritic arborizations (K.Kosaka et al '95, 96). In the present study, we analyzed structural features of a group of periglomerular interneurons containing a calcium-binding protein calbindin D28k (CB-neurons). The vast majority of CB-neurons were identified as a type of the periglomerular cell by three-dimensional observations with a confocal laser scanning light microscope (CLSM) and a high voltage electron microscope, although they exhibited some

microscope (CLSM) and a nign voltage electron microscope, although they exhibited some variations in their dendritic arborizations.

Electron microscopic (EM) analyses of CB-immunoreactive (CB-IR) profile in and around glomeruli revealed two major types of synapses on them; CB-IR processes made symmetrical synapses onto and received asymmetrical ones from mitral/fuffed cells' dendrites (M/Td), which occasionally formed reciprocal pairs. Furthermore CB-IR somata received symmetrical and asymmetrical synapses from CB-immunonegative (CB-IN) profiles, both of which and asymmetrical synapses from CB-innumbengative (CB-IN) printes, bottle of which contained numerous pleomorphic vesicles and the latter contained a few dense-cored vesicles. So far we encountered neither presynaptic sites on CB-IR somata nor synaptic contacts from olfactory receptor terminals (OR) to CB-IR elements.

Further EM reconstruction studies of a CB-periglomerular cell from 310 serial-sections which was identified with CLSM beforehand, clearly indicated the followings; (1) The CB which was identified with CLSM beforehand, clearly indicated the followings; (1) The CB-neuron received 49 asymmetrical synapses from and made 21 symmetrical ones onto M/Td, and 11 of these synapses were reciprocal pairs. (2) It received 14 synapses from CB-IN profiles of unknown origins containing numerous pleomorphic vesicles. (3) So far no synaptic contact with OR has been observed. (4) Direct contacts with no structural specialization such as gap junctions and chemical synapses were observed between the CB-neuron and 4 CB-IR processes, which were not continuous each other within this reconstruction. The present study indicated that CB-neurons made synaptic contacts mainly with M/Td including reciprocal synapses, but not with OR.

CALCIUM IMAGING OF MOUSE OLFACTORY SENSORY NEURONS THAT PROJECT TO DISCRETE REGIONS OF THE DORSAL OLFACTORY BULB. T. C. Bozza and J. S. Kauer. Department of Neuroscience, Tufts University School of Medicine, Boston, MA 02111.

Previous electrophysiological and optical recording studies have suggested that there may be odorant-related projection patterns from the olfactory epithelium to the olfactory bulb. Recent molecular investigations have shown that individual glomeruli receive inputs from distributed olfactory sensory neurons that express the same or similar putative olfactory receptor mRNAs. There are no data available, however, comparing odorant responses from different olfactory sensory neurons that project to one or a few neighboring glomeruli. We are presently asking whether olfactory sensory neurons that project to neighboring glomeruli have similar odorant-response profiles. To do this, we have injected retrograde tracers into small groups of visualized glomeruli in the mouse olfactory bulb, and isolated labeled cells for physiological analysis. Small injections of fluorescent latex microspheres into clusters of 2-5 glomeruli in the dorsal olfactory bulb label sensory neurons found predominantly in the anterior dorsal recess and dorsal surface of endoturbinate IId of the olfactory epithelium. Labeled neurons have been identified in acutely dissociated preparations and responses to 3 odorant mixtures are being examined using fura-2 calcium imaging techniques. These methods will allow us to describe the functional convergence of olfactory sensory neurons and to test the idea that the molecular convergence described by others correlates with a convergence of afferents with the same responsiveness to odorants.

Supported by research grants from the NIDCD and the ONR.

CALRETININ, CALBINDIN D-28K, AND PARVALBUMIN IMMUNOREACTIVITY IN THE MACAQUE MONKEY OLFACTORY BULB. C. Crespo, J.R. Alonso*, A. Porteros, R. Arévalo, J.G. Briñón, and J. Aijón. Universidad de Salamanca, Departamento de Biología Celular y Patología, 37007 Salamanca, Spain.

The distribution and morphological characteristics of calcium-binding proteins (calbindin D-28k, calretinin, and parvalbumin) immunoreactive elements were studied in the macaque monkey olfactory bulb by using specific monoclonal antibodies and the avidin-biotin-immunoperoxidase method. A characteristic

laminar pattern of immunoreactivity was observed for all three proteins.

Calretinin showed the highest number of immunoreactive elements with abundant labeled periglomerular cells and granula cells. In addition, scarce heterogeneous cells were observed in the external plexiform layer, horizontal cells in the internal plexiform layer, deep short-axon cells in the granule cell layer and fusiform cells in the white matter. The labeling for calbindin D-28k was qualitatively similar to that of calretinin in the deep layers but more scarce in all layers of the olfactory bulb. Positive neurons in the superficial layers were identified as superficial short-axon cells and superficial stellate cells.

Parvalbumin-immunoreactivity revealed the lowest number of positive elements. They were identified as superficial short-axon cells and small interneurons of the external plexiform layer, granule cell layer and white matter.

This distribution of calbindin D-28K-, calretinin- and parvalbumin-immunoreactivity showed substantial differences to what has been reported in the olfactory bulb of rodents (rat, mouse, and hamster) and in insectivores, all of them macrosmatic animals.

THE PRIMARY SENSORY OLFACTORY PROJECTION IS DISRUPTED IN MICE LACKING THE N-CAM-180 ISOFORM

H.B. Treloar*¹, T. Magnuson², H. Tomasiewicz² and B. Key¹, ¹Dept. Anat. and Cell Biol., Univ. of Melbourne, Parkville, Vic. 3052, Australia. ²Dept. Genetics, Case Western Reserve Univ., Ohio, 44106-4955, USA. Dept. Anat., Emory Univ., Atlanta,

The recent generation of transgenic mice lacking the 180 kDa neural cell adhesion molecule (N-CAM) revealed that these mice had a grossly normal CNS apart from a smaller olfactory bulb. Because N-CAM is expressed by primary olfactory neurons (PONs) we hypothesised that this molecule is critical in the growth and guidance of developing primary olfactory axons. Previous studies using lectin staining have revealed the mosaic nature of the olfactory pathway. That is, juxtaposed neurons in the olfactory epithelium project axons to disparate sites in the olfactory bulb. We examined the organisation of the olfactory projection in mice lacking the N-CAM-180 specific exon using both immunohistochemical and lectin staining techniques. Olfactory glomeruli were smaller and irregularly shaped in mutant mice compared to the control animals. These glomeruli were not clearly separated from the underlying nerve fibre layer. Lectin staining revealed that the normal mosaic projection was perturbed in the mutant mice. A subset of axons expressing a ligand for the lectin Dolichos biflorus agglutinin generally innervated the correct regions of the olfactory bulb. However, the distribution of glomeruli within target regions was abberant. These results indicate that N-CAM plays a critical role in axon growth and guidance during the development of the olfactory system

FUNCTION AND MORPHOLOGY OF OLFACTORY EPITHELIUM AND BULB NEURONS IN RELATION TO THEIR PROJECTION TARGETS STUDIED BY RETROGRADE LABELING WITH CALCIUM SENSITIVE AND REGULAR FLUORESCENT PROBES Z.Xiang* R.Farooqui, and A.R.Cinelli. Dept. Anatomy & Cell Biol. , SUNY Brooklyn, NY 11203.

In the salamander olfactory system, recent evidence shows that there is not a simple chemotopic mapping between the mucosa and the bulb. Although there is a broad topographical relationship between sectors of the epithelium and the bulb, most connections between these structures consist of complex convergent and divergent projections, and this pattern may reflect an important component for the integration of simple molecular determinants in complex odor compounds. In the olfactory bulb, mitral/tufted dendrites receiving projections from different glomeruli may gather this pattern in particular ways giving them response specificity. In the present study we have labeled retrogradely olfactory receptor neurons and mitral/tufted (M/T) cells with calcium indicators (Fura-2 and Calcium Green) and regular fluorescence probes (Lucifer Yellow and FITC) to correlate their morphology, spatial distribution and function in relation with their axonal targets. In the olfactory epithelium, receptor cells labeled from restricted bulb regions were densely located in particular epithelial regions but also found in other distal sites. In the olfactory bulb, M/T cells were labeled from different secondary olfactory region including the primordial hippocampal formation. Calcium transients evoked by olfactory nerve stimulation were recorded in vivo and exhibited similar characteristics and components than those obtained in slices by intracellular dye injections. These data show that this approach is highly useful not only for correlating the morphology and response characteristics of olfactory neurons with their axonal projection targets, but also to study odor response in the whole animal and the effects of centrifugal fiber and contralateral olfactory bulb activities on these responses. Supported by NIH. Grant RO1-DC01804-04 and Dept. Anat. & Cell Biol., SUNY, Brooklyn.

EPITHELIUM-TO-BULB PROJECTIONS OF SALAMANDER OLFACTORY NEURONS EXPRESSING IDENTIFIED ODORANT RECEPTOR TYPES. R. Farooqui, Z. Xiang and A.R. Cinelli, Dept. Anatomy & Cell Biol., SUNY Brooklyn, NY 11203.

Recent evidence provides support to the notion that olfactory coding involves some degree of topographical organization. Whether similar receptor types converge to single restricted sites in the bulb are still matter of controversy. In this study, we have correlated the expression of particular receptor-specific probes in the salamander olfactory epithelium with their projection target in the bulb. Several cDNA-clones of the putative seven-transmembrane G-protein linked odor receptors were isolated using regular PCR with primers from the odorant receptor families. Digoxigenin-labeled antisense probes from these clones were used for whole moun in situ hybridization. Similar technique was used in the olfactory bulb, but after performing in situ PCR to amplify the odorant receptor mRNAs from the receptor axons. In the epithelium, most of our receptor probes were expressed in rather broad zones, but with clustered expression maps. Both dorsal and ventral epithelia were labeled, but labeling was usually more dense in the ventral epithelium. In the olfactory bulb, expression maps were also clustered. For each probe, however, there was more than a single, restricted labeled region. By correlating the expression maps of particular receptor probes with the activity patterns monitored with voltage sensitive probes (RH-795) evoked odorant stimulation, it was possible to isolate in the epithelium and the bulb a receptor probe that was related with one of the odorants. This probe was expressed in the region of the olfactory epithelium that showed stronger responses to amyl acetate. In the olfactory bulb, it was expressed in the region corresponding to one of component evoked by the same odorant. These data suggest that in the salamander olfactory system, odor compounds are encoded predominantly in distributed patterns involving several bulb locations, and specific odor receptor cells project to more than a single bulb location. SEMAPHORINS IN OLFACTORY NEURON AXONAL GUIDANCE, L.C. Williams-Hogarth* X. Cai, N. Davarpanah, A.L. Kolodkin, and G.V. Ronnett. Dept. of Neuroscience, Johns Hopkins School of Medicine, Baltimore. MD 21205.

The olfactory neuroepithelium is a good model system for

examining axonal guidance mechanisms involved in the developing nervous system. The adult olfactory receptor neurons (ORN's) have the ability to constantly regenerate during the lifetime of most animals, including rat and man. The regenerating ORN's of most animals, including rat and man. The regenerating ORN's have demonstrated the capacity to not only extend new axons, but to relocate and successfully reinnervate their target with functional synaptic contacts. What is not known, however, is whether the adult ORN axons use a mechanism for regeneration that is comparable to that used by developing ORN axons for ontogenetic

pathfinding.
Semaphorins, a newly discovered gene family, have been shown to Semaphorins, a newly discovered gene family, have been shown to function in growth cone guidance by providing signals that guide growing axons to their appropriate destinations. A murine diffusible Semaphorin, M-sema III, has been shown to mediate inhibitory effects on the axons from a subclass of primary sensory neurons in E14 rat embryos (E.K. Messersmith et al., Neuron 14: 949-959, 1995). We localized M-sema III expression in E15 rat embryos by in situ hybridization techniques using a 35S-labeled cRNA probe. M-sema III expression is seen in the olfactory epithelium and surrounding the nasal septum. These findings suggest the possibility that M-sema III may play a role in directing ORN's out of the epithelium and to their target structure, the olfactory bulb. olfactory bulb.

DEVELOPMENTAL MORPHOMETRICS OF OLFACTORY RECEPTOR AXONAL ARBORS. <u>Jason R. Klenoff and Charles A. Greer*</u>, Sec. Neurosurg. & Neurobiol., Yale Univ. Sch. Med., New Haven, CT 06510

Haven, CT 06510

The mechanisms subserving the mature distribution of afferent axonal arbors in olfactory bulb (OB) glomeruli remain unknown. Elsewhere in the CNS a common theme is early axonal exuberance followed by activity-dependent pruning. This led to the hypothesis that afferent axons in the OB may follow a similar developmental scheme. To test this hypothesis we studied morphological features of olfactory receptor neuron (ORN) axons on postnatal days 0, 3, 6, 9, 12, and 21. Sprague-Dawley rats were anesthetized, sacrificed, and the OBs processed with a Golgi-Kopsch technique that impregnated ORN axons. Twenty axons from each age were reconstructed using cameralucida at 100X, oil immersion. Axons were evaluated for the number of branches (NB), varicosities (V), length of branches (LB), and area occupied (AO). Mean values for adults were: NB = 17, V = 9.6, LB sum = $169.67\mu m$, AO = $797.78\mu m^2$. The values from the younger age groups were not statistically different from those in the adult. Because our data suggest that ORN axons do not follow the hypothesized scheme, it would appear that the ORN axon, upon innervating a glomerulus, does not arborize beyond the mature limits. This argues strongly for the presence of highly specific guidance and trophic markers that the ORN employs during innervation. These data are the first to suggest that highly specific molecular markers underlie ORN arborizations rather than activity dependent mechanisms as seen in other sensory systems.

CHRONIC RECORDING OF ODOR-INDUCED ACTIVITY IN THE PROCEREBRAL LOBE OF A TERRESTRIAL MOLLUSC. I.R.C. Cooke*, P.P. Mitra¹ and A. Gelperin¹, School of Biological and Chemical Sciences, Deakin University, Geelong, Vic 3217, Australia and ¹Biological Computation Research Department, Lucent Technologies Bell Laboratories, Murray Hill, NJ 07974, USA.

The procerebral (PC) lobes of the cerebral ganglia of limacid slugs process olfactory information detected by the superior tentacles and may be involved in the robust olfactory learning exhibited by these animals. Each PC lobe contains of order 10⁵ highly interconnected interneurons and receives substantial input from primary sensory neurons and higher order olfactory interneurons located in the digitate ganglion in the superior tentacle. Isolated PC lobes exhibit spontaneous oscillatory network activity which is detected as regular oscillations in the PC field potential. These oscillations in vitro are interrupted by stimulation of olfactory afferents. In the present study we determined that oscillatory activity in the PC lobes occurs as part of the normal behaviour of intact slugs. Using general anaesthesia we implanted a pair of fine wire electrodes into the cell body layer of one implanted a pair of fine wire electrodes into the cell body layer of one PC lobe of large <u>Limax</u>. After allowing several days for recovery from surgery, we recorded the PC field potential from freely moving slugs. The PC field potential oscillated continuously with a frequency of 0.5-2 Hz as slugs explored their environment in the absence of strong olfactory stimuli. Abrupt presentation of strongly aversive olfactory stimuli (amyl acetate) caused substantial increases in the amplitude and frequency of the PC lobe oscillation which returned gradually to asselline levels when the etimulus was removed. New spectral analysis baseline levels when the stimulus was removed. New spectral analysis techniques will be used to quantify the oscillatory responses to odors

MINIMAL MODEL OF OSCILLATIONS AND WAVES IN THE LIMAX OLFACTORY LOBE WITH TESTS OF THE MODEL'S PREDICTIVE POWER. Ermentrout, J. Flores & A. Gelperin 1* Dept. Math., Univ. Pittsburgh, Pittsburgh, PA 15260 and ¹Biological Computation Res. Dept., Bell Labs, Lucent Technologies, Murray Hill, NJ 07974 To simulate the procerebral (PC) lobe of Limax, we created a

minimal model which incorporates several known facts of PC anatomy and dynamics and assumptions about connectivity. We use a one-dimensional network of bursting (B) cells with each cell modeled as a single compartment having a persistent Ca current, a leak, and a delayed rectifier. Model B cells are coupled with graded synapses and interactions between B cells are kept fairly local. We impose an apical-basal gradient in B cell frequency by making the conductance of the delayed rectifier a function of position along the apical-basal axis. With appropriate choices of parameters the model produces regular traveling waves. The input from odor sensors is modeled as a depolarizing current applied uniformly across the PC, so that odor-elicited input shortens the apical-basal phase-lag to nearly zero, as previously measured. The apical-basal gradient of B cell frequency was tested experimentally by embedding the desheathed PC in agar and making a series of 4 150 μm slices normal to the apical-basal axis. The frequency of local field potential oscillation was highest in the most apical slice and decreased in each successive more basal slice. Visualization of cells in the oscillating slice by DIC-IR microscopy will facilitate recording from B cells and allow further tests of the PC model.

SPIKE TIMING IN THE LIMAX OLFACTORY SYSTEM MEASURED WITH CALCIUM IMAGING IN NEURITES OF PROCEREBRAL INTERNEURONS. A. Gelperin, J. Flores & W. Denk* Biol. Comp. Res.Dept., Bell Labs, Lucent Technologies, Murray Hill, NJ 07974.

The olfactory system of the terrestrial molluse Limax maximus

a model system for studies of information processing in olfactory systems which share the almost universal property of spontaneous or odor-evoked coherent network oscillations. The procerebral (PC) lobe receives direct input from olfactory proceederal (PC) lobe receives direct input from offactory receptors and displays a coherent 0.7 Hz oscillation and wave-like propagation of excitation from distal to proximal poles. Calcium changes evoked by single action potentials were measured, using 2-photon excited fluorescence microscopy, with high spatial and temporal resolution (J. Neurobiol. 30:110, 1996) in processes of bursting (B) and nonbursting (NB) PC interneurons loaded by extracellular application of Ca-green 10K dextran. B and NB processes fire at different phases of the oscillation. In addition, application of NO increases and decreases activity in B and NB cells, respectively. Individual B cell processes could be traced in the cell body layer for 10-20 cell processes could be traced in the cell body layer for 10-20 soma diameters. Spike timing in B cells has a constant phase relation to the local field potential (J. Neurophys. 72:1402, 1994). Simultaneous meaurements of spike timing in adjacent B cell processes revealed differences between the 2 cells in the timing of burst onset that remained constant over many cycles. It will be interesting to see how the relative timing of activity in B cells is altered by odor-clicited inputs to the PC.

OPTICAL IMAGING OF OLFACTORY-EVOKED ACTIVITY IN THE BRAIN OF THE SPINY LOBSTER. L.B. Cohen*, M. Wachowiak and J. Fang. Dept. Physiology, Yale University, New Haven, CT 06520; Whitney Lab and Dept. Neuroscience, Univ. of Florida, St. Augustine, FL 32086

We have used voltage-sensitive dves to optically record activity in the brain of the spiny lobster following electrical and odor stimulation of olfactory receptor cells. Di-4-ANEPPS (.05 mg/ml) or JPW-2081P (provided by Joe Wuskell and Leslie Loew) (.2 mg/ml) was bath applied or perfused into the brain. In the olfactory lobe (OL), the first synaptic level of the olfactory pathway, electrical stimulation evoked shortlatency signals having an initial fast component followed by a slow long-lasting component. Paired pulse stimulation reduced the fast component by 30 - 50% and eliminated the slow component. Signals in the accessory lobe (AL), a second-order olfactory neuropile, were longer in latency and were sometimes expressed as a series of spike-like transients which traveled rapidly across the lobe. Similar transients were also observed in the lateral soma cluster, which contains somata of OL and AL projection (output) neurons. The transients had short latency in the region containing OL projection neuron somata and long latency in the region containing AL projection neuron somata, suggesting that signals in the soma cluster reflect the synchronized firing of action potentials in olfactory and accessory lobe projection neurons. Paired pulse stimulation eliminated all signals in the AL and soma cluster. These results agree with those obtained using intracellular recordings, confirming that olfactory processing occurs first in the OL and then in the AL. Odor-evoked signals in the OL were recorded in two preparations. While odors elicited activity across the entire lobe, the temporal pattern of activity varied slightly with spatial location and odor identity. Since activity in the lobster brain can be monitored simultaneously in three distinct regions of the olfactory pathway, this system should be useful in further studies on olfactory processing in the CNS.

POPULATION CODES FOR ODORS AND THEIR MIXTURES IN THE ANTENNAL LOBES AND MUSHROOM BODIES OF THE HONEYBEE REVEALED BY IN VIVO CALCIUM IMAGING. Jasdan Joerges, Giovanni Galizia* and Randolf Menzel. Institut für Neurobiologie, Königin-Luise Str. 28-30, 14195 Berlin, FRG

The neuronal representation of odors and their mixtures in olfactory neuropiles of the bee was assessed using calcium imaging in the intact brain during natural odor stimulation. Following incubation of the brain with the cell permeant dye Calcium-Green-2-AM for 1h, fluorescence signals were recorded for up to 2h.

Odor evoked activity patterns in the antennal lobe (AL) showed the existence of distinct population codes for odors and their mixtures. Single activity centers could be related to specific glomeruli of the AL. The qualitative patterns were conserved over a wide range of odor concentrations but signal sizes increased with higher concentrations. Mixtures led to activity patterns that contain activity centers of both single components. However the patterns cannot be predicted by the linear sum of the two single component patterns, indicating nonlinear interactions between glomeruli.

The mushroom bodies (MBs) are important in the context of associative learning and memory processes. We recorded odor specific patterns in the the MBs with the same techniques. Activated regions were more spatially restricted compared to activity patterns in the AL, and the time courses of the signals were faster. This may be due to recurrent inhibition within the MBs. In some cases signal size increased during repetitive stimulation indicating possible effects of neuronal plasticity

FUNCTIONAL HETEROGENEITY WITHIN OLFACTORY GLOMERULI OF THE SPINY LOBSTER. M. Wachowiak*, C.E. Diebel and B.W. Ache. Whitney Lab and Dept. Neuroscience, Univ. Florida, St. Augustine, FL 32086. Olfactory glomeruli in the lobster olfactory lobe (OL) are columnar in shape

and consist of three anatomically distinct regions: a peripheral cap region, an underlying subcap and a proximal base. Recent studies showing that neurons can preferentially innervate one or more of these regions suggest that olfactory processing within glomeruli may be functionally heterogeneous. Here we have morphologically and physiologically characterized four classes of local interneurons involved in intrinsic processing within OL glomeruli. One class branches only in the cap region and responds to electrical stimulation of the olfactory nerve with a burst of 1 - 3 spikes followed by a slow-onset hyperpolarization lasting 0.5 - 1 sec. The cap neurons also show spontaneous, 1 -2 Hz oscillations in membrane potential that sometimes give rise to spikes. A second class passes through the base but terminates only in the subcap, and responds to electrical stimulation with a burst of 1 - 4 spikes followed by a depolarization lasting 0.5 - 4 sec. A third class branches exclusively in the base and responds to electrical stimulation with a burst of 1 - 3 spikes followed rapidly by a hyperpolarization lasting approximately 1 sec. Finally, a fourth class innervates all three glomerular regions and responds to electrical stimulation with a burst of 1 to 20 spikes followed by a depolarization lasting 3 to 10 seconds, depending on stimulus intensity. Thus, each of the four interneuron classes has a distinct morphology with respect to the three glomerular zones and a different pattern of response to electrical stimulation of olfactory receptor cell axons. These findings confirm that the cap, subcap and base represent functionally distinct regions for olfactory processing within glomeruli of the lobster OL. Supported by NSF-IBN9222765.

BILATERAL SAMPLING AND CHEMOTAXIS IN TURBULENCE WITH A LOBSTER INSPIRED AUTONOMOUS UNDERWATER ROBOT. <u>F. Grasso*1, T. Consi², J. Dale¹, D. Mountain³ and J. Atema¹. ¹Boston University Marine Program, Woods Hole, MA. 02543, ²MIT Sea Grant, Cambridge MA 02139 and</u>

Program, Woods Hole, MA. 02543. "MIT Sea Grant, Cambridge MA 02139 and ³Biomedical Engineering, Boston University, Boston MA 02215. In the marine environment smooth concentration gradients that could guide an animal to an odor source over distances greater than a few centimeters do not exist on the time scale that the lobster makes its orientation decisions (Grasso, Basil and Atema 1996. Basil, Grasso and Atema 1996. We have been exploring alternative orientation strategies to concentration gradient ascent with a lobster-sized autonomous robot that uses the dynamics of turbulent odor dispersal as its sole cut on the odor source. The robot has speed and maneuverability which match or exceed those of the lobster. It senses its environment with two chemical sensors which sample the external concentration of tracer chemicals with a temporal resolution which exceeds that of lobster chemoreceptor cells. Using two alegorithms which sample the external concentration of tracer chemicals with a temporal resolution which exceeds that of lobster chemoreceptor cells. Using two algorithms which compare the signals arriving at the sensors to guide the robot we tested the effects of starting orientation, starting distance, and sensor separation on the accuracy of robot orientation in a turbulent odor plume. Depending on the performance measure: (htts, average closest approach, time to closest approach or path tortuosity) the two orientation strategies are more or less effective close (< 60 cm) to the odor source. Close to the source increased sensor separation (up to 7 cm from 1 cm) increases "hit" accuracy. This result is surprising as the lobster's primary distance chemoreceptor organs are separated by approximately 3 cm. However, farther from the source (60-100cm) all biologically reasonable sensor separations are equally poor at providing information on the direction to the source. The lobster's 3 cm sensor separation, though sub-optimal close to the source, may facilitate processing of cues at greater distances including sequential analysis of odor encounters. Experiments are now underway investigating algorithms that make use of the spatial organization of the odor dispersal dynamics in the 60-100 cm source distance range. cm source distance range

DIFFERENT INSECTS EMPLOY SIMILAR OLFACTORY PROCESSING MECHANISMS. M. Stopfer* and G. Laurent, Division of Biology, 139-74, California Institute of Technology, Pasadena, CA 91125.

Presentation of non-pheromonal odorants evokes synchronous neural

activity in the locust (*Schistocerca americana*) brain. This coherent activity can be detected extracellularly as large amplitude, oscillating local field potentials in the mushroom bodies, and intracellularly as oscillating membrane potentials in Kenyon cells and antennal lobe (AL) projection and local interneurons. We have now observed several key features of the locust olfactory response in the cockroach (*Periplaneta americana*) and honeybee (Apis mellifera) as well.

Odor-evoked oscillating field potentials recorded extracellularly from the alpha-lobes of both cockroach and honeybee reveal, as in the locust, the presence of synchronous, coherent neural activity. Furthermore, intracellular recordings from antennal lobe neurons of the cockroach reveal olfactory response patterns similar to those observed in the locust reveal olfactory response patterns similar to those observed in the locust in two interesting respects. First, individual neurons tend to respond to more than one odorant, suggesting that specific odor encoding is achieved by an overlapping ensemble mechanism. Second, a given neuron often responds to different odorants with different firing patterns, suggesting that slow temporal dynamics play a role in odor encoding. To further characterize the cockroach olfactory apparatus, AL neurons were visualized by intracellular cobalt fills. Neurons responding to odorants arborize broadly to a dozen or more glomeruli. The suitability of these insects for combined cellular and behavioral experiments will enable a mechanistic analysis of odor necreption and memory.

enable a mechanistic analysis of odor perception and memory.

Inhibitory Mechanisms Underlying Oscillatory Synchronization of Projection Neurons in the Locust Olfactory System. K. M. MacLeod* and G. Laurent, Division of Biology, 139-74, California Institute of Technology, Pasadona CA 91125

Odors appear to be represented in the locust (Schistocerca americana) olfactory system by specific but overlapping ensembles of synchronously firing neurons causing fast, odor-evoked oscillations that can be recorded in local field potentials (LFP) from the mushroom body (MB). We showed that the GABA antagonist picrotoxin (PTX) can block these fast oscillations when pressure injected into the antennal lobe (AL), but not the MB (MacLeod and Laurent, 1995, Soc. Neurosci. Abstr. 58.10.) Electron microscopy and GABA-like immuno-gold labelling show reciprocal synaptic connections between GABA-positive and -negative profiles (Laurent and Leitch, J. Comp. Neurol., in press.) These data together suggest that the LFP oscillations are the result of synchronous action potentials from the projection neurons (PN) of the AL, whose synchronization arises from reciprocal interactions between the PNs and the non-spiking, inhibitory, local interneurons (LN) in the AL. Studies in other olfactory systems and in the visual system of insects have shown that histamine may also mediate post synaptic inhibition. We attempted to better characterize the nature of inhibitory interactions in the locust AL by using known GABA-antagonists (cimetidine, pyrilamine) and testing their effectiveness in climinating synchronization. PTX was found to effectively reduce the power of the LFP oscillations at the lowest concentrations (0.1mM in bath). Gabazine reduced oscillations at higher concentrations (0.1mM in bath). Gabazine reduced oscillations at the lowest concentrations (0.1mM in bath). Gabazine reduced oscillations at the lowest concentrations for TN firing, it did not greatly affect their slow temporal firing patterns whose modulation thus appears to be under the control of different synaptic mechanisms than those underlying synchronization. OPTICAL RECORDING OF EVOKED ACTIVITY IN NEURAL CIRCUITS OF THE COCKROACH ANTENNAL LOBE USING A VOLTAGE-SENSITIVE DYE. J. Inouchi and H. Ai Lab. of Neurophysiology, Nat'l. Inst. Sericul. and Entomol. Sci., Tsukuba, lbaraki 305, Japan.

Optical recordings with high spatial (128x128 photodiodes) and temporal (0.6 ms) resolution of transmembrane activities were used to characterize the properties of the electrical signals in the antennal lobes (ALs.) of the adult cockroach (Periplaneta americana) in vivo. After electrical stimulation of the antennal nerve (AN), activity spreads centripetally from the sites of synaptic input to generate nonhomogenous response patterns that are presumably mediated by circuits within the glomerular organizations. The activities showed a characteristic sequence of depolarizing and hyperpolarizing responses both at macroglomerular (MG) and ordinary glomerular (OG) area, increasing the intensity of stimulation enhanced the size and duration of the depolarizing and hyperpolarizing responses. The size of the MG responses was always larger than that of OG responses. The optical events were correlated with feld-notential waves recorded simultaneously at MG and OG response response response responses responses.

organizations. The activities showed a characteristic sequence of depolarizing and hyperpolarizing responses both at macroglomerular (MG) and ordinary glomerular (OG) area. Increasing the intensity of stimulation enhanced the size and duration of the depolarizing gand hyperpolarizing responses. The size of the MG responses was always larger than that of OG responses. The optical events were correlated with field-potential waves recorded simultaneously at MG and OG regions, respectively. These optical signals were practically abolished after 1µM TTX application on the AL. A low Ca²⁺ (1mM), high Mg²⁺ (50mM), in the Ringer solution reduced the depolarizing and hyperpolarizing activities. The depolarizing activities consist of a fast and a slow component. The low Ca²⁺ medium suppressed the slow component of the activity. This suggests that the fast component is a fast presynaptic response representing synchronous compound EPSPs and action potentials from neurites of AL neurons. A GABA, receptor antagonist, picrotoxin (1µM), enhanced the size and duration of the depolarizing components, and the opposite effect was observed in the hyperpolarizing components. Probably, inhibitory actions of local interneurons in the AL contribute to the regulation of these depolarization.

EFFECTS OF ABNORMAL DEVELOPMENT ON THE ANATOMY OF THE PHEROMONE PROCESSING CENTER OF MALE MOTH BRAINS AND THE BEHAVIOR IT SUPPORTS. M.A. Willis*, J.D. Floyd, R.S. Kellar and L.P. Tolbert. ARL Div. of Neurobiology, Univ. of Arizona, Tusson, AZ. 85721.

Tolbert, ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

Virtually all vertebrates and higher invertebrates have the first synapses between olfactory receptor cells and central neurons organized into discrete spherical knots called glomeruli. In some animals, a small subset of glomeruli are specialized for processing information about specific social odors, pheromones. In a recent study we have focused on one such group of specialized glomeruli, the macroglomerular complex (MGC), which is responsible for processing information about the female sex-attractant pheromone in the male moth Manduca sexta. Previous studies have indicated that the degree of glomerulus formation can be affected by surgically reducing the number of sensory axons growing from the antennae into the antennal lobes of female brains during metamorphosis. When similar experiments are done on developing male moths, a distorted neuropil develops in the area normally occupied by the MGC. These surgically manipulated animals, possessing a very distorted "MGC-like" structure, have been shown to be capable of exhibiting pheromone-modulated behavior in a manner similar to that observed in normally developed moths. This suggests that the normal MGC structure is not necessary for processing reception of the female pheromone. It is possible that the MGC-specific olfactory neurons are still forming functionally specific synapses in the MGC region despite the anatomical disruption of the region. We have tested this hypothesis using florescent labeling to trace male-specific olfactory axons to their destinations. Our results reveal that, even though the gross anatomy of the MGC is disrupted, the pheromone-sensitive receptor neurons continue to form MGC-like projections in the antennal lobe. [This study was supported by NIH grants NS-20040 and DC-00348, and NSF grant IBN-9216532.]

ANALYSIS OF ODOR-EVOKED TRANSIENT SYNCHRONIZATION OF PROJECTION NEURONS IN THE LOCUST OLFACTORY SYSTEM.

Michael Wehr and Gilles Laurent, * California Institute of Technology, Biology Division, Computation and Neural Systems Program 139-74, Pasadena, CA 91125.

Fast odor-evoked field potential oscillations in the mushroom bodies of the locust result from the formation of odor-specific ensembles of coherently firing projection neurons in the antennal lobe (Laurent & Davidowitz 1994, Science 265:1872-1875). We recorded simultaneously from small (2-5) ensembles of projection neurons in addition to the mushroom body field potential in vivo. using extracellular electrodes. Subsets of projection neurons transiently synchronize their firing to each other and to the mushroom body field potential, at precise and odor-specific epochs of the response to an odor. We have quantified this synchronization and developed methods to analyze the statistical significance of these synchronized patterns and of the correlation functions calculated from simultaneously recorded spike trains. Because synchronization provides a means to encode signals via time and phase delays, we are currently investigating the stimulus specificity of phase relationships between synchronized neuron neurons and between these neurons and the mushroom body field potential. Preliminary evidence suggests that phase relationships between synchronized neurons may vary in a stimulus-specific fashion. Research supported by an NSF-PFF and NSF grant to GL.

SEX-SPECIFIC AND TEMPORAL ANALYSIS OF OLFACTORY CELL BIRTH IN THE ANTENNA OF THE MOTH MANDUCA SEXTA: SPECIFIC MITOTIC PATTERN. M. D. Franco, J. P. Poppy, P. Pierret and R. G. Vogt University of South Carolina, Columbia, SC 29201 and Departement de Pathologie, Universite de Montreal, Montreal, Quebec, Canada*

Montreal, Montreal, Quebec, Canada*

The olfactory epithelium of the male moth Manduca sexta expresses two predominant classes of sensillum; the long and the short hairs. The long hairs contain the pheromone binding proteins (PBPs) and the short hairs contain one of two classes of general odorant binding proteins (GOBP1 or GOBP2). Female antennae have only short hairs which contain primarily the GOBP1 and GOBP2 proteins. These odorant binding proteins (OBPs) are expressed in the support cells of the sensillum and are released into its lumen. The olfactory cells associating with a sensillum derive from a common sensory mother cell early in the adult development. After a series of cell division, the mother cell gives rise to its progeny: support cells and neurons. Using an *in vivo* labeling of DNA synthesis, we have studied the mitotic activity of the epithelial cells during the larval and adult antennal development. fWe have shown sex-specific and temporal patterns for the birth of PBP and GOBP cells in the pupal antenna. In both male and female, birth of the olfactory cells occurs at stage 3 (preapolysis) in the pupal development. However, the pattern of expression is different: two stripes per annulus for the male and homogeneous pattern for the female, thus corresponding respectively to the morphological organization of PBP and GOBP sensory hairs in the adult. The termination of mitotic events is different for the two classes of sensory hairs in the male: long hair mitoses end by stage late-5 (post apolysis) while short hair mitoses end at stage 6 after the long hairs have begun to form. In contrast, in the female antenna, the mitoses which give rise to the short hairs ends 1 day earlier than in the male, by stage medium-5 (post apolysis). All together, these results suggest a differential spatio-temporal development in the birth of the sensory cells in the male and female antennae of the moth Manduca sexta. HEAT-SHOCK REDUCES THERMOSENSITIVITY OF NEURAL PARAMETERS IN THE LOCUST FLIGHT SYSTEM J. R. Gray* and R. M. Robertson. Department of Biology, Queen's University, Kingston, Ontario, CANADA K7L 3N6.

Pretreatment of tissues or whole animals with high, sublethal temperatures (heat-shock) induces thermotolerance to normally lethal temperatures Thermotolerance can be manifested as increased survival or maintenance of physiological processes. We are interested in whether heat-shock induces protection of neuronal function at normally lethal temperatures. To this end we have investigated effects of heat-shock on the temperature sensitivity of neuronal parameters in the locust flight system

We measured the rhythm frequency of the deafferented flight motor as well as the conduction velocity and amplitude of extracellularly recorded action potentials conveyed along the forewing stretch receptor axon. Measurements were made at temperatures ranging from 15°C to 50°C in heat-shocked and

The deafferented rhythm was less sensitive to temperature changes above 35°C in heat-shocked animals. The conduction velocity and relative amplitude of action potentials conveyed along the stretch receptor axon were less sensitive to temperature increases above 20°C in heat-shocked animals.

These data suggest that heat-shock conserves the operation of the flight system at high temperatures. This may be accomplished by a decrease in the thermosensitivity of the conduction velocity and amplitude of action potentials within the central flight circuitry. The latter effect may serve to protect synaptic interactions and thus allow the circuitry to operate within optimal parameters.

LEG DESIGN AND RESPONSE SPECIFICITY OF CUTICULAR STRAIN DETECTORS. S. N. Zill*, R. A. DiCaprio and S. F. Frazier, Dept. Anat., Marshall Univ. Sch. Med., Huntington, WV 25755 and Dept. Biol. Sci., Ohio Univ., Athens, OH 45701

As part of a project to incorporate principles of sensory-motor integration into the design of legged robots, we are studying the morphological and physiological properties of the cockroach trochanteral campaniform sensilla. These sense organs are the largest collection of force sensitive mechanoreceptors in the limb and provide critical information for the control of walking. Our hypothesis is that and provide discontinuous aniion include the control of watering control of the receptors act as arrays of strain gauges encoding stresses from leg loading and muscle contractions. We have begun testing the effects of load by applying bending forces to the leg, both in the plane of joint movement and in planes perpendicular to the joint axis, while monitoring sensory activity extracellularly. Loads applied in any of these planes produce discrete patterns of discharges that may encode the direction and magnitude of leg loading in the firing of individual or subgroups of sensilla. We also are examining whether the responses of sensilla are delineated by their location relative to muscle insertions and the architecture of the exoskeleton. We have assembled 3D reconstructions of the anterior groups of sensilla (Groups 2-4) from confocal images of DII filled sensory neurons and have generated isocontour projections of the cuticular walls of the trochanter. The exoskeleton has a system of thickenings or buttresses with specific orientations relative to the principal sources of strain. These include a dorso-ventral buttress (perpendicular to the trochanteral long axis and distal to the Group 2 sensilla) which is linked to a cuticular 'gasket' at the trochanteral flexor muscle insertion, surrounding Group 3. We are extending these experiments to determine the specific information that individual sensilla provide during the interactions of internal and external forces that occur during walking Support: ONR N00014-93-1-0088 and N00014-96-1-0694.

SIMULATED DYNAMICS OF WALKING AND CLIMBING IN THE COCKROACH. G.M. Nelson, R.D. Quinn, J.T. Watson, A.K. Tryba, R.E. Ritzmann, H.J. Chiel, R.D. Beer*. Departments of Mechanical Engineering, Computer Science, Case Western Reserve University Biology, and Cleveland, OH 44106

We are designing and constructing biologically based robots. previous robots have demonstrated that neurobiologically inspired control systems can generate a range of movements over moderately rough terrain and slatted surfaces. The goal of our current research is to develop a robot that is more closely patterned on detailed observations of cockroach locomotion (see abstract of Watson, Tryba and Ritzmann).

We have developed a dynamic simulation tool that uses digitized video images of walking and climbing cockroaches to estimate joint torques and ground reaction forces. Our simulation indicates that straight walking on a level plane requires front and middle legs with three degrees of freedom each, and hind legs with two degrees of freedom. However, because we want this robot to achieve climbing capabilities similar to those of cockroaches, we have also simulated video records of climbing animals. Preliminary analysis of these data suggest that the front and middle legs require an additional degree of freedom. Ongoing investigations are demonstrating the degree of motion at each joint for both running and climbing, and providing insight into the power requirements for each joint in order to size joint actuators.

The simulation is also capable of integrating electrical records that have been recorded in conjunction with the digitized kinematics. These data can then be used to relate electrical activity to joint torque during complex motion in order to generate appropriate control algorithms. Supported by ONR grant N00014-90-J-1545.

NEURAL SEGMENTS SPECIALIZED FOR SEXUAL BEHAVIOR: COMPARISON OF MALE AND FEMALE GRASSHOPPERS. K.J. Thompson* and H.R. Campbell. Dept. of Biology, Agnes Scott College, Decatur, GA 30030

In a continuing study of the neural basis of dimorphism in sexual behavior of male and female grasshoppers, motorneurons (MNs), efferent dorsal unpaired median neurons (DUMs), and DUM interneurons are being studied. In females cobalt backfills of the 8th tergal nerves stain 24 MNs in the 7th abdominal segment (A7) including 8 ovipositor closer MNs, and 5 contralateral MNs in A8 including 3 ovipositor protractor MNs. The identical pattern of MNs is present in stains of males, with the matched 8 MNs in A7 supplying the male's median internal ventral muscle (247) and the matched 3 contralateral MNs in A8 supplying the male's paradorsal muscle. EMG recordings from male muscle 247 reveal a bursting pattern of activity that is elicited by the same experimental procedures that elicit the oviposition motor pattern in females. Backfills of the 8th sternal nerves of females stain MNs in 2 ipsilateral clusters in A8. The anteriormost cluster of 7 MNs contains the ovipositor retractor MNs and the more posterior group contains the 5 ovipositor opener MNs group. In addition, 6 efferent DUMs send axons to the ovipositor opener muscle, and one also supplies the ovipositor retractor. Male MNs backfilled from the sternal nerve fall into clusters similar to the female pattern, but with several of the male MNs notably smaller. The male's sternal nerve contains the axon of only 1 efferent DUM neuron. In both sexes neural segment A8 also contains the cell bodies of DUM interneurons. Their number is approximaltely 22 in females and 3 in males. The DUM neurons thus show dimorphism of cell number and of primary neurite structure in contrast to the minimal differences discovered when MNs are compared.

ANALYSIS OF PROTHORACIC LEG MOVEMENT DURING WALKING AND CLIMBING IN THE COCKROACH. <u>J.T. Watson*, A.K. Tryba and R.E. Ritzmann</u>. Department of Biology, Case Western Reserve University, Cleveland, OH 44106.

Our laboratory is involved in collaborative efforts to design robotic systems based upon the neuromuscular and mechanical properties of arthropods. The current robot design is intended to include agile movements that enable turning and climbing over complex terrains. Observations that we have made on freely behaving cockroaches (Blaberus discoidalis) suggests that the movements of the prothoracic (T1) legs are crucial to directing and executing these types of movements.

During walking movements, specific joints of the T1 leg are different from those in the T2 or T3 legs. Extension of the T1 femur-tibia (FT) joint occurs during swing phase, preceding the coxa-femur (CF) joint by about 40 msec. This difference is also seen in the EMG records. The slow extensor of the tibia (SETi) fires a high frequency burst in antiphase with the slow depressor of the femur (Ds). A low frequency burst in SETi occurs during FT flexion and coincides with Ds activity. These movements of the CF and FT joints

occur along with a rotation of the coxa around the thorax-coxa (TC) joint.

The animal also takes advantage of the mobility of the T1 legs during climbing. It typically rears up on its hind legs by rotating the TC joint of the T2 leg. The T1 legs then reach up to seek a foothold and the T3 legs extend to launch the climb up the obstacle. Electrically, Df activation in the mesothoracic leg is associated with the rearing up phase, whereas high frequency activity in Ds is associated with the actual climb. It appears that once the prothoracic leg has located the goal, the T2 and T3 legs simply use a follow-the-leader strategy to reach the same location.

THE EFFECT OF NOISE ON SIGNAL DETECTION AND TIME PRECISION IN A PARALLEL NEURAL NETWORK. X Pei1*, Wilkens² and F Moss¹, ². Center for Neurodynamics, Depts. of Physics¹ and Biology², Univ. of Missouri-St. Louis, St. Louis, MO 63121.

Noises are present in many sensory nerve systems, induced internally or externally. It has been demonstrated recently that noise can improve the coherence of the responses when stimulus amplitudes are below a threshold, a process known as Stochastic resonance (SR). How can nerve systems benefit from such noise enhanced coherence? This question arises frequently, because it is difficult to understand how an actual system can make use of the improved coherence. Here we demonstrate that SR can improve the detection performance for aperiodic signals in a parallel neural network. A two-layer network is constructed to simulate the mechanosensory system in the crayfish tail fan. The first layer contains 1000 neurons which mimic the hair cells. The second layer contains two neurons which evaluate the output from the first layer and generate responses to detected inputs. Uncorrelated noise is added to each cell of the system. For subthreshold signals, the noise-response function shows a peak at an optimal noise level. The probability of signal detection improves in the presence of noise. Also, the time precision of the spike response to the inputs is improved. For supra-threshold signals, adding noise to the system only degrades the performance of the system, that is, the detection probability and the time precision show only a monotonous decline. In conclusion, a system containing elements which process inputs in parallel can improve its performance by adjusting the internal noise level to an optimum.

STARTLE RESPONSE NEURAL SYSTEM AND ITS CHOLINERGIC ACTIVATION BY CEREBRAL INTERNEURONS IN THE MOLLUSC, CLIONE LIMACINA. T.P. Norekian* and R.A. Satterlie. Dept. Zoology, Arizona State Univ., Tempe, AZ 85287 & Friday Harbor Labs, Friday Harbor, WA 98250.

The holoplanktonic pteropod mollusc Clione limacina exhibits an active avoidance behavior, or escape swimming, which includes an initial, high-speed startle response that is followed by a period of fast swimming. The startle response is controlled by a pair of large pedal motoneurons with very low membrane potentials and extremely high thresholds for spike generation, whose activity is independent of the normal swim pattern generator. Each Startle motoneuron directly innervates insilateral swim musculature in the wings; one motoneuron induces contraction of dorsal swim musculature and dorsal flexion of the wings (d-phase), and the other motoneuron produces ventral flexion of the wings (v-phase). Two interneurons have been identified in the cerebral ganglia (Cr-St), which produce strong activation of the ipsilateral d-phase Startle motoneurons. Each spike in a Cr-St neuron produces a fast, high amplitude (up to 50 mV) EPSP in Startle motoneurons. This I spike: I EPSP ratio and the stable short synaptic latencies (2 ms) persist in high Mg^{++} /high Ca^{++} sea water suggesting monosynaptic connections. Synaptic transmission between Cr-St interneurons and Startle motoneurons appears to be cholinergic. 10 μ M atropine reversibly blocks EPSPs in Startle neurons. Hexamethonium and d-tubocurarine partially block EPSPs, although much higher concentrations are required. Exogenous acetylcholine (1 μM) produces a dramatic depolarization of Startle motoneurons in high Mg⁺⁺ sea water. Cr-St interneurons and Startle motoneurons are also electrically coupled, however the coupling is weak. Stimuli which are known to initiate escape responses in intact animals, such as tactile stimulation of the tail, produce excitatory inputs to Startle motoneurons and Cr-St interneurons. This study was supported by NIH grant NS-27951 and NSF grant IBN-9319927.

SYNAPTIC MECHANISMS ASSOCIATED WITH REFLEX ACTIVATION OF MOTONEURONS IN HERMIT CRAB ABDOMINAL NERVOUS SYSTEM. William Chapple*, Dept. Physiology and Neurobiology, University of Connecticut, Storrs, CT 06269-4156

Two prominent features of the reflex activation of Two prominent features of the reflex activation of ventral superficial muscle motoneurons in the fourth segment of the hermit crab abdomen are its complex phasic response and its adaptation. Intracellular recording from several of these motoneurons indicates that the mechanisms for these features are probably synaptic. The identity of the motoneurons was confirmed by antidromic stimulation of the motor root, and by a 1:1 association of motoneuron spikes with extracellular potentials in the motor root and EJPs in the muscles, both during tonic firing and during activation of the motoneuron by depolarizing current. Electrical stimulation of mechanoreceptor afferents in activation of the motoneuron by depolarizing current. Electrical stimulation of mechanoreceptor afferents in the first ganglionic root produces a complex synaptic potential consisting of a short latency (15 ms) EPSP followed by a longer latency (50 ms) IPSP; both are abolished by 10⁻³ M curare. Both components increase with stimulus intensity and habituate at frequencies greater than 1 Hz. A third component composed of a longer latency (200 ms) low frequency train of EPSPs was not abolished by curare.

ELECTRICAL ACTIVITY EVOKED AT THE CRAYFISH BRAIN IN EESPONSE TO VISUAL STIMULATION WITH MOVING BARS.

OSCAR H. Hernández, Jesús Serrato, Jesús HernándezFalcón, and Fidel Ramón*. Ctro. Inv. Enf. Tropicales,
Campeche, Camp., Depto. Fisiol. Biof. & Neurosci. CINVESTAV del IPN, Depto. Fisiol., Fac. Med., UNAM, and Div. Posgrado, Fac. Med., UNAM, Mexico.

We are studying characteristics of the electrical activity evoked at the brain of crayfish chronically implanted with extracellular electrodes. Animals were placed in a chamber with the eyes above the water level to avoid the air-water interface. Stimuli were black and white bars of various widths, angles and speeds, moving linearly across clear or dark backgrounds. In agreement with previous results by Wiersma and $\,$ Yamaguchi (1967), short trains of spikes were recorded in response to leading and trailing edges of black bars wider than about 4° at a distance of 30 cm. Some combinations of bar characteristics and speed elicited delayed electrical activity and animal movement. Electri cal activity was also recorded in response to moving black squares as small as 2 cm². White bars against a clear background do not produce responses. Results suggest that under these worst-case conditions, crayfish brain ac tivity can be evoked by moving objects larger than about $3\,^{\circ}$ at a speed of about $25\,^{\circ}/\text{sec.}$ Supported by: Prog. Div. Posgrado No. 359.

REFLEX ACTIVATION OF PNEUMOSTOME MOTOR NERVES IN THE PULMONATE SNAIL. E.M. Adams*, W.J. Benedict and D.M. Shope, Dept. of Biology, Univ. of Scranton, Scranton, PA 18510-4625.

Helix aspersa possesses a single lung in which gas exchange takes place. The lung opening is regulated by muscles innervated by neurons exiting the visceral and right parietal ganglia in three nerves: the anal (AN), medial right parietal (RPNm), and lateral right parietal (RPNI) nerves. This study assessed the reflex activation of these nerves. An isolated ganglion-pneumostome preparation was used to study (1) the rate of increase (dV/dt) of nerve activity and (2) the stimulus-response latency in each nerve in response to electrical stimuli applied individually to AN, RPNm, RPNI, or intestinal nerve (IN). Whole nerve recordings were obtained from electrodes placed on the nerves. Subsequent microelectrode mapping indicated that many cells having axons travelling in the RPN were located in the right parietal ganglion at the root of the nerve. Our results indicate that while reflex activation of RPN was possible, IN stimulation produced the greatest increase in activity and shortest latency in each of the three pneumostome nerves. Among the pneumostome nerves, RPNI activity was increased more than in either RPNm (-50%) or AN (-69%). Stimulus-response latency was also shortest between IN and RPNI and longer in both RPNm and AN. An inverse relationship was noted between latency period and magnitude of nerve response. (Supported by a grant from HHMIG.)

INVERTEBRATE ELECTROSENSATION: PASSIVE ELECTRORECEPTION MEDIATES PREY DETECTION IN THE CRAYFISH. M.J. Weissburg, S.J. Levett, P. Steullet, D.H. Edwards, and C.D. Derby*. Dept. of Biology, Georgia State Univ., Atlanta, GA, 30303.

The ability to detect weak electric fields is a sensory capability previously known only in vertebrates (e.g. sharks and rays, bony fish, urodeles, and monotremes). Here, we report the first observations of responses to weak electric fields in an invertebrate, the crayfish Procambarus clarkii. Behavioral observations indicate that crayfish can detect dipole fields that are similar in intensity to fields produced by small freshwater animals. Field strengths as low as 100 µV/cm elicit local search and intense digging and grabbing behaviors at the electrodes. These behaviors are not seen in the absence of the field. The percentage of animals grabbing or digging increases with field strength to reach a level of about 80% at field strengths near 300 µV/cm. Animals are more sensitive to low frequency (1-4 Hz) than high frequency (10 Hz) stimulation. Observations indicate that the first two pairs of walking legs must be in close proximity to the electrodes for a response to be evoked. Initial physiological evidence suggests the presence of electrosensitive neurons in these appendages. Data from single unit extracellular recordings show that the firing rates of some neurons can be modulated when stimulated by dipole fields of 100-400 μ V/cm. These responses show graded increases or decreases in firing rate with increasing field strength. and are sensitive to field polarity. We suggest that electrosensitivity in crayfish functions in a similar context to passive electroreception in other animals, namely as a way to locate cryptic prey. Supported by NSF IBN-95 14409

A STUDY OF INTERACTIONS BETWEEN OLFACTION AND TASTE IN CENTRAL NERVOUS SYSTEM OF A SLUG. A. Yamada*, T. Kimura, A. Iwama, Y. Suzuki¹, S. Kawahara¹, Y. Kirino¹ and T. Sekiguchi. Tsukuba Research Center, SANYO Electric Co.,Ltd., Tsukuba, Ibaraki, 305 JAPAN, Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo, 113 JAPAN.

To understand the mechanisms of learning and memory which results from integration of olfaction (conditioned stimulus) and taste (unconditioned stimulus) the investigation of interactions between these two senses is important. The procerebral (PC) lobe, an olfactory center of the terrestrial slug Limax marginatus, exhibits intrinsic oscillations in its field potential. Olfactory input from the nose modulates the frequency or the amplitude of the oscillations. On the other hand, gustatory input from the lip generates bouts of feeding motor program (FMP) in the buccal nerves. In this study, we made morphological and physiological investigation into interactions between these two senses

In morphological study (Co++ backfill through three lip nerves), we observed dense stain on the mesocerebrum and metacerebrum, but no stain on the PC. On the other hand, when we applied solution of quinidine sulfate to the lips in cerebral-buccal-lips preparation, the frequency of the PC oscillation increased. Even if we applied taste solution to one lip, there was an increase of frequency in both ipsilareral nd contralateral PC. The modulation occurred in the preparation with and without buccal ganglia, and started at the same time as the FMP. Electrical stimuli to a buccal nerve which triggered FMP generated no modulation of the PC frequency. These results suggest that there are parallel pathways which share a common initiator, and that the integration of olfactory and gustatory information occurs within the cerebral ganglion

The present study was supported by Special Coordination Funds of the Science and Technology Agency of the Japanese Government.

RESOLUTION OF GENERAL ODOR PULSES TEMPORAL

TEMPORAL RESOLUTION OF GENERAL ODOR PULSES BY OLFACTORY SENSORY NEURONS IN AMERICAN COCKROACHES. W.C. Lemon* and W.M. Getz. ESPM - Div. of Insect Biology, Univ. of California, Berkeley, CA 94720.

Behavioral and physiological evidence indicates that insect pheromone receptor cells respond to pulses of pheromone concentration as they occur down wind from a point source, but the abilities of insect sensory neurons sensitive to general food odors to respond to pulses of Temporal response characteristics of olfactory sensory neurons of female American cockroaches Periplaneta americana in response to general odors were measured using series of short odor pulses (1.2 - 50 Hz). Odor pulses were delivered to olfactory sensilla in a moving airstream controlled by electromagnetic valves. The responses of sensory neurons were recorded with a tungsten electrode placed at the base of the sensillum. The temporal responses of sensory neurons mirrored the temporal changes in stimulus concentration, which was estimated by replacing the odorant with oil smoke and measuring the concentration of smoke passing through a light beam. Spike frequency varied with odorant concentration with surprisingly fine temporal resolution. Cockroach offactory sensory neurons were able to reliably follow 40 Hz pulses of a pure odorant (1-hexanol) and a complex odor blend (coconut). Lower concentrations of odorants elicited responses with lower peak spike frequencies that still retained the temporal resolution of the stimulus pulses. Thus, responses of olfactory sensory neurons can reflect fine structures of non-uniform distributions of general odorants in a turbulent odor plume and not only the average concentration. SENSORY INTEGRATION IN THE LEECH AP CELL. C. E. Osborn* and B. Zipser. Depts. of Anat. and Physiol., Michigan State University, East Lansing, MI 48824

The AP cell of the leech is commonly used as a paradigm for studying the control of axon development in the leech nervous system, but the function of the AP cell is not known. Earlier work showed that but the function of the AP cell is not known. Earlier work showed that the AP cell receives direct input from central sensory neurons, the touch (T), pressure (P) and nociceptive (N) cells. We have now found evidence for other mechanosensory input. Using a standard body wall preparation, we recorded intracellularly from the AP cell while producing small amplitude surface waves. These waves did not excite the central mechanoreceptors (T, P, or N cells) and presumably acted via their effect on sensillar wave detectors. The greatest effect on the firing rate of an AP cell was for waves delivered to the contralateral thing rate of an AP cell was for waves delivered to the contralateral body wall of its own segment, or to the next anterior or posterior segment, but ipsilateral stimuli within its own segment was also effective. This input may be direct: using confocal microscopy we found that the AP processes bilaterally colocalize in the synaptic neuropil of the CNS ganglia with those sensory afferents that express CE1. Several lines of evidence suggest that this carbohydrate markers identifies mechanoreceptors. These findings, together with our earlier EM findings of colocalization between processes of the AP cell and the optic tract, suggests that the AP cell integrates a wide range of sensory information. NIH NS25117

MOTONELIBON ACTIVITY IN FREELY SWIMMING MEDICINAL LEECHES J.A. Murray*, R.J.A. Wilson, W.B. Kristan Jr. Dept. Biology, 0357 University of California, San Diego, La Jolla, CA 92093-0357

We have developed a method of recording activity in nerve roots in intact

We have developed a method of recording activity in nerve roots in intact behaving leeches with a fine silver wire extracellular electrode. We have used this technique to record extracellularly from the dorsal posterior nerve (DP). During swimming, we recorded bursts consisting of regularly-spaced spikes of constant amplitude. In semi-intact swimming preparations, similar bursts in the DP nerve are produced by an identified dorsal motoneuron, Cell 3, a dorsal excitor (DE) motoneuron involved in generating a contraction of the dorsal longitudinal muscles during each swimming cycle. Cell 3 recorded in freely swimming animals fired at a significantly higher rate (~90 Hz) than in semi-intact, restrained preparations (~50 Hz, Kristan et al. 1974; J Comp Physiol 94:155). Hence, recordings from semi-intact preparations, which compromise internal hydrostatic pressure, may differ quantitatively from natural firing patterns. The bursts of Cell 3 impulses occurred when ventral muscles in that body segment were still partially contracted and well before the dorsal longitudinal muscles reached maximal contraction. This delay between the bursts of the Cell 3 units and dorsal contraction suggests that sensory feedback from the District of the constraint of the constraint of the DE bursts within the same cycle of the swimming pattern. Other sensory feedback may, however, affect swimming in different ways. For instance, leeches reaching the end of the observation tank sometimes continued to undulate. During this "stationary swimming", swimming period (time/cycle) and burst

During this "stationary swimming", swimming period (time/cycle) and burst duration increased significantly while the average firing rate decreased. Although still preliminary, these recordings of the swimming motor program in intact leeches have indicated possible modes of sensory feedback that were

not foreseen from experiments on semi-intact preparations.

These experiments were supported by an NIH Fellowship (MH10705) to JAM and an NSF Research Grant (IBN11432) to WBK.

MEASUREMENT OF NEURAL ACTIVITIES IN AN ANTENNAL LOBE OF A MOTH BRAIN BY HIGH-SPEED, VOLTAGE-SENSITIVE DYE IMAGING. K. Okada*11, R. Kanzaki²³, and K. Kawachi^{11,33}, 1)Kawachi Millibioflight Project, ERATO, JRDC, Tokyo 153, Japan. 2)Inst. of Biol. Sci., University of Tsukuba, Tsukuba, 305. Japan. 3)Res. Cent. for Adv. Sci. and Techno., University of Tokyo. Tokyo 153. Japan We have improved an optical recording technique with high spatio-temporal resolution in order to investigate neural activities of an in vivo insect brain. We succeeded in acquiring neural activities of an antennal lobe neurons of a sweet potato hawk moth, Agrius convolvuli, elicited by an electrical antennal stimulation under a stereoscopic microscope condition. When the synaptic transmission was not blocked, hyperpolarization followed by depolarization were consistently recorded in the antennal lobe. While synaptic transmission was blocked by replacing the Ca2+ with Mg2+ or application of the picrotoxin, the hyperpolarization was reduced and was recovered by washing. No effect was observed in the depolarization. This suggests that the hyperpolarization is to be IPSPs of the antennal lobe neurons and the IPSPs may be caused through GABA-sensitive chloride channels (GABA-A like channels) of the antennal lobe neurons. Identical results were consistently observed by a repeat experiment, indicating that our optical recording system is available to investigate the neural systems of an in vivo insect brain.

SEROTONIN AND OCTOPAMINE MIXTURE EFFECTS ON THE SWIM MOTOR PATTERN IN THE LEECH, HIRUDO MEDICINALIS. L.S. Gilchrist* and K.A. Mesce. Graduate Program in Neuroscience (L.G. and K.M.) and Department of Entomology

in Neuroscience (L.G. and K.M.) and Department of Entonology (K.M.), University of Minnesota, St. Paul, MN 55108.

Through triple intracellular recordings, we have found that stimulation of either touch (T) or pressure (P) mechanosensory neurons activates both serotonergic cell 21 and the dorsolateral octopamine-immunoreactive (DLO) neuron. Based on these observations, we decided to investigate the action of mixtures of these two biogenic amines on leech nerve cords.

Mixture effects of octopamine and serotonin on the swim motor pattern were monitored by recording swim bursts extracellularly in the dorsal posterior (DP) nerve. Whole nerve cords of *Hirudo medicinalis*, including both the head and tail brains, were used in our studies. A mixture of $50\mu M$ octopamine and $50\mu M$ serotonin was bath applied to the nerve cord. Additional experiments were performed with either 25μM or 100μM octopamine and serotonin mixtures. For comparative purposes, nerve cords were subjected to either 50µM octopamine or 50µM serotonin.

As compared to octopamine or serotonin alone, we found that bath application of the 50µM or 100µM octopamine and serotonin mixtures resulted in a greater reduction in overall DP nerve activity. While both serotonin and octopamine have been reported to increase swimming activity in nerve cord preparations (Hashemzadeh-Gargari and Friesen, '89), we found that washout of the serotonin and octopamine mixture was the most reliable way to induce long-term expression of the swim motor pattern. DIFFERENTIAL RESPONSE OF RETZIUS CELL TO WARMING OF THE SKIN IN TWO SPECIES OF LEECHES. G. Maximov & A.L. Kleinhaus*. Dept. of Cell Biology & Anatomy, New York Medical College, Valhalla, N.Y. 10595.

Recently, we showed that the activity of the serotonergic Retzius cells increases during the appetitive phase of feeding in *Hirudo medicinalis*, but in contrast to previous claims, decreases at the onset of ingestion (J. Exp.Biol., 1996). The mechanism underlying this reduction is not understood at this time. Earlier work suggested that raising the temperature of the dorsal lip, but not the body wall, is an appropriate stimulus for the initiation of feeding. We now show that raising the temperature of the lip or skin on any part of the body including the tail from 23° 35 $^{\circ}$ C significantly increases the firing frequency of the Retzius cells of *Hirudo* both in the subesophageal and segmental ganglia. These results suggest that heat detected by any part of the body may alert the animal to a warm-blooded food source, assuming heat perception represents an appropriate appetitive stimulus.

Previous findings showed that heating the lip for less than two minutes caused a

rapid transient increase in the firing frequency of the Retzius cell which remained elevated above baseline for at least two minutes after the stimulus was turned off. To ascertain the response of the R cell to a thermal stimulus that is a closer facsimile to the heat stimulus during a feeding episode we warmed the lip or body wall for a prolonged period. We found that the Retzius cell did indeed respond transiently but returned to baseline within five minutes even if the stimulus was maintained. These findings are in line with our observations that the activity of the Retzius cell slows down at the beginning of ingestion.

In a comparative study we have found that the Retzius cell of Macrobdella does not respond to heat applied to either the lip or body wall. This is an interesting finding since both *Macrobdella* and *Hirudo* will feed on warm blooded animals. Supported by NIH grant # 5R01NS18055-10 to ALK.

QUANTIFICATION OF THE MOTOR PATTERN DURING INGESTION IN THE LEECH, HIRUDO MEDICINALIS. R. J. A. Wilson* & A. L. Kleinhaus. Dept. of Cell

Biology & Anatomy, New York Medical College, Valhalla, N.Y.10595. Several aspects of the ingestive behaviour of the blood-sucking leech, *Hirudo* medicinalis, have been described. After attaching to a host, the leech extends its jaws, bites through the skin, displays a feeding specific pattern of midbody contractions (peristalsis) and becomes less reponsive to noxious stimuli. Although the neural basis of several behaviors in the leech has been studied, the cellular basis of feeding remains largely unknown

We have recently developed a semi-intact preparation that allows recordings to be made from exposed ganglia in caudal segments whilst the rostral portion of the animal attaches to, bites through and feeds from a blood-filled sausage. Preliminary data, obtained from this preparation by recording extracellularly from nerve roots, suggests that the motor pattern which accompanies ingestion (peristalsis), persists in the denervated segments (Wilson et al. 1995, 1996). Here we present a quantitative analysis of peristalsis-associated activity recorded using EMG's from the muscles in the body wall of intact feeding leeches. The motor activity during ingestion is variable, only weakly rhythmic and can be divided into four classes; (a) rostral to caudal waves; (b) caudal to rostral waves; (c) discrete contractions of individual segments; and (d) dorsal-ventral undulations that resemble swimming and only occur when the animal is under water. Although the dorsal-ventral undulations resemble swimming, the rostral-caudal and caudal-rostral waves have an intersegmental travel time more in par with the intersegmental delays that occur during crawling. The same muscle groups appear to be active during both the peristaltic waves and the discrete contractions. To determine the effects of blood flowing through the gut we performed similar experiments on animals in which the gut had been cannulated in a rostral segment. Supported by NIH grant # 5R01NS18055-10 to ALK.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: INVERTEBRATE SENSORY AND MOTOR SYSTEMS III

429.1

G-PROTEIN SPECIFIC ION CHANNEL MODULATION IN A CILIATE M.J. Marino, T.G. Sherman and D.C. Wood*. Department of Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

The ciliate protozoan Stentor contracts in response to mechanical stimuli. These stimuli open mechanoreceptor channels producing a depolarizing receptor potential. Suprathreshold receptor potentials trigger action potentials and resultant contractions. GTP-γ-S, GDP-β-S, and cholera toxin alter the responsiveness of Stentor to mechanical stimuli by modulating mechanoreceptor channels or by changing the action potential threshold suggesting the involvement of G-proteins. Additionally, $\beta\text{-endorphin}$ depresses mechanoreceptor channel function through a pertussis toxin-sensitive pathway. In search of these modulatory G-proteins, we cloned partial cDNAs for 4 unique Stentor G-protein subunits which exhibit 24-57% identity with vertebrate G-proteins. Functionally important amino acids in the vertebrate Gproteins were conserved in Stentor G-proteins. Intracellular injection of antisense oligonucleotides for specific subunits was used to determine which of these G-protein subunits modulate Stentor ion channels and thus control its behavior. Antisense oligonucleotide directed against a cloned G_s-like subunit sequence and one of the three Gi-like sequences produced significant enhancements in mechanical stimulus sensitivity, whereas antisense against the other two Gi-like sequences produced no observed behavioral effects. Antisense against one of the Gi-like subunits blocked the inhibitory action of β -endorphin, whereas antisense against the other subunits did not. Therefore, specialized G-protein subunits appear to have evolved early to produce modulation of specific ion channels and alteration of overt behaviors (Private foundation support)

ABERRANT LARVAL LOCOMOTION IN DROSOPHILA Na+ AND K+ CHANNEL MUTANTS REVEALED BY COMPUTER-ASSISTED DYNAMIC IMAGE ANALYSIS SYSTEM. J.W. Wang A.W. Sylwester, D.R. Soll and C.-F. Wu. Dept of Biol. Sci., Univ. of Iowa, Iowa City, IA 52242

Genetic dissection has provided insights into molecular mechanisms

of the nervous system controlling behavior in Drosophila. There have been fewer attempts to exploit information with regard to larval behavior compared to the well established adult behavior, partly due to behavior compared to the well established adult behavior, party due to technological difficulties. We employed a computer-assisted motion analysis system useful for characterizing the peristaltic locomotion of *Drosophila* third-instar wandering larvae, and investigated the importance of ion channels to different quantifiable parameters in behavior repertoires. The gene Hyperkinetic (Hk) encodes a K channel beta subunit, which modulates IA channels in larval muscles; and paralytic (para) encodes a Na channel alpha subunit expressed in the nervous system. Using the Dynamic Image Analysis System (DIAS) initially developed for motion analysis of ameboid cells, we have analyzed videotaped behaviors of Drosophila larvae crawling on agar slabs. videotaped behaviors of *Drosophila* larvae crawling on agar slabs. Results demonstrate that mutant larvae exhibited marked locomotion abnormalities. *Hk* and *para* mutant larvae turned, respectively, less and more frequently than wild-type larvae. In addition, both *Hk* and *para* larvae crawled at slower velocities than wild-type larvae, apparently due to a lower efficiency in conversion of muscular contraction to distance translocation. Our results demonstrate that DIAS is a powerful tool to reveal subtle difference in animal behavior to quantify mutational effect on the interplay of discrete behavioral components. Supported by NIH grants to D.R.S. and C.-F.W.

MEMBRANE ION CURRENTS AND FUNCTIONAL PROPERTIES OF SPIKING AND NONSPIKING APLYSIA BUCCAL MUSCLES. Scott, M.L.*, V. Brezina, and K.R. Weiss. Dept. Physiol. & Biophys., Mt. Sinai Sch. Med., New York, NY

Molluscan muscles display different functional properties, which may optimize them for their specific roles in behavior. We have been studying a pair of antagonist muscles in the Aplysia feeding system, the accessory radula closer (ARC) and the radula opener (17 - 110) muscles. The ARC is a nonspiking muscle, with maintained contractions directly graded by synaptic depolarization. This may provide sustained power necessary to grip food while it is pulled into the mouth. In contrast, the opener muscles spike when depolarized by synaptic input or stretch. This may enable the openers to contract rapidly at the proper time to release food into the

To see if these differences reflect different membrane properties, we compared ion currents and voltage behavior expressed in enzymatically isolated fibers from the two muscles. Both muscles expressed similar currents, with variable amplitudes, including several K^+ currents (inward rectifier, A-type, delayed rectifier, and Ca^2 activated) and an L-type Ca^{2+} current. Furthermore, unexpectedly, isolated fibers from both muscles displayed a similar continuum of voltage behavior, from completely inexcitable to fully spiking. Excitability was increased or decreased by different physiological modulators. Our hypothesis is that the currents are so balanced that small changes in their amplitude or key properties can lead to qualitatively different voltage behavior. We have identified three differences in currents that are likely to predispose the opener muscles to spike: their A-type K* current activates at more depolarized voltages than in the ARC, their inhibitory ACh-activated Cl* current is much smaller, and they express a modulator-activated inward current. To test our hypothesis and examine the roles of specific currents in voltage behavior, we have developed a Hodgkin-Huxley type model of the muscle fibers. We are also evaluating how the ion currents, spiking, and stretch contribute to the different contractions of the two muscles. Supported by NIMH and the Whitehall Foundation.

AMILORIDE-SENSITIVE AND INSENSITIVE RECEPTOR SITES IN INSECT TASTE CHEMORECEPTORS, <u>A. Liscia, A. Bigiani, R. Majone, P. Muroni, P. Solari, I. Tomassini Barbarossa and R. Crnjar.</u> Dip. Biologia Sperimentale, Sez. Fisiologia Generale, Università di Cagliari, Viale Poetto 1, 1-09126 Cagliari, Italy: Dip. Scienze Biomediche, Sez. Fisiologia, Via Campi 287, I-41100 Modena, Italy

In vertebrates salt and sugar reception mechanisms are known to involve both amiloride-sensitive and insensitive (AIC) cation conductance components. In insects instead, no information is yet available on amiloride effects on membrane receptor sites. We thus studied whether salt and sugar chemoreception is mediated by amiloride-sensitive cation conductance mechanisms in the blowfly *Protophormia terraenovae*. Spike discharges obtained by means of the tip-recording technique were processed by spike waveform analysis in order to identify the various firing sensory cells. The results of our experiments show that: a) spike firing frequency of the "salt" cell in response to NaCl, sucrose and fructose is not influenced by the addition of amiloride (100 and 500 μM); b) addition of amiloride does not influence the spike firing frequency of the "sugar" receptor cell in response to sucrose, but depresses the response to fructose; c) amiloride 100 μ M only lowers the response of the "water" cell to sucrose and fructose, whereas at 500 μM it depresses the responses to all stimuli; d) pure amiloride, both at 100 and 500 µM, generally evokes a weak response from the "salt" cell. Our results point to the absence of amiloridesensitive receptor sites in the "salt" cell. Instead, the "sugar" cell seems to bear an amiloride-sensitive furanose site. However, since the fructose response is not completely abolished, an amiloride-insensitive component (AIC) may also be present. As for the 'water' cell, the inhibitory effect of amiloride seems to support the idea that this cell shows properties of a typical receptor cell, in contrast with the hypothesis of a simple osmometer mechanism.

CHEMOSENSORY ADAPTATION AND DESENSITIZATION BY RECEPTOR DOWN-REGULATION IN PARAMECIUM. M.Kim, H. Kuruvilla, T. Hennessey and C. Fourtner.* Dept. of Biol. Sci., S.U.N.Y.A.B., Buffalo, N.Y. 14260.

Like sensory neurons, Paramecium integrate sensory information as somatic membrane potential changes. In general, chemoattractants cause sustained hyperpolarizations while chemorepellents, such as GTP and lysozyme (at micromolar concentrations), produce transient depolarizing somatic receptor potentials that trigger Ca**-based action potentials and consequent bouts of backward swimming. Forward swimming returns after about 10 min. in either repellent due to chemosensory adaptation, an important process that is not well described in eukaryotic cells. Using a combination of behavioral bioassays, intracellular electrophysiology and in vivo chemoreceptor binding assays (with Scatchard analysis), we have shown that chemosensory adaptation is due to a gradual loss of surface receptors. The chemoreceptor potential amplitude also decreases along the same time course. These responses are specific for each chemorepellent. Lysozyme adapted cells (0.01uM for 10 min.) lose their behavioral and electrophysiological responses to lysozyme as well as their surface 3H lysozyme binding sites but their responses to GTP (and 32P GTP binding) are unaffected. Similarly, GTP adapted cells (10uM for 14 min.) respond normally to 0.01uM lysozyme and bind Hysozyme but they lose their GTP responses and 32P GTP binding sites. All of these changes seen are reversible within 10 min. after removal of the repellent. Cells adapted to either repellent still respond fully to other stimuli such as 40mM K+, 10mM Na+, 8mM Ba++ and the chemoattractant, acetate (5mM). We propose that lysozyme and GTP have separate high affinity surface receptors on the body membrane that are specifically down-regulated during chemosensory adaptation. Both receptors may activate the same somatic, receptor operated Ca++ conductance to generate their respective chemoreceptor potentials, suggesting a common sensory transduction pathway with at least two different receptors. ELECTROPHYSIOLOGICAL AND ULTRASTRUCTURAL OBSERVATIONS ON THE FIRST-ORDER GIANT NEURON OF THE GIANT FIBER SYSTEM OF THE SQUID, <u>L.D. Pozzo-Miller*</u>, <u>J.E. Moreira*</u>, and <u>R. Llinás*</u>. Marine Biological Laboratory, Woods Hole MA, 1 Laboratory of Neurobiology, NINDS, NIH, Bethesda MD, and 2 Department of Physiology & Neuroscience, NYU Medical Center, New York NY

The giant fiber system controlling the mantle contraction responsible for water/jet propulsion in the squid consists of two sets of three giant neurons organized in tandem. The first- and second-order cells are located in the head, and the third-order, that originate the "giant axon", in the stellate ganglion. The axons of the first- order neurons decussate in the midline forming a chiasma, where complete axoplasmic fusion occurs. This chiasma allows integration across the midline into a single complete axoplasmic fusion occurs. This chiasma allows integration across the midline into a single symmetrical connectivity. After the bridge, first-order axons branch and establish mixed synapses with several second-order axons. The largest of these neurons form the presynaptic element at the giant synapse in the stellate ganglion. The first-order neurons are multipolar exhibiting dendritic branches that arise from somatic level, resembling veterbrate neurons, and in particular, the Mauthhar cell of fish. The dendrites and soma of these cells receive massive synaptic input from the eye, statocyst, most of the skin surface propioception, and the supraesophageal ganglion. In order to define the integrative properties of such enormous synaptic load, especially given its incredible diversity, intracellular recordings and electron microscopic observations were implemented on first-order neurons in an isolated squid head preparation. Resting membrane potential was $42\pm 1mV$, and membrane input resistance was $12\pm 3M\Omega$ (n=6). Spontaneous bursts of action potentials, and spikes evoked by extracellular stimulation of afferent regions of the magnocellular ganglion were sensitive to bath applied 17x and intracellular Was 42±3M Ω (n=6). Spontaneous bursts of action potentials, and spikes evoked by extracellular stimulation of afferent regions of the magnocellular ganglion were sensitive to bath applied 17x and intracellular Was 42±3M Ω (n=6). Spontaneous bursts of action potentials, and spikes evoked by extracellular stimulation of afferent regions of the magnocellular ganglion were sensitive to bath applied 17x and intracellular Was 42±3M Ω (n=6). Spontaneous bursts of action potentials (20-40mV), the delay for the intracellular blockade of spikes by Ω x-314 (10-20 minuties from impalement), and the morphological observation of abundant synapsic input to dendrites and soma, suggest that the site of initiation of action potentials is remotely located from the recording site at the soma. It seems likely that subthres submireshool posisynapic potentials, in estimining togic of within we have just beguin to decipine, and integrated at dendritic and somatic levels, and propagate electrotinically down to the site of Na*-dependent spike generation, possibly at the cytoplasmic bridge where the two first-order neurons tuse. The characterization of the electroresponsive properties of the first-order neurons provides a description of the single cell integrative properties to the wide variety of sensory inputs which controls the complex rapid behavior of the squid.

INDIRECT CONNECTIONS BETWEEN CERCAL SENSORY NEURONS AND GIANT INTERNEURONS OF THE FIRST INSTAR COCKROACH. E.S. Hill* and J.M. Blagburn Dept. of Biology, Univ. of Puerto Rico and Institute of Neurobiology, UPR Medical Sciences Campus. 201 Blvd. del Valle, San Juan, PR 00901

The cercal sensory system of the first instar cockroach (Periplaneta americana) has two filiform hairs on each cercus, termed lateral (L) and medial (M). Each hair is associated with an individual sensory neuron. These neurons make connections with giant interneurons (GIs) in the terminal abdominal ganglion. The L sensory neuron is known to make direct connections with GIs 3, 4 and 6, and M with GIs 1, 2, 4 and 5. We were interested in determining whether indirect (polysynaptic) connections are present between sensory neurons and GIs. The appropriate sensory neuron was stimulated by mechanically pushing the filiform hair. The other hair on the same cercus was immobilized with Vaseline and the other cercal nerve was crushed. Simultaneous intracellular recordings were made from a GI known to have a monosynaptic connection from that sensory neuron, and from the GI under test. Criteria for determining the existence of an indirect connection were: (1) lack of correspondence between spontaneous EPSPs in the reference GI and those in the test GI, and (2) a delay between the onset of the evoked responses in the two GIs. Physiological evidence suggests a strong indirect, excitatory connection between the L sensory neuron and the contralateral GI1. An indirect, inhibitory connection was found between the M sensory neuron and the ipsilateral GI6. GI7 was found to receive indirect input from the contralateral L. A burst of EPSPs was observed in GI7 coincident with cessation of activity in the sensory neuron, suggesting a possible tri-synaptic pathway with an inhibitory and an excitatory interneuron. These experiments have shown that filiform hair sensory input can reach post-synaptic GIs via polysynaptic excitatory and inhibitory pathways. These pathways do not simply fine tune the receptive fields of the GIs, but may make an important contribution to their directional sensitivity

TRANSDUCTION CHANNELS OF A CL-RECEPTOR NEURON IN THE LEECH, HIRUDO MEDICINALIS. A. Wenning^{1*}, C. F. J. Erxleben¹ and R. L. Calabrese². ¹Fakultät für Biologie, Uiversität Konstanz, 78434 Konstanz, Germany; ²Biology Department, Emory University, 1510 Clifton Rd., Atlanta GA

Following a blood meal, the CI concentration of leech blood triples. These changes are monitored by the nephridial nerve cell (NNC), a peripheral neuron which innervates the leech nephridium. At normally, low extracellular Cl⁻ concentrations [CI⁻]₀, the NNC is spontaneously active. Its membrane potential $(V_{m} = -37 \text{ mV})$ is governed by E_{Cl} , due to a high resting Cl^{-} conductance. With increase in [Cl⁻]₀, the NNC hyperpolarizes by 23 mV) towards E_K due to a decrease in Cl⁻ conductance (Wenning & Calabrese 1991). Here we report on the poperties of the postulated CI⁻ channels and the mechanism by which they are regulated.

Cell attached patches were made on the soma of the NNC. At the NNC's resting potential, we recorded inward currents through a 48 $(\pm 8; s.d.)$ pS channel with either high or low [Cl⁻] in the recording pipette. Single-channel current amplitudes increased upon hyperpolarization and decreased with depolarization. The reversal potential was near the resting potential. The channel open probability was independent of the membrane potential. Changing the bath solution from high to low [Cl-] led to an increase of channel openings and channels closed upon superfusion with high [Cl⁻], regardless of the CI⁻ concentration in the pipette. Since the open probability of the channels under the pipette is altered by changes in [Cl $^{-}$] $_{bath}$, we conclude the involvement of an intracellular signalling pathway rather than direct interaction of extracellular Cl- with the channel.

THE EFFICIENCY OF INFORMATION TRANSFER FROM TRANSDUCTION TO ACTION POTENTIAL ENCODING IN MECHANORECEPTOR NEURONS. Mikko Juusola* and Andrew S. French Department of Physiology and Biophysics, Dalhousie University, Halifax, Nova Scotia B3H 4H7, Canada.

Little is known about how effectively single sensory neurons transmit stimulus information from transduction to action potential encoding. We examined the coding efficiency of primary mechanoreceptor neurons in a spider slit-sense organ using repeated sequences of pseudorandomly modulated displacement stimuli, and found that the information content of the analog receptor current was converted into trains of discrete action potentials with ~85% efficiency. This high efficiency resulted from low-pass filtering of the signal by the mechanoreceptor membrane as the receptor current was transformed into receptor potential. The removal of highfrequency noise boosted the signal-to-noise ratio at high-frequencies of the transduction signal more than 10-fold, before action potentials were encoded with about 30% efficiency. These data suggest that during dynamic stimulus modulation, a low intrinsic noise level during spike generation allows sensory neurons to accurately and reliably transform the sensory input into spike sequences.

INTRACELLULAR CA2- DYNAMICS ON DENDRITIC PROCESSING OF THE WIND-SENSITIVE INTERNEURONS IN THE CRICKET. H. Ogawa*1), Y. Baba2), K. Okada³, K. Oka⁴, 1), 3) Kawachi millibioflight project, ERATO, JRDC, Tokyo 153, Japan, 2) Neuro-Cybern, Lab., Res. Inst. for Electronic Science, Hokkaido Univ., Sapporo 060, Japan. 4) Dept. of System Design Engin., Fac. of Sci. and Tech., Keio Univ., Yokohama 223, Japan.

Some kinds of wind-sensitive interneurons, which contain the ascending interneurons such as giant interneurons, and the spiking and nonspiking local interneurons, have been identified in the terminal abdominal ganglion of the cricket (Mendenhall and Murphy, 1974; Baba et al., 1991, 1995). These neurons integrate the cercal afferents and convey information about air currents to motor systems driving the various behavior such as avoidance response. To visualize chemical computation in dendritic processing, we examined intracellular Ca2+ change in these cercal interneurons in the cricket, with a fluorescent imaging technique using conforcal laser-scanning microscopy and a fluorescent calcium indicator, 'Calcium Green 1'. Depolarization caused by current injection or electrical stimulation of cercal sensory nerves could induce fast Ca2- increase on dendritic site of these interneurons. This result provides an evidence of the voltage-dependent Ca2+ channels located on dendritic site of these interneurons. The amplitude and latency of Ca2+ increase by ipsilateral cercal afferents stimulation were different from those of contralateral one. The spatio-temporal differences between Ca2+ responses to ipsi- and contralateral cercal afferents stimulation suggest the importance of chemical computation in dendritic integration of synaptic inputs coding wind signals.

Neural mapping of multiple functional parameters in the cricket cercal

sensory system. Sussan Paydar*, Caitlin C. Doan, Gwen A. Jacobs. Dept. of Molecular and Cell Biology, Univ. of California, Berkeley, CA 94720.

The objective of this study is to determine how different functional parameters are organized within the neural map of the cricket cercal system. Mechanoreceptor hairs in this system are sensitive to the direction and dynamics of the air currents in the animal's environment. Directional tuning Mechanoreceptor nairs in this system are sensitive to the direction and dynamics of the air currents in the animal's environment. Directional tuning and the dynamic sensitivities to air currents are determined by the orientation of the hair socket on the cerci and the hair length respectively. Previous studies have shown that afferents associated with long hairs (1000µ-2000µ) constitute a single functional class. They are most sensitive to low frequency air currents and form a continuous map of wind direction in the terminal ganglion. In this study we examined the anatomical and functional characteristics of another class of afferents that are associated with medium length hairs (500µ-700µ), which respond maximally to high frequency air currents. We assessed their morphological characteristics and studied the spatial relationships of their terminal arbors with respect to each other and to the long-hair afferents with corresponding directional sensitivities. Afferents were filled with cobalt chloride, anatomically reconstructed, scaled, and aligned to a common set of highly reproducible fiducial marks. Preliminary data suggest that (1) arbors of the medium-hair afferents are significantly smaller than their corresponding long-hair afferents with the same directional target areas as their long-hair afferents counterparts (however some of their arbors extend to regions that are not occupied by long-hair directional target areas as their long-hair afferent counterparts (however some of their arbors extend to regions that are not occupied by long-hair afferents); and (3) medium-hair afferents appear to form a continuous map of wind direction similar to that observed for the long-hair afferents. The maps of direction formed by long-hair and medium-hair afferents are spatially segregated in some regions. These findings suggest that the representation of dynamic sensitivity may also be mapped in this system. This work was supported by NIH grant R29NS29847 to G.A.J.

PROCESSING OF MOVEMENT AND POSITION DEPENDENT FEEDBACK IN THE CRAYFISH BASAL LIMB. P. Skorupski* Dept. Physiol., Univ. Bristol, Bristol BS8 1TD, UK.

Movement of the basal joint of the crayfish leg evokes both positive and negative feedback reflexes in the motor neurons that control that joint. Positive feedback reflexes, termed assistance reflexes, occur when leg promotor motor neurons (PMNs) are excited by a promotion signal, and remotor motor neurons by a remotion signal In each case the proprioceptive inputs generating assistance reflexes are restricted to a subgroup of the motor pool. In a parallel system of negative feedback, separate motor subgroups are excited by inputs that generate resistance reflexes. During fictive locomotion both subgroups of motor neurons within a pool fire in phase, but the recruitment order within a burst is always assistance group followed by resistance group (Skorupski et al, J. Neurophysiol. 67, 648, 1992).

Feedback corresponding to static limb position generates negative, but not positive

feedback reflexes. This organization of movement dependent positive feedback and position dependent negative feedback may constitute a peripheral oscillator that can entrain the central oscillator (Elson et al, J. Neurophysiol. 67, 530, 1992). For PMNs, yet another subgroup is preferentially excited by position dependent feedback. The degree of static joint remotion is sensed by a nonspiking afferent termed the S fibre. At least two PMNs receive direct electrical input from the S fibre, but little or no excitatory input from the dynamically sensitive T fibre, which senses the angular velocity of joint remotion. In addition the S fibre makes weaker excitatory connec tions to other PMNs, and it inhibits, via a di- or polysynaptic pathway, low threshold PMNs of the assistance group. This inhibitory pathway may serve to prevent unwanted activation of the peripheral oscillator during maintenance of stable joint po-

MULTIPLE SENSORY INPUTS ONTO A SET OF SEGMENTALLY HOMOLOGOUS INTERNEURONS IN THE LOCUST. K. R. Prier* and G. S. Boyan, Zool. Inst. der Uni Basel, Rheinsprung 9, 4051 Basel, Switzerland. (Present Addresses: KRP: Inst. of Neurosci., U Oregon, Eugene, OR 97403; GSB: Zool. Inst. der Uni München, D-80333 München, Germany.)
The segmental nature of the insect nervous system offers a unique

The segmental nature of the insect nervous system offers a unique opportunity to study the effects of the specialization of peripheral structures on central processing neurons in the CNS. In the locust, the pleural chordotonal organ (piCO) system is a segmentally repeating sensory system arrayed along the body wall of the animal. This system has specialized to respond to three distinct sensory modalities. In the abdominal segments, the piCOs have remained in their basic form and respond mainly to respiratory vibrations. In the first abdominal segment, they have specialized to detect air-borne sound as tympanal organs (TOs). In the second and third thoracic segments, they have specialized to detect wing vibrations during flight as wing-hinge chordotonal organs (WCOs).

flight as wing-hinge chordotonal organs (wCOs).

The input from these three different sensory modalities is processed by a large number of identified interneurons, including many identified neurons derived from neuroblast 7-4 in each segment. This suggests an important role for the progeny of neuroblast 7-4 in the processing of chordotonal information. Among these are neurons 714, 531, and 529, which are three information. Among these are neurons 714, 531, and 529, which are three segmentally homologous interneurons in the second thoracic, third thoracic, and first abdominal neuromeres, respectively. Electrophysiological experiments show that neurons 714 and 529 respond to all three of these sensory modalities, while neuron 531 has specialized to receive exclusively tympanal input. The data from these three interneurons give insight into how the central processing elements of the basic pICO system have adapted to the segmental specialization of the sensory system.

SENSORY AND MOTOR CONTROL OF CERCAL DISPLACEMENT IN THE CRICKET. K.A. Killian* and J.P. Bollins. Dept. of Zoology and Center for Neuroscience, Miami University, Oxford, OH 45056.

Organisms are exposed to a barrage of sensory information which must be integrated by the central nervous system in order to produce behaviorally relevant motor output. We have begun to characterize a simple reflex system in the cricket *Acheta domesticus* with which to investigate this multisensory integration at the cellular level.

Wind puffs directed across the pair of cerci located on the terminal abdominal segment of orthopteran insects produces synchronous displacement of both cerci toward the midline. This cercal movement is produced by the contraction of muscles located at each cercal joint. Cobalt chloride backfills of a cercal motor nerve stained five efferent neuronal somata within the terminal abdominal ganglion (TAG). We have begun to anatomically and physiologically characterize one neuron, an excitatory cercal motor neuron, in detail. This neuron's soma lies in the 9th segment of the TAG and its dendrites are located in the dorsal neuropil and cercal glomerulus. Depolarizing current injected into the neuron's soma or dorsal dendrite produces medial displacement of the ipsilateral cercus with displacement amplitude determined by the number of action potentials elicited from the neuron. Motor neuron activity is evoked by several sensory stimuli including wind puffs on the cerci, manual displacement of the cercus and tactile stimulation of the ovipositor. The effectiveness each sensory input has in generating a motor response is under investigation. (Supported by Dept. of Zoology, Miami University).

SOMATOSENSORY INFORMATION PROCESSING IN THE LEECH LOCAL BEND NETWORK: STIMULUS ENCODING AND BEHAVIOR. J.E. Lewis* and W.B. Kristan Jr., Biology Department, University of California, San Diego, 9500 Gilman Dr., La Jolla, CA, 92093-0357.
Local bending in the leech, Hirudo medicinalis, is a withdrawal

reflex elicited by a mechanical stimulus to the tubular body wall. Bending away from a stimulus results from the contraction of longitudinal muscles in the vicinity of the stimulus and relaxation of muscles on the side opposite to the stimulus. Video analyses showed that behavioral output was centered within 10% (about 2mm) of the stimulus location. To address how this level of accuracy is achieved, we have made estimates on the accuracy of stimulus representation by the mechanosensory P neurons. After quantifying P cell firing statistics and spatial tuning properties, we used previously described stimulus reconstruction methods and found that the accuracy of P cell representation of stimulus location matched that of the behavior itself. This suggests that, either no information is lost through the remaining network layers (interneurons and motorneurons), or more likely, there are additional important features of stimulus encoding. This illustrates the importance of behavioral context in these types of analyses, and ideally, of monitoring sensory input and behavioral output simultaneously. We have extended our behavioral analyses with electromyographic (EMG) measurements at many body wall locations in semi-intact preparations. We can now measure the behavior along with the activity of all of the activated P cells on a trial-by-trial basis, and thus test more rigorously different

models of stimulus encoding and information processing.

ANATOMY AND PHYSIOLOGY OF AUDITORY RECEPTORS IN THE AUSTRALIAN FIELD CRICKET TELEOGRYLLUS OCEANICUS K. Imaizumi* and G. S. Pollack Department of Biology, McGill University, Montreal, Quebec, Canada, H3A 1B1

The cricket's tympanal organ consists of ca. 70 receptor cells, which respond to frequencies from 3 up to 100 kHz. Although auditory behavior and neural processing by interneurons have been well studied, little is yet known about the anatomy and physiology of cricket auditory receptors. We are using single unit recording and staining techniques to address this question.

Single receptors have clear best frequencies, but also have additional sensitivity peaks at other frequencies. The several sensitivity peaks correspond well to multiple sensitivity peaks seen in the whole tympanal nerve with extracellular recording. Based on their best frequencies, most receptors fall into one of two broad types, low frequency receptors (4-5.5 kHz) and ultrasound receptors. These frequency ranges are known to be important for intraspecific communi escape behavior, respectively.

Receptors can be roughly classified into two groups based on the anatomy of their axon terminals. Some receptors end near the midline in a densely packed arbor. Other receptors have more lateral arbors with widely spread endings, which extend further posteriorly than those of the first type. The first morphological type includes both low and high frequency (ultrasound) receptors. The second type appears to include only low frequency receptors.

Auditory receptors are, thus a diverse population, both anatomically and physiologically.

SIGNAL PROCESSING BY A MECHANOSENSORY ARRAY: DYNAMICS OF CRICKET AIR MOVEMENT RECEPTORS.

Leslie C. Osborne and John P. Miller* University of California, Berkeley, CA

The cricket's cercal sensory organs consist of an array of frequency-tuned, directional mechanoreceptors that detect, filter, and encode local air movements. Unlike the mammalian cochlea, where efferent neural feedback can fine-tune the responsiveness of the auditory transducers, mechanical filtering of stimulus information in the cercal system is accomplished by physical design alone. A hair's mass and the viscoelastic properties of its socket affect the resonant properties of the mechanosensor. A hair's length with respect to the boundary layer and its location on the cercus affect its flow environment and therefore its response properties. Mechanical filters were calculated from high-speed video recordings of hair responses to calibrated noise and tone burst stimuli (n>36). Comparing the mechanical filters of the hairs with physiological recordings of sensory afferent responses shows that the proportion of hair response bandwidth that is reliably encoded into spikes varies with receptor length. The mean frequency of the coding range of long hair afferents coincides with the mean frequency of the long hairs' coherent mechanical response. In contrast, the mean frequency of the coding bandwidth of shorter hair afferents is significantly greater than that of the short hairs' mechanical response. Thus, the overlap of the mechanical tuning curves for long, medium and short hairs is greater than the overlap in frequency sensitivity of the innervating afferents. If stimulus frequency information is extracted by comparison of activity in different length classes of the mechanosensors, these features may maximize the bandwidth over which the cricket can reliably distinguish stimulus frequency in the presence of noise, given the mechanical constraints on its receptors. INTRACORTICAL CONNECTIONS BETWEEN MOTOR CORTICAL ZONES CONTROLLING ANTAGONIST MUSCLES. L. Bertrand, C. Capaday*, H. Devanne and B. A. Lavoie. Centre de Recherche en Neurobiologie, Université Laval, Québec. (Qc) Canada, G1J 1Z4

Experiments were done on 8 cats lightly anesthetized with nembutal to determine whether motor cortical zones controlling antagonist muscles are synaptically interconnected. Motor cortical zones controlling wrist flexors, or extensors, were identified by microstimulation and intramuscular EMG recordings (stimulation: 11 pulses at 333 HZ, currents 10-40 μA). The position of each zone of interest was marked by a small ink spot on the surface of the cortex and on a scaled drawing of the cortical surface (cruciate region). Following the identification of wrist flexor and extensor zones the anterograde tracer biocytin was injected into one, or two, wrist extensor zones at three depths (400, 800 and 1500 μm) from the cortical surface. A small injection of HRP - producing a dark brown spot of approximately 500 um - was made in layer II/III of one or more wrist flexor zones. Similar HRP injections were made in the deep layers of wrist extensors zones that were not labeled by biocytin. The HRP injections served to mark the position of potential targets of biocytin labeled terminals. In all animals biocytin labeled terminals (blue) were found in cortical zones controlling the same muscle(s) and also in zones controlling the antagonists. There was no apparent difference in the number of terminals in synergistic or antagonistic cortical zones. Most terminals were found in the upper cortical layers (II-III), but some were also present in the lower cortical layers (V-VI). We conclude that there exist intracortical circuits linking motor cortical zones controlling antagonist motoneuron pools. Elucidating the nature and function of these circuits will be a challenging endeavour. (Supported by MRC of Canada)

DIRECT CORTICO-MOTONEURONAL (CM) CONNECTIONS IN THE SQUIRREL MONKEY (Saimiri sciureus) R.N. Lemon, M.A. Maier', E. Olivier, S.N. Baker and T. Morris' Sobell Dept. of Neurophysiology, Institute of Neurology, Queen Square, London WC1N 3BG and *SmithKline Beecham Pharmaceuticals, Harlow, Essex CM19 5AW UK

Are direct CM connections essential for relatively independent finger movements? In the squirrel monkey, which has rather poorly developed hand skill, anatomical evidence suggests that there are few CM projections from motor cortex to intrinsic hand muscle motor nuclei (Bortoff & Strick, 1993 *J. Neurosci.* 13, 5105-5118). We have made an electrophysiological study of the corticospinal (CS) system in this species.

In 5 adult squirrel monkeys under chloralose anaesthesia, CS fibres were excited by stimulation of the pyramidal tract (PT). The fastest CS axons conducted at 47.3 to 50.7 m.s⁻¹. We recorded intracellularly from 80 motoneurones identified from the radial, median or ulnar nerve. The response to a single PT stimulus was usually a small EPSP with a short segmental delay (0.7-1.1 ms), confirming its monosynaptic origin. These EPSPs were weak (mean only 0.9 mV) and had slow rise times (1.2-2.5 ms); they may derive from CM inputs to distal dendrites, possibly located outside lamina IX. Many motoneurones showed only weak responses to single stimuli but multiple shocks were followed by a large (>2 mV) EPSP with a disynaptic segmental delay (>1.4 ms).

In squirrel monkeys under ketamine sedation, we found that either single PT stimuli or magnetic stimulation (figure of-eight coil) of the motor cortex produced short-latency EMG responses in thenar muscles. The mean (\pm SD) latency was 9.1 ± 0.2 ms, a value comparable with that in the much larger macaque, which may reflect the slow CS fibres, weak monosynaptic pathway, and need for temporal summation of oligosynaptic effects in *Saimiri*. We suggest that the larger, faster-rising CM monosynaptic EPSPs of the macaque and other dexterous primates are of critical importance for the performance of fine finger movements. 430.2

ANATOMICAL CONNECTIVITY OF ELECTROPHYSIOLOGICALLY-IDENTIFIED MOVEMENT REPRESENTATIONS IN THE MI HAND AREA OF SQUIRREL MONKEYS. <u>E.J. Plautz*, G.W. Milliken, & R.J. Nudo.</u> Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, TX 77030.

Intracortical microstimulation (ICMS) techniques were used to generate bilateral maps of the primary motor cortex (MI) hand area in adult squirrel monkeys. Microelectrode penetrations were made at 250 µm interpenetration distances until the total extent of the distal forelimb region was explored. In a separate surgical procedure, a bi-directional tracer (biotinylated dextran amine, BDA) was injected iontophoretically into a region of locally uniform movement representation (e.g. a contiguous cluster of wrist extension sites). Regions were selected based on the results of the original mapping procedure and were confirmed by limited ICMS sampling immediately prior to tracer injection. To permit transport of the tracer, monkeys were sacrificed after a 2-week survival period. The cortex was flattened and cut tangentially at 40 µm thickness. BDA label was visualized using the ABC method followed by reaction in DAB. Sections were examined for the location of the injection site, anteregradely-labeled axons and synaptic terminals, and retrogradely-labeled necessaries.

Results were evaluated for both extrinsic projections between MI and other cortical areas as well as for intrinsic projections within MI. Injected sites were found to be reciprocally connected with several extrinsic cortical fields, including the (presumed) arcuate premotor area, SMA, and SI. Intrinsic terminal fields and retrogradely-labeled cells were primarily confined to zones of distal movement representations (i.e. digit and wrist regions), with relatively little labeling in more proximal zones (i.e. elbow and shoulder regions). These results extend previous findings on intrinsic connectivity within primate MI by demonstrating a greater degree of specificity in connections between functional modules.

INVESTIGATION INTO A POSSIBLE C3-C4 PROPRIOSPINAL TRANSMISSION OF CORTICOSPINAL EXCITATION TO FOREARM MOTONEURONS IN THE MACAQUE MONKEY. M.A. Maier¹, M. Iller², P.A. Kirkwood¹*, J. Nielsen² and R.N. Lemon¹, ¹Sobell Dept. of Neurophysiology, Institute of Neurology, London WC1N 3BG, UK, ²Dept. of Physiology, University of Kiel, D-24098, Germany

In the cat, corticospinal excitation of forelimb motoneurons (MNs) is disynaptically mediated via C3-C4 propriospinal neurons, in addition to segmental effects. Such a relay has been suggested to exist in man, though no direct investigations have yet been performed in primates.

no direct investigations have yet been performed in primates. In five monkeys (*m. fascicularis*) anaesthesia was induced with ketamine and surgery carried out under isoflurane. We performed intracellular recordings from identified forearm MNs in C5-C7 (chloralose anaesthesia with neuro-muscular paralysis, pneumothorax and artificial ventilation). The medullary pyramid (PT) and the lateral reticular nucleus (LRN) were stimulated. A total of 113 MNs were recorded, 46 before and 67 after a C5 dorsolateral funiculus lesion. With this lesion we attempted to abolish the PT inflow to the forelimb segments but to spare more ventral propriosbinal axons.

With intact spinal cord 70% of the MNs showed clear monosynaptic EPSPs upon PT stimulation, few had disynaptic EPSPs. Most common were monosynaptic EPSPs followed by disynaptic IPSPs. LRN stimulation evoked a variety of effects: monosynaptic excitation was the most common. After C5 lesion 42% of the MNs showed small monosynaptic EPSPs from the PT and only 20% had possible disynaptic EPSPs. Half of these late EPSPs were evoked by a single stimulus, did not show temporal facilitation and may have been monosynaptic from surviving slow PT fibres. LRN effects were virtually unchanged. Under these experimental conditions there is little evidence for a C3-C4 propriospinal mediation of corticospinal inputs to cervical MNs in the macaque monkey.

SPINAL CORD TERMINATIONS OF THE MEDIAL WALL MOTOR AREAS.

R.P. Dum' and P.L. Strick. Research Service, VAMC and Depts. Neurosurgery & Physiology, SUNY-HSC@Syracuse, NY 13210.

In macaques, substantial corticospinal projections originate from the supplementary motor area (SMA) and the two caudal cingulate motor areas which lie on the dorsal and ventral banks of the cingulate sulcus (CMAd and MAN). CMAv). We used anterograde transport of WGA-HRP to examine the pattern of spinal terminations of efferents from these motor areas. For comparison, we also examined the pattern of termination of efferents from the primary motor cortex (M1). All of the cortical areas examined terminated in the "intermediate zone" of the cervical spinal cord (laminae V-VIII) and in the ventral horn (lamina IX). Terminations from M1 were the densest, those from the CMAd and CMAv were least dense, and those from the SMA were intermediate. The terminations in lamina IX from all the cortical areas were densest dorsolaterally in regions where motoneurons which innervate distal forelimb muscles are located. Thus, the SMA, CMAd, and CMAv appear to be like M1 in having direct connections to spinal motoneurons, particularly those innervating muscles of the fingers and wrist. Within the intermediate zone, terminations from the SMA and M1 were densest at 3 sites: 1) dorsolaterally in laminae V-VII; 2) dorso-medially in lamina VI, at the base of the dorsal horn; and 3) ventromedially in laminae VII/VIII. In contrast, efferents from the CMAd terminated most densely at the dorsolateral site, whereas those from the CMAv were concentrated in the dorsomedial site. Thus, the CMAd and CMAv may influence different aspects of segmental motor control by connecting with separate sets of last order interneurons. These results suggest that the medial wall motor areas have the potential to generate and control movement through connections that are independent of M1. Furthermore, the corticospinal projections from the medial wall may provide an anatomical substrate for the recovery of motor function which follows damage to M1 or its output pathways. Support: VA Rehab. R&D and USPHS 24328 (PLS).

ORGANIZATION OF FACE REPRESENTATION IN THE CINGULATE ORGANIZATION OF FACE REPRESENTATION IN THE CINGULATE GYRUS OF THE RHESUS MONKEY, R.J. Morecraft, C.M. Schroeder and J. Keifer*. Department of Anatomy and Structural Biology, University of South Dakota School of Medicine, Vermillion, SD 57069

Areas 24c (or M3) and 23c of the cingulate gyrus represent a unique part of the cerebral cortex because both areas receive direct input from prefrontal and limbic cortices and both send projections to the spinal cord, red nucleus, basal ganglia and isocortical motor areas. Although a face representation has been identified in area 24c, it not known if a face representation resides within area 23c. Neuroanatomical and electrophysiological methodologies were used in 4 rhesus monkeys to investigate the organization of face representation in the cingulate gyrus and examine the possibility that cingulate face areas give rise to descending projections which target brains centers regulating face movements. Fluorescent tracer injections placed into electrophysiologically-defined subsectors of the primary (M1) and supplementary (M2) motor cortices demonstrated that the rostral part of area 24c and area 23c project to the face representations of M1 and M2. Injections of biotinylated dextran amine involving the rostral part of area 24c and area 23c demonstrated a direct projection from both regions to the facial nucleus (FN). The area 24c projection ended primarily in the dorsolateral part of the FN and the area 23c projection in the lateral part. Our data demonstrate that areas 24c and 23c each contain a face representation directly affecting cortical as well as subcortical centers controlling the face. The observation of face representation in the rostral part of areas 24c (M3) and 23c (M4) suggest the formation of two complete simisculi in cingulate cortex. Our results also indicate that face representation may assist in defining the rostral border of areas 24c and 23c. The projection from M3 to the dorsolateral part of the FN suggest preservation of upper facial movement following middle cerebral artery damage may be due in part, to sparing of the corticofacial projection from the cingulate motor cortex. 430.9

CORTICOCORTICAL AND THALAMIC CONNECTIONS OF MEDIAL AGRANULAR CORTEX (AGm) IN PRAIRIE VOLES (Microtus Ochrogaster). R.L. Reep* and B. Kirkpatrick, Dept. of Physiol. Sci., Univ. of Florida, Gainesville, FL 32610; and Dept. of Psychiatry, Univ. of Maryland School of Medicine, Baltimore, MD 21228.

Fluorescent axonal tracers were used to investigate the connections of AGm in prairie voles. As in rats, the rostral and caudal portions of AGm have different but partially overlapping patterns of connections.

Caudal AGm has extensive cortical connections with orbital cortex, cingulate and retrosplenial cortex, caudal Par1, Par2, posterior parietal cortex and visual areas. Rostral AGm has similar connections with areas Par1 and Par2, orbital connections limited to area VLO, no connections with posterior parietal or retrosplenial cortex, and greatly reduced connections with visual areas. Rostral AGm receives input from area AGI, whereas caudal AGm does not. The axons linking rostral and caudal AGm with other cortical areas travel in the deep gray matter of layer VI rather than in the white matter.

Thalamic labeling after caudal AGm injections was prominent in nuclei AM, VL, MDl, CL, Po and LPm. Labeling in nucleus VM and Rh formed a halo around the periphery of nucleus Sm. Rostral AGm has a similar pattern, but lacks input from LPm.

Supported by the University of Florida College of Veterinary Medicine and the Maryland Psychiatric Research Center.

PARIETAL INPUTS TO DORSAL VS. VENTRAL PREMOTOR AREAS IN THE MACAQUE MONKEY: A MULTIPLE ANATOMICAL TRACING STUDY, J. Tanné*(1), D. Boussaoud (1), N. Boyer-Zeller (1), V. Moret (2) and E.M. Rouiller (2), (1) INSERM U94. 69500 Bron (France), (2) Univ. Fribourg, CH-1700 Fribourg (Suisse).

The dorsal (PMd) and ventral (PMv) premotor areas are both involved in visually guided limb movements Recently, we (Tamé et al., Neuroreport, 7: 267-272, 1995) described direct visual inputs to PMd from medial and lateral parietal cortex. and from the parieto-occipital sulcus. These findings together with a substantial body of psychophysical and neurophysiological evidence support the view that PMd and PMv might be part of two separate visuomotor channels: a reaching channel involving PMd, and a grasping channel involving PMv. The present study was aimed at directly comparing the distribution of parietal cells projecting to PMd vs. those projecting to PMv. by means of injections of multiple retrograde tracers within the two areas in the same monkeys.

We found that many parietal areas project only or mostly to PMd. These include the parieto-occipital area (PO), areas 7m and 7a, the caudal part of the medial intraparietal area (MIP), the medial dorsal parietal area (MDP), and the ventral and lateral intraparietal areas (VIP and LIP, respectively). Projections directed to PMv, but not to PMd, arise from the anterior portion of the posterior bank of the intraparietal sulcus (AIP), the adjacent fundus and part of the medial bank Paricial regions projecting to both PMd and PMv are the rostral part of area MIP, and areas 7b and 5 on the convexity of the inferior and superior parietal lobules, respectively. Within MIP and 7b, labelled cells were largely segregated PMv-projecting cells are located rostrally, PMd-projecting cells are located caudally, with a small region of overlap in between. The findings show that PMd and PMv receive projections from largely separate regions of parietal cortex, and support the distinction between reaching vs. grasping visuomotor pathways. Supported by INSERM (Paris) and the Swiss National Science Foundation.

TOPOGRAPHY OF PROJECTION TO THE MOTOR CORTEX FROM FUNCTIONALLY IDENTIFIED CELL GROUPS IN CEREBELLAR NUCLEUS INTERPOSITUS ANTERIOR IN THE CAT. H. Jörntell* and C.-F. Ekerot. Dept of Physiology and Neuroscience, Lund University, Lund, Sweden

The projections to the motor cortex from different cell groups (sites) in the forelimb area of nucleus interpositus anterior (NIA) were investigated in barbiturate anaesthetized cats. NIA-sites were identified by their cutaneous climbing fibre receptive fields (cf-rfs) and microstimulated with relatively large microelectrodes. Motor cortical surface and depth responses were recorded with small surface and microelectrodes, respectively

The cortical responses were mainly located in the lateral part of the anterior sigmoid gyrus and displayed a fine topographical organization. The response topography for a given site was coupled to the exact location of its cf-rf. Powerful cortical projections were found from sites with cf-rfs located ventrally and radially on the paw and forearm, especially if the sensitivity centre of the cf-rf was on the first digit. The response amplitudes for sites with other types of cf-rfs were progressively smaller the more the cf-rf involved the dorsum of the paw or the ulnar forearm. For functional comparisons, the cortical projections from face and hindlimb areas of NIA and from the posterior interposed and dentate nuclei were also investigated.

Importantly, the relations between the topographical patterns for different NIA sites were constant despite that the relations to anatomical landmarks on the cortical surface occasionally could deviate from the usual pattern. This is in contrast to the large interindividual variations in the detailed topography of motor output that have been reported by several authors.

THALAMOCORTICAL AFFERENTS TO LAYER I OF RAT SENSORY-MOTOR CORTEX, B.D. Mitchell*, B. Clancy and L.J. Cauller, GR 41, Cognition and Neuroscience Program, University of Texas at Dallas, Richardson,

Layer I of the neocortex is a dense synaptic zone consisting of horizontal axons running in all directions (Cauller et al, 1996) making synapses with supragranular neurons and the distal apical dendrites of the layer V corticobulbar pyramidal neurons (R.M. Brown et al., ibid). In addition to the "backward" corticocortical and widespread layer VII projections (Clancy and Cauller, ibid), thalamic inputs also terminate in layer I of the rat although the horizontal extent of these thalamic projections has not been fully determined. We have studied the origin and extent of the thalamocortical projections to layer I of primary sensory/motor areas of rat neocortex. Thalamic origins of layer I inputs were identified by retrograde tracers, diamidino yellow and Fast Blue, applied directly to the pial surface (~1 mm2; 10 min. application) with penetration no deeper than layer II verified by the absence of labeled cells in layer IV which are consistently labeled by layer II injections. Applications in the forepaw area labeled cells scattered throughout VPI and Po thalamus in addition to a dense cluster of cells in VM. More anterior applications in lateral or medial agranular frontal cortex labeled many more cells in VL thalamus than found in VPI following application to the forepaw area. In addition, a dense cluster of cells in VM was also found following the frontal applications indicating VM projects widely to layer I across sensory/motor cortex. Injections of dextranamine (10kMW) into VM anterogradely labeled fibers extending to layer I with numerous horizontal branches. These anatomical findings are consistent with electrophysiological results (K. Paul et al., ibid) showing VM stimulation excites Supported by a grant from the Whitehall Foundation. superficial cortical layers.

CONNECTIVITY AND HIERARCHY IN THE OPOSSUM ISOCORTEX

S. MARTINICH, M.N.PONTES, E. VOLCHAN*. Lab. of Neurobiology II, IBCCF°, Federal University of Rio de Janeiro, RJ 21949-900. Brasil.

The analysis of tangential patterns of connections obtained after injections of anterograde and/or retrograde tracers (Fast Blue, Diamidino Yellow, HRP, WGA-HRP) into different cortical fields of Didelphis marsupialis have allowed us to state the following rules: 1) A primary area of one particular sensory modality connects unilaterally with primary and unimodal associative areas from other modalities. 2) The density of intrahemispheric connections between two areas increases with spatial proximity. 3) A primary area has multi-order contralateral inputs but their contralateral outputs are strictly homotopic. 4) Frontal (F), parietomarginal (PM) and insular (INS) cortices receive bilateral inputs from primary and associative (uni or multimodal) areas. 5) The connectivity of F, PM and INS is greatest with multimodal associative or "transitional" regions, decreases with unimodal associative areas and is lowest with primary areas. 6) The topography of connections is progressively coarser along an ascendent sequence of primary, unimodal and multimodal associative areas. 7) Descendent connections scatter more than ascendent ones. 8) Specific connections can emerge from areal modular subdivisions. These principles conform to a topologicalfunctional organization which minimizes connection distances and hierarchizes information processing in the opossum isocortex

IMPAIRMENT OF REACHING AFTER MUSCIMOL INACTIVATION OF GLOBUS PALLIDUS PARS INTERNA IN THE MONKEY W.T. Thach*, A.J. Bastian and J.W. Mink. Depts. of Neurology, Anatomy & Neurobiology and Program in Physical Therapy, Washington. Univ. School of Med., St. Louis, MO 63110. The purpose of this study was to investigate the kinematics of a reach and grasp in the monkey before and after reversible inactivation of the globus pallidus pars interna (CDB)

A rhesus monkey sat in a modified primate chair and reached in a para-sagittal plane A rhesus monkey sat in a modified primate chair and reached in a para-sagittal plane to grasp a 0.5 cm cube of apple that was presented at shoulder height and in front of the monkey. Markers were applied to arm overlying the shoulder, elbow, wrist, and tip of the index finger. Movements were videotaped at 60 fields/s, digitized with a Peak Performance video-based motion analysis system, and analyzed using custom-written software. In each session the monkey performed 12 - 15 reaches before and 12- 15 reaches after injection of 0.5 μ l of muscimol (1 μ g/ μ l) into GPi. The boundaries of GPi had been mapped previously with single unit recording during a trained wrist movement. Reaching was impaired after injection into 9 of 10 sites, each 1 mm apart. The impairment was qualitatively similar across sites. but the largest deficits were seen after injection into the more ventral and medial sites.

After all 9 GPi inactivation experiments that produced a deficit, reaching was slow

deficits were seen after injection into the more ventral and includar sites.

After all 9 GPi inactivation experiments that produced a deficit, reaching was slow and the monkey tended to over-reach the target in the vertical plane and under-reach in the horizontal plane. Separate kinematic analysis of movement at the different joints indicated that velocity of elbow extension was slowed by up to 50% whereas elbow flexion was nearly normal. In this task, extension of the elbow is aided by gravity and by interaction torques due to shoulder flexion and is thus accomplished by controlled relaxation of the elbow flexors. The inability to relax the elbow flexors is consistent with previous findings that GPi inactivation causes a tonic flexor bias and impairment of 'turning off' previously active muscles compared to 'turning on' active muscles. These results support the hypothesis that the basal ganglia act to

inhibit competing motor mechanisms.

THE NIGROSTRIATAL DOPAMINE SYSTEM INFLUENCES ACTIVITY OF TONICALLY ACTIVE STRIATAL NEURONS THROUGH D2-CLASS DOPAMINE RECEPTORS. K. Watanabe, N. Matsumoto, A.M. Graybiel and M. Kimura*. Fac. of Health and Sport Sci. Osaka Univ. Toyonaka Osaka, 560 JAPAN, and Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge MA 02139 U.S.A.

Tonically active neurons (TANs) of the monkey striatum fire at low rates, appear not

to fire in relation to movement, but show responses to conditioned sensory stimuli in behaving monkeys who learn a sensorimotor conditioning task. The acquired response has been shown to occur in 50-70% of TANs recorded in the caudate-putamen. Intrastriatal infusion of the toxin, MPTP, diminishes this population response to capre-conditioning levels of cue responsiveness (ca. 15-20%; Aosaki et al., 1994). This result suggests that intrastriatal dopamine is required for the conditioned responses of the TANs. In the present study, our goal was to identify the dopamine receptor subtypes through which the conditioned responsiveness of TANs is influenced. One monkey (Macaca fuscata) was conditioned with a click sound that was paired to the delivery of a liquid reward. TAN units were recorded in the putamen and caudate nucleus. Before conditioning. 14 % of TANs responded to the clicks. After 2 to 3 weeks of conditioning, more than 60% of TANs became responsive to the clicks. Dopamine receptor antagonists were locally applied through the cannula containing the tungsten wire recording electrode while the activities of TANs were recorded following behavioral conditioning. Infusion of the D2-class antagonist, (-) sulpiride (1 μ l, 20 μ g/ μ l, n=2), blocked or sharply reduced the responses of TANs to the reward-predictive clicks. However, neither of two D1-class antagonists, SCH23390 (10 µg/µl, n=4) and cis-flupenthixol (30 µg/µl, n=2), detectably modulated the responses of TANs to the clicks. These results suggest that the nigrostriatal dopamine system can influence the expression of conditioned responses of TANs in the primate striatum through D2-class dopamine receptors. NEOSTRIATAL NEURONAL ACTIVITY BECOMES BETTER RELATED TO MOVEMENTS WHEN CONDITIONS BECOME UNPREDICTABLE. R.J. Nelson* M.A. Lebedev, I. Opris and J.M. Denton. Department of Anatomy and Neurobiology, College of Medicine, University of Tennessee, Memphis, 875 Monroe Avenue, Memphis, TN 38163.

Recent evidence suggests that neostriatal (NS) neuronal activity may become better related to movements and sensory cues under novel behavioral conditions. We tested whether these improvements could occur after single trial changes in predictability of the linkage between cues, movements and rewards. Monkeys made vibratory or visually-cued ballistic wrist flexions and extensions after holding a steady position for visually-cued ballistic wrist flexions and extensions after folding a steady position in 0,5-2.0s against a light load. They were rewarded 75% of the time, pseudorandomly, for correct performance. Activity during groups of trials followed by rewards (Regular trials) was compared to that during trials following ones in which rewards were withheld (After trials). Animals were cared for according to NIH guidelines.

To date, 93 confirmed and 156 presumed NS neurons have been studied because the foregroup of the progressing of the progressing times.

their firing patterns changed before movement or after sensory cues. Reaction times (RTs), activity onsets relative to cue (R1) or movement (R2) onsets were calculated. Changes in position, velocity, acceleration and neuronal activity were compared to yield coefficients of determination (cD). Times at which the best cDs occurred (cT) relative to movements and rise times (R2-cT) were computed. Comparing After with Regular trials, RTs and R2s were shorter (38ms and 51ms - vibratory trials, 14ms and 15 ms visual trials, respectively). For vibratory but not visually-cued trials, R1s were shorter (~13ms). CTs were not different for either go-cue modality. The cDs were significantly larger in vibratory but not visually-cued trials, indicating a better correlation of neuronal activity with movement parameters. Rise times were significantly shorter for both vibratory (-40ms) and visually-cued (-17ms) trials. These observations suggest that NS neuronal activity becomes better correlated

with movements during unpredictable conditions, but does so differently dependent upon the type of sensory stimuli present. Thus, NS neurons may be gated during predictable behavioral conditions. This improved correlation parallels improvement in several task-related kinematic parameters. Supported by NIH Gr NS 26473.

Functional MRI Activation of Multiple Basal Ganglia-Thalamocortical Sites During Self-Generated Sequences of Arm Movements V. Menon, J. Johnson, E. V. Sullivan, K. O. Lim, G. H. Glover and A. Pfefferbaum Departments of Psychiatry and Behavioral Sciences and Radiology, Stanford University School of Medicine and VA Palo Alto Health Care System, CA 94305.

A number of cortico-subcortical loops may underlie planning, control, and execution of internally generated movements. In this study, brain areas involved in self-generated sequences of arm movements were investigated using fMRI. Four right-handed subjects performed an experiment consisting of 12 alternating 40s epochs of rest and a motor task. During the motor task, subjects first generated 3 numbers between 1 and 4 and then made arm movements to corresponding 3 numbers between 1 and 4 and then made arm movements to corresponding labeled positions on a keypad. Subjects repeated this procedure with a new sequence till they were instructed to stop. Functional images were acquired on a conventional 1.5T scanner using a T2* weighted gradient echo spiral pulse sequence with a temporal resolution of 4s. Twelve axial slices (overlap across subjects: -8mm < z < 46mm in Talairach coordinates) were acquired with slice thickness of 6mm and in-plane resolution of 2.8mm. Statistical Parametric Mapping was used to analyse the data. Results reported here are for Z > 5 (p < 0.001, corrected for multiple comparisons). Multisubject averaging revealed complications of left cardeta left partners bilderal number (left) significant activations of left caudate, left putamen, bilateral pulvinar (left > right), left ventral anterior-ventral lateral and right lateral-posterior nuclei of the thalamus, bilateral dorsolateral prefrontal cortex (BA 9/46, right > left), bilateral pre-motor cortex (BA 6), bilateral anterior cingulate cortex (BA 24), left insula, bilateral superior and inferior parietal lobules (BA 7 and BA 40/39), bilateral temporo-occipital cortex (BA 19/37) and anterior vermis. These results indicate that multiple basal ganglia-thalamocortical sites are engaged during self-generated sequences of arm movements. The pattern of activation is consistent with previous electrophysiological and histochemical findings of multiple basal ganglia-thalamocortical loops. Supported by The Sinclair Fund, NIH (MH30854. AA05965, AA10723) and the Department of Veterans Affairs.

NEURONAL ACTIVITY IN THE PUTAMEN AND CLAUSTRUM DURING PERFORMANCE OF MULTIPLE MOVEMENTS. E. Hoshi and J.Tanji*, Dept. of Physiol., Tohoku Univ. Sch. of Med.,

The purpose of the present study was to examine how neuronal activity in the putamen and claustrum is involved in performance of multiple movements. Two monkeys (Macaca fuscata) were trained to perform three different movements (push, pull or turn a manipulandum) sequentially in a temporal order. Individual movements were initiated from a neutral position, and each movement was triggered by a tone signal. Initially, a visual signal indicated what movement should be performed, and subsequently the same sequential movements were performed in the absence of the visual signal. In both putamen and claustrum, over 70% of task-related neurons were active in relation to execution of movements, and remaining neurons were active during waiting periods before go signals. In the putamen, a vast majority (over 80%) of movement-related neurons were active in relation to execution of a particular movement among the three movements, while only 6 % were active in relation to all three movements. By contrast, a large population (73%) of claustral movement-related neurons exhibited relation to all three movements. In a group of putamen neurons, magnitudes of activity changes during execution of movements were influenced by differences in the order of movements to be performed. Such activity was not common in the claustrum. These striking differences suggest that the putamen and claustrum are differentially involved in sequential execution of multiple movements.

TIME-FREQUENCY ENCODING OF VARIATIONS IN REACTION-TIME PERFORMANCE BY NEURONAL ENSEMBLES IN THE RODENT STRIATUM AND PREMOTOR CORTEX Mark G. Laubach* and Donald J. Woodward, Dept. of Physiology & Pharmacology, Bowman Gray School of Medicine, Wake Forest University,

Winston-Salem, NC 27157

The goal of this study was to examine whether variations in the firing patterns of neurons in the rodent striatum and premotor cortex are predictive of an animal's performance of a tone-cued, variable-delay, simple reaction-time task. A multi-site single-unit recording method was used to record from 10 to 30 neurons simultaneously. Spikes were collected in peri-event histograms (1 msec bins, 400 msec prior to the operant response) for trials with the fastest and slowest reaction-times, defined by the quartiles of the reaction-time distribution. 77 of 360 (~20%) striatal neurons and 36 of 185 (~20%) neurons in the medial agranular cortex recorded in 6 rats exhibited phasic modulations in spike output prior to the operant response (preparatory activity). A quantitative analysis of 50 neurons with wavelet discriminant analysis (Buckheit and Donoho 1995) found that variations in the firing patterns of 24 (~50%) of the neurons were predictive of variations in reaction-time performance at >20-50% over chance levels of prediction. Variations in reaction-time performance were associated with variations in the rate and temporal structure of bursts of spikes immediately prior to the operant response and in oscillatory patterns of spikes during the foreperiod. Spectral analysis found that the oscillatory firing patterns had power at 5-7 (n=6), 8-12 (n=12) and 15-25 (n=10) Hz. When groups of 4 to 8 simultaneously recorded neurons with preparatory activity were combined for discriminant analysis, there was a modest improvement in classification (~10%) over that of the best neuron in the group. Cross-correlation analysis found that spikes from neurons with oscillations were synchronized during the epoch of oscillation (JPSTH, 4 msec bins). These data suggest that information related to reaction-time performance is encoded in the firing patterns of neurons in the striatum and cortex, is related to the 10-20 Hz "mu" rhythm and is largely redundant across the neuronal population. Supported by AA05396 to MGL and DA02338 to DJW.

EXTRACTION OF NEOSTRIATAL FEATURES FROM DEOXYGLUCOSE AUTORADIOGRAMS. <u>S.M. Feldman*t, J.R.</u> Cavanaught, L.M.Goldbloomt and L.L. Brownt. †Center for Neural Science, New York University, New York, NY 10003 and ‡Department of Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

Albert Einstein College of Medicine, Bronx, NY 10461.

We used feature detection procedures in conjunction with deoxyglucose autoradiography to reveal a combinatorial map of somatosensory representation in rat neostriatum (Brown, PNAS, 1992). However, because the changes in metabolic activity that accompany tactile stimulation are subtle, it is often difficult to define the extent of a detected feature. We here describe a computer-assisted technique for detecting peaks of metabolic activity in 2DG autoradiograms that allows for improved definition of the edges of detected features, which can better be related to the neostriatal

Tactile stimulation was applied to awake rats after iv injection of radiolabelled deoxyglucose. Image analysis was carried out on digitized autoradiograms of coronal brain sections, with optical density coded as grey level. To detect features with high contrast edges, we used an iterative thresholding procedure to identify features that exceeded an empirically established preset minimum area (the equivalent of a circle with dia=425µm; this was the size of the largest features observed). The algorithm we used this was the size of the largest features observed). The algorithm we used automatically reduced the preset minimum area if the detected feature grew too quickly during iterative thresholding. Features with lower contrast edges grow more quickly than do features with higher contrast edges as the thresholding "window" includes increasingly lower gray levels. Higher contrast features do not grow as quickly, and are selectively extracted by the procedure. In this way we were able reliably to define and delimit the individual peaks of high optical density that resulted from the tactile stimulation. Supported by USPHS Grants NS21356 and MH19524.

ENSEMBLE RECORDINGS FROM STRIATUM OF FREELY-BEHAVING RATS

M. log C. Connolly V. Hillegaart M. Wilson and A.M. Graybiel* Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139

To study the functional organization of the striatum, we have developed an electrophysiological recording system with 4-6 mobile tetrodes implanted in the striatum of freely behaving rats.

Tetrodes were implanted surgically into the dorsolateral striatum of 17 rats. Each

tetrode was then advanced independently from the brain surface over a period of 3-5 days, and recordings were made for up to 12 weeks. Locations of tetrodes were histologically confirmed. Each spike was registered as an event on all four channels of a tetrode. Units were identified and analyzed using an in-house cluster

channels of a tetrode. Units were identified and analyzed using an in-house cluster analysis package developed for this purpose (Jog, Connolly, Hillegaart, Graybiel in prep.). A 3-D spike event plot generated clusters in parameter space. Location, frequency and phase of firing of each cluster was computed for each tetrode. We have analyzed 7 cell pairs from 3 animals to date. Selected pairs were from 3 tetrodes in rat 1, and 1 tetrode each from rats 2 & 3. Two pairs showed a low firing rate of 0.5Hz and stayed in phase, with calculated distances between units in the pairs of 100 µm and 22 µm. One in-phase pair fired at 4Hz with interunit distance of 39 µm. Two other pairs were out of phase with their partners at lower rates (0.5 Hz and 0.1 Hz), but were in phase at 2 Hz with interunit separations of 200 and 212 µm, respectively. A final pair showed firing out of phase at 0.5Hz but abrupt phase locking at 3Hz. This appeared behaviorally related to increased motor activity or changed sensory input prompted by turning off the room lights. Inter-unit distance was 88 µm. distance was 88 µm

Results from these experiments suggest that correlated striatal activity between unit pairs can occur at low and high frequencies. Those units that are out of phase at lower frequencies can become in-phase at higher frequencies. This phenomenon occurred in units that were both close and at a distance. The one instance of abrupt change in phase and frequency with lights off suggests that phase relationships may be correlated with behavior. FORCED OR VOLUNTARY LOCOMOTOR ACTIVITY ELICITS FOS-LIKE IMMUNOREACTIVITY IN THE RAT STRIATUM. W.M. Struthers and D. Wirtshafter. Department of Psychology, University of

Thinois at Chicago, Chicago, IL 60612.

The striatum is known to be involved in production of locomotor activity. Additionally, Fos-Like Immunoreactivity (FLI) has been used as a marker for trans-synaptic activation of neurons in the nervous system. Given the striatum's involvement in locomotor activity, two experiments were conducted in an attempt to elicit FLI in the striatum behaviorally. In the first experiment, males were placed in a running wheel and forced to run intermittently for one hour. showed that forced running induced FLI in the striatum.

In an additional experiment, estrogen and progesterone pretreatment of ovariectomized females produced a significant increase in voluntary running wheel activity. Striatal FLI was observed in these females, although to a lesser degree than that seen in forced running animals. There was an absence of FLI in the striatum of vehicle injected controls and also in steroid pretreated females who were not allowed access to the running wheel. These results suggest that Fos is produced in the striatum as a result of increased locomotor activity (Supported by NS33992).

THE STRIATAL REPRESENTATION OF VIBRISSAE CORRELATION OF ANATOMIC AND FUNCTIONAL STUDIES IN THE RAT, L.M. Goldbloom*, D.M. Smith and L.L. Brown. Depts. of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

In primary somatosensory cortex, the body map is segregated into receptive fields where leg, arm and face are represented in non-overlapping regions and functionally related neurons are in the same overlapping regions and unchonary related neurons are in the same vicinity. In contrast, metabolic mapping studies suggest that the striatum is organized in such a manner that the map of the body is in multiple disconnected regions where overlap between leg, arm and face may occur. To examine the underlying anatomy, an anterograde tracer was injected into electrophysiologically defined areas of somatosensory cortex. To uncover the functional neural activity, autoradiography using (\frac{1}{2}\)deoxyglucose was employed during tactile stimulation.

We found that somatosensory cortex projections from layers III, Va and Vb of the vibrissae area to the striatum had a distinct pattern that differed from the forearm and hindlimb projections. The dorsolateral striatum contained the major projection field while there were smaller projection fields medially. These projections extended in the anteroposterior direction from about 2.5 mm behind bregma up to 2.0 in front of bregma. The functional neural activity displayed discrete metabolic of bregma. The functional neural activity displayed discrete metabolic peaks in areas that corresponded to the anatomical projections, but the metabolic functional map was not as extensive as the corticostriate projections. We conclude that the body map is distributed in the striatum to allow extensive integration beyond sensorimotor function as opposed to the more segregated functions seen in primary somatosensory cortex. Supported by NIH NS21356

SOMATOSENSORY STIMULATION IN AWAKE RAT INDUCES PATCHY DOMAINS OF METABOLIC ACTIVITY IN THE STRIATAL MATRIX COMPARTMENT. <u>LL Brown*, L.M. Goldbloom, D.M. Smith, S.M. Feldman, A.M. Graybiel</u>. Dept. of Neurology, Albert Einstein College of Medicine, Bronx NY 10461; Center for Neural Science, NYU, NY, NY 10003; Dept. of Brain & Cognitive Sciences, MIT, Cambridge MA 02139.

The striatum has a large sensorimotor region in which cells fire in relation to the striatum has a large sensorimotor region in which cells fire in relation to

The striatum has a large sensorimotor region in which cells fire in relation to movement with a rough foot-up, head-down topography. This striatal region receives strong inputs from somatosensory and motor cortex. In the monkey, inputs representing particular body parts are organized in distributed arrays that in cross section appear as patches in the matrix ("matrisomes"). In the rat, neural metabolism peaks related to somatosensory stimulation also form patchy, distributed arrays. We used the [¹⁴C]deoxyglucose mapping technique to study functional activity in the striatum in unanesthetized, restrained rats given somatosensory (light touch) stimulation for 45 min on the hindlimb or vibrissac Sites of peak metabolic activity were identified by omputer-assisted methods and striosome and matrix compartments were identified by The naloxone binding. Peak metabolic activity appeared in the dorsolateral caudoputamen in distributed sets of patches ca 150-300µm wide and separated by 150-300 µm. Nearly all of the activity was in the matrix: there was only 1-5% overlap of metabolic peaks with striosomes. Some patches of metabolic activity abutted striosomes but others were separated from them. Almost every metabolic patch was clearly centered in the matrix. These findings demonstrate that the matrix compartment of the sensorimotor striatum is organized into patchy functional domains that can be activated by natural stimulation of localized body parts. These domains may correspond to matrisomes. Supported by NIH NS 21356 and NIH Javits Award NS 25529.

ACTION POTENTIAL THRESHOLD OF MEDIUM SPINY NEURONS IN THE RAT NEOSTRIATUM IN VIVO. J. R. Wickens and C. J. Wilson⁴ Dept Anatomy and Neurobiology, Univ. Tennessee, Memphis, TN 38163.

Previous work has shown that dopamine, acetylcholine and possibly other neuromodulators act in part to alter the threshold for action potential generation in striatal neurons, or the sensitivity of the threshold to the recent history of membrane potential changes. We measured the threshold for action potentials evoked in identified spiny neurons in urethane-anesthetized rats under three different conditions: (1) electrical stimulation of the contralateral cerebral cortex, (2) brief directly-applied current pulses, (3) spontaneous action potentials occuring during spontaneous episodes of depolarization (Up state). Threshold was defined as the point along the action potential trajectory at which the rate of depolarization exceeded 4 mV per msec. All neurons in the sample exhibited spontaneous membrane potential shifts, but not all fired action potentials while in the Up state. In both spontaneously firing neurons and silent ones, the threshold for action potentials evoked by current pulses was significantly higher than for those evoked by cortically-evoked PSPs. There was no significant threshold difference between spontaneously firing and silent spiny neurons. There was also no significant difference in thresholds of spontaneous action potentials occurring at the onset of an Up state and those occurring after a prolonged period of depolarization. Application of more intense current pulses adjusted to reproduce the EPSP rate of rise produced firing at correspondingly lower thresholds. Most of these observations were reproduced by rapid voltage-sensitive inactivation of fast sodium and potassium channels in a compartmental model of the spiny projection neuron. NIH NS20743 & H.R.C. (NZ)

NEUROLEPTIC-INDUCED ORAL DYSKINESIAS IN RATS TREATED WITH OLANZAPINE, SERTINDOLE AND HALOPERIDOL, K. Sakai* X.-M. Gao and C.A. Tamminga. Maryland Psychiatric Research Center, University of Maryland, School of Medicine, Baltimore, MD 21228.

Chronic treatment of schizophrenia with typical neuroleptics is associated with tardive diskinesia (TD) in humans, a condition often modeled by vacuous chewing movements (VCMs) in rats. The atypical antipsychotic drug, clozapine has no (or a low) incident of either TD in humans or VCMs in rats. But, because of its side effects, it has been important to develop new atypical neuroleptics. Sertindole (Abbott and Lundbeck) and olanzapine (Lilly) are new antipsychotic drugs, both of which have very low motor side effects in humans. We quantified VCMs after administration of sertindole (0.5 mg/kg/day) are 2.0 mg/kg/day), and olanzapine (0.5 mg/kg/day) or 2.0 mg/kg/day) in comparison with haloperidol (1.5 mg/kg/day) and water controls for six months. VCM rates are 3.3±0.5 and 5.1±2.7 VCM/5 min. respectively for the two doses of sertindole, 4.6±1.3 and 3.9±0.9 VCM/5 min. for haloperidol compared to 2.0±0.5 VCM/5 min. for water alone (mean±S.E.). Only with haloperidol was the VCM rate higher than with water. None of the groups treated with either sertindole or olanzapine showed VCMs higher than the water group. VCMs of the 0.5 mg/kg/day of sertindole group and 2.0 mg/kg/day of olanzapine group were significantly lower than that of the group treated with haloperidol. Plasma drug concentrations measured in trunk blood collected at sacrifice were 39.4±4.8 and 218.9±13.4 ng/ml respectively for the two doses of selmane from the proper treated with haloperidol. Plasma drug concentrations measured in trunk blood collected at sacrifice were 39.4±4.8 and 218.9±13.4 ng/ml respectively for the two doses of olanzapine and 13.0±3.2 ng/ml for haloperidol. Thus, two new antipsychotic drugs, which clinically show low motor side effects, have a lower incident of VCM in rats. Research supported by NIMH (MH 37073).

SIMULTANEOUS INTRACELLULAR RECORDING OF SPONTANEOUS ACTIVITY IN PAIRS OF STRIATAL SPINY NEURONS *IN VIVO*. E. A. Stern*1, D. Jaeger², and C. J. Wilson¹, ¹Dept. of Anatomy and Neurobiology, College of Medicine, University of Tennessee, Memphis, TN., ²Division of Biology 216-76, Caltech, Pasadena, CA.

Intracellular recordings were made from pairs of striatal spiny neurons in rats anesthetized with urethane. These neurons exhibited spontaneous, subthreshold membrane potential shifts, resulting in a two-state behavior of the membrane potential. The depolarized (Up) state of the neurons has previously been shown to result from convergent synaptic activity interacting with nonlinear membrane properties. We analyzed the correlation of membrane potentials among pairs of striatal neurons on three time scales: slow spontaneous subthreshold membrane potential shifts, high-frequency membrane potential fluctuations in the Up state, and spike activity. Correlated activity was measured with crosscorrelation, cross-spectral density, and time-dependent correlation analysis. Some pairs of neurons showed highly correlated slow spontaneous membrane potential shifts, while in others, the membrane potentials fluctuated independently. Few significant correlations of fluctuations within Up states or spike activity among neurons were found. The strength of the correlated activity decreased with distance between the cells. Previous studies have shown that the spontaneous membrane potential fluctuations of corticostriatal and striatal neurons have periodic and stochastic components. Within correlated pairs of striatal neurons, both the periodic and stochastic components were correlated. This shows that the stochastic as well as the periodic components of the corticostriatal input are preserved through convergence of the corticostriatal connectivity. NIH NS20473 and Sloan Foundation

431.14

HALOPERIDOL AND CLOZAPINE INDUCE FOS-LIKE IMMUNO-REACTIVITY IN THE PRIMATE BASAL GANGLIA. <u>D. Wirtshafter*</u>. Dept. Psychol., Univ. Ill. at Chicago, Chicago, Il 60607-7137.

Several authors have shown in rodents that the dopamine antagonist haloperidol induces Fos expression in the striatum and nucleus accumbens and we have found that this drug also induces Fos expression in the entopeduncular nucleus and substantia nigra. In contrast to haloperidol, the atypical neuroleptic clozapine appears to induce staining more effectively in the accumbens than in the striatum

In the current studies we examined the patterns of Fos expression induced in the monkey by haloperidol and clozapine. Eight macaque fasciculata were injected with either haloperidol (0.125, 0.5 or 2.5 mg/kg) or its vehicle three hours prior to sacrifice. Almost no Fos like immunoreactivity (FLI) was seen in the basal ganglia of animals injected with vehicle. Haloperidol induced a dose dependent increase in FLI in the striatum, accumbens, internal pallidal segment and substantia nigra. Nigral staining was most pronounced in the medial pars reticulata, but a few lightly stained neurons could also be detected in the pars compacta. Pronounced FLI was also seen in the lateral septum and in the bed nucleus of the stria terminalis. Only a few labeled cells could be seen in the external pallidal segment. These results are similar to those obtained in rat and are compatible with theories of basal ganglia organization which propose that blockade of D2 receptors excites striatopallidal cells resulting in disinhibition of nigral and entopeduncular neurons. In contrast, clozapine (25 mg/kg) induced only a small amount of staining in the striatum whereas much heavier labeling was seen in the accumbens Pronounced staining was seen in the septum, bed nucleus of the stria terminalis and the islets of Calleja, but only a few labeled cells were seen in the substantia nigra or globus pallidus. This pattern may be related to the low instance of extrapyramidal side effects produced by clozapine Supported, in part, by NS33992

THE EFFECTS OF ANTIPSYCHOTIC DRUGS ON LIMBIC SYSTEM OUTPUT TO THE MEDIODORSAL THALAMUS: DEPENDENCE ON AN INTACT PREFRONTAL CORTEX. A, Lavin* and A.A. Grace Depts. Neuroscience and Psychiatry, CNUP, Univ. Of Pittsburgh, Pittsburgh, PA, 15260.

Numerous studies into the pathophysiology of schizophrenia have pointed to the importance of the relationship between cortical and dopaminergic afferents to the n. accumbens in this disorder. However, comparatively little is known about how the n. accumbens ultimately affects the thalamocortical system via its projections to the output neurons in the ventral pallidum (VP). In this study, we examined the impact of classical and atypical antipsychotic drugs on the VP output to the thalamic mediodorsal nucleus (MD). Using in vivo intracellular recordings, we examined the effects of acute administration of the classical antipsychotic haloperidol (HAL) and the atypical antipsychotic drug clozapine (CLOZ) on VP and MD cell physiology. In intact rats, both HAL and CLOZ produced a decrease in the spontaneous firing rate of VP cells (62% and 92%) while producing a parallel increase in MD cell firing rate (by 145% and 59%, respectively). In rats that had received an ibotenic acid lesion of the prefrontal cortex (PFCtx) 1 month prior the recordings, MD cells exhibited a significantly higher spontaneous firing rate. However, the MD cells also showed a significantly smaller change in firing frequency in response to HAL The results of this study suggest that the ability of antipsychotic drugs to activate the VP-MD system depends on an intact prefrontal cortex Furthermore, given the hypofrontality reported to be present in schizophrenics, this may provide an explanation for the greater tolerance of these patients to the acute sedative actions of antipsychotic drugs. This work was funded by NIH grant # MH455156.

CHARACTERIZATION OF D3 DOPAMINE RECEPTOR FUNCTION IN D3 KNOCKOUT MICE. A. Carta, R. Rius*, S. Fuchs, D. Accili, and C.R. Gerfen. Lab of Neurophysiology, NIMH; Lab of Developmental Endocrinology Branch, NICHD, Bethesda, MD 20892; Weizmann Institute, Rehovot, ISRAEL.

The dopamine D3 receptor subtype, a member of the D2 class of dopamine receptor subtypes, has been implicated in "limbic" functions, largely on the basis of two lines of evidence. First, the D3 receptor displays a restricted expression in ventral forebrain structures, including "limbic" cortices, the lateral septum, ventral striatum and islands of Calleja. Second the D3 receptor displays a high affinity for "atypical" neuroleptics, D2 receptor antagonists with limited clinical motoric related side effects. Such circumstantial evidence is limited as there are many other receptors which share such anatomical distribution and pharmacologic profiles. To study the contribution of the D3 receptor to the effects of atypical neuroleptics, we have examined mice that lack a functional D3 dopamine receptor. The present study examined the induction patterns of immediate early genes in the forebrain of wild type and D3 deficient mice treated with the atypical neuroleptic clozapine using quantitative in situ hybridization localization of the mRNAs encoding c-fos and zif268. In the wild type mouse forebrain, clozapine treatment (15 and 30 mg/kg) results in immediate early gene induction in the cingulate and piriform cortex, lateral septal area, islands of Calleja and striatum. The pattern of induction in homozygote mice deficient in the D3 receptor was similar except for a reduction of clozapine-mediated immediate early gene induction in the striatum. These results suggest that These results suggest that although the pattern of immediate early gene induction by clozapine matches the distribution of the D3 dopamine receptor in many areas, in most areas, with the exception of the striatum, such induction is not attributable to blockade of this dopamine receptor subtype. (supported by NIMH)

AN ELECTRON MICROSCOPIC ANALYSIS OF NEOSTRIATAL DOPAMINE FIBERS. <u>J. Q. Ren* and H. Kita</u> Dept. Anatomy and Neurobiol, Coll. of Med., Univ. of Tennessee, Memphis, TN 38163.

An electron microscopic analysis of rat neostriatal tyrosine hydroxylase (TH) immunoreactive fibers was performed to reveal details of morphological features of dopaminergic fibers. TH-immunohistochemistry of the neostriatum revealed darkly stained patch areas and surrounding less darkly stained matrix areas. Blocks of tissues obtained from the patches and matrices areas were cut into thin serial sections and examined under the electron microscope and photographed. The morphological features of TH-immunoreactive fibers (TH-fibers) were analyzed with the aid of computers. The average diameters of the TH-fibers in the patch and matrix were 0.241 and 0.268 μm , respectively. The volume of the neuropil occupied by TH-fibers was 6.7 % in patches and 4.0 % in matrices. The average length of TH-fibers contained in an unit volume of the neuropil was estimated to be 0.94 and 0.42 $\mu m/\mu m^3$ in patch and matrix areas, respectively. Thirty two axons which were oriented roughly perpendicular to the plain of thin sections were selected and the synapses formed by these axons were counted. Each fiber formed synapses with both dendritic shafts and spines. The average number of synapses per unit length of TH-fibers was 0.5/ μm . This and the length of the fibers in the blocks gave the density of synapses to be 0.477 μm^3 in the patch and 0.21/ μm^3 in the matrix. Supported by NS-25783 and NS-26473.

EFFECTS OF DOPAMINE AGONISTS AND ANTAGONISTS ON OPTICAL RESPONSES RECORDED IN RAT FRONTAL CORTEX SLICES AFTER STIMULATION OF THE SUBCORTICAL WHITE MATTER. H. Kita*, K. Oda, M. Tanifuji, and K. Murase. Univ. Tennessee, Dept. Anat. and Neurobiol., Memphis, TN 38163 & Fukui Univ., Dept. Inf. Sci., Bunkyo, Fukui 910, Japan.

Effects of dopamine agonists and antagonists on the optical responses of the frontal cortex slices to stimulation of the subcortical white matter were examined using a voltage sensitive dye and a high speed image sensor. Repetitive white matter stimulation of the slices treated with bicuculline evoked optical responses propagating to the overlaying cortex. The responses often lasted for more than 400 msec Bath application of NMDA antagonists, CPP and APV, resulted in a large reduction in the optical responses. Bath application of D1 agonist, c-APB, consistently decreased the intensity of the early part (i.e., during repetitive stimulation) of the response but increased the intensity and the duration of the later part of the response. D1 antagonist, SCH 23390, also increased overall intensity and duration of the response. The effects of c-APB and SCH 23390 were additive. Bath application of D2 agonist, quinpirole, reduced the response Application of D2 agonist, eticlopride, did not cause significant change in the response but it effectively blocked the quinpirole effect. c-APB and quinpirole effects were difficult to reverse even when washing the slices for an extended period. However, the decrease of the response by quinpirole was restored or reversed by application of c-APB. Similarly, the increase of the response by c-APB was reversed by quinpirole. This study suggests that dopamine may modulate NMDA receptor mediated responses in the cortex through both D1 and D2 receptors. Supported by NIH, USA and MESC, Japan.

INTERACTIONS BETWEEN AMYGDALA AND PREFRONTAL CORTICAL AFFERENTS TO THE NUCLEUS ACCUMBENS AND THEIR MODULATION BY DOPAMINE RECEPTOR ACTIVATION

<u>H.Moore*, and A.A. Grace</u>, Depts. of Neuroscience and Psychiatry, Univ. of Pittsburgh, Pittsburgh PA 15260.

The basolateral amygdala (BLA), hippocampus and prefrontal cortex (PFC) provide excitatory inputs to the nucleus accumbens (NAC). Recently, O'Donnell & Grace (1995) demonstrated that the hippocampal input is necessary for the depolarized phase of the bistable membrane potential of NAC neurons. Moreover, it is only during this hippocampally-mediated depolarized state that PFC stimulation can evoke spikes in NAC cells. Given the strong input from the BLA to the NAC shell, we propose that the BLA inputs to the NAC might play a similar permissive role in PFC-NAC throughput. This was tested using extracellular single-unit recordings of NAC cells to characterize their responses to single- and paired-pulse stimulation of the PFC and to trains of stimuli in the BLA. We then tested whether a conditioning train of BLA stimuli would affect the probability of a PFC-evoked spike. Over 80% of the cells showed short-latency spikes in response to PFC stimulation but not to BLA stimulation, while a small proportion fired at longer latencies to stimulation of either site. In the PFC-responsive cells, a conditioning train of BLA stimuli, which in itself did not evoke spikes, increased the probability of a spike evoked by threshold-intensity PFC stimulation. Systemic administration of appomorphine, while decreasing the effectiveness of PFC stimulation in small set of these cells, more reliably decreased the BLA facilitation of PFC stimulation in the majority of cells. We conclude that the inputs from the BLA may shift a subset of NAC cells into a state in which they are more receptive to PFC inputs, and, furthermore, that BLA facilitation of PFC inputs is preferentially modulated by dopamine. Supported by USPHS MH45156 and an NRSA Fellowship to H.M.

BASAL GANGLIA: DOPAMINE

432.1

ACTIVATION OF D₂ DOPAMINE RECEPTORS REDUCES Ca²⁺ CURRENTS IN RAT NEOSTRIATAL CHOLINERGIC INTERNEURONS Zhen Yart, Wenlie Song and D. James Surmeier Dept. of Anatomy & Neurobiology, School of Medicine, University of Tennessee, Memphis, TN 38163.

The D₂ dopamine receptor mediated modulation of Ca²+ channels in neostriatal cholinergic interneurons was studied by combined whole-cell voltage-clamp recording and single cell RT-PCR. Cholinergic interneurons were identified by the presence of choline acetyltransferase mRNA. Of the 17 interneurons examined with RT-PCR, nearly all (~90%) co-expressed D₂ (short and long isoforms) and D_{1b} dopamine receptor mRNAs, whereas D_{1a} receptor mRNA was found in only a small subset (~20%) of the sample. $D_2\text{-class agonists reversibly reduced N-type Ca²+ currents, whereas D₁-$

 D_2 -class agonists reversibly reduced N-type Ca²⁺ currents, whereas D_1 -class agonists had little or no effect on these currents. This reduction was blocked by the D_2 antagonist sulpiride. The D_2 modulation was almost eliminated by application of N-ethylmaleimide at concentrations previously shown to selectively inactivate $G_{1/o}$ -class G proteins or by dialysis of $GDP\betaS$. The D_2 modulation had rapid onset kinetics and was unaffected by application of cAMP analogs. Furthermore, the modulation was not attenuated by strong, depolarizing pre-pulses.

depolarizing pre-pulses. Although the modulations produced by D₂ dopamine receptors and M2 muscarinic receptors were occlusive, activation of protein kinase C disrupted muscarinic modulation of Ca²+ currents, but not the dopaminergic modulation. Taken together, our results suggest that activation of D₂ dopamine receptors in cholinergic interneurons reduces N-type Ca²+ currents through a G_{1/o} class G-protein. Although M2 and D₂ signaling pathways both utilize G_{1/o} proteins that target N-type Ca²+ channels, the D₂ pathway appears to rely upon elements that are not regulated by protein kinase C. This work was supported by USPHS grants NS 26473 and NS 34696.

PRESYNAPTIC DOPAMINE MODULATION OF GABA-MEDIATED INTRASTRIATALLY EVOKED DEPOLARIZING POSTSYNAPTIC POTENTIALS A. Delgado, A. Sierra, R. Valdiosera and J. Aceves * Department of Physiology. CINVESTAV-IPN. 07300 México, D.F., México.

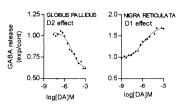

To study the role of dopamine in intrastriatal synaptic transmission, we used intracellular recording techniques in rat brain slices. Here we examined the role of D2 receptors. The experiments were done in the presence of CNQX and AP5 to eliminate the glutamatergic component of the evoked postsynaptic potential. In 30% of the recorded (n=33) neurons, dopamine (100 nM) reversibly depressed (by 60%) electrically evoked, picrotoxin-sensitive postsynaptic potentials, without changing the electrical properties of the impaled neurons. The effect was 1) antagonized by sulpiride (100 nM), 2) mimicked by quinpirole (20 nM), and 3) dose-dependent (see figure below). The IC50 was 13 nM. These results indicate the presence of presynaptic D2 receptors modulating GABA-mediated transmission within the striatum. It remains to be determined the location of the receptors, whether on collaterals of neighboring spiny projection neurons or on local circuit cells.

DIFFERENTIAL MODULATION OF GABA RELEASE BY D2 AND D1 RECEPTORS IN THE BASAL GANGLIA OF THE RAT. B. Floran., F. Paz-Bermudez, A. Sierra., J. Hernandez*., and J. Aceves. Department of Physiology, Biophysics and Neurosciences. CINVESTAV-IPN. 07300 México, D.F.

GABA projection neurons appear to have preferentially either D1 or D2 receptors Here, we have explored whether the same segregation exists on their nerve endings at the target nuclei.

The effect of DA or its agonists (quinpirole or SKF 38393) on [3H] GABA release was studied in K+-depolarized slices globus pallidus from (Gnall) caudate-putamen (CP), substantia nigra pars reticulata (SNr) entopeduncular nucleus (EPN). D2 effects were

studied blocking D1 receptors with SCH 23390 and D1 effects blocking D2 receptors with I-sulpiride. Quinpirole and dopamine inhibited GABA release in Gpall and CP, but had no effect in SNr and EPN. SKF and dopamine markedly increase the release in SNr, EPN, CP and only slighly in Gpall. Dose-response relationship (see fig.) showed similar values (1.3-4.6 μM) beetwen the EC₅₀'s for D1 receptors in all the studied nuclei, but for D-2 receptors IC50 was three orders of magnitude higher in Gpall than in CP (Gpall= 8.14 µM; CP=28.8 nM).

These observations suggest a differential modulation of GABA release by D1 and D2 receptors, and a differential location on striatal projections. They also suggest heterogenities beetwen D2 receptors.

432.5

CORRELATION OF ELECTROPHYSIOLOGICAL AND BEHAVIORAL OUTPUT OF THE RAT BASAL GANGLIA AFTER INTRASTRIATAL INFUSION OF DOPAMINE (DA) AGONISTS. L.P. Martin*, D. Ozsirin, A. Zelenchuk, J.R. Stellar and B.L. Waszczak. Depts. of Pharmaceutical Sciences and Psychology, Northeastern University, Boston, MA 02115.

Current basal ganglia functional models predict that DA acts on striatal efferents to inhibit output from the substantia nigra pars reticulata and internal pallidal segment (SNr/GPi). This inhibition should, in turn, disinhibit the thalamus to facilitate movement. We are testing this model in intact (unlesioned) rats by attempting to correlate changes in single unit activity of SNr neurons with motor (i.e. behavioral) effects observed in the 20-30 min after striatal infusions of DA agonists given at identical doses, infusion volumes and stereotaxic coordinates. For behavioral studies, we have fabricated a remote, computer-operated infusion pump which allows automatic infusion of drugs through a previously-implanted striatal cannula, avoiding behavioral activation due to handling. Rats are filmed to allow later assessment of stereotypies and circling behavior, and photobeam-breaks give an index of locomotor activity. In parallel SNr recording studies, rats are acutely implanted with striatal cannulae, and SNr cell firing is monitored before and 20-30 min after infusions. While preliminary, results are contrary to predictions of the model in that large (1 µl) unilateral infusions of d-amphetamine (AMPH) into the rostral dorsomedial striatum elicit only sporadic and modest changes in basal ganglia output in either assay. For instance, in anesthetized rats both 1 and 20 µg AMPH infusions (n=4-5 each) caused a few brief (<1 to 3 min) inhibitions (<20% of baseline) as well as some brief to sustained (>5 min) increases in firing (>20% of baseline) in about half of SNr cells tested. The remainder showed no changes. Anesthesia appeared not to be a factor since similar, minor fluctuations were seen in awake, locally-anesthetized rats. Future studies will attempt to elicit (and correlate) behavioral and electrophysiological output using other DA agonists, striatal injection sites, and bilateral infusions. (Support by NS 23541)

432.7

THE D_2 AGONIST QUINPIROLE ATTENUATES STRIATAL c-fos expression induced by serotonergic, opiate and muscarinic

EXPRESSION INDUCED BY SEROTONERGIC, OPIATE AND MUSCARINIC AGONISTS. D.F.Cook* & D.Wirtshafter. Dept. Psychology, University of Illinois at Chicago, IL 60607-7143.

Pretreatment with the dopamine D2 agonist quinpirole has been shown to markedly potentiate striatal fos-like immunoreactivity (FLI) induced by the administration of D1 agonists. Additionally, it has been demonstrated that FLI is elicited following injections of several serotonin (5-HT) agonists with different profiles of receptor subtype selectivity. In order to investigate whether D2 activation would potentiate 5-HT agonist-induced striatal FLI, the current study examined quinpirole pretreatment on FLI induced by several 5-HT agonists. The systemic administration of fenfluramine, TEMPP, RU-24969 and D01 produced significant increases in striatal FLI which were significantly reduced by quinpirole pretreatment; these

produced significant increases in striatal FLI which were significantly reduced by quinpirole pretreatment; these results are in contrast to the potentiation observed when quinpirole is combined with DI agonists.

Furthermore, quinpirole pretreatment significantly reduced striatal FLI induced by the muscarinic agonist pilocarpine and the opiate agonist morphine. Collectively, these data suggest that FLI induced in this region by 5-HT, pilocarpine and morphine may be mediated through a dopaminergic mechanism. One interpretation of these results would suggest that quinpirole activates D2through a dopaminergic mechanism. One interpretation or these results would suggest that quinpirole activates D2-like autoreceptors which reduce striatal dopamine release that is necessary for 5-HT, opiate and muscarinic induction of FII. DOPAMINE EXCITES RAT NEOSTRIATAL LARGE ASPINY NEURONS IN VITRO. Toshihiko Aosaki* and Yasuo Kawaguchi Lab. Neural Circuits, Inst. Phys. & Chem. Res. (RIKEN), Nagoya, Aichi 456, Japan.

Accumulating evidence suggests that dopamine (DA) inhibits release of

acetylcholine (ACh) from cholinergic large aspiny neurons of the neostriatum via activation of D2 DA receptor. In order to test this ACh-DA balance hypothesis directly, we made whole-cell patch clamp recordings from identified large aspiny neurons in a brain slice preparation to study the actions of dopaminergic agents on them. Unexpectedly, bath-applied DA (1-100 μM) evoked either depolarization or an inward current in 13 out of 21 cells tested. The remaining cells showed no response (7/21) or an outward current (1/21). Quinpirole (1-10 μM), D2-like DA receptor agonist, evoked an inward current in 7 cells, an outward current in 3 cells and no responses in 6 cells out of 16 cells tested. SKF 38393 (1-10 μ M), D1-like DA receptor agonist, evoked an inward current in 8, an outward current in 1 and no response in 5 out of 14 cells examined. The excitatory effect of DA was mostly accompanied by a decrease in input resistance. These results suggest that the neostriatal large aspiny neurons are quite heterogeneous in terms of dopamine actions and that, contrary to the hypothesis, DA excites rather than inhibits them. We suspect that, although there are no immunohistochemial studies on D3 receptor distribution in the neurons so far, the observed inward current by quinpirole might be due to activation of D3 DA receptors, because D2 receptor is reported to be coupled to K-channels, D4 receptor mRNA expression is very low in the dorsal neostriatum and quinpirole cannnot differentiate D2 from D3 receptors. The observed actions of SKF 38393 might contain a component of D5 DA receptor activation, because, although in situ hybridization study (Le Moine et al., 1991) showed that 30% of the neurons contained D1 receptor mRNA, recent immunohistochemical study (Bergson et al. 1995) showed a mismatch that the neurons were labeled only by D5 receptor antibodies, not by D1. Supported by Frontier Research Program.

DOPAMINE MODULATES MEMBRANE EXCITABILITY OF STRIATAL POTAMINE MODULAIES MEMBRANE EXCITABILITY OF STRINT AB SPINY NEURONS VIA DARPP-32 SIGNAL TRANSDUCTION PATHWAY S-P. Onn', A.A. Fienberg', V.A. Pieribone', P. Greengard', and A.A.Grace' Depts of Neurosci. and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260' & Lab. Molec. & Cell. Neurosci. Rockefeller University, New York, NY 100212

DARPP-32, dopamine- and cAMP-regulated phosphoprotein, is anatomically associated with striatal neurons that contain D1 receptors. However, the role of DARPP-32 in mediating DA actions on striatal neurons is not clear. In this study, we examined the effects of D1 and D2 agonists on the membrane physiology of identified striatal neurons recorded in slices obtained from wildtype vs DARPP-32-knockout mice. Bath application of SKF 38393 (5-10 uM) alone resulted in a 193% increase in the amplitude of current injection required to trigger spiking in spiny neurons. In contrast, SKF38393 failed to cause this reduction in the excitability of spiny neurons recorded from mutant mouse brain slices. Furthermore, subsequent bath application of D2 agonists quinpirole (5-10 uM) to D1-treated slices resulted in a membrane depolarization and a decrease in threshold currents to nearly the pre-drug (i.e., before D1) level in identified spiny neurons recorded from striatal slices from wildtype but not knockout mice. This net excitation in wildtype mice was opposite to the inhibitory actions typically observed when D1 and D2 agonists were co-applied. Thus, the temporal sequence of D1 and D2 agoinsts when the co-applied for determining the net effect on cell excitability. Such an interaction is not present in mouse striatal neurons in which DARPP-32 signal transduction has been disrupted. Support by USPHS MH45156, MH42217 and MH40899(to P.G.) and APDA (to A.A.F.)

BLOCKADE OF DOPAMINE RECEPTORS AMPLIFIES CORTICAL ACTIVATION ON INDUCTION OF IMMEDIATE-EARLY GENES IN THE STRIATUM. S. Berretta*, Z. Sachs and A. M. Graybiel. M.I.T. Dept. of Brain and Cognitive Sciences, Cambridge, MA 02139

Dopamine is thought to induce long-term changes in the efficacy

corticostriatal linkages. Dopamine D2-class receptor antagonists have been found to enhance the excitatory effects of cortical fibers on striatal neurons (Brown and Arbuthnott, 1983) and to reverse the decrease in excitability induced by amphetamine (Garcia-Munoz et al., 1991). To test whether D2-blockade amplifies contically-induced immediate-early gene (IEG) expression in the striatum, we combined, in awake freely-moving rats, stimulation of the prefrontal cortex by epidural local application of low concentrations (0.03 mM) of the GABA-A antagonist picrotoxin (Berretta et al. 1994) with low doses of haloperidol (0.05 amagonist pictotali (berrea et al., 1994) with own doses of maniperiod (0.03 mg/kg; i.p.), primarily a D2-class antagonist at the chosen dose (Sumiyoshi et al., 1994). We monitored striatal Fos- and JunB-like IEG proteins by immunohistochemistry; positive nuclei were counted with a quantitative computer-assisted method. At the doses chosen, neither haloperidol nor picrotoxin induced more than slight IEG expression in the striatum (haloperidol: n=6. Fos 2.7 ± 3.0 nuclei/striatal section, JunB 12.0 ± 21.4; picrotoxin: n=6, Fos = 0.3 ± 0.8; JunB 9.1 ±15.7). Co-administration of the subthreshold doses of picrotoxin and haloperidol produced a strong synergistic effect (n=9; Fos= 68.1 ± 79.6 SD; one-way ANOVA; p=0.0002; JunB= 133.5 ± 160.2, one-way ANOVA; p=0.005). Fos and JunB were induced in a distribution pattern similar to that induced by higher doses (0.3 mM) of picrotoxin alone. These results suggest that cellular activation and protein regulation in postsynaptic neurons induced by corticostriatal fibers is reduced by D2-class dopamine receptor activation. Our results also suggest one possible mechanism of action for antipsychotic drugs: they could correct the hypofrontality found in schizophrenia by amplifying corticostriatal signals, possibly through increased release of glutamate. Funded by the Stanley Foundation and NIH Javits Award R01 NS25529

DOPAMINE RECEPTOR AGONISTS REGULATE LEVELS OF THE SEROTONIN 5-HT₂ A RECEPTOR AND ITS mRNA IN A SUBPOPULATION OF RAT STRIATAL NEURONS. <u>I.-J. Soghomonian¹*</u>, <u>F. Radja² T. Reader² and N. Laprade¹, ¹Centre de Recherche en Neurobiologie, Fac. Med., Univ. Laval, Quebec (QC.) G1K 7P41 and ²Department of Physiology, Univ. of Montreal, CP6128, Succ.A, Montreal (QC.).</u>

The effects of dopamine receptor agonists on the levels of the striatal serotonin 5-HT_{2A} receptor and its mRNA were investigated in rats lesioned with 6-hydroxydopamine (6-OHDA) as neonates. The mRNA encoding for the 5-HT_{2A} receptor was detected by *in situ* hybridization histochemistry and the binding to 5-HT_{2A} receptors was revealed with [125I]DOI. In adult control unlesioned rats, labeling with the 5-HT_{2A} cRNA probe and with [125I]DOI was concentrated in medial sectors of the striatum. In 6-OHDA-lesioned rats, labeling with the 5-HT_{2A} cRNA probe or with [125I]DOI was increased in the striatum, particularly in its lateral subdivisions. These increases were abolished after chronic systemic administration of the dopamine receptor agonists apomorphine or SKF-38393. The mRNA levels encoding for the 5-HT_{2A} receptor were further measured in individual striatal neurons after double-labeling of sections with a 5-HT_{2A} and a preproenkephalin (PPE) cRNA probe. In control unlesioned rats, 5-HT_{2A} mRNA labeling was found only in PPE-unlabeled neurons and it was abolished following apomorphine or SKF-38393 administration. These results demonstrate that agonists of dopamine receptors inhibit the expression of 5-HT_{2A} receptors in a subpopulation of presumed striaton-ingral neurons. We propose that this regulation plays an important role in the control of motor activity by dopamine and serotonin in the basal ganglia. (Supported by the Parkinson Foundation of Canada, NSERC-0155607, FRSQ and CRM).

432.11

GAD67 and GAD65 mRNA levels are regulated in different striatal neurons following neonatal 6-hydroxydopamine (6-OHDA) lesions and treatment with dopamine receptor agonists. N. Laprade * and J.-J. Soghomonian. Centre de Recherche en Neurobiologie, Hôpital de l'Enfant-Jésus, Québec, Qué., Canada, G1J 1Z4.

We analyzed the levels of mRNAs encoding for the two isoforms of glutamate decarboxylase (GAD65 and GAD67) in striatal neuronal subpopulations following neonatal dopamine depletions with 6-OHDA and treatment with dopamine receptor agonists. mRNA levels encoding for the GAD65 or the GAD67 isoforms were measured in distinct subpopulations of striatal neurons after double *in situ* hybridization histochemistry using ³⁵S-labeled GAD65 or GAD67 and digoxigenin-labeled PPE cRNA probes (to identify striatopallidal neurons). Following neonatal 6-OHDA lesion, adult rats exhibited increased GAD65 mRNA levels in striatonigral and increased GAD67 mRNA levels in striatopallidal neurons. Chronic treatment with the dopamine D1 receptor agonist SKF-38393 increased GAD65 and GAD67 mRNA levels in striatonigral neurons only. The D1 dopamine receptor antagonist SCH-23390 reversed the effect of SKF-38393 on GAD65 mRNA levels but only partially reversed the increase in GAD67 mRNA levels. Chronic treatment with apomorphine increased GAD67 mRNA levels in striatonigral neurons only. These results confirm that the mRNAs encoding for the two GAD isoforms are differentially regulated in striatial neuronal subpopulations. In addition, the data suggest that the regulation of the two GADs isoforms in GABAergic striatonigral neurons is dependent on their pattern of activation (Supported by the Parkinson Foundation of Canada and NSERC 0155607).

432.10

EXPRESSION OF C-FOS mRNA IN STRIATUM OF RATS DEPLETED OF DOPAMINE AS NEONATES. M.J. Sandstrom^{2*}. J.P. Bruno² and J.-J. Soghomonian¹. ¹Centre de Recherche en Neurobiologie, Fac. Med., Univ. Laval, Quebec (QC.) G1K 7P4 and ²Neuroscience program, Ohio State University. Colombus. OH. 43210.

Lavai, Quebec (QC.) Off. 43210.

Rats depleted of striatal DA as neonates (PD3) are spared the gross ensorimotor deficits seen in comparably depleted adults. Stimulation of DI or D2 receptors is sufficient for sensorimotor behavior in adults depleted of DA as neonates whereas co-activation of DI and D2 receptors is necessary for intact rats or those depleted of DA as adults. We now report the effects of DI-receptor stimulation on c-fos mRNA levels in striatal neurons of adult unlesioned rats and rats lesioned with 6-OHDA as neonates. A [3*S]-labeled c-fos cRNA probe was detected at regional and cellular level after in situ hybridization histochemistry. Following acute administration of the agonist SKF-38393 (12.5mg/kg; i.p.), a potent increase in c-fos mRNA levels was observed in lesioned but not in unlesioned rats. By comparison, the mRNA levels encoding for the two GAD isoforms (GAD65 and GAD67) were also higher in lesioned rats injected with SKF-38393 but this difference was attributed to the lesion alone rather than the SKF-38393 challenge. On emulsion radioautographs, c-fos mRNA was distributed in neurons throughout the striatal surface of lesioned rats. Quantification at the cellular level in a dorso-lateral sector demonstrated that c-fos mRNA was expressed by an average of 79% of all striatal neurons such as visualized with an eosin-hematoxylin stain. These results suggest that in rats depleted of DA as neonates SKF-38393 induces c-fos in a majority of striatal projection neurons including the striatonigral and -pallidal neurons. Double-labeling studies are currently underway to demonstrate the phenotype of striatal neurons showing c-fos induction. We also anticipate comparing these results with those seen in animals depleted of DA as adults (Supported by the Parkinson Foundation of Canada, NSERC-0155607 (JIS) and the Whitehall Foundation (JB)).

CEREBELLUM: PHYSIOLOGY, MODELS

433.1

CEREBELLUM INVOLVEMENT IN TIMING OF MOTOR RESPONSES M.A. Weiler*, D. Storzbach, W. Spaulding, J. Sunderland, Maryland Psychiatric Research Center, University of Maryland School of Medicine, Baltimore, MD 21228.

We sought to determine brain areas involved in timed motor responses, hypothesizing frontal lobe involvement in prediction of regular intervals. We studied eleven right handed normal males using positron emission tomography and O¹⁵ labeled water to measure blood flow during performance of a simple reaction time task. Subjects were scanned during a finger-lift task during a baseline slow finger-lift and two conditions of rapid finger-lift; one with regular prepatory intervals and another with irregular prepatory intervals, all presented visually by a computer and repeated three times. Scan data was realigned, normalized, smoothed and analyzed using Statistical Parametric Mapping (SPM) software. Contrary to our hypothesis the cerebellum showed increases compared to the baseline and strong negative correlations to reaction time performance. There was also some indication of increases compared to the irregular interval condition. Frontal activation was more pronounced in the baseline and irregular condition. These results support cerebellar involvement in timing and "motor-set." Support: NIMH R03MH49433.

433.2

EVIDENCE FOR DENTATE NUCLEAR INVOLVEMENT IN MOTOR PREPARATION. M.S. Milak*, V. Bracha, J.R. Bloedel. Barrow Neurological Institute, Phoenix, Arizona 85013.

The purpose of this investigation is to study the role of the dentate nucleus in

The purpose of this investigation is to study the role of the dentate nucleus in the planning and execution of goal-directed movements. In this experiment an instructed delay paradigm was employed to determine whether this nucleus was essential for retaining information regarding target location for a specified period before the movement was initiated. Specifically, the cats were trained to stabilize their posture, watch for a light indicating the position of one of two targets, retain the information regarding the location of the target for 1 - 1.5 sec after the target light was tumed off, and respond to a go signal by reaching for and contacting the correct target ("Light-off" task). If the correct target were contacted, a food reward was provided. To evaluate the animals' performance in this task, the number of correct responses in the "Light-off" paradigm was contrasted with the same measurement in a paradigm in which the light indicating the correct target remained on throughout the trial ("Light-on" task). Cats with chronically implanted guide tubes over the cerebellar nuclei were tested using both paradigms in the same session before and after the temporary inactivation (800ng muscimol/1µl saline) of the dentate nucleus ipsilateral to the performing limb. We found that the animals' performance on the "Light-off" task fell to chance level during inactivation, whereas the performance on the "Light-on" task did not change significantly. In addition, there was a significant increase in the number of spontaneous responses in both tasks after the muscimol injection. These data suggest that the capacity to remember the location of the target for a brief period and/or to incorporate the specified target into the motor plan is impaired when the dentate is inactivated. The findings support the general view that this nucleus plays a role in the processing related to motor preparation. Supported by NIH grants NS30013 and NS21958.

DYNAMICS OF SACCADE BURST NEURONS IN THE BASAL INTERSTITIAL NUCLEUS IN THE MONKEY CEREBELLUM.

R. Kawagoe, Y. Takikawa, N. Miyashita*, and O. Hikosaka.

Dept. of Physiology, Juntendo Univ. Sch. of Med., Tokyo 113, Japan.

In order to study the saccade controlling mechanism of the cerebellum, we recorded saccade-related neurons in the dentate nucleus and peri-dentate regions in a monkey. A half of these neurons (32/69) exhibited omni-directional burst activities preceding the onset of the saccade. They were located in the area just ventral to the dentate nucleus, which corresponded to the region reported by Langer (1985) as the basal interstitial nucleus. A prominent feature of these neurons was the relationship of the duration of their burst activities and the duration of saccades. Thus, the burst onset and the burst peak preceded the saccade onset by 16.3±0.4 ms and 7.6±1.0 ms respectively, while the burst end preceded the saccade end by 32.5±1.8 ms (in visually guided saccades). These time relationships were kept nearly constant for different saccade amplitudes, directions, and different types of saccade (i.e. visually guided, memory-guided, and spontaneous saccade). Consequently, the burst duration was linearly related to the saccade duration regardless of different dynamics of saccade. These results suggest that neurons in the basal interstitial nucleus may carry the information to determine the saccade duration.

433.5

HEAD MOVEMENT CONTROL DEMONSTRATED IN THE C2 ZONE OF THE FLOCCULUS. C.I. De Zeeuw*, S.K.E. Koekkoek, M. Arts. J. V.D. Burg, and J. Voogd. Department of Anatomy, Erasmus University Rotterdam, The Netherlands.

The rabbit flocculus consists of five zones (1,2,3,4, and C2). Microstimulation in zones 1 to 4 can evoke short latency eye movements that rotate predominantly about the vertical axis or a horizontal axis perpendicular to the ipsilateral anterior semicircular canal (135° axis). In the present study, we investigated what type of movements can be evoked by stimulation in zone C2. Dutch Belted rabbits were prepared for electrical stimulation in the flocculus, and search coils were implanted on their head pedestal and left eye. The stimulation sites were marked by lesions and evaluated in acetylcholinesterase stained sections. In all animals in which the C2 zone of the flocculus was stimulated, short latency head movements could be evoked. The largest response component of these movements was usually a clockwise rotation about the ipsilateral 135° axis in the horizontal plane, but rotations into other directions and other movements, such as translations, also occurred. The amplitude varied from 0.5 to 7 degrees and the peak speed occurred 30-80 msec after movement onset and reached a maximum value of 54 deg/sec. The latencies varied from 15 to 60 msec; the average latency of the five stimulations with the shortest latencies was 19 msec. The smallest threshold was 4 µA (average 16 µA). In some cases the stimulations in zone C2 evoked simultaneous head and eye movements. The largest response component of the eye movements was usually also a rotation about the ipsilateral 135° axis, but in the opposite, i.e. counter clockwise, direction. When we stimulated zone 3 for control, we were unable to evoke short latency head movements. The present study is the first to show that the C2 zone is involved in head movements. The observation that electrical stimulation in zone C2 cannot only produce a head movement, but also a concomitant eye movement in the opposite direction, raises the possibility that the C2 zone is involved in the control of gaze stabilization during head movements.

SIMPLE-SPIKE ACTIVITY OF FLOCCULAR PURKINJE CELLS RESPONDING TO VERTICAL PURSUIT AND PITCH ROTATION IN ALERT MONKEYS. K. Fukushima*, J. Fukushima, H. Tsunekawa and C.R.S. Kaneko. Dept. of Physiol., Hokkaido Univ. Sch. Med., Sapporo, 060 Japan and Dep. of Physiol. & Biophysics Regional Primate Res. Ctr., Univ. of Washington, Seattle, WA 98195 Recently, we suggested that the vertical vestibulo-ocular reflex (VOP) nearly integration cast requires a transflocutory in bilitima.

Recently, we suggested that the vertical vestibulo-ocular reflex (VOR) neural integrator in cats requires a transfloccular inhibitory pathway (i.e., contralateral posterior canal inputs that inhibit anterior canal related VOR interneurons; Fukushima & Kaneko, 1995). To test this scheme in primates, we recorded simple-spike activity of Purkinje (P) cells in the flocculus and ventral paraflocculus of Japanese macaques that were trained to track a smoothly moving spot during whole-body rotation. The preferred direction of the majority of vertical pursuit P cells was downward. Down pursuit P cells were excited by up pitch, whereas up pursuit P cells respond to down pitch during fixation of an earth-staionary spot. About half of the related P cells showed phase reversal during VOR suppression compared to their responses during VOR enhancement, similar to the behavior of GVP cells. The remaining half were different; their response amplitudes decreased during VOR suppression and increased during VOR enhancement while their phase response was consistent in the 3 conditions (i.e., within 90°) suggesting that they receive eye velocity-related responses. Response phase of some of these cells reversed during vertical rotation in the roll plane, consistent with responses induced by vertical canal inputs. We are now analyzing these discharge properties quantitatively. Supported in parts by JMESC grants (07680886, 07252201, 07671043), Marna Cosmetics, and PHS grants EY06558 (NEI) and RR00166(NIH).

NONINVASIVE DETECTION OF HUMAN CEREBELLAR ACTIVITY ASSOCIATED WITH VISUALLY-GUIDED SACCADES. V. Jousmäki*, M. Hämäläinen, and R. Hari. Brain Research Unit, Low Temperature Laboratory, Helsinki University of Technology, FIN-02150 Espoo, Finland.

Visually-guided saccades, necessitating precise control of eye movements, are known to involve cerebellar activation. We recorded magnetoencephalographic (MEG) signals associated with visually-guided horizontal saccades (extent 21°) from 8 healthy adults. MEG signals, averaged on the basis of horizontal electro-

oculogram, showed prominent eye-ball generated deflections close to the orbits, coinciding with the electro-oculogram, and posterior signals peaking 145–195 ms after the saccade onset. Source modelling suggested temporally overlapping activation (i) in the posterior parietal cortex close to midline and (ii) in the cerebellum. Decrease of illumination delayed the peak activation in both areas by 15–20 ms and dampened the parietal source more than the cerebellar one (62% vs. 35%, respectively). Our results show, for the first time, that signals from the human cerebellum can be recorded noninvasively by means of MEG. The observed cerebellar signals, following the saccades, may reflect reafferent input. Supported by the Academy of Finland and by the EC's HCM Programme through Large-Scale Facility BIRCH at LTL, HUT.

SIMPLE SPIKE ACTIVITY MODULATED BY VESTIBULARLY-EVOKED CLIMBING FIBER RESPONSES IN THE RABBIT CEREBELLAR NODULUS. H. Fushiki*i-and N. H. Barmack'. ¹R. S. Dow Neurol. Sciences Inst., Portland, OR 07209. ²Dept. of Ordang. Toward Med. & Pharm. Link. Toward 970.01. Jana

P7209, *Dept. of Otolaryae, *Toyama Med. & Pharm. Univ., Toyama 930-01, Japan. In the rabbit uvula-nodulus, vestibular information is mapped onto parasagittal zones by climbing fibers (CFs). Vestibular stimulation in the plane of the ipsilateral posterior and contralateral anterior semicircular canals modulates climbing fiber responses (CFRs) in a zone restricted to the most medial 1.5 mm. Lateral to this zone lies a zone of Purkinje cells whose CFRs are modulated optimally by vestibular stimulation in the plane of the ipsilateral anterior and contralateral posterior semicircular canals. Inserted between these two semicircular canal-related CF zones is a zone of Purkinje cells whose CFRs are excited by posterior-anterior optokinetic stimulation of the ipsilateral eye. Within each of these zones, simple spikes (SSs) are modulated reciprocally with CFRs. In rabbits anesthetized with chloralose-urethan, we have used vestibular stimulation to evoke CFRs within particular zones and we have determined the effect of these evoked CFRs on SSs within the same and adjacent zones. CFRs and SSs were recorded during roll vestibular stimulation in the CF "optimal plane" and "null plane".

In all Purkinje cells, SSs were modulated reciprocally during rotation in the CF "optimal plane". In approximately 30% of the recorded cells, the modulation of SSs led the modulation of CFRs from the same Purkinje cell. The modulation of SSs was always reduced during rotation in the CF "null plane". We conclude that: 1) The influence of CFRs in one CF zone within the uvula-nodulus is restricted to SSs within the same zone, and 2) Modulation of a CFR is not necessary for modulation of the SS in the same Purkinje cell. Rather, this reciprocal modulation might be attributed to CF-driven Golgi cells whose axons are distributed orthogonally with respect to the sagittal CF zones. 3) The vestibular and optokinetic CF zones in the nodulus provide a map of visual-vestibular space that may be used to regulate movement. Supported by NEI EVO4778.

RESPONSES OF SQUIRREL MONKEY VERTICAL ZONE FLOCCULUS PURKINJE CELLS DURING ADAPTATION OF THE VESTIBULO OCULAR REFLEX. R. Arikan and S. M. Highstein*. Dept. of Otolaryngology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Dept. of Otolaryngology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Vertical zone floccular Purkinje cells (P-cells) are hypothesized to have a role both in the control and adaptation of the vertical vestibulo coular reflex (vVOR). P-cells were recorded in four alert naive and vVOR adapted squirrel monkeys using standard techniques during VOR in the light (VOR), dark (VORd), visual following, enhanced and suppressed VOR (VORe and VORs) at 0.5 Hz. VOR gains in naive monkeys averaged 0.9, and P-cells were modulated when the eyes moved down. 25% were modulated during gaze velocity, and 75% during eye velocity only. Mean naive head velocity sensitivity of gaze velocity cells was 0.76 sp/deg/sec with mean phase lag of 30 deg. Of 8 gaze velocity cells recorded from high gain animals (mean gain 1.1) mean head velocity sensitivity decreased to 0.69 sp/deg/sec with mean phase lag of 76 deg. Of 12 cells recorded from low gain animals (mean gain 0.7) mean head velocity sensitivity increased to 1.20 sp/deg/sec with mean phase lag of 4 deg. While gaze velocity P-cells did not modulate during VORd in naive animals, when the gain was high, cells responded in phase with head velocity with a phase lag of 180 deg; when VOR gain was low, cells responded out of phase with head velocity sensitivity and phase lag of 0 deg on the average. These findings demonstrate that head velocity sensitivity and phase relationships of P-cells change during adaptation of the VOR and support the hypothesis that these cells play a role in adaptation or motor learning of the vVOR. Supported by NIH grant EY 05433.

EFFECTS OF NUCLEUS PREPOSITUS HYPOGLOSSI LESIONS ON THE VISUAL CLIMBING FIBER ACTIVITY IN THE RABBIT'S FLOCCULUS M. P. Arts, C. I. De Zeeuw and J. I. Simpson*, Dept. Physiology and Neuroscience, NYU School of Medicine, New York, NY 10016. Like other parts of the inferior olive, the caudal dorsal cap, which is the

ource of the visually modulated vertical axis climbing fibers of the flocculus, has one predominant excitatory input and one predominant inhibitory input. The excitatory input comes from the ipsilateral nucleus of the optic tract and the dorsal terminal nucleus. The inhibitory (GABAergic) input comes from the contralateral nucleus prepositus hypoglossi (NPH) (De Zeeuw et al. 1993, 1994; Barmack et al. 1993). Little is known about the function of the NPH input. In an attempt to change this situation, the NPH was aspirated unilaterally in 9 rabbits (anesthetized with ketamine, xylazine and acepromazine) to determine if the spontaneous complex spike activity of Purkinje cells in the ipsilateral flocculus changed and/or if the depth of modulation to visual stimulation changed. Spontaneous activity was recorded in the dark. Visual stimulation consisted of 15 cycles of wholefield movement for 5 sec each in the excitatory and inhibitory directions. Prior to lesion, the average spontaneous activity in the dark was 1.08±.31 spikes/sec (mean±s.d.; n=19). After lesioning from 60% to more than 95% of the part of the NPH that projects to the contralateral dorsal cap, the spontaneous activity was not significantly different (1.16±.35 spikes/sec, n=20; t-test). Modulation depth was characterized by the ratio of the firing rates during excitation and inhibition. This ratio was not significantly different after lesioning (median 6.98 before, n=32; 8.10 after, n=27; Mann-Whitney test). The absence of a change in either the spontaneous activity or the modulation depth is puzzling. A next step is to block the GABAergic input directly in the dorsal cap by microinjection of picrotoxin. (NS-13742).

NON-CLOCK-LIKE DISCHARGE OF CELLS IN THE DEEP CEREBELLAR NUCLEI OF THE AWAKE BEHAVING MONKEY . J.G. Keating* and W.T. Thach. Dept. of Anatomy, Washington Univ. Sch. Med. St Louis, MO 63110

We have recorded from deep nuclear cells in two Rhesus monkeys during the performance of a targeted wrist flexion/extension task.

Previously we showed that no oscillatory discharge can be found in complex spike recordings from Purkinje cells when monkeys performed non-cyclic wrist movements (Keating and Thach, J Neurophys 73 (4) 1329-40, 1995). There we questioned the physiological relevance of quasi-periodic inferior olive discharge seen in reduced and drugged preparations. Using the same analysis method we have examined deep nuclear cell discharge for periodicity (frequencies up to 100Hz). Interspike intervals for all spikes recorded for a unit were placed in 1ms 100Hz). Interspike intervals for all spikes recorded for a unit were placed in Ims bins. Autocorrelation analysis was done. The autocorrelograms were then Fourier transformed to reveal the spectral frequency of the units discharge. Periodicity was seen in the 2Hz range for some of the 89 units analyzed. No periodicity was found near 10Hz. To determine the nature of the peri-2Hz periodicity, we examined cell discharge during the "move" phase of the task, and during the "hold" phase of the task. The peri-2Hz signal was prominent during the move phase, and less so during the "move" phase. In addition, spectral analysis of wrist position during the "move" phase revealed a prominent component also at 2Hz. As was seen for complex spikes, units with large numbers of spikes gave flatter more even histograms than those with fewer, arguing against the existence of any underlying periodic tendency.

the existence of any underlying periodic tendency.

The failure to observe clock-like timing in awake behaving animals, in either complex spike or deep nuclear cell discharge argues against the inferior olive acting as a "motor clock". (supported by NIH grant NS12777)

CEREBELLAR UNITS WITH SIMPLE AND COMPLEX SPIKE ACTIVITY HAVE DIFFERENT RESPONSES TO CLICK BEFORE AS WELL AS AFTER CONDITIONING WITH CLICK AS A CS. <u>C. Woody*, A. Nahvi, G. Palermo, J. Wan and E. Gruen</u>. UCLA Med. Ctr., Los Angeles, CA 90024

Mean onsets and profiles of increased activity to click were compared before and after conditioning in neurons with complex spikes [Type I - initial spike followed 1-3 ms by multiple spikes; Type II - followed < 1 ms (in absolute refractory period); Type III - followed < 3 ms by spikes in baseline noise] and only simple spikes (S). Recordings were from flocculus and lateral and medial ansiform areas of cats. Type I & III cells are thought to be Purkinje cells with complex spikes representing climbing fiber responses. Type II cells are thought to be coupled Purkinje/Golgi II cells (Nahvi et al., Ribak et al. Exp. Neurol. 1980a,b). S cells were other cerebellar neurons plus some Pur-

kinje cells not identified due to the low frequency of complex spike activity.

Before conditioning, baseline activity differed among the four groups (two tail T tests), and was greatest in Type I cells. Type II cells had the greatest mean response to click (activity relative to baseline) with a peak 18Z above baseline noise. S cells had the second largest response (10Z above baseline). Activity of Type II cells best reflected temporal properties of the click

After conditioning, baseline activity decreased significantly in each of three groups that were compared (Type I & II cells and S cells). Differences in response to click were found in each cerebellar region before as well as after conditioning. In S cells the response to click increased 8Z and that to hiss 17Z above baseline mean after conditioning. In cells with Type II complex spikes, the response to click did not change significantly after conditioning (<1Z difference), but the response to hiss increased (7Z). The findings demonstrate differences in acoustic response by cell type as well as cerebellar region and behavioral state. (Supported by HD 05958.)

INFERIOR OLIVE SENSITIVITY IS REDUCED BY INCREASED CEREBELLAR OUTPUT. K. M. Horn*, P. L. E. van Kan, T. J. H. Ruigrok and A. R. Gibson. Division of Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85013.

Interpositus (IP), the output nucleus of intermediate cerebellum, has a strong GABAergic projection to the rostral dorsal accessory olive (rDAO). Many nucleo-olivary fibers terminate close to gap junctions between olivary neurons, and the nucleo-olivary pathway may mediate coupling between neurons. Another possible function of the nucleo-olivary pathway may be to modulate olivary sensitivity, since several studies indicate that sensitivity changes during movement. If the IP-rDAO projection is largely concerned with the regulation of olivary coupling, increased IP activity might reduce the size of rDAO receptive fields, since a given neuron would be less coupled to the activity of neighboring neurons. If the IP-rDAO projection is mainly involved in regulating sensitivity of rDAO neurons, increased IP activity should reduce the responses of rDAO neurons to somatosensory

Two cats were anesthetized with sodium pentobarbital. Cutaneous receptive fields of rDAO neurons were mapped, and stimulating electrodes were implanted at several locations across the receptive fields. Interpositus neurons were excited by either cooling the overlying cerebellar cortex or by injection of bicuculline into the IP. Cooling cerebellar cortex led to a 40% reduction of the evoked rDAO activity across all stimulation sites: no change in receptive field size was apparent. Bicuculline injections eliminated all activity in rDAO. The predominant effect of increased activity in interpositus is inhibition of rDAO, more refined testing would be required to reveal the action of inhibitory synapses near gap junctions. Supported by NIH grant NS30013.

OPTICAL MEASUREMENTS OF CEREBELLAR RESPONSES TO SURFACE STIMULATION IN AN ISOLATED IN-VITRO CEREBELLUM. D. Cohen, I. Segev and Y. Yarom.* Department of Neurobiology, Life Sciences Institute, The

Hebrew University, Jerusalem, Israel.

Cerebellar responses to surface stimulation were analyzed in an isolated guinea pig cerebellum, which was maintained at room temperature and perfused, via the vertebral arteries, with physiological solution. The voltage sensitive dye RH-414 was applied extracellularly for 1 hour (0.05mg/ml). Optical signals were recorded from 128 photodiodes organized in a 12x12 array. Using a 10x power objective, each clement of the array detects light from a surface of about 200µmx200µm. The signals were amplified, sampled and digitized, with 12-bit accuracy. Using two A/D boards (AT-MIO-64F-5) a time resolution of about 300 µsec per channel was obtained. Surface (parallel fiber) stimulation generates a wave of changes in fluorescence (of

up to 0.2%) that propagates along the cerebellar folium at a constant velocity of 0.2m/s. This wave of activity is characterized by a fast initial positive peak followed by a prolonged tail. Both components were partially blocked by CNQX (10-5M). The positive wave of activity is confined, by what seems to be a lateral inhibition, to a 400µm beam. The inhibition is recorded as a negative signal located laterally to the active beam. A train of stimuli delivered to the parallel fibers activates on-beam inhibition which is expressed as a slow, negative signal that follows the positive response. Neither the lateral inhibition nor the width of the activated beam are affected by the train of stimuli. The on-beam inhibition, which is non-linearly related to the number of stimuli in the train, was reversibly blocked by bicuculin (10-5M).

We conclude that: 1. The optical signals recorded from the isolated cerebellum reflect the electrical activity of the cerebellar cortex. 2. This optical system enables the detection of excitatory and inhibitory synaptic potentials from layers as deep as that of the Purkinje cells (the target site of the basket cell lateral inhibition). 3. These results reconfirm the concept that both the lateral inhibition, as well as the on-beam inhibition, shape the spatio-temporal organization of the cerebellar cortex activity. Supported by HFSF and the ONR.

INFLUENCE OF THE BÖTZINGER COMPLEX (BÖtC) ON THE APNEA PRODUCED BY CAPSAICIN. Z. Zhang, F. Xu, L.Y. Lee and D.T. Frazier. Dept. of Physiology, Univ. of KY, Lexington, KY40536

Intravenous capsaicin elicits pulmonary chemoreflexes (apnea, rapid shallow breathing, bradycardia, and hypotension) presumably through the stimulation of pulmonary C-fibers. The present study was designed to evaluate the influence of the BÖtC on the apneic component of the above reflex responses. Experiments were performed on 7 anesthetized, paralyzed and ventilated cats using the phrenic neurogram (PN) as the index of the respiratory motor output. Capsaicin (3.3-10µg/kg) was administered via left femoral vein to produce a pronounced apnea. After bilateral BötC lesions, the same dosage of capsaicin failed to produce a significant apnea, i.e., the expiratory time (T_E) was not statistically different from the baseline T_E. The baseline T_E following the lesions was somewhat shorter than in the intact but not significantly different. In 6 other animals, the apneic response elicited by capsaicin injections were not affected by bilateral lesions of pontine respiratory group (PRG). The baseline TE was prolonged but not significantly. These results suggest that an intact BötC is important for the expression of the apneic component of the reflexes elicited by capsaicin while the PRG is not. (Supported by HL40369)

DYNAMICS OF A DETAILED MODEL OF THE LAYER OF THE CEREBELLUM. R. Maex, B.P. Vos* and E. De Theoretische Neurobiologie, Antwerpen, Belgium.

Antwerpen, Belgium.

In order to provide a detailed Purkinje cell model (De Schutter E. & Bower J. 1994 J.Neurophysiol. 71, 401) with a more realistic pattern of parallel fiber synaptic inputs, we initiated simulations of the granular layer of the rat cerebellar cortex. The parameters of the one-compartmental model neurons were adapted from Gabbiani et al. (1994 J.Neurophysiol. 72, 999) for granule cells and chosen to reproduce known current-clamp data for Golgi cells. A circuit of tens of Golgi cells and thousands of granule cells positioned on an array along a folium was then activated by random mossy fiber input. The dynamics of this network depends principally on the distribution of the excitatory synapses on Golgi cells. A highly dominant parallel fiber excitation of Golgi cells forces all neurons in the network, over a length of several millimeters, to fire synchronized and at regular time intervals. This Golgi cells forces all neurons in the network, over a length of several millimeters, to fire synchronized and at regular time intervals. This oscillatory behavior gradually breaks down when the strength of parallel fiber synapses is decreased and/or the strength of mossy fiber synapses on Golgi cells is increased. The average granule cell firing rate decreases strongly if Golgi cell axonal arbors overlap, but only, when the Golgi cells are not synchronized, i.e. when their mossy fiber inputs dominate. Our results suggest that the Golgi cell ⇔ granule cell feedback loop is able to generate a very rhythmic pattern of parallel fiber activity. Moreover, if granule cells receive inhibition from a pair of Golgi cells, a dynamical switching between the Golgi cells' dominant sources of excitation would be a powerful mechanism for gain control.

Grants from HFSPO, NFWO (Belgium) and UA (Antwerp).

A MODEL OF ADAPTATION IN THE CEREBELLUM FOR LEARNING THE MODULATION OF THE VESTIBULO-OCULAR REFLEX (VOR). Olivier J.M.D. Coenen* and T.J. Sejnowski. UC San Diego, Howard Hughes Medical Institute, CNL, The Salk Institute, PO Box 85800, San Diego, CA 92186-

The gain of the VOR in monkeys is modulated by many inputs including eye position, vergence angle and otolith signals. These inputs insure stabi lization of retinal images during head movements regardless of gaze direction, head rotation axis and translation. We have shown that a dynamical model which combines these inputs can match the VOR dynamics observed in monkeys (Coenen & Sejnowski, NIPS 8, MIT Press). Based on a cerebellar theory that we have developed, we have extended this dynamical model to explain anticipatory gain changes of the VOR with vergence movements (Snyder & King; Vision Res. 32:3,1992). In the model, the cerebellum predicts the sensory feedback which is used to improve performance. Adaptation in the cerebellum and the cerebellar nuclei is mediated by the inferior olive. We demonstrate the importance of synchronous firing of climbing fibers for appropriate adaptation when the synergy of multiple Purkinje cells is necessary for good performance.

The modulation of the VOR with eye position, vergence and otolith inputs is a highly nonlinear function which can be learned with our model. Computer simulations of the model indicate how the cerebellum may selectively combine input signals to adaptively reduce VOR retinal slip. This is accomplished by constructing predictive representations of neural signals which can modulate the gain of the VOR in anticipation of new behavioral conditions. Supported by a McDonnell-Pew Foundation Fellowship and The Howard

Hughes Medical Institute.

A QUALITATIVE MODEL OF CEREBELLAR SACCADIC CONTROL. J.L. Krichmar*, L. Hunter and J.L. Olds., Krasnow Institute for Advanced Study at George Mason University, Fairfax, VA.

Evidence suggests that the oculomotor vermis (OV) region of the cerebellar cortex is necessary for the execution and maintenance of accurate saccades. We present a unique computational model, based on current knowledge of the present a unique computational model, based on current knowledge of manatomy and physiology of the OV, that tests probable strategies for saccadic processing. The model employs the Qualitative Reasoning Neuron (QRN) methodology to create a highly detailed model of the Purkinje cells (PC), stellate cells and basket cells that are found within the cerebellar cortex. The technique is extremely efficient because no quantitative values need to be calculated. However, accurately detailed and predictive properties emerge from QRN simulations. QRN demonstrates that a PC population code can accurately encode the direction of a saccade. QRN demonstrates that a state machine is adequate to store and execute a saccadic motor program in the OV; we were unable to accurately recreate empirical observations using an alternative feedback controller approach. The firing patterns of QRN, during intact and lesion experiments qualitatively match in detail recordings in the OV during saccades. simulates adaptation from inaccuracies in gradual and rapid adaptation paradigms. The adaptation is achieved with an error signal carried by the parallel fiber input The QRN model demonstrates adaptation is possible when climbing fiber (CF) is periodic and contains no error signal. Instead, CF input may dictate when an evaluation of the previous movement should occur. QRN suggests plausible explanations for the dysmetria seen in cerebellar lesion, excessive tremor, and Wallenberg's syndrome patients. This research illustrates the ability of QRN to efficiently simulate complex behaviors without sacrificing important details

NON-LINEAR HABITUATION OF THE GOLDFISH VESTIBULO-OCULAR REFLEX. E. R. Dow and T. J. Anastasio*. University of Illinois. Beckman Institu 405 N. Mathews Ave., Urbana, IL 61801.

Experiments in mammalian species show that the vestibulo-ocular reflex (VOR) habituates following prolonged low-frequency stimulation. Using linear system descriptors, the VOR can modeled as a high-pass filter. Habituation is a form of time-variance in the VOR. In mammals, habituation can be characterized by an increase in low-frequency phase lead and a commensurable decrease in gain that can be modeled by a decrease in the VOR time constant.

In habituating the goldfish VOR, we also found an increase in phase lead that could be explained by an decrease in the VOR time constant. However, we found an extreme low-frequency gain reduction that was incommensurable with the linear system description of phase. This suggests a non-linear component to habituation of gain in the goldfish VOR. Analysis of VOR time series data during habituation show several different time-variant and non-linear phenomena including: either a gradual or an abrupt bilateral or unilateral decrease in gain, complete unilateral rectification, DC shift which can result in spontaneous nystagmus, magnitudedependent response only to large accelerations (dead-zone non-linearity), or combination of these

Habituation can be eliminated permanently by cerebellectomy or transiently by injecting lidocaine onto the Purkinje cells of the vestibulo-cerebellum. A nonlinear. recurrent neural network model can simulate the full spectrum of these phenomena simply by modifying the Purkinje cell inhibition of the vestibular nuclei This work was supported by NIH grant MH50577.

EFFECT OF SPACEFLIGHT ON VESTIBULO-OCULAR REFLEXES (VORS) DURING ANGULAR HEAD MOTION. D.L.Tomko* and J.O.Clifford. Gravitational Research Branch, Life Sciences Division, NASA Ames Research Center, Moffett Field, CA 94035-1000

VORs stabilize the eyes when the head moves. During Earth-horizontal (E-H) pitch or roll rotations, canal and totlith stimuli occur coincidentally. In Earth-vertical (E-V) pitch or roll rotations, only canal signals occur. In cats and squirrel monkeys, pitch/roll VOR gains during E-H motion have been shown to be closer to one (more compensatory) than during E-V motion, implying that otolith modulation plays a role in producing angular VORs (AVORs). The present experiments replicated this study in rhesus monkeys, and examined how spaceflight affected AVOR gain. During yaw, pitch and roll (0.5 - 1.0 Hz, 40-507s pk) motion, 3-d eye movements were recorded in 4 Rhesus monkeys using scleral search coils. Mean E-H and E-V pitch VOR gains were 0.85 and 0.71, respectively. Torsional VOR gains during E-H and E-V roll were 0.47 and 0.39. Gains were thus more compensatory during E-H pitch or roll, when otolith modulation was added to canal stimuli. Two of the 4 monkeys flew for 11 days on the Soviet COSMOS 2229 Biosatellite. Bion 10 in 1992. E-H pitch VOR gains measured immediately (within 48 hrs) post-flight were attenuated, with gain values similar to those during pre-flight E-V head pitch. Torsional VOR gains in response to head roll were reduced in one flight subject and were similar pre- and post-flight. Results of both components of this study support the notion that signals of angular motion by semicircular to pre-tright varies in the second, riorizontal yaw Vox gains in the instability subjects were similar pre- and post-flight. Results of both components of this study support the notion that signals of angular motion by semicircular canals interact with otolith modulated signals to produce compensatory AVORs during E-H pitch.

Support-NASA Space Medicine Tasks 199-16-12-23 & 106-30-04-40

EFFECT OF HEAD POSITION ON TORSIONAL AND HORIZONTAL VESTIBULAR OCULAR REFLEX (VOR) ADAPTATION. <u>D. Solomon*, D. Straumann, D. S. Zee</u>. Dept. Neurology, Johns Hopkins Hosp, Baltimore, MD 21287

We studied short-term torsional (T) and horizontal (H) VOR adaptation. Five normal subjects underwent sinusoidal vertical axis whole-body rotation for 30 minutes (.3 Hz, pk-vel 37 deg/sec) viewing a chair fixed radial pattern (x0 viewing). The head was pitched up or down 35°. Eye movements were kept near zero orbital elevation and recorded in complete darkness with a dual search coil. VOR gain was (mean peak eye velocity over 10 cycles)/(peak chair velocity). Static ocular counter-roll gain following adaptation of the angular TVOR was unchanged.

Mean control TVOR gain was 0.43 (.31 to .64), decreasing 15% following head up and 28% following head down training. Horizontal gains followed a different pattern: mean control HVOR gain was .85 (.67 to .95), decreasing 37% following head up and 25% following head down training. Eye angular velocity (ω) axes were calculated relative to a head fixed coordinate system. The orientation of ω in the x-z plane was determined by the ratio of horizontal to torsional peak velocity. ω tilted on average 19.6° (13.5° to 26.2°) from the head's yaw axis (stimulus axis=35°) prior to adaptation, consistent with the observed gain anisotropy. Following x0 viewing, the mean tilt was 25.4° (18.9° to 32.2°) with head up and 19.8° (15.6° to 27.3°) with head down training. Following post-adaptation testing, VOR was measured with subjects imagining a chair fixed target in darkness. With the head up, TVOR gain decreased 39% and ω tilted 46.6°. With the head down, TVOR gain decreased 67% and ω tilted 25.2°. HVOR gain decreased 80% with head up and 73% with head down.

These results suggest that torsional and horizontal VOR gain adaptation, even when elicited together, are subject to different influences (differential contributions of the horizontal and vertical semicircular canals, neck afferents or graviceptive cues)

depending upon head orientation.

EFFECTS OF MOTOR LEARNING ON THE RESPONSE OF THE VESTIBULO-OCULAR REFLEX TO CURRENT PULSES AND HIGH-FREQUENCY ROTATION IN CATS. D. M. Broussard*, I. A. Hong, J. K. Bhatia and A. R. Butt. Playfair Neuroscience Unit, Univ. of Toronto, Toronto, Ontario M5T 2S8, Canada.

Motor learning modifies the response of the cat's horizontal angular VOR in a frequency-dependent fashion. We induced motor learning by unilateral vestibular damage (injury-induced learning) and by fitting cats with telescopic lenses (optically-induced learning). After a unilateral labyrinthectomy, the gain of the VOR at 5-10 Hz recovered to near-normal values, but a large dynamic asymmetry remained. There was no residual asymmetry at 0.5-2 Hz. Plugging the horizontal canal did not eliminate the canal's contribution to the VOR at high frequencies; after a bilateral plug, the VOR at 10 Hz had a near-normal gain, although plugging introduced a significant phase lead. Nevertheless, learning induced by a unilateral plug failed to restore symmetry in the VOR gain at 5-8 Hz. In general, the VOR's response to rotation at 0.05-2 Hz showed larger changes during optically-induced learning, and better recovery of symmetry during injury-induced learning, than the response at 5-10 Hz. We activated vestibular primary afferents synchronously with a 0.1-ms biphasic current pulse applied to the labyrinth; this stimulus evoked a biphasic twitch of eye velocity. During optically-induced learning, the learning-related change in the evoked response was small and most of it appeared after the first peak in eye velocity. However, during injury-induced learning, large changes appeared in the amplitude and latency of the response to a current pulse. Some of the changes were transient, persisting only for a few hours or days after surgery. (Supported by MRC:MT-12254)

Asymmetries in the horizontal VOR after unilateral plugging of the three semicircular canals in the squirrel monkey. D.D. Backous,* D. Lasker, L.B. Minor, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21203

Eye movements in response to 3000 deg/s2 impulses of angular acceleration delivered with the horizontal canals aligned in the yaw plane have been recorded (search coil) in darkness in two squirrel monkeys before and after unilateral canal plugging. Prior to plugging, horizontal vestibuloocular responses began after a latency of $7.9 \pm .4$ ms (mean \pm s.d.) with eye velocity rising at an acceleration gain of $.81 \pm .09$ until the first fast phase that occurred at 83 ± 26 ms. Velocity gain for 150 deg/s plateau head velocity was $.74 \pm .13$.

Within one week after unilateral canal plugging, ipsilesional acceleration gain decreased to .46 \pm .10 with the first fast phase occurring 123 \pm 27 ms into the response. Contralesional acceleration gain and timing of the first fast phase were unchanged after plugging. Ipsilesional velocity gain decreased to .42 \pm .01 whereas contralesional velocity gain measured .56 \pm .09. A further decrease in ipsilesional velocity gain was noted for velocity steps up to 500 deg/sec. Responses to .05-8 Hz sinusoidal rotations showed decreased gain after plugging with cut-off in eye velocity occurring for ipsilesional half-cycles at rotations reaching 500 deg/s maximum velocity. These directional asymmetries noted after unilateral canal plugging have been modeled through a closed-loop system with inhibitory commissural inputs and varying rotational sensitivities of secondary vestibular neurons.(Supported by NIH DC02390 and by the American Otological Society)

ROLL- AND PITCH-TILT PERCEPTION AND EYE MOVEMENT DURING LOW-FREQUENCY LINEAR ACCELERATION. S.H. Seidman*, L. Telford, a G.D. Paige, Dept. of Neurology and Ctr for Visual Science, Univ. of Rochester, Rochester, NY 14642

The otolith organs transduce linear acceleration, and respond to both translation and tilt stimuli. This ambiguity seems to be largely resolved using a frequency parsing scheme, by which high-frequency signals convey translation, and low frequency, tilt. To quantify the dynamic properties of low-frequency linear acceleration processing, we asked human subjects to report their perception of tilt during centripetal acceleration profiles generated by constant-velocity centrifugation (127°/sec) while the radius of centrifugation was dynamically modulated at 0.005, 0.01, or 0.025Hz (±50cm). Centripetal forces were aligned with the naso-occipital or inter-aural axes, producing resultant force profiles consistent with $\pm 14^\circ$ of pitch- or roll-tilt, respectively. Subjects reported tilt perception by maintaining a laser spot on the horizon. This spot was located straight-ahead during pitch-tilt trials or displaced 20° horizontally during roll-tilt trials. Perception during roll-tilt was also assessed by aligning a projected light bar with the perceived vertical. In different trials, eye movements were monitored in darkness while subjects attempted to maintain gaze on the perceived horizon.

Subjects perceived tilt, and not translation, during all trials. Perceptual responses for all horizon-matching tasks (pitch and roll) were similar. Gains averaged ~ 0.55 with a phase lag of $\sim 20^{\circ}$ at 0.005 Hz, decreasing to ~ 0.35 with a phase lag of $\sim 30^{\circ}$ at 0.025Hz. The overall dynamics of the bar-alignment task were essentially the same as for the horizon-matching task, with similar phase lags and an attenuation with increasing frequency, but with mean gains roughly twice as large. Eye movement responses mimicked corresponding perception responses, and were compensatory for tilt. These findings are consistent with low-pass dynamics of tilt processing from (Supp. by NIH grants AG06442, RR09283, EY01319) otolithic signals.

AUTOMATED 3D ANALYSIS OF FREE-FALL TEST ON HEMI-LABYRINTH-PLUGGED RATS. L. Simon*, Z. Papp, I. Rényi*, P. Csillag* Dept. of Anatomy, Semmelweis University Medical School and *Section of Image Analysis, KFKI-Research Inst. for Measurement and Computing Technique, Budapest, H-1450 Hungary

Plugging of the labyrinth serves as an earth-based model of motor control and orientation disorders of vestibular origin in weightlessness. After the unilateral surgical treatment under Nembutal anaesthesia (35 mg/kg.,i.p.) the essential motor asymmetry of animal results in side twirls (saltos) at free-fall test (1,5 m unconditioned fall from a cage onto a soft net, preventing any injury of the animals). The reduction of the number and of completeness of side turns indicates the ongoing sensorimotor adaptation. Stereo pairs of pictures of free fall were recorded by two CCD cameras in 20 mS sequence, and digitally stored in PC.

Three steps of analysis were performed as follows:
i, false-colored pairs were used for anaglyph observations on the test scenes. ii, computerized stereogrammetric

measurements were manually made for identifiable points of

the body scheme.
iii, Automatic stereo evaluation was attempted through motion field analysis of picture pairs. Surface shells of the animal's view given by a pair of cameras should than be completed either by a more complete (4 to 6 cameras) recording system, or by using a background mirror for the backside shell, in a merging procedure. A model of animal and the sequence of free fall should than be elaborated for abstract parameters of free fall.

ADAPTATION OF VESTIBULO-OCULAR REFLEX AFTER SELECTIVE SEMICIRCULAR CANAL PLUGGING D. E. Angelaki*, B. J. M. Hess, and J.-I. Suzuki. Neurology Dept., Univ. Hospital Zürich, 8091 Zürich, Switzerland and Univ. of Mississippi Medical Center, Surgery (Otolaryngology) Dept., Jackson, MS 39216, USA

The three-dimensional spatial and temporal vestibulo-ocular reflex (VOR) properties were investigated in five rhesus monkeys, two with the lateral semicircular canals plugged, two with the right anterior/left posterior canals plugged and one with all but the left posterior canal plugged. Threedimensional VOR was systematically tested in these animals at different head positions) i.e., upright, supine, prone, ear-down and intermediate positions) during transient displacements and sinusoidal oscillations about an earthvertical axis. Acutely after plugging, VOR gain was minimal during rotation in the plugged canal planes. Over time, however, VOR gains increased in a frequency-specific manner: At high frequencies, VOR gains reached values up to $\approx 0.3-0.5$ (1.1 Hz) after approximately three to five months. In contrast, there was no significant change in VOR gain at frequencies below approximately 0.1 Hz. These gain changes were also accompanied by a spatio-temporal reorganization of slow phase velocity, whereby the adapted responses were characterized by non-cosine tuned properties such that the spatial specificity of the elicited eye movement was restored at the expense of temporal response properties. These results suggest a complex spatio-temporal modification of three-dimensional vestibulo-ocular connectivity within the

THREE-DIMENSIONAL EYE MOVEMENT DEFICITS AFTER REVERSIBLE LESIONS OF THE INTERSTITIAL NUCLEUS OF CAIAL (IC) OF THE ALERT MONKEY. C. Helmchen, L. Fuhry, H. Rambold, U Büttner*. Dept. of Neurology, University of Munich, 81377 Munich, Germany

The mesencephalic interstitial nucleus of Cajal (iC) is thought to be the neural integrator for vertical and torsional eye movements. We performed reversible lesions

in iC of the alert monkey (Macaca mulatta) to study the following questions:

1) Do iC lesions cause upbeating or downbeating spontaneous nystagmus? 2) Is lesions suggesting different time constants and hence a parallel processing of neural integration (Crawford and Vilis 1993) ? 4) How do iC lesions affect the torsional vestibulo-ocular reflex (VOR) ? 5) How do iC lesions affect vertical saccade amplitude and saccade velocities

Rhesus monkeys were trained to sit in a primate chair with the head immobilized. Spontaneous eye movements were recorded and monkeys were a) brought in different static roll and pitch positions and b) passively rotated sinusoidally in the pitch and roll plane. iC was localized by single unit recordings according to their typical neuronal discharge

iC lesions (Muscimol) consistently showed a downbeating spontaneous nystagmus with downward gaze evoked nystagmus. During the late course of the lesion there could be an additional upbeating gaze evoked nystagmus but we never exclusively found an upbeat nystagmus. Listing's plane was shifted to the contralesional side (up to 20 deg). There was always an ipsilesionally beating torsional nystagmus, a strong asymmetry of the torsional VOR with diminished or lost torsional quick phases to the contralesional side. Time constants of exponential drift ranged from 100 -700 ms. Vertical oculomotor range became significantly smaller but saccade amplitude/velocity relationship remained normal. Horizontal saccades were not affected. [Supported by the Deutsche Forschungsgemeinschaft].

3D OPTOKINETIC RESPONSES IN HUMANS ARE NOT INFLUENCED BY THE GRAVITO-INERTIAL FORCE VECTOR. $\underline{\mathbf{M}}$ Fetter*, G. Pfaff, J. Heimberger, T. Haslwanter. Dept. of Neurology, University of Tübingen, 72076 Tübingen, Germany

When optokinetic nystagmus is elicited in monkeys by movement of the visual surround in their yaw plane, and the animals are in a tilted position in the roll or pitch plane, inappropriate (cross coupled) vertical or torsional eye movement components appear both during optokinetic nystagmus (OKN) and afternystagmus (OKAN). This has been explained by models assuming a "gravity centered" 3D velocity storage in monkeys. To test if similar cross coupled components can also be observed in humans, we studied in 10 normals the effect of head position on 3D optokinetic responses. Subjects were seated in a 3D rotator. Optokinetic responses were clicited by a planetarium-like optokinetic stimulator (40°/s for 40 s). Movement of the left eye was monitored using a 3D magnetic search coil during and after stimulation. Subjects were positioned at different roll angles (0-90° right car down) with the optokinetic stimulation axis varying in the roll plane relative to the subject and at different pitch angles (0-90° nose up) with the stimulation axis varying in the pitch plane Apart from the well-know fact that torsional optokinctic responses are weak in humans, OKN and OKAN showed identical eye rotation axes for identical optokinetic stimulation axes relativ to the head, independent of the head position relativ to gravity. Unlike in monkeys, no cross coupled components other than those due to smaller torsional than vertical or horizontal OKN gains could be detected. These findings support the notion of a fundamentally different organization of 3D velocity storage in humans and monkeys. Supported by DFG SFB 307-A2

THE USE OF A VIRTUAL REALITY DISPLAY FOR VESTIBULAR AND OCULOMOTOR RESEARCH. P. D. Kramer*, D. Roberts, M. Shelhamer, and D. S. Zee. Johns Hopkins University, School of Medicine, Baltimore, MD 21287.

Testing of the vestibular system requires a vestibular stimulus (motion) and/or a

visual stimulus. We have developed a versatile, relatively low cost (\$13,000), stereoscopic visual display stimulus, using "virtual reality" (VR) technology. The display has a field of view of at least 110° vertically and horizontally, and is under computer control. We tested 2 subjects for smooth pursuit and stare optokinetic nystagmus (OKN) and after-nystagmus (OKAN); 4 subjects for short-term adaptation of the angular vestibulo-ocular reflex (AVOR); and 2 subjects for short-term adaptation of the linear VOR (LVOR). All tests were performed with a conventional display (OKN drum or laser target) and with the stereoscopic VR display.

OKN slow phase velocity averaged 16% greater with the VR display. Both displays produced OKAN; the conventional OKN drum produced OKAN of greater amplitude and longer duration. Smooth pursuit gains were almost identical with both displays
Using the VR device and a rotating chair in a 1 hr visual-vestibular conflict

paradigm, we were able to induce adaptive changes in AVOR phase (lead and lag) and gain (increase and decrease) that ranged from 50% to 100% of those induced with identical paradigms using an OKN drum as the visual display. Adaptive changes in LVOR phase were also induced on a linear sled, averaging -16° after 20 min. There was no conventional visual stimulus for comparison in this case; we have no visual stimulus capable of producing a moving visual scene with a phase that is adjustable relative to sled motion.

While VR has some limitations, such as aliasing at high stimulus velocities and difficulty accommodating subjects who wear spectacles, it can provide a versatile visual stimulus for both the clinic and laboratory

OTOLITH INPUT TO THE CENTRAL VELOCITY STORAGE IN HUMANS. T. Haslwanter*, M. Fetter, S. Mayr, J. Heimberger. Dept of Neurology, Univ. Hospital, D-72076 Tübingen, Germany

The central velocity storage in humans can be charged not only through input from the semicircular canals - the primary source of information about the velocity of the head in space - but also through optokinetic or otolith stimulation. Recent experiments which tested the response of nystagmus immediately after constant velocity rotation to repositioning of the body in space have shown that there are fundamental differences of the velocity storage in humans and monkeys: while in monkeys the axis of eye rotation stays approximately aligned with the earth vertical axis, in humans it is aligned with the bodyfixed yaw-axis. To investigate these differences between humans and monkeys in more detail, we have tested the 3dimensional eye-movement response of 11 humans to off-vertical-axis rotation (OVAR) at 100°/s, with the axis of rotation tilted by 15° or 30° with respect to the earth vertical axis. During OVAR, the velocity storage gets charged through dynamic otolith input, and produces in monkeys a unidirectional eye-velocity which is modulated with the orientation of the body in space. Our results show that in humans the steady state average eye-velocity is close to zero, but still shows a significant modulation with the body position. This experiment emphasizes the differences of the 3-dimensional velocity storage organization in humans and monkeys. Supported by DFG SFB 307 - A2

THREE-DIMENSIONAL ANALYSIS OF NORMAL HUMAN CALORIC NYSTAGMUS S. T. Aw¹, M. Fetter², T. Haslwanter², J. Heimberger², G. M. Halmagyi¹*. Eye and Ear Research Unit, Royal Prince Alfred Hospital, Sydney, NSW 2050 Australia¹, Department of Neurology, University of Tuebingen, D 72076 Germany

NSW 2050 Australia', Department of Neurology, University of Tuebingen, D-72076 Germany ².

The aim of this study was to investigate whether some response components of the caloric nystagmus can be attributed to a stimulation of the vertical semicircular canals. Each caloric irrigation was maintained for 3 minutes during which time the subject's head was positioned in the multi-axis rotator in one of four positions; such that either the lateral, anterior or posterior canals was horizontal, or the lateral canal was vertical. Following irrigation of the right external auditory canal with warm and cold air at 44°C and 27°C respectively, three dimensional eye movement recordings, using a dual search coil technique, showed horizontal, vertical and torsional nystagmus in 5 normal subjects. The results of the analysis were expressed as quaternions. We showed that the predominant response was from the lateral canal. The contribution of vertical canals to the caloric response was evidenced by the appropriately changing vertical component of the nystagmus when either the anterior or posterior canal stimulation was minimised by being positioned horizontally. We also irrigated 4 subjects, each continuously with warm air while the head was pitched at different angles. The lateral canal was initially pitched 45° backwards from the earth vertical position in each subject and then pitched forwards in nine 45° steps through a range of 270°, at 3 min intervals. We showed that the horizontal component of the nystagmus approximated a cosine function that varied with head pitch angle and confirmed that thermovective mechanism played an important role in caloric nystagmus. The vertical and torsional components were in the inverse direction of the horizontal component.

A NEW METHOD FOR MEASURING PODOKINETIC AFTER-EFFECTS WITHOUT VESTIBULAR STIMULATION. K. Weber, WA Fletcher, G. Melvill Jones, E. Block. Dept. of Clinical Neurosciences, University of Calgary, Calgary, Canada T2N 4N1. In previous communications (Gordon et al., EBR 102:540-545, 1994; Weber et al., Soc

Neurosci Abstr 21:2085, 1995) we described a robust non-visual "podokinetic" somatosensory/motor system thought to control spatial orientation during locomotion through trunk rotation relative to the space-stationary stance foot. However, after adaptive remodelling of the system by prolonged "walking-in-place" on a rotating treadmill, subjects could no longer walk straight without vision. Instead they all described markedly curved pathways (podokinetic after-effect) without any sense of turning, despite incurring body angular velocities an order of magnitude above vestibular sensory threshold Similarly, following adaptation by "stepping-in-place" over the axis of the turntable, subjects turned relative to space without perception of turning. We now ask whether such UNPERCEIVED vestibular stimulation did nevertheless influence the subconscious podokinetic after-effect? Subjects were equipped with an electromagnetic search coil which senses angular POSITION and servo-drives the turntable at a proportionate angular VELOCITY in the OPPOSITE direction. After adaptation subjects stepped-inplace over the axis of the turntable, using the search coil to servo-control turntable velocity until they sensed it was NOT turning. The turntable tachometer then registered both magnitude and direction of the after-effect (UNPERCEIVED foot rotation-re-trunk) without any relevant vestibular stimulation. Initial results from 3 subjects and 3 condition showed no obvious difference from the corresponding previous responses in which actual rotation relative to space occurred. Consequently, we conclude that the original expression of podokinetic after-effects described previously was not significantly influenced by the associated vestibular stimulation.

RESULTS OF VESTIBULAR REHABILITATION AFTER ACOUSTIC NEUROMA RESECTION. H Cohen* and K T Kimball. Depts. of Otorhinolaryngology and Medicine, Baylor Coll. Med., Houston, TX 77030

Immediately following resection of an acoustic neuroma or vestibular nerve section patients have decreased vestibular-ocular reflex (VOR) gain, decreased postural responses, vertigo, disorientation and decreased independence in daily life skills Although patients recover some physiological responses rapidly they remain impaired for long periods of time. Exercise treatments are often used in the attempt to facilitate that improvement, although little evidence supports the use of these treatments.

In this study pre-operative subjects with acoustic neuromas were pre-tested on caloric tests, sinusoidal tests of the horizontal VOR, computerized dynamic posturography, and qualitative measures of vertigo, gait, and independence in daily life tasks. For the 4 to 5 inpatient days after surgery subjects were treated twice daily at bedside in attention or exercise groups and then retested at discharge and at monthly intervals for three months. Subjects improved significantly on measures of vertigo and functional skills during the course of the week, and improved on physiological measures during the chronic recovery period. Exercise facilitated functional recovery

REFLEX FUNCTION: ANIMAL STUDIES

435.1

DYSFUNCTIONAL CONTROL OF THE FLUCTUATIONS OF THE H REFLEX IN THE NEUROLOGICAL MUTANT taiep RAT. J.R. Eguibar J.E. Salceda-Ruanova¹, M. Roncangliolo² and E. Manjarrez¹. ¹Institute of Physiology, B. Universidad Autónoma de Puebla, Puebla, Pue., México. ²Dept. of Physiology, Fac. of Sciences, Universidad de Valparaiso, Chile

Presynaptic inhibition is associated with the control of the afferent information flow into the spinal cord. Electrical stimulation of group I flexor afferents diminish the fluctuations (variance) of the monosynaptic reflexes (Rudomin and Dutton, 1969). Taiep rat is a neurological mutant that progressively presents tremor, ataxia, immobility episodes, epilepsy and paralysis (Holmgren et al., 1989). Comparison of the fluctuations of the H reflexes in normal rats and in taiep rats, allowed us to evaluate the effects produced by electrical stimulation of pathways that mediate presynaptic inhibition. We studied 9 control rats and 4 tatep rats (2 months age), under urethane or ketamine anesthesia. Stimulation was delivered through the sciatic or medial gastrocnemius (MG) nerves and the H reflexes were recorded by means of platinum electrodes inserted in the interdigital muscles of the hindlimb, or in the MG muscle, respectively

Our experiments showed that conditioning stimulus of common peroneous nerve decreased the amplitude (A) and variance (S) of the H reflexes in normal rats: A=31.1% of control value, with S from 0.127 to 0.011, but not in the taiep rats A=81.7% of control value, with S from 0.005 to 0.003. This effect was maximal at 20-25 ms and had an average duration of 180 ms. The present results suggest that in young taiep rats the pathways associated with a reduction of the variability of H reflexes are dysfunctional. It seems possible that these alterations may be due, at least in part, to a failure in the presynaptic inhibition mechanisms in the spinal cord of talep rat. HINDLIMB MOVEMENTS OF ADULT RATS WITH TRANSECTED SPINAL CORDS. J.G. Broton*, X.M. Xu, M.B. Bunge, S. Lutton, T. Cuthbert, and B. Calancie, The Miami Project to Cure Paralysis, Depts. Neurol. Surg. and Cell Biology and Anatomy, University of Miami. Miami FL In studies of therapeutic interventions after adult rat spinal cord injury,

restoration of hindlimb movements has often been equated with recovery of voluntary function. The present investigation describes the <u>reflex</u> hindlimb movements of rats with transected spinal cords. Movements were observed while rats were suspended over a moving treadmill.

Adult female rats underwent spinal cord transections at T8-T10. Rats were videotaped 1, 2 and 4 weeks post-transection (post-t) with the treadmill surface moving at 0.05, 0.10 or 0.15 m/sec, for a minimum of 2.5 minutes. The informing at 0.03, 0.10 of 0.17 insect, for a hindrating of 2.23 infinites. The videotage was replayed, and the times during which specific hindlimb movements (or their absence) were seen (i.e. dragging, scratching, kicking, flexion, extension, or stepping movements - unilateral or bilateral) were noted. Times were scored as percent of the total time analyzed for that rat. When 20s of continuous bilateral stepping movements (BSMs) were seen, the coordinates of ink spots on the left forelimb and hindlimb were determined and used to

of ink spots on the left forelimb and hindlimb were determined and used to calculate position auto- and crosscorrelations for that time period. Five of the seven tested rats displayed non-weight-supported BSMs at times ranging from 20-46% of the total time analyzed. BSMs were first evident 2 wks post-t. Average autocorrelation coefficients for the hindlimb were 0.34± 0.14 at 0.05m/s and 0.40±0.14 at 0.10m/s. Forelimb autocorrelations were 0.25± 0.05 at 0.05m/s and 0.43±.18 at 0.10m/s. The average hindlimb cross-correlations with the forelimb were 0.22±0.07 at 0.05m/s and 0.11±0.07 at 0.10m/s, much lower than control data from able-bodied rats (0.71±0.12 at 0.10m/s). These results indicate that movements that may easily be confused with voluntary movements - BSMs - can be generated by the isolated adult rat spinal cord. The use of correlation analysis may be helpful in the determination and quantification of voluntary hindlimb function after spinal cord injury in rats. Supported by The Miami Project to Cure Paralysis.

INCREASED STRETCH REFLEX EXCITABILITY CAUSED BY SPASTICITY FOLLOWING SPINAL CORD INJURY IS PREDOMINANTLY CAUSED BY THE REFLEXIVE ATTRIBUTES OF A MONOSYNAPTIC REFLEX

Browd, C.R., Thompson, F.J., Carvalho, P.M., Semple-Rowland, S.L.* Dept. of Neuroscience, Univ. Of Florida Brain Institute, Gainesville, FL 23610-0244. Spasticity has been clinically defined as a velocity dependent increase in the

lengthening tension of the affected muscles. Increases in reflex (Thilmann, 1991) and non-reflex-mediated (Sinkjaer, 1993) stiffness have been documented in spastic subjects. The threshold of monosynaptic reflexes in the stretch reflex pathway were significantly reduced (Thompson, 1993) subsequent to midthoracic spinal contusion injury. This experiment tested the respective contributions of reflexive compared to non-reflexive properties, to the exaggerated velocity dependent resistance to muscle lengthening in the spastic rat. This was determined by analysis of velocity dependent lengthening resistance using a repeated measure paradigm. An anesthetic was used to isolate the non-reflexive response from the reflexive component of the stretch. We have seen under general anesthesia of a normal rodent, only passive qualities are present. There was a marked attenuation of RMS of the EMG by 87.6% at a velocity of 306 deg/sec. The stiffness of the triceps surae muscle was also attenuated by 46.8% at the same velocity. The tentative conclusion would therefore be that the reflex mediated stiffness of the dynamic stretch reflex provides the predominant contribution to velocity dependent increase in ankle torque. (Supported by: R01 NS 33333-01A1, the Brain and Spinal Cord Injury Rehabilitation Trust Fund, and the Spinal Cord Research Foundation-PVA-1226.01)

STRETCH AND H REFLEXES IN SOLEUS MUSCLE OF HIGH DECEREBRATE CATS DURING TONIC AND PHASIC CONTRACTIONS. De Serres, S.J. Misiaszek, J.E., Stein, R.B. and Pearson, K.G., University of Alberta, Edmonton, Canada, T6G 2H7. Department of Physiology,

Opposite relationships exist between reflex force and background muscle activity when stretching the triceps surae muscles during tonic and phasic contractions. While the reflex force decreases when the background activity increases in a tonically contracting muscle, the reflex force increases when the background force is increased by phasic activation (locomotion). This difference could arise from events at two sites: 1) altered fusimotor drive at the muscle spindle, or 2) altered transmission through the reflex arc. In the present study, electrically evoked soleus H reflexes were compared to mechanical stretch reflexes of the same muscle during both types of contraction in high decerebrate cats. H reflexes arise from activation of the primary afferents proximal to the muscle spindles and thus are not influenced by fusimotor drive. Electrical stimuli or mechanical stretches were applied during periods of either tonic contractions or spontaneous locomotion entrained by a treadmill. The muscle was held isometric during both types of contraction. During locomotion the H reflex modulated strongly as its peak-to-peak amplitude increased with increasing background activity. During tonic contractions the amplitude of the H reflex also increased with increasing background activity. In general, H reflexes obtained during tonic contractions were greater than reflexes obtained during locomotion. The stretch responses behaved in a similar fashion to previous studies That is, the reflex force and EMG increased with increasing background activity during locomotion, but decreased with increasing background activity during tonic contractions. The lack of a difference, between the tonic and phasic conditions, in the relationship of the H reflex with background activity suggests that the difference described for the stretch reflex arises from a variation in fusimotor drive between the two types of contraction. Supported by MRC (Canada) and AHFMR (Alberta).

EFFECTS OF STIMULATION OF EXTENSOR MUSCLE AFFERENTS DURING WALKING IN ADULT RATS. K. Fouad and K.G. Pearson*. Dept. of Physiology, Univ. of Alberta, Edmonton, Alberta, Canada T6G 2H7.

Little is known about the influence of muscle proprioceptors on the walking pattern in the rat; the only information comes from studies in neonates. In P4-6 animals stimulation of extensor afferents during extension causes either no change or a truncation of extensor activity, depending on the intensity of the stimulation. Low or high intensity stimulation during flexion can truncate or prolong flexor activity respectively (O. Kiehn personal communication).

To address this issue in adult rats, we stimulated extensor nerves in the hindlimbs of decerebrate animals walking on a wheel. Bouts of walking either occurred spontaneously or were evoked by electrical stimulation of the mesencephalic locomotor region (MLR). An ankle extensor nerve (either Lg-Sol or Mg) was cut close to the muscle and the proximal end tied into a stimulation cuff, which was anchored to the tibial nerve. To monitor the stimulus intensity, a recording cuff was placed around the sciatic nerve. Stimulating an extensor nerve (300-500 ms duration, 50 Hz, 2-5 x T) during the early extensor phase of the step-cycle resulted in prolongation of the extensor burst and a delay of the flexor burst. This effect was weaker, but qualitatively similar to the effect of extensor nerve stimulation in the cat. Stimulation at the end of the flexor burst resulted in a delay of extension, a phenomenon that does not occur in the cat. These effects were larger during spontaneous walking compared to those during MLR evoked walking. Stimulating during other phases of the step cycle did not influence the timing of locomotor activity. No differences were found in stimulating Mg or Lg-Sol afferents. Because these observations differ from those in neonatal rats, we conclude that a major change occurs in the integration of afferent input to the walking pattern generator during late postnatal development.

A MODERN APPRAISAL OF DENNY-BROWN'S CONCEPTIONS OF GRASPING AND AVOIDING. <u>J.A. Vilensky* and S. Gilman</u>. Dept. of Anatomy, Indiana Univ. Sch. of Med., Ft. Wayne, IN 4805 and Dept. of Neurology, Univ. of Michigan Sch. of Med., Ann Arbor, MI 48109.

"Grasping" and "avoiding" responses are two positive clinical signs that Denny-Brown observed in his patients after localized brain lesions, and that he was able to reproduce in monkeys by cerebral ablations. Recent investigations of these responses in patients using imaging techniques have tended to support Denny-Brown's association of grasping with frontal lobe lesions and avoiding with parietal lobe lesions. Here we illustrate the types of grasping (traction response, grasp reflex, instinctive grasp reaction) and avoiding (avoiding response, levitation) phenomena that Denny-Brown described and how each may be elicited using sketches, photographs and a videotape.

We also illustrate how grasping and avoiding responses fit into Denny-Brown's view on nervous system integration. He believed that the CNS was organized such that reactions to sensory stimuli have "positive" and "negative" elements. Positive reactions (e.g., grasping) are those that reach out into the environment and negative reactions (e.g., avoiding) retreat from the environment. Based on this perspective, Denny-Brown explained how, for example, the chorea of Huntington's disease results from released but conflicting positive and negative cortical automatisms.

The continued verification of Denny-Brown's conclusions on the

The continuous verification of Definity-nown's Conclusions on the localization of grasping and avoiding phenomena suggests that his views on nervous system integration should be reexamined in the light of contemporary data, e.g., the success of pallidotomy for relieving some of the disorders of Parkinson's disease.

HABITUATION OF THE EYEBLINK AND OF FULL-BODY STARTLE: A COMPARISON OF TWO REFLEX RESPONSES. A. S. Powers* and J. Cranney², ¹Department of Psychology, St. John's University, Jamaica, NY 11439, and ²School of Psychology, University of New South Wales, Sydney, New South Wales 2052, Australia.

In rats, the acoustic startle response is typically measured as a full-body response, while in humans, it is measured as an eyeblink. The present study investigated whether both measures would show the same patterns when examined in a single species. We used the same procedures in two experiments in rats, one examining the full-body startle and the other the eyeblink. In one experiment we implanted electrodes in 10 rats for recording electromyograms (EMG's) from the orbicularis oculi muscle, which closes the eye. Then blink responses to a loud (105 dB) white-noise stimulus were measured in one 80-trial session. This stimulus was presented every 10 sec for 40 trials. Ten seconds after the fortieth trial, the rats received a single 0.5 s 0.5 mA footshock. Within 72 s of receiving the footshock, another sequence of 40 acoustic stimuli began. Freezing, a measure of fear, was recorded throughout the session. In the other experiment, a separate group of 10 rats was run on the same sequence of stimuli, but their full-body response was measured in a startle chamber. Freezing was also recorded in this group. The results showed that EMG, startle, and freezing in both experiments showed an initial sensitization, followed by habituation during the first 40 trials, then another sensitization caused by the footshock. Freezing was more marked in the EMG experiment, and the degree of sensitization to the shock was less. The results indicate that eyeblink and full-body startle follow similar patterns and suggest that the full-body startle in rats is probably measuring the same processes as the eyeblink in humans

SYNAPTIC EFFECTS OF TRICEPS SURAE (TS) GROUPS I AND II AFFERENT FIBERS IN TS SCRATCHING MOTOR PROGRAM, <u>S. H. Dueñas</u>. Lab. de Neurofisiología, Departamento de Neurociencias, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

The present study was performed to analize the synaptic actions of TS groups I and II afferent fibers in TS motoneurons during fictive scratching in thalamic cats (n=12). TS group la and lb afferent fibers were activated by TS tendon vibration (180-200Hz and 25-35 Hz, respectively), and group II afferent fibers by medial gastrocnemious (MG) nerve electrical stimulation (2-3 x T). TS la afferent fibers did not evoke fictive scratching episodes but a small increase (10%) in scartching cycle duration ocurred. TS burst amplitude increased as TS homonymous and heteronynimous monosynaptic reflexe amplitude before (10-30 ms) and during scratching (extensor) phase increased. TS lb afferent fibers evoked episodes of fictive scratching but scratching cycle duration changes were not observed (n=4). In the period elapsing between lb stimulation and the appearence of scratching episodes, forerunner exitatory posynaptic potentials (EPSPs) occurred in MG motoneurons. TS group II afferent fibers reduces tibialis anterior scartching postural (aimung) period duration, produces MG tonic motoneuron activity at the onset of scratching episodes and prolonged (2-3 times) the MG cyclic scratching phase duration with a consequent flexor phase reduction. Summing effects of group I and II afferent fibers in extensor Ia rhytmically activated interneurons and in TS motoneurons could prolong extensor and reduce flexor scratching cycle phases during TS motor program. A DESCRIPTION OF THE LICK-CHEW RESPONSE IN THE RABBIT. K. Asher, N. R. Myslinski* and J. Buxbaum, Department of OCBS, School of Dentistry, University of Maryland, Baltimore, MD 21201.

The lick-chew response (LCĤ) is a complex oral-facial reflex seen in the rabbit after tooth pulp stimulation. It has been used to study the pharmacology of trigeminal pain systems, but has never been described in detail. This paper attempts to characterize this reflex in order to make it a more useful experimental technique. Six adult naive New Zealand white rabbits (1.5 - 3.0 kg) were prepared with 0.1 mm cavities in their maxillary incisors bilaterally half way between the gingival margin and incisal edge of the tooth. Electrical stimuli were applied to the tooth pulp using a ramp stimulator and the voltage that evoked the LCR was recorded. Monopolar EMG recordings were made of the masseter and digastric muscles. The LCR occurred in 2 phases: the bruxing phase and the licking phase. Time and distance measurements were made of multiple aspects of each phase. The truing phase averaged 4.26 sec and the licking phase averaged 6.1 sec. The average number of licks was 15. In order to determine the location of the critical circuits of this response the skulls of 2 additional anesthetized rabbits were opened and serial cross sections of the brains were performed. The sections began near the anterior commissure and proceeded caudally while testing the LCR after each section. The LCR remained intact after sections up to and including the pons-midbrain junction. A SIGNAL DETECTION THEORY ANALYSIS OF THE EFFECTS OF QUINPIROLE ON ACOUSTIC STARTLE IN THE RAT. D. S. Leitnert*, E. M. Girten; and D. P. Carmody. 1Psychology Dept., St. Joseph's Univ., Philadelphia, PA 19131, and 2Psychology Dept., St. Peter's College, Jersey City, NJ 07306

If a weak sensory event (a prestimulus) is presented prior to the onset of a startle-eliciting stimulus (SES), the amplitude of the subsequently elicited startle reflex will be reduced. Currently no consensus concerning the best way to quantify this phenomenon exists. The present study used analyses based on signal detection theory (SDT) to quantify the ability of gaps, brief silent periods in otherwise continuous 60 dB broad-band noise, to reduce the amplitude of the rat's acoustic startle reflex. The SDT analyses were compared to analyses of amplitude, and difference and percentage scores. Also examined were the effects of the dopamine D2/D3 receptor agonist quinpirole on startle amplitude and the inhibition produced by gaps. Dopamine D2 receptor agonists have been shown to interfere with the ability of prestimuli to modulate startle amplitude.

Twenty-four rats were exposed to four stimulus configurations representing the factorial combination of two gaps (4- and 50-ms-long) presented at two interstimulus intervals (20 and 50 ms) in addition to control trials of the SES alone. These five types of trials were presented 25 times each in block-random sequence. Each subject was tested once following an injection of saline (1 ml/kg) and once following an injection of quinpirole hydrocholoride (5 mg/kg).

Analyses based on amplitude showed that quinpirole decreased startle amplitude, and its effects on amplitude reduction produced by gaps varied with stimulus configuration. Because of the simultaneous drug-induced decrease in startle amplitude and the ability of the gaps to reduce startle amplitude, these data were not readily interpretable. Analyses based on difference scores showed that quinpirole reduced the ability of a gap to inhibit startle. Analyses based on percent and SDT showed a similar pattern in that quinpirole enhanced the ability of a gap to inhibit startle.

IMIQUIMOD ELICITS EMESIS IN FERRETS THAT IS MEDIATED BY AREA POSTREMA (AP) BUT DOES NOT DIRECTLY ACTIVATE NEURONS IN THE AP OF BRAIN STEM SLICES. N. L. Strominger*. R. J. Brady*. D. O. Carpenter² and G. Gullikson³. 'Albany Medical College, Albany, NY 12208, "Wadsworth Labs, School of Public Health, Albany, NY 12201 and "3M Pharmaceuticals, St. Paul, MN 55144.

The immunomodulator, imiquimod, has been shown to have antiviral and antitumor properties in animal models. It has also been reported to alter cytokine levels in both animals and humans. However, imiquimod appears to be emetic. Subcutaneous administration of ≥10 mg/kg imiquimod to ferrets elicits emesis with latencies as short as 2'; 12 and 15 mg/kg were optimal doses. Emetic responsiveness was eliminated by complete ablation of the AP, but was unaffected by bilateral supradiaphragmatic section of the vagus nerve. This indicates that the emesis is produced by an activation of the chemical trigger zone, the AP.

Brain stem slices (400 µm), prepared from deeply anesthetized ferrets, were

Brain stem slices (400 μm), prepared from deeply anesthetized ferrets, were preincubated in oxygenated Krebs-Ringer and then mounted in a submerged slice recording chamber. Extracellular recordings of spontaneous and ionophoretically-evoked activity of AP neurons were obtained for up to 8 hours while the effect of bath applied imiquimod was determined. Under control conditions neurons showed a low frequency spontaneous discharge. Introduction of imiquimod (concentration range 10-7 to 5 x 10-8 M) had no effect on neuronal firing. With ionophoresis of glutamate from an independent micropipette, a brief excitatory response was obtained. The bath application of imiquimod also did not significantly alter this neuronal response. Imiquimod at concentrations of up to 50 μM does not significantly alter the activity of AP neurons. We conclude that imiquimod does not directly excite area postrema neurons. It is likely that imiquimod causes synthesis and release of some emetic substance. Supported by 3M Pharmaceuticals.

IMPAIRED VELOCITY-SENSITIVE RESPONSE TO STRETCH IN PLANTARFLEXORS AFTER SPINAL CORD LESION. A. Lamontagne, F. Malouin, C.L. Richards*, F. Dumas and D. Tardif. Physiotherapy Dept., Faculty of Medicine, Laval University, Quebec City, Canada, GIK 7P4

The primary aim of this study was to compare the effect of stretch velocity on the non-reflex resistive torque (RT) of the plantarflexors in subjects (n=6) with a complete chronic (1-3 yrs) spinal cord nipury (SCI) to normal (n=12) subjects (CTL.). Series of 5 passive ankle movements, ranging from -35° to 5° of dorsiflexion (DF), were randomly imposed at 5°/s, 10°/s, 20°/s, 40°/s, 60°/s, 120°/s, 180°/s using a Kin-Com dynamometer. Surface electrodes detected unwanted activity during the tests. RT of the last 4 trials of each series recorded at -10° and 0° of DF was averaged. The effect of velocity on RT values was determined by an analysis of variance (ANOVA) followed by post-hoc procedures and net RT increments (RT at each velocity minus RT at 5°/s) were compared between the SCI and CTL groups using t-tests. Results first show that RT recorded at 5°/s for the SCI group was similar to that of the CTL group, which contrasts with increased muscle stiffness seen in spastic disorders of cerebral origin (cerebral palsy, stroke). Secondly, a significant increase in RT was found at a higher velocity (p<0.01) in the SCI group (60°/s) compared to the CTL group (40°/s). Finally, larger (p<0.001) net increments of RT were calculated at 180°/s for the CTL group than for the SCI group whose RT plateaued at 60°/s. These results show that plantarflexors in subjects with a chronic and complete SCI have no increase in muscle stiffness but demonstrate an impaired velocity-sensitive behavior, especially at high velocity. This impaired behavior likely reflects changes of muscle tensile properties that may have taken place because of disuse and of the alteration of descending neural input. (Supported by MRC Canada)

M-WAVE DEPRESSION AND POTENTIATION FOLLOWING ECCENTRIC MUSCLE CONTRACTION. A.B. Leger, P. Bawa and T.E. Milner*. School of Kingsiology. Simple Fraser Lipiuspity, Burnaby, B.C. VSA 156.

Kinesiology, Simon Fraser University, Burnaby, B.C. V5A 1S6.
Previous studies have shown a decrease in amplitude and an increase in duration of the M-wave during fatiguing concentric muscle contraction. This study examined the changes in the M-wave immediately after (post) and 24 hours following a series of maximal eccentric contractions. Nine male subjects performed an exercise regime of 100 maximal eccentric contractions with the FDI muscle in abduction-adduction. A maximal M-wave was elicited by supramaximal stimulation of the ulnar nerve proximal to the wrist joint and recorded with surface EMG electrodes placed over the muscle belly. Accurate repeated placement was ensured by marking the skin.

Peak to peak amplitude and peak to peak duration decreased significantly from the pre- to post-test (-23.6% and -11.8%, respectively; P-c.0.05). This decline in M-wave amplitude may have been the result of neuromuscular propagation failure which has been reported to occur during fatiguing concentric contractions. The M-wave was tested again 24 hours later. Peak to peak amplitude was found to have increased by 47.7% over the pre-test values (P-c.0.01). No significant differences were found in peak to peak duration or delay from stimulus to M-wave onset. Since maximal voluntary force was significantly lower than pre-test (-19%, P-c.0.01), it is unlikely that the M-wave potentiation was due to increased motor unit recruitment. Repeated high intensity eccentric contractions have been reported to cause damage to muscle fibers. We suggest that the M-wave potentiation was due to changes in membrane properties produced either directly or indirectly by the injury to muscle fibers. These findings may be useful in determining which fibers are most susceptible to injury during eccentric exercise.

MUSCLE FATIGUE IN INDIVIDUALS WITH HEALED BURNS, <u>S.W.Chau. D.M.M. St-Pierre*</u>. <u>M.Choinière and D.R. Garrel</u>. School of Physical and Occupational Therapy, McGill University, and Centre des grands brûlés, Hôtel Dieu de Montréal, Québec H3G1Y5, Canada.

The purpose of the study was to compare the effects of a submaximal intermittent isometric fatigue protocol of the quadriceps in individuals with healed burns (BURNS) versus healthy controls (CONTROLS). Seven subjects (40±11.9 y) with second and third degree burns (mean $44.2 \pm 12.3\%$ total body surface area, range of 35.0 to 67.3%) were evaluated at 53.4 ± 15.1 months (range 31 to 74) post-trauma. They were matched to five CONTROLS (43.2±12.9 y) of similar fitness level. The fatigue protocol consisted of two sets of 50% maximal voluntary contractions (MVC) held for 10s, with 3s ramps followed by a 4s rest. The inability to maintain the target level during the 10s hold marked the end of a set and 10 mins were allowed between each. All subjects performed contractions while seated with hips and knees flexed at 90°. Voluntary and evoked contractile properties were evaluated pre, post and during the two 10 min recovery periods. Preliminary data revealed that BURNS performed significantly fewer total contractions than CONTROLS (9.6±2.4 vs 13.0±2.3 respectively, p=0.04). The first set of fatiguing contractions produced similar changes in MVC, activation as measured by the interpolated twitch technique, M-wave and twitch contractile properties, suggesting that the mechanisms underlying fatigue were similar in both groups. The second set of fatiguing contractions produced greater decreases in MVC in the BURNS (39.6 versus 32.9%, respectively, p=0.05,). However, BURNS also had a greater degree of inactivation (15.0 versus 5.9%, respectively, p=0.008). These findings suggest that the greater fatigue in the BURNS was associated with a decrease in central Funded by FRSQ-FPQGB and NATO. drive

RE-EVALUATION OF MUSCLE WISDOM USING PHYSIOLOGICAL STIMULATION RATES. <u>A.J. Fuglevand*</u>. John B. Pierce Laboratory, 290 Congress Ave., New Haven, CT 06519.

Motor unit discharge rates decline by about 50% over 60 s of a maximum voluntary contraction (MVC) from an initial rate of ~30 Hz (Bigland-Ritchie et al. *J Physiol* 1983). It has been suggested that the decline in discharge rate functions to optimize force output by maintaining a match between activation rate and the changing mechanical properties of motor units and by protecting against conduction failure associated with prolonged high discharge rates (Bigland-Ritchie et al. 1983). This hypothesis, known as muscle wisdom, was based in part on studies in which muscle force was shown to decline more rapidly when stimulation was maintained at a high rate than when stimulus rate was reduced over time (Jones et al. *Exp Neurol* 1979). The stimulus rates used by Jones et al., however, were higher than that normally encountered during MVCs. The purpose of this study was to compare force loss under constant and declining-stimulus rate conditions using rates similar to those that occur during voluntary effort. Isometric force and surface EMG responses were recorded from human adductor pollicis in response to supramaximal stimuli delivered to ulnar nerve. Four fatigue tasks were performed on separate days: 1) stimulation at 30 Hz for 60 s, 2) stimulation decreased from 30 to 15 Hz over 60 s, 3) intermittent stimulation at 30 Hz, 330 ms, 1/s, for total of 1800 stimuli, 4) sustained MVC for 60 s. Immediately following each fatigue task, 2.5 s trains were delivered at 30 and 15 Hz. Force loss was greatest for the MVC condition (~60%) and similar across the three stimulation conditions (~40%). In all cases, change of stimulus rate from 30 to 15 Hz at the end of the fatigue task caused force to decrease (17±12%). These findings imply that diminution of discharge rate may not function to preserve force during fatigue. Supported by NIH grant AR 42893.

INCOMPLETE MUSCLE ACTIVATION AFTER TRAINING.

T.Hortobágyi*, K.Scott, N.Lambett†, J.Hill†, and C.Webb†.

Biomechanics Lab and †Dept. of Physical Therapy, East Carolina
University, Greenville, NC 27858.

One aspect of neural adaptation to exercise is an increase in muscle activation allowing for greater strength following training. Because eccentric contractions and electromyostimulation (EMS) tend to preferentially recruit large motor units, we postulated that training with voluntary eccentric or with EMS-evoked eccentric contractions should result in complete muscle activation. Eighteen women (age 18-40 y) were randomly assigned to a voluntary (VOL), an EMS, or a control group. VOL and EMS groups trained the quadriceps muscle at the same but increasing force levels for 6 wks, 4/wks using voluntary eccentric or EMS-evoked eccentric contractions. The Table shows the results (mean ±SD in N, * p < .05). Because EMS-evoked forces exceeded maximal

Training	Test mode	Pre	Po	st	Δ	$-\%\Delta$
VOL	VOL	456 7	617	158	161	35*
	EMS	238 123	5 310	128	72	30*
	Ratio (%)	57 3	4 51	17	-6	
EMS	VOL	505 9	7 605	108	100	20*
	EMS	277 80	615	85	338	122*
	Ratio (%)	58 1.	3 120	40	62	

voluntary forces after training in the EMS group (120% for the ratio), voluntary muscle activation was not complete after training. Even if one becomes trained, an inhibitory mechanism may protect muscles and joints from excessive forces during eccentric contractions.

Supported in part by NICHD-30422.

OLDER ADULTS EXHIBIT A REDUCED ABILITY TO MAXIMALLY ACTIVATE THEIR ELBOW FLEXOR MUSCLES. G.H. Yue*, S.J. De Serres and R.M. Enoka. Department of Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, OH, 44195.

Reorganization of the sensorimotor system due to aging results in a reduction in the maximal muscle force that can be voluntarily produced by older adults. Although a decrease in muscle mass contributes significantly to the decline in muscle force, little is known about whether the neural command for a maximal voluntary contraction (MVC) is adequate to achieve full muscle activation. The purpose of this study was to determine the ability of elderly subjects to maximally activate their biceps brachii muscle using the twitch interpolation technique. This method consisted of delivering a supramaximal electrical stimulus to the muscle while an MVC was sustained. Two groups of volunteers (young adults, <35 yrs; older adults, >65 yrs) performed isometric MVCs with the elbow flexor muscles of the left arm. Each maximal contraction lasted for about 3 seconds during which a short train of supramaximal stimuli (10 pulses at 100 Hz, 0.1-0.3 ms in duration) was applied to the biceps brachii muscle. All the elderly subjects demonstrated an inability to fully activate their biceps brachii muscle. In contrast, 38% of the young subjects were able to maximally activate their The remaining young subjects showed a comparable deficit in voluntary activation to the elderly subjects. These findings suggest that an inability to achieve a full muscle activation is among the physiological changes seen in the aging sensorimotor system Supported by a NIH grant (AG 09000-04) to RME.

SYNAPTIC PLASTICITY IN A POPULATION OF NEUROMUSCULAR JUNCTIONS. S. A. Jaboori and R. S. Manalis*. Department of Biology, Indiana University-Purdue University Fort Wayne, IN 46805.

In order to study synaptic plasticity in populations of neuromuscular junctions, a paired-pulse stimulus protocol was used to indirectly stimulate pharmacologically blocked frog <u>cutaneous pectoris</u> nerve-muscle preparations. Blockade was achieved either presynaptically with high Mg*(3.0 mM) - low Ca**(0.3 mM) Ringer's or postsynaptically with curare (2 µM) in normal Ringer's. Synaptic plasticity, or, more specifically, facilitation, was used to describe the increase in the TEST response relative to that of the CONDITIONING response. The amplitude of the test response divided by that of the conditioning response yielded a T/C ratio, which was our measure of facilitation. In either case, the T/C ratio was maximal at short interpulse intervals (5-30 msec) whereas it decreased toward unity as the interval approached 1000 msec. Comparison of contractile and EPP ratios illustrates: 1) the time courses of facilitation are very similar and 2) contractile ratios are considerably greater than are EPP ratios. For contractile ratios, some members of the motor unit population were close to threshold upon the arrival of the conditioning stimulus, and some of them were recruited to contract when the test stimulus arrived. Changes in synaptic plasticity occurring within a population of nerve-muscle synapses is an example of integrative physiology.

PRELIMINARY ANATOMIC EVIDENCE OF PARTITIONING IN THE MUSCLES OF THE ANTERIOR COMPARTMENT OF THE HUMAN LEG, B.W. Bakkum*, K. Russell, T. Adamcryck and M. Keyes. The National College of Chiropractic. Lombard, II. 60148.

College of Chiropractic, Lombard, IL 60148. Many mammalian muscles appear to be partitioned into neuromuscular segments. Each segment of a muscle is a subvolume of fibers that is innervated by an individual muscle nerve branch and contains motor unit territories with a unique array of physiological characteristics. The muscles of the anterior compartment of the human leg have not been investigated for anatomic evidence of these neuromuscular segments. From each of 10 embalmed adult cadavers, one leg (4 - right, 6 - left) was dissected to expose the muscles of the anterior compartment and the branches of the deep fibular nerve. Perimysium consistently partitioned the tibialis anterior (TA) muscle into three segments: lateral longitudinal, medial longitudinal and oblique. The extensor digitorum longus (EDL) and extensor hallucis longus (EHL) muscles each had two segments: longitudinal and oblique. The fibularis tertius muscle had a muscle belly distinct from EDL and a separate nerve branch in 40% of the legs. Muscle nerve branches to each of the longitudinal segments of TA were found to arise consistently, with one exception, from the recurrent genicular nerve. A branch to the oblique segment of TA was found in 70% of the legs. Branches to both segments of EDL were consistently located. Branches to the longitudinal and oblique segments of EHL were found in 80% and 90% of the legs, respectively. These results show that there is gross anatomic evidence of three neuromuscular segments in TA and two segments each in EDL and EHL. Supported by Natl. Coll. Chiro.

EFFECTS OF DIFFERENT MECHANICAL ACTIVATION PATTERNS ON THE FUNCTIONAL PROPERTIES OF INACTIVE SOLEUS MUSCLES. <u>V. H. Zhong, R. R. Roy* J. A. Hodgson, E. J. Grossman and V.R. Edgerton.</u> Brain Research Institute and Dent Physiological Science. UCL A. LA. CA 90095.

Research Institute and Dept. Physiological Science, UCLA, LA, CA 90095.

Inactivity was produced in the soleus muscle of adult, female cats via spinal isolation (SI), i.e., complete cord transections at T12-13 and L7-S1 and bilateral deafferentation between the transection sites. After 1 week of recovery, mechanical activity was imposed via maximum stimulation of the soleus nerve at 40 Hz for 300 ms, once/sec for 30 min/day, 5 days/week during either the lengthening (SI-L) or shortening (SI-S) phase of a simulated step cycle or isometrically (SI-I). Tendon force measurements verified maximum muscle stimulation. After 4 months, the mass, maximum tetanic tension (Po), tension produced at 20 Hz (P20), isometric contraction time (CT), maximum velocity of shortening (Vmax) and fatigue index (FI) for each experimental group expressed as % of control were:

Group (n)	mass	Po	P20	CT	Vmax	FI
	(g)	(g)	(g)	(msec)	(mm/sec)	
(a) SI (13)	33±2b,c,d	17±1b,c,d	12 ± 1 b,c,d	56±6	179±12 ^d	93±2
(b) SI-S (12)	55±4a	33±3a,d	25±3a,d	58±3	158±13 ^d	99±5
(c) SI-L (11)	53±3a	46±4a	32±4a	61±4	194±10 ^d	102±2
(d) SI-I (13)	63±3a	47±3a,b	41±3a,b	54±3	115±6a,b,c	89±3

(Letters indicate a significant difference from that group at P < 0.05. All values except for the Vmax for S1-1 and all FI were different from normal control) Thus inactivity resulted in a dramatic loss of force generating potential and a shift towards faster velocities of shortening, whereas the fatigue properties were unaffected. All mechanical interventions ameliorated the loss in mass and force potential, whereas only the isometric regime had a significant effect on Vmax. These data suggest that short bouts of high-load, isometric contractions were, in general, the most efficacious in maintaining the normal functional properties of inactive soleus muscles. Supported by NIH Grant NS16333.

NEUROMUSCULAR COMPARTMENTS OF THE MASSETER MUSCLE PRODUCE UNIQUE FORCE TRAJECTORIES. <u>A.W. English* and C.G. Widmer</u>. Dept. Anat. Cell Biol., Emory Univ., Atlanta GA 30322 and Dept. Oral Surgery, Univ. Fla., Gainesville FL 32610

The rabbit masseter contains at least 25 neuromuscular compartments. To determine the mechanical effect of activating different compartments, they were activated using visually guided intramuscular microstimulation. Reaction forces were measured using a multiaxis force moment transducer mounted via two pins attached to small drill holes in the sides of the mandible. Evoked EMG activity was recorded from multiple sites to document the very localized nature of the contractions. Each compartment produced a jaw closing force of different magnitudes, but each also produced significant ipsilateral (working) or contralateral (balancing) forces relative to the side of stimulation and also moved the mandible rostral (protrusion) or caudal (retrusion). The relative contributions of these three components determines the resultant trajectory of force. Each compartment produced a relatively unique trajectory of force. In the coronal plane, the range of trajectories associated with different compartments is greater than 90°. Our results are consistent with our previous hypothesis that each neuromuscular compartment exerts a distinct mechanical effect on the skeletal system. We propose that the neuromuscular compartments of the rabbit masseter form elements by which the nervous system interacts with the musculoskeletal system to bring about precise control of movements of the mandible. Supported by DE11536 (AWE), HD 32571 (AWE), DE00333 (CGW), and DE10130 (CGW) from the USPHS.

VELOCITY SENSITIVITY OF SHORT-RANGE STIFFNESS AND YIELD OF HETEROGENEOUS MUSCLES IN THE CAT. C.M.J.I Huyghues-Despointes*, T.A. Abelew and T.R Nichols. Department of Physiology, Emory university, Atlanta, GA 30322, USA. The responses of intact cat solcus (SOL) to ramp stretches resemble the

responses obtained from the type I single muscles fibers of which this homogeneous muscle is composed. The intrinsic mechanical properties of heterogeneous muscles, such as flexor hallicus longus (FHL), are expected to also reflect the properties of its active muscle fibers and their underlying cellular mechanisms. Preliminary data show that some type II muscle fibers exhibit velocity-dependent short-range stiffness (SRS) and yielding (Malamud et al., J. Neurophysiol., in press). However, the velocity sensitivity could be masked by the filtering properties of the in-series tendon. Since the mechanical properties of a heterogeneous muscle have not been explored, we hypothesized that any velocity sensitivity of short-range stiffness (SRS) and yield expressed by single muscle fibers should also be apparent in the intact muscle. To test this hypothesis we stretched cat FHL and SOL at different velocities and different lengths of in-series tendon in anesthetized or decerebrate cats. Muscles were electrically or reflexly activated. Regardless of the length of the tendon, the heterogeneous FHL muscle expressed a distinct yield which is not characteristic of most type II single fibers. As expected, the SRS of both hetero-and homogeneous muscles was consistently higher when the muscle tendon was shortened. We found no velocity sensitivity of SRS in either muscle. Our results confirm the linearity of the response during the short-range period, further validating the assumption that prior to yield the muscle-tendon unit behaves much like a spring. However, following the yield point, the response becomes highly non-linear (Supported by NS 20855 and HD 32571)

EXPRESSION OF AN ALTERNATIVELY SPLICED ISOFORM OF NITRIC OXIDE SYNTHASE IN DIFFERENTIATED SKELETAL MISCLE

F. Silvagno, H. Xia and D.S. Bredt*. Dept. of Physiology, Univ. of California at San Francisco Sch. of Med., San Francisco, CA 94143

In skeletal muscle the calcium-dependent, neuronal form of nitric oxide synthase (nNOS), is membrane bound and strictly associated with the dystrophin glycoprotein complex. The nNOS mRNA in muscle differs from the typical neuronal form because of a 102-base pair cassette inserted by alternative splicing between exons 16 and 17. A polyclonal antibody specific for a peptide encoded by the alternative splice has been developed. Western blotting indicates that this novel muscle isoform, nNOSµ, occurs only in skeletal and cardiac muscles. nNOSµ expression appears only after the fusion of myotubes in primary culture. The catalytic activity of nNOSµ, expressed in transfected COS cells, is similar to that of the neuronal isoform. A peptide from the alternatively spliced cassette is phosphorylated in vitro by a calmodulin-dependent kinase (CamK), and this may modify the catalytic properties of the enzyme. Interestingly, among the substrates for CamK in muscle are dystrophin and the sarcoplasmic reticulum calcium channels, suggesting a simultaneous regulation of NOS and these proteins by phosphorylation.

SPHINGOSYLPHOSPHORYLCHOLINE-INDUCED CALCIUM MOBILIZATION AND CELLULAR PROLIFERATION IN PORCINE VASCULAR SMOOTH MUSCLE CELLS. M.-Y. Ho*, T.-Y. Chin and S.-H. Chueh Biochemistry Dept. National Defense Medical Center, Taipei, Taiwan.

Sphingolipid metabolites, including sphingosine, sphingosine-1-phosphate (S-1-P) and sphingosylphosphorylcholine (SPC) have recently been implicated as lipid mediators in signal transduction pathways. We have investigated the SPC-induced cell proliferation and calcium mobilization in porcine aortic vascular smooth muscle cells (VSMC). Cytosolic [Ca2+], was monitored by fluorescence indicator, fura-2. As previously reported, unchallenged VSMC were found to fall into one of two functionally distinct groups: those with stable [Ca2+]; and those with spontaneous oscillating [Ca2+]; with various onand-off times that might reflect the intrinsic properties within each and every VSMC. Application of SPC elicited a fast rise in [Ca2+]; in a dose-dependent manner with apparent EC₅₀ at 0.5 μM and 1 μM in the presence and absence of extracellular Ca2+, respectively. SPC-induced [Ca2+]; elevation was unaffected by ryanodine or ER CaATPase blocker, thapsigargin (TG); yet was diminished by application of 2 mM caffeine or preincubation with 50 ng/ml PTX. SPC was also found to stimulate quiescent cell growth of VSMC and syngeristically enhanced PDGF-induced cell proliferation by 1.8 folds. The data indicates that SPC is a potent mitogen and mobilizes Ca2+ from caffeine-sensitive Ca2+ store via a PTX-sensitive G protein pathway in porcine VSMC

DEHYDRATION ATTENUATES FLEXOR MUSCLE CONTRACTILITY IN ACUTE LEAD-TREATED MICE. M.A. Fahim', F. El-Sabban, F.S. D'souza and S. Singh. Dept. of Physiology, Faculty of Medicine, U.A.E. University, P.O. Box 17666, Al Ain, United Arab Emirates.

Effect of water deprivation for 24 h on skeletal muscle contractility of lead-treated mice was investigated. Exposure to lead was made by i.p. injections for 24 h of lead acetate dissolved in a 5% glucose solution. Three doses of lead were used: low, 0.1; intermediate, 0.5 and high, 1.0 mg/kg. Comparative analyses of insitu muscle isometric contractile characteristics were studied in urethane-anesthetized (2 mg/g, i.p.) control and lead-exposed in both hydrated and dehydrated male mice. In hydrated mice, acute lead treatment did not affect muscle contraction characteristics. However, water deprivation for 24 hr. brought about reduction of twitch tension by a factor of 4, compared to hydrated control animals. In dehydrated animals, control muscle twitch tension reached 3.64 ± 0.14q. Under dehydration condition, lead treatment did not affect muscle contractile speed, but significantly reduced the twitch tension in all three lead-treated groups. The recorded twitch tension values were: 1.68 \pm 0.27, 1.74 \pm 0.06 and 1.83 \pm 0.01g for low, intermediate and high dose, respectively. There was a marked elevation in the tetanic tension in all lead-treated animals, which indicated changes in the contractile apparatus function. These results revealed that acute lead treatment had no effect, but concurrent dehydration significantly (P< 0.01) affected contractile strength of the skeletal muscle.

INCREASED CHLORIDE CONDUCTANCE IN CULTURED TRISOMY 16 MOUSE TONGUE MUSCLE SUGGEST A MECHANISM FOR THE HYPOTONIA IN DOWN SYNDROME S. Peng*, S. Rapoport, R. Pearce, and Z. Galdzicki Lab of Neuroscience, NIA, NIH, Bethesda, MD 20892

Trisomy 16 (Ts16) mouse is a genetic animal model of Down syndrome (DS; human trisomy 21, Ts21). DS patients develop hypotonia in striated muscle, including tongue. A whole-cell patch-clamp method was used to study membrane properties of isolated mouse embryonic Ts16 and diploid control tongue muscle cells in primary culture. Recordings were obtained using physiological solutions from colcemid induced myoballs. Membrane resistance ($R_{\rm m}$) and capacitance ($C_{\rm m}$) were measured from a holding potential of -60 mV. Mean Ts16 $R_{\rm m}$ was 369 M Ω (SEM, ± 31 : n=26), whereas control $R_{\rm m}$ was 505 M Ω (SEM, ± 38 ; n=33). Thus the mean Ts16 $R_{\rm m}$ was significantly reduced (27%) as compared to control. However, we did not detect a significant difference in $C_{\rm m}$ between the two groups of cells. In addition, we applied depolarizing voltage steps to elicit total membrane current. The mean normalized maximum outward conductance ($G_{\rm max,cur}/C_{\rm m}$) was 491 pS/pF (SEM, ± 58 ; n=25) and 840 pS/pF (SEM, ± 78 ; n=33) for Ts16 and control, respectively. This 42% reduction in $G_{\rm max,cur}/C_{\rm m}$ was significant. However, no significant difference in inward current or conductance was found. Direct measurements of C1 current showed that the mean of $G_{\rm max,cr}/C_{\rm m}$ was 103 pS/pF (SEM, ± 10 n= 25) and 68 pS/pF (SEM, ± 6 n=25) for Ts16 and control cells, respectively. Alterations in membrane excitability as a result of this increased C1 conductance could contribute to the hypotonia in DS.

IMMUNOCYTOCHEMICAL AND ELECTROPHYSIOLOGICAL CHARACTERIZATION OF CONDITIONALLY IMMORTAL HUMAN SKELETAL MUSCLE CELLS, I. Deschênes, J. Puymirat and M. Chahine*. Laval Hosp. Research Center and CHUL, Laval Univ. Fac. Med., Sainte-Foy, Quebec, Canada. Primary human muscle cells culture is a good experimental tool but has a lot of limitations. The use of human muscle immortalized cell lines is a good alternative.

In this study, we immortalized human skeletal muscle cells using the human vimentin promotor controlling the expression of a SV40 thermosensitive T antigen. Human myoblasts were obtained from a postmortem biopsy and purified by limiting dilution. Isolated cells were transfected with a plasmid vector encoding the SV40 T antigen. We characterized those immortalized cells by immunocytochemistry and electrophysiology. Normal immortalized cell lines proliferate in dividing medium at 34°C and differentiate into myotubes in differentiating medium by increasing the temperature to 39°C Myoblasts expressed vimentin and desmin, and myotubes expressed several markers of differentiation (dystrophin, carbonic anhydrase II and fast myosin heavy chains). The immortalized cells were also characterized electrophysiologicaly using the patch-clamp technique. Sodium currents were recorded from both myoblasts and myotubes (myoballs). On myoballs, 100nM (tetrodotoxin) TTX induced a reduction of 90.6% of the amplitude of the current. On myoblasts, at $1\mu M$ of TTX, we observed a reduction of only 20.7% of the amplitude of the current. Those results show that these sodium currents are comparable to what was reported in primary skeletal muscle cells where two types of sodium channels coexist: insensitive to TTX in early development and sensitive in adult form. Those data suggest again that immortalized human skeletal muscle cells do differentiate. We also recorded from those cells a sustained potassium current sensitive to tetraethylamonium (TEA). The immortalization of skeletal muscle cells from human deseased muscles was also succesfull. Our results suggest that immortalized cells may represent a strong model to study the molecular mechanisms of muscle dystrophy. Supported by the Association Française contre les Myopathies.

DEGENERATION AND RE-INNERVATION OF SUBSTANCE P-LIKE IMMUNOREACTIVE NERVES TO THE CARDIAC MUSCLE OF THE MONKEY (MACACA FASCICULARIS) AFTER BILATERAL VAGOTOMY. S.S.W. TAY and W.C. WONG*. Department of Anatomy, National University of Singapore, Singapore 119260.

Bilateral vagotomy has a drastic effect on substance P-like immunoreactive (SP-IR) nerves innervating the cardiac muscle. At 1 week postoperation, fragments of SP-IR nerve fibres were observed in the interstitial spaces between cardiac muscle fibres. A few macrophages were present in the vicinity of the degenerating SP-IR nerve fibres had disappeared. However, the muscle fibres appeared to be normal At 6 months postoperation, there was re-innervation of the cardiac muscle fibres by SP-IR nerve fibres. Fine varicose and non-varicose nerve fibres were observed to traverse towards the cardiac muscle fibres. A few scattered macrophages could still be observed. By 12 months postoperation, numerous fine varicose and non-varicose nerve fibres were seen in the interstitial spaces between individual or groups of cardiac muscle fibres. These fine nerve fibres formed reticulated networks, similar to those seen in the sham-operated control animals. It is concluded that there is re-innervation of the cardiac muscle fibres by SP-IR nerve fibres in long term bilaterally vagotomized monkeys. The origin of these SP-IR nerve fibres remains unknown.

INNERVATION-INDEPENDENT TRANSCRIPTIONAL REGULATION OF THE ACETYLCHOLINESTERASE GENE IN ADULT SKELETAL MUSCLE FIBERS. C. Boudreau-Larivière*, R.Y.Y. Chan, F.A. Mankal and B.J. Jasmin. Department of Physiology, University of Ottawa, Ottawa, Ontario, Canada, K1H 8M5.

mRNAs encoding acetylcholinesterase (AChE) are highly concentrated within the postsynaptic sarcoplasm of adult skeletal muscle fibers where their expression is markedly influenced by nerve-evoked electrical activity. To determine whether transcriptional regulatory mechanisms account for the localization and activity-dependent regulation of AChE transcripts, we examined the pattern of expression of the LacZ reporter gene driven by the functional rat AChE promoter (FRAP) along muscle fibers. Direct injection of FRAP-LacZ gene constructs into diaphragm and tibialis anterior (TA) muscles resulted in intense and widespread transgene expression in both muscles 7 to 42 days later. In diaphragm muscle, LacZ expression was observed near and away from the phrenic nerve region indicating that FRAP is capable of directing expression in both synaptic and extrasynaptic compartments. Analysis of cryostat sections further showed that expression of the transgene was confined to muscle fibers and confirmed similar transcriptional activity in synaptic and extrasynaptic regions. Deletion of a 600 bp fragment outside of the basal promoter region of FRAP abolished its transcriptional activity. Subsequent experiments revealed that the 600 bp fragment does not possess promoter activity. Similar results were obtained in vitro by transfecting these various constructs into C2 cells and monitoring histochemically and biochemically LacZ expression. In separate experiments, we examined by nuclear run-on assays transcriptional activity of the AChE gene in denervated muscles and showed that it remained essentially unchanged in comparison to controls despite a marked reduction in the levels of both 2.4 and 3.2 kb AChE transcripts. Taken together, these results suggest that transcription of the AChE gene in adentive timuscle fibers is largely innervation-independent. Furthermore, these findings are coherent with the notion that the AChE basal promoter requires an enhancer element for transcriptional activity in skeletal muscle fibers in vivo.

A THYROID HORMONE-DEPENDENT MECHANISM DIRECTS FIBER TYPE-SPECIFIC EXPRESSION OF FAST SKELETAL MUSCLE TROPONIN I IN TRANSGENIC MICE H. L. Bradshaw* and K. E. M. Hastings, Molecular Genetics Laboratory, Montreal Neurological Institute, McGill University, Montreal, P.Q. Canada H3A 2B4

We are using transgenic mice to study the developmental regulation of fiber typespecific contractile protein isoforms in skeletal muscle. We have studied the gene expression pattern in transgenic mice that carry an E.coli beta-galactosidase reporter construct (LacZ1) driven by promoter/enhancer elements of the quail troponin I gene (Tnl) of fast muscle. TnlLacZ1 is expressed only in skeletal muscle, and is further restricted to fast, not slow muscle fibers. During the first two weeks of postnatal life, TnlLacZ1 progresses from low level, equivalent expression in all fast fibers to a marked differential expression pattern that is correlated with the appearance of the three distinct adult fast fiber subtypes IIB, IIX, and IIA. The result is a striking range of TnlLacZ1 expression, ie. IIB > IIX > IIA. This differential expression is unexpected given that the endogenous Tnlfast gene shows equal expression in all three fast subtypes in the adult mouse. The results suggest that the adult levels of muscle gene expression are achieved by a two-step mechanism, ie. an initial gene activation in all fast fibers at or before birth followed by an augmentation of transcription to adult levels. In perinatal animals rendered hypothyroid by propythiouracil treatment, TnlLacZ1 expression remains at low, equal levels for up to 21 days. This result indicates that the augmentation of TnlLacZ1 gene expression in maturing IIB and IIX fibers involves a thyroid hormone-dependent mechanism. Thus, the TnlLacZ1 transgene has provided novel insight into muscle gene regulatory mechanisms. Our present efforts are focused on further characterization of this thyroid-dependent mechanism. SPECTRIN-BASED MEMBRANE SKELETON OF SKELETAL MUSCLE: EFFECT OF DENERVATION, M. Williams, N. Porter, D. Zhou and R.J. Bloch*, Departments of Physiology and Neurology, University of Maryland School of Medicine, Baltimore, MD 21201

We have used isoform-specific antibodies and confocal microscopy to learn how spectrins and ankyrins are organized at the sarcolemma and intracellular membranes of skeletal muscle. The spectrins are present at the sarcolemma of fast twitch fibers in a rectilinear lattice arranged over the Z and M lines of superficial myofibrils, and in longitudinally oriented lines. No spectrins are detected in the spaces between these lines. Slow twitch fibers, by contrast, have a less well-defined lattice in which it is harder to identify spectrin-free regions. Denervation of fast muscle alters the spectrin lattice to a pattern resembling that of slow fibers. Denervation of slow muscle has no obvious effect on its spectrin organization. The levels of expression of the spectrin proteins do not change significantly following denervation. Notably, \(\beta\)-fodrin, which is absent from adult muscle fibers but present in embryonic muscle, is not up-regulated by denervation.

Denervation also affects expression of ankyrin. An alternatively spliced product of the ankyrin 1 gene is normally expressed at higher levels in fast twitch than in slow twitch fibers. After denervation, this splice form of ankyrin decreases in fast twitch fibers and becomes almost undetectable in slow fibers.

EFFECT OF PERINATAL DENERVATION ON THE STRUCTURE OF CHICKEN LEG MUSCLE SPINDLES. <u>Alfred Maier</u>. Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL 35294.

Leg muscles of chickens were denervated by cutting the sciatic nerve 1-6 days after hatching. Muscles were examined for regenerating spindles during periods of recovery ranging from 1-8 weeks. There was variability in how muscles responded to denervation, presenting mild to severe deficits. Inflammatory infiltrate and conspicuous degenerative changes were recognized as early as 6 days after nerve section. The greatest number of degenerating spindles was observed 1-2 weeks after cutting the nerve. The fewest spindles were encountered 2-3 weeks after denervation when immunostaining for neurofilament was negative or weakest. By 5-8 weeks of regeneration the equatorial region was still more affected than the polar region. The volume of the periaxial space was greatly reduced, intrafusal fiber outlines were diffuse, and the perifibril sheath presented fetal characteristics. At polar regions there was some atrophy of slow and fast fibers, but myosin heavy chain profiles were not greatly altered, and the proportions of slow to fast intrafusal fibers were not significantly different from those in the intact contralateral muscles. In developing mammalian spindles sensory innervation is necessary for slow-tonic MHC to be expressed (Kucera and Walro, Histochemistry 90:151-160, 1988). Intrafusal fibers containing slow-tonic myosin heavy chain were present in the chicken spindles that had regenerated, suggesting that afferents reinnervated the spindles and induced slow-tonic myosin heavy chains; however, the general anatomy at the equator continued to show abnormal features, despite its presumed innervation by afferents. This supports the alternate view that afferent innnervation of chicken spindles is not the only formative factor. This argument is especially valid when considering that chicken extrafusal fibers have no sensory innervation, but also express slow-tonic myosin heavy chains

IN VIVO MONITORING OF CORTICAL NADH USING LASER-INDUCED FLUORESCENCE SPECTROSCOPY IN ANAESTHETISED RATS. A.REX*, K.SCHMALZIGAUG, F.FINK' and H.FINK institute of Pharmacology and Toxicology, Humboldt University, 10098 Berlin, FHTW, Warschauer Platz 6, 10245 Berlin, FRG. The nicotinamide adenine dinucleotide (NADH) is an important coenzyme for energy transfer in the mitochondrial respiratory chain and a parameter of cellular metabolism. NADH can be detected by fluorescence and various fluorometric methods have been developed. In this study a commercial laser fluorescence detector [LLA GmbH Berlin] was used to induce and measure NADH fluorescence on the cortical surface Berlin was used to induce and ineasure involve induces the office of the control assistance. The aim of the study was to assess the suitability of the laser induced fluorescence for *in vivo* and on line measurement of NADH in neuroscience.

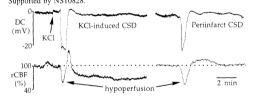

Preliminary tests using the vasodilator nitro-glycerine showed that an increased

blood flow in the brain increased not only NADH fluorescence but also the scattered light of the excitation pulse. Including a compensation factor for the scattered light the NADH fluorescence was corrected to exclude occurring hemodynamic artefacts. The effects of potassium cyanide and cortical spreading depressions (CSD) on cortical NADH fluorescence were determined. Potassium cyanide inhibits the mitochondrial respiratory chain at the cytochrome oxydase. Local administration of 1µmol potassium cyanide near the optic fibre resulted in a transient increase of NADH fluorescence. A single CSD is characterised by EEG disturbances accompanied by an initial excitation and then depression of cortical neurones. The occurrence and the time course of the CSD were determined by parallel registration of the cortical direct current slow potential. Single CSD induced by local application (1cm from the fibre) of 1.5µmol potassium chloride decreased cortical NADH fluorescence followed by a 5-10 minutes increase. These changes in NADH levels correspond with the excitation and inhibition of neuronal metabolism, respectively.

In summary, the measurement of NADH fluorescence using the laser technique allows the determination of changes in oxidative phosphorylation with high regional selectively and time resolution. This work is supported by the BMBF (Fkz. Fosped), the DFG (INK 21/A1-1) and the LLA GmbH Berlin.

A PRONOUNCED HYPOPERFUSION PRECEDES THE HYPEREMIA DURING KCI-INDUCED AND PERI-INFARCT CORTICAL SPREADING DEPRESSIONS IN MICE. M.A. Moskowitz. C. Ayata. M. Fujii, V. Limmroth*. Stroke and Neurovascular Res., Massachusetts General Hospital, Charlestown MA. 02129. We investigated the regional cerebral blood flow (rCBF) response to KCI-induced and spontaneous peri-infarct spreading depressions (CSD) in mice. rCBF was measured by laser Doppler-flowmentry and was coupled to DC potential recordings from the same cortical area by glass micropipettes. KCI-induced CSD was accompanied by an early and pronounced hypoperfusion (51±21% of baseline; ESD; n=5) simultaneous with the DC shift, after which rCBF increased to a peak (134±23%), followed by a prolonged hypoperfusion (67±4%). This prolonged hypoperfusion gradually and completely recovered within 40 min. Intraluminal filament occlusion of middle cerebral artery caused spontaneous peri-infarct CSDs (-9/hr; n=5) that spread in the nonischemic cortex. rCBF changes induced by perinfarct CSDs were similar to those induced by KCI including an initial hypoperfusion preceding the hyperemia. Our findings showed that rCBF response to CSD in mice is different from other species, including rats, in that it has a pronounced hypoperfusion that was highly reproducible. Therefore, in addition to the metabolic load imposed by CSD-induced ionic imbalances, the active vasoconstriction during CSD may result in a larger mismatch between the rCBF and the energy demand in ischemic penumbra. Supported by NS10828.

THE SPREADING DEPRESSION RELATED ISCHEMIC EVENT IS PARTIALLY ABOLISHED BY VASODILATORS J.P. Dreier, K. Körner, A. Görner, T. Back, U. Lindauer, A. Villringer, U. Dirnagl. Dept. of Neurology, Humboldt University, Berlin, German

We have recently reported the induction of a spreading depression (SD) related ischemic event (spreading ischemia, SI) by elevated cerebrospinal K* (20 mM) and NOS inhibition (1 mM L-NA) in a rat cranial window preparation. During SI the cerebral blood flow (CBF) sometimes declined to 10 % of the baseline and occasionally remained below 30 % for more than 20 min. Brain topical superfusion of the NO-donor SNAP did not block the SD but reduced the hypoperfusion. In this study we tested the effect of adenosine, papaverine, 8-bromo-cGMP, or nimodipine. We found that all vasodilators did not block the SD but reduced the hypoperfusion. Amplitude and duration of the SD related surface potential (SP) were reduced as well (fig.: CBF (upper trace) and SP (lower trace), a = 0 min: control, b = 180 min: superfusion of L-NA plus elevated K^+ , c = 240 min: L-NA plus elevated K^+ plus nimodipine. Note reduction of the hypoperfusion and SP by nimodipine). We conclude that the vascular tone is an important factor involved in the mechanism of SI. However, a short initial hypoperfusion always persists in presence of the vasodilator as can be seen in the figure. Only SNAP often blocks the initial hypoperfusion completely indicating differences between the early and later phases of

Psychology, CNR, Rome; *

Inst. of Neurology, Catholic University, Rome, Italy.

Diaschisis is currently used as a "cover" name to indicate different phenomena

of transitory postlesional functional impairment whose neurobiological substrates are at best ill-understood. A very common clinical evidence, that has deserved by clinicians the term of diaschisis, is the crossed modification of cerebral blood flow rate (CBFr) observed in cerebral cortex or cerebellum after focal cerebellar or not yet been elucitaded. The present study was aimed to investigate the neocortical neurochemical changes induced by cerebellar lesions. Under barbiturate anesthesia, adult rats underwent hemicerebellectomy by suction and were perfused one month after surgery. The metabolic activity in the cerebral cortex was evaluated by means of cytochromoxidase (CO) quantitative histochemistry, while nitric oxide (NO) expressing neuronal population was evidenced by NADPH-diaphorase (NADPH-d) histochemistry. Densitometric analysis of the CO reaction indicates that hemicerebellectomy produces oxidative neuronal activity depression in contralateral prefrontal and parietal cortices. In the same areas a significant reduction was observed in the number of NADPH-d positive neurons, as well as in the intensity of the NADPH-d reaction. Further analysis on CO and NADPH-d expression in frontal, temporal and occipital cortices are at present under processing. The present data demonstrate that unilateral cerebellar lesions in rat induce depression of the activity in functional related cortical areas. In light of the proposed role of NO as mediator in local CBRFr changes, the reported association between NADPH-d and CO reduction suggests NO neuronal system as a candidate in affecting postlesional CBRFr changes. ENDOTHELIN (ET) 2 OVEREXPRESSING RATS ARE RESISTANT TO THE ELICITATION OF CORTICAL SPREADING DEPRESSION (CSD) WHEREAS THEY PRODUCE NORMAL PERINFARCT DEPOLARISATIONS (PID) Reuter, U, Arnold, G., Wiegand, F., Lindauer, U., Liefeldt, L. Paul, M. Dirnagl, U.* Dept. of Neurology, Humboldt University, Berlin, and Dept. of Pharmacology, Free University, Berlin, Germany

ETs are potent vasoconstictor polypeptides, capable of blocking gap junction coupling in astrocytes (Giaume, Eur J Neurosci, 4:877:1992). Because CSD involves a cerebrovascular response (hyper-followed by hypoperfusion) and their propagation is thought to involve astrocytic gap junctions (Nedergaard, Science 263:1768: 1994) we investigated the characteristics of CSD in normotensive transgenic (tg) rats overexpressing human ET-2 in the brain. In addition, we characterized PIDs in ET-2 transgenic rats. PID is a CSD like phenom occuring after focal cerebral ischemia linked to ischemic tissue damage. CSD was induced by KCl application on the dura mater over the frontal cortex in pentobarbital anesthetized rats. Two calomel DC-electrodes were positioned on the dura mater fronto-parietally (together with a laser Doppler flowprobe, LDF) and parieto-occipitally. In the wildtype animals (n=5) typical CSDs were elicited by KCl application (neg. DC potential, CBF-hyperemia). In contrast, in ET-2 tg rats (n=5) no CSDs (DC or CBF) could be elicited. Even when cortical pin prick was used as a stimulus, CSD could only be elicited in 2 of 5 tg rats, in which it did not propagate to the distant DC-electrode. In contrast, after induction of focal cerebral ischemia by distal middle cerebral artery occlusion combined with bilateral common carotid artery occlusion in halothane N_2O anesthetized rats, both wild type (n=4) and tg rats (n=3) showed spontaneous PIDs which propagated from one DC electrode parieto-frontally (over the penumbra) to one located parietooccipitally (no LDF measurement). In summary, ET-2 tg rats are resistant to the elicitation of CSD, whereas they produce normal PIDs. We speculate that ET mediated blockade of gap junctions prevents CSD propagation and that CSD and PID propagate by different mechanisms

437.6

NITRIC OXIDE (NO) IS A PERMISSIVE FACTOR IN THE REGIONAL CEREBRAL BLOOD FLOW (RCBF) RESPONSE TO WHISKER DEFLECTION IN THE RAT. T.Wolf, J.Schulz*, O.Peters, C.Busch, F.Wiegand, U.Dirnagl

U.Lindauer Dept. of Neurology, Humboldt University, Berlin, Germany.
Nitric oxide (NO) is involved in the coupling of the rCBF response to neuronal activation (for review see Iadecola, Trends Neurosci 16:206-214, 1993). Recently several studies have challenged the role of NO as a mediator, and proposed a modulatory function. It has been shown that the vasodilation to hypercapnia (Iadecola et al., Am J.Physiol 267:R228-R235) and extracellular potassium (Dreier et al, J.Cereb.Blood Flow Metab.15:914-919), when attenuated by NO synthase (NOS) inhibition, can be restored by NO donors. We investigated the role of NO in the coupling of rCBF to somatosensory stimulation. In 5 α-chloralose anesthetized Wistar rats, equipped with a closed cranial window (dura mater removed) over the whisker barrel cortex, rCBF responses to mystacial vibrissae deflection (2-3x/sec, 60 see stimulation period) were measured with laser-Doppler flowmetry (LDF). After attenuation of the CBF responsc due to topical NOS inhibition (L-NA, 10^3 M), the NO donor SNAP (5×10^3 M in 10^3 M L-NA) or SIN-1 (10^5 M in 10^3 M L-NA) was superfused over the cortical surface. CBF responses (% of resting flow) were significantly reduced during NOS inhibition from 17.7±2.5 % to 7.1±2.8 % and increased again during SNAP application to 12.9±1.2 %. An example with SIN-1 is shown in the figure

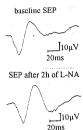

The results suggest a permissive function for NO in the coupling of the rCBF response to somatosensory stimulation in the rat. (Supported by the DFG).

NITRIC OXIDE SYNTHASE (NOS) INHIBITION DOES NOT AFFECT SOMATOSENSORY POTENTIALS (SEPS) EVOKED BY WHISKER DEFLECTION IN THE RAT. U.Lindauer*, J.Schulze, D.Megow, U.Dirnagl. Dept. of Neurology, Humboldt University, 10098 Berlin, Germany.

Nitric oxide (NO) is involved in cerebrovascular regulation and neurotransmission.

Ngai et al. (Am.J.Physiol.269:H1803-H1810, 1995) described a suppression of SEPs evoked by electrical sciatic nerve stimulation due to NOS inhibition in the rat. They concluded that NOS-inhibition reduces cerebrovascular responses by suppression of neuronal activity. We investigated the influence of NOS inhibition on neuronal activity during whisker deflection. In 6 rats a closed cranial window (dura mater removed) was implanted over the right whisker barrel cortex with a silver ball-tip electrode positioned over the pial surface. After switching anaesthesia from halothane/N₂O to α-chloralose-urethane, single contralateral whisker hairs (2-3, same row)

were continuously deflected (3 Hz). 100 consecutive SEPs were averaged, using a Nihon Kohden Neuropack Moni-tor. NOS inhibition was induced by brain topical superfusion of 10-3 M L-Nitroarginine (L-NA) for 2 hours and SEPs were recorded 0.5, 1, and 2h after start of L-NA application. During NOS inhibition (NOS activity was inhibited by 85±9 %, measured by citrulline conversion HPLC assay) SEPs did not change, neither in amplitude (57±25 μV at baseline, 59±27 μV at 0.5h, 56±28 μV at 1h, $57\pm28~\mu V$ at 2h of NOS inhibition), nor in latency. A typical example is given in the figure. We conclude that inhibition of NOS in the cerebral cortex, which significantly reduces regional cerebral blood flow responses, does not change neuronal activity due to whisker deflection. (Supported by the DFG)

437.9

INHIBITION OF NITRIC OXIDE SYNTHASE ATTENUATES BLOOD FLOW INCREASE EVOKED BY CLIMBING FIBER ACTIVATION IN CEREBELLAR CORTEX. N. Akgören*, I. Rubin and M. Lauritzen. Dept. of Med. Physiol.and Dep.of Biochem., Univ. of Copenhagen; Dept. of Clin.

Neurophysiol. Glostrup Hospital, Denmark.

In this study, we examined the laminar profile of CBF changes after stimulation of climbing fibers (CFs) by harmaline injection and after stimulation of parallel fibers (PFs) by local electrical stimulation. Inhibition of nitric oxide (NO) synthase (NOS) by N° -nitro-L-arginine (L-NNA) attenuates the PF-evoked CBF rise. Harmaline increases cGMP levels of cerebellar cortex that may be related to NOS activation. Therefore we investigated the effect of NOS inhibition on the CBF rise evoked by harmaline stimulation in halothane-anesthetized and artificially ventilated trats. CBF was monitored by laser-Doppler flowmetry using a combination probe holding four combinations of wavelength and fiber separation to record CBF in four different depths in cerebellar cortex. NOS activity was blocked by topical application (1mM) and/or local injection of 300 nl (20 mM) of L-NNA

Harmaline (40mg/kg i.p) induced a uniform CBF increase by 99-136% Harmaline (40mg/kg i,p) induced a uniform CBF increase by 99-136 % in all layers of cerebellar cortex, whereas stimulation of PFs increased CBF by 48 ± 8 % mainly in the upper layers. The latency to onset of harmaline induced CBF increase was 15-20 min and the evoked CBF increase was maximal for 0.5-1 h and then gradually declined to baseline values in the following 1-3 h. Local application of TTX (20 µm) abolished both PF- and CF-evoked CBF rises. NOS activity increased by 20 % after harmaline injection (p>0.05). L-NNA inhibited NOS activity by 90 % (p<0.05) and attenuated harmaline-evoked CBF increase by 60-70 % in the upper layers gradually declining with depth. PF-evoked CBF increase was attenuated by 40-60 %. These findings suggest that different input systems (CFs and PFs) ending on the same target cell share similar mechanisms in coupling of neuronal activity to CBF.

NITRO-L-ARGININE-SENSITIVE REGIONAL CBF AUGMENTATION DURING HYPERCAPNIA IN MICE WITH TYPE III NITRIC OXIDE SYNTHASE GENE DELETION J.Ma*, W.Meng, C.Ayata, P.L.Huang, M.C.Fishman, M.A.Moskowitz Stroke and Neurovascular Regulation Lab & Cardiovascular Research Center, MGH, Harvard Medical School

We investigated the regional cerebral blood flow (rCBF) changes during hypercapnia (5%CO₂) and the effects of L-NA in SV-129 (Wt, n=12) and hypercapnia (5%CO₂) and the effects of L-NA in SV-129 (Wt, n=12) and type III NOS deficient mice (n=14) under controlled physiological conditions and urethane anesthesia. We measured rCBF by laser-Doppler flowmetry over a closed cranial window. Resting rCBF decreased by ~25% at 60min after topical L-NA (1 mM) superfusion in wild-type mice only. Hypercapnia augmented rCBF approximately 50% in both wild-type and type III NOS mutant mice. L-NA superfusion (1mM, 60min) inhibited this increase by approximately 60% in both strains. Our results suggest that: (1)NO partially mediates hypercapnic rCBF increase in both wild type and type III NOS mutant mice, (2) type I NOS, but not type III NOS, mediates the rCBF response to hypercapnia in both wild type and type III NOS mutant mice, (3) NO generated by type III NOS contributes to resting rCBF during normocapnia in the wild type mouse.

normocapnia in the wild type mouse.

NEURONAL NITRIC OXIDE IS CRITICALLY INVOLVED IN CEREBRAL CAPILLARY FLOW RESPONSE TO HYPOXIA. A. G. Hudetz* B. Biswal, J. D. Wood, J. P. Kampine, Department of Anesthesiology, Medical College of Wisconsin, Milwaukee, WI 53226. Nitric oxide (NO) has been suggested to play a role in cerebral hyperemic response to hypoxia. Whether NO synthase (NOS) containing neurons may selectively regulate blood flow in cerebral capillaries under hyperemic response to hypoxia. Whether NO synthase (NOS) containing neurons may selectively regulate blood flow in cerebral capillaries under normoxic and hypoxic conditions has not been elucidated. We determined the effect of selective neuronal NOS inhibitor 7-nitroindazole (7-NI) on cerebrocortical capillary flow velocity and its response to moderate hypoxia. Capillary circulation of the right parietal cortex was studied using epifluorescence video-microscopy through a closed, perfused cranial window in pentobarbital-anesthetized, artificially ventilated (30% O₂ in N₂), adult male Sprague-Dawley rats. The velocity fluorescently labeled red blood cells (V_{FRBC}) in individual capillaries was measured from 1-minute long video recordings using frame-by-frame analysis. Hypoxia was achieved by lowering the inspired O₂ concentration to 15% for 5 minutes; the arterial pressure was maintained with methoxamine. A separate group of rats was treated with 7-NI, 20 mg/kg ip., and the response to hypoxia was tested 45 minutes later. 7-NI decreased V_{FRBC} from 0.72±0.06 to 0.64±0.05 mm/s (-11%, p<0.001, N=7). Repeated injections of the NO donor MAHMA-NONOate (10 M) under the cranial window produced transient, 2-3-fold increases in V_{FRBC}. In the control group, V_{FRBC} increased during hypoxia from 0.64±0.06 to 0.85±0.09 mm/s (+34±7%, p<0.001, N=7). In the 7-NI treated group, V_{FRBC} failed to increase in hypoxia (0.64±0.05 to 0.58±0.04 mm/s, -7±3%, p<0.05, N=7). These results suggest that neuronal NOS is involved in the maintenance of red blood cell flow in the cerebral capillaries and that NO from neuronal NOS plays a critical role in the cerebral capillaries on the Nos on defrate hypoxia. NITRIC OXIDE SYNTHASE (NOS) INHIBITION SUGGESTS THERE ARE REGIONAL DIFFERENCES IN THE ROLE OF NITRIC OXIDE (NO) IN CBF AUTOREGULATION IN NEWBORN PIGLETS. J. T. Berkenbaugh, Jr., J. J. Palacino, A.-L. Sirén* and J. T. O'Neill Uniformed Services Univ. of Health Sciences, Bethesda, MD 20814

We examined the effect of NOS inhibition with Nω-nitro-L-arginine methyl ester (L-NAME, 50 mg/kg) on total brain and regional blood flows (mL/min/100g) measured by microsphere technique in 12 piglets (<14 d) at baseline and at elevated MAP obtained by aortic occlusion and/or norepinephrine infusion. Cerebral perfusion pressure (CPP) was increased from baseline to 111±2 mmHg in Control (CON) group (n=6), and to 110±3 mmHg in L-NAME (n=6). Cortical gray blood flow increased (65 \pm 8 to 119 \pm 20) in CON but not in L-NAME (52 \pm 4 to 47 \pm 2). Blood flow (BF) to cerebrum increased in CON (52±11 to 74±15) but not in L-NAME (43±4 to 37±4). Brainstem BF remained constant in CON, but medulla-pons BF decreased in L-NAME (52±5 to 38±3) as CPP was increased. Oxygen uptake of the cerebrum was not different between groups. These results indicate that NOS inhibition attenuates increased BF to the cerebrum and cortical gray matter, and may contribute to a decrease in brainstem BF, when CPP is increased in newborn piglets. NO production may contribute to forced vasodilation and breakthrough of autoregulation in the cerebrum and cortical gray matter, and NO may also contribute to the maintenance of brainstem BF by counteracting myogenic constriction when CPP is increased. (Funded by DCI, Walter Reed Army Medical Center, Washington, DC)

OBLIGATORY ROLE OF NITRIC OXIDE IN GLUTAMATE-MEDIATED VASODILATION IN CEREBELLAR CORTEX G. Yang*

MEDIATED VASODILATION IN CEHEBELLAR CORTEX G. Yang' and C. ladecola, Dept. of Neurology, Univ. of MN, Minneapolis, MN 55455.
Electrical stimulation of the cerebellar parallel fibers (PF) increases cerebellar blood flow (BFcrb), a response mediated by glutamate (J. Neurophysiol 75:940, 1996). Nitric oxide synthase (NOS) inhibitors attenuate Neurophysiol 75:940, 1996). Nitric oxide synthase (NOS) inhibitors attenuate the vasodilation suggesting that NO is involved in the vascular response (AJP, 270: R914, 1996). In this study we investigated whether administration of NO donors could counteract the attenuation by NOS inhibitors of the vasodilation produced by PF stimulation. In anesthetized rats, the cerebellar cortex was exposed and the site was superfused with Ringer. PF were stimulated with microelectrodes (100 μA, 30 Hz) and BFcrb recorded by a laser-Doppler probe. During Ringer superfusion, PF stimulation increased BFcrb by 55±5% and hypercapnia by 75±5% (n=5). Superfusion with L-NA (1 mM) attenuated the response to PF stimulation (-47±5%) and hypercapnia (-46±7%). After L-NA, superfusion with the NO donors SIN-1 (100 μM; n=5) or SNAP (5 μM; n=5) re-established resting BFcrb (p>0.05 from before L-NA) and reversed the L-NA-induced attenuation of the response to hypercapnia (p>0.05 from before L-NA). However, NO donors did not reverse the attenuation of the the L-NA-induced attenuation of the response to hypercapnia (p>0.05 from before L-NA). However, NO donors did not reverse the attenuation of the response to PF stimulation (before SIN-1:-47±5%; after SIN-1:-57±7%; p>0.05). The NO-independent vasodilator papaverine (100 µM; n=5) did not re-establish the response to either hypercapnia or PF stimulation. Topical L-NA inhibited NOS activity, measured by the citrulline assay, by 98±1% (p<0.05). Thus, in PF stimulation, unlike in hypercapnia, NO donors cannot counteract the effects of NOS inhibition on the vasodilation. The data suggest that while in hypercapnia basal levels of NO are needed to facilitate vasodilation initiated by other mechanisms, in the vasodilation produce by PF stimulation glutamate-induced NOS activation is required to produce NO which in turn mediates the vasodilation. Thus, NO plays an obligatory role in the glutamate-induced vasodilation produced by PF stimulation.

HOMOCYSTEINE IMPAIRS NITRIC OXIDE-RELATED CEREBROVASODILATION BY SUPEROXIDE-DEPENDENT MECHANISMS. F. Zhang*, A. Slungaard¹, G. Vercellotti¹ and C. ladecola, Dept. of Neurology and Medicine¹, Univ. of MN, Minneapolis, MN 55455.

Elevated plasma levels of homocysteine (HC) may be a risk factor for ischemic cerebrovascular diseases. However, little is known about the cerebrovascular effects of HC. HC may impair cerebrovascular function by producing activated oxygen species. We studied whether HC alters the reactivity of the cerebral circulation and, if so, whether this effect depends on O₂ generation. In halothane-anesthetized rats the parietal cortex was exposed and superfused with Ringer. Cerebrocortical blood flow (CBF) was monitored by a laser-Doppler probe. With Ringer superfusion, CBF increased with hypercapnia (+134±7%), with topical application of acetylcholine (ACF, 10 μM; +35±3%), of the NO donor SNAP (500 μM; +66±6%) or papaverine (PAP; 1 mM; +100±6%)(n=5). Superfusion with HC (1 mM) or Cu²- (40 μM) alone did not perturb resting CBF nor responses to hypercapnia (-43±9%), ACh (-71±4%) ar SNAP (-42±4%), but not PAP. The cerebrovascular effects of HC+Cu²- were prevented by co-administration of superoxide dismutase (SOD; 1000U/ml; n=5). SOD alone did not affect resting CBF or CBF reactivity (n=5). The observation that HC+Cu²- attenuates the response to hypercapnia, ACh and SNAP, but not to the NO-independent vasodilator PAP, suggests that HC+Cu²- belectively impairs NO-related cerebrovascular responses. The fact that SOD prevents such impairment, indicates that the effect of HC is O₂-dependent. The data support the conclusion that O₂-generated by the reaction of HC with Cu²- hinibits NO-related cerebrovascular responses by scavenging NO, perhaps, through peroxynitrite formation. O₂-mediated scavenging of NO might be one of the mechanisms by which hyperhomocysteinemia predisposes to cerebrovascular diseases.

L-NAME INDUCED REDUCTION OF CEREBRAL BLOOD VOLUME CAN BE RESTORED BY OPIATE RECEPTOR BLOCKADE WITH NALTREXONE. K. Komjati*. J. Bencze, M. H-Velkei and P. Sandor. Experimental Research Dept. 2nd Inst. of Physiology, Semmelweis Univ. of Medicine, Budapest, H-1082 Hungary

Involvement of L-arginine-nitric oxide system and the endogenous opioid peptide system in the regulation of regional (hemispheric) cerebral blood volume (CBV) and local hypothalamic blood flow (HBF) was investigated in Urethane anesthetized, ventilated, normoxic, normocapnic, male Spraque-Dowley rats (n=8). CBV and HBF was measured simultaneously, CBV by Tomita's photoelectric method in our modification (Sándor et al Life Sci 1986) and HBF by Aukland's H2-gas clearance method. Selective blockade of the NC-synthase enzyme by 30 mg/kg i.v. administered L-Name (N ω -nitro-L-arginine methyl ester) resulted in a significant reduction of both hemispheric CBV (from 5.25±0.72 vol% to 4.13±0.51 vol%, p≤0.01) and local HBF (from 0.89±0.09 ml/g/min to 0.60±0.07 ml/g/min, p≤0.05), while systemic arterial pressure increased and heart rate decreased significantly. General opiate receptor blockade by 2 mg/kg i.v. administered Nattrexone caused no change in the HBF, MAP and HR values of the NOS-blocked animals. CBV, however, returned to it's steady state control value (5.4±0.72 vol%) at the same time. These findings suggest 1.) a major role of the L-arginine-nitric oxide system in the regulation of both hemispheric CBV and local HBF of the rat, and 2.) a possible involvement of opioid peptides and/or opiate receptors in the NOS-blockade induced reduction of the cerebral blood volume. DISTURBANCE OF CEREBRAL BLOOD FLOW AUTOREGULATION FOLLOWING SUBARACHNOID HEMORRHAGE IS ATTRIBUTABLE TO ISCHEMIA IN RAT: A PET STUDY. S. Yamamoto^{1*}, S. Nishizawa¹, H. Tsukada² and K. Uemura¹. ¹Dept. of Neurosurgery, Hamamatsu University School of Medicine, ²Central Research Lab., Hamamamatsu Photonics K.K., Hamamatsu, 431-31, 1922.

The effects of subarachnoid hemorrhage (SAH) on cerebral blood flow (CBF) response to induced hypertension were studied during chronic vasospasm in anesthetized Sprague-Dawley rats. SAH was induced by intracisternal injection of autologous blood (SAH group) or saline (control group). This method produces angiographical vasospasm of major arteries 48h later in the SAH group (Yamamoto et al., Soc. Neurosci. Abstr. 20:1761, 1994). During this period, CBF was measured in each side of parietal and occipital sections using positron emission tomography (PET) with or without induced hypertension in the SAH group (n=5) and the control group (n=6). Mean arterial blood pressure (MABP) was increased from 94±8 to 140±1 mmHg by the injection of phenylephrine. Autoregulatory Index (AI) expressed as delta CBF (%) per 10-mmHg increase in MABP was employed to analyze CBF response. Intracranial pressure (ICP) was measured in different animals 48h after SAH was induced.

SAH did not affect ICP 48h later (control 9.2 ± 0.30 vs. SAH 10.0 ± 0.47 mmHg, n=5). However, SAH significantly reduced (p=0.0001) basal CBF (ml/100g/min) by 26.2% (control 60.0 ± 1.9 n=24, SAH 44.3 ± 4.5 n=20). A territorial CBF that decreased by 50% or more over controls was used to define ischemia and was identified in five out of 20 regions (25%) in the SAH group. AI (%/10-mmHg) was 13.5 ± 2.4 in the control group (n=24). In the SAH group AI decreased (p<0.05) to 4.5 ± 2.5 in the non-ischemic areas (n=15), while in the ischemic areas (n=5) AI increased (p<0.05) to 25.2 ± 4.1 .

During chronic vasospasm following SAH, the spastic artery by itself is resistant to hypertension. Marked increase in CBF in case of hypertension is attributable to ischemia following SAH.

STIMULATION OF ENDOTHELIAL P2u PURINOCEPTORS DILATES THE RAT MIDDLE CEREBRAL ARTERY (MCA) THROUGH A MECHANISM INVOLVING NITRIC OXIDE (NO) AND A PATHWAY SENSITIVE TO TIN PROTOPORPHYRIN-9. J.P You, T.D. Johnson, W.F. Childres, W. Durante, and R.M. Bryan, Jr.* Dept. of Anesthesiology, Baylor College of Medicine, Houston, TX 77030

We previously reported that stimulation of P2u receptors by UTP dilated the rat MCA through an unknown mechanism. The purpose of this study was to investigate this mechanism. Rat MCAs were isolated, cannulated at each end with a micropipet, and pressurized to 85 mm Hg. The MCAs were immersed in a bath (37° C) and luminally perfused. Resting outside diameter of the MCAs in one study was 213 \pm 6 μm (n=11). The MCAs showed large concentration dependent dilations when UTP was applied luminally. The maximum dilation was 30% and the ECs0 (concentration producing half the maximal response) was 4.2 \times 10° 7 \pm 1.1 \times 10° M (n=13). The dilations elicited by UTP were completely blocked by removal of the endothelium (n=9). L-NAME (10° M), an inhibitor of NO formation, did not alter the maximum response to UTP (n=9) but did shift the ECs0 to the right tenfold. The L-NAME insensitive component of UTP dilation was not altered by 10° M indomethacin (n=6) or 5 \times 10° M aspirin (n=5). This indicates that cyclo-oxygenase metabolites such as prostacyclin were not involved in the dilation. The L-NAME insensitive component of the dilation was blocked by the heme oxygenase inhibitor, tin protoporphyrin-9 (SnPP-9) at concentrations of 10 μ M (n=5). Heme oxygenase is the enzyme responsible for the synthesis of CO. We conclude that the dilation mediated by the stimulation of P2u receptors on endothelium of the rat MCA involves NO and a pathway sensitive to SnPP-9. (PHS grant PO1 NS 27616)

437.16

HALOTHANE INHIBITS THE PRESSOR BUT NOT THE CEREBROVASCULAR EFFECT OF THE NITRIC OXIDE SYNTHASE (NOS) INHIBITOR 7-NITROINDAZOLE (7NI) IN RATS. Y.S. Zagvazdin*, G. Sancesario, M.E.C. Fitzgerald and A. Reiner. Dept. of Anatomy & Neurobiology Univ. of Tennessee and Dept. of Biology, Christian Brothers Univ., Memphis, TN, and Dept. of Neurology Univ. di Roma "Tor Vergata", Rome, Italy

Inhibition of endothelial NOS reduces cerebral blood flow (CBF) and leads to a profound systemic hypertension in rats. Decrease in CBF after inhibition of NOS by 7NI, a relatively specific inhibitor of the neuronal isoform of NOS, is associated with a moderate pressor effect. The pressor effect of L-arginine analogs or 7NI is blunted by using halothane for maintenance or even for induction of anesthesia, presumably by interference with endothelial NO production (Dawson et al., 1993; Zagvazdin et al., 1996, European. J. Pharmacol.). The goal of this study was to examine whether the cerebrovasoconstrictor effect of 7NI is abolished by halothane. Sprague-Dawley rats were anesthetized using urethane either with or without induction by halothane or using halothane (2%) only. CBF, measured by Laser Doppler flowmetry, decreased after 7NI injection (50 mg/kg i.p.) in all groups by 20-28 %. Increasing the dose of 7NI (75 mg/kg i.p.) id alot result in a greater reduction in CBF. In contrast, mean arterial blood pressure after 7NI was increased significantly only if halothane was not used. Thus, the systemic pressor and cerebrovascular effect of 7NI is mediated by a different mechanism. The inability of the halothane to abolish the decrease in CBF after 7NI suggests a contribution of neurally derived NO to the maintanance of cerebrovascular tone. MAPPING PATHOLOGY TO METABOLISM: COREGISTRATION OF STAINED WHOLE BRAIN SECTIONS TO PET. M.S. Mega. S.S. Chen. A Tiwari, T.J. Karaca, L.L. Thompson*, H.V. Vinters, P.M. Thompson, A.W. Toga Lab of Neuro Imaging, UCLA School of Medicine, Los Angeles, CA 90024.

Objective. Demonstrate a methodology using a 3D cryomacrotome reference for the coregistration of PET and stained whole brain sections.

<u>Background.</u> Localizing histologic data to functional imaging requires a common spatial reference. Whole brain slices, obtained from cryomacrotome common spatial reference. Whole brain slices, obtained from cryomacrotome sectioning, can be localized to a high resolution 3D digital reference reconstructed from the sectioned block-face. This model serves as a warping reference for functional imaging and histologic data. Using this methodology we evaluated the contribution of neurofibrillary tangles (NFTs) to the metabolic abnormalities seen on FDG-PET in a patient with Alzheimer's disease.

Methods. PET was obtained 8 hours before death and the brain was frozen 12

hours after death. Cryomacrotome images were obtained every 500µ in the coronal plane. Every 1 cm a 250µ whole brain slice was collected and stained with the Gallyas method to reveal NFT density. Digital images of these stained sections were elastically warped onto the coregistered PET-cryo dataset to evaluate associations between NFT density and regional hypometabolism.

Results. Hypometabolism was generalized but greatest in the posterior temporoparietal and frontal cortex, NFT density was maximal in the limbic and paralimbic cortex. Microscopic verification of NFT staining was not possible due to freeze artifact.

Conclusion. Cryomacrotome reconstruction serves as a reference space for warping pathological and functional data allowing an evaluation of the cellular basis for metabolic defects in humans. CORTICAL FLAT MAPS OF THE VISIBLE MAN LINKED TO THE TALAIRACH STEREOTAXIC ATLAS H.A. Drury* and D.C. Van Essen. Department of Anatomy and Neurobiology.

Washington University School of Medicine, St. Louis, MO, USA 63110.

We have generated computerized reconstructions of the surface of cortical layer 4 for both cerebral hemispheres of the Visible Man (Visible Human Project, National Library of Medicine). The surface areas of the left and right hemispheres were 757 cm² and 795 cm², respectively. We then generated 2-D cortical flat maps for each hemisphere using our automated flattening algorithm. The geography of cortical convolutions can be readily visualized on the flat maps using displays of mean

Comparison of the cortical geography of the left hemisphere to that of the right hemisphere shows strong similarities in their overall size and shape and close correspondence between most major sulci. However, there are conspicuous differences in the pattern of many minor sulci. Although the cortical geography of the flat maps of the human cortex is clearly more complex than those of the macaque, the overall

configuration of the maps share important similarities across species.

We transformed the volume of the Visible Man and associated cortical surface data we transformed the volume of the visible Man and associated cortical surface data to the Talairach coordinate system. A surface-based coordinate system was also established on the flat map of each hemisphere (with each origin chosen as the ventral tip of the central sulci). Because the 3-D representation has been transformed to Talairach coordinate space, each point on the flat map can be assigned a unique 2-D surface-based coordinate and a corresponding 3-D Talairach coordinate. Representation of activity foci from PET and fMRI (reported using Talairach coordinates) can readily be modeled using an appropriate volume distribution, allowing visualization of which gyri and sulci of the Visible Man are within a specified distance of any given Talairach coordinate. Linkage between these first flat maps of the entire human cerebral cortex and the Talairach atlas will help in incorporating data from the many approaches available for studying cerebral organization and function. Supported by NIH Human Brain Project MH52158 and NIH EYO2091.

FMRI BLOOD OXYGENATION LEVEL DEPENDENT CONTRAST (BOLD) CHANGES REFLECT CHANGES IN BLOOD FLOW. F.M. Lalonde, A.W. Song, J.V. Haxby and A. Martin*. National Institute of Mental Health, NIH, Bethesda, MD, 20892

An inversion recovery (IR) MRI pulse sequence sensitive to regional changes in blood flow was used to investigate the relationship between blood flow and blood oxygenation. Four right-handed female subjects (24 to 29 years of age) viewed line drawings of common objects and noise patterns. Each stimulus was presented for 180 msec; one per 2 seconds. Subjects were instructed to silently name the objects and stare at the patterns. Alternating lists of 10 objects and 10 noise patterns were presented. This on-off sequence was repeated three times during each run. Two subjects viewed each object only once. The other two subjects viewed the same objects in a different order during the second on-off sequence of each run. Each session had between 6 to 8 runs. One, 10 mm sagittal slice, centered 30 mm from the left lateral surface, was obtained from a GE Signa 1.5T scanner using a gradient echo EPI sequence (TR = 3000 msec, TE = 40 msec, FOV = 24 cm, 64X64 matrix). Protons within the slice were saturated using a 180 degree inversion pulse (TI = 1000 msec) prior to data collection. Changes in signal intensity were therefore primarily due to unsaturated protons flowing into the slice. The results from this study agree with previous findings obtained using the BOLD contrast effect. Namely that the silent naming of objects was associated with increased signal intensity in the inferior temporal gyrus and decreased signal intensity in the perisylvian region, relative to viewing noise patterns. Moreover, the more subtle BOLD signal intensity changes observed when objects are shown a second time (Martin et al., Neurosci. Abstr., 1995) were also detected with the IR sequence. These results support the notion that BOLD contrast signal intensity changes are tightly coupled to changes in blood flow. Funded by the NIMH, DIRP.

3D PROBABILISTIC ATLAS AND AVERAGE SURFACE REPRESENTATION OF THE ALZHEIMER'S BRAIN, WITH LOCAL VARIABILITY AND PROBABILITY MAPS OF VENTRICLES AND DEEP CORTEX. Thompson PM, Mega MS, Moussai J, Zohoori S, Xu LQ, Goldkorn A, Khan AA, Coryell J, Small G* Cummings J and Toga AW, Laboratory of Neuro Imaging, Dept. Neurology and Division of Brain Mapping, UCLA School of Medicine, Los Angeles CA 90095.

A high-resolution probabilistic atlas of the Alzheimer's brain was constructed from a reference archive of MRI scans of patients with clinically determined Alzheimer's disease. MRI volumes, acquired from 10 subjects (5 males, mean age: 72 yrs.) as datasets of 170 contiguous T₁-weighted 1-mm thick slices, were digitally transformed into Talairach stereotaxic space. Outlines of 29 different structures were directly identified at high magnification on sagittally-resampled sections. Connected systems of parametric meshes were used to model major lobar, ventricular and cytoarchilectural boundaries in 3 dimensions. These included complex internal trajectories of the parieto-occipital, calcarine, cingulate, marginal and callosal sulci and Sylvian fissure in both hemispheres. The ventricular system was partitioned into a system of 14 connected surface elements whose junctions reflected cytoarchitectonic boundaries of the adjacent tissue. A family of surface maps was constructed, encoding statistical properties of local anatomical variation across the surfaces of individual structures. A complete system of probability density functions was computed, yielding confidence limits on surface variation within the Talairach stereotaxic grid. Local variability maps revealed striking directional trends in the patterns of anatomic variation. Confidence limits on surface variation increased dramatically towards the posterior Sylvian and anterior cingulate cortex. These probabilistic atlasing techniques provide a basis for the generation of anatomical templates and expert diagnostic systems which retain information on inter-subject and inter-group variations in brain architecture.

Different techniques to infer the in vivo dynamics of electrical activity in brain, including fMRI, wide-field optical imaging of intrinsic signals and with voltagesensitive dyes, are corrupted by the presence of physiological fluctuations. Using data from fMRI studies of humans and a rat model, as well as optical imaging studies of the rat barrel cortex, the characteristics of these fluctuations were investigated to develop optimal post-processing strategies.

The main sources of fluctuations are respiration, cardiac oscillations, and vasomotor activity. Each source has defined frequencies and is spatially coherent Conventional schemes, such as gating of data acquisition based on the heart rate, are found to be inadequate due to variability in the oscillations. We are able to extract these oscillations using a combination of singular value decomposition (SVD) (principal components analysis) and multiple window spectral techniques. The removal of signals that are solely correlated with a physiological mode can be done on the basis of the imaging data alone; however, auxiliary measurements of the relevant physiology, e.g, the EKG, assist in the process

In both fMRI and optical imaging, respiration causes global changes characterised by a spatial structure resembling a derivative of the image, corresponding to motion. Cardiac oscillations in fMRI have a more complex spatial structure, presumably originating in hemodynamic effects. In optical images where resolution is higher, the dilation of the vessels is also observed. The vasmotor oscillations also show a complex spatial structure. In addition, in the rat studies we observed singular events associated with the blood vessels that could not be ascribed to any of the above sources. (Supported by Bell Labs and NIH grant RR08079)

NEGATIVE FUNCTIONAL MRI SIGNALS AND MODELS OF BLOOD FLOW AND OXYGEN METABOLISM J.G. Ojemannt, R. C. McKinstrys, T. E. Conturos, A. Z. Snydert, E. Akbudaks, R.L.Bucknert, R.L. Grubb Jr. t*, and M.E. Raichlets Departments of †-Neurology and Neurological Surgery and §-Radiology, Washington University School of Medicine, St. Louis, MO.

The signal in functional magnetic resonance imaging (fMRI) arises from increased blood oxygenation due to uncoupling of regional cerebral blood flow (rCBF) and oxygen metabolism (rCMRO2) during functional activation. In the resting state, however, rCBF and rCMRO2 are tightly correlated. Under barbiturate anesthesia, parallel decreases in CBF and CMRO2 have been observed. If this relationship holds for regional changes during decreased functional activity, then uncoupling of rCMRO2 and rCBF would not occur and no signal would be seen by fMRI. To test this hypothesis, we examined two paradigms known to induce rCBF decreases and increases from a resting state. Subjects underwent whole brain echo-planar imaging at 1.5T (Siemens Vision, contiguous 8mm slices, TR=2s, TE=50ms) during runs of multiple, alternating blocks of control and task: one group (n=4) with vibratory stimulation of the left hand (control eyes closed) and the other (n=6), word stem completion task (control = visual fixation). Task minus control images were created after realignment and normalization across time. In the vibratory study, reliable signal increases were seen in right primary sensory cortex and reliable decreases in right primary motor cortex. In the stem completion study, strong increases were seen in visual cortex and left prefrontal cortex along with robust signal decreases in medial parietal cortex. Our results imply that the resting correlation between rCBF and rCMRO2 does not apply bidirectionally to focal activity modulation. But negative fMRI signals do not distinguish between neuronal activity decreases due to "task" performance vs. increases in the "control" state. In the former case, negative fMRI signals suggest that rCMRO2 does not couple with rCBF decreases. Further understanding the relationship of rCBF and rCMRO2 will require defining a resting brain state relative to which uncoupling may occur (Supported by NIH grant NS 06833 and the Charles A. Dana foundation)

STIMULUS INDUCED FOCAL DECREASE IN DEOXY-HAEMOGLOBIN CONCENTRATION

STIMULUS INDUCED FOCAL DECREASE IN DEOXY-HAEMOGLOBIN CONCENTRATION RESOLVES DURING SUSTAINED VISUAL STIMULATION.

Near-infrared spectroscopy (NIRS) monitors the time course of the haemodynamic response to functional neuronal activation. In previous studies we demonstrated a decrease in deoxygenated haemoglobin [deoxy-Hb] in response to motor and visual stimulation. The [deoxy-Hb] response develops with a 5-6 s latency and is almost stable during the stimulation period (up to 30s). In the present study we examined whether the [deoxy-Hb] response is also stable over a longer stimulation period. We continuously measured oxygenation changes in 6 subjects during 5 min of visual stimulation followed by 3 min of rest (8 cycles per subject) using a NIRO-500-monitor (Hamamatsu, Japan), interoptode distance 3.5 cm, sampling time 1 s, optodes placed over the right occipital cortex. The stimulus consisted of a coloured dodecahedron. The results confirmed the [deoxy-Hb] decrease during the first 30 s. However a gradual increase in [deoxy-Hb] occurred, almost reaching the baseline level after 4 min of stimulation. There is a pronounced post-stimulus overshoot lasting about 1 min. gradual increase in [deoxy-Hb] occurred, almost reaching the baseline level after 4 min of stimulation. There is a pronounced post-stimulus overshoot lasting about 1 min. According to the current theory of neurovascular coupling the decrease in [deoxy-Hb] results from an increase in rCBF not mirrored by an equally large increase in oxygen consumption. The results may therefore indicate changes in the degree of this _focal uncoupling' between rCBF and oxygen consumption over the course of longer stimulation periods, although habituation of neuronal activation can not be excluded. These findings are in line with recent functional MRI studies using a similar experimental protocol showing a vanishing BGI Deportractive. protocol showing a vanishing BOLD-contrast15

Near infrared spectroscopy (NIRS) can be used to measure oxygenation changes induced by functional brain activation (1) We applied multisite NIRS (NIRO 500. Hamamatsu, Japan) in combination with anatomical MRI to study localisation and spatial distribution of functional oxygenation response during performance of three different motor tasks. 5 subjects performed finger, elbow and foot movement in a fixed order. Concentration changes of oxy-Hb and deoxy-Hb were continuously measured (sample time 1s) (2). Measurements were obtained from 8-10 different positions over the left parietal cortex using C3 as a fix point. Measurement positions were localised on brain surface of 3D rendered MRI. All tasks were followed by a localised increase in [oxy-Hb] and a decrease in [deoxy-Hb]. Whereas only slight task dependent spatial differences in [oxy-Hb] were found. [deoxy-Hb] demonstrated topographical differences in localisation of maximal response. Significant changes in [deoxy-Hb] during finger movement were found in the vicinity of C3, and during elbow movement additionally in positions above C3. Foot movement elicited significant changes in positions near interhemispheric fissure. Localisation of maximal response corresponded anatomically to presumably activated brain regions. The results indicate that NIRS findings during functional activation are localised. however changes in [deoxy-Hb] seem to be more localised and more related to topographical location of activated brain regions than changes in [oxv-Hb]. We conclude that multilocal NIRS may be used for non-invasive functional brain mapping. Improved spatial resolution and simultaneous assessment of pathlength is necessary to enhance the potential of this method. Obrig et al. In press 1996; Cope M. Delpv DT. 1988.

MODULATION OF OPTICAL INTRINSIC SIGNAL TIME-TO-PEAK RESPONSE DURING TEMPORALLY STAGGERED COMPETITIVE STIMULATION. A.J. Blood* and A.W. Toga. Laboratory of Neuro Imaging and Division of Brain Mapping, Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90095.

Optical intrinsic signal imaging (OIS) was used to examine response characteristics of two temporally staggered somatosensory stimuli. whisker C1 and forelimb digits 3 through 5 were stimulated simultaneously or in staggered (overlapping, but not simultaneous) order. Time-to-peak and magnitude of OIS responses in the barrel region were determined for each paradigm and compared to lone whisker stimulated controls. Simultaneous stimulation consisted of a 3 second whisker deflection commencing at the same time as a 3 second forelimb vibration. During staggered stimulation, whiskers were deflected for 3 seconds at 10 Hz, and a 3 second, vibratory forelimb stimulus commenced after the first second of whisker stimulation. This paradigm was also reversed so that forelimb stimulation preceded whisker stimulation by one second. Simultaneous stimulation slightly decreased response time-to-peak and caused response magnitude to either increase or decrease relative to controls. Staggered competitive forelimb stimulation caused a delay of the peak OIS signal in barrel cortex. Peak response magnitude changed in the same direction from controls as did responses to simultaneous stimulation, but to a lesser degree. staggered competitive forelimb stimulus preceded whisker stimulation, OIS response time-to-peak decreased relative to controls. These results demonstrate the ability to alter temporal and magnitude characteristics of OIS responses by varying temporal order of competitive stimulus presentation. This suggests there are temporally dependent interactions between spatially and functionally distinct cortical systems

CONTINUOUS SPECTRUM NIRS APPROACH CAN QUANTIFY OXYGENATION CHANGES

IN RESPONSE TO FUNCTIONAL STIMULATION IN HUMANS,

H. Obrig*, J. Ruben, C. Hirth, R. Wenzel, U. Dirnagl and A. Villringer

Dept. of Neurology, Charité, Humboldt-Univ., Berlin, F.R. Germany

With a commercial NIRS monitor (NIRO-500) we have previously shown changes in cerebral oxygenation in response to motor and visual stimuli^{1,2}. Whereas commercial with a commercial NIKS monitor (NIRO-500) we have previously shown changes in cerebral oxygenation in response to motor and visual stimuli. Whereas commercial NIRS monitors use discrete single wavelengths to calculate concentration changes in oxy and deoxy haemoglobin a new approach illuminates the tissue with a continuous NIR spectrum, thus enhancing spectral information. To test the feasibility of this approach for functional activation studies we examined 8 ss. performing a motor task for 20s contra- and ipsilaterally to probe positioning over the left motor region (40s of rest). Ten cycles of each condition were performed in an interleaved fashion. The NIRS system was composed of a halogen lamp (400-1100nm), a spectrograph spectrally resolving the collected light and a CCD camera with a 567 point (= 0.5 nm spectral) resolving the collected light and a CCD camera with a 567 point (= 0.5 nm spectral) resolving the collected light and a CCD camera with a 567 point (= 0.5 nm spectral) resolving the optical perspective one were collected every second and averaged across all subjects with respect to movement onset for both conditions. Fig. 1 showing the difference in optical densities at all wavelengths between the resting and the stimulation period, demonstrates that the optical properties of the tissue change over the whole spectral range from 675 to 975nm. Fig. 2a shows the changes in [oxy-Hb] and [deoxy-Hb] when applying the algorithm of Cope et al. *confirming the lateralized hyperoxygenation previously described, Fig. 2b plots the integral over the OD changes covering the spectral absorption peak of deoxy-Hb at 760nm and that of H₂O tig. *centra* [ps] at 970nm indicating changes in either spectral region in response to the stimulus. We conclude that the continuous spectrum approach is feasible for functional NIRS studies.

EVIDENCE FOR VASCULAR REFRACTORY PERIODS OBSERVED WITH OPTICAL INTRINSIC SIGNAL IMAGING A.F. Cannestra* and A.W. Toga Lab. of Neuro Imaging, Division of Brain Mapping, Department of Neurology,

Lab. of Neuro imaging, Division of Brain Mapping, Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90095
Optical Imaging of intrinsic signals (OIS) and repetitive proprioceptive stimulation paradigms were employed to investigate potential vascular refractory periods and response capacities observed in rodent somatosensory cortex. Primary stimuli were presented to the animal, followed by a period of no stimulation (interstimulus interval), and a subsequent secondary stimulus. Close temporal proximity of repetitive stimuli decreased the magnitude (intensity and spatial involvement) of the secondary optical response. Stereotaxic evoked potentials were recorded and indicated no change in neuronal activity between stimulations. The interstimulus interval required to obtain an equal magnitude second optical response was defined as the refractory period. Increasing primary stimulus duration response was defined as the refractory period. Increasing primary stimulus duration increased interstimulus intervals required to obtain equal secondary responses. The relationship between multiple stimulus durations (2s to 15s) and observed refractory periods was determined and may be represented by a quadratic function. Increasing secondary stimulus frequency increased secondary optical response during the refractory period, indicating the relative nature of the refractory periods. During long duration stimulations, a second stimulus initiated a response that only attained steady state level observed during primary stimulation, foregoing the initial overcompensation phase. Therefore, observed decreases in secondary response correlate with loss of luxury perfusion phenomena. Since current functional imaging techniques rely upon neurovascular behavior, this study suggests frequency and duration of repetitive cortical activation may dramatically affect intensity and extent of response. CORTICAL BARREL PATTERNS AND THEIR CAPILLARIES AFTER POSTNATAL WHISKER LESIONS. J. SUI , C. M. ROVAINEN and T.A.WOOLSEY.* Departments of Neurology and Neurosurgery and of Cell Biology and Physiology, Washington University School of Medicine, St. Louis MO 63110.

Blood flow increases locally in rodent barrel cortex with stimulation of whiskers. The vascular units defined by injection of single penetrating arterioles are anatomically related to the barrels as neural groups. Our hypothesis is that the development of cerebral vessels is directed by the patterns and activities of neurons. The normal cytoarchitectonic pattern of barrels in layer IV of mouse SmI face cortex is altered by early damage to the mystacial vibrissae. Row-C or rows-BCD on one side of the face in groups of Swiss mice were cauterized. Animals lesioned on P1, 2, 3, 4, 5, 6, 7 or 8 were perfused with FITC-gelatin on P30; animals lesioned on P30 were perfused on P60. The brains were sectioned parallel to SmI layer IV at 100µm, and sections reacted for cytochrome oxidase (CO). The sections were scanned twice at a primary magnification of 20 x on a Zeiss LSM-310 confocal microscope; first with transmitted light to show the CO stain and a second time with epi-ilumination in three-dimensions for volume rendering of intravascular fluorescence. Images from the two channels were combined to demonstrate the relationship of the vessels to the CO staining patterns and images of the fluorescent marker were used to measure capillary

Images of the exposed cortical surface can be processed to reveal information about the modulation of regional cerebral blood flow (rCBF) by neuronal activity. Images of rat sensory motor cortex and testes were processed using different analysis methodologies. The study compared the use of generalised linear models (GLM) and canonical variate analysis, against standard signal processing and de-noising methods (including principal components analysis, The GLM method is used in the analysis of fMRI data (Friston et al, Neurolmage, 1995, 2, 45-53) to identify regions of focal activity. We explore the use of this method to analyse video image data from the cortex of anaesthetised rats in which rCBF was modulated by sensory stimulation and by exsanguination. The results show indudated by sensory stimulation and by exsangumation. In results since statistically significant local spatio-temporal variations in rCBF in response to stimulation. Using different wavelengths of illumination, and the appropriate models of the neural haemodynamic coupling it was possible to disassociate changes in blood volume from changes in blood oxygenation. An advantage of the GLM method is that it provides an estimate of statistical reliability for the spatial structures revealed by the analysis (which of course were also revealed by the standard signal processing methods). The method is sensitive to the choice of the parameters used in the haemodynamic models (good news; it 'forces' model development). Importantly, it can be used to remove the effects of the low frequency (~0.1Hz) oscillations (the V-signal) without extensive averaging strategies commonly used. The 0.1 Hz oscillations are now known to be the principal source of widely acknowledged "vascular artefacts" present in intrinsic

2Dept. of Neurology, Keic University School of Medicine. Tokyo 160, Japan.
Depolarization elicited by elevations in extracellular K* concentration

causes rapid Na* influx through voltage-sensitive Na* channels and leads to stimulation of glucose utilization in neurons. In cultured astroglia, however, elevated extracellular K* does not stimulate rates of glucose utilization while direct elevation in intracellular Na* concentration does (Takahashi, S. et al. Proc. Natl. Acad. Sci. USA 92, 4616-4620). In the present study the effects of increasing extracellular K concentration

on Na* influx into cultured rat astroglia were examined. Cells were incubated with bicarbonate buffer containing 1 mM ouabain, tracer amounts of [22Na]Cl, and various concentrations (5.4, 28, 56 mM) of K* for 0 to 60 min. Cells were digested and assayed for ²²Na*. K* did not facilitate but rather suppressed Na influx astroglia (Fig.). Veratridine (75 μM), which opens Na* channels, significantly raised rates of Na* influx (144%), and this elevation was completely blocked by 10

 μM of tetrodotoxin, an inhibitor of voltage-sensitive Na* channels. These results indicate that elevated extracellular K* concentration does not lead to an activation of voltage-sensitive Na* channels in astroglia and therefore does not stimulate rates of glucose utilization.

COGNITION: FRONTAL/PREFRONTAL

439.1

A FUNCTIONAL MAGNETIC RESONANCE IMAGING (FMRI) STUDY OF VENTRAL PREFRONTAL CORTEX MEDIATION OF RESPONSE INHIBITION. B.J. Casey*, R. Trainor, J. Orendi, A. Schubert. Psychiatry Depart., WPIC, UPMC, Pittsburgh, PA 15213. The proposed role of prefrontal cortex (PFC) in behavioral inhibition has been supported by a number of parient and house left.

has been supported by a number of animal and human lesion studies These studies show that lesions to PFC, especially ventral PFC, produce deficits in performance of tasks that require inhibition of prepotent response tendencies. The current study examines differences in PFC activation during performance of a GoNoGo task in subjects with high versus low numbers of false alarms. Eighteen right-handed subjects (mean age 16 years) were scanned during task performance using echo planar fMRI. The task consisted of the subjects responding to any letter but X with 75% of the total number of trials being targets (i.e., non Xs). There were three conditions: 1) a No-go condition with nontargets (i.e. Xs) and targets intermixed; 2) a Go_s condition consisting of all targets and controlling for number of stimuli: and 3) a Go_R condition consisting of all targets and controlling for number of responses. Two groups were defined with a median-split on the number of false alarms. The results indicate that only activation in ventral PFC (i.e. orbital and inferior frontal) and anterior cingulate ventral PFC (i.e. orbital and interior frontal) and anterior cingulate cortex discriminated between groups on comparisons of NoGo vs. Go conditions. The comparison of the two Go conditions did not discriminate between groups. These results lay the critical groundwork in paradigm development for examining disorders with deficits in response inhibition (e.g., ADHD) using fMRI.

DORSOLATERAL PREFRONTAL CORTEX MODULATES VISUAL PROCESSING IN EXTRASTRIATE CORTEX. D. Swick* & R.T. Knight. Dept. of Neurology & Center for Neuroscience, UC Davis, VAMC, Martinez, CA 94553.

Dorsolateral prefrontal cortex is crucial for the control of sustained and

phasic attention to environmental events. A prefrontal-thalamic inhibitory system provides a mechanism for suppressing irrelevant inputs at an early stage of sensory processing. Patients with prefrontal lesions show attention deficits, perseveration, and distractibility, in part due to a lack of inhibitory control that begins with processing in primary sensory cortices. The present experiment examined the influence of prefrontal cortex on a later stage of sensory processing. Event-related potentials (ERPs) were recorded from age-matched controls and patients with unilateral frontal lesions caused by strokes (10 left, 1 right hemisphere). Lesions were centered in areas 9 and 46, but damage extended into areas 6, 8, 10, 44, or 45 in some subjects. Subjects read centrally presented words and pronounceable nonwords and performed lexical decision or recognition memory tasks. In controls, words and nonwords both elicited a focal negative potential peaking at 165 msec and maximal at posterior temporal and occipital electrodes. The amplitude of this N170 component was greater over the left hemisphere in both tasks (p<.01), similar to previous studies using verbal stimuli (Neville et al., 1986; Curran et al., 1993). A related temporal-occipital N1 to lateralized nonverbal stimuli is presumably generated in extrastriate cortex (Gonzalez et al 1994; Johannes et al., 1995). N170 amplitude was reduced in frontal patients ipsilateral to damage (p<.05), but peak latency was unaffected. These results agree with previous findings in a visual oddball task (Knight, in press) and suggest that dorsolateral prefrontal cortex provides an ipsilateral facilitory input to neural processing in extrastriate cortex that begins within 120 msec post-stimulus Funded by NS21135 and PO NS17778 from the NINDS.

EVIDENCE FOR SEQUENTIAL DEVELOPMENT OF TEMPORAL THEN FRONTAL LOBE FUNCTIONS IN 4-TO-8 YEAR-OLD CHILDREN Monica Luciana and Charles A. Nelson*. Institute of Child Development Univ. of Minnesota, Minneapolis, MN 55455

To investigate the emergence of cognitive functions mediated by prefrontal cortical networks, 180 normal children, ages 4 to 8 (N=30 within each age group), completed a standardized battery of computerized neuropsychological tests (the CANTAB**) to index the following functions: psychomotor speed & accuracy, sequential spatial memory, spatial working memory, planning & inhibition, set-shifting, pattern and spatial recognition, and visual paired associate learning. Performance on each task was compared across age groups matched for sex and socioeconomic status

Results demonstrate an early emergence of abilities attributable to functioning within subcortical and temporal lobe structures (psychomotor speed/accuracy, pattern recognition, visual paired associate learning) but a more protracted development of cognitive abilities mediated by prefrontal cortex (sequential spatial memory, spatial working memory, planning, and set-shifting). The observation that performance on the prefrontal tasks has not yet approached adult values by the age of 8 is consistent with neurophysiological studies suggesting that the frontal lobe is unique among brain regions in failing to reach full maturity until early adulthood

ABNORMAL BASAL-GANGLIA OUTFLOW IN PARKINSON'S DISEASE ABNORMAL BASAL-GANGLIA OUTFLOW IN PARKINSON'S DISEASE IDENTIFIED WITH PET: IMPLICATIONS FOR HIGHER CORTICAL FUNCTIONS. A. M. Owen*, J. Doyon, A. Dagher and A. C. Evans. Montreal Neurological Institute, McGill University, Montreal, Quebec, H3A 2B4, Canada and Department of Psychology and Research Center in Neurobiology, Laval University, Quebec City, Quebec, GIK 7P4, Canada.

Quebec City, Quebec, G1K 7P4, Canada. In this study we examined the effects of striatal dopamine depletion on cortical and subcortical blood flow changes during two tasks known to involve fronto-striatal circuitry. Regional cerebral blood flow was measured in six patients with moderate Parkinson's disease and in six age-matched controls while subjects performed easy and difficult versions of i) a modified Tower of London planning task; ii) a mnemonic variant of this task that required short-term retention and reproduction of problem solutions and iii) a control condition that involved identical visual stimuli and motor responses. Relative to control conditions, the planning task was associated with an increase in cerebral blood flow in the internal segment of the right globus pallidus in the age-matched controls subjects, and a decrease in the same region in spallidus in the age-matched controls subjects, and a decrease in the same region in the patients with Parkinson's disease. A similar inverse relationship between the task specific blood flow change observed in the control group and that observed in the Parkinson's disease patients was not found in any other subcortical or cortical area examined, including regions of the dorsolateral frontal cortex known to be involved in this task. When blood flow in the spatial working memory task was examined, a consideration between the two groups of cultivates was expended to similarly specific dissociation between the two groups of subjects was observed at comparable coordinates in the right pallidum.

We conclude that striatal dopamine depletion disrupts the normal pattern of basal-ganglia outflow in Parkinson's disease and consequently, affects the expression of frontal-lobe functions by interupting normal transmission of information through frontostriatal circuitry

Boulevard de l'Hôpital , 75651 Paris Cedex 13, FRANCE, 2CEA, Orsay. 3INSERM CREARE, 4Cognitive Neuroscience Unit, NIH, Bethesda.

Neuropsychological studies have suggested that the prefrontal cortex is important in Neuropsychological studies have suggested that the prefrontal cortex is important in planning sequences of actions. It has been suggested that script-like mental structures serving as vehicles for representing complex acts, are stored in the prefrontal cortex (Grafman, N.Y. Acad. of Sci., 1995). We reported that patients with prefrontal lesions are impaired at generating and sorting temporally-ordered sequences of actions (Sirigu et al., Cortex, 1995, 1996). This raises the question whether the maintenance of chronology for action sequences is subserved by specific neural substrates within the frontal lobes. This hypothesis was investigated in normal human subjects (n=5) during the processing of action or word sequences, using functional Magnetic Resonance Imaging (fMRI). Brain MRI images were acquired using Bold activation at 3 Tesla and with Echo-Planar. Subjects were shown pairs of written sentences. In condition A they detected errors in the acquired using Bold activation at 3 Tesla and with Echo-Planar. Subjects were shown pairs of written sentences. In condition A, they detected errors in the temporal order of actions depicted by the sentences (script). In condition B, they detected errors in the order of words within the sentences (syntax). The control condition consisted in checking for double consonants in non-words. Subtraction of the control condition from conditions A and B revealed different patterns of activation for script and syntax processing. The script task activated a large area in the dorsolateral prefrontal cortex (Brodmann areas 6 and 8) in both hemispheres. The syntax task resulted in a lesser activation of the same region but only in the left hemisphere, as well as Broca's and Wernicke's areas. These results indicate that script and syntax analysis are based on different types of sequential relations and may depend on domain-specific representations within the prefrontal cortex.

SPATIAL WORKING MEMORY IN PATIENTS WITH FRONTAL LOBE LESIONS. J. V. Baldo* and A. P. Shimamura. Dept. of Psychology, University of California, Berkeley, CA 94720.

Patients with lateral prefrontal cortex lesions and elderly controls were tested on a spatial working memory task that was similar to one used in Participants had to remember the location of a black dot presented randomly on the computer monitor. Following a delay of 0, 3, or 9 sec, participants responded by moving the mouse cursor to the remembered location. In one condition, during the delay, participants had a secondary task to perform. A series of digits was rapidly presented at central fixation, and participants had to press the mouse button every time a '0' was detected. In the control condition, the digits appeared but no response was required. Based on previous human and animal studies of prefrontal function, we hypothesized that patients would be worse overall on this working memory task and that they would be disproportionately impaired on the digit task condition and with longer delays. There was a main effect of group, such that patients were impaired overall. Numerically, this effect in the patients was exaggerated with longer delays (3 and 9 sec), compared to the baseline (0 sec). However, there was no interaction of group with task condition. Patients' and controls' performance declined comparably when they had to perform the secondary digit task. Further studies will be presented that manipulate the type of interference occurring during the delay

Characterization of the Decision-Making Defect of Subjects With Ventromedial Frontal Lobe Damage. S. W. Anderson*, A. Bechara, D. Tranel, H. Damasio, and A.R. Damasio. Dept. Neurology, Univ. of Iowa, Iowa City, IA, 52242. In a novel gambling task, control subjects learn to avoid the decks which yield high

immediate rewards and larger future losses, and opt for choices that yield low immediate rewards and larger future losses, and opt for choices that yield low immediate gains, but lower future losses. Subjects with ventromedial frontal (VMF) lobe damage do the opposite. Three possibilities may account for the behavior of VMF subjects: 1) Hypersensitivity to reward, so that the prospect of future (delayed) punishment is outweighed by that of immediate gain. 2) Insensitivity to punishment, so that the prospect of reward always prevails. 3) Insensitivity to future consequences, positive or negative, so that the behavior of the VMF subject is always guided by immediate prospects. To explore which possibility provides the best account, we designed a variant of the original gambling task, in which control subjects learn to prefer the decks with high immediate punishment, but higher future subjects team to prefer the decks with high immediate punishment, but lower future reward (good decks), and avoid the decks with low immediate punishment, but lower future reward (bad decks). Although a few VMF subjects (n=3) chose the good decks in the variant task, the majority (n=9) did the opposite, i.e., avoided the decks with high immediate punishment/ high delayed reward. In both the original and the variant tasks, the skin conductance responses (SCRs) of controls and VMF subjects after receiving a reward or punishment were not significantly different. The findings that most VMF subjects avoided the decks with high immediate punishment, and that they showed SCRs after receiving punishment, are inconsistent with the insensitivity to punishment explanation. The findings that most VMF subjects were not lured by the high reward in the decks with high immediate punishment, and that their SCRs after receiving a reward were not abnormally high, are inconsistent with the hypersensitivity to reward explanation. Thus, the impairment of VMF subjects on both the original and variant tasks leaves one plausible explanation, that most VMF subjects are insensitive to future consequences, whatever they may be Supported by NINDS PO1 NS19632, JSMF, and Centennial MRC.

INTERAREAL EEG SYNCHRONIZATION DURING SPATIOTEMPO-RAL REASONING IN MAN, J. Sarnthein, A. von Stein, G.L. Shaw[†]* F.H. Rauscher †, P. Rappelsberger, and H. Petsche. Instit. Neurophysiol., Univ. Wien, 1090 Vienna, Austria; † CNLM, UCI, Irvine, Ca, 92717, USA.

The neuronal basis of mental activity is assumed to be related to distributed assemblies of cortical nerve cells. These neuronal cell assemblies are formed by synchronous activity of their member neurons. We measured the coherence in the signals of pairs of scalp EEG electrodes placed over different cortical areas. Synchronicity is related to coherence, which may be considered as measure for information transfer between two electrodes. Higher brain function is thought to be based on the synchronization of cell assemblies distributed within different cortical areas.

In our experiment, EEG was recorded over several minutes while (female) subjects solved spatio-temporal reasoning tasks that also required working memory. This ongoing EEG was analysed for coherence changes with respect to a resting condition. In our group of 14 subjects we found a highly significant increase of coherence between parietal and frontal cortex in the high beta frequency band (18.5 - 31.5 Hz) in both hemispheres. The EEG coherence patterns were highly reproducible over several tasks for each subject

Using scalp EEG and the concept of distributed neuronal cell assemblies, one may thus gain insight in the cooperativity of working memory and spatial reasoning needed for complex spatio-temporal reasoning tasks. Funding: Ralph and Leona Gerard Foundation, Seaver Institute

NEURAL ACTIVITY IN THE PRIMATE PREFRONTAL CORTEX DURING A PROBLEM-SOLVING TASK.

E. Procyk, Y.L. Tanaka and J.-P. Joseph*. INSERM U94, 16 av.du doyen Lépine, 69500 Bron, FRANCE.

It has been shown that rhesus monkeys can perform complex spatial tasks by using a trial-and-error strategy (Procyk and Joseph, in press). The animal, facing a touch-screen monitor, had to search for the touching order (chosen in a set of 6 by a computer), of 3 fixed spatial targets illuminated on the screen.

After an incorrect touch all targets were extinguished and the monkey had to After an incorrect touch, all targets were extinguished and the monkey had to start another trial from the very beginning. After a correct touch, all targets remained illuminated and the monkey could choose the following target. When the correct order was repeated 4 times, a new search was initiated. Unit activities were recorded from superior arcuate area (SA) and caudal part of sulcus principalis (SP) in 2 rhesus monkeys during execution of this task.

Preliminary data show 2 groups of activities specific to the task: 1) visual-attentional activities which are associated with the selection of the successive targets. Some of these activities show allocentric characteristics. 2) error-specific activities with spatial- and/or rank-selectivity. They reflect the encoding of an error-event that is a cue for the forthcoming choices. These preliminary data show that SA and SP are involved in attentional control on preliminally dual slow that SA and SF are involved in attentional control on the target selection and in encoding the action feedbacks. However, putative working memory processes involved in trial-and-error strategies and in the construction and storage of the correct solution remain to be elucidated. The data suggest that these processes (memory of a movement and of its result) are quite different from those involved in simple DR-tasks (i.e. memory of a single sensory event provided by the environment) and/or are located in other structures. structures

Fear Conditioning After Ventromedial Frontal Lobe Damage in Humans, D. Tranel*, A. Bechara, H. Damasio, and A.R. Damasio. Div. of Cognitive Neuroscience. Dept. Neurology, Univ. of Iowa, Iowa City, IA, 52242.

The somatic marker hypothesis proposes that the ventromedial prefrontal (VMF) cortex is a critical site in a neural circuit subserving somatic state activation. We asked whether the role of the prefrontal cortex in this process is similar to that of the amygdala, i.e., to acquire simple associations between exteroceptive sensory information and interoceptive information concerning somatic states. We tested infolination and interoceptive morniagon contenting solution spaces. To controls (n=6) and VMF subjects (n=9) in a fear conditioning experiment, using 4 different colors of monochrome slides or 4 different computer-generated tones as conditioned stimuli (CS), and a startlingly loud sound (100 db) as the unconditioned stimuli (CS), and a startlingly loud sound (100 db) as the unconditioned stimulus (US). Electrodermal activity (SCR) was the dependent measure of autonomic conditioning. Each experiment involved 1)a habituation phase, 2) a conditioning phase in which only one of the colors or the tones were paired with the US, and they were presented at random among the other colors or tones, 3) an extinction phase, and 4) a debriefing phase in which the subjects were asked to recall specific facts about the experiment. All control subjects conditioned and began to generate SCRs after the presentation of a slide or a tone previously paired with the US. They also recalled specific facts about the experiment. Five of the VMF subjects acquired the conditioning and recalled the facts at the same level as the controls. Four of the VMF subjects failed to show any conditioned SCRs, and were also defective in recalling the facts. Preliminary anatomical analysis reveals that the lesions in the impaired VMF subjects extended more posteriorly and probably involved the basal forebrain. The lesions in the unimpaired VMF subjects were more anterior. The findings suggest that the anterior component of the ventromedial prefrontal cortex is not necessary for the acquisition of simple associations between exteroceptive and interoceptive information. Supported by NINDS PO1 NS19632, JSMF, and Centennial MRC.

Insensitivity to Future Consequences Following Bilateral Damage to the Human Amygdala: Contrasts With Ventromedial Frontal Lobe Lesions. A. Bechara*, G.P. Lee. R. Adolphs, D. Tranel, and A.R. Damasio. Div. of Cognitive Neuroscience Dept. Neurology, Univ. of Iowa, Iowa City, IA, 52242.

The somatic marker hypothesis proposes that both the amygdala the ventromedial prefrontal (VMPF) cortex are parts of a neural circuit subserving decision-making. Here we hypothesize that although both structures couple exteroceptive sensory information with interoceptive information concerning somatic states, they do so at information with interoceptive information concerning somatic states, they do so at different levels, thus making different contributions to the process. Using a gambling task sensitive to the decision-making defect observed in VMPF subjects, we task sensitive to the decision-making defect observed in VMPF subjects, we predicted that subjects with bilateral amygdala damage would show 1) impairment on the gambling task, 2) defective autonomic activity when given information which implies a state of reward or punishment, and 3) defective autonomic activity when pondering a choice among several options associated with various magnitudes of immediate reward and delayed punishment. We tested 3 subjects with bilateral amygdala damage, and 5 subjects with bilateral VMPF damage, during their performance of the gambling task, and while recording their electrodermal activity. All amygdala subjects were 1) impaired on the gambling task, 2) unable to generate skin conductance responses (SCRs) when given rewards or punishment (they generate normal SCRs in response to a loud startling noise), and 3) unable to generate incipators CSRs when choosing among various response ontions. By generate anticipatory SCRs when choosing among various response options. By contrast, VMF subjects were similar to the amygdala subjects with respect to conditions 1) and 3), but they were normal in condition 2). The results support the hypothesis that the amygdala and VMPF cortex make different contributions to a neural circuit subserving decision-making. Supported by NINDS PO1 NS19632, JSMF, and Centennial MRC.

FRONTAL, PARIETAL AND CEREBELLAR NETWORKS FOR CONDITIONAL MOTOR LEARNING. M.-P. Deiber, S.P. Wise*, M. Honda, J. Grafman and M. Hallett. Med. Neurol. Br., NINDS, Lab. Neurophysiol., NIMH, Bethesda, MD 20892

Frontal cortex has been hypothesized to function in the learning and rejection of behavior guiding rules. To test this hypothesis, 6 normal, right handed subjects centrally fixated a 9° square display and dextrally moved a joystick in the direction arbitrarily instructed by: (1) a 2° visual pattern (PATTERN RULE) or (2) the pattern's adultarily instructed by (1) a 2 visual patient (ATLEN ROLE) of (2) lite patients location (PLACE RULE). For these MOTOR TASKS, the same 4 stimuli appeared in the same 4 places and were attended on each trial. On another day, subjects moved the joystick in a visually displayed "YES" direction if an arrow's direction agreed with each rule or in a "NO" direction if it did not (EVALUATION TASKS). Both tasks had a FIXED-response condition. Subjects improved performance over 4 consecutive scans while rCBF was measured with PET (15-O water). Variance was evaluated with principal component analysis (PCA), contrasts with SPM.

PCA revealed a first principal component corresponding to rule adherence (vs. fixed responding), which accounted for ~50% of the variance. A second component reflected a time-in-rule effect, presumably learning (~20%). Only one frontal area showed a significant increase in TCBF during learning, the caudal part of the left premotor cortex (PM, area 6). It did so during the pattern rule-evaluation task. Several frontal areas, (PM, area 6). It did so during the pattern rule-evaluation task. Several frontal areas, along with the left lateral cerebellar hemisphere, showed rCBF decreases during learning, also during the pattern rule-evaluation task: the left ventro-orbital prefrontal (PF) cortex (area 47/12 of Petrides & Pandya) and, in the right hemisphere, the dorsal and rostral aspect of PM (PMdr) plus dorsal PF (PFd, area 9). During the place rule-motor task, a more caudoventral part of the right PM and the right dorsolateral PF (PFdl, area 46) showed decreasing rCBF during learning. A largely common posterior parietal region (area 39/40) showed decreasing rCBF during learning in all tasks. These data are consistent with the hypothesis that localized frontal areas, as well as the cerebellar and parietal networks associated with them, receive potentiated inputs (reflected by higher rCBF in the first scan compared to later ones) when routine rules (reflected by higher rCBF in the first scan compared to later ones) when routine rules need to be rejected and new ones adopted, with different frontal areas "activated" while learning different rules.

AGRAPHIA WITHOUT ALEXIA: ISOLATION OF GRAPHEMIC OUTPUT IN A SPLIT-BRAIN PATIENT.

K. Baynes[†], J.C. Eliassen[†], and M.S. Gazzaniga[‡].

†Center for Neuroscience, University of California, Davis, CA 95616; ‡ Department of Psychology, Dartmouth College, Hanover, NH 03754 .

Dejeurine first described the striking loss of reading ability in a patient who could write. Our patient VJ, a 43-year-old left-handed female, presented with agraphia following tworefirmanced remaie, presented with agraphia following two-stage callosotomy. She continues to read for pleasure, but can perform only rudimentary writing tasks, and then not always at will. We used tachistoscopically lateralized letters, numbers, nouns, verbs, adjectives, adverbs and pictures to demonstrate the unique lateralization of language in VJ. She is able to name RVF/LH stimuli aloud, but cannot write the names. In contrast, she writes the names of LVF/RH stimuli, but cannot name them aloud. We argue that in this familially left-handed patient, phonological output is isolated in the left hemisphere whereas graphemic output is isolated in the right. This hemispheric separation of input and output for visual language suggests that the evolutionarily late skill of

written language has varied cortical representation. Supported by NIH/NIDCD grant R29 DC00811 to K.B. and NIH/NINDS grant PO1 NS 17778-14 and the McDonnell-Pew Foundation to M.S.G.

SELECTIVE SPEECH MOTOR, SYNTAX, AND COGNITIVE DEFICITS ASSOCIATED WITH BILATERAL DAMAGE TO THE HEAD OF THE CAUDATE NUCLEUS AND THE PUTAMEN. A CASE STUDY.

Emily R. Pickett, Athanassios Protopapas, Joseph Friedman[†], Philip Lieberman, and James A. Anderson*. Department of Cognitive & Linguistic Sciences, Brown University, Providence RI 02912; †Department of Clinical Neurosciences, Brown University, and Department of Neurology, Roger Williams Medical Center.

Deficits in speech production, sentence comprehension, and abstract reasoning occurred in a subject having profound bilateral damage to the anterior caudate nucleus and putamen. Acoustic analyses indicated that the subject's speech was degraded due to inappropriate sequencing of articulatory gestures that involve different articulatory structures. Transitions between sounds were slow and often did not achieve target configurations. The subject had a 14% error rate comprehending distinctions in meaning conveyed by syntax in English sentences; normal controls make virtually no errors in this test. Cognitive deficits involving impaired sequencing occurred: the subject had a 70% error rate on the Odd Man Out test when making decisions within a single category. Cognitive perseveration occurred when the subject was asked to shift categories. In contrast, performance vas within normal ranges in tests of lexical access and memory. The pattern of deficits provides evidence for basal ganglia involvement in the regulation of sequencing across modalities.

DETECTING ABNORMAL BRAIN ACTIVATION IN INDIVIDUAL SUBJECTS USING POSITION EMISSION TOMOGRAPHY. T. J Grabowski*, R. J. Frank, C. K. Brown and H. Damasio. Div. Cognitive Neurosci., Dept. Neurology, Univ. of Iowa, Iowa City, IA 52242.

The application of pixelwise linear models to the analysis of position emission tomography (PET) activation images from individual subjects has not been thoroughly explored. We report the specificity and sensitivity of an outlier detection method for detecting deviations from a normative pattern of activation

Data from a verb generation paradigm (16 subjects; 4 task-pairs) were analyzed with a standard two-way ANCOVA (Model I), two-way ANCOVA with a subjectby-task (SXT) interaction term (II), and two-way ANCOVA with an "outlier SXT" interaction term (III). Model III contrasted individual subjects with the normative group under three conditions: A. no putative outliers (control), B. simulated location outliers and C. simulated negative intensity outliers (i.e. lack of expected activation) A consistent pattern of activation occurred in individual subjects, evidenced by the absence of significant SXT interaction in Model II and the absence of outliers in target regions when individuals were contrasted with the group using Model IIIA

When each subject was analyzed with respect to the group using Models IIIB and IIIC, simulated blood flow increase in 3 homologous regions was detected in 79% of instances (N=48) and simulated lack of activation in 6 regions of expected increase was detected in 56% of instances (N=96). Greater variance in regions with significant task effect reduced power in the latter case. Regions whose activity could be predicted to be correlated were detected jointly more powerfully than individually.

Despite the noisy nature of PET activation images, it is possible to investigate hypotheses with individual subjects when activation data from a normative group is available. This method is applicable to the undamaged hemispheres of subjects with acquired lesions

ACTIVATION OF FRONTAL MOTOR AREAS DURING SILENT LIP READING: A PET ACTIVATION STUDY. S. T. Grafton*, L. Fadiga, M.A. Arbib, G. Rizzolatti. Dept. of Neurology, Univ. Southern CA School of Med., Los Angeles, CA 90033

Verbal communication relies on acoustic and visual information, with acoustic pathways normally predominating. Lip movements that are incongruous with sounds can lead to startling comprehension errors (McGurk effect). We used PET CBF imaging to trace the cortical circuitry underlying lip reading and in particular to see which speech areas were involved

7 normal right handed subjects were scanned during: (1) control condition of object viewing; (2) observing the investigator making silent monosyllable mouth movements (e.g. ba, da, me, go...); (3) same as condition 2 with subjects silently mimicking the observed lip movements. Images were coregistered in Talairach coordinates and a threshold of p<0.005 was used for all categorical comparisons.

Silent lip reading vs. control activated left frontal operculum (Talairach coordinates: -39, 17, 3) in Brodmann's area B.A. 45.

Mimicking with precise regime of the proportion of the

Mimicking vs. lip reading activated left precentral sulcus (-39,8,12), B.A. 44, bilateral precentral gyrus (-50 & +50, 5, 30), B.A. 6, and bilateral central sulcus (L>R) (-50 & +50, -12, 33), B.A. 4. The B.A. 45 activation was attenuated when mimicked movements were performed. No acoustic or "receptive" language areas were activated.

The findings suggest visual information enters the language circuit in frontal motor areas including B.A. 45, consistent with motor theories

of speech.

EXPLAINING CATEGORY-RELATED EFFECTS IN THE RETRIEVAL OF CONCEPTUALAND LEXICAL KNOWLEDGE: OPERATIONALIZATION AND ANALYSIS OF FACTORS, C. G. Logan*, D. Tranel, R. J. Frank, and A. R. Damasio. Div. of Cognitive Neurosci., Dept. of Neurology, University of Iowa, Iowa City, IA 52242.

Category-related effects in the retrieval of conceptual and lexical knowledge for concrete entities presented visually have been well documented in lesion studies, and more recently, with functional imaging and electrophysiological approaches. For example, brain-damaged patients may lose the ability to recognize (or to name) most animals but not tools; or the opposite pattern may obtain. Several stimulus- and subject-related factors have been proposed to underlie such effects, including homomorphy (shared shape), manipulability, characteristic motion, sensory modality of transaction, familiarity, age of acquisition, and value. Here, we report a study in which we operationalized these factors and analyzed their intercorrelations. Stimuli were slides of 215 items from the conceptual categories of animals and birds, fruits and vegetables, tools and utensils, vehicles, and musical instruments. The factors were operationalized through ratings from 218 normal control subjects or by computer analysis of the objects' digitized outlines. Principal components analysis revealed that 86% of the variability across items could be accounted for by 3 factors: Items that loaded highly on Factor 1 had high homomorphy and low ratings on characteristic motion and manipulability. Items loading highly on Factor 2 had high ratings on value, touch, and familiarity, and low age of acquisition. Items loading highly on Factor 3 had high ratings on hearing and highly distinctive sounds. In another analysis, we found that homomorphy, characteristic motion, manipulability, touch, familiarity, and value all significantly differentiated between animals and tools/utensils. These findings allow us to test the notion that the driving force behind the regionalization of neural systems related to acquisition and retrieval of conceptual and lexical knowledge results from systematic differences in physical characteristics and contextual specification of concrete entities

MODULATION OF N400 AND Dm EVENT-RELATED POTENTIALS BY IMAGINAL AND SEMANTIC PROCESSING OF CONCRETE AND ABSTRACT SPOKEN WORDS. W.C. West* C.D. Hong. and P.J. Holcomb. Department of Psychology, Tufts University, Medford MA 02155.

Visually presented concrete words have been shown to elicit more negative event-related potentials beginning as early as 250 msec after stimulus onset than have abstract words (Kounios & Holcomb, 1994). The duration, amplitude, and scalp distribution of this effect was found to vary with the type of processing strategy used by subjects (West & Holcomb, 1995). In particular, semantic strategies produced large concreteness effects across the entire scalp while imaginal strategies produced smaller effects which were restricted to anterior sites. The present study replicated the methodology of West & Holcomb (1995) in the auditory modality. Two groups of 12 subjects performed a sentence verification task in which the final word of each sentence (160 trials) was either a concrete or abstract noun. For the first group, the truthfulness judgement required the use of imagery and for the second group it involved a semantic decision which was not aided by imagery. ERPs to concrete words were more negative than to abstract words between 350 and 750 msec post-stimulus onset (N400). This effect increased toward anterior sites for both groups and was larger over the right hemisphere for the semantic group. Subjects in this experiment were also tested for recall of the sentence final words after every 20 trials. Subsequently recalled concrete words elicited a more positive ERP during encoding between 500 and 900 msec post-stimulus onset than non-recalled concrete words (Dm), while recalled abstract words did not differ from non-recalled abstract words. Comparison of these results to previous ERP memory research as well as implications for the role of imagery in language processing and memory will be discussed.

440.9

WHEN YOU LEAST EXPECT IT: CONTEXT EFFECTS AND CATEGORIZATION IN SENTENCE PROCESSING.

Kara D. Federmeier*† & Marta Kutas*°, Departments of Cognitive Science† and Neuroscience°, UCSD, La Jolla, CA 92093

Neurosterice (1981), La Man, CA 2008. Context and category membership have both been shown to influence the amplitude of the same electrophysiological component, the N400 (e.g., Kutas & Hillyard, 1984; Harbin et al., 1984). We hypothesize that this relationship arises because sentence context activates world knowledge which is stored in long term memory and organized according to perceptual and functional similarities as reflected in taxonomic categories. In this experiment we examined the extent to which category structure is used in on-line sentence processing. We recorded event related brain potentials (ERPs) as subjects read pairs of sentences for comprehension. The first sentence set up an expectation for a particular exemplar of a particular category while the second sentence ended with (1) the expected exemplar (2) an unexpected exemplar from the expected category. of 3n an unexpected exemplar from an unexpected category (e.g., "She wanted to treat her guests to an all-American pie. She went out in the back yard and picked some (1) apples/(2) oranges/(3) carrots"). Although all unexpected items elicited an N400, it was significantly smaller (i.e. closer to the response for the expected exemplar) if the item was a member of the expected category than if it was from a different category. Moreover, we found that if the expectation for a particular item was strong the N400 to an unexpected category member was smaller than if the expectation was weak, despite the fact that its fit to the context was poorer. This not only supports our view that category structure influences sentence processing on-line but also suggests that its impact may be a function of the degree to which the

category member is expected.

PET STUDIES OF SEMANTIC ANALYSIS A. L. Roskies*, J.A. Fiez, D. A. Balota, J.G. Ojemann, M.E. Raichle, and S. E. Petersen, Washington Univ. Sch. of Med., Box 8225, St. Louis, MO 63110.

A semantic categorization task was used to examine activation related to the processing of word meaning using PET. Subjects viewed word pairs, one member of which was a category name, and indicated by keypress if the second member of the pair was an exemplar of that category. Subjects were scanned while performing this task both in an easy condition with typical category-member pairs (e.g. bird - robin), and a <u>hard condition</u> with atypical pairs (bird - ostrich); each word was used in both the <u>easy</u> and <u>hard</u> tasks.

Responses were slower and less accurate (p<.01) in the <u>hard</u> than the <u>easy</u> task. Several regions showed similar activation across tasks, including regions in the left frontal operculum and the right cerebellum. Other regions showed greater activation in the <u>hard</u> than the <u>easy</u> task (p<.01), including one area in right lateral cerebellum, and one at or near left BA47.

The same subjects performed two other tasks of equivalent difficulty: synonym and rhyme judgment. The left frontal operculum was again active for both tasks, while the BA47 region was more active during synonym than rhyme (p<.07). Previous experiments have revealed similar distinctions between a verb-generation and a stem-completion task. Both tasks activated a region in the left frontal operculum, while the verb-generation task, which had clear semantic demands, activated a more anterior frontal region near area 47.

The combined results from this and previous studies provide evidence that there are dissociable frontal regions involved in language processing, and that a region in left anterior prefrontal cortex may specifically contribute to semantic processing. Supported by NIH grant NSO6833, the Charles A. Dana Fndn., and the McDonnell Ctr. for Higher Brain Function.

440.8

BILATERAL REPRESENTATION OF COORDINATE SEMANTIC RELATIONS: EVIDENCE FROM EVENT-RELATED POTENTIALS. D. J. Wegesin.* College of Physicians and Surgeons, Columbia University, New York, NY USA.

Though language centers are situated primarily in the left hemisphere (LH), right hemispheric (RH) mediation of semantic processing has been frequently reported. We herein summarize electrophysiological evidence which supports bilateral mediation of coordinate semantic relations (i.e. shared categorical membership like apple-pear). Forty right-handed men and women completed a divided-visual field Lexical-Decision/Semantic Monitoring task. Subjects identified Pseudowords in a serially presented list of Pseudowords, Semantically-related words, and Control words. Analysis of the P2 complex - computed using the mean amplitude in the latency ranges 230 - 530 - revealed that Semantic words presented to the RVF were similar to Control words; both evoked a large P2c asymmetry suggestive of greater LH involvement. However, when words were presented to the LVF, the asymmetry remained only for Control words. LVF Semantic words evoked more equivalent activity across the two hemispheres suggestive of bilateral processing of Semantic but not Control words. Latency analyses revealed that while both hemispheres responded differentially to Control and Semantic words, the LH did so earlier than the RH

WORD REPETITION WITHIN- AND ACROSS- VISUAL FIELDS: AN EVENT-RELATED POTENTIAL (ERP) STUDY.

M.C. Doyle and M.D. Rugg*. Wellcome Brain Research Group, School of Psychology, University of St. Andrews, St. Andrews, Fife, UK.

The present experiment investigated the sensitivity of the ERP word repetition effect to the visual field in which the words are encountered. 12 subjects performed a go/nogo lexical decision task, responding only to nonwords. First and second encounters with repeating words occurred on immediately successive trials. For each visual field of presentation there were three experimental conditions. First presentation (left;right), repetition within visual field (left-left; right-right) and repetition across-visual field (left-right; right-left). ERPs (28 scalp sites) were formed for each experimental condition. Non-words were detected more quickly and more accurately when presented to the right visual field. Between 400 and 600 ms post-stimulus onset a reliable ERP repetition effect was found in each repetition condition. In the left-left and right-right conditions the repetition effect was greater over the right hemisphere than over the left, particularly at posterior sites. This pattern of results suggests that the processes reflected by the ERP repetition effect are dissociable from those responsible for lexical analysis, and are more strongly represented in the right hemisphere

Wellcome Trust, UK.

WHAT DO FACES AND LETTER-STRINGS HAVE IN COMMON? EARLY EVENT-RELATED POTENTIAL EVIDENCE. G. Ganis*®, H.E. Schendam®, and M. Kutas. Cognitive Science, UCSD, La Jolla, CA 92093-0515. Neuropsychological and behavioral studies have noted processing differences between written words and non-linguistic visual objects. Previously we reported on the nature and time course of such processing differences from ERPs recorded to word-like (concrete nouns, pronounceable nonwords, pseudo-font strings) and object-like stimuli (line drawings of common objects and pseudo-objects) as well as icon strings, which are both word- and object- like, in three tasks. We found that word-like stimuli elicited a much larger P150 than objects or pseudo-objects. On the basis of its latency and distribution we put forth the hypothesis that this P150 may be a reflection at the scalp of the intracranial-recorded 'letter-string' N200 observed over discrete regions of the posterior fusiform gyrus. (Allison et al., 1994). Intracranial 'face' N200s have been observed adjacent to intracranial 'letter-string' N200s in regions of posterior fusiform gyrus. Thus, if our hypothesis is correct, faces should elicit a scalp P150 that is very similar in distribution, amplitude, and latency to that elicited by letter-strings. To test this hypothesis, we replicated and extended out previous experiment with the addition of a face condition. Consistent with our hypothesis, results show that letter-strings and faces do indeed elicit nearly identical scalp P150s, while objects and pseudo-objects elicit much smaller P150s. The P150 to faces is probably equivalent to the 'vertex positive peak' discussed by Jeffreys (1992). Since the P150 to letter-strings and face detection, If the P150s, or a subcomponent of this ERP, is the reflection of the intracranial N200 at the scalp, then it can be used as an important tool to study early visual processes in intact individuals. UNIVERSAL GRAMMAR'S EMERGENCE FROM PROTOLANGUAGE: CORTICOCORTICAL COHERENCE COULD ENABLE BINDING AND RECURSIVE EMBEDDING. WILLIAM H. CALVIN*, University of Washington, Psychiatry, Seattle WA 98195-1800. http://weber.u.washington.edu/~wcalvin

Psychiatry, Seattle WA 98195-1800. http://weber.u.washington.edu/~wcalvin A brain mechanism for recursive embedding (such as sentences within sentences: I think I saw him leave to go home) is considered essential for Universal Grammar (features common to all known languages except pidgins). Among the linguists' other desiderata are mechanisms for long-range dependencies, including binding of pronouns to their referents. Such binding requires longer-than-local links; recursive embedding requires structuring a hierarchy of them.

Corticocortical axon bundles are considerably worse than the incoherent fiber optic bundles where neighbors fail to remain neighbors. I have predicted (Soc. Neurosci. Abstr. 1993), however, an error-correction ability that should emerge from the lattice connectivity of the superficial pyramidal neurons. Were it not well tuned, linkages would be restricted to well-practiced special cases, analogous to the mariners' signal flags – and to only a few at a time, limiting the possible associations conveyed. Embedding would be restricted to stock phrases. Properly tuned up, the error-correction circuitry could reconstitute an arbitrary spatiotemporal firing pattern in the target cortex – and thus convey novel associations, even passing them through a hierarchy of embeddings. This makes corticocortical coherence a candidate for what converted protolanguage (structureless pidgins) into Language Itself (linguists doubt that intermediate forms exist). Indeed, the transition from special-case to arbitrary code conveyance could have implemented both major innovations of Universal Grammar – embedding and long-range links. The versatile linkages described here, in the context of a darwinian process at each end to bootstrap quality, might also have helped convert the infrequently-innovating cultures of Homo erectus into the constantly-evolving ones of Homo sapiens. ERPs AND SEX DIFFERENCES IN REGULAR AND IRREGULAR PAST TENSE VERB FORMATION. D.W. Shucard*, J.L. Shucard, G.L. Ciupak, J.J. Jaeger, A.H. Lockwood. Depts Of Neurology, Linguistics, and Nuclear Medicine, SUNY @ Buffalo, 100 High Street (D-6), Buffalo, NY 14203. The purpose of the present study was to investigate the neural patterns of activation during the production of regular and irregular past tense forms of English verbs. Currently, there are two competing theories that implicate different brain systems or mechanisms in these functions. One theory suggests that separate systems are responsible for regular and irregular verb production, whereas the opposing theory posits that one system serves both functions.

Young adults (7 males, 7 females) performed five visually presented tasks: 1) read aloud a series of verbs, 2) read aloud a series of verbs, 2) read aloud a series of verbs, 2) read aloud a series of orthographically regular nonce verbs, 3) form the past tense of regular verbs and speak them, 4) form the past tense of irregular verbs and speak them, and 5) form the past tense of nonce verbs and speak them. Measures of cerebral blood flow with positron emission tomography (PET) and cortical event-related potentials (ERPs) were obtained simultaneously while the tasks were performed. Here, only ERP data are presented. Three peaks between 58 and 270 msecs were identified from 18 electrode sites. Several findings are noteworthy: 1) The occipital leads showed a significant condition effect (P<.006) indicating that the amplitude of the Peak 2 ERP component (N₁-P₂) was different across conditions, irrespective of the sex of the subject. 2) Significant sex-related ERP amplitude differences were present that were dependent on both the conditions and the scalp sites. Males, but not females, showed a significant Condition x Site interaction (p<009). The highest ERP amplitude was seen at the frontal sites for the formation of past tense regular verbs. Further, the temporal scalp sites showed a significant Sex x Condition x Hemisphere interaction (P<008) indicating that there was a different pattern of hemispheric asymmetry present between males and females across conditions. The findings are related to differences in brain organization between males and females and reflect functional relationships between grammatical tasks and brain mechanisms responsible for these tasks. HEMISPHERIC COOPERATION DURING MOTOR PROGRAMMING AND LANGUAGE PERCEPTION. F. Pulvermüller *, B. Mohr & W. Lutzenberger Institute of Medical Psychology and Behav. Neurobiology, University of Tübingen, 72074 Tübingen, Germany Execution of complex tasks involves both hemispheres. For

Execution of complex tasks involves both hemispheres. For example, sequential finger movements with only one hand are accompanied by both contralateral and ipsilateral cortical activity. To demonstrate that both hemispheres significantly contribute to lateralized processes, language processes were investigated. Word processing is speeded if not only the language-dominant left hemisphere, but, in addition, the right hemisphere is directly stimulated. Thus, in this case, the inferior hemisphere contributes to better performance. However, this does still not demonstrate that activity flow between the hemispheres is relevant for better performance. Therefore, electrocortical activity was recorded when verbal stimuli reached the left, right, and both hemispheres. Bilateral presentation led to enhancement of activity signs over left-hemispheric language areas (relative to LH stimulation), indicating that activity flow from the right hemisphere takes place. Thus, (i) both hemispheres are activated when complex tasks are being performed; (ii) both hemispheres can contribute to better task performance when they are coactivated; (iii) if coactivation leads to better task performance, activity flow between the hemispheres can be demonstrated. These data support models of interhemispheric cooperation.

DIFFERENTIAL ACTIVATION OF HUMAN CORTICAL AREAS DURING MENTAL ROTATION AND MEMORY SCANNING: A HIGH FIELD FUNCTIONAL MRI STUDY. G.A. Tagaris*, W. Richter, S-G. Kim, G. Pellizzer, P. Andersen, K. Ugurbil and A.P. Georgopoulos Brain Sciences Center, VAMC and Center for Magnetic Resonance Research, Univ. of Minnesota Medical School, Minneapolis, MN.

Six human subjects performed two variants of mental rotation and memory scanning tasks while multislice BOLD functional MR images were acquired with a 4 Tesla system. The tasks used included (a) mental rotation of a figure, (b) mental rotation of an intended movement direction, (c) memory scanning to determine the order of presentation of a sequence of lights and (d) memory scanning to generate a movement in a direction based on a serial order rule. Appropriate control tasks were used. The main results are summarized below.

(i) In both mental rotation tasks the superior parietal lobule was activated, whereas in the memory scanning tasks activation was observed predominantly in the inferior parietal lobule, (ii) all four tasks activated the precentral gyrus, (iii) cerebellum was preferentially engaged in tasks that required directed movements (tasks b and d) and (iv) all four tasks activated extrastriate visual areas.

These results reveal for the first time the differential activation of two parietal areas in mental rotation and memory scanning. They also demarcate the role of precentral motor areas and the extrastriate visual cortex as common nodes in both cognitive processes. Finally, these results demonstrate the preferential involvement of the cerebellum in cognitive operations on spatial motor representations (Supported by NIH grants NS32919 and RR088079)

AN fMRI STUDY OF FRONTAL CORTEX AND CEREBELLUM DURING SEMANTIC AND WORKING MEMORY TASKS. J.E. Desmond*. J.D.E. Gabrieli, N. Sobel, L.A. Rabin, A.D. Wagner, C.A. Seger, and G.H. Glover, Depts of Psychology and Radiology, Stanford University, Stanford, CA 94305.

Prior studies have shown that retrieval of semantic information activates left frontal and right cerebellar networks, and these regions are also activated during verbal working memory tasks. The present study directly compares frontal and cerebellar activation in two tasks of semantic retrieval, verb generation (VG) and levels of processing (LOP), as well as in a Sternberg working memory (WM) task. For both VG and LOP, the non-semantic control condition required deciding if a visually-presented word was in upper- or lowercase letters. The semantic task tor VG required covertly generating an appropriate verb to a noun, and for LOP. covertly deciding if the word was abstract or concrete. For WM, difficult (6 letters to remember) and easy (0 letters to remember) conditions were alternated. Brain images were collected in 7 oblique axial planes rotated 25° from AC-PC line to image frontal and cerebellar structures. Functional MRI (fMRI) was obtained with a T2*-weighted gradient echo spiral pulse sequence (1.5T, TR=630 ms, TE=40 ms, flip=66°, inplane resolution=2.35 mm, thickness=6 mm). Results from 6 subjects show overlapping activation in left prefrontal areas in VG, LOP, and WM tasks, including portions of inferior and middle frontal gyri and insular cortex. However, WM produced more bilateral activation, suggesting that frontal semantic working memory networks invoked by VG and LOP may be part of a verbal working memory network. In cerebellum VG, LOP, and WM activated right HVIIB. More superiorly, VG activated right posterior HVIIA, whereas WM activated vermis and bilateral HVI (right > left). Less cerebellar activation was observed for LOP than for VG even when frontal activation was comparable, suggesting possible differences in cerebellar computation during performance of these semantic tasks. Supported by NIH (F32NS09628) and NIA (AG 12995).

RESPONSE-RELATED ERP COMPONENTS IN NEWLY LEARNED AND OVERLEARNED S-R COMPATIBILITY TASKS. C. A. Christensen* and K. J. Drake. Dept. of Psychology, Vassar College, Poughkeepsie, N.Y., 12601.

Response times (RTs) and ERP components were evaluated in two S-R compatibility tasks to evaluate whether RT prolongation makes a late response-related component (RRC) more evident. Subjects pressed either a right or left key in response to the words LEFT and RIGHT (overlearned) or CAJ and PUY (newly learned), following an instruction stimulus that indicated whether a compatible or incompatible response was required. Obvious P2, P3a and P3b peaks were observed in both the instructionstimulus and action-stimulus ERPs, though a fourth positive peak was observed in the action-stimulus ERP only, consistent with its identification as response related. The RRC, which followed the P3b, was more evident when RTs were prolonged, on incompatible trials and early in learning the new task. RT splits of trials into the fastest and slowest halves showed that the RRC was pronounced on slow trials, though it often was less apparent or absent on fast trials because of temporal overlap with the P3b component.

RETROACTIVE INTERFERENCE IN MEMORY: AN EVENT-RELATED POTENTIAL STUDY, I. Tendolkar. M.C.Doyle, M.D.Rugg . Wellcome Brain Research Group, School of Psychology, University of St Andrews, St Andrews, Fife KY169JU, UK. (SPON:European Brain and Behavior Society)

The purpose of this study was to search for an ERP correlate of retroactive interference. Word pairs were presented visually in two different study lists. At test subjects (n=16) were presented with a mixture of new items and the first members of the word pairs from list 1. They made an old/new judgement, and for items judged old, attempted to recall the item with which it had been associated in the first study list. In the interference condition, the same word was paired with different items in the two study lists (A-B; A-C). In one control condition item pairs were presented in only one list (D-E; F-G), while in another control condition same item pairs were presented in both study lists (J-K; J-K). Associates from the interference condition were recalled reliably less often than in each of the control conditions. Event-related potentials to items correctly judged old, and for which the second word was recalled, differed reliably from new items. This "old/new" effect was reliable over midline and lateral sites, and was greater in magnitude over the left than over the right hemisphere. There was no reliable difference in the size or topografy of this effect between interference and control conditions. The findings suggest that event-related potentials reflect retrieval operations yielding episode-specific information. There was no evidence for a specific electrophysiological correlate of the behavioral interference effect.

AN EVENT-RELATED BRAIN POTENTIAL CORRELATE OF CENTRAL EXECUTIVE FUNCTION: ADDITIONAL EVIDENCE. <u>I. Kiss*, H. Pazderka-</u> Robinson, and D. Schopflocher. Toupin Psychophysiology Lab. & University of Alberta, Edmonton, AB T5G 0B7

In a previous series of experiments, we employed a working memory (WM) task (Morris and Jones, 1990) shown to provide access to the central executive (CE) as described in Baddeley's (1986) model of WM. Subjects viewed variable length (e.g., 2 to 5 item) series of individually presented digits followed by sets of (e.g., 2) digits. Dynamic revision (updating) of WM contents was required for subjects to correctly indicate whether sets matched the single digits immediately preceding them. We recorded ERPs to provide non-invasive, on-line access to brain electrical activity, permitting potential behavioral and electrophysiological measures associable with CE function (updating). However, the ERP data were also interpretable as reflecting non-CE processes, including activities associable with storage components of WM (i.e., rehearsal) and processes related to proactive interference. We present recent studies designed to investigate both alternate explanations. One employed visual and auditory versions of a memory updating task. A second involved specific manipulations to compare ERP correlates of rehearsal and updating and incudes several interstimulus intervals to examine proactive interference. These appear to indicate that our original interpretations of our ERP findings as reflecting CE activity remain valid. Implications for Baddeley's model and basic and applied uses for this methodology are discussed.

WORD REPETITION EFFECTS ON EVENT RELATED POTENTIALS (ERPs) AND MEMORY IN HUMAN VOLUNTEERS BREATHING AIR OR ISOFLURANE C.Villemure, G.Plourde*, P.Fiset, D. Lorrain. Départ. Physiologie, Univ. de Montréal; Anesthesia Dept. Royal Victoria Hosp., McGill Univ., Montréal (Québec) Canada, H3A 1A1.

It is unclear whether repetition effects on ERPs reflect processes underlying implicit or explicit memory. We recorded ERPs while presenting 24 digitized spoken words repeated 10 times to 11 non-medicated controls (CTRL) and 13 volunteers (EXP) breathing 0.26% end-tidal isoflurane. Subjects responded to rare (10%) male voice targets. ERPs to female voice at Pz were averaged separately for the first, second, and implicit (syllable completion) lasks. ERP repetition effects, involving a decreased P2 amplitude and an increased positivity of a late component (LC) for the repetitions, were observed in both grand averages. We measured P2 amplitude and the mean amplitude in the range 400-700 ms (CTRL) and 800-1050 ms (EXP). For CTRL (mean \pm SD; first, second, ninth and last presentations respectively) P2: 7.64 \pm 3.76, 6.81±4.72, 5.04±3.41, 4.92±4.21; LC: -1.47±3.44, -0.94±3.51, 2.79±3.55, 1.10±2.94 and for EXP P2: 1.95±2.72, 0.41±2.39, 0.88±1.85, 0.85±1.59; LC: $0.33\pm2.38,\ 0.92\pm1.83,\ 1.78\pm1.74,\ 1.62\pm2.24$. Planned comparisons between the first and the mean of the 3 other presentations showed that, for CTRL, the amplitude differences were significant (P2: p=0.037; LC: p=0.048). They approached significance in the EXP (P2: p=0.063; LC: p=0.070). ANOVAs' results showed that significance in the EAT (12.75–50.05), $E_{\rm p}$ = 0.000. ANOVAS is stories shown that both groups had implicit memory (CTRL (mean % ±SD): hits= 4.39 ± 11.24 ; base= 3.79 ± 4.35 ; p=0.029; EXP: hits= 6.41 ± 4.99 ; base= 3.52 ± 4.11 ; p=0.013). T-tests indicated that only CTRL had explicit memory (CTRL: $21.97\%\pm14.08$; p < 0.01; EXP: 1.28% ± 2.63 ; p > 0.1). We observed evidence of ERPs repetition effects in the presence of implicit memory without free recall. We conclude that ERPs repetition effects are not linked to explicit memory measured with free recall. Support: FCAR, FRSQ, F.E.S. of UdeM.

EVENT RELATED POTENTIALS TO FALSE MEMORY J. Hopfinger*.1,2 EVENT RELATED POTENTIALS TO FALSE MEMORY 1. Topinger—
E. Duezel's A.P. Yonelinas' E. Tulving G.R. Mangun's Center for Neuroscience & Dept. of Psychology². University of California. Davis CA 95616; Dept. of Clinical Neurophysiology, Otto-v-Cuericke University, D-39120 Magdeburg, FRG's Dept. of Psychology, University of Toronto & The Rotman Research Institute of The Baycrest Center, Ontario M6A 2E1 Canada⁴

False memories were examined using a modified version of Roediger and McDermotts (1995) false recognition paradigm based on the semantic relatedness effect. Event related potentials (ERPs) were obtained during a recognition memory test for studied words, semantically related words ("lures") recognition memory test for studied words, semantically related words ("lures") and nonstudied words, eliciting either remember, know or new responses. A large proportion of lures were falsely accepted. Lures and studied words elicited smaller N400 components over parietotemporal electrodes than nonstudied words, indicating semantic priming effects. Remember responses to studied words and to lures elicited more positive going ERPs than rejections and know responses. This positivity to remember responses appeared bifrontally within a time window from 600 to 1200 ms and was most prominent over eight freaty electrodes. These were no enablishing differences in the EPPs right frontal electrodes. There were no qualitative differences in the ERPs elicited by remember responses to accepted studied words and lures. But more elicited by remember responses to accepted studied words and lures. But more remember responses were given to accepted studied words than to lures, and this was reflected in slightly more positive going ERPs to accepted studied words as compared to accepted lures. These data indicate different ERP components to remembering and knowing and provide evidence for a physiological basis for the mental phenomenon of remembering events that did not happen. H.M. REVISITS THE TOWER OF HANOI PUZZLE. Y. Xu* and S. Dept. of Brain and Cognitive Sciences, and the Clinical Research Center, Mass. Institute of Technology, Cambridge, MA 02139

Cohen and Corkin (1985) reported that the amnesic patient, H.M., acquired the skill for solving the Tower-of-Hanoi puzzle during 4 days of testing, ultimately solving the problem in the minimum number of moves. During their testing, a set of questions was posed to H.M. repeatedly to encourage his adoption of an effective strategy. However, when H.M. was tested again by Gabrieli et al. (1987) with a different experimenter and minimal experimenter-subject interaction (no questions posed), he failed to improve his performance in solving the puzzle. Gabrieli et al. attributed H.M.'s failure to the absence of frequent experimenter-subject interactions. The present study compared H.M.'s performance in the two conditions, administrated by a single experimenter. H.M. (age, 69; education, 12) was tested twice, first, following the Cohen and Corkin protocol, and then 4 months later, following the Gabrieli et al. protocol. On both occasions, H.M. failed to improve his performance either within or across the four days of testing. The average number of moves on each testing day was greater than twice the minimum number of moves. To our surprise, of the 8 normal control subjects (NCS) (mean age, 68.3; mean education, 12) tested under the Gabrieli et al. protocol, only 2 NCS improved their performance consistently and solved the puzzle in the minimum number of moves; the other 6 NCS performed like H.M. Among the NCS, success in solving the puzzle was not related to verbal IQ, or gender, but may have been related to prior experience in puzzle solving.

Cognitive Neuroscience

EVIDENCE THAT NICOTINE-INDUCED COGNITIVE ENHANCEMENT DOES NOT INVOLVE ANTIOXIDANT ACTIONS. K.B. Bjugstad, B.M. Crandall, and G.W. Arendash*. Dept. of Psychology and Biology, and Institute on Aging, Univ. of South Florida, Tampa, FL 33620.

Studies involving non-neural peripheral tissues have yield conflicting results regarding an antioxidant vs. pro-oxidant potential of nicotine. Given the large number of studies that demonstrate nicotine's ability to enhance cognition in both animals and humans, the present study sought to: 1) determine if nicotine exerts antioxidant effects on brain tissue in vitro and in vivo, and 2) determine if any in vivo antioxidant effects of nicotine could be linked to it's ability to improve cognition. Male rats (S.D., 5 mos) were injected twice daily with nicotine (0.8 mg/kg ip.) or vehicle for 10 days. Beginning on Day 5 of injections, rats were tested for acquisition and retention in the Morris water maze. Nicotine-treated rats showed greater retention for the platform location than the saline group. Neurochemical analysis of neocortex, hippocampus, and neostriatum from behaviorally tested rats revealed no group differences in reactive oxygen species formation (DCF fluorescense) or lipid peroxidation (TBAR formation) for any brain region studied. In a follow-up in vitro study involving addition of nicotine (7.5-50 mM) or Desferol (7.5-50 mM) to neocortical homogenates, nicotine increased TBAR formation by 334 - 706% while Desferol decreased TBAR formation by 24 - 82% compared to salinetreated tissues. The results of these studies suggest that antioxidant actions may not be involved in nicotine's ability to improve cognition and that, to the contrary, nicotine appears to exert pro-oxidant actions on brain tissue. IMPLICIT MEMORY FOR NONVERBAL ASSOCIATIONS UNDER DUAL TASK CONDITIONS. G. Musen*, S. Sehgal, and W.S. Brooks Barnard College, Columbia University, New York, NY 10027.

Familiarity and unitization of items play a role in priming of nonverbal associations. When a color and an abstract shape were unitized (e.g., presented as a colored shape), evidence for associative priming was obtained. However, no evidence for priming of color-shape associations was observed when the color and abstract shape were presented separately (e.g., a shape on top of a colored frame) (Musen & O'Neill, 1994). Perhaps working memory is needed to form the association, and its capacity is reached when the stimuli are neither familiar or unitized. In contrast, when only one of these processes must be carried out during learning, priming of associations readily occurs

If working memory resources are crucial for priming, then a secondary task should interfere with priming. The present experiments examined this issue. We used both a visual and an auditory secondary task across two different experiments. In the visual task, unitized colored shapes were presented on top of the same or different colored backgrounds as the shapes. Participants were to image the color and shape and to decide whether the background color was the same as or different from the color of the shape. There were no errors on the secondary task, and evidence for associative priming was still obtained. However, in the auditory tone-counting task, errors were made in the counting task and associative priming was not obtained. It is possible that a more difficult visual secondary task would also disrupt priming. We suggest that difficulty of both the stimuli to be learned and task demands contribute to the probability of obtaining priming. When the stimuli are neither unitized nor familiar, or the secondary task is difficult, priming is disrupted. Thus, implicit memory is affected by resource limitations. Supported by Edward J. King Memorial Fund.

CHARACTERIZING rCBF RESPONSE IN A PET STUDY OF GRADED WORKING MEMORY LOAD J.D. Van Horn*, J.L. Austin-Lane, B.S. Kirkby, G. Esposito, D.R. Weinberger, and K.F. Berman Unit on PET, CBDB, NIMH, Bethesda, MD 20892

Esposito, D.R. Weinberger, and K.F. Berman Unit on PET, CBDB, NIMH, Bethesda, MD 20892

Few studies have been conducted to document the neural response to increasing cognitive load. Such responses may demonstrate linear and nonlinear (e.g. quadratic, cubic, etc.) components as the demand for neural resources increases. Within the context of a working memory paradigm, we used PET to investigate the neurophysiological effects of varying the amount of remembered material and the number of manipulations performed on that material. Nine normal subjects were studied with oxygen-15 water IV bolus PET (10 mCiscan) on a GE Advance 3-D PET scanner. Seven different cognitive conditions were repeated four times for a total of 28 rCBF measurements pseudorandomly distributed over three days. Stimuli consisted of strings of two, four, and six elements (50% numbers, 50% letters per stimulus) presented on a computer screen for 1.5 sec. For the six cognitive conditions, subjects responded after a 4 sec delay. For the control condition, subjects immediately read the string aloud. The amount of remembered material was varied across three separate conditions (2, 4, or 6 items) in which no manipulation was varied across three separate conditions in which subjects were cued with four items upon which they performed one, two, or three separate sequencing steps during the delay, strict the delay, they responded with the reordered string. All scans for each subject were aligned via the method of Woods et al. (1992) and analyzed with SPM95 (Friston et al., 1995) using polynomial contrasts to map voxels in which there was a statistically significant (p<0.001) linear, quadratic, or cubic rCBF response to increasing either the amount of rememberd material or the number of manipulations performed on the material. Linear increases in rCBF with increasing manipulation were seen in dorsolateral prefrontal cortex (Brodmann areas 9 and 46), bilateral inferior parietal lobule and cerebellum, whereas quadratic and cubic contrasts were also present

EFFECTS OF SMOKING ON EVENT-RELATED POTENTIALS IN A MEMORY

EFFECTS OF SMOKING ON EVENT-RELATED POTENTIALS IN A MEMORY SCANNING TASK. J. A. Pineda*, C. Herrera, and A. Sandler. Cognitive Science and Neuroscience Departments, University of California, San Diego, La Jolla, CA 92093-0515.

Event-related potentials (ERPs), reaction times (RTs), and performance accuracy were recorded from smokers during the performance of a memory task under a smoking and a 12-hour deprived condition. Stimuli consisted of lists of words presented one at a time in blocks of five to a monitor located in front of the subject. Following each block, a probe word was presented. Subjects responded to the probe as either part of the previously displayed set (in-set) or not (out-of-set). In the smoking condition, the magnitude of the P300 was larger to both in-set and out-of-set probes. In contrast, latencies were different only to the in-set probes. Amplitudes exhibited a U-shaped function to in-set probes according to their position on the list. That is, words in the first and fifth position typically elicited larger potentials than those in the middle positions. These primacy and recency effects were enhanced in the smoking condition. Although latencies did not exhibit primacy and recency effects were enhanced in the smoking condition. Although latencies did not exhibit primacy and recency effects, RTs to in-set probes did show an inverted U-shaped function. Words in the first and fifth position exhibited faster RTs, with smoking causing a uniform slowing of RTs but a preservation of the inverted U-function. The P300 amplitude results support the hypothesis that smoking produces an enhanced attentional state, most likely due to the effect of nicotine on perceptual function. The P300 latency results suggest some degree of specificity in these effects. That is, memory search is specifically enhanced when an in-set but not an out-of-set probe occurs. The RT results indicate that smoking causes a slowing of motor function.

BEHAVIOR AND PHYSIOLOGY OF PICTURE-WORD PROCESSING IN HUMAN WORKING MEMORY. S.L. Provencal*, J.D. Lewine, P. Amrhein, J.C. Edgar, K. White, K. Paulson, and W.W. Orrison. New Mexico Institute of Neuroimaging and University of New Mexico. Albuquerque, New Mexico.

A Sternberg serial probe recognition task was used to examine mnemonic processing for within and between stimulus domains. At the start of each test block, subjects memorized a set of target stimuli (e.g., memory load of 2, 4, or 6 items) and determined whether a subsequently presented probe stimulus was a member of the memorized target set. Three domains of stimuli were evaluated - written words, corresponding visual pictures, and corresponding spoken words. Target-probe evaluations were either intra-domain (e.g., picture-picture) or inter-domain (e.g., picture-written word). During task performance, behavioral data were collected in conjunction with high-density electroencephalographic data (62-channels) and whole-head magnetoencephalographic data (122-channels). Preliminary results demonstrate that inter-modality processing (e.g.,

returninary results demonstrate that inter-modality processing (e.g., picture targets and spoken probes) is markedly different from intra-modality processing for both early and long latencies. On the other hand, within the visual modality, intra- and inter-domain processing (picture-picture and picture-word) engaged comparable brain mechanisms. For example, auditory probes being evaluated with respect to picture targets tended to elicit hiltered acceptance and the processing and the processing th bilateral responses, whereas picture and word probes being evaluated with ct to picture targets elicited left-lateralized long-latency responses

MEG source modeling suggests that left hemisphere auditory cortex may be active even in the evaluation of visual stimuli (e.g., picture-picture trials). The available data suggest that both modality specific and modality independent mnemonic mechanisms are engaged in the processing of visual and auditory mnemonic information.

THE EFFECTS OF HIPPOCAMPAL AND NEOSTRIATAL LESIONS ON DURATION ESTIMATION, SHORT-TERM MEMORY, AND TRANSFER PERFORMANCE OF TEMPORAL EVENTS IN THE PIGEON. J.M. Dose*, P.J. Kraemer & J.F. Zolman. Depts. of Psychology and Physiology, University of Kentucky, Lexington, KY 40506

The role of the avian hippocampus and neostriatum in duration estimation, short-term memory (STM) and transfer performance of temporal events was studied using a duration matching-to-sample (MTS) procedure. Pigeons were initially trained on two duration MTS problems in succession. Signals consisted of 2- and 10-s durations of red or white light presented from either the ceiling or front wall of a standard operant chamber. Choice stimuli consisted of red, green, yellow and blue solid colors presented on two side keys. Correct choices were followed by 2-s access to grain before a 15-s ITI commenced; incorrect choices immediately produced the 15-s ITI. Before and after receiving bilateral aspiration lesions of either the hippocampus or neostriatum, pigeons were tested with normal (nonprobe) and probe trials in duration estimation, short-term memory, and transfer performance tasks. Nonprobe trials for all test sessions consisted of red or white signals immediately followed by the appropriate choice stimuli. Probe trials in duration estimation consisted of the red or white signals being presented for intermediate signal durations (3-, 5-, 7-, or 9-s). Compared with pre-lesion performance, pigeons were more likely to respond "long" following hippocampus Probe trials in STM involved 2- or 10-s presentation of red and white signals: but, 1-, 3-, 6-, 9-, or 12-s delays were imposed between signal offset and choice onset Pre-lesion performance showed a "choose-short" effect, but this effect was disrupted following neostriatum lesions. Transfer probe trials consisted of red or white signals followed immediately by unexpected choice stimuli. Transfer performance was not disrupted by either lesion condition. Results will be discussed in terms of changes in temporal processing following disruption of normal hippocampal and neostriatal functioning

DUAL-TASK PERFORMANCE OF ROTARY PURSUIT AND EYEBLINK CLASSICAL CONDITIONING. J. T. Green and D. S. Woodruff-Pak. Dept. of Psychology, Temple Univ., Phila., PA 19122.

The purpose of this study was to test the hypothesis that different nondeclarative memory tasks are mediated by different brain substrates. A total of 80 young, normal adults participated in one of four conditions. Twenty subjects were simultaneously engaged in EBCC and rotary pursuit for half of an experimental session and EBCC alone for the other half. Twenty control subjects were engaged in EBCC alone for an entire session and twenty control subjects were engaged in rotary pursuit alone for an entire session. A fourth group of twenty subjects was simultaneously engaged in an explicitly unpaired paradigm and rotary pursuit for half of a session and an explicitly unpaired paradigm alone for the other half. The presumed essential brain substrate for EBCC is the cerebellum. The presumed substrate for rotary pursuit is ipsilateral motor cortex. The results revealed that performance of the rotary pursuit task caused excessive blinking during EBCC which mimicked learning by increasing eyeblinks during the CR period. When rotary pursuit was discontinued in the second half of a session, CRs declined, but to a level that remained significantly above performance of the EBCC-alone group, demonstrating that acquisition was slowed but not prevented during and level that learning that performance. The results from simultaneous performance of the province of that remained significantly above performance of the EBCC-alone group, demonstrating that acquisition was slowed but not prevented during dual task performance. The results from simultaneous performance of the explicitly unpaired paradigm and rotary pursuit supported this interpretation because responses to the unpaired CS declined after these subjects stopped simultaneous performance of the rotary pursuit task. Subjects learned rotary pursuit in all conditions. The results provide evidence for the independence of different measures of nondeclarative memory and highlight the difference between performance and learning of EBCC. Supported by AG09752 from NIA.

LEARNING OF SPATIAL AND MOTOR-RESPONSE SEQUENCES IN PATIENTS WITH PARKINSON'S DISEASE.

L.L. Helmuth* 1,2, U. Mayr³, and I. Daum¹ University of Tübingen, Germany; University of California at Berkeley, U.S.A.; University of Potsdam, Germany,

Sequence learning studies of patients with Parkinson's disease (PD) have yielded inconsistent results. Among the unresolved questions in this field are: a) whether PD patients are impaired in the acquisition of a sequence or in its execution, b) whether PD leads to comparable deficits in motor and attentional abilities, and c) whether sequence learning is related to the severity of PD.

The serial reaction time learning task used in the present study allows a separate assessment of the learning of two different types of sequence: one a stimulus-response sequence and the other a sequence of spatial positions in which stimuli appear on a screen We compare the performance of PD patients in early and more advanced stages of the disease, and control subjects, in both types of sequence learning. Preliminary evidence suggests that early PD patients do not differ from controls in their ability to improve performance in the presence of either type of sequence, whereas more advanced PD patients may show impairments

STM & LTM FOR A SPATIAL LEARNING TASK IN BLACK CAPPED CHICKADEES AND WHITE CROWNED SPARROWS.

CAPPED CHICKADEES AND WHITE CHOWNED SPARHOWS.

D.W. Lee* & N.S. Clayton. Section N.P.B., UC Davis, Davis, CA, 95616.

Hippocampal involvement in the distinction between short-term memory (STM) and long-term memory (LTM) has been demonstrated repeatedly:

STM is independent, but various forms of LTM depend upon the integrity of the hippocampal formation. Some species of food storing birds spend more time scaping, each more items and leave their caches for longer periods of time caching, cache more items, and leave their caches for longer periods of time during the fall than in the spring indicating that LTM may be superior during the fall. Also, the hippocampus of food storers 1) increases in volume and neurogenesis during the fall; 2) is necessary for memory formation of spatial but not visual cued tasks; and 3) is larger than non-storers. Furthermore, storing birds are better than non-storers at spatial learning tasks. If LTM for spatial learning in food storing birds is hippocampus-dependent but STM is not, storers should have superior LTM but not STM compared to non-storers. To test this hypothesis, food storing black capped chickadees (Parus atricapillus) and non-storing white crowned sparrows (Zonotrichia leucophrys) were trained to search and remove string knots on the faces of 7 visually and spatially unique "peanut feeders" to find food hidden in 1 of the feeders. They were then tested either 5 min or 24 h later. Seven new visually identical feeders were placed in the same spatial locations as those used during training; thus to find the food birds could rely on spatial but not visual cues. Data indicated that 1) both species showed memory in fewer trials when given the short rather than the long interval; 2) at both intervals, chickadees showed memory in fewer trials than sparrows; and 3) at the long interval, chickadees showed better memory for this task than sparrows. Results partially confirm the hypothesis: the food storing chickadee shows faster acquisition of both STM and LTM and superior LTM formation for this spatial learning task compared to the non-storing sparrow. ADAPTING TO ROTATED AND/OR INVERTED COORDINATE SYSTEMS. R.L. Savoy , K.M. O'Craven, R. Bergida The Rowland Institute for Science, 100 Edwin H. Land Blvd, Cambridge, MA 02142; MGH-NMR Center, Charlestown, MA; Boston University, Boston, MA

We implemented a computer controlled generalization of the "mirror-tracing" task. Subjects controlled the movement of a cursor on a computer display to trace a fixed path. In addition to traditional mirror inversions (either left/right and up/down), we implemented 180°-rotation (which is the composition of a left/right with an up/down mirror transformation), 90°-rotation, and 90°- rotation-plus-mirror-inversion. Instructions discouraged the use of

and 90°- rotation-plus-mirror-inversion. Instructions discouraged the use of cognitive strategies and encouraged visuo-motor learning. When both axes are reversed (180° rotation), most subjects find the task much easier than for either reversal alone. Performance in both speed and accuracy is much better than for the mirror inversion task, even shortly after the first trial begins. Performance on the 90° rotation task is particularly intriguing. Many begins. Performance on the 90° rotation task is particularly intriguing. Many subjects exhibit extremely poor performance for a period of time on the order of 20-120 seconds, and then suddenly perform at a level comparable to the 180° rotation task. This change is in the absence of reported cognitive changes. In contrast, when there is also a mirror inversion added to the 90° rotation, performance remains poor. EFFECTS OF FRONTAL LESIONS ON THE LEARNING OF A NEW SENSORIMOTOR MAPPING. M.J. Chouinard*, I. Rouleau and F. Richer. Lab. de Neuroscience de la Cognition, Univ. du Québec à Montréal, Montréal, Oc, Canada, H3C 3P8

In a previous study, we have observed that frontal lobe lesions in humans result in a longer tracing time in a mirror drawing task compared to temporal patients and controls (Chouinard & Rouleau, 1994). That slowing was mainly due to more frequent episodes of non-progressive tracing suggesting that frontals have difficulty adapting to a new sensorimotor mapping. To further explore that deficit, we tested patients with frontal excisions, temporal excisions and controls (N=39) in a computerized tracing task which modified sensorimotor mappings (Cunningham,1989). The subject had to move a cursor on a graphic tablet from the center to one of 4 peripheral targets. Ten blocks of 16 trials were administered: 2 blocks with no transformation, 3 blocks with a rotation of 180° of motor space, 1 block with no transformation, and 4 blocks with a reflection of the horizontal axis of motor space. Subjects visually controlled their movements on a monitor placed in front of them and an occluding screen hid the arm from view. Frontals showed longer trace lengths in the reflection condition than the other groups but showed normal improvement with practice. Tracing speed did not increase with practice in frontals as it did for the others. The results suggest that frontal lesions affect sensorimotor control when a new mapping is involved but not sensorimotor learning.

PREDICTIVE CODING OF STRUCTURED FORMS THROUGH DIVERGENCE OF CORTICAL

PREDICTIVE CODING OF STRUCTURED FORMS THROUGH DIVERGENCE OF CORTICAL CONNECTIONS P.Grandguilaume †.Y.Burnod†. K.S.Rockland† SPON: European Brain and Behaviour Society †CREARE.UPMC,75252 Paris ‡Dept Neurol,U lowa,lowa City,1A52242

We investigate how cortical circuits along sensory pathways may handle prediction while extracting growing selectivity to structured form, accounting for the reciprocal constraints between the connectivity and the spatial and temporal form of activity. We have developed a model, continuous in time and space, of the neural mechanisms underlying this cortical function. The formalism accounts for the propagation of intrinsic and extrinsic neuronal activity within and between the cortical areas of a processing pathway. The visual pathway is taken in reference. The operation performed by the model takes place progressively during the first few hundred of milliseconds of the steady input flow.

In the model, the populations of horizontally connected neurons in each area integrate and selectively transmit synchronous spatial patterns of input activity. This activation sustained over the populations plays the role of an error function. The basic operation in the model consists in progressively turning down, through backward propagation, this unspecified activation on the basis of the predicted spatial pattern transmitted to upper processing stages. The resulting spatio-temporal pattern of forward activity acts as a reinforcement for a few neurons in the upper area, while enabling the learning of specific metrical relations associating neurons of other overlapping populations. A structured form is thus broken down into a set of nested spatio-temporal forms relating locally defined temporal axes to longitudinal cortical regions. The activities of the populations of neurons representing incomponents of the structured form are thus extracted from those related to coarser components while being kept embedded in them. The model also settles the related issue of how to transmit faithfully fine compo

NEURONS OF THE LATERAL NUCLEUS OF THE AMYGDALA THAT PROJECT TO THE BASAL NUCLEUS ARE INNERVATED BY CALBINDIN AND PARVALBUMIN IMMUNOREACTIVE NEURONS. W. Woodson*, and J. E. LeDoux. Center for Neural Science, New York University, 4

Washington Place, New York, N.Y. 10003

The lateral nucleus (LA) is the sensory interface of the amygdala and the origin of projections to other amygdala nuclei, such as the basal nucleus (B), that participate in the intraamygdala processing of basal nucleus (B), that participate in the intraamygdata processing of sensory inputs. In order to determine whether LA neurons that project to the basal nucleus are innervated by different subpopulations of inhibitory cells, the retrograde tracer cholera toxin subunit B (CTb) was injected into B, and the immunocytochemical double labelling technique was employed to identify retrogradely labelled cells and calcium binding neurons in LA. Following CTb injections into B, retrogradely labelled cells were found throughout the rostro-caudal extent of LA. Morphologically distinct types of parvalbumin (PARV) and calbindin (CAL) immunoreactive (IR) neurons made presumptive axo-somatic terminals upon neighboring projection neurons in LA, as determined by confocal microscopy. Each projection cell was usually innervated by many PARV-IR and CAL-IR neurons. Terminals were made between 0.5 and 1 µm of section thickness. These results emphasize that inhibitory cells modulate the excitatory responses of LA neurons, and probably influence the flow of sensory information through intraamygdala microcircuitries. FEAR-POTENTIATED STARTLE (FPS) IN THREE INBRED MOUSE STRAINS, <u>S.</u> Carlson*, W.A. Falls, J.G. Turner, S.E. Webster, and J.F. Willott. Dept. of Psychol., Northern Illinois Univ., DeKalb, IL 60115.

The FPS paradigm has been widely used to study the neural basis of conditioned fear, but the unique advantages of mice as animal models have yet to be tapped in FPS research. The present study uses mice of the C57BL/6J (C57), DBA/2J (DBA), and CBA/CaJ (CBA) inbred strains in the first of a series examining FPS in mic

Amplitude of startle was measured in 1-month-old mice in a quiet background and when a 70 dB SPL, 12 kHz tone (to be the conditioned stimulus, CS) was present. Mice were then randomly assigned to either an experimental or control group (N= 10 per group). On two consecutive days, experimental mice were presented with 10 paired tone-shock training trials (a 30-sec CS coterminating with a 0.5-sec, 0.6-mA foot shock). Control mice received unpaired tones and shocks. Startle responses were measured 1 day later with 10 CS-on and 10 CS-off trials. A ratio of startle amplitude with CS-on/CS-off was computed for each mouse for pre- and post-training sessions. These were subjected to a 3 (strain) X 2 (training condition) X 2 (pre-post test session) mixed ANOVA. FPS occurred if the CS-on/CS-off ratio was significantly larger in post- vs. pre-training sessions in experimental animals but not in controls.

None of the control groups exhibited a significant change in the CS-on/CS-off ratio for pre-vs. post-training sessions. In experimental C57 mice, the CS-on/Cs-off ratio increased significantly, by 41%, in post-training sessions, indicating the occurrence of FPS. In experimental DBA mice, the ratio increased by 146%, which was significantly greater than the increase in C57s; thus, FPS was more pronounced in DBA mice. In experimental CBA mice, the pre-post-training difference in the CS-on/CS-off ratio was only 2%, a nonsignificant effect. These findings indicate that inbred mice can be used as subjects for FPS, but that dramatic differences occur among strains with the present procedures. Elucidating the factors that underlie these differences should provide new insights into the neurobiological mechanism of FPS

EXTERNAL INHIBITION OF FEAR-POTENTIATED STARTLE: A PROCEDURE

EXTERNAL INHIBITION OF FEAR-POTENTIATED STARTLE: A PROCEDURE FOR INVESTIGATING THE EFFECT OF DISTRACTING STIMULI ON THE EXPRESSION OF CONDITIONED FEAR. W.A. Falls*, S. Heldt & S.E. Webster Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

Presentation of a novel stimulus in compound with a well trained conditioned stimulus results in a significant reduction in the conditioned response. Pavlov described this as external inhibition. When considered in the context of conditioned fear, external inhibition represents one way in which fear can be inhibited. With the recent interest in identifying the neural systems responsible for the inhibition of fear, it would seem important to consider the systems that may be responsible for external inhibition. The purpose of the present experiments was to investigate a procedure for producing external inhibition of conditioned fear using the fear-potentiated startle paradigm.

Rats were given 10 noise+shock pairings on each of 2 days. Testing occurred 1 day later. All rats showed conditioned fear to the noise as defined by greater startle amplitude in the presence of the noise than in its absence (i.e., fear-potentiated startle). Fear-potentiated startle to the noise was reduced on trials in which a novel light was presented in compound with the noise (i.e., external inhibition). This external inhibition cannot be attributed to the light&noise compound being perceived as a unique (i.e., configural) stimulus because rats given noise+shock training followed by light+shock training showed enhanced fear-potentiated startle on light&noise compound trials. This external inhibition also cannot be solely attributed to an inhibitory effect of the light on the startle reflex because a novel light did not reduce startle that was potentiated startle appears to be a function of the magnitude of fear-potentiated startle in reduction in fear-potentiated startle appears to be a function of training. The amount of external inhibition was related to the magnitude of fear

ANATOMICAL TRACING AND LESION STUDIES OF VISUAL PATHWAYS INVOLVED IN FEAR CONDITIONING MEASURED WITH FEAR POTENTIATED STARTLE. C-J SHI* & M. Davis. Dept. of Psychiatry & Psychology, Yale Univ., New Haven, CT 06508

Previous work indicated that complete removal of the visual cortex did not prevent the expression of fear potentiated startle to a visual conditioned stimulus (CS) in rats In contrast, electrolytic or chemical lesions of rostral perirhinal cortex fully blocked the expression of conditioned fear using a visual CS. However, perirhinal lesions made before training did not block acquisition and rats could still relearn if retrained after perirhinal lesions. These results suggest that subcortical visual inputs may project directly or indirectly to the perirhinal cortex to allow visual information to access the basolateral amygdala, also critical for fear potentiated startle. This hypotheses was tested using both anatomical tracing and lesion methods

Following iontophoretic injection of biotinylated dextran amine into different subareas of the lateral posterior nucleus of the thalamus (LP) in rats, heavy anterograde labeling was differentially present in areas Oc2L, Oc2M and caudal area Te2. Additionally, a light to moderate density of labeled fibers and terminals was consistently detected in the perirhinal cortex. This labeling concentrated in the fundus of the rhinal sulcus and extended to all layers. Electrolytic or chemical lesions after training were placed in LP, or lateral geniculate complex (LG) or both and the effects on fear conditioning were examined. Either electrolytic or chemical lesions of both LP and LG, but not lesions of LP or LG alone, blocked the expression of fear potentiated startle. However, neither electrolytic nor chemical lesions of LG/LP prevented relearning of conditioned fear trained with a visual CS. These results implicate two parallel thalamocortical pathways involved in fear conditioning with a visual CS. In addition, there must be other visual pathways to the basolateral amygdala which by pass the visual thalamus to allow relearning to occur. EFFECTS OF TONE-DEPENDENT FEAR CONDITIONING ON HEART RATE IN MICE (C57BL/6J).

O. Stiedl*, S. Milanovic, and J. Spiess. Department of Molecular Neuro-

O. Stiedl*, S. Milanovic, and J. Spiess. Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, HermannRein-Str. 3, D-37075 Goettingen, Germany
Male mice were subjected to a single fear conditioning (acquisition) trial in
order to investigate specific changes in heart rate (HR) and c-FOS immunoreactivity during and after a tone-dependent (memory) retention test. HR
was measured in freely moving mice with an ECG transmitter system.
Groups of animals were subjected to different conditioning sequences

Groups of animals were subjected to different conditioning sequences during acquisition. For paired conditioning, animals were placed in a box for 3 min, then presented with a pulsed (5 Hz) tone stimulus (CS: 75 dB SPL, 10 kHz, 30 s) followed by a foot shock (US: 2 s, 0.7 mA, constant current). In addition, separation (unpairing) of CS and US by 30 s and 60 s, respectively, and exposure to tone and foot shock alone was carried out to determine whether HR effects and c-FOS production are specific for associative learning. Twentyfour h after training, tone-dependent retention was tested in the homecage without tone (preCS phase) followed by tone stimulation (CS phase) for 3 min each.

In all animals, HR was elevated to maximal physiological levels during the fear conditioning trial. It was impossible to differentiate, whether an animal received shock or not. However, HR was significantly increased and HR variability was significantly decreased in the CS phase compared to preCS values of tone-dependent retention in mice subjected to paired conditioning. Unpairing of CS and US by 30 s triggered a significant increase of HR and decrease in HR variability during the first but not the second and third minute of the CS phase. CS did not significantly affect HR in any other group.

Brain sections of mice are currently evaluated for *C-FOS* production with regard to the sequence and presence of CS and US during acquisition.

NMDA Antagonists Infused into the Amygdala Block Second-Order Conditioning, Measured with Fear Potentiated Startle. J.C. Gewirtz*, W.A Falls, & M. Davis, Dept. Psychiatry, Yale University, New Haven, CT 05508, & Dept. Psychology, Northern Illinois University, DeKalb, IL 60115. Pavlovian second-order conditioning is produced by pairing a neutral stimulus (S2) with another stimulus (S1) that previously was paired with an unconditioned stimulus (US). This was done by presenting a 3.7-s S1 coterminating with \$1.7 reduce extinction of first-order conditioning coterminating with a 0.6-mA footshock, and then placing S2 in serial compound with S1. To reduce extinction of first-order conditioning, additional S1-US pairings were intermixed with S2-S1 pairings. Acquisition of second-order conditioning, assessed by fear-potentiated startle, was blocked by intra-amygdala infusion of the NMDA receptor antagonist, AP5. This suggests that NMDA receptor-dependent plasticity in the amygdala is critical for the acquisition of second-order fear conditioning.

However AP5 could have interfered with first-order conditioning on the

amygdala is critical for the acquisition of second-order fear conditioning. However, APS could have interfered with first-order conditioning on the intermixed S1-US pairings. Hence, it is necessary to have S2-S1 and S1-US pairings on different days, so that APS can be infused only on S2-S1 days. To enhance second-order conditioning, which is typically weaker using this procedure, we varied the temporal arrangement between S1 and the US. Second-order conditioning was more robust with a brief S1-US interstimulus interval (0.2 s as opposed to 3.2 s), and was especially strong when fear was sustained throughout the duration of S1, achieved by varying the onset of the US during a 6.7-s S1. The fact that contiguity between S2 and the fear elicited by S1 was more critical than contiguity between S2 and the onset of S1 itself, provides support for the involvement of "stimulus-response" learning in second-order conditioning.

These procedures produce robust second-order conditioning, even when S2-S1 and S1-US pairings are presented on separate days. We are thus in a position to assess further the role of glutamate receptors in the amygdala in the acquisition of second-order conditioning. THE EFFECTS OF SEPTAL LESIONS ON CONTEXTUAL SHIFTS IN CONDITIONED FEAR. P.D. Sparks* and J.E. LeDoux. Dept. of Exp. Psychology, NYU, NY, NY 10003. Lesions of the septum increase conditioned fear (freezing) expressed in

the presence of contextual, but not phasic conditioned stimuli (Sparks and LeDoux, 1995). To investigate this effect further, the effects of septal lesions were examined in a context shift paradigm. Two weeks after surgery, septal rats and sham operated controls were placed for 15 after surgery, septal rats and sham operated controls were placed for 15 minutes in the shock chamber (chamber A, Coulborn shock chamber), without the presence of tones or shocks (day 0). For each of the following two days (days 1-2), all rats were returned to chamber A and presented with two tone-shock parings (10kHz, 74dB tone for 20 secs, co-terminating with a 0.5mA shock, of 0.5 sec duration). On days 3-4, half the septal and sham operated rats (non-shift group; NS) were placed in chamber A, and the other half (shift group; S) were placed in a new chamber (chamber B, very distinct from chamber A), and were presented with two tone alone trials daily. The time spent freezing during the tone and during a 20 sec period before the tone (freezing to the chamber cues) for days 1-4, were used as the measures of conditioning. As shown before, NS-septal rats freeze more to the chamber cues but not to the tone as compared to NS-control s. S-control rats froze less to both the tone as compared to NS-controls. S-control rats froze less to both the tone and chamber cues as compared to the NS-controls. S-septal rats froze more than S-controls to the chamber cues, but froze similarly to the tone as compared to the NS-septal rats, thus did not show reduced freezing to the tone in the new chamber. These findings clarify the role of the septum in contextual control of conditioned fear. We are presently investigating the effects of hippocampal lesions on this task as well. Supported by MH46516, MH00956.

INACTIVATION OF THE LATERAL AND BASAL AMYGDALA DISRUPTS ACQUISITION AND EXPRESSION OF CONDITIONED FEAR J. Muller, Z. Fridel, and J.E. LeDoux*. Center for Neural Science, New York University, NY, NY 10003. The lateral and basal nuclei of the amygdala are believed to play an

The lateral and basai nuclei of the amygaala are believed to play an essential role in the acquisition of conditioned fear. However, previous studies involving temporary inactivation of these regions found significant disruption of the expression but not the acquisition of conditioned fear using a contextual conditioning procedure. In the present study we reexamined the effects of inactivation of the lateral and basal amygdala on the conditioning of fear responses to an explicit auditory conditioned stimulus (CS) and to contextual simuli. The GABA_A agonist, muscimol $(0.5 \, \mu \mathrm{g} \, \mathrm{m} \, \mathrm{o}.5 \, \mu)$ saline), or vehicle was infused in the amygdala through indwelling cannulae about 30 minutes before conditioning and testing. The day after conditioning (pairing of the tone CS with a footshock), rats were exposed to the CS in a novel context. A CS with a footshock), rats were exposed to the CS in a novel context. A day later, they were reexposed to the original training apparatus (with no CS presented). On each testing day, conditioned fear was assessed by measuring the percent of time accounted for by freezing behavior during a three minute period. Localization of the cannulae in the lateral and basal amygdala was verified histologically. Rats with muscimol infusions prior to conditioning and vehicle prior to testing exhibited significantly less freezing during exposure to the CS in a novel context and during exposure to the conditioning context than did animals with vehicle infusions before conditioning and muscimol prior to testing. Animals given vehicle prior to conditioning and muscimol prior to testing froze less to the CS and conditioning and muscimol prior to testing froze less to the CS and context than did controls. Thus, activity in the lateral and basal amygdala appears to play an essential role in both the acquisition and expression of fear conditioning both to the CS and its context. Supported by grants MH 38774, MH 46516, and MH 00956.

AMYGDALA LESIONS BLOCK AVERSIONS TO CONTEXTUAL CUES BUT NOT THE ABILITY OF CONTEXTS TO SERVE AS OCCASION SETTERS. D.M. Skinner* and D. van GERGOY, Dept of Anatomy and Cell Biology, University of Toronto, Toronto, Ontario, MSS

Occasion setting involves discriminative cues that predict whether or not a target stimulus Occasion setting involves discriminative cues that predict whether or not a target stimulus will be followed by a motivational event (the US). We have previously suggested that most of the discriminative control is not due to simple, Pavlovian associations between the discriminative cue and the US or between the discriminative cue and the target stimulus, but to a more complex, higher-order type of association among all three elements. In a typical conditional discrimination one novel context predicts that access to sacharin will be followed by an injection of LiCl while a second context predicts that saccharin will be followed by a saline injection. In a Paylovian control procedure one novel context is paired directly with LiCl and the second context is paired with saline injections. Rats trained on the conditional task suppress fluid consumption in the first relative to the second context and also avoid the context associated with LiCl on a place choice test, suggesting that Pavlovian associations and occasion setting are acquired simultaneously. Rats trained on the Pavlovian task also show a large aversion to the context associated with LiCl on a place test but never show fluid suppression in the aversive context, suggesting that the Pavlovian properties of the context are not sufficient to produce occasion setting. In the present study rats with bilateral ibotenic acid lesions of the amygdala were compared to sham controls on a contextual discrimination task. Both groups learned to suppress fluid consumption in the first, relative to the second, context. Sham lesioned rats also showed a large aversion to the first context on a choice test whereas the amygdala lesioned rats did not significantly avoid the context associated with LiCl. Amygdial and sham Pavlovian control groups were given direct pairings of context 1 with LiCl and context 2 with saline. Again, sham lesioned rats showed large aversions to context 1 while amygdial elesioned rats showed no hint of a place aversion. These findings suggest that the Pavlovian aversive properties of the context are not necessary for acquisition of occasion setting and support previous behavioral data suggesting that simple Pavlovian conditioning and occasion setting are fundamentally

MEDIAL PREFRONTAL CORTEX (mPFC) AND THE EXTINCTION OF FEAR: DIFFERENTIAL EFFECTS OF PRE- OR POST- TRAINING LESIONS M.A. Morgan,* J.E. LeDoux, Dept of Psychology, New York University, NY, NY 10003

In a previous study of fear conditioning, pre-training lesions of ventral mPFC produced resistance to extinction to a CS without affecting acquisition. Stage 1 of the present study looked at the effect of these lesions, now made post-training, on the expression and extinction of the same fear conditioning task. Rats underwent 2 days of tone (CS)-footshock (US) pairings prior to receiving mPFCv (n=16) or sham (n=13) lesions. Two weeks later they underwent extinction training: 2 trials a day of the CS presented alone, until extinction criterion was met. Acquisition and extinction of conditioned fear, as measured by freezing behavior to the CS and to the context, were examined. mPFCv lesioned rats froze significantly less than controls during the test of context acquisition, and showed no other effects. Stage 2 looked at reacquisition and reextinction of the same task. Lesioned rats froze more than controls during reacquisition of the CS and context, and showed resistance to extinction to both. Comparing lesioned rats with their own performance during stage 1, they froze somewhat less to the CS during reacquisition than acquisition, and now showed resistance to extinction, relatively more to the CS than to the context. These results confirm earlier findings that mPFCv is involved in extinction of fear responses, and suggest that an intact mPFCv may be necessary during acquisition in order for normal extinction to occur. mPFCv may be involved in the inhibition of conditioned responding during extinction, perhaps by utilizing appropriate contextual cues. Supported by MH46516, MH00956.

DISRUPTION OF FEAR CONDITIONING TO CONTEXTUAL STIMULI BUT NOT TO A TONE BY LESIONS OF THE ACCESSORY BASAL NUCLEUS OF THE AMYGDALA. P. Majidishad, D. G. Pelli* and J. E. LeDoux. Center for Neural Science, New York University, NY, NY 10003.

P. Majdishad, D. G. Pelli* ____ and J. E. LeDoux. Center for Neural Science, New York University, NY, NY 10003.

Lesions of the hippocampus or amygdala interfere with the conditioning fear responses to contextual stimuli, and projections from the hippocampus to the amygdala are believed to be involved in this form of learning. Two major recipients of hippocampal projections are the basal (B) and accessory basal (AB) nuclei. In the present study we examined the effects of electrolytic lesions of these two regions on the conditioning of fear responses to contextual stimuli and to a tone. Twenty days after surgery, rats received two days of tone - shock pairings (2 trials each day). The next day, cumulative time spent freezing to a 60 sec tone presentation (no shock) was measured in a novel test chamber. Contextual conditioning was assessed by measuring the amount of freezing occurring during a 600 sec period in which the rat was in the conditioning chamber (no tones or shocks presented). Lesions were verified histologically. Relative to controls (n=10), lesions of AB (n=6) significantly reduced freezing to the conditioning context but not to the tone. In contrast, neither freezing to the conditioning context but not to the tone. In contrast, neither freezing to the tone nor the context was significance. AB thus seems to be an important link in the pathways involved in contextual conditioning. While B may also contribute, further studies are needed to clarify its role. Supported by grants MH 38774, and MH 00956.

AMYGDALA AND PERIAQUEDUCTAL GRAY SUBDIVISIONS NECESSARY FOR THE ACQUISITION AND PERFORMANCE OF DISCRETE AND CONTEXTUAL FEAR CONDITIONING

P.S.F. Bellgowan*, F.J. Helmstetter and D.J. Bailey
Department of Psychology, University of Wisconsin, Milwaukee, WI 53201.

A neural circuit that includes the amygdala and periaqueductal gray (PAG) has been shown to be essential for the expression of Pavolvian fear conditioning to both discrete unimodal and complex contextual cues. However, the role of specific amygdala and PAG subdivisions in these forms of learning is not clearly defined. Independent test for the roles of the lateral (LA) and central (CeA) nucleus of the amygdala, or dorsal (dPAG) and ventral PAG (vPAG) in the acquisition and performance of fear conditioning using contextual and discrete cues were conducted. Rats were prepared with chronic cannula in either the LA, CeA, dPAG, or vPAG and injected with the GABA_A agonist muscimol (MUS; 0.25 $\mu\text{g}).$ Injections were given either before training, before testing conducted 24 and 48 hrs after training, or both in a factorial design. During training subjects received four paired presentations of white noise (WN; 10 sec / 72 dB) with shock (1 mA / 1sec) in a distinctive observation chamber. Testing consisted of measuring fear responses both in the shock-associated training environment and to a single 5 min WN presentation independently during extinction. MUS applied to the LA prior to training reduced freezing to both discrete and contextual cues. Performance to both CS's was blocked by pre-testing MUS injections in the CeA, however, pre-testing injections in the LA only blocked performance to the discrete CS. Performance to the discrete CS was also attenuated by pre-testing MUS in the vPAG but not the dPAG. The present results suggest that differential intra-amygdala neural circuitry is necessary for the acquisition and performance of conditional fear to discrete and contextual cues

AMYGDALA KINDLING AND FEAR CONDITIONING

T. J. Hoeppner*, M. C. Smith, L.deToledo-Morrell, T. E Reimschisel, J. A. Wolter. Departments of Neurological Sciences and Neurosurgery, Rush Medical College, Chicago, IL 60612

Since amygdala kindling produces permanent changes in the excitability of the amygdala with spread of electrical abnormalities to distant neural structures and fear conditioning is blocked by bilateral amygdala lesions, amygdala kindling might interfere with subsequent fear conditioning. Amygdala electrodes were implanted in rats. Half of the rats were kindled, while the other half were handled in the same way, but received no electrical stimulation. All rats received i.p. saline prior to each trial for comparison with the effects of anticonvulsants in other experiments. Kindling proceeded for 15 days or until 3 stage 5 seizures occurred. Two weeks after kindling was completed, rats were given 2 days of sound-footshock fear conditioning followed by 5 days of extinction. Fear conditioning was assessed by the duration of freezing during the 20 second conditioned stimulus (sound)

Kindled seizures started locally in the amygdala and progressively engaged the contralateral amygdala. Kindled rats showed impaired fear conditioning compared to the unkindled controls. Thus unilateral epileptogenic foci may produce behavioral deficits indicative of bilateral dysfunction long after the occurrence of seizures. (Supported in part by Abbott Laboratories.)

MEMORY MODULATION AND THE STRIA TERMINALIS

MEMORY MODULATION AND THE STRIA TERMINALIS.

A.M.Schneider*, E. Thomas, R. Ayyagari, M. Grossman, and A. Kakoyannis. Depts. of Psychology, Swarthmore College, Swarthmore, PA 19081 and Bryn Mawr College, Bryn Mawr, PA 19010.

It is generally agreed that there are two systems involved in the formation of recently-acquired memories, an information system, devoted to the content of memory, and a modulatory system, regulating the strength of memory. Several brain areas have been implicated in the modulatory system, the stria terminalis (ST) among the more notable.

notable. Evidence for ST involvement comes from studies that have shown that ST lesions affect retention, but the effect appears to be selective: ST lesions prevent enhancement or impairment of retention produced by drugs, but they do not affect retention produced by the training experience itself. The purpose of the present experiment was to reexamine the effect of ST lesions on retention produced by the training

reexamine the effect of \$1 lesions on retention produced by the training experience.

We gave ST-lesioned rats (male, Long Evans) two types of passive-avoidance training. In one procedure the animals were given a single training trial, and shock was set at 0.8 mA, 2 sec. in the other procedure the animals were given 3 training trials, 1 trial per day, and shock was set at 0.4 mA, 2 sec on each trial.

at 0.4 mA. 2 sec on each trial.

We found that ST lesions impaired retention produced by the singletrial procedure but had no effect on retention produced by the multitrial
procedure, and we attributed the different effects to differences in
arousal produced by the two training procedures. In the single-trial
procedure when shock is intense, arousal is high, and thus ST lesions
impair retention; in the multitrial procedure when shock is weak, arousal
is low, and thus ST lesions do not impair retention.

Supported by a grant from the Howard Hughes Medical Institute.

c-fos EXPRESSION IN ANTERIOR OLFACTORY NUCLEUS AND AMYGDALA ASSOCIATED WITH ODOR-GUIDED FEAR CONDITIONING IN THE RAT. L.F. Schettino* and T.A. Otto. Dept. of Psychology, Rutgers University. New Brunswick, NJ 08903.

The activity of olfactory pathways and amygdaloid nuclei during an odor-fear conditioning paradigm was traced through immunochemical staining for the

Eight naive male Sprague-Dawley rats weighing 225-249g were used. The animals were handled for 5 minutes on 3 consecutive days. Experimental animals were trained on a fear conditioning paradigm with forward pairings of pyridine odor (Pyr) as the CS and shock as the US. The parameters (ten pairings of Pyr infused into the cage for 20s and shock (0.8mA) overlapping the last 2s. ITI=2 min.) were determined by pilot studies to produce robust "freezing" behavior to subsequent presentations of the odorant alone. Control subjects were not trained. Thirty min after training, all animals were deeply anesthetized by an IP injection of sodium pentobarbital (160 mg/kg) and perfused with PBS/paraformaldehyde 4%.

The brains were sectioned coronally (50µm) and immunostained for c-fos expression. The nuclear staining was quantified by light microscopy counts on a 0.5mm grid at 100X.

The results showed that, compared to controls, trained animals exhibited robust c-fos expression in the anterior olfactory nucleus (AON) and medial nucleus of amygdala (p<0.05). These preliminary data are consistent with the notion that the AON and the amygdala may participate in the acquisition or expression of odor-guided conditioned fear

AMPA RECEPTOR BLOCKADE IN THE BED NUCLEUS OF THE AMPA RECEPTOR BLOCKADE IN THE BED NUCLEUS OF THE STRIA TERMINALIS (BNST) BUT NOT THE CENTRAL NUCLEUS OF THE AMYGDALA (CNA) DISRUPTS LIGHT-ENHANCED STARTLE: A NOVEL PARADIGM FOR THE ASSESSMENT OF ANXIETY IN RATS. D. L. Walker* and M. Davis. Dept. Psychiatry, Yale University, New Haven, CT 06508. The amplitude of the acoustic startle response is reliably increased if elicited in the presence of a cue previously paired with shock (fear-potentiated startle). We recently observed that startle is also increased, without prior conditioning if testing occurs in a brightly lit vs. darkened

without prior conditioning, if testing occurs in a brightly lit vs. darkened environment (light-enhanced startle). For these experiments, startle was assessed for 20 min in the dark (phase I) followed by a second test (phase II) either in the dark or in a well-lit chamber. Although a small increase, from phase I to II, often was observed on dark-sessions, a large and significant increase was reliably observed on dark->light sessions. This increase was linearly related to light intensity, did on thabituate either within or across sessions, and was blocked by the anxiolytic compound, buspirone. We believe that this phenomenon reflects the anxiogenic properties of bright lights in nocturnal animals.

To evaluate the anatomical substrates of light-enhanced startle, the

AMPA antagonist, NBQX, was infused into two structures which project to the startle circuit. Infusions into the BNST disrupted the phase I to phase II increase for light-enhanced startle, but had no effect on fear-potentiated startle. In contrast, infusions into the CNA blocked rear-potentiated startle but had no effect on light-enhanced startle. This double dissociation may reflect complementary roles for the BNST and CNA in unconditioned anxiety vs. conditioned fear. [Supported by MH 47840, MH 00004 and AFOSR F49620-93-1-0293 DEF].

REGIONAL PATTERNS OF c-fos EXPRESSION IN THE AMYGDALA SHIFT BETWEEN THE SEQUENTIAL STAGES OF ACQUIRING AN ODOR DISCRIMINATION. U.S. Hess*, G. Lynch, and C.M. Gall. Dept. of Psychobiology, Univ. of CA at Irvine, 92717.

Expression of the activity-dependent gene c-fos was used to assess relative levels of neuronal activity in the amygdala of rats engaged in odor learning. Five groups of rats, each at a different point of the learning sequence, were used: 1) "Naive" controls were left in their home cage. 2) "Exploration" rats explored the novel training apparatus, 3) "Nose poke" rats performed a familiar nose-poke response for water rewards, 4) "Exploration" rats explored the novel training apparatus, 3) "Nose poke" rats performed a familiar nose-poke response for water rewards, 4) "Initial learners" were exposed for the first time to a pair of odors, response to one of which was reinforced with water, and 5) "Overtrained" rats performed the same, but well-learned discrimination. Comparisons (both absolute and internally normalized) of the experimental groups to the naive controls indicated that the basolateral nuclei had elevated levels of c-fos mRNA in all stages of the learning paradigm except for overtraining, the medial nucleus was not significantly different from control in any of the experimental groups. Comparisons between the experimental groups produced the following results: i) exploration and initial learning had the largest overall effects on c-fos mRNA levels, ii) the medial nucleus was unusually active during exploration, and iii) the initial learning had the largest overall effects on c-fos mRNA levels, ii) the medial nucleus was unusually active during exploration, and iii) the basolateral amygdala was disproportionately active during the shift from free to cued responding (i.e., initial learning). Activation of the medial nucleus may be part of a stress response triggered by a novel environment, while the unusual basolateral activation during initial learning could reflect the necessity of assigning positive and negative valences to discriminative cues. STRESS INCREASES PKC TRANSLOCATION IN THE AMYGDALA THROUGH NMDA RECEPTOR ACTIVATION, AND CONTEXTUAL CUES REINTRODUCE TRANSLOCATION. T. J. Shors*¹, S. Elkabes², J. C. Selcher¹, I.B. Black². Dept. Psychol, Prog. Neurosci., Princeton Univ., Princeton, NJ 08544, Dept. Neurosci. Cell Biol., UMDNJ/RWJ Med. Sch., Piscataway, NJ 08854.

The long-term consequences of acute stress on the [3H] phorbol 12,13-dibutyrate (PDBu) binding, an activator of protein kinase ((PKC), were investigated. Exposure to a brief episode of restraint and intermittent tailshock increased [3H] PDBu binding in the amygdala. The increase was persistent, lasting 24 hrs after stressor cessation. The contribution of NMDA receptor activation to the increased PKC translocation was evaluated. Rats injected with an NMDA approach in the other property in the stressor did not exhibit the increase in NMDA antagonist prior to the stressor did not exhibit the increase in PKC activity in the amygdala 24 hrs later. Finally, we tested whether exposure to contextual cues associated with the stressor would reintroduce the increase in PKC translocation. Two groups of rats were stressed, one was briefly returned to the stressful context 96 hrs later. A group was exposed only to context and another was naive to stress and context. Stressed rats reexposed to the context 96 hrs later displayed an increase in PKC translocation in the amygdala, thalamus, and area CA1 of the hippocampus. These results suggest that a "psychological" manipulation, namely context reexposure, can induce long-lasting increases in PKC activity. These effects may represent biological indices of stress-related disorders, such as posttraumatic stress disorder (PTSD).

LESIONS OF THE NUCLEUS ACCUMBENS CORE, BUT NOT BASOLATERAL AMYGDALA OR SUBICULUM, DISRUPT STIMULUS-REWARD LEARNING IN A NOVEL AUTOSHAPING PROCEDURE. LA. REWARD LEARNING IN A NOVEL AUTOSHAPING PROCEDURE. J.A. Parkinson, T.W. Robbins, B.J. Everitt, (SPON: European Neuroscience Association). Dept of Experimental Psychology, University of Cambridge, UK. This autoshaping paradigm involves the presentation of two identical visual stimuli on either side of a computer screen, one of which always predicts reward (CS+), the other never (CS-). Although there is no contingent reinforcement, animals show discriminated approach to the CS+ with decreasing latency (see T.J. Bussey Soc. Neurosci. Abstr. 1996). The underlying mechanism for this appears to be one of Pavlovian CS-US association, as animals continue to approach the CS+ even when this action prevents reward (omission schedule).

Animals with selective excitotoxic lesions of the core subregion of the nucleus accumbens were disrupted in this procedure; they took significantly longer to learn the discriminated approach never reaching a level of learning comparable to that of sham-operated controls. The nucleus accumbens receives major projections from cortical and limbic structures such as the basolateral amygdala, medial prefrontal cortex and hippocampal formation which have themselves been implicated in aspects of reward-related learning. We therefore investigated the effects on autoshaping of lesions of the cortical elements of these limbic-ventral striatal systems. However, excitotoxic lesions of the basolateral amygdala, ventral subiculum or dorsal subiculum had no effect on the acquisition of approach behaviour. This is in contrast to the effects of lesions of the anterior cingulate cortex which greatly impaired discriminated approach (see T.J. Bussey Soc. Neurosci.

These results will be discussed in terms of the connectivity of afferents to the nucleus accumbens and also their potential functional significance in terms of cortico-striatal learning systems

A ROLE FOR THE ANTERIOR CINGULATE CORTEX OF THE RAT IN STIMULUS-REWARD LEARNING USING A NOVEL AUTOSHAPING PROCEDURE. T.J. Bussey*, B.J. Everitt and T.W. Robbins. Dept. of Experimental Psychology, University of Cambridge, UK.

Recent results from our laboratory suggest that the anterior cingulate cortex may be

involved in stimulus-reward learning (Bussey et al., in press). For example, quinolinic acid-induced lesions of this region disrupt the acquisition of a task in which rats were required to learn 8 stimulus-reward associations concurrently (Muir et al., Soc Neurosci. Abstr. 20:1211, 1994). While suggestive, this effect could have been due to factors other than the stimulus-reward learning requirements of the task, such as the high degree of inter-item interference, the discriminability of stimuli, or the relatively long inter-stimulus intervals in this task. We have therefore developed a method for studying stimulus-reward learning which attempts to eliminate these possibilities. The procedure is carried out in an apparatus which allows for the automated presentation of computer-graphic stimuli (Bussey et al., 1994). White vertical bars are presented on a VI40 sec schedule on either the left or the right of a computer screen. One of these stimuli, (the CS+), is always followed by a sucrose pellet. The other, the CS-, is never followed by reward. As a result of this training, rats come to approach the CS+ much more often than the CS-, and with decreasing latency. The introduction of an omission schedule, under which approaches prevent the delivery of reward, does not disrupt discriminated approach, suggesting that rats' behaviour in this task is governed by knowledge of the stimulus-reward association acquired via Paylovian conditioning This procedure was used to assess stimulus-reward learning in animals with cytotoxic lesions of the anterior cingulate, posterior cingulate and medial frontal cortices. Anterior cingulate-lesioned animals did not demonstrate normal Pavlovian approach, making significantly more approaches to the CS- than sham-lesioned animals. Furthermore, these animals approached the CS+ with significantly longer latencies than did shams. Medial frontal cortex-lesioned animals demonstrated normal task acquisition, but had longer overall approach latencies. Posterior cingulate lesions had no effect on this task. The implications of these results for the neurobiology of motivation and

PERIRHINAL AND POSTRHINAL CONNECTIONS WITH THE RAT ENTORHINAL CORTEX R.D. Burwell* I and D.G. Amaral². ¹Center for Behavioral Neuroscience, State University of New York at Stony Brook, Stony Brook, NY 11794-2575, and ²University of California, Davis, Department of Psychiatry and Center for Neuroscience, Davis, CA 95616.

We have previously demonstrated that entorhinal projections to septal versus temporal levels of the dentate gyrus (DG) of the rat originate from largely non-overlapping bands of the entorhinal cortex (EC). A caudolaterally situated band projects to the septal half of the DG while intermediate and medially situated bands project to the third and fourth quarters, respectively (Dolorfo, C.L. and Amaral, D.G., 1996). Intrinsic entorhinal connections also respect this band-like organization such that the associational projections preferentially terminate within the band of origin (Dolorfo, C.L. and Amaral, D.G., 1996).

In light of this new partitioning of the EC into DG projecting bands, the present study examined the topography of the EC connections with the regions that provide its primary cortical input, the perirhinal (PR) and postrhinal cortices (POR). The study is based on anterograde and retrograde injections placed in the PR, POR, and EC. The PR to EC projections were strongest to the laterally situated (and septally projecting) band; progressively lighter projections terminated in the intermediate and medial bands. The return entorhinal projection to the PR appeared to arise from a somewhat larger portion of the entorhinal cortex. The PR to EC projections are also topographically organized in that rostral PR projects more strongly to rostral EC and caudal PR projects more strongly to caudal EC. The POR to EC projection is similar to the perirhinal projection but appears to more extensively involve the laterally situated band. This pattern of connectivity suggests that the POR may exert a stronger influence than the PR over the septal half of the DG. Funded by Grant NS 16980 to DGA and NS 09247 to RDB.

HIPPOCAMPAL-DEPENDENT MEMORY CONSOLIDATION: AN EVALUATION OF THREE HYPOTHESES. A. Koerner*, M.J. Thomas, M.P. Weisend, and R.J. Sutherland. Depts. of Psychology and Physiology, University of New Mexico, Albuquerque, NM 87131

reward will be discussed. (Supported by a Wellcome Trust Programme Grant.)

Hippocampal damage is thought to cause temporally-graded retrograde amnesia by interrupting a long-lasting memory consolidation process. We examined 3 factors which have been posited to influence this consolidation process: time, practice, and memory load. factor was examined using different training regimens in the hidden platform version of the Morris water task before the hippocampus was damaged. Afterwards, each group of rats was retested in the pool. The influence of time was examined by providing 24 training trials and waiting 10 weeks before surgery. The effect of practice was evaluated by overtraining (240 trials over 10 weeks). The influence of memory load was evaluated by providing training in 10 different rooms. Hippocampal damage was produced with intrahippocampal injections of kainate/colchicine. Hippocampal damage produced equivalent, severe retrograde amnesia for the original pool problem in all training conditions. There is no support for the idea that extensive hippocampal damage produces temporally graded retrograde amnesia. Likewise, anterograde amnesia was also severe and not affected by prelesion This study provides no evidence for a long-lasting, hippocampal-dependent memory consolidation process. [Supported by UNMI

THE SPECIFICITY AND TEMPORAL CHARACTERISTICS OF RETROGRADE AMNESIA AFTER HIPPOCAMPAL LESIONS M.P. Weisend*, R.S. Astur, & R.J. Sutherland. Depts. of Psychology and Physiology, University of New Mexico, Albuquerque, NM 87131.

Anterograde and retrograde amnesia are consistent findings after hippocampal lesions. Anterograde amnesia is known to be specific for certain types of memories. It is less clear if retrograde amnesia shares this specificity. Further, the severity of retrograde amnesia is sometimes reported to vary as a function of the interval of time between learning and lesion. The specificity and temporal characteristics of retrograde amnesia were examined in the following experiments. Rats were trained on configural and elemental versions of the Morris water task, Pavlovian fear conditioning, or appetitive operant conditioning. Rats were then returned to their home cages for periods of time that varied between 1 day and 36 weeks. Lesions were produced by intrahippocampal injections of quaint/colchicine. Rats with hippocampal damage showed retrograde amnesia for both configural and elemental versions of all tasks. In contrast, anterograde amnesia was observed for only configural information in these rats. The severity of retrograde amnesia did not vary as a function of time for any version of any task. These results indicate that the hippocampal formation may play a more general role in memory than previously thought. In addition, these results yield no evidence for a hippocampal-dependent memory consolidation process. Supported by UNM's RAC, SRAC, & RPT funds

TEMPORALLY GRADED RETROGRADE AMNESIA FOLLOWING SEPARATE AND COMBINED LESIONS OF THE PERIRHINAL CORTEX AND FORNIX IN THE RAT. K.A. Wiig* L.N Cooper, and M.F. Bear. Department of Neuroscience, Brown University, Providence, RI, 02912, USA.

The involvement of the perirhinal cortex and fornix in retrograde and anterograde amnesia in the rat was investigated. Male, Sprague-Dawley rats were trained on a series of five visual discrimination problems at distinct time intervals prior to receiving bilateral, electrolytic lesions of the perirhinal cortex, fornix, combined lesions of both these structures, or sham operations. Following recovery from surgery, rats were re-tested on the preoperatively learned discrimination problems, as well as learning a new discrimination and discrimination reversal. Results indicated that all animals with lesions exhibited temporally graded retrograde amnesia, whereby memories acquired in the recent past (1-3 weeks) were impaired, and memories acquired in the remote past (6-8 weeks) were spared. There was no difference in the magnitude of retrograde amnesia between the three lesion groups. Animals in the perirhinal, fornix, and combined lesion groups were able to learn a new discrimination problem at a rate comparable to control rats, however, the animals with lesions were impaired at learning the discrimination reversal. The perirhinal, fornix and combined lesion animals also exhibited a significantly faster forgetting rate over a two week retention interval than control rats. These results suggest that medial temporal structures including the perirhinal cortex and fornix are involved in the consolidation of mnemonic information, and that their involvements in this reason course accurate discrete position of times. their involvement in this process occurs over a discrete period of time. Supported by NIH and the Charles A. Dana Foundation.

RETROGRADE MEMORY FOR OBJECTS AND PLACES FOLLOWING LESIONS OF THE HIPPOCAMPUS OR PERIRHINAL CORTEX IN RATS. <u>L.H. Francis, M.J. Glenn, and D.G. Mumby*</u>. Department of Psychology, Concordia University, Montreal, Quebec, Canada.

Retrograde and anterograde memory for object information and retrograde memory for place information was assessed in rats with bilateral aspiration lesions of the perirhinal cortex (PRh) or NMDA lesions of the hippocampal formation (HPC; including hippocampus proper, dentate gyrus, and subicular complex). Rats learned three different object discrimination problems at 72, 24, and 1 hr prior to surgery, and a water-maze place navigation task at either 72 or 3 hr prior to surgery. Retention of all problems was assessed postsurgery. Lesioned rats did not differ from controls in performance on 30 postsurgery object discrimination trials, however PRh but not HPC rats made more errors on the first 10 trials than did control rats. PRh but not HPC rats were impaired at acquisition of a new object discrimination. HPC but not PRh rats were impaired on the place navigation task that had been learned prior to surgery. The findings suggest that HPC and PRh belong to dissociable memory systems that deal with information about places and objects, respectively. MAPPING RECOGNITION MEMORY: PERIRHINAL AND HIPPOCAMPAL NEURONAL EXPRESSION OF C-FOS EVOKED BY NOVEL AND FAMILIAR VISUAL STIMULI. H. Wan¹, X.O. Zhu¹, J.W. Crabtree¹, J.P. Aggleton², B.J. McCabo³ and M.W. Brown¹, ¹Anatomy Department University of Bristol, Bristol BS8 1TD, ²School of Psychology, UWCC, Cardiff CFI 3YG. Zoology ¹Department. University of Cambridge. Cambridge CB2 3EJ. UK

Orniversity of Bristol, Bristol, Bristol, Standin or School of Psychology, OweC, Carlin Cri 3YG; Zoology ³Department, University of Cambridge, Cambridge CB2 3EI, UK.

The results of recording and ablation experiments in both rats and monkeys indicate that cortical areas near to the rhinal sulcus are important for judgement of the prior occurrence of individual stimuli; such judgement is central to recognition memory. We have determined the relative numbers of neurons activated by novel and familiar visual stimuli in different rat brain regions by immunohistochemically staining for the products (Fos) of the immediate early gene c-fos. Rats viewed two objects simultaneously: a novel object in the monocular field of one eye and a familiar object in the monocular field of the other eye. By this means sets of novel and familiar objects were viewed under the same conditions of alertness and with similar eye movements. The number of Fos stained neurons in area TE of the hemisphere first receiving information concerning familiar stimuli was only 74% (P < 0.01) of that in the contralateral hemisphere which had first received information concerning the novel stimuli; it was only 80% in perirhinal cortex (P < 0.05). No other sampled cortical areas, including the hippocampus, demonstrated significant differences. Moreover, the number of activated neurons in the hippocampal formation was very low. When rats were given either lorazepam or diazepam to block the acquisition of stimulus familiarity, the novel and repeatedly seen objects each activated similar numbers of neurones in TE and perirhinal cortex (± 4%). Further, preliminary results indicate a threefold increase in the ratio of the number of hippocampal to perirhinal neurons activated by compound stimuli (scenes or groups of items) rather than individual objects. Thus perirhinal cortex is involved in detection of the relative familiarity of individual items while the hippocampus

MUSCARINIC RECEPTOR BLOCKADE IN PERIRHINAL CORTEX IMPAIRS VISUAL RECOGNITION MEMORY IN MONKEYS. Y. Tang* and T. G. Aigner. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892

Acetylcholine efflux in the inferior temporal gyrus (IT), perirhinal cortex (PR), and dentate gyrus (DG) of the hippocampus increases quickly in response to visually mediated behaviors (Tang & Aigner, Soc. Neurosci. Abstr. 21:1447, 1995). To clarify further the contributions of acetylcholine in IT, PR, and DG to visual recognition memory, the effects of muscarinic receptor blockade by scopolamine were examined in three rhesus monkeys performing a computer-automated version of delayed nonmatching-tosample (DNMS) with a list length of 20 trial-unique graphic symbols. Muscarinic receptors were blocked by 3 µl of 1, 5, 10, or 50 mM scopolamine injected unilaterally through a needle at a rate of 0.15 µl/min into the left IT, PR, or DG over a 20-min interval just prior to DNMS. Scopolamine administered into PR impaired significantly the monkeys' performance. The percent correct responses after all but the lowest dose were significantly lower than for saline control (RM ANOVA with Dunn's method, n=6, p<0.05). The best-effect dose was 10 mM, which reduced correct choices by approximately 10%; the lowest dose (1 mM) caused approximately a 5% reduction in correct choices. Scopolamine unilaterally injected into either IT or DG induced no significant change in performance (RM ANOVA, n=6, p>0.05). The results suggest that the cholinergic system in PR, but not in IT or DG, is critically involved in visual recognition memory in nonhuman primates, and provide the first direct pharmacological evidence to support the recently proposed role of rhinal cortex in this form of memory. Support: IRP/NIMH.NIH.

443.6

HIPPOCAMPAL DAMAGE DOES NOT IMPAIR OBJECT RECOGNITION IN RATS WITH NO PRESURGERY TRAINING. J. Yates *, L. Schattmann and D.G. Mumby, Dept. Psychology, Concordia Univ., Montreal, QC, Canada H4B

Previous lesion experiments indicated that the hippocampus plays a nonessential role in the performance of object-recognition tasks by rats that receive extensive presurgery training. The present experiment examined whether hippocampal functions are critical for normal acquisition and performance of an object-recognition task in rats with no presurgery training. Rats with bilateral hippocampal lesions made either by aspiration or transient cerebral ischemia were trained on the nonrecurring-items delayed nonmatching-to-sample (DNMS) task at a 4-sec retention delay. Neither group performed worse than controls in terms of the number of trials or errors to reach a criterion of 76% over 3 consecutive sessions. Both groups of rats with hippocampal damage continued to perform as accurately as controls as the retention delay was increased to 15, 30, and 60-sec. The only exception to the foregoing observations was a single ischemic rat that failed to perform above chance levels of accuracy throughout 1000 DNMS trials at the 4-sec delay; notably, this was also the only rat that displayed postischemic seizures. The results suggest that the hippocampus plays a nonessential role in the performance of object-recognition tasks by rats. The findings are also consistent with those of previous studies, which suggest that postischemic seizures play a significant role in mediating ischemia-induced object-recognition deficits in rats.

BILATERAL NEUROTOXIC LESION OF THE RHINAL CORTEX IN BABOONS IMPAIRS VISUAL RECOGNITION BUT NOT HABIT MEMORY. X. Biaizot, K. Meguro, C. Le Mestric, A. Rossard, F. Hansen, F. Mézenge, J.C. Baron and C. Chavoix*. INSERM U320, Centre Cyceron, Univ. of Caen, BP 5229, 14074 Caen, France.

Ablation studies in non-human primates have shown that the rhinal cortex (Rh) may play a major part in the visual recognition impairment observed after larger damage to the temporal lobe. In addition, we have shown that neurotoxic Rh lesions induce long-lasting brain glucose hypometabolism in young adult *Papio anubis* baboons (Meguro et al., Soc Neurosci Abstr, 1995, 21:1723) suggesting a crucial role of the affected Rh in both memory deflicits and brain hypometabolism in Alzheimer's disease (AD). We report here, from 6 of our previously studied baboons, the effects of entorhinal (ERh) and perirhinal (PRh) neuronal loss induced by stereotaxic ibotenic acid lesions on visual recognition and habit memory; these memories were assessed by automated tasks of visual delayed nonmatching-to-sample (DNMS) with trial-unique drawings (delay and list length conditions) and ten-pair concurrent drawing discrimination, respectively. Pre-operatively, the baboons were trained on the DNMS task and tested on the delay condition with single targets of mixed delays (1 to 60 sec). Following MRI-guided neurotoxin injections into the Rh, at ~D30 and D95, the Rh group (n=3) was unimpaired on the DNMS delay condition but performed significantly worse than the sham-operated baboons (n=3) for the multiple-stimuli memorization (list condition with mixed list lengths up to 15 stimuli). However, at ~D45, no significant difference between groups was observed on the concurrent loss (confirmed in each baboon) 1) induces similar memory performance dissociation than observed in AD, and 2) affects the storage capacity but not the 60 sec single-item memorization. Relationships between memory impairment and brain hypometabolism are currently being investigated.

443.10

FURTHER EVIDENCE OF A DISSOCIATION BETWEEN THE NEURAL SYSTEMS UNDERLYING OBJECT RECOGNITION AND SPATIAL MEMORY IN THE RAT, J.P.,Aggleton, E. C. Warburton and R.K. Nakamura*. School of Psychology, University of Wales, Cardiff, U.K. CF1 3YG and NIMH, Rockville, MD20857

In two separate experiments we examined the effects of lesions in i) the fornix and the anterior thalamic nuclei and ii) the perirhinal, postrhinal and TE cortices. Rats were tested on a series of object recognition tests that used spontaneous preference for exploring novelty as a measure of recognition. Following exposure to the sample stimulus and a delay of 15 mins, it was found that radiofrequency lesions of the fornix or cytotoxic lesions of the anterior thalamic nuclei had no effect on the standard task i.e. they showed heightened exploration of the novel object similar to that in a group of control rats. In contrast, rats with extensive cytotoxic lesions of the rhinal cortices failed to discriminate the novel objects and differed significantly from their control animals. rhinal rats were, however, able to perform normally on a T-maze alternation task, even when increasing delays were added between choice run and test. In contrast, both the fornix and anterior thalamic lesioned rats were impaired on spatial memory tasks. This double dissocation contradicts the notion that the hippocampus is reliant on inputs from the rhinal cortices for spatial memory, and highlights a marked degree of independence in the functioning of these two regions. (Supported by U.K. MRC and Wellcome Trust)

PLACE- AND OBJECT-RECOGNITION DEFICITS FOLLOWING LESIONS OF THE HIPPOCAMPUS OR PERIRHINAL CORTEX IN RATS: A DOUBLE DISSOCIATION. M.J. Glenn* and D.G. Mumby, Dept. Psychology, Concordia Univ., Montreal, QC, Canada H4B 1R6

A within-subjects experiment tested the hypothesis that the hippocampus and perirhinal cortex are specialized to deal with information about places and objects, respectively. Rats were trained on a delayed matching-to-place (DMTP) task in a water maze at delays of 4, 60, 300, and 600 seconds, and a trial-unique delayed nonmatching-to-sample (DNMS) task, with objects as stimuli, at delays of 4, 15, 30, 60, and 120 seconds. Following presurgery training, the rats received either bilateral NMDA lesions of the hippocampal formation, bilateral aspiration lesions of perirhinal cortex, or sham surgery. Rats with hippocampal lesions were impaired on the DMTP task at all retention delays, whereas rats with perirhinal cortex lesions performed normally. By contrast, rats with lesions of the perirhinal cortex were impaired on the DNMS task, whereas rats with hippocampal lesions performed normally. This double dissociation suggests that the functions of the hippocampus and perirhinal cortex contribute independently to rats' ability to recognize places and objects, respectively.

EFFECTS OF RHINAL CORTEX LESIONS ON RETENTION OF PREOPERATIVELY LEARNED OBJECT DISCRIMINATIONS IN RHESUS MONKEYS. J.A. Thornton^{1.2*} and E.A. Murray¹. ¹Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD 20892 USA, and ²Dept. of Psychology, The George Washington University, Washington, DC 20052 USA.

To test whether the rhinal cortex (i.e., entorhinal cortex and perirhinal cortex) plays a time-limited role in information storage, eight rhesus monkeys were trained to criterion on two sets of 60 object discrimination problems, one set at each of two different time periods (16 weeks and 1 week), prior to bilateral ablation of the rhinal cortex (Group Rh; n=4) or no surgery (Group Con; n=4). Following a twoweek rest period, monkeys were assessed for their retention of the object discriminations in two ways: 1) by administering 120 critical trials, one per object discrimination problem; and 2) by measuring the savings exhibited in relearning. Preoperatively, there was no group difference in the rate of acquisition, nor was there a difference in the rate at which the two sets were learned. Postoperatively, monkeys in Group Rh were significantly impaired relative to those in Group Con (68 vs. 91% correct) on the critical trials (F(1,6) = 25.34, p < 0.05). The ANOVA also yielded a significant main effect of set, with slightly better retention of the discriminations from the more recently learned set (F(1,6) = 7.41, p < 0.05), but there was no interaction of group and set. In addition, the mean savings for Group Rh was lower than that for Group Con (61 vs. 100%). Finally, monkeys in Group Rh subsequently learned a new set of 10 object discriminations as quickly as monkeys in Group Con, thus ruling out the possibility of a gross impairment in visual perception or discrimination abilities. These findings indicate that the rhinal cortex is critical for the retention of object discrimination problems that were learned up to 16 weeks preoperatively. The results provide no support for the idea that the rhinal cortex plays a time-limited role in information storage. This work is supported by the NIMH, NIH.

LONG-TERM EFFECTS OF NEONATAL HIPPOCAMPAL LESIONS ON SPATIAL RECOGNITION MEMORY IN RHESUS MONKEYS. M.C. Alvarado.* J.W. Barnhill, and J. Bachevalier, Dept. of Neurobiology and Anatomy, Univ. Texas Houston Medical School, Houston, TX 77225.

Adult monkeys with early damage to the hippocampal region were unimpaired on visual delayed nonmatching-to-sample (DNMS) using trial-unique objects (Beauregard & Bachevalier, Soc. Neurosci., 23, 1993). However, these same animals were severely impaired on a test of relational memory, the transverse patterning problem (Alvarado et al., Soc. Neurosci., 25, 1995). In the present study, we further tested this group of animals on a location DNMS task. Subjects were four monkeys with neonatal aspiration lesions of the hippocampal formation and subjacent cortex (H), and five age-matched controls (N), 9-11 years old. Animals were trained to a criterion of 90% or 1000 trials. They were then given a performance test of 100 trials at each of four delays (30 s, 60 s, 120 s, and 10 min.). Group N learned the task in an average of 480 trials (one required additional correction training), whereas Group H reached criterion in an average of 835 trials (3 required additional correction training). A comparison of performance across delays for both Groups on object DNMS and location DNMS revealed no Group difference for object DNMS [F(1,7)=2.24, n.s.]. By contrast, Group H was severely impaired on location DNMS [F(1,7)=40.52, p< .0001]. Performance scores of each Group were affected by delay in both tasks, and that effect was greater in the location task. As a function of delay, performance on object DNMS dropped 2% for Group N and 4% for Group H, whereas on location DNMS, it fell 7% and 16%, respectively. These results confirm that early hippocampal formation damage produces a permanent and specific memory loss. They further suggest that the hippocampal formation is not required for visual recognition memory for delays of up to 10 min., but is required for aquisition and retention of relational information, even at short delays. EFFECTS OF LATERAL vs. MEDIAL ENTORHINAL CORTEX ASPIRATION ON THE ACQUISITION OF ODOR-PLACE ASSOCIATIONS. <u>T. Otto*</u>, <u>C. Ding</u>, <u>G. Cousens</u>, <u>K. Schiller</u>. Dept. of Psychology, Rutgers University, New Brunswick, NI. 08903.

We have recently developed a task in which successful performance requires acquisition and retention of associations between specific, spatially neutral odorants and unique spatial locations. Briefly, water deprived rats were placed in a square arena with a combination water- and odor- port in the center and in each of the four corners, and were trained to associate one odorant with one corner and a second odorant with a different corner; visits to the either of the other two corners were never reinforced. Rats were reinforced when they visited the corner that was "paired" with that particular odor.

Errors were divided into two types: "spatial memory errors" consisted in visiting one of the two corners that were never reinforced, and "odor-place association errors" consisted in visiting the incorrect one of the two corners at which reinforcement was available. Both sham-operated rats (n=19) and rats with lesions limited to lateral entorhinal cortex (n=4), but NOT rats with combined lesions of lateral and medial entorhinal cortex (n=4), rapidly acquired the spatial components of the task as reflected in the number of spatial memory errors across sessions.

While there was little difference in the performance of sham-operated rats and rats with lesions limited to lateral entorhinal cortex in spatial memory errors, rats with selective lesions of lateral entorhinal cortex were dramatically and persistently impaired in learning the associations between odors and spatial locations. These data suggest that, while lateral entorhinal cortex may not play a necessary role in spatial learning, it is critically involved in the acquisition of the relationships between odors and places, and are consistent with predictions based on both the anatomical projections to this area and their putative mnemonic functions.

EFFECTS OF EXCITOTOXIC HIPPOCAMPAL LESIONS ON LEARNING AND RETENTION OF TOUCHSCREEN VISUOSPATIAL TASKS IN RHESUS MONKEYS. F.Y. Doré*, J.A. Thornton, N.M. White¹ and E.A. Murray, Laboratory of Neuropsychology, NIMH, NIH, Bethesda, MD 20892. ¹ Department of Psychology, McGill University, Montréal, Québec, Canada.

Early as well as more recent studies (Angeli, Murray & Mishkin., 1993; Gaffan, 1994; Parkinson, Murray & Mishkin., 1988) in monkeys converge with the research on rodents: spatial learning and memory are impaired by damage to the hippocampal formation or fornix. In order to define further the conditions and the neural basis for this impairment in monkeys, the present study used a new automated allocentric spatial task. On each trial, naive rhesus monkeys were required to search for and to find a specific unmarked location (target square) within stimulus arrays presented on a touchscreen monitor. Each array was composed of 5 different objects, had a unique asymmetrical shape, and a unique location of the target square. Further, each array was presented in various positions and rotations across trials. Measures included: distance from, and number of touches and latency to find, the target square. After learning the task, two groups (n=3), matched for preoperative scores, either received bilateral ibotenate lesions of the hippocampus (fields CA1-CA4 plus dentate gyrus) based on MRI from those animals or were retained as unoperated controls. Hippocampectomized monkeys showed very good retention of the arrays learned preoperatively but were impaired in the first sessions of acquisition of new arrays. They learned additional arrays composed of identical instead of different objects at the same rate as controls. The transient and specific nature of the impairment suggests that the hippocampus plays a more limited role in allocentric visuospatial tasks than in navigational tasks. EFFECTS OF FORNIX LESIONS ON THE TRANSVERSE PATTERNING TASK. J.L. Muir*, T.J. Bussey and J.P. Aggleton. School of Psychology, University of Wales College of Cardiff, CF1 3YG, Wales, UK.

Configural association theory (Sutherland and Rudy, 1989) is one of the more influential theories of hippocampal functioning, as it attempts to account for a wide range of disparate data. However, subsequent studies have failed to provide unanimous support for this theory. Recently these authors have provided a modification of their original theory, in which the hippocampus is hypothesised to increase the salience of configural representations, relative to elemental ones. One of the predictions of this theory is that disconnection of the hippocampus should impair the acquisition of the transverse patterning task, in which animals learn three "ambiguous cue" discrimination problems of the type A+B-, B+C-, C+A- Animals must respond directly to the elements A, B and C, thus creating a conflict between associations involving representations of these elements, and configural representations comprised of these elements (Rudy and Sutherland, 1995).

Recently a method has been developed for testing rats using computer-graphic stimuli (Bussey et al., 1994) which provides an ideal opportunity for investigating this suggestion further. In this apparatus, animals must respond by nose-poking a small touch-sensitive response area in the centre of the stimulus. Thus the transverse patterning task, when administered using this method should, according to the analysis of Rudy and Sutherland (1995), be especially sensitive to hippocampal dysfunction. However, pilot studies in our laboratory have shown that animals with complete fornical transection were not only unimpaired on this task, they showed a facilitation of acquisition.

In the present study we examine subsequent data from fornix-lesioned animals on the transverse patterning task, with particular attention to the nature of learning by normal animals. We also examine session-by-session data from fornix-lesioned animals in an attempt to shed light on the precise effects of fornix lesions in discrimination learning in general. THE EFFECTS OF LESIONS TO THE PERIRHINAL AND ENTORHINAL CORTICES OR FORNIX ON THE TRANSITIVE INFERENCE TASK.

Jeff Dusek* & Howard Eichenbaum.

Center for Behavioral Neuroscience, SUNY-Stony Brook, NY 11794.

Bryant & Trabasso (Nature 267:694, 1971) hypothesized that the ability to make a transitive inference (if A > B and B > C, then A > C) is dependent on the ability to recall previously learned premise information. The present experiment examined whether memory impairments consequent to hippocampal system damage would decrease transitivity levels on a nonspatial ordering of olfactory stimuli

nonspatial ordering of olfactory stimuli. Male Long Evans rats underwent a combined lesion of the perirhinal and entorhinal cortices (PRER), which provide much of the sensory input to the hippocampus, a fornix lesion (FX), which disrupts subcortical connections of the hippocampus, or a sham surgery (SHAM). All rats were trained with four adjacent pairs of odors (A+ vs B-, B+ vs C-, C+ vs D-, D+ vs E-) that formed a sequéntial hierarchy (A > B > C > D > E). After acquiring all premise problems, rats were subsequently tested with the non-adjacent pair, BD, to assess their capacity for making a transitive inference (B > D). All subjects were able to acquire the four problems; however, only the SHAM subjects were able to develop a flexible representation of the odor series as evidenced by their ability to choose correctly on the pair BD. Conversely, both the FX and PRER subjects were limited to nonrelational strategies that permitted only a repetitive expression of the premise problems. These results extend previous findings linking transitivity to hippocampal function (Bunsey & Eichenbaum, Nature 379:255, 1996) and strongly support the conclusion that the hippocampus subserves declarative memory as characterized by the encoding and flexible expression of relational information. THE EFFECT OF ANTERIOR THALAMIC AND CINGULATE CORTEX LESIONS ON 'OBJECT-IN-PLACE' MEMORY IN NON-HUMAN PRIMATES Amanda Parker & David Gaffan, Dept. of Experimental Psychology, University of Oxford, England, UK.

Macaque monkeys (Macaca mulatta) were trained in an object-in-place memory task, designed to capture the 'whole scene' nature of episodic memory. In the object-in-place memory task the correct, rewarded, response in each scene is to a particular object of a pair, which always occupies a particular position in a unique background which has been generated using randomly chosen colours and shapes. In each session, the monkey learns a new list of these unique scenes. Following stereotaxic lesions of the anterior thalamic nuclei, 3 animals showed a severe impairment in performance. In contrast, following surgical ablation of cingulate cortex a second group of 3 animals were only mildly impaired at the task. These results are

compared with those of animals with mamillary body lesions and fornix transection who have been tested using the same behavioral paradigm (Gaffan, J.CogNeurosci 1994, 6, 305; Parker & Gaffan, in press). The results show that cingulate lesions produce a milder amnesia than that caused by anterior thalamic or mamillary body lesions or fornix transection.

HIPPOCAMPAL LESIONS WITHOUT INJURY TO THE RHINAL CORTEX DO NOT IMPAIR AUDITORY RECOGNITION MEMORY IN DOGS

<u>D.M. Kowalska and P. Kuśmierek</u>, (SPON: European Brain and Behaviour Society) Nencki Institute of Experimental Biology, Pasteur St. 3, 02-093 Warsaw, Poland

Three male mongrel dogs were trained to perform a delayed matching-to-sample (DMS) task with auditory trial-unique stimuli with an inter-stimulus delay of 1.5 s. To reach the criterion of 90% correct in 90 consecutive trials, they required an average of 1565 trials (T; range 1300-2075) and 507 errors (E; range 346-718). After a 2 week break, they were retrained to criterion (mean: T=153, E=17). They were then given performance tests with delays 10, 30, 60 and 90 s in blocks of 90 trials (mean for all delays=70% correct, range: 68%-74%). Next, they were retrained on the original 1.5 s delay (mean: T=270, E=40) and then received surgery. The hippocampus was removed bilaterally through a small opening in the parietal cortex (Kowalska & Kosmal, Acta Neurobiol. Exp., 1992, 52:119). The rhinal cortex was not damaged. Postoperatively, the criterion was reattained on the 1.5 s delay in an average of T=227 and E=33. Mean score on the performance tests was 79% correct (range: 73%-83%).

The results indicate that, in dogs, bilateral removal of the hippocampus does not impair performance on an auditory recognition DMS task with trial-unique stimuli.

HOMING PIGEON VISUAL RELATIONAL LEARNING IS UNAFFECTED BY HIPPOCAMPAL LESIONS. Y. P. Bingman*, C. Baker, L. Y. Riters and R. Strasser. Dept. of Psychology, Bowling Green State Univ., Bowling Green, OH, 43403.

Eichenbaum and his colleagues have proposed that the role of the hippocampal formation and neighboring structures in learning and memory can be best explained by assuming these structures participate in relational learning processes. To test the generality of their hypothesis, homing pigeons were trained on a visual relational learning task modeled on the olfactory task used by Bunsey and Eichenbaum (Behav. Neurosci. 107: 740-747, 1993). Specifically, 8 visual stimuli (A-F, X and Y), varying in color and shape, were presented on a video monitor in an operant chamber. Untreated control, neostriatal lesioned and hippocampal lesioned homing pigeons were trained to recognize and respond to 6 stimulus pairs (drawn from stimuli A-F) with the two stimuli of a pair being presented sequentially (e.g., A-B, B-A, C-D etc., paired associates) and NOT to respond to other stimulus pairs made up from the same stimulus pool (e.g., A-C, A-D, etc., mispair sequences) as well as pairs that contained either stimulus X or Y (non-relational sequences). All groups quickly learned not to respond to stimulus pairs that contained A and Y. Across 40 test sessions, pigeons from all groups continued to respond vigorously to paired associates while responses to mispair sequences dropped significantly indicating that the birds had learned the relational nature of the paired associates. No difference was found in the performance of control/neostriatal pigeons compared to birds with hippocampal lesions. Further, a subsequent correlational analysis revealed no relationship between the extent of hippocampal damage among the hippocampal lesioned birds and performance on the task. The data suggest that homing pigeons can rely on a relational strategy to learn to preferentially respond to paired associates and that the hippocampal formation is passed and the hippocampal formation is passed and the hippocampal formation is passed and the hippocampal formation is passed to passed the hippocampal formation be a consequence of the different stimuli use

PERIRHINAL .CORTEX ABLATION AND DISCONNECTION OF FRONTAL LOBE FROM TEMPORAL LOBE DO NOT IMPAIR OBJECT-REWARD ASSOCIATION LEARNING ACROSS A DELAY IN MONKEYS. S.A. Gutnikov*, Y.-Y. Ma, M. Buckley & D. Gaffan. Department of Experimental Psychology, Oxford University. England, OX1 3UD, UK.

In monkeys information about the features of visually perceived objects is processed in area TE of the temporal cortex. Area TE projects to the perirhinal cortex (PRC) and, via uncinate fascicle (UF), to the prefrontal cortex (PFC). A widely accepted hypothesis of long-term potentiation (LTP) as a neural mechanism of associative memory requires simultaneous depolarisation of two neurons: the presynaptic neuron which conveys information about the object properties (a neuron in TE) and the postsynaptic neuron which holds information about the reward. Most importantly, in order to form associative LTP, depolarisation of these two neurons must coincide with the temporal gap of no longer than 100 ms. Neurons in TE have been shown to fire during presentation of the object but not after object offset. Thus, in the view of the memory-LTP hypothesis, if object-reward association is formed when the reward is delayed for longer than 100 ms after object offset, the information about the object must be kept somewhere else in order to bridge the delay until the information about the reward is available. In the present study monkeys learned concurrent visual object-reward discriminations with reward delayed for up to 1000 ms after object offset. The rate of learning with 1000 ms delay of reward was no slower than the rate of learning with zero delay. Thus, either the mechanism of associative memory is different from that of associative LTP, or information about objects is kept somewhere outside TE. Ablations of PRC or disconnection of PFC from TE (by transection of UF) did not impair learning, indicating that information about the visually perceived objects is not kept in PRC or PFC across the delay. HIPPOCAMPAL AND PARIETAL CORTEX PROCESSING OF OBJECT SCENES. W.E. DeCoteau* and R.P. Kesner. Department of Psychology, University of Utah, Salt Lake City, UT 84112.

Using a successive go/no-go paradigm with object scenes, rats were trained on object-based discrimination (OBD), location-based discrimination (LBD), or object/location-based discrimination (O/LBD) tasks. In each of these tasks, rewarded trials consisted of a standard scene of four objects placed over baited food wells. Non-rewarded trials for the OBD consisted of replacing any one of the four objects of the standard scene with a novel object. Negative trials for the LBD consisted of displacing any one of the four objects in the standard scene. Negative trials for the O/LBD consisted of replacing and displacing any one of the four objects in the standard scene. After reaching a criterion of at least a four sec. difference between rewarded and non-rewarded trials, rats were given either hippocampal, parietal cortex or cortical control lesions. None of the lesion groups showed an impairment on the OBD task. Parietal cortex and hippocampal lesions produced impairments on the LBD and O/LBD tasks. On the O/LBD, parietal cortex lesions produced a profound impairment, but the hippocampal lesions resulted in a mild impairment followed by recovery. Based on transfer tests, the recovery appeared to be due to use of an object-oriented strategy. These results indicate that the hippocampus and parietal cortex are important in processing the spatial properties of scenes. Additionally, unlike the parietal cortex, the hippocampus seems unable to flexibly switch from an object/place to an object strategy in solving the O/LBD task. NSF IBN9511635

PRACTICE ON AUDITORY TEMPORAL-INTERVAL DISCRIMINATION PRODUCES LEARNING THAT GENERALIZES TO DIFFERENT FREQUENCIES BUT NOT OTHER INTERVALS. M.M. Merzenich*, D.V. Buonomano,

CIES BUT NOT OTHER INTERVALS. M.M. Merzenich*, D.V. Buonomano, H.W. Mahncke, B.A. Wright. Keck Center, UCSF, San Francisco, CA 94143-0732

The sensory encoding of the interval, duration, and order of different stimulus features provides vital information to the nervous system. For example, data indicate that temporal processing in the range of tens to hundreds of milliseconds is important to the perception of speech, and that deficits in temporal processing may underlie language impairments. The present study focuses on the influence of practice on temporal processing. The goals of the experiment were to determine: (1) whether practice improved the ability to discriminate between temporal intervals marked by tones of one frequency, and, if so, (2) whether this improvement reperalized to a different tonal frequency and/or temporal interval. These issues vals marked by tones of one frequency, and, if so, (2) whether this improvement generalized to a different tonal frequency and/or temporal interval. These issues were examined in eleven human subjects using a two-alternative, forced-choice procedure: two brief tones were separated by a standard temporal interval in one presentation, and by a standard plus a variable interval in the other presentation Subjects were required to indicate whether the longer interval occurred during the first or second presentation. The duration of the variable interval was adjusted adaptively over 60 trials to determine the discrimination threshold. Each subject was trained on 900 trials per day for ten days using a standard interval of 100 ms presented at 1 kHz. The average discrimination threshold decreased from 20 ms on Day 1 to 11 ms on Day 10. A one-way ANOVA of variance revealed a significant learning curve over the ten days of training (F_{9.97}=6.7, p<0.001). Before and after the training period, subjects were tested on a standard interval of 100 ms presented at 4 kHz, and on a standard interval of 200 ms presented at 1 kHz, in addition to the trained condition. Comparison of the pre- and post-test results revealed that tempoat 4 kHz, and on a standard interval of 200 ms presented at 1 kHz, in addition to the trained condition. Comparison of the pre- and post-test results revealed that temporal-interval discrimination improved significantly in the 100-ms/4-kHz condition, but not in the 200-ms/1-kHz condition. These results indicate that (1) auditory temporal-interval discrimination improves with practice, and that (2) this learning is temporally, but not spectrally, specific. PERCEPTUAL LEARNING OF AN IMPLICIT SEQUENCE. L. Salidis, D.B.Willingham*, P.B.Sederberg, and J.A. Hollier. Dept. of Psychology, University of Charlottesville, VA 22903.

Motor skills tasks are learned normally by amnesic patients, defining these tasks as implicit rather than explicit tasks. Learning outside the awareness of normal subjects is also considered implicit. Subjects' ability to learn an implicit pattern was tested in two experiments in which they tracked with a joystick a target moving in a one dimensional pattern for the mid portion of each trial; this sequence was embedded between two segments of random movement. Subjects showed greater improvement on the repeating segment than on the random segments. The basis of this learning, perceptual or motor, was evaluated by this learning, perceptual or motor, was evaluated by comparing the performance of a group who initially only watched the target with one who tracked. Subjects who watched the embedded repeating sequence showed more pattern specific knowledge than those who had watched only random movement, but less than those who tracked for the entire experiment. In contrast, a third experiment, in which the pattern was apparent (the target moved within the outline of a square or diamond), did not indicate any watching-facilitated sequence learning.

HUMAN WORKING MEMORY IN A RADIAL MAZE PERSISTS OVER LONG INTERRUPTION: GENERAL MAMMALIAN NEURAL WM MECHANISM? R. B. Glassman*, K. M. Leniek and T. M. Haegerich. Dept. Psychol., Lake Forest College, Lake Forest, IL 60045

Our studies have shown that spatial working memory (WM) capacity of humans in radial mazes having 13 or 17 arms is the same as that of lab rats; with correction for probable guesses, capacity is within the range of traditional verbal measures of human short-term memory ("the magical number" 7±2 items). We now report that humans doing a radial maze task, like lab rats, sustain memory over surprisingly long interruption-delays. Twenty-one undergraduates were asked to retrieve place markers hidden at the end of each arm of an 8-arm radial maze, 15 m dia., painted on the grass in an area with many nearby visual cues. Subjects were asked to choose arms unsystematically, and to depend on memory to avoid repeating. Most subjects accomplished this task with no repeat-errors even when a delay of 15 minutes, filled with a spatial interfering task, was interposed after the fourth arm-choice (mean=7.67). Somewhat less capacity was observed in testing the same people with an analogous recitation task - to say the letters A through H in random order with no repeats - with an interruption-delay of 30 seconds at the halfway point, occupied by a subtraction task (mean=7.14). The radial maze WM persistence over delay is additional evidence for a common mammalian brain mechanism, perhaps an aspect of cortical structure (also see Soc. Neurosci. Abstr. 1991-1994; Brain Research Bulletin, 1993, 1994). Forest College Richter Scholar Fund. Supported in part by the Lake

PERCEPTUAL LEARNING OF TEXTURE DISCRIMINATION: SUBJECT AND TASK DEPENDENT VARIABLES. A. Karni*, G. Bertini, P. De Weerd, R. Desimone and L.G. Ungerleider. NIMH, NIH, Bethesda MD 20892.

Several paradigms of perceptual learning suggest that practice can trigger long-term, experience-dependent changes in early processing stages within the adult visual system. In a texture target discrimination task, learning was specific for stimulus parameters such as the target's location and the background elements' orientation as well as the eye receiving training (Karni & Sagi PNAS 1991), suggesting mechanisms of figure-ground segmentation in striate cortex as a possible locus of plasticity. To study the responses of V1 neurons in an awake monkey, a modified version of the task was developed (Bertini et al Soc. Neurosci. Abs. 1995, 1996). Another version of the paradigm was set up to train human subjects for an imaging study. Here we report our findings using the "monkey" and the "imaging" versions of the task.

The task required the discrimination of the shape of a small parafoveal target consisting of 3 oblique line elements embedded in a background texture made of identical

The task required the discrimination of the shape of a shall paraloveat taget consisting of 3 oblique line elements embedded in a background texture made of identical but horizontal line elements. Discrimination performance was measured as a function of the time interval between the briefly presented target stimuli and a patterned mask. Fixation was enforced by a concurrent letter discrimination task at the fovea. The main changes made in the "monkey" task were: no letter discrimination task at fixation, tar-

changes made in the "monkey" task were: no letter discrimination task at fixation, target location was pre-cued, the area within which the targets appeared (spatial uncertainty) was reduced, and the amount of practice per session (for human subjects only) was more than halved. The last two changes were also made in the "imaging" task. A rhesus monkey and 15 humans (6 of them in the "monkey" task) were tested. In the monkey, as well as in 13 humans, experience-specific learning effects were found. Nine subjects showed clear monocular learning. Of the 6 subjects who showed no monocular learning, 4 showed learning specific for orientation or retinal location but in 2 (both trained on the "monkey" task) learning was not specific to either. In the monkey, learning did not transfer across visual-field quadrants, and was critically dependent on background element orientation. The effects of training, however, transferred between eyes. Our results confirm that percentual learning is highly specific for the training exeyes. Our results confirm that perceptual learning is highly specific for the training experience but raise the possibility that task and subject variables are related to different degrees of specificity of training effects. VISUAL RECALL FROM LONG-TERM MEMORY INTERFERES WITH PERCEPTION Alumit Ishai* and Dov Sagi, Dept, of Neurobiology, Brain Research, Weizmann Institute of Science, Rehovot 76100, Israel

Visual imagery is the ability to create a perceptual experience in the absence of retinal input. Using a lateral masking detection paradigm of a Gabor target, flanked by two high-contrast Gabor masks placed at different eccentricities, we have shown an imagery-induced facilitation that was subserved by a stimulus-specific short-term memory (STM) (Ishai and Sagi, Science 1995, 268: 1772). No interference was seen when the observer imagined Gabor stimuli under STM conditions. To obtain an imageryinduced interference (Perky effect), new experiments were designed, in which the observer had to detect a Gabor target and to imagine lines, using either long-term memory (LTM) or STM. The results showed an orientation-specific interference under LTM conditions. When recall of lines was based on STM, neither interference nor facilitation were seen. These results suggest that imagery-induced interference and facilitation are memory dependent - visual recall from LTM can interfere with perception, while in STM tasks facilitation can be obtained, and support the distinction between low-level and structural representations in visual memory.

AN IMPLICIT SEQUENCE LEARNING TASK ACTIVATES STRIATUM AS MEASURED BY FUNCTIONAL MRI. P.J. Whalen*, C.R. Savage, T. Curran, A. Kendrick, H.C. Breiter, G. Bush, H.D. Brown, B.R. Rosen & S.L. Rauch. Psychiatric Neuroscience Program & MGH-NMR Center, Harvard Medical School & Massachusetts General Hospital, Charlestown, MA 02129.

The serial reaction time (SRT) paradigm is a well characterized measure of implicit sequence learning. Using a noncontrast functional MRI (fMRI) technique, we sough to replicate PET studies in our lab implicating the striatum as a key structure involved in this task. Subjects were 8 healthy, right-handed, adult males and were instructed to press one of four keys; each key corresponding to one stimulus position of an asterisk appearing at one of four spatial locations at a fixed interstimulus interval. Stimuli were presented during two runs while reaction times (RT) were measured. Each run consisted of three Baseline condition blocks (30 secs) where the order of the stimulus locations was random, alternating with three Implicit Learning (IL) condition blocks (90 secs) where, unbeknownst to the subjects, a twelve item repeating sequence

All subjects exhibited a decrease in mean RT between the Baseline and IL conditions (p < .05). FMRI data were acquired as 15 contiguous 8 mm thick horizontal slices using a 1.5T MRI instascan device and an asymmetric spin echo T2*-weighted sequence (TR/TE/Flip = 2750/70/90). Structural data were obtained via a T1-weighted echo planar sequence. Foci of significant activation ($p < 10^4$) across all subjects for the motion-corrected, Talairach transformed and concatenated IL vs Baseline comparison were found bilaterally in striatum, in right premotor cortex, and in visual cortex. Inspection of statistical non-parametric maps from individuals revealed that 8/8 subjects demonstrated significant striatal activation. The SRT is shown here to be a reliable fMRI probe of striatal activity and may prove useful for studying neuropsychiatric conditions believed to involve cortico-striatal systems, such as

obsessive-compulsive disorder and Tourette syndrome. Supported by NIMH (MH01215), TSA, Inc. & the David A, Judah Research Fund

EFFECTS OF FEATURE MANIPULATIONS ON BRAIN POTENTIALS DURING A LEXICAL DECISION TEST. C.A. Joyce*†, K.A. Paller§,

H. McIsaac^o, & M. Kutas†‡. Cognitive Science† and Neuroscience‡. Univ. of California at San Diego, La Jolla, CA 92093-0515; Psychology, Northwestern Univ.§; Psychology, Univ. of British Columbia, Canada°.

We report on a series of studies in which event-related potentials (ERPs) were recorded while words were presented during lexical decision tests. In the first experiment, the physical presentation was manipulated by presenting some words letter-byletter and others as whole words at study, but all as whole words at test. Reaction time (RT) showed a repetition priming effect (RT faster for repeated than novel words) as well as a perceptual effect (RT faster for words presented as whole words on both occasions than those presented letter-by-letter at study and whole at test). Recognition scores did not differ for the two study conditions. ERP responses to repeated words were more positive than those to novel words between 300 and 600 msec. There was also a marginally significant perceptually-modulated ERP effect between 400 and 500 msec. In another experiment, font was changed from study to test. RT's again showed repetition priming and perceptual effects with no differences in recognition scores. The ERP repetition effect was also replicated, however the perceptual effect was diminished from that in the first experiment. In order to ascertain whether the diminished perceptual effect was a consequence of the greater perceptual ease of the font compared to form manipulation, a third study utilized a font that was more perceptually challenging. Preliminary RT data revealed a repetition priming effect, but no perceptual effect. Repeated words also elicited more positive potentials between 300 and 400 msec than novel words. Because the ERP repetition priming effect seems relatively unaffected by physical feature changes, it may index declarative memory processes.

CONCEPTUAL PRIMING WITH BRIEF MULTIPLE PRESENTATION TECHNIQUE: PRESERVATION IN AMMESIA.

M. Beauregard*, H. Chertkow, D. Gold, S. Karema, J. Benhamou, A. Faucher. Lady Davis Institute, Jewish General Hospital; Centre de Recherche du Centre Hospitalier Côte-des-Neiges, St-Anne de Bellevue Veterans Hospital, Montreal, Quebec, Canada. Considerable controversy surrounds the status of implicit memory processes in patients with amnesia; the original claim that such processes were spared has not been ronfirmed in recent studies demonstrating decreased conceptual priming for words. Possible contamination of most implicit tasks by impaired explicit strategies, however, may be responsible for such results. We have developed a method of circumventing explicit strategies by using brief duration repeated primes below the awareness threshold explicit strategies by using brief duration repeated primes below the awareness threshold of subjects. We have used this approach to evaluate the status of implicit memory in amnesic patients. One group of fifteen amnesic patients with alcoholic Korsakoff's syndrome (KS) and one group of fifteen normal elderly control subjects (NCS) were tested for word priming on a speeded category membership decision task carried out in two blocks. In each block, groups KS and NCS first studied 10 category members, and were then tested on a set of 40 word stimuli. Of these, 10 were the previously studied category members, 10 were new category members (20 "Yes" responses), and 20 were category non-members. List study conditions were manipulated in two experiments. In category non-memors. List study condutions were manipulated in two experiments. In Experiment 1, subjects were presented in each block with 10 study words. Word presentation consisted of a brief duration (17 ms) pattern masked exposure of the word. Each word was presented 10 times in succession at this exposure duration. No subject or patient could reliably report the words presented. In Experiment 2, subjects of the same two groups were presented in each block with 10 different study words, each structure of the case of duration. In both configuration was contact, and the support of the configuration of same two groups were presented in each notek with 10 different study words, each shown twice for a one second duration. In both experiments, the average reaction time for "Yes" decisions to the primed words was significantly faster than that to the unprimed words for both KS and NCS groups. Moreover, there was no significant difference in the magnitude of the priming effect between these groups in the two experiments. These findings demonstrate that amnesic patients can exhibit normal levels of conceptual word priming. Furthermore, they are consistent with a previous study from our laboratory showing that priming effects can occur even in the absence of explicit recognition or recall of presented material in normal individuals.

CONDITIONAL DISCRIMINATION LEARNING IN SCHIZOPHRENIA K. Dantendorfer*, D. Maierhofer, I. Daum, M. Schugens, P. Anderer, H. V. Semlitsch, H. Katschnig. Dept. of Psychiatry, Univ. of Vienna, Austria 1090.

Recent reports suggest, that memory and learning deficits seem to be more specific to schizophrenia (SZ) than previously accepted. Conditional discrimination learning based on eyelid conditioning has been shown to be selectively sensitive in testing temporal lobe function and has the advantage of making minimal demands on attentional capacities and motivation

An eyelid conditional discrimination learning task (Daum et al., Behavioral Neuroscience 1991) is used to examine healthy controls and two groups of SZ patients (DSM-III-R paranoid type SZ with predominant positive symptoms and disorganized type with predominant thought disorders). The occurrence of the first conditioned response (FCR) and response frequency to reinforced (CRR) and unreinforced trials (CRU) are quantified. 17 controls showed a FCR after 5 ± 2.25 trials as well as a frequency of

32% \pm 5,5% CRRs and 14% \pm 3% CRUs. Two paranoid type SZ patients tested up to now, showed high rates of CRRs as well as CRUs (CRR/CRU; 23%/25% and 29%/21%). On the other hand, the two disorganized type patients showed low rates of CRRs and CRUs (CRR/CRU; <math display="inline">2%/4% and 4%/4%). All four patients had the FCR on unreinforced trials and three of them showed delayed FCRs (trials 9, 14, 17) compared to controls

Our preliminary data suggest, that while paranoid as well as disorganized type schizophrenics show reduced discrimination learning capacity, the two subgroups might be differentiated by conditioned response frequency probably due to differences in temporal lobe functions. PATTERN PRIMING, INTACT IN ALZHEIMER'S DISEASE, REVEALS PERCEPTUAL NONDECLARATIVE LEARNING THAT IS INSENSITIVE TO ENCODING TIME. B.R. Postle*1, J.H. Growdon 1,2, & S. Corkin 1. 1 Dept. of Brain and Cognitive Sciences and the Clinical Research Center, Mass. Institute of Technology, Cambridge, MA 02139; ²Dept. of Neurology, Mass. General Hospital, Boston, MA 02114.

This experiment was designed to answer two questions about pattern priming: 1) Does pattern priming represent perceptual, motor, or haptic learning? and 2) Are pattern priming and pattern recognition memory differently sensitive to study encoding time? Subjects (AD = 12, NCS = 14) copied each of six target figures onto dot patterns, and then a) were given the same dot patterns and asked to draw the first figure that came to mind by connecting the dots with straight lines forming), or b) viewed each of the same six patterns of dots and were asked to indicate which of four possible completions corresponded to the figure that they had just copied (recognition). Confirming previous results (Postle et al. 1995; 1996), the AD and NCS groups achieved comparable priming scores, but AD subjects were significantly impaired on the recognition test. On the priming test, sequence and direction of pen strokes were considerably different between study and test, and uncertaint of persistors were constantly an extended to the terminal ruling out motor learning or haptic learning as plausible explanations of the learning in either group, and confirming that pattern priming represents perceptual nondeclarative learning. Analysis of mean encoding time for "correct" trials suggested that pattern priming was not sensitive to differences in encoding time at study (AD mean encoding time for "correct" trials = 9.0 sec, for "incorrect" trials = 11.3 sec; NCS "correct" mean = 5.8 sec, NCS "incorrect" mean = 5.6 sec), but hat pattern recognition was sensitive to encoding time differences (AD mean encoding time for "correct" trials = 13.8 sec, for "incorrect" trials = 9.4 sec; NCS "correct" mean = 6.0 sec, NCS "incorrect" mean = 5.3 sec). This result suggests that pattern priming, like some forms of verbal nondeclarative perceptual priming, is insensitive to the manipulation of encoding time, while the declarative memory analog of this test is sensitive to this manipulation. REPEATED VERB GENERATION IN AMNESIC PATIENTS: NORMAL PRIMING AND VERB SPECIFICITY. <u>C. A. Seger^{1*}, L. A. Rabin¹, M. M. Keang², M. Zarella², <u>& J. D. E. Gabrieli, ¹²</u> Dept. of Psychology, Stanford</u> University, Stanford, CA 94305 and ²Memory Disorders Research Center, Boston VA, Boston, MA 02130.

In the verb generation task subjects are presented with nouns and generate for each mean every generation task subjects are presented with nouns and generate for each one an appropriate very, the nouns can be repeated across blocks, with the result that generation latencies are reduced and different patterns of brain activation are present (Raichle et al., 1994). Research in our laboratory has indicated that reduced generation latency occurs when a verb is repeated, regardless of whether the stimulus noun is repeated or novel. These results suggested that in repeated verb generation verbs are primed as a result of being previously generated. Since many priming tasks are dependent on nondeclarative memory, we decided to test whether verb generation is impaired or preserved in patients with amnesia, who manifest impaired declarative memory but preserved nondeclarative memory. Amnesic patients and matched controls were tested in a verb generation task with 4 repeated blocks of nouns followed by a novel block. The amnesic patients showed the same pattern of performance as controls: they became faster across blocks on repeated nouns and returned to original performance levels when novel nouns were introduced. An examination of patients' responses indicated that the verb generation effect was verb specific: when patients responded to a novel noun with a repeated verb from an earlier block, they showed reduced generation latency equivalent to that found when a repeated verb was generated in response to a

EARLY COGNITIVE IMPAIRMENTS IN SCHIZOPHRENIA: A EARLY COGNITIVE IMPAIRMENTS IN SCHIZOPHRENIA: A COMPARISON OF DRUG NAIVE AND NEUROLEPTIC TREATED PATIENTS. I. Lussier, E. Stip, M. Babaï, J.B. Debruille and I. Peretz*. Centre de recherche Fernand Seguin, Département de psychiatrie, Université de Montréal, 7331, rue Hochelaga, Montréal, Québec, Canada, H1N 3V2.

In the present study, we examined attention and memory functionis in expliciphenic articlets. In order to avaluate the effects

functioning in schizophrenic patients. In order to evaluate the effects of the illness per se, drug naive patients were compared to patients treated with traditional neuroleptics, and to a group of matched normal controls. All subjects groups were submitted to a series of cognitive measures. For memory functioning, verbal (span) and attentional (dual task) working memory components and explicit and implicit recall were measured. For attentionnal functioning, reaction implicit recall were measured. For attentionial functioning, features time (alertness), sustained attention (CPT) and selective attention were examined. Results showed that, overall, drug naive patients performed better than patients treated with traditional neuroleptics. Moreover, not all cognitive processes were disturbed in drug free patients: Alertness, working memory, and implicit recall were in the normal range. These observations suggest that there are impairments in information processing early in the disease process but that other factors, such as medication, contribute to the cognitive impairments reported in the schizophrenic population. The effect of illness related factors, such as diagnostic, positive and negative symptoms, and hospitalization will be discussed.

NEUROPHYSIOLOGICAL MECHANISMS OF CORTEX-SUBCORTEX INTERACTIONS DURING ORGANIZING OF BEHAVIORAL REACTIONS. V.T.Shuvaev, V.I.Shefer* and A.V.Michailov, Lab. of Higher Nervous Activity, Pavlov Institute of Physiology, St. Petersburg, Russia.

A correlational analysis of neuronal activity in cortex and subcortex (neostriatum, VA, VL-thalamus and amygdala) of dogs and cats was carried out. The changes of synchronization level and of the temporal parameters of correlating periods in spike activity of neurons during the formation and realization of different behavioral reactions were investigated. The following scheme of these changes was developed: the maximum of correlation corresponds at first to the interactions neostriatum-amygdala, than to the interaction cortex-amygdala and 100-300 ms later to the interactions cortexneostriatum (before the formation of a reaction); at the begining of the realization of a reaction this maximum can be observed in the interaction thalamus-cortex and thalamus-neostriatum, but later the simultaneous increase of synchronization cortex-neostriatum and cortex-amygdala becomes more important. New data of the plastic changes of neuronal activity during the formation of the reactions were also obtained. The data suggest that on one hand activity of the neurons is determined by a particular brain structure, which they belong to, but on the other hand, they may form a neuronal networks constituting a kind of net with properties allowing qualitatively a new functions to be implemented.

MODEL OF CORTICO-HIPPOCAMPAL MEMORY CONSOLIDATION PROCESS BY ACCUMULATION OF CASE MEMORIES AND RE-ORGANIZATION INTO MAPS, T. Omori*, BASE, Tokyo Univ. of Agriculture & Technology / PRESTO, Japan Research and Development Cooperation, Nakamachi, Koganei, Tokyo 184, Japan

A memory formation process has three time constants of short, middle and long. We suppose a hippocampal LTP as the middle term memory that encodes an events by a configural association. We propose a model of memory consolidation process from the hippocampal events to a cortical long term memory in a feature map structure, and discuss about their theory.

The model has two different typed memory systems between an input and an output layers. One is a case memory system that has fast configural association ability. Another is a self organizing feature map(SOFM) with slow learning rate. Given an input, it is memorized in the case memory system, and associated to an output neuron by a teacher signal. When the cases are accumulated, the cases that correspond to an output are back projected to the input layer, and averaged to extract essential features for the output. When, the averaged patterns are givento the SOFM iteratively, multiple feature maps that have same dimensions with the teacher signal are formed. The model can explain the primary brain map formation as a memory re-organization process.

DO FIRING RATE DISTRIBUTIONS REFLECT ANYTHING BEYOND JUST CHANCE?

S. Panzeri*1, M. Booth², E.A. Wakeman², E.T. Rolls² and A. Treves¹

¹SISSA, Cognitive Neuroscience, via Beirut 2, 34013 Trieste, Italy and ²Univ. of Oxford, Experimental Psychology, OX1 3UD, UK.

The firing rate responses of a typical cortical pyramidal neuron to large, ecological, sets of stimuli usually follow a graded unimodal distribution, with a tail extending to high rates, as seen in many plots of the number of spikes emitted in a fixed time window. The mode of the distribution is close to the spontaneous firing rate (sometimes, and more often the further from sensory inputs, at zero firing) and the tail is close to exponential. A full exponential distribution would maximise, under the constraint of fixed average rate, the information transmitted by an artificial unit that used a definite number of spikes as a noiseless code for each stimulus. This has led to the recent suggestion (R.Baddeley) that the exponential tail might be an attempt to optimize information transmission. However most of the information would be transmitted at low rates, where the distribution is often far from exponential and moreover real within-stimulus variability makes the noiseless coding theorem inapplicable. We therefore explore the al-

inapplicable. We therefore explore the alternative hypothesis that typical distributions merely reflect a random (Gaussian) input activation, taking into account a physiological input-output transform and real noise levels. This leads to better and more economical fits: Supported by the MRC (UK), INFM and INFN (Italy) and the HCM program of the EC.

ENCODING SERIAL ORDER IN A MODEL OF THE PREFRONTAL CORTEX AND BASAL GANGLIA. <u>D.G. Beiser, J.C. Houk*</u>. Dept. of Physiology, Northwestern University Medical School, Chicago, IL. 60611.

Several lines of evidence suggest that the prefrontal cortex (PFc) and basal ganglia play an important role in the cognitive aspects of serial behavior. We present a modular neural network model of these areas that encodes serial inputs within spatial patterns of PFc activity. The model is based on the topographically-specific circuits linking the PFc with the basal ganglia. Each module traces a pathway from the PFc, through the basal ganglia and thalamus, and back to the PFc. The complete model consists of an array of modules interacting through recurrent corticostriatal projections and collateral inhibition between striatal spiny units. Other computational features include: sharp firing thresholds for effective context detection by spiny units and bi-stable corticothalamic loops for sustaining contexts in working memory.

The model was tested in a simulated version of a delayed-sequencing task. Experimentally, this task begins with the presentation of a sequence of target lights. After a short delay, the monkey must touch the targets in the order by which they were presented. In the simulated paradigm, the untrained model produces different patterns of PFc activation in response to different target sequences — giving an unambiguous spatially-distributed representation of the sequence. The codes are stable and largely independent of the target presentation rate. In addition, responses from the model's PFc and caudate units, many of which display responses that depend on the serial-order of the target inputs, qualitatively resemble those from the relevant single-unit studies. The model offers several predictions regarding the response characteristics and location of sequential activity in the brain. Supported by: NIMH Center Grant #P50-MH48185-05.

INFORMATION DYNAMICS IN ASSOCIATIVE MEMORIES WITH SPIKING NEURONS

F.P. Battaglia*1, and A. Treves¹. ¹SISSA, Cognitive Neuroscience, via Beirut 2, 34013 Trieste, Italy.

Processing speed is a crucial constraint on the organization of sensory modules. Here, a simulation study is presented of the dynamics of a recurrent network with spiking neurons. The network is composed of excitatory and inhibitory units, with shunting inhibitory synapses. Excitatory-excitatory synapses encode memories in an hebbian fashion, with a boundary forgetting mechanism (Parisi G., 1986, J. Phys. 19 L617). Shunting inhibition has proved to be helpful in stabilizing the dynamics of the network allowing for a larger stability window in parameter space and for more variance in synaptic strengths, resulting in a much larger memory capacity. We show analitically that shunting inhibition, unlike subtractive inhibition, stabilizes network dynamics for memory loading up to the theoretical capacity limit. As a measure of retrieval speed two kinds of information-related quantities are considered: the full information contained in the steady, attractor state reached by the network following the presentation of a partial cue (Treves A., 1990, Phys. Rev. A 42 2418); and the information about which one of the encoded memories has been associated to the cue, which is what can be measured in multicellular recording experiments (see related Abstract by Treves et al.). The dependence of the time scales for these quantities on the parameters is studied. It is seen that synaptic conductance time constants have a major effect on retrieval speed (Treves A., 1993, Network 4 259). For realistic parameters values, it is shown that recurrent modules can operate fast enough to contribute to rapid perceptual

MODELING OF ARTIFICIAL NEURONS WITH COMPLEX DENDRITE STRUCTURES. M. Ichikawa, H. Yamada, T. Iijima and G. Matsumoto*. Molecular and Cellular Neuroscience section, Electrotechnical Lab. Tsukuba, Ibaraki 305 Japan.

Generally, neuron models in artificial neural networks were too simple in structure, however each living neuron forms dendrites of very complex structure. Some physiological results shows that spikes are generated not only at cell body but also in the proximal dendrites. The results suggest that the conventional neuron model used in artificial neuro-network may not mimic living neural network. We propose a novel method of modeling an artificial neuron having multiple dendrites of various properties. Our model consists of four components, each of which will be called basic primitive, "begincell", "dendrite", "link" and "endcell". Any cell should be declared with a nesting of "begincell" and "endcell" primitives, and the other primitives should be inserted between this nesting according to the design of cell. For instance, CA1 pyramidal cells in hippocampus will have at least three "dendrite" primitives, each of which may correspond to the Schaffer collateral, commissural fibers and Perforant path. Each "dendrite" primitive has its own property such as synaptic connectivity, learning rule, scaling factor and so on. Based on the new idea, we recently developed a novel processor. The processor can execute calculations using huge number of synthesized neurons and networks composed of those neurons, effectively. We will present an application for reconstruction of neural activities detected with optical imagings in rat hippocampal slices. Part of this work was supported by NEDO.

DEVELOPMENTAL PLASTICITY FORMS STABLE ATTRACTOR

DEVELOPMENTAL PLASTICITY FORMS STABLE ATTRACTOR NETWORKS. S. E. Hua*, F. A. Mussa-Ivaldi and J. C. Houk. Dept. of Physiology, Northwestern Univ. Med. Sch., Chicago, IL. 60611
Neural network models with purely feedforward connections have been used effectively to characterize sensory systems. On the other hand, networks with feedback connections have additional properties that are potentially more capable of characterizing motor systems and behavioral problems; however, such networks may exhibit chaotic or oscillatory dynamics which are difficult regulate. Feedback networks which satisfy a symmetry requirement or a detailed balance condition do have stable dynamics, and these "attractor" networks have been used to model associative memory and the generation of motor commands. Experimental findings supporting the existence of attractor networks have been used to model associative memory and the generation or motor commands. Experimental findings supporting the existence of attractor dynamics have been found in single unit recordings. However, the acceptance of the attractor architecture as a plausible model of CNS function has been impeded by concerns that symmetry conditions may be too demanding to be biologically realistic.

biologically realistic.

Here we feport that recurrent networks with random initial connections will develop into attractor networks when guided by biologically plausible developmental rules. We assume only a Hebbian learning rule with either weight decay or weight normalization. Hebbian learning with simple weight decay results in symmetric connections. Similarly. Hebbian learning with concurrent pre- and postsynaptic normalization also leads to a symmetric network. Furthermore, Hebbian learning with either pre- or postsynaptic normalization alone leads to a network that satisfies a weaker form of symmetry known as a detailed balance condition. These analytic results hold for both linear and nonlinear networks and are valid for networks with continuous or discrete learning. We conclude that Hebbian learning with various biologically plausible forms of weight normalization leads to the natural development of dynamically stable networks. COMPUTER MODEL OF INFORMATION TRANSFER FROM THETA TO SHARP WAVE (SPW) STATES DURING MEMORY CONSOLIDATION IN

COMPUTER MODEL OF INFORMATION TRANSFER FROM THETA TO SHARP WAVE (SPW) STATES DURING MEMORY CONSOLIDATION IN THE HIPPOCAMPUS. Andrea Bibbig*, Thomas Wennekers. University of Ulm, Department of Neural Information Processing, D-89069 Ulm, Germany.

In rats hippocampal EEG activity is clearly related to behavior. Two states can be distinguished: (1) theta-concurrent exploratory behavior characterized by small active cell assemblies in dentate gyrus (DG), CA3 and CA1 firing in response to specific environments (place neurons?), and (2) immobility, consummatory behavior and slow wave sleep with large arhythmical population bursts (SPW) of almost all cells in CA3 and CA1. G. Buzsáki proposes that memory consolidation involves both stages [1]: During theta synapses between 'place cells' are weakly and transiently potentiated, whereas strong and longer lasting potentiation is achieved during SPW. Our computer model investigates how specific information can be transferred from theta to SPW states and eventually learned in spite the fact that SPW activity is extremely unspecific.

Our network consists of enthorhial cortex, DG, CA3 and CA1 implemented as associative memories [2] with bursting principal cells and integrate-and-fire interneurons. Learning is implemented as a Hebbian learning rule to mimic LTP-like plasticity. The efficacy of a synapse is strengthened, if (1) the postsynaptic Ca²⁺-concentration, given as an average (50 ms-range) of the presynaptic spike activity, exceeds a given threshold, and the postsynaptic cell activity we compared several measures: the local subsynaptic EPSP, the 'global' membrane potential V or spike activity, or short-time averages of those (V.O.). Learning is very unspecific in the purely local case, at least some neighbouring synapses should be taken into account. Best results are achieved with averages (20 ms-range) of postsynaptic spike activity. Furthermore we need some mechanism to prevent that former learned assemblies are always stronger than 'new ones'. We choosed a cell fac

REPEATING SPATIO-TEMPORAL PATTERNS OF NEURONAL ACTIVITY IN THE HIPPOCAMPUS DURING SLEEP. Z. Nádasdy*, A. Bragin and G. Buzsáki, CMBN, Rutgers University, Newark, NJ 07102.

Parallel recordings of unit activity from the CA1 and CA3 areas of Parallel recordings of unit activity from the CA1 and CA3 areas of the rat hippocampus were analyzed by a "spatial clustering" method during slow wave and REM sleep episodes. The temporal structure of spatially distinct neurons was determined and combined to a "spatio-temporal" spike chart. The time structure of the spike chart was scanned by various sequence searching algorithms. Since the number and complexity of patterns depended on the search parameters, we investigated the parameter space in order to determine an optimal time window. The probability of by chance repetition was determined analytically and by using a simulated (shuffled) database. The patterns multiple spike sequences were (1) temporally coordinated with better than 10 msec precision, (2) stable (3) Markov-chain type and (4) correlated with the sharp wave bursts (3) Markov-chain type and (4) correlated with the sharp wave bursts during slow wave sleep. The functional connectivity of the subnetwork was also determined on the basis of relative position within the spike sequences. The finding revealed that complex but reliably repeating spatio-temporal patterns are present during sharp wave bursts which are determined by the coincident discharge of neurons during preceding REM sleep episodes.

TEMPORAL SYMMETRY OF SPIKE PATTERNS IN ACTIVE MEMORY Yongdi Zhou*, Mark Bodner, Gordon L. Shaw, and Joaquín M. Fuster. Dept. Psychiatry and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024; Dept. Physics and Center for Neurobiology of Learning and Memory, UCI, Irvine, CA 92717.

The importance of symmetry in biological systems is well recognized. The purpose of present research is to determine whether symmetry plays a role in the temporal domain of neuronal spike discharge. A related aim is to find out whether specific patterns in the firing of cortical neurons exhibit symmetries during the short-term retention of sensory information. Using a new method of time-series analysis, single-unit spike trains were scrutinized for specific patterns and symmetries. The spike trains were recorded from parietal cortex of monkeys performing a tactile short-term memory task (delayed matching to sample). The results indicate that specific temporal patterns are present in the spike trains during the memory period of the task. These patterns can be almost 2-sec long and may repeat within a given spike train. That a pattern repeats in the period during which the memorandum must be retained is consistent with the hypothesis that short-term memory networks are maintained active by reverberation of impulses in closed circuits (Zipser et al., 1993). More generally, the patterns encountered are related to one another by symmetry operations that have been predicted by a highly structured model of cortical activity (Shaw et al., 1985).

SYNCHRONIZED NEURAL ENSEMBLES ACROSS THE ENTORHINAL-HIPPOCAMPAL CORTICES OF THE FREELY-BEHAVING RAT J.J. Chrobak* & G. Buzsáki, CMBN, Rutgers Univ., Newark, NJ 07102

Patterns of activity in neuronal ensembles have Patterns of activity in neuronal ensembles have computational relevance to the cognitive operations of the mammalian brain. We have described slow synchronizing potentials (theta, sharp wave and dentate spikes), their associated high-frequency oscillations (gamma band [40-100 Hz] and 200 Hz), and the relationship of specific neuronal populations to each pattern in the entorhinal-hippocampal cortices. The present findings describe the coordination of oscillations between distant locations within this circuitry

Our observations indicate that there is greater synchronization between sites within the dorsal CA1 region than between dorsal and ventral CA1 sites during 200 Hz cortex neurons and coupled CAI sites duffing 200 Hz cortex neurons and coupled CAI cells may be higher than the coherence between distal CAI sites. Thus, there can be greater synchronization across structures than within a single lamina of the same structure. Similar findings were observed with regards to synchronization of the entorhinal-hippocampal input pathway (layer II-III to dentate/hilar region) during gamma oscillations. These findings indicate the importance of "physiological connectivity" of neuronal ensembles in the hippocampal formation.

A PLAUSIBLE LEARNING ALGORITHM FOR THE ADJUSTMENT OF THE NOCICEPTIVE WITHDRAWAL REFLEX. C. Fåhraeus*, H. Holmberg and J. Schouenborg. Dept. of Physiology and Neuroscience, Lund University, Sölvegatan 19. S-223 62 Lund, Sweden.

The nociceptive withdrawal reflex is responsible for a complex sensorimotor transformation, adapted to protect the organism from harmful stimuli. In the hindpaw of the rat pups, we have recently shown that alteration of (a) single muscle's movement patterns and (b) cutaneous afferent innervation, both lead to appropriate adjustments of the reflex input-output function. It is therefore plausible that the polysynaptic withdrawal reflex is the result of a tuning algorithm rather than of detailed genetic programming

Here we present a learning algorithm, founded, trained and tested on biological data, capable of learning sensorimotor transformation fast and accurately. Key features of the model is

- 1. Spontaneous activity of premotoneurones in deep dorsal horn
- 2. Muscles twitch by motoneurones causing unloading of skin
- 3. Afferent cutaneous sensory feedback terminating on interneurones in the superficial
- 4. Broadcasting by 1st order interneurones in superficial dorsal horn to premotoneurones in deep dorsal horn.

 5. Hebbian correlation of 1st order interneurones in superficial dorsal with
- spontaneously active premotoneurones

From model simulations, it can be concluded that one computational layer is sufficient for the highly non-linear (in cartesian coordinates) sensorimotor transformation of the withdrawal reflex. Also, in this model, activity of single muscles is a superior learning base compared to complex muscle activity. Further simulations, implications, and experimental foundation of the model are discussed.

OPTICAL IMAGING OF NEURONAL ACTIVITY WITH VOLTAGE-SENSITIVE DYES IN THE ISOLATED GUINEA PIG BRAIN. Toshio lijima*, Ichiro Takashima and Marco de Curtis(†) Electrotechnical Laboratory, 1-1-4 Umezono, Tsukuba, Ibaraki 305, Japan and (†) Istituto Neurologico, via Celoria 11, 20133 Milan, Italy.

The neuronal activity of limbic and olfactory cortices was analyzed with high resolution optical imaging (Iijima et al., Science 1996, in press) in the isolated guinea pig brain preparation maintained in vitro by arterial perfusion (de Curtis et al., Hippocampus 1, 341, 1991). The utilization of optical recordings in the isolated brain preparation allows to study without spatial restrictions the distribution and propagation of the activity generated by large assemblies of neurons in an intact brain. Moreover, because of the complete brain surface exposure, optical recordings are facilitated in those structures difficult to reach in in vivo conditions, such as the ventral cortical regions. The study focuses on the activity evoked by afferent stimulation in the piriform, entorhinal and perirhinal cortices

Optical signals recorded after staining the brain with the voltage-sensitive dye RH-795, were compared to the electrophysiological recordings performed simultaneously with extracellular electrodes. Diffuse brain staining was achieved by circulating 1 mg of the dye for 5 minutes at a perfusion rate of 5 ml/min. Optical recordings were performed for several hours after a single exposure to the dye. Electrical stimulation of specific afferents and cortio-cortical associative fibers gave rise to optical signals that propagated along anatomical pathways. Lateral olfactory tract stimulation induced throughout the piriform cortex two peaks of optical signal corresponding to the afferent monosynaptic and the associative disynaptic responses, with a latency of circa 5 and 35 msec, respectively. Dentate gyrus stimulation was followed by the activation of the entorhinal cortex with a latency of about 25 msec, suggesting that a polisynaptic circuit was activated. Further experiments are in progress to define the depth of the optical signal generators.

CELLULAR EVENTS AND CURRENTS RESPONSIBLE FOR EVOKED NEUROMAGNETIC SIGNALS FROM THE HIPPOCAMPAL SLICE OF THE GUINEA PIG. I. Wu*, and Y. C. Okada. Depts. Neurol. & Physiol., Univ. New Mexico Sch. Med., Albuquerque, NM 87131.

New Mexico Sch. Med., Albuquerque, NM 87131.

Synchronized population activities in the hippocampal slices produce magnetic fields detectable outside the tissue. The cellular events and currents generating the magnetic evoked field (MEF) were analyzed using longitudinal CA3 slices obtained conventionally from guinea pigs (250-350 g) under barbiturate anesthesia. Synchronized activities were elicited by depolarizing the apical dendrites of the pyramidal cells across the entire slice with an array of bipolar electrodes in the presence of 0.1 mM picrotoxin in the Ringer. The MEF consisted of a spike lasting 5-10 ms followed by a slow wave lasting about 100 ms, both produced by longitudinal currents in the pyramidal cells directed from the apical to the basal side. Field potentials recorded simultaneously with the MEF consisted of a train of population spikes during the MEF spike followed by a slow wave similar in latency to that of the MEF. Increasing [Ca²⁺]₀ from 2.5 mM up to 7 mM increasingly reduced the later part of the slow wave of the extra- and intracellular potentials as well as the MEF, indicating that this part was predominantly due to polysynaptically mediated currents. Adding a non-specific blocker of excitatory amino acid neurotransmitters (kynurenic acid, 1 mM) to the bath eliminated the slow wave and some of the spike train, suggesting that they were generated predominantly by monosynaptically mediated currents. Part of the initial component of the MEF spike and the first 1-3 spikes in the field potential remaining in Ringer with kynurenate appear to have been generated by direct activations of voltage-sensitive conductances by the apical depolarization. The results provide a new insight into the genesis of magnetic signals in a mammalian CNS structure. Supported by NIH grant RO1-NS21149.

INDEXING THE NEOCORTEX THROUGH ASSOCIATIVE LEARNING IN THE HIPPOCAMPUS: A QUALITATIVE APPROACH. J.L. Olds*, J.L. Krichmar and L. Hunter, Krasnow Institute for Advanced Study at George Mason University, Fairfax, VA.

The unique anatomy and physiology of the hippocampus appears appropriate for associating cortical columns that are related by an episode (i.e. a cell assembly). Input to the hippocampal region derives from many areas of the neocortex and a wide range of modalities. We propose a computational model that investigates the hippocampus' ability to index cell assemblies. The dentate granule (DG) cells process the multimodal input from the entorhinal cortex (EC) and create a key for the CA3 pyramidal cells. The CA3 pyramidal cells, which make up an associative memory matrix, learn combinations of cortical column indices through classical conditioning. It is assumed that learning occurs during an exploration period corresponding with the theta rhythm. The output of the CA3 region is a population of activity representing indices to cortical columns in the neocortex. The CA1 region compares input from CA3 with input from EC. If the match is appropriate, the output of CA1 is a set of indices to the neocortex. Otherwise, the model repeats the DG to CA3 to CA1 cycle with additional information from EC. We employ the Qualitative Reasoning Neuron (QRN) methodology to create a highly detailed model of the hippocampal pyramidal and basket cells. AMPA, GABA, NMDA, metabotropic and muscarinic receptors are modeled in detail. The technique is extremely efficient because no quantitative values need to be calculated. However, properties of the hippocampus described above emerge from QRN simulations. The results of the model suggest the role of the hippocampus is to process partial cortical information and return a completed cortical activation

PURINERGIC MODULATION OF CA2 ACTIVITY IN SIGNAL TRANSMISSION BETWEEN CA3 AND CA1 IN THE RAT HIPPOCAMPAL SLICES.

Y, Sekino^{1*}, K, Kato² and K, Obata³, ¹PRESTO, JRDC, Dept. of Neurobiol. & Behav., Gunma Univ. Sch. of Med. Maebashi 371, ²Lab. of Physiol., ERATO, JRDC, Meguro-ku 153, ³Lab. Neurochem, National Inst. for Physiol. Sci., Okazaki 444, Japan.

In order to further understand signal processing in the hippocampus, we are studying the polysynaptic transmission from mossy fibers to CA1 cells in the rat hippocampal slices with optical recording using a voltage sensitive dye (RH482). We have demonstrated a slow transmission between CA3 and CA1 mediated by CA2 cells in addition to a conventional pathway via Schaffer collateral (Sekino, Y., et al., Soc. Neurosci. Abstr. 1992 and 1995). The mossy-fibers induced optical signals and population spikes (PSs) in CA1 were observed on the slices dissected at an angle of 30-45 degrees to the long axis of hippocampus but rarely in the transversely dissected slices. However, treatment with an antagonist of adenosine A1 receptor, 8-cyclopentyltheophylline (8-CPT; 2 μM), revealed these responses of CA1. They were eliminated by microsurgical removal of the CA2 cell layer or the local application of 0.1 % pentobarbial to the stratum oriens of CA2. These results suggest that CA2 modulates the activity of mossy fiber-CA1 pathway through adenosine A1 receptor. Facilitatory effects of 8-CPT on the strength-response relation of PSS and miniature excitatory postsynaptic currents were confirmed by field potential and patch clamp recording respectively from CA2 cells.

LEARNING AND MEMORY: PHARMACOLOGY VI

446.1

THE ALPHA-2A NORADRENERGIC AGONIST GUANFACINE REVERSES THE WORKING MEMORY DEFICITS INDUCED BY PHARMACOLOGICAL STRESS (FG7142). S.G. Birnbaum* and A.F.T. Arnsten, Interdepart, Neurosci. Prog. and Sect. Neurobiol., Yale Univ. Sch. Med., New Haven, CT 06520

The $\alpha 2_A$ adrenergic agonist, guanfacine, appears to be beneficial in the treatment of prefrontal cortical (PFC) deficits in patients with Attention Deficit Hyperactivity Disorder (ADHD), and has fewer side effects than the $\alpha 2_{A,B,C}$ agonist, clonidine. Interestingly, guanfacine also may relieve ADHD symptoms associated with the stress of child abuse. In animals studies, stress exposure has been shown to impair PFC cognitive function by a hyperdopaminergic mechanism. For example, the pharmacological stressor FG7142 have been shown to increase dopamine (DA) turnover in the PFC and impair delayed alternation performance in the rat (Murphy et al., 1996). Pretreatment with clonidine blocks the deficit induced by FG7142 (see Murphy, Arnsten, Jentsch and Roth, this volume).

Murphy, Arnsten, Jentsch and Roth, this volume). In this study, we explored the subtype of noradrenergic $\alpha 2$ receptor effective in reversing the FG7142 induced impairment by comparing clonidine with the more selective $\alpha 2A$ agonist, guanfacine. Pretreatment with clonidine (0.1 mg/kg) blocked the FG7142 (30 mg/kg) induced impairment in most rats. The rats which were not improved by this dose of clonidine exhibited fairly severe clonidine side-effects (ataxia and sedation). Pretreatment with an equimolar dose of guanfacine (0.11 mg/kg), completely blocked the FG7142-induced impairment without any observable side effects. Neither clonidine nor guanfacine significantly altered performance when given alone. Guanfacine also appears to be equally effective in blocking the stress-induced rise in PFC DA turnover (Morrow, George and Roth, this volume), consistent with an $\alpha 2A$ mechanism modulating the meso-PFC DA stress response. This mechanism may contribute to guanfacine's beneficial clinical effects, protecting PFC cognitive function from the detrimental effects of stress. This research was supported by PHS grant AG06036.

ALPHA-1 NORADRENERGIC STIMULATION IMPAIRS, WHILE ALPHA-2 STIMULATION IMPROVES, PREFRONTAL CORTEX SPATIAL WORKING MEMORY FUNCTION. J.C. Steere*, B.-M. Li, J.D. Jentsch, R. Mathews, J.R. Taylor and A.F.T. Arnsten. Shanghai Institute of Physiology, Shanghai, China 200031; and Sect. Neurobiology and Dept. Psychiatry, Yale Medical School, New Haven, CT, USA 06510. Studies in animals and humans indicate that norepinephrine (NE) improves

Studies in animals and humans indicate that norepinephrine (NE) improves prefrontal cortex (PFC) cognitive functioning through actions at post-synaptic, alpha-2 adrenergic receptors in the PFC (see Arnsten, Steere and Hunt, Arch Gen Psych 53: 448-455, 1996 for review). For example, systemic administration of the alpha-2 adrenergic agonist, guantacine, to young or aged monkeys significantly improves delayed response performance, a spatial working memory task dependent on PFC function. However, few studies have examined the effects of increasing stimulation of alpha-1 adrenergic receptors on PFC Cognitive abilities. The current study examined the effects of systemic administration of the alpha-1 agonist, cirazoline, on delayed response performance in aged monkeys. Cirazoline is the first alpha-1 agonist to readily penetrate the brain; however, it has additional actions at imidazoline receptors. Results indicate that low doses of cirazoline impaired delayed response performance in a delay-dependent manner. The impairment was blocked by the alpha-1 antagonist, prazosin, consistent with actions at alpha-1 receptors. Additional findings indicate that impairment resulted from actions in the PFC. Infusion of the selective alpha-1 agonist, phenylephrine into the principal sulcal PFC of a young monkey significantly impaired delayed response performance in a delay-dependent manner. In contrast, intra-PFC infusion of the alpha-2 agonist, guanfacine, improved performance following longer delays. Parallel studies in the rodent with PFC infusions are in progress. These data suggest that NE has opposing actions at post-synaptic alpha-2 vs. alpha-1 receptors in the PFC. This research was supported by PHS grant no. AG06036 to AFTA and NSFC grant no. 39000032 to BML.

CHANGES IN AMYGDALA NOREPINEPHRINE RELEASE FOLLOWING FOOTSHOCK OR SYSTEMIC ADMINISTRATION OF EPINEPHRINE. C.L. Williams*, P.E. Gold and D. Men. Dept. of

Psychology, University of Virginia, Charlottesville, VA 22903. It is well established that elevations in peripheral hormones in response to emotionally arousing experiences influence memory storage. Although peripheral hormones such as epinephrine (EPI) posses a limited capacity to cross the BBB to produce direct effects on the brain, recent evidence indicates that EPTs effects on memory are mediated in part, through noradrenergic (NE) activation of the amygdala. The present study examined whether experimental manipulations designed to increase EPI concentrations in the periphery, produce corresponding elevations in extracellular levels of NE in the amygdala. A microdialysis probe (2 mm) was inserted into a guide cannula positioned 1 mm above the amygdala in male Sprague Dawley rats 1 hr before testing. Throughout the experiment aCSF was perfused through the probe at 1 µl/min and dialysate samples were collected every 20 min. After 3 baseline samples were collected, saline was given ip to control for possible injection effects on NE levels. EPI (0.3 mg/kg) was given ip 1 hr after saline and a single 0.8 mA footshock (1 sec) was administered 1 hr and 40 min after the injection of EPI. NE levels were determined using HPLC and EC detection. NE levels after ip injection of saline did not differ from basal levels. EPI produced a significant elevation in extracellular NE that persisted for 40 min after injection. Footshock also produced elevated NE levels although the magnitude and duration of the increase was not as pronounced. These results extend previous findings indicating that peripheral hormones influence memory storage processes via activation of NE in the amygdala. Supported by NIA (AG07648) and NINDS (NS32914).

MOTORIC AND ASSOCIATIVE LEARNING EFFECTS OF 5-HT04/20

MOTORIC AND ASSOCIATIVE LEARNING EFFECTS OF 5-HT_{2A/2C} ANTAGONISTS IN THE RABBIT. S. Welsh, A.G. Romano* and J.A. Harvey. Div. of Behavioral Neurobiology, Dept. of Pharmacology, The Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA 19129.

Drugs classified as partial agonists at the 5-HT₂ receptor (e.g., LSD) are known to enhance associative learning. We previously reported that ritanserin, a 5-HT_{2A/2C} antagonist, retarded acquisition of the rabbit's classically conditioned nictitating membrane (NM) response and reduced the amplitude of the unconditioned reflex response. We now report the effects of several other 5-HT_{2A/2C} antagonists on acquisition of NM conditioning and on elicitation of the NM reflex. Ritanserin and MDL-11,939 but not LY-53,857 produced a dose-dependent retardation of acquisition to a tone CS and a reduction in the amplitude of the NM reflex. None of these three drugs had an effect on nonassociative learning. We then examined the effects of these and other drugs on elicitation of the unconditioned NM reflex. The 5-HT_{2A/2C} agonist, LSD and the 5-HT_{2A/2C} antagonists, BOL and LY-53,857 had no effect on the NM reflex. However, four other 5-HT_{2A/2C} antagonists significantly reduced the amplitude of the NM reflex with the magnitude of their effects being mianserin > ritanserin = MDL-11,939 > ketanserin. These data suggest that mianserin, ritanserin, MDL-11,939 and ketanserin may be inverse agonists at the 5-HT_{2A/2C} receptor, while BOL and LY-53,857 are neutral antagonists. These data also demonstrate that activation of the 5-HT_{2A/2C} receptors in the brain are necessary for normal learning and motor performance. Supported by NIMH MERIT award MH16841.

BLOCKADE OF 5-HT1A RECEPTORS COMPENSATES LOSS OF HIPPOCAMPAL CHOLINERGIC NEUROTRANSMISSION INVOLVED IN WORKING MEMORY OF RATS. M. Ohno* and S. Watanabe. Dept. of Pharmacology, Faculty of Pharmaceutical Sci., Kyushu Univ., Fukuoka 812, Japan.

To clarify roles of hippocampal 5-HT_{1A} receptors in regulating working memory function of rats, the effects of intrahippocampal administration of the agonist and antagonist at this receptor type on working memory performance were examined with a three-panel runway task. The 5-HT1A receptor agonist 8-OH-DPAT, injected bilaterally at 1-10 µg/side into the dorsal hippocampus, dose-dependently increased the number of errors (attempts to pass through two incorrect panels of the three panel-gates at four choice points) in the working memory task, but it had no effect on reference memory errors. NAN-190, a selective 5-HT1A receptor antagonist, did not affect the number of working memory errors, when injected intrahippocampally at 0.32 or 1.0 µg/side. Intrahippocampal administration of the muscarinic receptor antagonist scopolamine at 0.32-3.2 µg/side or the competitive NMDA receptor antagonist CPP at 3.2-32 ng/side caused a dose-dependent increase in the number of working memory errors without affecting reference memory errors. The increase in working memory errors induced by intrahippocampal scopolamine (3.2 µg/side) was reduced by concurrent infusion of 1.0 µg/side NAN-190. In contrast, NAN-190 at 1.0 ug/side did not affect the increse in working memory errors, when infused intrahippocampally together with 32 ng/side CPP. These results indicate that activation of hippocampal 5-HT_{1A} receptors interferes with working memory processing. Also, it is suggested that blockade of hippocampal 5-HT $_{1\mathrm{A}}$ receptors can compensate deficiency of septohippocampal cholinergic activity involved in working memory function of rats, but it does not affect impairment of working memory resulting from block of NMDA receptor-mediated neurotransmission.

DIFFERENTIAL HOUSING HAS SEXUALLY DIMORPHIC EFFECTS ON ODOR PREFERENCES, IMMUNE CELL PHENOTYPES AND WEIGHT ODOR PREFERENCES, IMMONE CELL PHENOTYPES AND WEIGHT LOSS IN CONTROL AND DSP-4 TREATED CD-1 MICE. C. Cormwell', J. Gavalchin, T. Dewey, H. McFarlane, M.F.E.M. Sarao, C. Coticchia, W. Gerlach, H. McLeod and K. O'Leary. Depts of Psychology and Biology, Syracuse Univ., and Dept. of Medicine, SUNY Health Science Center, Syracuse, NY, 13244.

Norepinephrine (NE) neurotoxins impair behavioral and neurochemical responsiveness by rats and mice to changes in the olfactory and social environments (Comwell et. al., 1996, Brain Research; Dewey et al., 1995, Soc. environments (comwell et. al., 1996, <u>Brain Research</u>; Dewey et al., 1995, <u>Soc. Neurosci. Abstr.</u>) The present study evaluated immune status in differentially housed NE depleted CD-1 mice. On postnatal day 61, mice in same-sex living groups of 8 were weighed and assigned to one of three housing conditions: untreated (UNT), laminar flow (LF) or isolated olfactory enclosure (IOE). LF and In the latest (DNT), latinitar how (LP) of isolated offactory efficiency efficiency for the latinitary has been beed in smaller cages, with a new bedding type, in groups of 4 and injected with 50 µg/g of the NE neurotoxin, N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP-4) or water vehicle. Preferences for male vs. female nest odors were tested 3 days later. The next day, the mice were weighed, sacrificed, and hippocampal and splenic tissue was dissected for assay of monamine concentrations and lymphocyte populations respectively. Only IOE males (in both treatment groups) showed significant odor preferences (for female odor). Only LF, DSP-4 and IOE, vehicle and DSP-4 females lost significant weight (5-7%). Immune cell phenotypes were altered in both injection groups as measured in differences of percentages of T-cell and B-cell populations in UNT vs. experimental mice of both sexes. Thus, DSP-4 treatment influenced housing effects on weight loss, but not immune measures. The results also suggest that sex influences the biobehavioral effects of differential housing. CHANGES IN CA1 HIPPOCAMPAL CELL FIRING PATTERNS AND THEIR THETA RHYTHM PHASE RELATIONSHIPS FOLLOWING 5-HT3 RECEPTOR ANTAGONISM.

<u>J. Reznic*</u> and <u>U. Staubli</u>, Center for Neural Science, New York University, New York, NY 10003.

5-HT3 receptor antagonism has been shown to facilitate induction of long-term potentiation in CA1 and CA3 hippocampal subfields, to increase the frequency of the hippocampal theta rhythm in vivo, and to enhance performance in learning paradigms. Recent work from our lab has demonstrated that the majority of recorded interneurons decrease, and pyramidal cells increase, their mean firing rate following systemic injection of the 5-HT3 receptor antagonist ondansetron. The present study investigated the effects of 5-HT3 blockade on 1) the firing patterns and rhythmicity of 19 CA1 hippocampal cells (14 interneurons and 5 pyramidal cells) as well as 2) changes in their phase relationship with the theta rhythm. For part 1, changes in both the number of single events and in burstiness (number of bursts, burst duration, number of components and inter-component duration per burst) were examined. Autocorrelograms were computed to assess changes in rhythmicity of both cell types. To accomplish part 2, a computer program extracted sequential one second segments of EEG and spike data from five minute recordings and constructed a phase-of-firing histogram to evaluate phase changes between pre- and post-drug administration. Preliminary data suggest that the firing patterns, rhythmicity, and theta-phase relationships of both cell types are modified as a consequence of 5-HT3 receptor blockade; these changes are currently being quantified.

INHIBITION OF PROTEIN KINASE A IN THE NUCLEUS ACCUMBENS BLOCKS AMPHETAMINE-PRODUCED CONDITIONED PLACE PREFERENCE IN R.J. Beninger*, P.L. Nakonechny and M. J. Todd. Depts. Psychology and Psychiatry, Queen's Univ., Kingston, Canada, K7L 3N6.

The nucleus accumbens is an important structure for place conditioning and some data implicate D1-like dopamine receptors, those that activate the cyclic AMP pathway. The present study further evaluated the role of D1-like receptors by inhibiting cyclic AMP dependent protein kinase (PMA) during conditioning. Pats were pre-exposed (15) receptors by inhibiting cyclic AMP dependent protein kinase (PKA) during conditioning. Rats were pre-exposed (15 min/day for 3 days) to an apparatus with two distinct chambers connected by a tunnel. During conditioning (30 min/day for 8 days) one side was paired with intra-accumbens drug injections (0.5 $\mu \rm l)$ on alternate days and the other side with vehicle injections. Drugs included amphetamine (20 $\mu \rm g/side)$, amphetamine co-injected with the PKA inhibitor Rp-cAMPS (2,5, 25,0, 250.0 ng/side) or the same doses of the inhibitor alone. Testing sessions were like pre-exposure sessions. Results revealed a significant increase in time spent on the drug-paired side from pre-exposure to test for animals treated with amphetamine or increase in time spent on the drug-paired side from pre-exposure to test for animals treated with amphetamine or amphetamine plus 2.5 ng/side of Rp-cAMPS; 25.0 ng/side of Rp-cAMPS partially blocked the effect and 250.0 ng/side totally blocked it. Rp-cAMPS alone had no significant effect. Results suggest that place preference conditioning produced by intra-accumbens amphetamine depends on stimulation of D1-like dopamine receptors and activation of cyclic AMP dependent protein kinase. N.s.E.R.C.(Funded by

SYSTEMIC BUT NOT INTRA-ACCUMBENS INJECTIONS OF 7-OH-DPAT PRODUCE A PLACE PREFERENCE IN RATS. <u>D. P. Nocent*</u>, <u>P. F. Mallet and R. J. Beninger</u>. Depts. Psychol. and Psychiat., Queen's Univ., Kingston, K7L 3N6, Canada

Dopamine neurotransmission in the nucleus accumbens has been implicated in place preference conditioning but little is known regarding the function of D3 receptors in the accumbens. The present experiment evaluated place conditioning following intra-accumbens 7-OH-DPAT, a dopamine D3-receptor preferring agonist. The paradigm involved three phases: preconditioning (three 15-min drug-free exposures to an apparatus with two distinctive compartments connected by a tunnel); conditioning (four 30-min pairings of one compartment with drug and four 30-min pairings of the other compartment with saline on alternating days); and test (like preconditioning). During the conditioning has part as (N=12) implanted with bilateral chronic indwelling cannulae received intra-accumbens injections (0.5 μl) of amphetamine (10 μg/side) or 7-OH-DPAT (0.1, 1.0, 5.0, 10.0 or 15.0 μg/side); in addition, uncannulated rats (N=12) were treated with 7-OH-DPAT (5.0 mg/kg, s.c.). Intra-accumbens amphetamine and systemic 7-OH-DPAT produced a significant place preference. Intra-accumbens 7-OH-DPAT failed to produce a place preference at 0.1, 1.0, 10.0, and 15.0 μg/side; a significant place aversion was found at 5.0 μg/side. The place preference with systemic 7-OH-DPAT suggest that this structure may not mediate the preference produced by systemic 7-OH-DPAT. (Supported by NSERC).

HIPPOCAMPAL D1 AND D2 SYSTEMS AND WORKING MEMORY FUNCTION. A. Wilkerson and E.D. Levin*. Neurobehavioral Research Laboratory, Psychiatry Department, Duke University Medical Center., Durham, NC 27710 USA.

The hippocampus has long been known to be important for memory function. However, the involvement of hippocampal dopamine (DA) systems has received little attention. Bilateral local infusions of DA D1 and D2 agonists and antagonists were made into the ventral hippocampus of female Sprague-Dawley rats. Then working memory function was assessed in the radial-arm maze. The D1 agonist dihydrexidine (1.1 ug/side) caused a significant (p<0.05) improvement in radial-arm maze choice accuracy. Higher doses of 3.3 or 10 ug/side were not effective. The D1 antagonist SCH 23390 was ineffective over a dose range of 0.19-1.67 ug/side. The D2 agonist quinpirole caused a significant (p<0.05) dose-related improvement in choice accuracy over a dose range of 1.1-10 ug/side. In a complementary fashion, the D2 antagonist raclopride caused a significant memory deficit at 1.67 ug/side. Lower doses of 0.19 and 0.56 ug/side were ineffective. This study provides clear evidence that hippocampal D2 activity is positively related to working memory performance. Evidence for D1 systems is less compelling. DA systems in the hippocampus may work with the well-characterized hippocampal cholinergic systems in the basis of (This research was supported by the working memory function. National Alliance for Research on Schizophrenia and Depression.)

TYPICAL AND ATYPICAL NEUROLEPTICS DIFFERENTIALLY AFFECT PSYCHO-MOTOR SKILLS ACQUISITION IN SCHIZOPHRENIA: FURTHER CONSIDERATION ON THE ROLE OF THE STRIATUM IN PROCEDURAL LEARNING. H. Scherer, M.A. Bédard, E. Stip and H. Cohen *, Lab. de Neurosciences de la Cognition, UQAM, Montreal, Canada.

Thirty-nine schizophrenic patients were divided in 3 groups according to their pharmacological treatment: 1) drug naïve 2) haloperidol 3) clozapine. They were all assessed on psychiatric and extrapyramidal clinical scales (BPRS, PANSS and ESRS). Procedural learning was assessed with the Mirror Drawing task, in which the subject must draw in outline a picture (a star) by looking only to its mirror reflect. Results revealed that drug-naïve patients showed a normal and gradual procedural learning, up until they reached and maintained their optimal level of performance. Patients treated with clozapine showed also a gradual learning as a function of trials, although performances per se in the first trials were significantly worse than the two other groups. Finally, patients treated with haloperidol showed large fluctuations in performance between trials that indicates a procedural learning difficulty. Further analysis using ANCOVA indicates that these effects may not be explained by clinical or sociodemographic differences between groups. This suggests that classical and atypical neuroleptics can differentially affect procedural learning in schizophrenia, presumably by a differential dopamine D2 blocking action of these substances in the striatum

SUPRANORMAL STIMULATION OF DOPAMINE DI RECEPTORS IN THE PREFRONTAL CORTEX IMPAIRS SPATIAL WORKING MEMORY PERFORMANCE IN RATS. J. Zahrt, J.R. Taylor, and A.F.T. Arnsten*.

Sect. Neurobiology, Dept. Psychiatry, Yale Med. School, New Haven, CT 06510. Previous research has shown that increasing endogenous dopamine (DA) turnover in the prefrontal cortex (PFC) by administering the anxiogenic beta carboline FG7142 results in impaired PFC cognitive performance on a spatial working memory task (Murphy et al., 1994; 1996). This impairment correlated with increased DA turnover in the PFC, and was blocked by pretreatment with the D1 receptor antagonists, SCH23390 (ibid). Similarly, low concentrations of D1 receptor antagonists can enhance delayed-related firing in PFC neurons (Williams and Goldman-Rakic, 1995). These results suggest that supranormal D1 receptor stimulation in the PFC can impair working memory performance. The current study tested this hypothesis by infusing the full D1 agonist, SKF81297, into the medial PFC in rats performing the delayed alternation task. In the first experiment, bilateral infusions of SKF81297 (0, 0.01 or 0.1 ug in 0.5 ul) were made through indwelling cannula aimed at the PFC. SKF81297 produced a dose related reduction in working memory performance; only the 0.1 ug dose significantly impaired performance. This dose had no significant effect on response time in the maze, and no effect on behavioral ratings of anxious behaviors, consistent with effects on PFC cognitive function. A second experiment tested for D1 receptor mechanisms underlying the impairment in working memory performance. Rats were pretreated with saline or SCH23390 (0.01-0.03 mg/kg, i.p.) 60 min before receiving PFC infusions of SKF81297 (0.1 ug) or saline into the PFC. As before, 0.1 ug SKF81297 significantly impaired performance in saline pretreated animals. SCI123390 pretreatment, which had no effect on its own, significantly blocked the impairment induced by intra-PFC SKF81297 infusion. These results are consistent with supranormal DA D1 receptor situalition impairing PFC cognitive function.

446.12

DOPAMINE D2, AND NOT D3 OR D4, RECEPTORS ARE RESPONSIBLE FOR THE REINFORCING EFFECT OF BRAIN STIMULATION IN THE RAT. Shinshu Nakajima* Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada.

Self-stimulation of the medial forebrain bundle can be suppressed by injection of either SCH 23390 or raclopride into the nucleus accumbens. The involvement of D1 dopaminergic receptor in the reinforcing effect is evident because SCH 23390 is known to act selectively on D1 receptors. The involvement of D2 receptor is not so clear because raclopride has about equal affinity for D2 and D3 receptors. In the present study, rats were implanted with a bipolar electrode into the medial forebrain bundle, and a cannula into the nucleus accumbens, and trained to press a bar for electrical stimulation. The frequency-response function was plotted 30 min. before and 10 min. after injection of 1 µl of dopamine antagonist solutions or physiological saline through the cannula.

The threshold of reinforcement (the frequency for 50% of maximal pre-injection rate) significantly increased after injection of 10 nmol haloperidol or 10 nmol raclopride, but not after 30 nmol of UH 232 (selective D3 antagonist) or 20 nmol of clozapine (antagonist with high affinity for D4 receptors). Among dopamine receptors in the nucleus accumbens, D2 receptors, along with D1 receptors, seem to be critically involved in producing the reinforcing effect of medial forebrain stimulation, but D3 and D4 receptors are not.

DRUGS OF ABUSE DISRUPT MEMORY MEASURED UNDER A DELAYED MATCHING-TO-SAMPLE PROCEDURE IN SQUIRREL MONKEYS. S.P. Baron, W.D. Wessinger* and G.R. Wenger. Dept. of Pharmacology and Toxicology, Univ. of Arkansas for Medical Sciences, 4301 W. Markham, Little Rock, AR 72205.

The abilities of drugs of abuse from several pharmacological classes to disrupt memory were examined in four adult male squirrel monkeys responding under a delayed matching-to-sample schedule of food presentation. Subjects were required to emit 20 responses on a sample key transilluminated by either a constant white or a flashing blue light. The twentieth response initiated a 3-second delay followed by presentation of two comparison stimuli. If a response was made to the key that matched the sample stimulus (correct match), a single food pellet (97 mg) was delivered. Pentobarbital (0.32 - 10 mg/kg), diazepam (0.1 - 5.6 mg/kg), phencyclidine (0.01 - 0.32 mg/kg), and cocaine (0.1 - 3.2 mg/kg) dose-dependently reduced accuracy of matching performance towards chance levels. Amphetamine (0.01 - 1.0 mg/kg) administration resulted in a small, but statistically significant, reduction in accuracy at a dose of 0.56 mg/kg, while 1.0 mg/kg completely suppressed responding. Signal-detection analyses indicated that decrements in discriminability of stimuli accounted for a greater proportion of error than the did the development of color- or key-response biases. These results may indicate that drugs of abuse share detrimental effects on cognitive processes. This research was supported by NIDA Grant # DA 05815.

SELECTIVE DISRUPTION OF CS AND US INPUTS BY PHARMACOLOGICAL AGENTS: THE BRAINSTEM AS A SITE OF CS-US ASSOCIATIVITY IN TASTE AVERSION LEARNING. M. W. Swank, A.E. Ellis, and W.D. Blaker. Furman University. Greenville. SC 29613. (Supported by NIH/NICHHD #HD33138-01 to MWS)

A recent report from this lab describes the disruption of taste aversion learning in mice by 4th ventricular infusions of c-Fos antisense. These data suggest that antisense disrupts associative events by blocking US-mediated events in the nucleus. Here we tested a variety of pharmacological agents and examined their effect on taste aversion learning when infused into the fourth ventricle. The tyrosine kinase inhibitor genistein blocks acquisition of taste aversion learning when administered before the CS saccharin. Genistein had no effect on saccharin intakes during conditioning, suggesting that it does not impair basic sensory processing of taste. The drug had no effect on learning when infused after CS saccharin, suggesting that the effect of genistein is to disrupt intracellular events necessary for association of the CS taste with the antecedent US toxin. Although high doses of genistein can inhibit serine/threonine kinase activity, higher doses were ineffective in blocking taste aversion learning. Furthermore, H-7, a serine/threonine kinase inhibitor which blocks protein kinase C, A and G, was ineffective in blocking learning at any dose tested. Current work is focussed on identifying the signal transduction pathways activated by both the CS and US in the brainstem of the mouse

447.5

EFFECTS OF SPECIFIC OPIATE RECEPTOR ANTAGONISTS ON THE HABITUATION OF NOVELTY-INDUCED HYPOALGESIA.

E. Spreekmeester* and J. Rochford, Douglas Hospital Research Center, Department of Psychiatry, McGill University, Montreal, P.Q., H4H1R3.

Exposure to novel stimuli has been shown to activate endogenous antinociceptive substrates. This novelty-induced hypoalgesia (NIH) habituates with repeated exposure to the stimuli. Previous studies have shown that the habituation of NIH can be attenuated by systemic or intracerebroventricular (ICV) naloxone administration. order to determine the opiate receptor subtype that is involved in this effect, CTOP, naltrindole and nor-binaltorphimine were used as specific mu, delta and kappa receptor antagonists, respectively. Male Wistar rats were exposed to a hot-plate apparatus which was heated to 48.5°C once a day for 8 days. The latency to lick the hind paw was used as an index of pain sensitivity and a cut-off period of 90s was imposed to avoid tissue damage. CTOP (0.5, 1.0 or 2.0 μ g), naltrindole (2.5, 12.5 or 31 μ g), nor-binaltorphimine (4, 20 or 50 μ g) or vehicle were injected ICV 30 min. prior to each plate exposure. Both 1.0 and 2.0 µg of CTOP prevented the habituation of NIH. Naltrindole and nor-binaltorphimine failed to prevent the habituation of NIH at the doses used. These results suggest that the mu, but not the delta or kappa, receptor is involved in the habituation of NIH. (Funded by the Natural Sciences & Engineering Research Council of Canada)

A TWO DAY PROCEDURE TO ASSESS DRUG EFFECTS IN THE SPATIAL WATER MAZE. L. Rajachandran*, A.B. Johnson, M.R. Gates, A.C. Enders, D.L. Gambini, and J.V. Cassella. Neurogen Corporation, Branford, CT 06405.

The Morris water maze has been used extensively as a tool to study spatial learning. In this task, rats must navigate using distal extramaze spatial cues to find a submerged platform in order to escape from water. Typically, multiple training days are employed. We are describing a two day procedure employing either a four or six trial training (acquisition) procedure. The four trial procedure best detects cognitively enhancing properties of drugs while the six trial procedure best detects drugs that produce cognitive deficits. To illustrate these differences male Sprague Dawley rats were pretreated with either physostigmine or scopolamine prior to training in this task. Animals began each training trial from a different quadrant of the tank and were allowed to remain on the platform for ten seconds once they found it. Twenty-four hours later animals were tested for retention on one trial. Latency to locate the platform as well as other measures were taken during acquisition and retention testing. Physostigmine produced significant improvements in retention (MED .003 mg/kg,IV) whereas scopolamine produced deficits in this task (MED .125 mg/kg,IP). These data illustrate the sensitivity of this two day procedure to detect amnestic or memory enhancing effects of drugs. (Funding provided by Neurogen Corporation.)

EVALUATION OF EMOTIONAL MEMORY IN THE ELEVATED T-MAZE: IMPORTANCE OF A MULTIPLE-TRIAL TRAINING-TO-CRITERION PROCEDURE. C. A. Conde: V. Costa and C. Tomaz. Laboratory of Syschobiology and Center for Neuroscience and Behavior, University of São Paulo, Ribeirão Preto, Brazil.

The present study investigate the importance of a multiple-trial, training-tocriterion procedure to provide a more detailed analysis of the mnemonic component in the elevated T maze test. For this purpose, two experiments were undertaken. In the first one, we compared the standard (three-trials) test procedure versus the training to criterion-continuos trial procedure. The second one, the effects of diazepam (i.p. doses of 1, 2 and 4 mg/Kg administered 30 min. before training) was assessed on acquisition and retention of the elevated T maze in the training-tocriterion procedure. The training was conducted using either multiple trials in which the rat was free to shuttle back and forth between open and closed arms until it stayed in the closed arm for 300 seconds or placing the rat 3 times (1 minute intertrial intervals) at the end of the enclosed arm and the time taken to withdraw from this arm was recorded. Following this avoidance training (1 min), the same rat was placed at the distal end of the right open arm, and the time taken to withdraw from this arm was recorded (escape training). To assess memory, inhibitory avoidance and escape were measured again three days later without drug. The results of the first experiment indicate that the criterion-continuos-trial procedure warrant a confinable evaluation of memory, probably because it offer an good level of information acquisition. The second experiment, showed a dose-dependent amnesia in the retention tested 72 hours later on inhibitory avoidance without differences on acquisition performance. The escape latency showed a trend for a decrease in every animal tested 72 h after. These results indicate the importance to use a training-to-criterion procedure when using pre-trial drug treatment to evaluate mnemonic processes in the elevated T-maze test

NALOXONE HAS OPPOSITE EFFECTS ON PAVLOVIAN CONDITIONED BRADYCARDIA AND AMYGDALA NEURONAL ACTIVITY. L.L. Hernández*, K.L. Watson and S.L. Thompson. Neuroscience Lab., Dorn VA Medical Center, Columbia, SC 29209.

Pretraining, intravenous treatment with the opiate antagonist naloxone-HCl promotes Pavlovian cardiac conditioning in rabbits, delays extinction, and inhibits associated multiple unit neuronal activity in amygdala central nucleus (ACN; Behav. Brain Res., 1990, 41, 71-79). We further investigated naloxone (0.5 mg/kg, i.v.) effects on Pavlovian conditioning and extinction of heart rate and ACN neuronal discrimination, using one 4-s tone (the CS+) to signal a shock US, and another (the CS-) to signal no US. In saline-treated rabbits, increases in CS-evoked neuronal activity, that were larger during the CS+ than the CS-, accompanied development of cardiac discrimination. Naloxone promoted bradycardiac CRs, delayed extinction of cardiac discrimination, and reduced evoked neuronal activity during both CSs, compared to saline. These findings extend our previous conclusions that the increase in CS-evoked ACN neuronal activity early in training normally serves to inhibit conditioned bradycardia, whereas conditioned decreases in ACN neuronal activity disinhibit bradycardiac CRs, and that the circuitry driving these changes is inhibited by endogenous opioids acting afferent to the ACN

MUSCIMOL INACTIVATION OF CEREBELLAR CORTEX DURING ELECTRICAL MICROSTIMULATION CLASSICAL CONDITIONING OF DISCRETE MOTOR MOVEMENTS. A. J. Annala*, R.E. Clark, A.T.M. Moro, P.G. Shinkman, R.A. Swain, and R.F. Thompson. Neurosciences Program, University of Southern California, Los Angeles, CA 90089-2520.

New Zealand White rabbits (Oryctolagus cuniculus) acquire, extinguish, and reacquire conditioned responses when exposed to low intensity electrical stimulation (conditioned stimulus, CS) at the base of cerebellar lobule HVI in place of exteroceptive tone conditioned stimulus and high intensity electrical stimulation (unconditioned stimulus, US) at the base of cerebellar lobule HVI (through the same electrodes) in place of exteroceptive air puff unconditioned stimulus. Repeated presentation of tow intensity electrical stimulation paired with high intensity electrical stimulation results in robust acquisition of conditioned responses. Repeated presentation of low intensity electrical stimulation in well trained animals results in extinction of conditioned responses. Subsequent repeated presentation of low intensity electrical stimulation paired with high intensity electrical stimulation results in robust reacquisition of conditioned responses. Acquisition is completely prevented by infusion of muscimol into cerebellar lobule HVI during paired training. Extinction is completely prevented by infusion of muscimol into cerebellar lobule HVI during CS alone training. Infusion of muscimol has no significant effect on the amplitude of unconditioned responses. Extensive pre-exposure through repeated presentation of electrical microstimulation where the delivery of CS and US are uncorrelated has no significant effect on subsequent acquisition of conditioned responses. These results strongly support the view that the site of plasticity underlaying acquisition and extinction is highly localized in cerebellar lobule HVI. (Supported by NSF IBN-9215069, ONR N00014-95-1-1152, and NIMH 5-P20-MH-52194 to R.F. Thompson.)

ENHANCEMENT OF MEMORY-BASED LEARNING WITH D-AMPHETAMINE TREATMENT IN RAT PUPS WITH HIPPOCAMPAL GRANULE CELL HYPOPLASIA: A POSSIBLE MODEL FOR ADHD. <u>D.A.</u>

<u>Highfield*, D. Hu and A. Amsel</u>. Univ. of Texas at Austin, Austin, Tx. 78712 Selective exposure to x-irradiation during infancy, from postnatal days (PND) 2-11 in the rat, results in hippocampal granule cell hypoplasia (e.g., Altman, 1986). Preweanling rats with such hippocampal granule-cell agenesis show deficits in patterned single alternation (PSA), a form of memory-based learning (Diaz-Granados et al., 1992), and in the partialreinforcement extinction effect (PREE), reflecting, particularly, absence of the normal persistence in extinction after partial-reinforcement training (Diaz-Granados et al., 1994). Deficits in attention and persistence, along with increased arousal, have also been discussed in relation to learning deficits observed in children diagnosed with Attention Deficit-Hyperactivity Disorder (ADHD, Amsel, 1990). The present study examined the effects of damphetamine, a drug commonly used in the treatment of ADHD, on PSA, after infantile exposure to x-irradiation (PND2-15). Following i.p. injections of 0.3 mg/kg d-amphetamine, x-irradiated preweanling rats (PND 17-18) were trained on PSA. Initial results indicate that d-amphetamine enhances PSA in x-irradiated rats relative to x-irradiated controls. These results, showing alleviation of x-irradiation-related deficits in short-term memory by d-amphetamine injections, along with our earlier results showing deficits after x-irradiation (Diaz-Granados et al., 1992, 1994), encourage the hypothesis that hippocampal granule cell hypoplasia, Altman's model of "minimal brain dysfunction," may be a contributing factor in ADHD, and may provide a good animal model of the disease

CHANGES IN RESCALING TEMPORAL RESPONDING ON THE TRI-PEAK PROCEDURE AFTER MODULATION OF COCAINE REACTIVITY. M.S. Matell'*, W.H. Meck', & G.R. King'. Depts. of Psychology:Expt & Psychiatry', Duke University, Durham, NC 27708. The "tri-peak" procedure, a modified version of the peak-interval timing procedure, was developed allowing the determination of multiple peaks of temporal responding within a single trial without relying on different signal modalities. Three times of possible reinforcement (10, 30, & 90 s) were mapped to three spatially distinct response levers allowing separate responding for each duration during a single trial. Food reward is given on 50% of the 10- and/or 30-s durations, and 100% of the 90-s durations, thus allowing from one to three food rewards per trial. In order to assess the validity of this procedure and to assess the role of cocaine sensitzation and tolerance in rescaling temporal perception after dopaminergic drug administration, male Sprague Dawley rats (n=15, 12 mo of age) were trained and tested. After reaching criterion levels of peak time responding, 20 mg/kg cocaine HCL was administered for 14 days via either daily subcutaneous injections (.5cc) or continous infusion from an osmotic minipump (5 µL/hr, 100mg/ml)). Previous work has demonstated that these two modes of delivery result in either sensitivity (injection) or tolerance (continuous) to the behavioral activating effects of a challenge injection of cocaine (15 mg/kg) 7 days after withdrawal. Preliminary data indicate that daily cocaine injections cause an immediate horizontal rightward shift in peak times. In contrast, continuous cocaine did not cause any initial changes in peak times. These data can be interpreted in terms of changes in clock speed by examining the pattern did not cause any initial changes in peak times. These data can be interpreted in terms of changes in clock speed by examining the pattern of changes in peak time and spread seen during drug administration, withdrawal and challenge phases. AUTOPHOSPHORYLATION OF CA2+/CALMODULIN DEPENDENT PROTEIN KINASE II IS INVOLVED IN FORMATION OF SHORT TERM MEMORY FOLLOWING PASSIVE AVOIDANCE LEARNING W. O. Zhao* and K. T. Ng Dept. of Psychology, Monash University, Clayton, Victoria 3168, Australia

We have previously reported an elevation of Ca²⁺/calmodulin-stimulated Ca²⁺/calmodulin-dependent protein kinase II (CaMK II) activity in short-term memory (STM) formation induced by a passive avoidance training experience in day-old chicks (Zhao et al., Neurobiol. Learning and Memory, 65: 1996 in print). In the present study, in order to identify training-induced calcium-independent activity of CaMK II, we investigated, using immunobiochemical methods, changes in in vivo autophoshorylation of CaMK II associated with memory formation. One day-old chicks were trained on a single trial passive avoidance task. CaMK II were isolated by immunoprecipitation from a specific brain region, the intermediate medial hyperstriatum ventrale (IMHV), dissected from both trained and control animals. Autophoshorylation of CaMK II was examined by anti-phosphoserine and anti-phosphothreoine antibodies in the Western blotting. An increase in autophosphorylation of CaMK II was detected in IMHV tissue from the right hemisphere 10 min following training in comparison with that from the control animal. In the left hemisphere, however, this increased autophosphorylation of CaMK II was not seen unless the animal was subject to the test trial during which a memory retrieval process is theoretically involved. No increase in autophosphorylation of CaMK II was shown in IMHV tissue from chicks subjected to training but did not remember the experience when tested. Furthermore, when KN-62, a CaMK II inhibitor shown to impair STM, was administered into the IMHV immediately after training, the increases in both autophosphorylation and Ca2+/calmodulin-stimulated activity of CaMK II were abolished. These results suggest that changes in autophosphorylation of CaMK II are required for formation of STM, and that these changes may play different roles in the two hemispheres during memory processing.

THE IMPROVING EFFECTS OF COCAINE ON MEMORY CONSOLIDATION IN MICE ARE ANTAGONIZED BY THE NON-COMPETITIVE NMDA RECEPTOR ANTAGONIST MK-801. C. Rossi-Arnaud*1, V. Cestari, C. Castellano. Istituto di Psicobiologia e

Psicofarmacologia (C.N.R.) Via Reno 1, 00198 Roma, Italy

¹Facoltà di Psicologia, Università degli Studi di Roma "La Sapienza", Via dei Marsi 78, 00185 Roma, Italy.
The interaction between cocaine and MK-801 was studied in CD1 mice injected intraperitoneally immediately after training with these drugs and tested in two tasks (one-trial inhibitory avoidance and active avoidance). In the inhibitory avoidance task cocaine (1, 2.5 and 5 mg/kg) dose-dependently improved memory consolidation while MK-801 (0.1, 0.25 and improved memory consolidation while MK-801 (0.1, 0.25 and 0.5 mg/kg) impaired it. The administration of a per se ineffective dose of MK-801 (0.1 mg/kg) antagonized the memory improving effects of cocaine (2.5 and 5 mg/kg). In the active avoidance task cocaine improved memory consolidation at 5 mg/kg, while 2.5 and 10 mg/kg were ineffective. The administration of a per se ineffective dose of MK-801 (0.1 mg/kg) also in this case antagonized the facilitating effect of cocaine. These results suggest the existence of an interaction between the excitatory amino acid and catecholaminergic systems in modulating memory consolidation. Since dopaminergic mechanisms are involved in the effects of both MK-801 and cocaine on memory in the effects of both MK-801 and cocaine on memory consolidation, a main role of the dopaminergic systems in the effects observed can be envisaged.

EFFECT OF Δ^9 -TETRAHYDROCANNABINOL MICROINJECTION THE RAT BRAIN ON DELAYED MATCHING-TO-SAMPLE PERFORMANCE. A. Miyamoto, T. Yamamoto, S. Watanabe and C. Hara*.
Dept. Pharmacol. Fac. Pharmacout. Sci. Kyushu Univ. Fukuoka 812-82, Japan, *Dept. Pharmacol. Daiichi-pharmacout. Univ. Fukuoka 815, Japan.
Administration of Δ⁹-tetrahydrocannabinol (THC), a major psychoactive

constituent in marijuana, has been reported to produce an impairment of short-term memory in human and animals. However, the brain regions through which THC affects short-term memory remain unknown. Therefore, the effects of THC injections directly into the rat brain on the delayed matching-to-sample (DMTS) performance using 3-lever operant apparatus were examined and were compared with those of the muscarinic receptor antagonist scopolamine.

Intraperitoneal administration of THC at 1.8 mg/kg decreased significantly the

number of reinforcements in the test trial but not in the training trial (specific impairment of DMTS performance). THC at 3.2 mg kg (i.p.) decreased the number of reinforcements both in the test trial and in the training trial (non-specific impairment of DMTS performance). THC at 5.6 µg side, injected bilaterally into the dorsal hippocampus, produced a significant decrease in the number of reinforcements only in the test trial. In the same way, the specific impairment of DMTS performance was also observed following microinjection of scopolamine at dose of $18 \mu g/side$ in the dorsal hippocampus. Scopolamine at $10 \mu g$ side injected into either the medial prefrontal cortex or basolateral amygdala showed the specific impairment of DMTS performance. However, THC at doses up 32 μ g side injected into the medial prefrontal cortex or at doses up 10 μ g side into the basolateral amygdala failed to produce the impariment of DMTS performance. THC at dose of more than 32 μ g side or 10 μ g side injected into the medial prefrontal cortex or the basolateral amygdala, respectively, showed the non-specific impairment of DMTS performance.

These findings indicate that THC impairs the DMTS performance, at least in part,

via hippocampus

INJECTIONS OF Δ°-THC, BUT NOT ANANDAMIDE, PRODUCE A CONDITIONED PLACE AVERSION IN WISTAR RATS.

P. E. Mallet* and R. J. Beninger. Departments of Psychology and Psychiatry, Queen's University, Kingston, Ontario, K7L 3N6, Canada.

Although exogenous cannabinoid ligands such as Δ9-tetrahydrocannabinol (THC) have been implicated in reward-related learning, the role of endogenous cannabinoid agonists such as anandamide (arachidonylethanolamide) has never been tested. Thus, the effects of anandamide were tested in a place conditioning task, consisting of three distinct phases: preconditioning (three undrugged 15-min exposures to an apparatus consisting of two visually distinct compartments joined by a tunnel); conditioning (four 30-min pairings of one compartment with drug and four pairings of the other compartment with vehicle); and test (one undrugged 15-min exposure to the same apparatus). Time spent in each compartment was recorded during preconditioning and test; locomotor activity was measured during all experimental phases. Male Wistar rats (N=122) received THC (0.1, 0.5, 1.0, 1.5, 2.0, 4.0 or 8.0 mg/kg) or anandamide (0.5 or 2.0 mg/kg) during the conditioning sessions. The half-life of anandamide was increased by pretreatment with the protease inhibitor phenylmethylsulfonyl fluoride (2.0 mg/kg) during conditioning. A significant place aversion was found at the 1.0 mg/kg dose of THC. No significant place conditioning effect was found with anandamide. Locomotor activity during conditioning was significantly decreased by the 1.0, 1.5, 2.0, 4.0 and 8.0 mg/kg doses of THC and the 0.5 mg/kg dose of anandamide. These preliminary results fail to implicate anandamide in reward-related learning. (supported by NSERC)

ENHANCEMENT OF RAT HIPPOCAMPAL ENSEMBLE ACTIVITY BY CX516 PROTECTS AGAINST ERRORS IN SPATIAL DNMS. <u>Sam A. Deadwyler*</u>, <u>Douglas R. Byrd, Joanne K. Konstantopoulos, Gareth J.O. Evans, Gary Rogers* and Robert E. Hampson.</u> Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157. *Cortex Pharmaceuticals, Irvine, CA 92718.

This laboratory has shown that ensembles of hippocampal neurons encode information utilized during the performance of a spatial DNMS task in rats (Deadwyler et al 1996, J Neurosci). Different sources of variance extracted from overall ensemble activity included lever position, phase of the task and performance outcome in all animals (n = 7). Recent analyses of DNMS ensemble activity in the same task make it possible to delineate 1) the sequence of events which lead to an error, 2) the cascade of events which follow that error including obligatory miscoding on the next trial, and finally 3) the process by which correct DNMS performance gets reestablished. Such analyses showed that in hippocampal lesioned animals a proactive interference (PI) effect was present on all DNMS trials regardless of length of delay of the prior trial. In normal animals PI only occurred if the delay in the preceding trial was longer than 15 sec and the trial was an error. However if animals were pretreated before the session with the drug CX516 (aka BDP12, Cortex Pharmaceuticals), an AMPA channel modulator (Staubli et al 1994, *Proc Natl Acad Sch*), they were completely protected from Pl. Ensemble recording verified that CX516 enhanced task-relevant, as well as delay period firing in all hippocampal cells in the ensemble during the DNMS trial. Such enhanced within trial ensemble activity may have been the basis for protection in animals normally influenced by PI in this task. THE EFFECTS OF PENTOBARBITAL, PHENCYCLIDINE AND DIAZEPAM ON TWO DELAYED ALTERNATION PROCEDURES IN PIGEONS A.F. Nordholm*1, C. Dayer' and G. Wenger'. 'Naval Medical Research Institute-Detachment (Toxicology), WPAFB, OH 45433 and ³University of Arkansas for Medical Sciences, Department of Pharmacology and Toxicology, Little Rock, AR 72205

macology and Toxicology, Little Rock, AR 72205

We have previously reported on the detrimental effects of drugs of abuse in rats responding under a delayed alternation to position procedure. In this abstract we extend those observations to pigeons responding under a delayed alternation to position procedure (spatial discrimination task), and to a separate group of pigeons responding under a delayed alternation to colors procedure (color discrimination task). In the delayed alternation to position rask, pigeons pecked (FR-20) on alternating side keys of a standard three-key operant chamber to receive a food presentation. In the delayed alternation to color procedure, pigeons were required to alternate pecks (FR-20) between two of three keys transilluminated with red or green stimulus lights to obtain a food presentation. In both procedures, delay values were randomly scheeted among 4, 8 and 12 seconds with a mean delay value of 8 sec. Three drugs of abuse, pentobarbital (0.3-13 mg/kg), phencyclidine (0.03-3 mg/kg) and diazepam (0.03-3 mg/kg) were administered (im), and performance (percent correct and response rate) was compared to saline control values. In both procedures, pentobarbital at doses above 5.6 mg/kg produced dose dependent decreases in percent correct, while response rate was decreased at only the highest dose (13 mg/kg). Phencyclidine was without significant effect on percent correct at all doses tested, yet decreased response rate at the 1 and 3 mg/kg doses, while response rate was unaffected in animals responding under to the consistent with previously published reports of pigeons responding under a titrating matching-to-sample). Behavioral assay (delayed alternation procedure versus titrating matching-to-sample): although in other species, the neural circuitry subservient to similar procedures is thought to be different. DELTA-9-TETRAHYDROCANNABINOL INFLUENCES SEQUENTIAL MEMORY IN RATS PERFORMING A DELAYED-NONMATCH-TO-SAMPLE TASK. Robert Handson', Douglas R. Byrd, Joanne, K. Konstantopoulos, Terence Bunn, and Sam A. Deadwyler. Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157.

Previous studies have demonstrated that the cannabinoid, delta-9-THC disrupts processing of sequential memory in rats (Hampson *et al.* JPET, 1989). In rats trained to perform a spatial delayed-match-to-sample (DMS) task, within-trial, delay-dependent memory was also disrupted in the presence of 2.0 mg/kg THC (Heyser *et al.* JPET, 1993). Recently an aspect of sequential memory has been demonstrated in the form of proactive interference in a delayed-nonmatch (DNMS) form of the task (Hampson *et al.* SN Abstr. 1995). The degree of proactive interference was dependent on the length of the delay interval on the preceding DNMS trial. Hippocampal lesions eliminated the delay-dependency of proactive interference.

Administration of THC (1.0-2.0 mg/kg) produced the same effect as hippocampal lesions on within-trial DNMS performance and on between-trial proactive interference. Performance following vehicle-only injections was not significantly different from control sessions. Behavioral effects of THC were completely blocked by coadministered SR141716A (Sanofi), the cannabinoid receptor antagonist. Results suggest that THC disrupted cognitive processing via cannabinoid receptor-mediated effects on hippocampal cellular activity (Heyser et al. 1993), providing further evidence for the role of endogenous cannabinoids in modulating hippocampally-dependent memory processes. /Supported by NIDA grants DA08549 (REH), DA03502 & DA00114 (SAD)I

IS THE CONDITIONED RESPONSE TO A DRUG CONDITIONED STIMULUS ACTUALLY BASED ON STATE DEPENDENT LEARNING? C. H. Epstein and D. A. Overton. Depts. of Psychology and Psychiatry, Temple University, Philadelphia, PA 19122.

Prior studies show that if ethanol injection consistently precedes

Prior studies show that if ethanol injection consistently precedes electric shock, then after several pairings rats will become fearful when injected with ethanol, as indicated by suppression of drinking. This is generally viewed as classical conditioning with ethanol the conditioned stimulus (CS), electric shock the unconditioned stimulus (US), and suppression of drinking the conditioned emotional response (CER). Alternately, one could suggest that rats learned a CER to a conditioning box or technician CS, and that the CER was state dependent and hence only subsequently occurred when the animal was drugged.

In the present study, ethanol was injected just after the onset of shock so that the onset of ethanol's drug actions would occur while shock was still ongoing. The goal was to test whether rats would form state dependent memories of shock which would subsequently be retrieved only when the rats were again drugged. In this study, 5 groups were tested. Groups 1 and 2 were conventional forward-conditioning groups in which ethanol was injected 10 or 20 min., respectively, before onset of shock. Group 3 was the experimental group which received ethanol 1 min. after the onset of shock. Group 4, a control group, received saline 1 min. after shock onset. Group 5, another control group, received ethanol 20 min. after shock offset. Shock was a 15 min. series of 0.5-sec pulses of 1 ma RMS scrambled footshock with an average interpulse interval of 15 sec. Ethanol 1000 mg/kg was injected ip.

During subsequent test sessions, ethanol produced suppression of

During subsequent test sessions, ethanol produced suppression of drinking in Groups 1 and 2 but no suppression in Groups 3,4,5. Hence the results fail to show the occurrence of a state dependent CER in Group 3 and are congruent with the prevailing classical conditioning model.

SUBCELLULAR LOCALIZATION OF FRAGILE X MENTAL RETARDATION PROTEIN IN DENDRITIC SPINES: AN ELECTRON MICROSCOPIC STUDY Anthony D. Brazelton, Anna Y. Klintsova, Jvan Jeanne Weiler, Thomas A. Comery, Nicholas Hawrylak*, and William T. Greenough. Depts. of Psych. and Cell & Struct. Biol. and Beckman Inst., Univ. of Illinois, Urbana, IL 61801 and Dept. of Phys. Ther., Sch. of Med., W. Va. Univ., Morgantown, WV 26506.

A monoclonal antibody, PIGI1, was made against a C-terminal polypeptide designed from the published sequence of Fragile X Mental Retardation Protein, FMRP. This antibody was shown to stain a protein of about 78 kDa on Western blots of rat synaptoneurosomal protein preparations, and to stain brain sections with the same pattern of immunoreactivity as previously resported for a commercially available antibody (Devys et al, 1993).

P1G11 antibody was used to study the subcellular distribution of FMRP in the visual cortex and cerebellar molecular layer of P12-P15 rats. Colloidal gold post-embedding and HRP pre-embedding labelling has revealed immunoreactivity located in spines near postsynaptic densities, in dendrites, and associated with some polyribosomal aggregates in neuronal somata. Immunoreactivity was not observed in axons or glial cells. Often one or more spines in a field of view will exhibit strong labelling, while others exhibit no detectable signal, suggesting the occurrence of selective expression at some synapses. Localization of the protein in spines is compatible with our reports indicating neurotransmitter-induced FMRP translation in synaptoneurosomes and our conclusion that FMRP is translated at synapses under synaptic control. Supported by MH 35321 and the MacArthur Psychopathology Development Network.

mGluR STIMULATION MEDIATES PHOSPHORYLATION OF SOME POLYRIBOSOME-BINDING PROTEINS IN RAT BRAIN SYNAPTO-NEUROSOMES. <u>1J. Weiler', A.D. Brazelton, W.T. Greenough</u>, Depts. of Psych. & Cell & Struct. Biol. & Beckman Inst., Univ. of IL, Urbana, II. 61801.

Synaptoneurosomes contain postynaptic polyribosomal aggregates (PRA), in which proteins are translated upon stimulation by agonists for metabotropic glutamate receptors (mGluR). We are studying the PRA-associated proteins by gel analysis of serial salt washes. SDS-PAGE separated 16 prominent bands of approximate molecular weights of 115, 100-105, 95, 80-82, 75-78, 72, 65, 60-62, 55, 50-52, 45, 42, 38, 36, 32 and 28 kDa when proteins were dissociated from PRA in 0.5M K+. After a more stringent wash at 2M K+, additional proteins of MW 88, 73, 57 and 43 were seen in the eluate. Synaptoneurosomes were stimulated briefly by the mGluR-specific agonist 1S,3R-trans-ACPD in the presence of γ-32P-ATP. Stimulation for 1 min. increased the level of phosphorylation of 4 PRA-associated proteins (100-105, 80-82, 75-78 and 60-62 kDa). In the presence of the PKC antagonist calphostin, these 4 phosphorylated bands were much reduced. This suggests that mGluR-mediated phosphorylation of some PRA-associated proteins is dependent on PKC activation. One of these proteins may be the Fragile X Mental Retardation protein (FMRP), since in preliminary experiments, the phosphorylated band at 75-78 kDa was stained by PIG11, a monoclonal antibody against the C-terminal polypeptide of FMRP (see poster by S.A. Irwin et al.). In the presence of calphostin, this band was no longer present in the 0.5 M K+ salt eluate. If these results are confirmed, it would suggest that PKC plays a role in the association between FMRP and PRAs. Supported by FRAXA Research Foundation and MH 33321.

ENRICHED MOTOR LEARNING ENHANCES NEURO-PLASTICITY IN THE YOUNG LURCHER MOUSE. <u>K.C. Goss¹, L. Coudsi², R. Dvorak², and R.F. Mervis²*</u>, ¹Univ. Tennessee Med Ctr, Knoxville, TN 37920, ² NeuroMetrix Research, Inc. Columbus, OH 43212.

The Lurcher mutant mouse is characterized by apoptosis of Purkinje cells in the postnatal cerebellum, their dropout being essentially complete by 60 days-old (P60). This study was designed to assess the effects of an enriched motor environment from P10-P40 (i.e., "trained") on motor learning and on cerebellar and cortical histology in Lurcher and normal mice. "Non-trained" Lurcher and normal controls were reared in standard housing conditions for the same 30 day period. "Trained' Lurchers and control mice showed several changes from the "non-trained" mice: Behavioral tests showed that motor enrichment resulted in enhanced performance in both controls and Lurchers. Golgi-impregnation studies of Purkinje cells showed that motor learning resulted in a significantly enlarged dendritic arbor in the normal nice. And, in the somatosensory cortex, motor learning resulted in a more extensive dendritic arbor in the basilar tree of layer V pyramids. Cortical pyramidal cells of non-trained Lurchers also showed a neuroplastic enhancement of their dendritic arbor suggesting involvement of cortical circuits to compensate for loss of cerebellar neurons. Evidence of plasticity in response to motor learning was also reflected by an increase in the depth of the cerebellar molecular layer in both trained normal and Lurcher mice. These results, in combination with the behavioral data, provide evidence that enforced motor learning can reorganize cortical circuits in the Lurcher mutant when demanded by the genetically programmed death of Purkinje cells. (Supported in part by the Physicians Medical Education Foundation of the University of Tennessee)

DENDRITIC SPINE MORPHOLOGY IN THE FRAGILE-X KNOCKOUT MOUSE: A MODEL OF THE FRAGILE-X SYNDROME? T.A. Comery*, I.B. Harris, P.J. Willems, B.A. Oostra, & W.T. Greenough. Neurosc. Prog., Depts. of Psych., Cell & Struct. Bio., & Beckman Inst., Univ. Illinois, Urbana It. 61801, Depts. of Med. Gen. & Neurochem. & Behav., Univ. of Antwerp, Belgium, & Dept. of Clin. Gen., Erasmus Univ. Rotterdam, Netherlands.

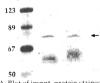

Fragile-X mental retardation syndrome occurs as a result of a decreased expression of the Fragile-X protein (FMRP). An examination of Gogli impregnated brain tissue from human Fragile-X patients reveals a spine morphology characterized by long, thin tortuous spines resembling those observed during development. It is thought that this dysgenesis may account for at least some of the behavioral symptoms of Fragile-X syndrome. Recently, in an attempt to produce an animal model of this sydrome, a transgenic knockout mouse has been produced thatlacks FMRP expression. These knockout mice display no gross brain abnormalities. We have examined the morphology of dendritic spines in the knockout mice utilizing the Golgi-Cox method. Prelimary results suggest that the spines on the apical dendrites of layer V pyramidal cells in occipital cortex of Fmr-1 knockout mice have spines that are significantly longer than those observed in wild-type controls. Spine density along the apical dendrite is also increased in the knockout mice. These results suggest that the Fmr-1 knockout mouse may be a good model of human Fragile-X syndrome and that FMRP expression may be essential for the production of dendritic spines with a normal, adult-like, morphology. EVIDENCE FOR TRANSLATION OF THE FRAGILE-X MENTAL RETARDATION PROTEIN IN A SYNAPTONEUROSOME PREPARATION S.A. Irwin*, LJ. Weiler, B.N. Patel, and W.T. Greenough. Neurosci. and Med. Schol. Progs., Depts. of Psych. and Cell & MW(kD) A B

Struct. Bio., and Beckman Inst., Univ. of Illinois, Urbana, IL 61801.

The absence of the Fragile-X Mental Retardation Protein (FMRP) in humans leads to fragile-X syndrome, a leading genetic cause of mental retardation. A salient feature of this syndrome is the relative absence of mature cortical dendritic spines in humans and mice. The mRNA for the gene (FMR-1) encoding this protein has been shown to associate with polyribosomal aggregates in response to metabotropic glutamate receptor.

A. Blot of imppt, protein stained with P1G11. B. Autoradiogram of same blot, showing ³⁵S-met, incorp. into immppt, protein.

response to metabotropic glutamate receptor (mGluR) stimulation of a synaptoneurosome preparation made from P14 rat cerebral cortices. In this study a similar preparation was stimulated with trans-ACPD in the presence of ³⁵S-methionine for 20 minutes, and a single radiolabeled protein (approx. 78 kDa) was immunoprecipitated with a monoclonal antibody (P1G11) to a polypeptide designed from the C-terminal end of both human and mouse FMRP. This finding provides further evidence for the translation of FMRP at synapses in response to mGluR stimulation, and may provide another link between synaptic stimulation and anatomical synaptic change. SPATIAL LEARNING AND HYPPOCAMPAL SYNAPTIC PLASTICITY IN ADULT RATS WITH INTRAVENTRICULAR IMPLANT OF HYBRIDOMA CELLS SECRETING NEUTRALIZING ANTIBODIES TO NGF F. Ruberti, RM Costagliola, MC Cenni, E. Cherubini, L. Maffei, A. Cattaneo and N. Berardi Ist, di Neurofisiologia CNR,I-56127 Pisa, Scuola Normale Superiore, Pisa, SISSA, Trieste (Italy) Recent results indicate that neurotrophins, such as NGF and BDNF, play a

Recent results indicate that neurotrophins, such as NGF and BDNF, play a role in neural plasticity not only during development but also in adults. We have assessed spatial learning performance and hyppocampal synaptic plasticity in adult rats after a treatment aimed at blocking endogenous NGF activity. 9 adult Long Evans rats were intraventricularly implanted with αD11 hybridoma cells secreting antibodies preventing NGF binding to its receptors. As a control, 9 littermates were implanted with parental P3U myeloma cells. Antibody titre was determined in samples of CSF with enzyme-immunoassay (ELISA). Performance of αD11 rats was significantly impaired with respect to controls, both in terms of acquisition rate and of final level of accuracy. Impairment in performance correlated with αD11 titre in CSF. In hyppocampal slices prepared from behaviourally characterized P3U and αD11 rats we have then examined long term synaptic plasticity (LTP). Field excitatory postsynaptic potentials (IEPSP) were recorded in stratum radiatum of CA1 area after stimulation of Schaffer collaterals. LTP was elicited by 2 trains of tetani (100 Hz, 1 sec) with an interval of 10 sec. We found that in the majority of slices from αD11 animals LTP was inducible and its early phase (up to 1.5 hours after tetanus) was essentially the same as that found in slices prepared from P3U rats.

Experience related molecular and structural plasticity of glial cells in the chicken brain.

A. Zimmermann* and E. Besemfelder, Zoologisches Institut der THD.

Schnittspahnstr. 3, 64287 Darmstadt, FRG.
While work on neuronal plasticity in the context of learning has covered

while work on neuronal plasticity in the context of learning has covered much ground, little is known about glial cell responses. With an interest in gliabiology within the general framework of potential experience related changes, we have used GFAP and E1 antibodies to monitor aspects of glial cell plasticity. E1 is a cell surface glycoepitope defined by E1 monoclonal antibody. It is abundantly present on many GFAP negative glial cells as well as on certain neurons throughout the chicken brain.

Western blot analyses showed that the levels of E1 expression in the tectum dropped precipitously after hatching. Posthatching day 1 (P1) levels were several fold lower than on the last day in ovo (E20). P4 socially-raised chickens (se-chicken) had higher tectal and forebrain E1 levels than same age chickens reared in isolation (i-chicken). Western blots of tectum proteins of i-chickens which had been subjected to an auditorily provoked learning (imprinting) experience in a Y shaped arena with few visual cues often showed significantly higher levels of E1 one hour following two 5-10 min sessions in the arena than their unexperienced counterparts. This detectability of changes in E1 expression following confrontation with an early learning (imprinting) task in Western blots of tissue homogenates suggests that alterations in E1 expression occur in a general or large scale fashion. Thus, although the E1 epitope is not exclusively glia cell associated, it appears

amough the 2-replicipe in the Extrasvely glid cell associated, it appears necessary to invoke changes in glid ET expression.

Experience related structural plasticity of astrocytes was apparent in GFAP stainings. Astrocytic processes of extensive length were present in the brains of i- but not s-chickens 4 weeks after hatching, particularly in tectum and hippocampus. Supported by DFG Zi 455/2-5.

SINGLE-CELL CORRELATES OF REPRESENTATIONAL BOUNDARIES IN

SINGLE-CELL CORRELA IES OF REPRESENTATIONAL BOUNDARIES IN RODENT SI CORTEX. P.W. Hickmott* & M.M. Merzenich. Reck Center for Integrative Neuroscience, UCSF, San Francisco, CA 94143.

Many regions of adult neocortex are capable of considerable reorganization as a result of changes in the activity patterns of their inputs. The cellular and circuit properties that underlie this plasticity are incompletely understood, but it has been hypothesized that strengthening and/or weakening of already existing intracortical excitatory and/or inhibitory synapses may be one mechanism underlying these cortical reorganizations.

hypothesized that strengthening and/or weakening of already existing intracortical excitatory and/or inhibitory synapses may be one mechanism underlying these cortical reorganizations.

To examine this hypothesis we mapped a ~1.2 mm length of the boundary between the forepaw and lower jaw representation in rat SI cortex using standard extracellular recording with penetrations at ~50 micron intervals. After mapping, the boundary was marked by iontophoresis of pontamine sky blue (2%, in .5 M NaAc), and 400 micron thick coronal slices were taken from the marked region. Current-clamp recordings are made from single layer 2/3 neurons within 300 microns of the mark using blind whole-cell recording. Electrical stimuli are applied at the same cortical depth either across the boundary (CB) or at the same horizontal distance on the other side of the cell (NCB). Stimulus intensities for both sites ranged from the minimum necessary to evoke a PSP to that causing a maximal PSP. In 9/20 cells, PSPs resulting from NCB stimulation had peak and average amplitudes ~20% greater than PSPs from CB stimulation, and also had a >20% more rapid fall time from peak to 1/2 peak amplitude. In an attempt to develop a preparation that shows more robust boundary effects, we have recently begun using a slice in which the supragranular layers are isolated by cutting in the slice at a depth of 500-700 microns, and have preliminary data that a higher percentage of neurons from these slices have greater PSP amplitudes for NCB stimulation.

These experiments indicate that it is possible to detect cellular correlates of representational boundaries in sensory cortex. Using this preparation we are investigating specific differences in EPSPs and IPSPs across these boundaries and hope to use it to investigate plasticity of cortical representations.

A HIPPOCAMPUS FOR ALL SEASONS: PHOTOPERIODIC MODULATION OF HIPPOCAMPAL VOLUME IN MEADOW VOLES. L.F. Jacobs^{*1}, K.M. Grady², K. O_Lstott¹, F. Marouf¹, K. Allen¹ and T.M. <u>Lee</u>². ¹Dept. Psych., Univ. California Berkeley, CA 94720-1650; ²Dept. of Psych., Univ. Michigan, Ann Arbor, MI 48104-1687.

Psych, Univ. Michigan, Ann Arbor, MI 48104-1687.

Hippocampal size shows seasonal patterns of sexual dimorphism in wild rodents: in spring, but not winter, the hippocampus is significantly larger in males. Other structures, such as cerebellum, show no seasonal cnange in size. The present study replicated this result in laboratory voles, using photoperiod as the seasonal cue. Males and females were raised in either long (LD) (14:10) or short (SD) (10:14) photoperiods. Voles were autopsied at 9.5 weeks of age and brains were postfixed in 10% buffered formalin. Brains were embedded in gelatin-albumin, frozen sections were cut in the horizontal plane at 40 μ m intervals and every fourth section was mounted horizontal plane at 40 µm intervals and every fourth section was mounted and stained with cresyl viole. Volume of whole brain, CB and HP were determined by stereological assessment of area in mounted sections, using a 45X projected image of the section; all slides were coded. The accuracy of this method was confirmed using a computer-based image measuring workstation. Residual values from a line of best fit between whole brain and substructure (HP, CB) were used to measure the relative size of substructures. Analysis of these residuals revealed, as predicted, a significant photoperiod-by-sex interaction in HP size, but not in brain size or in CB size. In the LD group, hippocampal size was larger in males; in SD, larger in females; CB size did not differ between groups. Thus, the same parger in ternaies; GB size did not differ between groups. Thus, the same pattern seen in wild voles was confirmed in laboratory voles. Given the widespread distrbution of this effect in wild rodents, is likely that domestic laboratory rodent species, although normally kept under constant photoperiod, would also show dramatic hippocampal plasticity in response to photoperiod. Effects of protein synthesis inhibition on long-term cholinergic enhancement in somatosensory cortex of anaesthetized rats. <u>D. Verdier, M. Maalouf, N. Tremblay* and R.W. Dykes.</u> Département de physiologie, Faculté de Médecine, Université de Montréal, Montréal, Québec

Previous work by Verdier et al. (1995) demonstrated that pairing electrical hindpaw stimulation with basal forebrain (BF) stimulation induces a long term increase in the size of the evoked potential in rat somatosensory cortex. This long-term in the size of the evoked potential in Tasoniausensory cortex. This folg-term cholinergic enhancement (LTCE) was shown to require NMDA receptor activation and nitrous oxide synthesis. Because LTCE could possibly result from an activation of nociceptive fibers by the electrical stimulus, we developed a analogous preparation where the hindpaw was stimulated using a light mechanical stimulus. In addition, we tested the effects of the protein synthesis inhibitor Anisomycin.

Our results indicate that when a 10 ms cutaneous stimulus is presented 30 ms after a 1 ms BF stimulation during 10 trials, the evoked potential in the somatosensory cortex was significantly enhanced by up to 40% in 7 out of 33 experiments. This enhancement lasted over 90 min and was observed immediately after pairing in all but one animal where the increase in the size of the evoked potential was progressive. Three rats were treated with Anisomycin (60 mg/kg, systemic) 90 min prior to the pairing. In two cases, the evoked potential was not enhanced. In the third case, an enhancement was seen immediately after pairing and lasted until the end of the recording (90 min after paring). We conclude that a light mechanical stimulus is effective in inducing LTCE when it is paired with BF stimulation. However, the effects of Anisomycin remain unclear. Additional experiments will be performed to determine if 1)Anisomycin blocks LTCE completely, 2) does not affect LTCE or 3) inhibits only the long-term component as has been traditionally observed in hippocampal long-term potentiation. EXPERIENCE-DEPENDENT CHANGES IN CORTICAL CELL MORPHOLOGY ARE AGE-DEPENDENT. B. Kolb*, R. Gibb, G. Gorny, and A. Oullette. Univ. of Lethbridge, Lethbridge, AB, Canada, T1K 3M4

The morphology of cortical pyramidal cells was examined in rats given 1 of 3 different experiences (tactile stroking, 'enriched' housing, or specific forelimb training). Tactile stroking was given 3X daily for 15 min, beginning in the first few days of life and continuing until postnatal day 21 (PN21). Environmental housing was manipulated by placing rats in large enclosures with novel objects (enrichment) beginning on PN21, PN200, or PN800 and continuing for 90 days. Forelimb training involved either reaching through bars for food or pulling up strings to obtain food, and began on PN120 and continued for 30 days. Morphology of cortical neurons was examined in adulthood.

Both enrichment and stroking during development led to increased dendritic length and <u>decreased</u> spine density in pyramidal cells. In contrast, both enrichment and forelimb training in adulthood <u>increased</u> dendritic length but had no effect upon spine density.

These results suggest that environmental experiences during development effect cortical morphology differently than similar experiences in adulthood. This age-related experience-dependent difference in cortical neuron morphology may account for differences in the effects of earlier vs later experience on behaviour. The failure to observe increased spine density with experience contrasts with the increases in both dendritic length and spine density in response to trophic factors, gonadal hormones or early lesions.

ENRICHMENT DURING DEVELOPMENT INDUCES ENDURING INCREASES IN RESTING CEREBRAL GLUCOSE METABOLISM IN MONKEYS. M. J. Raleigh*, W. P. Melega, S-C. Huang, S. R. Cherry, M. T. McGuire, and M. Blurton-Jones, M. E. Phelps. Depts. of Psychiatry and Molecular and Medical Pharmacology, UCLA, Los Angeles, CA 90024.

This positron emission tomography (PET) study used 2-deoxy-2[¹⁸] fluoro-D-

deoxyglucose (FDG) to examine the enduring effects of enrichment on local cerebral metabolic rates for glucose (ICMRglc) in developing vervet monkeys. PET scans were performed while the monkeys were in a conscious, resting state and we determined ICMRglc in nine regions of interest (ROI). The 8 subjects ranged in age from 5 to 7 months, the period of maximal metabolic neuroplasticity in this species. The 4 enriched and the 4 age- and sex- matched controls lived in complex, species typical social groups. During the 45 day enrichment regime, enriched subjects had access to a joy-stick controlled computer and learned to solve delayed response and visual tracking problems. Control subjects could see but not manipulate the computer. Three quantitative FDG PET scans were obtained per subject: prior to enrichment, at the conclusion of the enrichment regime, and eight months later.

Before enrichment, control and enriched subjects did not differ in ICMRglc in any

ROI. Immediately after enrichment, relative to control subjects, experimental subjects exhibited significant bilateral increases in ICMRglc in the dorsolateral frontal, orbitofrontal, temporal, and parietal cortices by 34%, 28%, 32%, and 19% respectively (p <.01). Eight months later ICMRglc remained elevated in dorsolateral frontal, orbitofrontal, and temporal cortices by 24%, 18%, and 21%. There were no differences in ICMRglc in the visual cortex, somatosensory cortex, brain stem, cerebellum, or cortical white matter. Thus early enrichment induces substantial, enduring, regionally-specific increases in lCMRglc

ESTRADIOL INCREASES SENSITIVITY OF CA1 PYRAMIDAL CELLS TO NMDA RECEPTOR-MEDIATED SYNAPTIC INPUT. C.S. Woolley* and P.A. Schwartzkroin. Neurosurgery Dept., Univ. of Washington, Seattle, WA 98195

Previous studies have shown that, in the adult female rat, the density of dendritic spines and synapses on hippocampal CA1 pyramidal cells is sensitive to the ovarian steroid, estradiol, and fluctuates naturally as estradiol levels rise and fall during the estrous cycle. Currently, the consequences of hormone-induced changes in spine/synapse density for synaptic transmission are not known. To address this issue, we have compared synaptic responsiveness of CA1 pyramidal cells to the density of dendritic spines on each cell. Hippocampal slices were prepared from adult female rats that were ovariectomized and treated with either estradiol or oil vehicle. EPSPs evoked by Schaffer collateral stimulation were recorded from neurons within the CA1 pyramidal cell layer. Following recording, each cell was filled with biocytin to visualize dendritic spines. The slope of an input/output relationship (EPSP slope vs. stimulus intensity) was compared to spine density for each cell. Analysis of the dendrites of biocytin-filled CA1 pyramidal cells demonstrated that the density of dendritic spines is increased in ovariectomized animals treated with estradiol compared to that in animals receiving vehicle alone. In initial experiments, no correlation between I/O slope and spine density was observed when composite EPSPs were elicited in cells at resting membrane potential. However, when the NMDA receptor mediated component of the EPSP was isolated pharmacologically, a significant correlation between I/O slope and spine density was observed (R=0.65, p<0.01); the mean I/O slope and spine density was observed from estradiol-treated animals compared to vehicle-treated controls (p<0.01). These results demonstrate that estradiol increases CA1 pyramidal cell sensitivity to NMDA receptor-mediated synaptic input. Supported by NS 18895 (PAS) and NS 09787 (CSW)

ROLE OF ESTROGEN IN MODYFING SYNAPTIC FUNCTION

Heather N. Fugger*1 and Thomas C. Foster, 1,2 1 Neuroscience Graduate Program and 2 Department of Psychology, University of Virginia, Charlottesville, VA 22903

Virginia. Charlottesville, VA 22903

Anatomical studies demonstrate that dendritic spine number in region CA1 of the hippocampus varies with the level of ovarian hormones. To determine if the increase in synapse number following estrogen treatment represents a population of functional synapses, female (4 mo) Sprague-Dawley rats were ovariectomized, and three days later rats were injected with 100 µg estradiol benzoate in 1 ml sesame oil or 1 ml oil vehicle. A second injection was given 24 hours later. 48 hrs following the second injection CA1 physiology was examined in an *in vitro* hippocampal slice preparation. Paired-pulse stimulation (50ms ISI) was delivered in order to measure fiber potential (ft) amplitude. EPSP slope, and paired-pulse ratio. To examine changes in magnitude and susceptibility to induction of hippocampal synaptic plasticity, long-term depression (LTD) and long-term potentiation (LTP) inducing stimulation were given. The results indicate that fp amplitude and EPSP slope were not different for the OVX (n=11, n=slices) and OVX+E (n=12) groups suggesting no difference in synaptic strength. A small but reliable LTD could be induced, however. LTP was not different between groups (OVX+E (n=5), 134±0.08 mean±SEM. OVX (n=5), 1.17±0.07, p≤0.1). These data suggest that estrogen may alter the potential for LTP. Supported by NS31830 to TCF.

AN INNOCUOUS BIAS IN WHISKER USE IN ADULT RATS ALTERS RELATIVE NMDA AND AMPA RECEPTOR SENSORY TRANSMISSION IN BARREL FIELD CORTEX. ¹M. Armstrong-James*, ¹Jane H. Houchen.

²Ford F. Ebner. Department of Physiology, QMW, London University, U.K. El 4NS1 and I.D.N., Kennedy Center, Vanderbilt University, Nashville, Tn-372032 Cortical plasticity can be induced in adult rat cortex by cutting all except two whiskers, D2 and D3, for 3-30 days ("whisker-pairing"; WP). WP cause Hebbian potentiation of single unit responses in barrel D2 to the center (D2) and 'paired' surround (D3) whiskers. Responses to disused (e.g. cut D1) whiskers decrease. We used antagonists to NMDAR (AP5) and AMPAR (CNQX) to demonstrate changes in NMDA/AMPA receptor mediated responses after 30 days of WP for cells in the D2 barrel. (1) For response to the D2 principal whisker potentiation was restricted to the earliest (<10 ms latency), thalamo-cortical (T-C)discharges, and this was attributable solely to potentiation of AMPA-dependent activity (p<.001, Mann-Whitney U test). Later response components (discharge latencies 10-100 ms) exhibited decreased NMDA-dependence. (2) In controls AMPA/NMDA receptor profiles were highly NMDA receptor-dependent and indistinguishable for D1 and D3 surround responses. For WP animals, bias in response to the paired D3 surround whisker was attributable to enhancement of both AMPA- and NMDA-dependent components of late discharges relative to cut D1 whisker responses (p<.001 and .01 respectively). Hence, AMPAR transmission is potentiated and NMDAR components are decreased in the direct T-C relay, while both AMPA and NMDA receptor transmission are potentiated between columns for paired surround inputs. These results show that a novel sensory activation pattern can initiate different changes in glutamate receptors of at least two different types; thalamocortical synapses readjust receptor efficacy differently from corticocortical synapses between two columns receiving increased activity. CONTEXTUAL FEAR CONDITIONING ACROSS THE RAT ESTROUS CYCLE. Etan J. Markus', Maja Zecevic, & Michael L. Anderson, Behavioral Neuroscience Div. Deut. of Psychology. Univ. of Connecticut. Storrs. CT 0626'

Neuroscience Div., Dept. of Psychology, Univ. of Connecticut, Storrs, CT 06269

The natural 4-5 day female rat estrous cycle has been related to changes in hippocampal structure (CA1 synaptic density - Woolley et al., 1990; 1992) and physiology (LTP - Humphreys et al., 1994; Korol et al., 1994). This is especially apparent during the 24 hour period between the peak of estradiol (proestrus) and the low estradiol part of the cycle (estrus). This increase in synapses and plasticity during proestrus is accompanied by a decrease in the water maze ability of the rats (Frye, 1994; Warren et al. 1995). To examine whether this proestrus-related decline is limited only to the water maze, rats were tested on different paradigm also shown to be sensitive to hippocampal function, contextual fear conditioning.

24 female and 12 male, 4-5 months old Fisher 344 rats were examined for contextual and cued fear conditioning. The rats experienced two tone-foot-shock pairings in a distinctive chamber (3 minute baseline, followed by 30 sec tone, followed by a 2 sec 0.4 mA current, twice). Retention was tested 2-3 weeks later, first the animals were placed in the original conditioning chamber, with no tone or shock administered (3 min., context retention), followed by placement in a novel chamber for 3 min. after which the conditioning tone was presented for 3 min. (cued tone retention). Half the females were conditioned and tested for retention during proestrus and the other half during the estrus part of the cycle. The males were yoked to the female rats conditioning and retention testing schedules.

It was found that proestus rats show less contextual fear conditioning than male or estrus female rats. There was however no difference among the three groups in their conditioning to the tone stimulus. These results suggest that the changes found during the proestrus part of the cycle are related to spatial-contextual information processing and not to a general change in learning ability

VARIATIONS IN LEVELS OF CIRCULATING OVARIAN HORMONES INFLUENCE ASTROCYTES IN THE CEREBRAL CORTEX OF THE ADULT FEMALE RAT. M.L. Forgie*, P.M. Burke and B. Kolb. Dept. of Psychology, The Univ. of Lethbridge, Lethbridge, AB, Canada, T1K 3M4. Previously we reported that ovariectomy (OVX) of adult female rats increased the surface density (Sv) of glial fibrillary acidic protein-immunoreactive material (GFAP-IR) in certain cortical areas (Forgie et al., <u>Soc. Neurosci. Abst.</u>, 1995,74.1). Our results for intact females were inconsistent, however. One explanation is that variations in Sv across the estrous cycle may be as great as those that occur in response to OVX, and rats were sacrificed without regard to the stage of the cycle. In the present study, adult females were either OVX'ed or sham-operated and vaginal lavages were taken for 4 weeks following surgery. Intact rats were sacrificed on the afternoon of proestrus, estrus, or diestrus, and all brains were processed for GFAP immunohistochemistry. Using a stereology system, the Sv of GFAP-IR was quantified in five different cortical areas Variations in Sv of GFAP-IR according to stage of the estrous cycle, and in response to OVX, were observed in many, but not all, of the cortical areas examined. In some regions, OVX increased Sv of GFAP-IR, although no significant variations in Sv occurred over the cycle. Conversely, in other regions, the changes across the estrous cycle (e.g., diestrus vs. proestrus) were as large as those produced by OVX. These data confirm and extend our previous finding that fluctuations in levels of circulating ovarian hormones can produce alterations to astrocytes in the cerebral cortex of the adult female rat.

CHRONIC ORAL ANIRACETAM DOES NOT MODIFY BEHAVIOURAL OR CORTICAL PLASTICITY ASSOCIATED WITH "ENRICHED" HOUSING. M. Osborne, J. Chadbourn, M. Campbell, D. Travis and M. Saari*. Neuroscience Research Unit, Nipissing University, 100 College Dr., North Bay, Ontario, Canada, P1B 9L7.

Forty male rats were randomly allocated to a 2 X 2 factorial design. The 41 day old rats were housed for six days in either "enriched" or "isolated" environments. Half of the rats in each housing condition were administered oral aniracetam (50mg/kg) or vehicle (45g cyclodextrin/100ml H.O). This yielded 4 groups with 10 subjects per cell. "Enrichment" consisted of social housing with daily exposure to an open field scattered with various objects. The "isolated" rats were housed individually in hanging cages (21 X 21 X 28cm) with routine care. Humidity and temperature were controlled and the light cycle reversed. As expected, "enrichment" influenced adaptation to a novel open field and place navigation whereas an unexpected increase in activity was found with the aniracetam treatment. Thickness of the occipital cortex was increased by "enrichment" but not aniracetam. Aniracetam did not influence brain morphology except for the pyramidal cell layer of the hippocampus.

HANDEDNESS AND NEUROPSYCHOLOGICAL PERFORMANCE IN PATIENTS WITH LEFT TEMPORAL-LOBE EPILEPSY OR LEFT HEMISPHERE ARTERIOVENOUS MALFORMATIONS. R. Roth, Z. Caramanos, G. Leonard* and R. Leblanc. Neurological Institute, McGill University, Montreal, Canada, H3A 2B4

It is known that left temporal-lobe epilepsy (LTLE) is associated with a shift in handedness (Leonard et al, 1991), and it has been suggested that left hemisphere arteriovenous malformations (LAVM) can have a similar effect.

In order to examine this directly we compared the handedness of groups of patients with either LTLE (n=34) or LAVM (n=29), as well as their performance on an extensive battery of neuropsychological tests. LTLE patients had significantly lower mean IQ ratings and mean verbal and visuospatial performance than the LAVM subjects. No differences were found on tests of cognitive flexibility, language ability, or sensorimotor function. Six of the LTLE cases, but only two LAVM cases were lefthanded. Given the small sample sizes, this distribution did not differ from that expected by chance. Nevertheless, when we compared the LAVM group to a larger group of LTLE patients (in whom 40 of 145 cases were left handed), there were significantly fewer left-handed LAVM cases than expected (Fisher Exact Test, p = 0.017)

Thus, our findings suggest that LAVM may be less disruptive, both in terms of cognitive function and cerebral organization, than LTLE

DOPAMINE (DA) AND ACETYLCHOLINE (ACh) RELEASE IN THE RAT LATERAL HYPOTHALAMUS (LH): OPPOSITE CHANGES IN RELATION WITH DRINKING. M. Puig de Parada*, G. Molina de Chacón, X. Páez, M.A. Parada, and L. Hernández. Department of Physiology, Universidad de los Andes, Mérida 5101-A, Venezuela.

Drinking behavior after local administration of dopaminergic and cholinergic drugs suggests that DA in the LH plays an inhibitory, and ACh a facilitatory role in water intake. A described interaction within the LH is the dopaminergic inhibition of cholinergic elements. Those facts suggest that the basal release of both neurotransmitters should display opposite changes in relation with deprivation-induced drinking. This study explored that possibility. Male Wistar rats were trained for 2 weeks to drink just during one hr daily. The test day animals had access to water while undergoing microdialysis in the LH and usually drank during the first 40 min. DA turnover (n=6) or ACh release (n=5) were monitored. DA increased above 3.9 ± 0.8 pg/20µl in the four 20-min samples taken after water was above 3.9 ± 0.8 pg/20µl in the rour 20-min samples taken after water was available, peaking $(5.6 \pm 1.4 \text{ pg})$ in the 2nd sample $(155 \pm 4.7\%; \text{ F:}23.5;$ p<0.0001). DOPAC (basal: $42 \pm 5.4 \text{ pg/}(20µl)$ increased gradually after water was presented and peaked $(55 \pm 5.8 \text{ pg})$ 80 min later $(132 \pm 9.7\%; \text{ F:}25.2; \text{ p<0.0001})$. HVA did not change. ACh release decreased from $2.5 \pm 3.8 \text{ pg}$ 10 min later $(132 \pm 9.7\%; \text{ F:}25.2; \text{ p<0.0001})$. HVA did not change. ACh release decreased from $2.5 \pm 3.8 \text{ pg}$ 10 min later $(132 \pm 9.7\%; \text{ F:}25.2; \text{ p<0.0001})$. $0.7 \, \text{pmol}/20 \mu \text{l}$ to $1.36 \pm 0.7 \, \text{pmol}$ in the 2nd sample post-water presentation, which represented a decrease to $40 \pm 18\%$ of the pre-water mean basal level (F:4.9; p<0.05). These modifications confirm the prediction that oriented the present study, but the temporal resolution does not allow a valid interpretation in regard with its physiological significance. We propose that they could represent factors involved in the development of water

STUDY DEFENSIVE REACTIONS INDUCED MICROINJECTION OF EXCITATORY AMINO IN THE INFERIOR OF RATS S.H. Cardoso, N.C. Coimbra, V. Sardaryanst and M.L. Brandão Laboratório de Psicobiologia FFCL-RP/USP Ribeirão

The inferior colliculus (IC) is primarily involved in conveying auditory information to higher cortical structures. Recently we have shown that this structure may also be part of a brain system commanding defensive behavior. Here we present evidence for the involvement of excitatory amino acids in the expression of these defensive reactions. Microinjections of increasing doses (5, 10, 20 and 40 nmol) of NMDA - an excitatory amino acid - into the central nucleus of the IC of rats placed inside a circular arena induced gradual aversive reactions characterized by runnigs, rearings, and jumps. These reactions were inhibited by the NMDA specific antagonist AP7 previously microinjected within the IC. It is suggested that NMDA receptors mediated mechanisms are called into play during the expression of the defense reaction.

THE INFLUENCE OF SOCIAL ISOLATION ON SENSITIVITY TO THE

THE INFLUENCE OF SOCIAL ISOLATION ON SENSITIVITY TO THE REINFORCING EFFECTS OF D-AMPHETAMINE AND COCAINE. J.K.Smith* J.C.Neill & B.Costall Postgraduate Studies in Pharmacology, University of Bradford, West Yorkshire, BD7 IDP, U.K. Previous research has demonstrated that rearing rats in social isolation can lead to hyperactivity, enhanced responding for reward related stimuli, and increased sensitivity to psychomotor stimulant drugs (Robbins T.W. 1996; J. Psychopharmacology 10(1):39-47). The aim of the present study was to assess the influence of long term post-weaning social deprivation on the printering officers of both of metaltrapine and contine reinforcing effects of both d-amphetamine and cocaine.
Female Hooded Lister rats (n=24) were housed individually or in groups of

Femiliae Hooded Lister rats (fi=24) were floused individually of high gloups of from weaning (21 days) for a period of 12 weeks. The socially reared rats were environmentally enriched with various toys, and handled daily. Rats were trained to respond either for a previously food paired conditioned stimulus (CS) or on a progressive ratio (PR) schedule of food reinforcement in one of four identical operant chambers. Responding was then assessed 30min after administration of amphetamine (0.5mg/kg i.p.), cocaine (5mg/kg

30min after administration of amphetamine (0.5mg/kg i.p.), cocaine (5mg/kg i.p.) or saline vehicle (i.p).

Isolated rats responded at a significantly higher level for presentation of the CS (p<0.01), and this difference was further enhanced following administration of both *d*-amphetamine (0.5mg/kg; P<0.05) and cocaine (5mg/kg; P<0.01). In addition isolated rats responded at a higher level (p<0.05), and achieved a higher break point under a PR schedule of reinforcement, which was similarly enhanced following treatment with both *d*-amphetamine (0.5mg/kg; P<0.05) and cocaine (5mg/kg; P<0.05).

Results of the present study, in agreement with previous studies (Jones et al Psychopharmacology 102:364-372; 1990) demonstrate that isolated rats exhibit enhanced responding for rewarding stimuli. In addition results show that isolation rearing leads to an enhanced sensitivity to the reward enhancing

that isolation rearing leads to an enhanced sensitivity to the reward enhancing properties of both coaine and d-amphetamine.

SEX STEROID EFFECTS ON SOCIAL BEHAVIOR IN CHICKS. L. Normansell*, M. Holmes, A. Kennedy, & S. Eastek, Program in Neuroscience, Muskingum College, New Concord, OH 43762. Following chronic testosterone (T) administration, young chicks

crow regularly and become very aggressive towards conspecifics. Since T follows two metabolic pathways, aromatization to estradiol (EB) and reduction to dihydrotestosterone (DHT), we investigated the effects of administration of these hormones on social behavior in effects of administration of these hormones on social behavior in young domestic chicks. Chicks were obtained at one day post hatch, housed in like-treated flocks, and administered either 2.5mg T, 2.5mg EB, 2.5mg DHT, 2.5mg of both DHT & EB, or oil vehicle control. Animals in the various experimental conditions did not differ from each other in either body weight or testes weight. When isolated, DHT-treated chicks emitted slightly fewer distress calls than the other chicks, but significantly more calls of other types. When animals were observed in their home cages, T-treated animals were significantly more aggressive than the other groups. While they displayed no aggression towards their flockmates, the EB-treated chicks directed more aggressive acts towards the experimenters' hands when they were systematically placed within the cages. Both the T and EB/DHT animals emitted crows, while neither the EB, DHT, or Veh chicks ever did. When tested on a social approach task, where a separated animal had to move to rejoin the flock, there were no differences between the groups. In summary, while testosterone treatment induces many adult-like patterns of behavior in young chicks, which of those are modulated by each of the separate metabolic pathways will require additional testing.

DIFFERENTIAL EFFECTS OF INTRA-SEPTAL R(+)8-OH-DPAT IN TWO ANIMAL MODELS OF ANXIETY. J. Menard* and D. Treit. University of Alberta, Edmonton, Alberta, CANADA T6G 2E9

Previous studies (Pesold & Treit, 1992; 1994) have shown that lesions or intra-septal infusions of the GABAAbenzodiazepine agonist midazolam produced anxiolytic effects in two animal models of anxiety (i.e., decreased open-arm avoidance in the elevated plus-maze test and decreased burying in the shockprobe burying test). Because similar anxiolytic effects are seen after PCPA-induced depletion of serotonin (5-HT), and lesions of the dorsal raphe, which innervates the septum (Treit et al., 1993), it seems possible that 5-HT participates in the septal regulation of these fear behaviors. The present study was designed to examine the effects of intra-septal infusions of the selective and highly potent 5-HT_{IA} receptor agonist R(+)-8-OH-DPAT in these tests. Intra-septal infusions of R(+)-8-OH-DPAT (5 or 10 μ g) produced a selective decrease in rats' burying behavior in the shock-probe burying test, but did not impair rats' open-arm avoidance in the plus-maze test. Combined with our earlier results, these results suggest that distinct receptor sub-types within the septum mediate certain fear responses (burying behavior), but not others (open-arm avoidance). CHRONIC CHANGES IN SOCIAL BEHAVIORS OF THE RAT FOLLOWING SHORT-TERM TREATMENT WITH A BRIDGED ORGANOPHOSPHATE. M. Y. V. Bekkedal*, J. Rossi III. and J. Panksepp, Dept. of Psychology, Bowling Green, OH 43403.

State Univesity, Bowling Green, OH 43403.

Previous research reports long-term behavioral changes resulting from short-term treatment with inverse agonists of the benzodiazepine receptor. In this research, a putative inverse agonist, trimethylolpropane phosphate (TMPP) was evaluated for its short- and long-term effects on social behaviors in laboratory rats.

short- and long-term effects on social behaviors in laboratory rats.

Long Evans rats received 3-4 daily treatments of TMPP (0.1 mg/kg i.p.), and the following behavioral measures were investigated several days post-treatment: rough-and-tumble play, gregariousness, open field exploration, and elevated plus-maze investigation. No group differences were found in measures from the plus-maze. In the open field there was a main effect for elevated activity in the TMPP group. Measures of social behavior showed group differences such that play, as measured with pins and dorsal contacts, and gregariousness, as measured with an automatic social investigation appartus, increased in animals previously treated with TMPP. Most of these chronic changes in social behaviors were observed in female rats only, and were demonstrated to interact with the environment in which TMPP exposure occurred (ie; positive vs. negative). The effects of TMPP were most evident if the drug had been experienced in a negative environment which was chilled (55° F), brightly lit (550 lux), and a loud sound was presented for 30 sec at 15 min intervals for 2 brs.

These results indicate that short-term exposure to the compound TMPP can lead to long lasting changes in social behavior, and possibly altered neurochemistries or brain structures. Preliminary results show that some chronic effects are blocked by the co-administration of TMPP and the benzodiazepine, chlordiazepoxide, suggesting antagonist or inverse agonist actions of TMPP at the benzodiazepine receptor. EFFECTS OF 5-HT₂/5-HT_{1C} RECEPTORS BLOCKADE ON FEAR-INDUCED ANALGESIA ELICITED BY ELECTRICAL STIMULATION OF THE DORSAL PERIAQUEDUCTAL GRAY. M.L. Brandão* and N.C. Coimbra. Lab. of Psychobiology, FFCLRP-USP, Brasil, 14049-901.

The dorsal periaqueductal gray matter (DPAG) has been implicated in the control of defensive behaviors. Electrical and chemical stimulation of this structure elicits fear and escape behaviour, expressed by immobility (freezing) and wild running and jumps. There is evidence that the neural substrates responsible for defensive behaviour in this level of the midbrain tectum may also be responsible for fear-induced analgesia. This study was aimed to examine the characteristics of the analgesia that follows the defense reactions induced by electrical midbrain tectum stimulation at freezing and escape thresholds. The animals were submitted to the tail-flick test, following the induction of the defensive behavioral responses. The obtained results show that the antinociception that follows the freezing and escape behaviors were not antagonized by central microinjections of the opioid antagonist naltrexone. On the other hand, the fear-induced analgesia was inhibited by microinjections of the serotonergic blockers, methysergide and ketanserin in the DPAG. Since methysergide is a non-specific antagonist of 5-HT receptors and ketanserin acts with high degree of specificity at 5-HT_{1/C} receptors may be implicated in the antinociception induced by DPAG stimulation. Immunohistochemical evidence is also presented for the occurrence of 5-HT-positive perikarya and nerve terminals in the DPAG.

THE ANXIOLYTIC EFFECTS OF R(+)-8-OH-DPAT DIFFER IN THE SEPTUM AND IN THE AMYGDALA. <u>D. Treit* and J. Menard.</u> University of Alberta, Edmonton, Alberta, T6G 2E9.

Previous studies (Pesold & Treit, 1994) showed that intra-septal infusions of a GABA_A-benzodiazepine type anxiolytic (midazolam) decreased shock-probe burying but not shock-probe avoidance, whereas intra-amygdaloid infusions of midazolam decreased shockprobe avoidance but not shock-probe burying. These site-specific effects suggest that the amygdala and the septum exert differential control over different fear reactions. It is not known, however, whether these structures also mediate the effects of nonbenzodiazepine anxiolytics, such as 5-HT_{1A} agonists (e.g., 8-OH-DPAT). In the present experiment, anesthetized rats were chronically implanted with guide cannulae in either the septum or the amygdala. Intra-septal infusions of the selective and highly potent [R] enantiomer of 8-OH-DPAT (5 or 10 μ g) produced a selective decrease in rats' shock-probe burying without affecting the number shock-probe contacts. Conversely, intra-amygdaloid infusions of R(+)-8-OH-DPAT (5 μ g/side) increased the number of shock-probe contacts without decreasing shock-probe burying. These results extend the generality of our previous findings to 5-HT_{1A} type compounds, and further reinforce the contention that the septum and amygdala exert parallel but distinct control over different fear reactions. BEHAVIORAL EFFECTS OF ANABOLIC ANDROGENIC STEROIDS IN PREPUBERTAL RATS

Augustus R. Lumia, Marilyn Y. McGinnis*, Jenna Calabrese and Kirsten Legg Biopsychology Program, Skidmore College, Saratoga Springs, NY 12866, Department of Cell Biology and Anatomy, Mt. Sinai School of Medicine, CUNY, New York, NY, 10029

Anabolic androgenic steroid (AAS) use has increased among adolescents and is associated with increased aggression and violence. This study assessed the effects of chronic AAS exposure on male sexual behavior, sexual preference and aggression in prepubertal male rats. Males were assigned to one of three groups: Group 1 received three weekly injections of Img testosterone propionate (TP); for eleven weeks, Group 2 received TP for five weeks and was then given propylene glycol (PG) for six weeks (withdrawal condition: TPw), Group 3 received PG for eleven weeks. Beginning after the eleventh week of injections, weekly behavioral tests were conducted. Males received 30 min tests for sexual behavior, ten min tests for sexual preference and a ten min test for aggression. Mounts, intromissions and ejaculations were recorded for male sexual behavior tests. For sexual preference, males were placed in a three compartment apparatus and the time spent in the presence of either a sexually receptive or non receptive female was recorded. For aggression tests, males were placed with either an intact or castrated opponent, under three environmental conditions: home cage, opponents cage or neutral cage. The frequency of attacks/fights initiated and submission were recorded. Prepubertal AAS did not effect either sexual behavior or sexual preference. TPw males fought significantly more with intact opponents. TPw males also showed the least aggression against castrated opponents. TPw males were the least aggression was the highest in the home cage against intact opponents for TP males. The results suggest that the potentiation of aggression by AAS is modulated by both the environmental context and the stimulus qualities of the opponent.

REVERSIBLE INACTIVATION OF PREFRONTAL CORTEX DECREASES SPONTANEOUS AND AMPHETAMINE-INDUCED LOCOMOTION IN RATS. M. F. Dent* and D. B. Neill. Department of Psychology, Emory University, Atlanta, GA 30322.

Ablation or dopaminergic denervation of prefrontal cortex (PFC; Cg1 and Cg3) in rats generally yields an increase in locomotion with systemic amphetamine. However, such lesions require a recovery period during which denervation supersensitivity or other reorganizations could develop, thereby enhancing the effects of the amphetamine. Temporary inactivation of PFC with lidocaine has been shown to decrease extracellular DA levels in nucleus accumbens and to suppress burst firing of VTA cells; these effects were the opposite of those obtained from the infusion of glutamate into the PFC. This study examined the effect of reversible inactivation of the PFC on the locomotor response to amphetamine, thought to be mediated by the mesocorticolimbic DA system. Lidocaine (20 µg in 1 µl) infusion into PFC significantly decreased locomotion in a photocell box and attenuated the effect of amphetamine (1 mg/kg IP) in increasing locomotion. These results are consistent with the neurochemical and electrophysiological results and different from the behavioral effects of irreversible ablation

VENTRAL HIPPOCAMPAL INFUSION OF 2% LIDOCAINE ENHANCES AUDITORY STARTLE. J.H. Evans*, C.W. Harley and G. Snedden. Psychology Dept., Memorial Univ., St. John's, NF A1B 3X9 Canada.

In earlier work we observed that large aspiration lesions of hippocampus increased auditory startle. In contrast, ibotenate lesions which affected only the dorsal hippocampus failed to elevate the startle response. Since the large aspiration lesions included much of the ventral hippocampus and since this area is preferentially connected to amygdalar structures we hypothesized that ventral not dorsal hippocampus might modulate auditory startle. Following a 5 minute adaptation to the test chamber, 11 male rats were exposed to 15 8kHz tones of 115dB at 30 s intertrial intervals against a 70dB background noise. The subjects were then implanted with bilateral guide cannulae directed at ventral CA1. Following recovery from surgery they were tested under the same conditions; once following a 1µL injection of 2% Lidocaine hydrochloride (Astra) and once without an injection. Exposure to lidocaine and no lidocaine conditions was counterbalanced. On completion of startle testing subjects were anaesthetized and india ink injected to localize cannulae. One subject was discarded based on lateral placement. The results show that ventral hippocampal lidocaine injections significantly increased auditory startle for the first half of the testing, the probable duration of lidocaine effectiveness. We interpret this finding in terms of a possible inhibitory modulation of amygdala by ventral hippocampus and the known role for amygdala in fear enhanced startle.

ABECARNIL ANTAGONIZES THE ENHANCED ACETYLCHOLINE RELEASE IN RAT BRAIN DURING THE ANTICIPATION BUT NOT CONSUMPTION OF FOOD, C.A.Ghiani*, L. Dazzi, E. Maciocco, G. Maira, G. Flore and G. Biggio, Dept. of Experimental Biology, Chair of Pharmacology, University of Cagliari, 09123 Cagliari, Italy.

The effect of food deprivation, food intake and satiety on acetylcholine (ACh) release from prefrontal cortex and hippocampus was investigated in freely moving rats trained to eat their daily food in 2 h (10-12 a.m./light phase). ACh release increased in cortex (+42%) and hippocampus (+55%) 40-60 min before food presentation. Food intake further increased ACh release 40-80 min from food presentation in hippocampus (+75%) and cortex (+91%). The increase in ACh output from cortex and hippocampus persisted during the two hours of food consumption returning to basal values at different time in cortex and hippocampus after food removal. The increase in ACh output measured before food presentation was prevented by the anxiolytic drug abecarnil (0.05 - 0.1 mg/kg i.p.). In contrast, this drug, also at a dose able to reduce (-50%) markedly ACh release in both brain areas, failed to antagonize the increase of ACh output elicited by food consumption. ³⁵S-TBPS binding to the GABA_A receptors was higher in the brain of fasted rats when compared to fed animals. Our results suggest that while activation of GABA_A receptors by abecamil is crucial to antagonize the increase of ACh output elicited by food consumption of food it failed to prevent the enhancement of ACh output elicited by food consumption suggesting that different mechanisms (GABAergic and nonGABAergic) are involved in the regulation of cortical and hippocampal cholinergic function before and during feeding behaviour.

EFFECTS OF ESTROGEN AND PROGESTERONE ON DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS OF THE FEMALE RAT IN RESPONSE TO SEXUALLY RELEVANT ODORS AND PALATABLE FOOD. E.P. Bless* and J.B. Mitchell. Department of Psychology, Boston College, Chestnut Hill, MA 02167

Existing evidence indicates that activity in the mesolimbic dopamine (DA) system (MLDA) is associated with reward and motivation. One method of recording activity within this system is by measuring DA release in a terminal region, the nucleus accumbens (NACC). Previously, our laboratory has found that DA release in the NACC of the female rat in response to odors from a sexually active male rat is greatest when the animal is in estrus. Conversely, DA release in response to a palatable food (Froot Loops) is greatest during diestrus. The present experiment examined the involvement of the specific ovarian hormones in this effect. DA release in the NACC was measured using electrochemistry in ovariectomized female rats injected with one of the following (each injection was 20 hours apart): estrogen and oil (E), estrogen and progesterone (E) or oil and oil (Oil). Electrochemical recordings were performed while subjects were presented with either male odors or with a palatable food. Subjects were tested 4, 24, 48 and 72 hours after the first hormone injection with each stimulus. Preliminary data indicate that the greatest DA release in response to bedding occurred 24 hours after E+P a scompared to any other time point and hormone treatment. E alone and P alone at the same time point increased release over Oil but not to the same extent as E+P. On the contrary, DA release in response to palatable food was lowest 24 hours after E+P compared with any other time after E+P injection. The largest DA release in response to palatable food occurred 72 hours after E alone. Therefore, it does appear that estrogen and progesterone or either hormone alone alters MLDA activity. Interestingly, the modulation is not to produce a general increase or decrease, but rather is dependent on the stimulus with which the animal is presented.

NALOXONE REVERSES DISINHIBITORY/AGGRESSIVE BEHAVIOR AND SYNAPTIC HYPOACTIVITY IN 5-HT DEFICIENT RATS. B. Söderpalm*. A.I. Svensson. G. Andersson. H. Billig and J.A. Engel. Inst. of Physiol. and Pharmacol, Göteborg Univ., Medicinaregatan 7, S-413 90 Göteborg, Sweden.
Disinhibited, impulsive behavior of e.g. violent offenders, suicidal patients and pati-

Disinhibited, impulsive behavior of e.g. violent offenders, suicidal patients and patients suffering from antisocial personality or substance abuse disorders may involve deficient brain serotonin (5-HT) systems. Brain 5-HT depletion produces aggression/disinhibition also in experimental animals, as exemplified by the 5-HT depletion induced anticonflict effect in conflict models, an effect that may reflect anxiolysis and/or poor impulse control (Soubrié, 1986). Pharmacological manipulations reversing the 5-HT depletion induced anticonflict effect, e.g. negative modulators of GABA_A/benzo-diazepine receptors (cf. Söderpalm & Engel, Life Sci 49:139-153, 1991), also decrease aggressive and alcohol self-administrating behaviors in rats. Naloxone reduces ethanol self-administration and using the stable analogue naltrexone this effect has been confirmed in humans. These findings and indications of GABA_A antagonistic actions of naloxone prompted us to investigate the effects of naloxone on 5-HT depletion induced disinhibitory behaviors, and on the expression of brain c-fos after conflict exposure.

naloxone prompted us to investigate the effects of naloxone on 5-HT depletion induced disinhibitory behaviors, and on the expression of brain *c-fos* after conflict exposure.

1) The anticonflict effect observed after selective 5-HT depletion (5,7-DHT, i.c.v.) in a modified Vogel's conflict model was counteracted by naloxone (0.5-5.0 mg/kg, s.c.). This effect was in turn reversed by a low dose of amobarbital (2.0 mg/kg, i.p.). 2) The number of attacks made by 5,7-DHT-lesioned residents, and the total time spent fighting, was reduced after pretreatment with naloxone (5.0 mg/kg) or the partial inverse benzodiazepine receptor agonist Ro 15-4513 (2.0 mg/kg, p.o.). 3) Exposure to conflict induced less *c-fos*, measured with Northern blot, in the amygdala and frontal cortex in 5,7-DHT-lesioned animals than in controls. This effect was reversed by naloxone.

The present results suggest that naloxone is stable analogue naltexone, or other

The present results suggest that naloxone, its stable analogue naltrexone, or other weak negative modulators of GABA_A/benzodiazepine receptors may alone or in combination with indirect or direct 5-HT receptor agonists represent a new treatment principle for disorders chracterized by poor impulse control and/or low 5-HT function.

VENTRAL TEGMENTAL AREA NON-DOPAMINE NEURONAL ACTIVITY AND RESPONSIVENESS TO ANESTHESIA S.C. Steffensen, S.A. Raymond*, R.-S. Lee, and S.J. Henriksen. Scripps Research Institute, La Jolla, CA 92037 and Anesthesia Research Lab. Harvard Medical School Roston MA 0213.

Anosthesia Research Labs, Harvard Medical School, Boston, MA 0215

The ventral tegmental area (VTA) is an important component of the mesocorticolimbic system and has been implicated in reward, locomotor activity and cognition. Anesthesia alters the firing of VTA dopamine (DA) neurons as well as their responsiveness to dopaminergics and to drugs of abuse. Inhibition of VTA DA neurons by GABAergic (putative non-DA) neurons may be particularly sensitive to specific anesthetics which may contribute to the difficulty in studying the physiology and interdependence of both VTA DA and non-DA neurons in isolation. Therefore, we characterized VTA non-DA neurons nervice and observed their activity during freely-behaving and anesthetized conditions. The following criteria were invoked to distinquish VTA DA and VTA non-DA neurons. VTA DA neurons were driven antidromically from the nucleus accumbens (NAcc) with conduction velocities renging from 0.6-0.8 m/s and spike durations > 500 µs. VTA non-DA neurons were characterized by the following criteria: 1) Exhibited non-bursting spontaneous activity characterized by negative-going action potentials with spike duration < 500 µs; 2) Inhibited by stimulation of the NAcc; 3) Driven antidromically by stimulation of the thalamus, but not NAcc; and 4) Not inhibited by high firing rates (72 ± 5 Hz) that increased 85 ± 6 % before and during the onset of movement. Administration of halothane (1%) while recording from VTA non-DA neurons decreased VTA non-DA firing rate by 71 % and changed the firing pattern into an intermittent oscillation consisting of alternating 0.5-2s on and 0.5-2.0 s off periods (mean=0.43 ± 0.07 Hz), identical to the pattern we had observed for these units in the anesthetized preparation. Chloral hydrate (60 mg/kg) suppressed VTA non-DA activity. These results demonstrate that VTA non-DA neurons are strongly affected by anesthesia and are differentially affected by two anesthetic agents that each produce adequate systemic anesthesia. 449.16

EFFECTS OF NON-SELECTIVE AND BZ-1 (ω1) SELECTIVE, BENZODIAZEPINE RECEPTOR LIGANDS IN THE MOUSE DEFENSE TEST BATTERY. G. Griebel*, D.J. Sanger and G. Perrault. CNS Research Department, Synthélabo Recherche, 31, avenue Paul-Vaillant Couturier, 92220 Bagneux, France.

The behavioral effects of several BZ (ω) receptor ligands were compared using

the Mouse Defense Test Battery (MDTB) which assesses defensive reactions of Swiss mice confronted with a natural threat (a rat) and behavior in situations associated with this threat. Primary measures taken before, during and after rat confrontation were escape attempts, flight, risk assessment and defensive threat and attack. The drugs used included non-selective BZ (ω) full (clonazepam, clorazepate, chlordiazepoxide and diazepam) and partial (bretazenil and imidazenil) agonists, and BZ-1 $(\omega 1)$ selective (abecarnil, CL 218,872 and zolpidem) receptor ligands. The non-selective BZ (ω) receptor compounds only partially reduced some flight measures in response to the approaching rat, except clonazepam which attenuated all flight reactions. In contrast to their mild and inconsistent actions on flight, the non-selective BZ (ω) receptor agonists displayed clear effects on risk assessment when subjects were chased by the rat, but did not affect risk assessment responses when mice were trapped in a straight alley. When contact was forced between the subject and the rat, the agonists reduced defensive threat and attack reactions, while the partial agonists imidazenil and bretazenil only weakly attenuated defensive attack. Similarly, after the rat had been removed from the test area, the non-selective full agonists displayed greater efficacy than the partial agonists in reducing escape attempts. The selective BZ-1 (ω 1) receptor ligands produced no specific effects on defensive behavior. Taken together, these data demonstrate that (1) non-selective BZ (ω) agonists displaying high intrinsic activity affect a wider range of defensive behaviors than non-selective BZ (ω) receptor partial agonists; (2) the defense system does not involve primarily BZ (ω) receptors containing the α 1 subunit.

EFFECTS OF ACUTE AND CHRONIC SOCIAL ISOLATION IN FISCHER-344 AND SPRAGUE-DAWLEY RATS. S.M. Siviy*, B.J. Brubaker, J.H. Birkholz. M.J. Pineault. & T.S. Gilbert, Department of Psychology, Gettysburg College, Gettysburg, PA 17325.

Fischer-344 (F344) rats exhibit a number of neurobehavioral characteristics which make them especially interesting for studying the neural basis of behavior in juvenile rats. In particular, we have found that juvenile F344 rats engage in significantly less play behavior than either Buffalo or Sprague-Dawley rats. Since these differences are exaggerated following longer periods of social isolation, we assessed the extent to which acute and chronic social isolation affected behavior in both F344 and Sprague-Dawley (SD) rats. Rats arrived on postnatal day 21 (P21) and were immediately housed either individually (isolates) or in groups of four (socials). After 7 days, rats were placed in an open field for 60 minutes and activity was automatically monitored. While SD isolates were significantly more active than SD socials, there were no differences in activity between F344 isolates and F344 socials. Housing conditions were maintained and the rats were tested again as adults (P80-P85). At this later time, the isolates of both strains were found to be slightly less active and reared less than the socials. These data show that while these two strains differ in their acute response to isolation-housing, they respond similarly to more prolonged isolation. The extent to which strain differences after acute isolation may reflect age-specific alterations in dopaminergic functioning is currently being pursued and will also be presented, (Supported by a Gettysburg College Professional Development and Research Grant to S.M. Siviv)

EFFECTS OF FOOD RESTRICTION ON MESOACCUMEBENS DOPAMINE RESPONSE TO STRESS

<u>Stefano Puglisi-Allegra*, Rossella Ventura and Simona Cabib,</u> Dip. Psicologia, Universita' di Roma "La Sapienza" and Istituto di Psicobiologia e Psicofarmacologia (CNR), Roma, Italy

Exposure to stressors produces a time-dependent biphasic alteration of dopamine (DA) release in the nucleus accumbens septi (NAS): an initial increase of DA release is followed by a decrease below control levels. This response has been reported in two species, rat and mouse, under different stressful conditions, and using different technical approaches (intracerebral microdialysis and ex vivo tissue levels of 3-methoxytyramine (3-MT)). In mice, 10 but not 3 min of restraint stress induce a significant increase of 3-MT levels in the NAS. A return to basal levels is observed within 20 min of stress exposure and a significant decrease of 3-MT levels below basal vaues is evidend following 30 min of restraint. Mice food restricted for 13 days and then free fed for the following 48 hrs showed a significant increase of 3-MT levels in response to 3 min of retraint. A return to basal levels was observed within 10 min of stress exposure, whilst 30 min of restraint were unable to significantly reduce 3-MT levels below basal values. These results suggest that food restriction is a chronic stressful condition that renders animals more susceptible to stress-induced activation and less susceptible to stress-induced activation and less susceptible to stress-induced activation and less susceptible to stress-induced activation and less susceptible

EFFECTS OF SATIATION ON MONKEY SEPTAL NEURAL ACTIVITY

T. Ono*¹, H. Nishijo¹, T. Kita², K. Terasawa², R. Tamura¹, Depts.
¹Physiol. and ²Japn. Orient. Med., Fac. Med., Toyama Med. & Pharmaceu. Univ., Toyama 930-01, Japan.

Single neuron activity in the septal nuclei (SP) was recorded from water- and food-deprived monkeys during discrimination of objects associated with and without juice. Motivational state of the monkeys was assessed by a clinical test based on behavioral responses to the object associated with juice and raisin. Of 349 neurons recorded from two monkeys, 67 responded in the ingestion phase. Of these 67 neurons, 31 were further tested with the clinical-liquid (juice or water) test in which liquid was provided until the monkey became satiated. These 31 SP neurons were classified into 2 groups: type-I neurons (n=10) responded to juice ingestion with inhibition, and type-II neurons (n=21) with excitation. Spontaneous activity of the type-I, but not type-II, neurons was higher in deprived condition, and decreased as the monkey became satiated by intake of liquid. When the monkey was further tested with juice after satiation with raisin, both spontaneous neural activity and motivational state resumed. Nine type-II neurons responded to the sight of the object associated with juice as well as ingestion of juice in the operant discrimination task. The responses of these type II neurons to both the sight of the object associated with juice and ingestion of juice also decreased by satiation. Both the neural and behavioral responses resumed when the monkey was further tested with raisin. These types-II and II neurons were located mainly in the anterior part of the SP. The results suggest that the activity of type-I neuron might reflect thirst or hunger drive levels, and that responses of type-II neurons might be related to reward perception.

CORRELATIONAL ANALYSIS OF ANIMAL MODELS OF ANXIETY, FEAR, AND DISAPPOINTMENT. <u>Charles F. Flaherty*, Anna Greenwood, and Cynthia Coppotelli</u>. Rutgers University, New Brunswick, NJ Sixty rats were tested in each of four procedures: Elevated plus

Sixty rats were tested in each of four procedures: Elevated plus maze; emergence from home cage to novel open field; conditioned fear to a context (shock US); and successive negative contrast (shift from 32% to 4% sucrose). Correlational analysis revealed only a few interrelationships. For example, rats which tended to emerge sooner into the open field and rats which tended to spend more time in the open arms of the plus maze also tended to show larger decrements in licking following reward reduction—all of which suggested a bias toward exploratory behavior. Factor analysis (oblique rotation) indicated four factors: Elevated plus maze Trial 1 (Generalized anxiety?); Elevated Plus Maze Trial 2 (Phobia?); Conditioned fear and open field emergence (Fear/Timidity?); and negative contrast—degree of behavioral decrement following reward reduction (Disappointment?). The independence of negative contrast and fear was further illustrated by the failure of electrolytic lesions of the central nucleus of the amygdala to affect negative contrast, although fear conditioning, in the same animals, was largely eliminated by this lesion. The data suggest that different emotional states are generated by these tests and that they can be isolated neurobiologically as well as behaviorally.

DIFFERENT MEASURES OF EMOTIONALITY IN CXB MICE.

D. F. Peeler Department of Neurosurgery, Univ. of Mississippi Medical Center, Jackson, MS 39216.

Various measures have been used as indices of emotionality in mice. Different behavioral measures may give different, sometimes conflicting, indications. The contributions of contextual and genetic factors to measures of emotionality were assessed by observing adult male mice (n=51) of the CXB set (2 progenitor, 7 RI strains) in an open-field. Behaviors observed included locomotor activity, grooming, rearing, leaning (rearing against sides), defecation, illumination preference, contact with objects in the field and responses to contextual change. Mice were observed over 3 sessions; 1/3 of the field area was in deep shadow. Objects in the field were relocated between sessions 2 and 3.

There were complex interactions involving genetic and contextual variables. Strain was a pervasively significant factor which interacted with amount of locomotor activity, sector in which locomotion occurred (field center or periphery), illumination level, leaning, defecation, contact with objects and response to object relocation. Behaviors often interpreted as indicative of emotionality in rodents (e.g., defecation) were in some strains contradicted by other supposed measures of emotionality (e.g., exploration). The results indicate that different strains may react differently within a given context and/or that different strains may exhibit different manifestations of emotionality. The interpretation of any behavioral measure must accommodate the potential influences and interactions of both contextual and genetic variables. (Support: Neurosurgery Dept., UMMC.)

DEFENSIVE QUIESCENCE TO SOCIAL STRESS: RELATIONSHIP TO OTHER "IMMOBILE" DEFENSES R.J. Blanchard*, and D.C. Blanchard University of Hawaii, Honolulu, HI 96822.

The mammalian defense repertory encompasses a range of responses, some of them long-lasting. In addition to active, oriented behaviors (e.g. flight and defensive threat and attack) and immobility with orientation and enhanced responsivity to startle stimuli (freezing), there are response patterns involving reduced activity or performance without an orientation component. These have often been labelled in accord with their presumed functions (e.g. submission; as an attack-limiting signal) or psychological processes (e.g. helplessness) which they are presumed to parallel. Relatively little attention has been given to the topography of the responses involved, or to their potential interrelationships.

An emerging body of research on the immediate and long-term consequences of subordination and social stress in rats, mice, and insectivores suggests that subordinate or defeated males may show patterns of reduced activity characterized by hyporesponsivity to a variety of external stimuli, including lowered movement celerity; lack of orientation to danger sources: and an increased duration of immobility in to neck pinch. These may involve specific (midbrain?) neuroanatomic mechanisms with reciprocal inhibitory relationships to those involved in active or oriented defensive responses. We describe these behaviors and suggest the inclusive term of "defensive quiescence" to cover the variety of related behaviors previously described by similar and dissimilar labels.

INDIVIDUAL DIFFERENCES IN THE DEVELOPMENT OF DEFENSIVE BEHAVIORS IN RHESUS MONKEYS: IMPLICATIONS FOR PSYCHOPATHOLOGY. S. Shelton*, N. Kalin . Dept. of Psychiatry, Univ. of Wisconsin Sch. of Med., Madison, WI 33719

Twenty-six rhesus monkeys were tested repeatedly at 4, 8, and 12 months to characterize the expression and development of their defensive responses induced by maternal separation and exposure to a potential threat. By 4 months of age, monkeys showed adult-like adaptive context dependent responses. separated and alone, infants emitted frequent coo vocalizations; when exposed to the facial profile of a human intruder, infants engaged in freezing behavior. By 8 months of age, separation-induced coos were dramatically reduced, whereas the duration of threat-induced freezing remained unchanged. At 12 months, a further decrease in cooing occurred without a reduction in freezing. Individual differences in responding to the different contexts occurred and remained stable. However, no relation was found between the amount of cooing emitted during separation and the duration of threat-induced freezing. Over the entire period of testing, separation-induced coos demonstrated a logarithmic decrease in all but 3 of the animals tested. These 3 animals may provide a model to study factors of the animals tested. These 3 animals may provide a model to state associated with a vulnerability to develop psychopathology induced by loss. Greater individual variability in the patterns of change in freezing behavior occurred over the period of testing; 17 animals were unchanged, 6 animals decreased, and 3 increased their amount of freezing from 4 to 12 months. Taken together, these results demonstrate stable individual differences in separationinduced cooing and threat-induced freezing and lend support to data suggesting that defensive responses elicited by attachment bond disruption are regulated differently than those elicited by exposure to threatening situations. In addition, this developmental approach provides a strategy to identify, early in life, individuals at risk to develop stress-related psychopathology.

BIOLOGICAL RHYTHMS AND SLEEP: CIRCADIAN RHYTHMS II

451.1

ARE THERE MORPHOLOGICALLY AND ELECTROPHYSIOLOGICALLY DISTINCT SUBPOPULATIONS OF CHICKEN PINEAL CELLS? Theresa D'Souza* & Stuart E. Dryer Prog. Neurosci., Florida State University, Tallahassee, Fl 32306.

Chicken pineal cells express an intrinsic circadian oscillator that persists in dissociated cell culture. In previous studies we noted that acutely-isolated chick pineal cells exhibit marked variability in the nature and amplitude of voltage-evoked K+ currents (1). Here we have examined the electrophysiological properties of chicken pineal cells maintained in dissociated cell culture for five days under 12:12 light-dark cycles. Whole-cell recordings were made under normal illumination 4-6 hr after light-on or under infrared illumination 4-6 hr after lights-off. In addition to fibroblasts, these cultures contained two types of cells that could be distinguished on the basis of size and shape. The first type had a small cell body (7-9 µm in diameter) with a single rod-shaped process extending a few microns from the cell body. The second type was spherical and larger (10-14 µm diameter), and did not elaborate any processes. These cells also had a larger nucleus and a more granular appearance under modulation contrast optics. Currents were evoked by a series of depolarizing voltage-steps from a holding potential of -60 mV. Peak outward currents measured at +20 mV in the small cells as a group were 318 ± 26 pA (mean ± s.e.m.). Peak currents during the day were 340 \pm 35 pA (n. s.). Peak outward currents in the larger cells as a group were 84 \pm 10 pA (P < 0.001 compared to small cells). Peak currents during the day were 92 \pm 18 pA, whereas currents during the daytime were 80 \pm 12 These results suggest that voltage-activated K+ currents of chick pineal cells are not under circadian control and they raise the possibility that the pineal gland contains morphologically and functionally distinct cell types. ZINC SENSITIVITY OF GABA $_{\Lambda}$ -MEDIATED SYNAPTIC CURRENTS IN THE RAT SUPRACHIASMATIC NUCLEUS.

G.J. Strecker* and F.E. Dudek. Dept. Anatomy and Neurobiology, Colorado State Univ., Fort Collins, CO 80523.

GABA is the main neurotransmitter in the suprachiasmatic nucleus (SCN). Little is known, however, about which form of GABA receptor exists in this region. The SCN appears to contain significant levels of Zn^{2+} , which could modulate GABAergic function. Zn^{2+} is known to block some GABA_A-receptor channels, but not others. We have used whole-cell voltage-clamp recordings from acute hypothalamic slices containing the SCN to determine the Zn^{2+} sensitivity of SCN neurons from rats aged 22-28 days.

Miniature GABA_A-receptor-mediated IPSCs (mIPSCs) were recorded in a mixture of TTX (1 μ M) and glutamate receptor channel antagonists AP5 (15 μ M) and DNQX (30 μ M). The addition of ZnSO₄ (200 μ M) significantly reduced the amplitude of mIPSCs in 7 of 8 cells (Kolmogorov-Smirnov test, 2-sample) to 57% \pm 4% (8.E.M.) of control mean amplitude. Zn²-induced amplitude reductions were significantly reversed after Zn²- removal (n = 3), but only partially.

 Zn^{2+} also reduced the apparent frequency of mIPSCs in 7 of 8 cells $(\chi^2$ test, 2-sample) to 57 ± 9% of control. All PSCs remaining in the presence of Zn^{2+} were completely and reversibly blocked with the GABA_r-receptor antagonist bicuculline methiodide (30 μM_{\star} n = 3). Zn^{2+} -induced frequency reductions were significantly reversed after Zn^{2+} removal (n = 3). These results suggest that GABA_r-mediated synaptic transmission in the SCN can be attenuated by Zn^{2+} and raise the possibility that Zn^{2+} is a modulatory element in the function of the circadian timing system

ULTRASTRUCTURAL DISTRIBUTION OF POLYSIALYLATED NEURAL CELL ADHESION MOLECULE (PSA-NCAM) IN THE SUPRACHIASMATIC NUCLEI OF THE ADULT MOUSE. H. Shen', M. Watanabe ² & J. D. Glass' 1 Dept. of Biological Sciences. Kent State Univ., Kent. Ohio 44242; ² Division of Pediatric Cardiology. Dept. of Pediatrics, Rainbow Babies & Children Hospital, Case Western Reserve Univ., Cleveland. Ohio 44106.

In a previous study we demonstrated robust expression of polysialylated neural cell adhesion molecule (PSA-NCAM) in the hamster suprachiasmatic nuclei (SCN). In the present study, this characterization was extended to the ultrastructural level using immunoelectron microscopy. Neuronal and glial elements both expressed immunoreactive PSA-NCAM on the cell membrane. In neurons, reaction product was unevenly distributed on the plasmalemma of somata, dendrites and axons. The closely packed unmyelinated axon fascicules were particularly immunoreactive. For glia, immunostaining was sparse on the somata and main shafts of astrocytes. However, fine astrocytic processes were frequently immunopositive in regions where they were interposed between adjacent neuronal somata. Labeling of glial processes was also associated with the neuropil and their investment of outer capillary walls. Consistent with an antiadhesion property of PSA-NCAM, direct neuronal and/or glial cell surface contacts were existent in membrane regions not expressing PSA-NCAM. In view of the hypothesized role of PSA-NCAM in modulating contact-dependent cell-cell interactions and facilitating neuroplasticity in the adult brain, these findings are evidence for a role of this molecule in regulating cellular interactions in the mammalian biological clock (AFOSR F49620-93-0086 JDG)

AFFERENT CONNECTIONS OF THE INTERGENICULATE LEAFLET OF THE GOLDEN HAMSTER: A COMBINED RETROGRADE AND ANTEROGRADE TRACING STUDY. N. Vrang* 1 and J. D. Mikkelsen². Inst. of Med. Anat., Univ. of Copenhagen, Denmark and ² Dept. Neurobiol., Res. and Dev., H. Lundbeck A/S. Copenhagen, Denmark.

Recently, it has been proposed that the NPY-containing geniculohypothalamic tract plays a central role in mediating non-photic phase-shifting. However the central areas conveying non-photic information to the IGL are unknown. To investigate the afferent connections of the IGL in the golden hamster the retrograde tracer Cholera toxin, subunit B were injected into the IGL. Subsequently, the anatomical organization of fibers projecting to the area of the IGL were studied in a series of anterograde tracing experiments using Phaseolus vulgaris-leucoagglutinin. The tracings revealed projections to the IGL from relatively few but widespread areas in the fore- and mid-brain. Limbic system: A projection to the IGL arising from cells in layer 5 and 6 of the ipsi-lateral prefrontal cortex (cingulate areas CG1 and CG2) was identified. A dense ipsilateral projection to the IGL was found from the rostral part of the zona incerta Hypothalamus: Neurons with a bilateral distribution in the dorsal cap of the SCN and in the retrochiasmatic area project to the SCN. Additionally the IGL is bilaterally innervated from the ventromedial hypothalamic nucleus. Visual system: Besides a dense innervation from the contralateral IGL, the IGL receives a predominantly ipsilateral projection from the olivary, posterior and medial pretectal nuclei. Brainstem: Ipsilateral projections from the cuneiform nucleus and the dorsal raphe nucleus were identified. The present data demonstrates, that in addition to its direct retinal input, the IGL receives inputs from other visual areas as well as regions belonging to the limbic system, the latter possibly involved in non-photic (arousing) mechanisms. Located upstream and reciprocally connected to the clock the IGL is therefore in a position to integrate/ modulate photic and non-photic information before it is relayed to the clock itself. This study was supported by a grant from the Danish Medical Research Council.

DIURNAL OSCILLATION OF FOS-LIKE IMMUNOREACTIVITY IN AFFERENT CELL POPULATIONS OF THE RAT SUPRACHIASMATIC NUCLEUS. M. M. Moga.* Dept. Anatomy, Indiana Univ. School of Medicine, Terre Haute, IN 47809

In the rat brain, the proto-oncogene c-fos shows a spontaneous oscillation in its basal expression corresponding to the sleepwake cycle. Increased levels of Fos protein and c-fos mRNA are observed in specific cell populations during periods of wakefulness (e.g., subjective night in the rat). In the present study, we examine whether any of these state-dependent Fos-like immunoreactive (Fos-lir) cell populations project to the suprachiasmatic nucleus (SCN), the mammalian circadian Cholera toxin subunit B (CTB) injections were placed into the SCN of albino rats. Five days later, animals were sacrificed at one of two timepoints, ZT 3/4 or ZT 15/16 (12:12 L:D cycle; lights on at ZT 0). At ZT 3/4, a few double-labeled cells (i.e., cells containing both Fos-lir and CTB) were found in the anterior part of the paraventricular thalamic nucleus. At ZT 15/16, a small number of double-labeled cells were observed in several different SCN afferent cell populations, including the paraventricular thalamic nucleus, the posterior hypothalamic area and the medial pretectal area. These findings show that the SCN receives input from cell groups which are metabolically active at specific circadian timepoints, and suggest that the SCN receives state-dependent feedback from a variety of neural sources. Supported by Indiana Univ. School of Medicine.

ELECTROPHYSIOLOGICAL EVIDENCE FOR THE ROLE OF SUBSTANCE P IN RETINOHYPOTHALAMIC TRANSMISSION IN RATS. Y.I.Kim*, H.C.Shin!, J.-M.Chung² and S.K.Hong. Dept. Physiol., Korea Univ. Coll. Med., Dept. Physiol.

Hallym Univ. Sch. Med. and ²Dept. Biol., Ewha Womans Univ., Seoul, Korea. In mammals, the retinohypothalamic transmission is a key step for entrainment of circadian rhythms to the environmental light-dark cycle. Although excitatory amino acids are thought to be the neurotransmitters utilized in this transmission, other neuroactive substances such as substance P (SP) have also been suggested. SP-like immunoreactivity has been reported to be present in the retinal ganglion cell fibers projecting to the hypothalamic suprachiasmatic nucleus (SCN). Furthermore, the phase-shifting effects of exogenously applied SP on the circadian rhythms of SCN neuronal activity have been demonstrated employing rat hypothalamic slice preparations. In the present study, we sought to provide physiological evidence for the role of SP by examining the effect of a sought to provide physiological evidence for the role of SF by examining the critect of SP antagonist on the phase delay of the circadian unit activity rhythm induced by optic nerve stimulation. Male S-D rats (80-150g), kept in 12-h 1/12-h D environment (light started at ZT0) for ≥ 2 wk, were used in this study. Under Nembutal anesthesia (100 mg/kg, ip.; at ZT11-12), the brain was removed and parasagittal brain slices (550 μ m) containing the SCN and the optic nerve were cut. These slices were transferred to a modified Haas-type gas interface recording chamber perfused with HEPES-buffered artificial cerebrospinal fluid (pH 7.4, 34-36°C, bubbled with 100% O2). At ZT15, the arthrical cerebrospinal hind tpt 7.4, 34-36*C, buddled with 100% 02.3 At 2115. at coptic nerve was stimulated (50V, 0.5 ms. 2 Hz, 10 min) with or without bath application (-15 min) of the SP antagonist L-703,606 (10 µM, NK1 type; RBI, USA). For control slices, sham stimulation was performed. On the next day single-unit recordings were obtained from the SCN. In control slices, the peak of the unit activity rhythm was detected at ZT5.67±0.67 (SEM, n=3). In slices stimulated in the presence and absence of the antagonist, the peaks were at ZT7.17±0.79 (n=6) and 9.0±0.71(n=5), respectively. These data demonstrate partial blockade of the optic nerve stimulation-induced phase delay by the SP antagonist, and therefore, support the hypothesis that SP plays a role in retinohypothalamic transmission in the rat. (This research was supported by The Hallym Academy of Sciences, Hallym University.)

RETINAL SYNAPSES ON CALBINDIN-IR CELLS OF THE HAMSTER SUPRACHIASMATIC NUCLEUS: A DOUBLE LABEL IMMUNO ELECTRON MICROSCOPY STUDY. D.N. Bryant*1, J. LeSauter2, R. Silver2 and M-T. Romero 1. 1 Depart. of Psychol., SUNY at Binghamton, Binghamton, NY 13902; ²Barnard Col. Columbia Univ. NYC, NY 10027.

It is well established that pacemaker cells of the suprachiasmatic nucleus (SCN), a heterogeneous hypothalamic region, regulate circadian rhythmicity, and that light a heterogeneous hypothalamic region, regulate curcadian rhythmicity, and that light acts as an entraining signal. In the search for the identity of the pacemaker cells within the SCN, one method involves following the pathway of photic input from the eye to specific cells of the SCN. We recently described a subregion within the hamster SCN which expresses calbinindin-D28K (CaBP) (Silver et al., Neuroreport, 1996). Several lines of evidence suggest that these cells may be pacemaker neurons: First: approximately 75% of the CaBP-ir cells co-express fos in hamsters exposed to light at CT 18. Second, destruction of the CaBP-ir cells co-express for the campaign and the control of the cabp-ir cells co-express for the capped and the capped of subnucleus renders animals arrythmic in their locomotor activity, even when other parts of the SCN are spared (LeSauter et al., Soc. Neurosci. Abstr.,1995, 21: 178).

Light microscopic evidence indicates that retinal inputs visualized following bilateral intraocular choleratoxin B subunit (CT) injections terminate in the CaBP rich area of the SCN. In order to assess whether the CaBP-ir cells receive direct retinal input, we used double label immunoelectron microscopy to identify retinal terminals on CaBP neurons or dendrites. A random sampling at a single level of CaBP-ir neurons and dendrites shows that labeled CT retinal terminals appose both CaBP perikarya and dendrites. CT labeled terminals also contact other, nonidentified neurons and dendrites. CaBP labeled terminals are found in close apposition with other CaBP-ir perikarya and dendrites. The results indicate that CaBP-ir cells of the core region of the SCN may be important in the entrainment effects of light in the hamster. Furthermore, there is reciprocal innervation among CaBP elements, consistent with the integration if activity among pacemakers necessary for controlling circadian rhythms.

EXPRESSION OF FOS-LIKE IMMUNOREACTIVITY IN SYRIAN HAMSTER HYPOTHALAMUS IN RELATION TO BEHAVIORAL STATE. C. Henschel and F.C. Davis*. Dept. of Biology, Northeastern Univ., Boston, MA 02115.

The expression of Fos-like immunoreactivity has been shown to be highly correlated with sleep and sleep duration prior to sacrifice in the ventrolateral preoptic area of the rat hypothalamus (Sherin et al., 1995). Using immunohistochemistry we examined the expression of Fos-IR in the brains of adult Syrian hamsters (Mesocricetus auratus) that were observed to be in different behavioral states in the hour preceeding sacrifice. Hamsters were individually housed in wheel-running cages maintained in constant dim light (-1 lx) and there wheel-running activity rhythms were measured for several weeks prior to observation. On the day of sacrifice, 7 hamsters were observed every 5 minutes for at least an hour. Three hamster were awake (by behavioral criteria) for the preceeding hour, one was asleep for at least the last 35 minutes before sacrifice, and three were asleep for at least 45 minutes. Hamsters were deeply anesthetized with sodium pentobarbitol before being intracardially perfused with phosphate buffered saline followed by 4% paraformaldehyde. Brains were postfixed overnight, then cryoprotected with 20% sucrose in PBS. 60 µm coronal sections were cut and put through an IHS procedure. Preliminary results indicate that in sleeping hamsters, cell nuclei showing Fos-IR were most common in an area just lateral to the paraventricular nucleus of the hypothalamus with a few also observed in the dorsal suprachiasmatic nucleus (SCN). In awake hamsters, Fos expression was common throughout much of the hypothalamus with particularly high density of stained nuclei in the ventral SCN. These results suggest that Fos expression in the hypothalamus, particularly the SCN, is correlated with behavioral state. The observed differences in Fos expression are not likely be the animals' behavioral states which might not have been influenced by the

451.8

THE DIURNAL RHYTHM OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) GENE EXPRESSION IN THE SUPRACHIASMATIC NUCLEI (SCN) IS DIFFERENT IN MALE AND FEMALE RATS. K. Krajnak*, K.L. Rosewell and P.M. Wise. Dept. of Physiology, Univ. of Kentucky, Lexington, KY 40536. In female rats, the timing of the surge of luteinizing hormone (LH) is supplyed to the light (and if D) wide. Studies appropriate to the light (and if D) wide. Studies appropriate to the light (and if D) wide.

synchronized to the light/dark (LD) cycle. Studies suggest that VIP neurons in the SCN influence both the timing and amplitude of the LH surge by regulating gonadotropin releasing hormone (GnRH) neurons. If true, we would speculate that VIP gene expression changes during the morning, just prior to the LH surge to signal a change in GnRH release. Such a pattern of expression would be dramatically different than that reported in males, in which VIP mRNA levels are suppressed during the light period. To test this, we examined VIP gene expression in the SCN of female rats that were housed in a 14:10 LD cycle (lights on 0400h), ovariectomized for one week and treated with estradiol to induce a daily LH surge. VIP mRNA was measured at various points over the LD cycle, using *in situ* hybridization. A riboprobe was transcribed using a 1kb fragment of the VIP cDNA that encodes for exon 6 and VIP mRNA was assessed in individual cells. VIP gene expression was low at 0300h peaked at 1200h prior to the afternoon surge of LH and then decreased by 2300h. These results indicate that the diurnal rhythm of VIP gene expression is different in male and female rats, and suggest that changes in VIP mRNA within the SCN of females are correlated with the activation of GnRH neurons. (Supported by NIH AG02224 to PMW).

IMMUNOCYTOCHEMICAL ANALYSIS OF THE SUPRACHIASMATIC NUCLEUS OF COMMON MARMOSET Callithrix jacchus . J. Lu*1, L. F. S. Moreira^{1,2}, V. Alones¹, M. S. O. Costa², A. A. L. Menezes², M. Menaker¹, Dept. of Biology¹, Univ. Virginia, VA 22903, USA; Depto.de Fisiologia², Univ. Fed. Rio Grande do Norte, RN, Brazil.

The common marmoset, Callithrix jacchus, a new world diurnal primate, shows a free-running locomotor circadian rhythm in constant dim light. The animals also display a phase response pattern similar to other mammals. In this study, we tried to identify the suprachiasmatic nucleus (SCN), the biological clock using immunohistochemical techniques. Perfused marmoset brains were shipped from Natal, RN (Brazil) to UVa where histology was performed. 30 µm frozen transverse sections were collected in a series of six and stained for vasopressin (VP), vasoactive intestinal polypeptide (VIP), neuropeptide Y (NPY), glial fibrillary acidic protein (GFAP), mammalian GnRH and GABA, and visualized with standard ICC techniques. The SCN is located above the opticchiasm, lateral to the third ventricle in the anterior hypothalamus, which is consistent with a previous tract-tracing study done in our laboratory. A few small VP immunostained cells were found in the SCN. In contrast, numerous large VP-IR cells were found in the supraoptic nucleus (SON). GFAP, the astrocyte marker, heavily labeled the SCN. NPY-IR fibers were found in the SCN, but no NPY-IR neurons were found in the presumed intergeniculate leaflet (IGL) which has been shown to project the NPY to the SCN in many species in mammals including primates. Intraventricular injections of colchicine may be necessary to visualize NPY cells in the IGL. Supported by NIH T32-HD07328 (JL), CNP4(LFSM) and AFOSR F49620-1-0356 (MM and VA)

TUESDAY AM

NEUROTROPHIN AND NEUROTROPHIN RECEPTOR EXPRESSION IN THE SUPRACHIASMATIC NUCLEUS (SCN) OF RATS AND HAMSTERS, M.N. SUPRACHIASMATIC NUCLEUS (SCN) OF RATS AND HAMSTERS. M.N. Lehman*, H.T. Jansen, M. Wortman, P. Stevens², C. Kim, R.B. Norgren¹ and P. Zeitler² Dept. Cell Biol., Neurobiol. & Anat. and Neurosci. Program, Univ. Cincinnati, Cincinnati, OH 45267; ¹Dept. Cell Biol., U. Nebraska Med. Ctr., NE 68198; ²Div. Endocrinol., Children's Hosp. Res. Foundation, Cincinnati, OH 45267

In addition to their trophic actions, neurotrophins (NT) may act as neuromodulators in the adult brain (Kang and Schuman, Science, 267:1658). One example may be in the SCN circadian pacemaker, since NGF injections can phase shift circadian activity rhythms in the hamster (Golombek et al., Physiologist, 38:A22). Neurons in the rat SCN express BDNF (Liang et al., Neurosci. Abstr., 21:453) and p75 (Sofroniew et al., Brain Res., 476:358), but other NTs and NT receptors have not been examined. We used reverse transcription-polymerase chain reaction (RT-PCR) to screen the rat and hamster SCN for mRNAs encoding NGF, BDNF, and NT-3, and the receptors p75, TrkA, and TrkC. Total RNA (2µg) was reverse transcribed from microdissected SCN, forebrain and hippocampus of juvenile male rats (n=3) and hamsters (n=5). Primers specific for each NT and NT receptor were used to identify corresponding cDNAs. A constitutive ribosomal mRNA species (S12) served as an internal control Forebrain and hippocampal extracts of both rat and hamster contained PCR products of appropriate size. The rat SCN region contained NGF, BDNF, NT-3, and TrkC, but not TrkA mRNAs. By contrast, the hamster SCN region contained NT-3, TrkA, and TrkC mRNAs; NGF, BDNF and p75 mRNAs were not detected. Cloning and equencing of cDNAs for hamster NGF, NT-3 and TrkC demonstrated strong homology to NT sequences in other species. Immunocytochemistry confirmed the species differences in TrkA and p75 in the SCN: the hamster SCN contained TrkApositive cells but not p75, while the converse was true for the rat SCN. Despite these differences, it appears that both rat and hamster SCN regions contain TrkC and NT-3 mRNAs. The precise localization of these NTs and receptors, and their role in circadian pacemaker function, are under investigation. Supported by Univ. Cincinnati.

PEPTIDERGIC INNERVATION OF GONADOTROPIN RELEASING HORMONE (GnRH) NEURONS IN FEMALE SYRIAN HAMSTERS. Kim L. Huhman* & Eline M. van der Beek. Dept. Psych., Georgia State Univ., Atlanta, GA 30303; Dept. Human & Animal Physiol., Agricultural Univ. Wageningen, Haarweg 10, Wageningen 6709 PJ, Netherlands.

The GnRH cells that control the preovulatory surge of luteinizing hormone (LH) are known to receive timing information from the circadian clock in the suprachiasmatic nucleus (SCN). In rats, SCN projections to GnRH neurons contain vasoactive intestinal peptide (VIP). Other SCN efferents contain vasopressin (AVP) and perhaps peptide histidine isoleucine (PHI). The purpose of the present experiment was to examine the peptidergic innervation of GnRH neurons that are activated during the LH surge (as evidenced by colocalization of Fos-ir) in female hamsters. Groups of 3 hamsters were killed at 4 time points on the afternoon of proestrus (1100, 1300, 1500, 1700 hr with lights off at 1800 hr) and triple-stained immunohistochemically for GnRH, Fos and either VIP, PHI or AVP. PHI fibers were apposed to 12-28% of GnRH neurons including those activated during the LH surge, and the distribution of these fibers appeared to be very similar to that seen in rats. In contrast to rats, only a small percentage of the GnRH neurons were found in association with VIP-ir fibers. Finally, GnRH neurons in the caudal preoptic area were consistently innervated by AVP fibers These data suggest that PHI, and to a lesser extent VIP and AVP, might signal the LH surge via SCN efferents in hamsters.

SEROTONIN (5-HT) RECEPTOR BINDING AND mRNA EXPRESSION IN THE RAT SUPRACHIASMATIC NUCLEUS (SCN). P.A. Scott*, M. Cagle, & M.A. Rea. Krug Life Sci. and BRAIN Res. Inst., Armstrong Lab., Brooks AFB, TX 78235, and Dept. of Pharm., UTHSCSA, San Antonio, TX, 78284.

Circadian rhythms are entrained to the environmental light-dark cycle as a consequence of daily light-induced adjustments in the phase of the circadian clock located in the suprachiasmatic nuclei (SCN) of the hypothalamus. Previous work has shown that serotonin (5-HT) serves to modulate the response of the circadian clock to light through a mechanism involving activation of a 5-HT_{1A}-like receptor (Rea et al, 1994). To further elucidate the nature of the 5-HT receptor(s) responsible for the regulation of the photic response of the SCN, we have characterized the pattern of expression of 5-HT receptors in the SCN using in situ hybridization and quantitative receptor autoradiography.

In situ hybridization using an antisense cRNA probe for the rat 5-ht, receptor revealed the presence of a dense cluster of 5-ht₇-positive cells localized to the anterior SCN. At more caudal levels, the major band of 5-ht₇-expressing cells extended from the dorsal lateral border of the SCN into the subparaventricular zone. Only a few scattered 5-ht₇-positive cells were observed in the ventral aspect of the SCN throughout its rostro-caudal extent.

Quantitative receptor autoradiography was performed on SCN sections prepared at circadian time 19 using 1 H]-8-OH-DPAT (0.6-0.8 nM) in the presence of either pindolol (1 μ M) or ritanserin (0.5 μ M). Nonspecific binding was defined using 10 µM 5-HT. Results showed that approximately 80% of [3H]-8-OH-DPAT binding was pindolol-sensitive, while approximately 20% was ritanserin-sensitive. This suggests that the majority of [³H]-8-OH-DPAT binding in the SCN is to the 5-HT_{1A} receptor subtype

BRAIN-DERIVED NEUROTROPHIC FACTOR AND TrkB RECEPTORS IN THE RAT SCN: DISTRIBUTION AND FUNCTIONAL IMPLICATIONS. F.-O. Liang*, R. Miranda, F. Sohrabji, C. Brooks and D. Earnest. Dept. of Human Anatomy, Texas A&M Univ., College of Medicine, College Station, TX 77843.

Since light regulates expression of the mRNAs for brain-derived neurotrophic factor (BDNF) and its cognate receptor, TrkB, in other retinorecipient targets and TrkB tyrosine kinase receptors have been localized in retinal ganglion cell axons within the optic chiasm, the present study examined anatomical and functional associations between this neurotrophic and its receptor in the rat suprachiasmatic nucleus this neurotrophin and its receptor in the rat suprachiasmatic nucleus

(SCN).

Cytoplasmic expression of hybridization signal for BDNF mRNA and BDNF-immunoreactivity was separately observed within a number of cells in the rat SCN. Cells expressing BDNF mRNA and BDNF-immunoreactive profiles were distributed in similar patterns throughout the entire SCN. Expression of BDNF mRNA and protein was also evident within some cells in the optic chiasm. Immunostaining for the TrkB receptor, which preferentially binds BDNF, was mainly observed in terminals and small fibers within the ventrolateral SCN and within the optic chiasm. Dual application of in situ hybridization and immunocytochemical techniques revealed that cells expressing BDNF mRNA in the ventrolateral SCN were often closely apposed to TrkB-positive fibers emanating from the optic chiasm. Some cells within the dorsomedial SCN were uniquely characterized by the coexpression of both TrkB-immunoreactivity and BDNF mRNA.

Since interactions between BDNF and the TrkB receptor have been implicated in the short-term regulation of synaptic transmission within

implicated in the short-term regulation of synaptic transmission within the CNS, continuing research will examine the possibility that similar mechanisms may play a role in the circadian and/or photoentrainment functions of the SCN.

CHARACTERIZATION OF RECEPTORS MEDIATING EFFECTS OF SEROTONIN (5-HT) ON PHOTIC RESPONSES OF HAMSTER SUPRACHIASMATIC NUCLEUS (SCN) CELLS. S.-W. Ying and B. Rusak, Dept. of Psychology, Dalhousie Univ., Halifax, Nova Scotia, Canada B3H 4J1

5-HT has been shown to phase-shift rodent circadian rhythms, but the receptors mediating these effects remain uncertain. We demonstrated previously that 5-HT agonists active at the 5-HT_{1A} receptor suppress photic responses of hamster SCN cells, but these drugs also have high affinity for the recently cloned 5-HT₇ receptor. We therefore assessed drugs with differential affinities for 5-HT₇ and 5-HT_{1A} receptors for their effects on photic responses of hamster SCN cells. Hamsters were anesthetized with urethane and responses of cells to retinal illumination, and their sensitivity to drugs were studied using multibarrel micropipettes to record single-unit activity and to apply drugs iontophoretically.

The 5-HT agonists 5-HT, 8-OH-DPAT and 5-carboxamidotryptamine

all depressed spontaneous activity and photic responses of SCN cells. Drugs with high affinities for the 5-HT, receptor, but not the 5-HT $_{1A}$ receptor, clozapine and ritanserin, were able to antagonize these effects of 5-HT agonists, while cyanopindolol was ineffective. The putative 5-HT_{1A} antagonists WAY100635 and p-MPPI did not antagonize the effects of 8-OH-DPAT on SCN cells, but did antagonize those on hippocampal cells. In the cerebellar cortex, where there are few 5-HT₇ receptors, ritanserin was not an effective antagonist for the effects of 8-OH-DPAT. These results support the hypothesis that the influence of 5-HT on SCN cells is mediated by a receptor that is pharmacologically most similar to the 5-HT₇ receptor.

LOCAL SEROTONIN AGONISTS DOSE-DEPENDENTLY ATTENUATE LIGHT-INDUCED PHASE ADVANCES OF CIRCADIAN ACTIVITY RHYTHMS IN HAMSTERS. E.Todd Weber*, Anna.M. Michel, Robert L. Gannon and Michael A. Rea. Biological Rhythms and Integrative Neuroscience Research Institute, Armstrong Laboratory (CFTO), Brooks AFB, TX.

Light-induced phase shifts of the suprachiasmatic nuclei (SCN) are modulated by serotonin (5-HT). In order to elucidate the site of action of 5-HT agonists on light-induced phase advances and the receptor subtype(s) responsible for serotonergic modulation of phase advances and the receptor subtype(s) responsible for serotonergic modulation of phase advances, 80-H-DPAT and 5-carboxyamidotryptamine (5-CT), compounds with high affinities for 5-HT_{1A} and 5-HT₁ receptors, were injected into the region of the SCN of Syrian hamsters prior to light pulses sufficient to induce phase advances of the circadian clock. Animals received 0.3 μl of either vehicle, 5-CT or 8-OH-DPAT, 10 minutes prior to 10 minutes of 20 lux white light at circadian time (CT) 19 and returned to DD for 10-14 days. Pretreatment with either 5-CT (1 μM= 72 ± 15, 10 μM= 40 ± 8, 100 μM= 28 ± 7 mins, mean ± SEM) or 8-OH-DPAT (1 μM= 47 ± 14, 10 μM= 33 ± 6, 100 μM= 23 ± 11 mins) dose-dependently attenuated light-induced phase advances (vehicle controls= 73 ± 9 minutes). Furthermore, systemic 8-OH-DPAT was equally effective at inhibiting light-induced phase shifts in 5,7-dihydroxytryptamine-lesioned hamsters (21 + 7 mins versus control, 87 ± 8 mins). Systemic 8-OH-DPAT (0.5 mg/kg; 1), attenuation of light-induced phase advances (53 ± 12 mins) so control 17 ± 29 mins) was blocked by WAY 100,635 (5 mg/kg, 98 ± 16 mins), but not by pMPPF (5 mg/kg, 65 ± 16 mins), both reportedly 5-HT_{1A}-specific antagonists. Together, these results strongly support serotonergic modulation of photic input at the level of the SCN. Furthermore, the serotonin receptor(s) that mediate the inhibitory effect of 8-OH-DPAT in the hamster has pharmacological properties of both 5-H

ACTIVITY OF 8-OH-DPAT ENANTIOMERS AT THE 5HT7 RECEPTOR IN SCN AND TRANSFECTED CHO CELLS. J. D. Miller, Z. W. Liu, and T. Tenner. Deptartment of Pharmacology, Texas Tech University School of Medicine, Lubbock, TX79430.

A new member of the 5HT receptor family, 5HT7, has recently been cloned and characterized. This receptor is positively coupled to adenylate cyclase. If has been suggested that this receptor is responsible for 5HT-induced phase advances in the suprachiasmatic nucleus (SCN). A complicating factor is the presence of 5HT1A receptors in the SCN, which may also be occupied by the most selective known ligand for 5HT7, 8-OH-DPAT. To further investigate the pharmacology of the 5HT7 receptor, we have examined the activity of the enantiomers of 8-OH-DPAT in 5HT7-transfected CHO cells. We have found that (+) 8-OH-DPAT (EC50=75 nM) is about 25 times more potent at the 5HT7 receptor than (-) 8-OH-DPAT (EC50=1.9 μM) in elevating the activity of the cyclase. In contrast, the published (Cornfield et al., 1991) potency ratio (for inhibition of hippocampal adenylate cyclase) of the 8-OH-DPAT enantiomers at 5HT1A is about 2.4 (EC50(-) / EC50(+) =135 nM / 57.4 nM), suggesting that the (+) isomer is roughly equipotent at the two receptors and that the (-) isomer is much more potent at 5HT1A. The 5HT7/5HT2 antagonist, ritanserin (10 µM), suppresses cyclase activity in the transfected CHO cells (57% reduction in basal cyclase activity). In cultured SCN cells (21 days postnatal) preliminary results indicate that (+) 8-OH-DPAT (10 µM) elevates an outward, voltage dependent, TEA-sensitive current that appears to be I_{K^*} (-) 8-OH-DPAT (10 μ M) and the 5HT1A antagonist, pindolol, have no effect on this current, but it is potently suppressed by ritanserin (10 µM). These results support the hypothesis that the 5HT7 receptor is the functionally important 5HT receptor for 5HT-induced phase advances in the SCN and that the phase shift may involve the opening of a potassium channel. Supported by NIA AG11084-03.

LABEL AND ELECTRICAL COUPLING OF NEURONS IN RAT SUPRACHIASMATIC NUCLEUS (SCN). Z. G. Jiang*, Y. Q. Yang and C.N. Allen Center for Research on Occupational and Environmental Toxicology and Department of Physiology and Pharmacology, Oregon Health Sciences University, Portland, OR 97201.

Whole-cell recording from single neurons of the suprachiasmatic nucleus in horizontal brain slices with an electrode containing the label neurobiotin resulted in staining of single and multiple neurons in 55% and 30% cases, respectively (n=71). Typically, the recorded neuron soma was darkly stained with the HRP-DAB reaction method and its dendritic processes and an axon were clearly visible. In cases of multiple cell staining, additional adjacent 1-5 neurons were lightly stained and termed as the coupled neurons. The resting membrane potential, input membrane conductance, membrane capacitance, the decay time constant and the maximum H-current amplitude of the recorded neurons having coupled cells were not significantly different from those of neurons not showing label coupling. Stimulation of the preoptic area activated an antidromic action potential or an all-or-none small slow inward current in some neurons when the synaptic transmission was blocked by a calcium-free/Mn²⁺ solution. The small slow inward current did not "collide" with an orthodromically activated action spike suggesting that the current represents the signal from an electrotonically coupled neuron. In addition, the frequency of biphasic field currents from a neighboring cell firing were increased by depolarization and decreased by hyperpolarization of the recorded cell in half the cases. These data demonstrate a chemical and electrical low-resistance coupling between the SCN neurons, which could be important in synthesizing a circadian rhythm in the principal pacemaker of the biological clock in mammalians. 5HT_{1B} PRESYNAPTIC RECEPTORS ON RETINAL AXONS MEDIATE 5HT INHIBITION OF PHOTIC RESPONSES IN THE SCN. G.E. Pickard*, P.A. Scott, A.F. Riberdy, E.T. Weber and M.A. REBRAIN Research Institute, Armstrong Lab. (CFTO), Brooks AFB, TX 78235 and *Department of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104.

5HT fibers arising from the median raphe nucleus innervate the suprachiasmatic nucleus (SCN). To test the hypothesis that 5HT modulates SCN retinal input via 5HT_{1B} presynaptic receptors on RHT axons, we examined the effects of 5HT_{1B} agonists on light-induced behavioral phase shifts and Fos expression in hamster and mouse SCN. The effect of enucleation on SCN 5HT_{1B} receptors was determined by quantitative autoradiography using [125I]-ICYP to label 5HT_{1B} binding sites.

Injection of the 5HT_{1B} agonists TFMPP and CGS 12066A, 30 min prior to light (10 min at 20 lux) at CT 14 and CT 19 (hamster) or CT 16 (mouse) inhibited light-induced phase shifts of wheel-running activity in a dose-dependent manner. Injection (†+)WAY 100135, a selective 5HT_{1A} antagonist, or mesulergine, a 5HT_{2A/2C} antagonist, 30 min prior to TFMPP injection had no effect on TFMPP inhibition of light-induced phase shifts. Methiothepin, a non-selective 5HT₁ antagonist, attenuated the TFMPP effect. TFMPP (1mM) infused into the SCN 10 min prior to light stimulation blocked phase shifts. Systemic injection of TFMPP dose-dependently inhibited SCN Fos expression although some cells in the dorsolateral caudal SCN were TFMPP insensitive. Enucleation reduced [1251]-1CYP binding sites in the ventral SCN by 35%. The results are consistent with the interpretation that 5HT_{1B} presynaptic receptors on RHT axon terminals inhibit retinal input to the SCN. Thus, 5HT tone in the SCN may play an important role in the regulation of circadian phase by serving to modulate the response of the circadian oscillator to photic stimuli. METABOTROPIC GLUTAMATE RECEPTOR mRNA, INCLUDING MGLUR6 AND NEW SPLICE VARIANTS OF MGLUR7, ARE EXPRESSED AND DEVELOPMENTALLY REGULATED IN SCN. A.N. van den Pol*, P.K. Ghosh, N. Baskaran. Sect. Neurosurgery, Yale Med. Sch., New Haven, CT. 06520.

Using RT-PCR, we studied the expression of metabotropic glutamate receptors (mGluR) in the rat suprachiasmatic (SCN) and arcuate (ARC) nuclei. Glutamate is the primary excitatory transmitter innervating both the SCN and ARC. Metabotropic glutamate receptors have not received much attention in the hypothalamus. Some reports indicate greater physiological responses to metabotropic agonists in the developing brain than in the adult. Unique non-overlapping primers were chosen from the C-terminal regions of mGluRs1-8. mRNA was isolated from punches of SCN, ARC, and whole brain, converted to cDNA by reverse transcription, and amplified by PCR. In contrast to previous reports that mGluR6 was only expressed in retina, we found it also expressed in the adult SCN and ARC with RT-PCR, but not with conventional Northern blots. We found two new mRNA splice variants of mGluR7, mGluR7B, and mGluR7C. Sequencing the mGluR7B cDNA revealed a unique 92 bp insert. Within the mGluR7B C-terminal insert is a stop codon (UAG) that would generate a C-terminal amino acid sequence different than mGluR7. All splice variants of mGluR7 were strongly expressed in adults, but only weakly in neonates. Two of the mGluRs (4 and 5) were expressed more strongly in the P10 neonatal SCN and ARC than in adults. Others (mGluR2,3,6) were expressed more strongly in adults. These data indicate that all cloned mGluRs are expressed in the hypothalamus. Each is regulated independently on the basis of hypothalamic region and developmental age.

RESPIRATORY PUMPING IN APLYSIA FASCIATA HAS A VENTILLATORY FUNCTION IN NATURAL AND ARTIFICIAL TIDE POOLS. M. Levy & A.J. Susswein*. Dept. of Life Sciences, Bar Ilan University, Ramat Gan, 52 900 Israel.

Respiratory pumping in Aplysia is a behavior whose neural circuitry has been explored, but whose natural functions are incompletely understood. Although the form of the movement suggests that it has a ventillatory function, previous studies trying to establish such a function have been inconclusive. Respiratory pumping has been shown to function in a defensive context, to act as an adjunct to osmoregulation, and also to have a sexual function, perhaps in dispersal of pheromones. We have now examined whether respiratory pumping might have a ventillatory function in natural and artificial tide pools.

The rate of respiratory pumping was found to be increased when Aplysia fasciata are trapped in natural tide pools, as well as in artificial tide pools in which the oxygen concentration is systematically decreased, and temperature, salinity and CO2 concentration are systematically increased. Artificial tide pools also lead to an increase in the time spent immobile, and decreases in the time spent feeding and mating. The increase in respiratory pumping contributes to the ability of Aplysia to persevere in artificial tide pools, since ablation of the osphradium and cutting the pleural-abdominal connectives, procedures leading to a decrease in the respiratory pump rate, also cause an increase in the number of animal observed to collapse (characterized by the animal's losing contact with the substrate and lying on its side with no sign of movement). Respiratory pumping in artificial tide pools is triggered by a combination of all four simuli that are changed, but the effects of change in the oxygen concentration and temperature are the largest. Changes in other behaviors were also observed in response to all of the stimuli that are present artificial tide pools.

HYPOXIA INDUCED RESPIRATORY PATTERNED ACTIVITY IN LYMNAEA ORIGINATES AT THE PERIPHERY: ROLE OF THE DOPAMINE CELL. T. Inoue*, Z. Haque, M. Takasaki, K. Lukowiak and N. Syed, Neuroscience and Respiratory Research Groups. University of Calgary, Calgary, Alberta, T2N 4N1 and Arabian Gulf University/CMMS, Manama,

A central pattern generator (CPG), appears sufficient for respiratory rhythmogenesis in both isolated and semi-intact preparations of the fresh water snail Lymnaea stagnalis. Identified respiratory CPG neurons, VD4 and IP31, control inspiration and expiration respectively, whereas RPeD1 initiates the respiratory cycle in these cells. The source of excitatory input that drives RPeD1 is, however, unknown. In this study, we demonstrate that the hypoxia drive underlying respiratory rhythmogenesis in Lymnaea originates at the periphery. Specifically, patterned respiratory activity was monitored electrophysiologically in both semi-intact (CNS-peripheralorgans attached) and isolated brain preparations that were maintained either under normoxic (21% O₂), hypoxic (10% O₂) or anoxic (100% N₂) saline conditions. Superfusion of semi-intact preparations with hypoxic saline, either initiated the respiratory activity in a previously quiescent preparations. Anoxic conditions, on the other hand, suppressed respiratory discharge in the semi-intact preparations. The spontaneously occurring respiratory activity in isolated brain preparations, however, remained unchanged under hypoxic conditions, suggesting that the hypoxia induced respiratory activity in Lymnaea has peripheral origin. Utilizing semi-intact and intact animal preparations, we present evidence to support the hypothesis that synaptic interactions between the peripheral chemoreceptors and RPeD1 are necessary for respiratory rhythmogenesis in Lymnaea. Together, our data suggest that although central CPG neurons appear sufficient for the basic respiratory rhythm in Lymnaea, the peripheral chemoreceptor are essential for the initiation of the respiratory activity in this animal. Supported by MRC (Canada).

THE ROLE OF SENSORY FEEDBACK IN CRAWLING BEHAVIOR IN NORMAL AND SURGICALLY MANIPULATED MEDICINAL LEECHES. T.W. Cacciatore, **B. Rozenshleyn, J. Gharakhani, W.B. Kristan Jr., Department of Neuroscience, UCSD, La Jolla CA 92093

The medicinal leech crawls to locomote across a solid substrate. A crawling step consists of an elongation wave followed by a contraction wave which pass from the anterior to posterior of the animal. The front and rear suckers attach and detach from the substrate in coordination with the segmental movements to propel the animal forward. The crawling behavior is variable: steps vary in length, coordination between elongation and contraction, and may include searching movements in the anterior during elongation. However, stereotyped movement patterns underlie all crawling steps. We performed a detailed analysis of stereotyped crawling movements in normal and surgically manipulated animals to help gain insight into the nature of the underlying neuronal circuitry. Animals with markers sewn between most midbody segments were filmed crawling to determine the length of segments throughout a step. Each segmental length profile was then parameterized by a sum of 2 sigmoidal functions. The amplitude and timing of these movements, along with sucker movements, completely characterize the behavior and were used to quantitate the coordination between segments. Leeches with surgical manipulations were also analyzed to test the role of sensory feedback in coordinating the motor pattern. Leeches denervated in midbody segments 7-12 crawled normally suggesting that sensory feedback is not required for producing the stereotyped crawling pattern. However, animals which were stretched during a crawling step showed abnormal coordination waves. The role of the head and tail brains was examined by analyzing animals which had the connectives to each brain cut. Supported by NIH Training Grant #GM08107 and Research Grant #MH43396.

ALTERED EXCITABILITY OF CRAYFISH ESCAPE REFLEX DURING AGONISTIC ENCOUNTERS A. Shamsian, R. Kulkarni, & F. Krasne*. Dept. Psychology & Brain Res. Inst., UCLA, LA, CA, 90095.

In crayfish 5-HT, which is suspected of being released during agonistic encounters, increases lateral giant (LG) escape reflex excitability in social dominants and reduces it in subordinates (Yeh et al, Science, 1996, 271, 366). Hoping to gain insight into the functional significance of this counter-intuitive finding we studied the effect of agonistic encounters on excitability of the LG reflex in freely behaving crayfish with chronic electrodes. We found that during encounters escape is inhibited substantially in subordinates but only slightly and in some cases not at all in dominants, a finding rather analogous to the 5HT result. Escape in crayfish can be generated both by the reflex circuitry studied here, which produces highly stereotyped and prompt responses, and by a "voluntary" system that produces less stereotyped, visually guided tail-flip swimming but at longer latency. We suggest that subordinates, under constant threat of attack, continuously engage voluntary decision circuitry and inhibit reflex circuitry whereas dominants go about their business, relying on reflex escape responses of subordinates, which are common during fights, are not mediated by reflex circuitry. We believe that both GABA and 5-HT contribute to the modulation of LG reflex excitability during social interactions.

INFLUENCE OF HIGHER CENTERS ON THORACIC CIRCUITS OF THE ESCAPE SYSTEM IN COCKROACH. P.L. Schaefer and R.E. Ritzmannt. Department of Biology, Case Western Reserve University, Cleveland, OH 44106-7080.

The cockroach escape system has been studied at the level of behavioral observations as well as individual cell circuitry. Most studies on cell circuitry have focused upon connections to giant interneurons in the terminal ganglion and there output to thoracic interneurons and ultimately to leg motor neurons within thoracic ganglia. These studies have produced a fairly complete description of neural circuitry from sensory inputs to motor outputs. Other observations by C.M. Comer et al. have documented other forms of phasic sensory input that include tactile stimulation of antennae. However, little emphasis has been placed upon tonic influences from higher centers which may modulate sensory inputs from other regions, even thought several pieces of evidence suggest that descending tonic activity may play an important role in the escape system.

may play an important role in the escape system.

These observations prompted us to compare the leg movements associated with the escape response in decapitated animals to those movements seen in intact individuals. Observations were made both on free ranging animals and on tethered animals walking on a lightly oiled plate. The movements of critical joints in the metathoracic legs of decapitated animals were normal. In the mesothoracic legs the direction of movement of leg joints was normal, but the magnitude of movement assignificantly lower. However, prothoracic legs were dramatically affected by decapitation. Subjects made little or no movement of prothoracic legs.

These data suggest that prothoracic circuitry is influenced to a greater extent than circuitry in other thoracic ganglia. Ongoing experiments will attempt to localize the origin of this tonic effect within higher centers. Supported by Whitehall Foundation Grant #J95-02 to RER.

CHANGES IN SEROTONIN ARE CORRELATED WITH PARASITE-INDUCED ALTERATIONS IN HOST BEHAVIOR. <u>B.J. Maynard, L.J. DeMartini, and W.G. Wright*</u>. Dept. of Biology, Colorado State University. Fort Collins, CO 80523.

The acanthocephalan parasite *Polymorphus paradoxus* appears to manipulate the behavior of its crustacean intermediate host, the amphipod *Gammarus lacustris*. Amphipods infected with *P. paradoxus* show an abnormal preference for brightly lit environments and respond to disturbance by clinging to floating objects. These altered behaviors bring the amphipod to the water surface, thus increasing transmission of the parasite to its surface-feeding definitive host, mallard ducks. A related species of parasite, *P. marilis*, also uses *G. lacustris* as its intermediate host, but induces a much milder behavioral change, i.e. a preference for only slightly brighter environments, and no change in response to disturbance. Once again, these altered behaviors likely increase transmission, since *P. marilis* uses a diving duck, the lesser scaup, as its definitive host, rather than surface-feeding mallards. The question of how these two parasites induce behavioral changes in their amphipod hosts remains unanswered. Both parasites exist as free-floating cysts in the hemocoels of their hosts, causing no mechanical damage. It is known that injections of serotonin (5HT) into the hemocoel of non-parasitzed amphipods are able to mimic the behavioral effects of *P. paradoxus*, suggesting the possibility of neurochemical manipulation by the parasite. We compared the pattern of 5-HT immunoreactivity in whole mounts of the ventral nerve cords of uninfected amphipods with those from amphipods infected with *P. paradoxus or P. marilis*. All nerve cords showed one bilateral pair of 5HT immunoreactive cell bodies in the hird thoracic ganglion, but the fine structure varied dramatically, depending on the infection state of the host. Nerve cords from amphipods harboring *P. paradoxus* showed a 2.8 fold increase in the number of visible 5HT storage sites in comparison with non-infected preparations processed in the same dish; no such increase was observed with the *P. marilis*-infected preparations. These results further implicate 5HT in t

BEHAVIORAL SEQUENCING DURING ADAPTATION TO CURRENT AND SURGE IN THE AMERICAN LOBSTER.

L. Schlichting and J. Ayers*. Marine Science Center, Northeastern University. East Point. Nahant, MA 01908

We are developing a detailed object-based computational model for the control of omnidirectional ambulation based on the lobster walking system. We use reverse kinematic and electromyographic analysis to segment rheotaxic behavior into stereotypic units to establish the sequences utilized to adapt to translational flow and surge. Walking movements in flow and surge involve yaw corrections as well as rotations. When walking into flow specimens compensate by lowering the body and increasing the period of stepping. In addition to leg mediated yaw compensation, lobsters use their claws, abdomen and swimmerets as hydrodynamic control surfaces. As flow increases, specimens lower the chelipeds and elevate the abdomen and telson to generate a force vector to the substrate.

These findings are integrated into our ambulation controller and extend the library of object classes to include sensors, command interactions, behavioral hierarchies and sequences. The goal of these studies is a robotic control architecture capable of operation in the turbulent littoral environment. Supported by ONR.

LOCALIZATION OF VIBRATIONAL SOURCES BY THE FIDDLER CRAB *Uca Pugilator*. T. Haresign*, J. LaPolla, and B. Vemulapalli. Biology Program, Richard Stockton College, Jimmy Leeds Road, Pomona, NJ 08240

Fiddler crabs (genus Uca) have long been thought to be sensitive to substrate-borne vibrations. The ability to localize vibrational signals would provide an adaptive mechanism that would be useful to the crab in terms of predator avoidance and possibly also in localization of conspecifics. To test localization ability crabs were placed in the center of a circular behavior arena. These crabs all had their vision occluded by prior application of an opaque paint over the eyes. A vibrational source located at a specific position in the arena was activated and the crab's direction of movement relative to the source was quantified Results in U. pugilator indicate that there is a significant movement away from the vibrational source, suggesting that the crabs are able to localize the source. Furthermore, our results suggest that the localization task is easier when the long axis of the body is aligned perpendicular to the oncoming vibrational waves. This may indicate that the crab is comparing arrival times of the wavefronts between the legs on either side of the body. Comparison of arrival times would entail time measurements of less than 1 millisecond. Further experiments are being conducted to further explore the computational basis for localization in these crabs

JUVENILE HORMONE REDUCES AUDITORY SENSITIVITY IN THE PRAYING MANTIS, TAUMANTIS EHRMANNII. A.L.Harron and D.D.Yager*, Dept of Psychology, Univ. of MD, College Park, MD 20742.

Juvenile hormone (JH) is present in insects throughout their life. Within each instar, or developmental stage, there is variation in the amount present. In all nymphal instars except the last, a high level is present at the time of ecdysis, or molting. In the final instar, the level is low at ecdysis. Thus, high JH levels present at ecdysis result in maintenance of juvenile characteristics into the next instar. When administered during the final instar, hydroprene (a synthetic JH) results in adult insects that retain some juvenile characteristics

Taumantis ehrmannii adults demonstrate sexual dimorphism for wing length and hearing, such that long wings are associated with low auditory thresholds. This raises the question of whether JH, which can produce shortened wings, can also raise auditory thresholds. Males, which have long wings, have a single ear on the ventral metathorax midline with physiological best-frequency (70 kHz) threshold of 70 dB SPL and demonstrate an in-flight escape response at this frequency. Females, which have short wings, are functionally deaf, as they have a physiological best-frequency (30kHz) threshold of 92 dB SPL and demonstrate no behavioral response to sound. Hydroprene-treated adult males have a best-frequency (70 kHz) threshold of 90 dB SPL, display abnormal ear anatomy, and have shortened, deformed wings that prevent flight. Life span, feeding behavior, and general activity level of these treated males are not affected. The auditory sensitivity reduction indicates that the final instar is crucial for normal auditory sensitivity and leads to the question of what differences occur in auditory development of deaf versus hearing mantises.

HORMONAL AND EXTERNAL EFFECTS ON PHONOTACTIC AND NEURONAL THRESHOLDS OF FEMALE CRICKETS. J. Stout, M. Bronsert , J. Hao, D. Mbungu, T. Standish, and G. Atkins. Biology Dept., Andrews Univ. Berrien Springs, MI 49104.

Juvenile hormone III (JHIII), applied to the abdomen of 1-day-old female Acheta domesticus caused a significant decrease in phonotactic thresholds. Removal of the corpora allata from 5-day-old females with low phonotactic thresholds caused increased phonotactic thresholds 2 to 5 days later. After a temporary increase of abou 25 dB, the phonotactic thresholds drop to 10 dB above preallatectomy levels. Application of JHIII to allatectomized females, with a mean increase in thresholds of 20 dB, results in decreased thresholds (mean of about 15 dB) over the next 12 hours. Also, a variety of external factors influence phonotactic thresholds of females (e.g. exposure to males,

time of day, previous phonotactic testing, Stout et al. 1996).

In 1-day-old females with high phonotactic thresholds, the threshold of the L1 auditory interneuron can be 30 or more dB lower than their phonotactic threshold. In females with phonotactic thresholds of 70 dB or lower, the L1 threshold is within 10 dB of their phonotactic threshold. Thus factors other than the threshold of the L1 auditory neuron influence phonotactic thresholds

The JHIII levels that influence phonotactic thresholds also influence the th esholds of the L1 auditory interneuron and the expression of a gene in the L1 neuron like the alpha subunit of nicotinic receptors in locusts. The causal relationships between expression of this gene in the L1 (or other) auditory interneuron and JHIII levels will be evaluated as a means for translating external influences into changes in phonotactic thresholds

FASCICLIN II AND DROSOPHILA MYOCYTE ENHANCER BINDING FACTOR 2 IN THE MUSHROOM BODIES OF THE HONEY BEE. S.M. Farris¹, S.E. Fahrbach¹, G.E. Robinson*¹ and R.L. Davis². ¹Dept. of Entomology, University of Illinois at Urbana-Champaign, Urbana, IL 61801, and ²Dept. of Cell Biology, Baylor College of Medicine, Houston, TX 77030.

The mushroom bodies are centers of learning and memory in the

insect brain. The Kenyon cells are intrinsic neurons of the mushroom bodies, receiving offactory and visual input in the calyces and relaying information to other parts of the protocerebrum via the alpha and beta lobes. Antibodies directed against two proteins expressed in the mushroom bodies of the fly *Drosophila melanogaster* show robust staining patterns in the brain of the honey bee, *Apis mellifera*. Drosophila myocyte enhancer binding factor 2 (Dmef2) is a transcription factor first recognized for its role in myogenesis. In the mushroom bodies, nuclei of the non-compact Kenyon cells stain intensely for Dmef2, while those of the compact Kenyon cells do not. A subset of neuronal nuclei in the antennal lobes and subesophageal ganglion also show intense Dmef2 immunoreactivity. Fasciclin II (fasII), an insect cell adhesion molecule homologous to vertebrate NCAM, is detected as a discreet band of staining in the calycal, alpha and beta lobe neuropils of the mushroom bodies. Neurons in the central bodies also show fasII immunoreactivity, as do several large fiber tracts in the deuterocerebrum. Dmef2 and fasII will be used as markers to study neuronal plasticity in the mushroom bodies that is associated with behavioral development in the adult honey bee. EFFECTS OF UNNATURAL CALLING SONGS ON PHONOTAXIS ANL. AN AUDITORY INTERNEURON IN THE CRICKET. G. Atkins*, H. Bingo!, D. Kim. N. Carlson and J. Stout Dept. of Biology, Andrews University, Berrien

Phonotaxis of young female Acheta domesticus is selective for the syllable period of the males conspecific calling song, with syllable periods of 50-70 ms being most attractive. This selectivity decreases with age (Walikonis et al. 1991).

L3 is an ascending, prothoracic, auditory interneuron that responds in a bandselective manner that matches the selectivity of phonotaxis. In young females, L3 shows a strong decrementing response to calling songs (the first syllable of the call produces twice as many spikes by L3 than the third syllable) that have syllable periods of 50-70 ms. Shorter and longer syllable periods do not induce a strong decrement. L3s in older females do not show this decrement at any syllable period tested and thus are unselective (Henley et al. 1992).

We have formed a working model of the circuit by which L3 exhibits a t andselective response and how this might change with age. The model proposes excitation and delayed inhibition on the side ipsilateral to L3s axon and contralateral inhibition of both insilateral inputs (Atkins et al. 1995).

Our current experiments center around phonotaxis and the responses o. 1.3s during stimulation with unnatural calling song models. The paradigm consists of songs in which parameters of the syllables can be changed within a given Chirp. For example, what happens phonotactically in old females, which are unselective for syllable period, when a loud syllable is follow by 2 less intense ones in a given chirp. This should produce a "decrementing-like" response in L3 and thus, does it cause changes in selectivity in old females? With these and similar types of experiments, it is our intent to learn more about the function of L3 in selectivity of females and to elucidate further how the L3s response is shaped. FORAGING BEHAVIOR AND MUSHROOM BODIES IN ALLATECTOMIZED HONEY BEES. Joseph P. Sullivan, Gene E. Robinson, and Susan E. Fahrbach* Dept. of Entomology, University of Illinois at Urbana-Champaign, Urbana, IL 61801

Foraging behavior in honey bees is associated with high juvenile hormone (JH) titers and reorganization of the mushroom bodies, the region of the insect brain that mediates learning. To test the hypothesis that juvenile hormone influences the development of both foraging behavior and mushroom body structure, the corpora allata, the glands that produce juvenile hormone (JH), were surgically removed from day-old worker bees. Allatectomized (CA-), sham, and control bees were individually marked and introduced into a colony within a glass-walled hive. Radioimmunoassay was used to verify that CA- bees had undetectably low JH titers. Regular behavioral censuses showed CA- bees performed the full repertoire of tasks inside the hive to support colony growth and maintenance. Observations at the hive entrance revealed flight activity between CA and sham bees was not significantly different. The CA bees demonstrated flight capability but foraged significantly less than shams. Brains from 1 day old, foraging shams and controls, and nonforaging CA- bees were dissected and sectioned to investigate whether the absence of JH during adult life affects the reorganization of the mushroom bodies. Measurements of the volume occupied by the neuropil and intrinsic cells of the mushroom bodies (Kenyon cells) using the Cavalieri method are in progress. SEX PHEROMONE RESPONSE SPECIFICITY IN TWO RACES AND HYBRIDS OF THE EUROPEAN CORN BORER MOTH. C. E. Linn Jr.*1, M. S. Young², T. J. Glover², and W. L. Roelofs¹. ¹Dept Entomology, NY State Agric. Exp. Station, Cornell University, Geneva, NY ² Dept. Biology, Hobart and William Smith Colleges, Geneva, NY.

Two races of the European corn borer moth, Ostrinia nubilalis, use opposite ratios of Z- and E11-tetradecenyl acetate in their sex pheromones. Behavior/genetic studies demonstrated that male antennal receptor responses are controlled by an autosomal gene, but that blend recognition and upwind flight are controlled by a sex-linked factor. As part of a program to understand how these genetic factors influence neurophysiological processes and behavior, response specificity of males in the two races and their hybrids to a large array of ratios/concentrations was studied in the sustained-flight tunnel. Males of each race completed flights to the source to a wide range of concentrations (0.3 to 3000 µg on rubber septa), but maximal response was exhibited to a narrow concentration range of the natural ratios of isomers (3:97 and 99:1 E.Z). The races differed significantly in their sensitivity to increasing proportions of the minor isomer, with higher concentrations of off-ratios eliciting source contact in the race using 99:1 E:Z with the complete set of ratios tested Finally, F1 hybrids exhibited no specificity, with high levels of response occurring to a wide range of ratios/concentrations. In agreement with previous studies, response specificity was the result of a lower concentration/lower ratio threshold on orientation to the odor plume, and a higher concentration/higher ratio threshold on arrestment of upwind flight. The results also agree with the current integrated model explaining the orientation mechanisms and neurophysiological processing involved in perception of odor quality and response to pheromone, suggesting a link between the sex-linked factor and antennal lobe processing. Supported by Howard Hughes Medical Foundation summer intern grant to Hobart and William Smith Colleges.

NOVEL FEATURES OF EXTRINSIC MUSHROOM BODY NEURONS IN COCKROACH BRAIN <u>Y.-S. Li*</u> and <u>N.J. Strausfeld.</u> ARLDN, Univ. Arizona. Tucson, AZ 85721

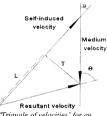

The paired mushroom body (MB) neuropils of insects are believed to underlie olfactory associative learning and memory (Menzel, R. [1993] Associative learning in honey bees. Apidologie, 24 (3) 157-168). However, although the MBs receive a substantial afferent supply from olfactory interneurons, in many insects the main receptive regions of the MBs (the calyces) are also invaded by visual and mechanosensory relays, suggesting that MBs are multimodal integrators. So far, previous models of MBs suggest that computations are performed by networks of parallel intrinsic neurons, the axons of which are transected by, and presynaptic to efferent (output) neurons which then lead to premotor neuropils or other brain regions. New intracellular recordings and dye fills from efferent neurons in the cockroach Periplaneta americana have revealed novel features of the MB's internal organization and relationships with other brain areas. Efferent neurons arising in either of the MB's two lobes respond to a variety of sensory stimuli (odor, light, sound and touch) and many efferents have complex morphologies consisting of multiple dendritic trees both within and outside the MBs. Furthermore, afferent neurons have been identified that supply the MB lobes rather than the calyx. Comparisons with anosmic taxa, whose MBs lack calyx and pedunculus, show that their lobes exclusively receive the MB's afferent sensory supply. These features, and ongoing intracellular recordings, suggest that the MBs are not relatively isolated neuropils, as previously supposed, but are highly integrated with other brain areas in modulating the activity of premotor pathways supplying locomotion circuitry in the thoracic ganglia.

A multimodal control system for navigation in a moving fluid medium: Visual flow fields are not enough. Jim H.Belanger.* ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

An organism attempting to navigate while suspended in a moving fluid medium faces a task of considerable complexity. Its motion through the environment is the vector sum of its self-induced motion, and that of the medium (see figure). Because it is suspended in the medium, the organism is unable to detect the velocity of the medium using mechanosensory cues, but instead must rely on visual input to deduce this. (Visual inputs are shown in the figure as T, for transverse visual flow, and L, for longitudinal visual flow). However, consideration of this problem reveals that, in the absence of independent knowledge of the velocity of either the organism or the medium, visual cues alone are insufficient to steer a desired course (0) with respect to the flow. Based on

"Triangle of velocities' for an organism in a moving fluid medium.

behavioral and neurophysiological data, largely derived from studies of olfactory-guided locomotion in insects, I have developed a model which is capable of solving this problem. The essential addition to the control system is information on the animal's self-induced speed. In flying insects, this is the animal's air speed, which is available via mechanosensory receptors. The values of air speed, T, and L are sufficient to define all sides and angles of the 'triangle of velocities', and thus can form the basis of a control system. Such a controller has been tested using simulations of olfactory-guided locomotion in moths, and can successfully steer any desired course across a range of wind velocities. VISUAL MOTION PROCESSING IN THE LOBULA PLATE OF BLOWFLIES: DIRECTION AND NON-DIRECTION SENSITIVE OUTPUTS TO THE LOBULA AND CENTRAL BRAIN. John K. Douglass' and Nicholas J. Strausfeld. ARLDN, Univ. Arizona. Tucson AZ 85721, USA.

An important feature of insect as well as primate visual systems is the functional and anatomical segregation of parallel retinotopic pathways for processing distinct features of the visual world. In the fly brain, there is a major separation of achromatic, motion sensitive pathways to the lobula plate from wavelength-sensitive pathways to the lobula. Anatomical and physiological observations suggest a further subdivision of retinotopic, motion-sensitive pathways to the lobula plate into directionally-selective (DS) and non-DS channels (Douglass and Strausfeld [1996] J. Neurosci., in press). Within the lobula plate, there is evidence for continued segregation and integration of motion information. In addition to the well-known DS giant tangential neurons at this level, there exist at least 15 morphologically distinct types of small-field retinotopic neurons which relay information among the lobula plate, lobula and lateral deutocerebrum. Consistent with earlier recordings from this diverse group (Gilbert and Strausfeld [1992] J. Comp. Neurol. 316:72-86) we find that some small-field lobula plate efferent neurons having outputs to the lateral deutocerebrum are DS, while others, though non-DS, nevertheless exhibit distinct responses to motion and flicker. In contrast with these, limited data from medullary inputs to the lobula so far provide no evidence for DS activity within this neuropil other than by large male specific neurons (Gilbert and Strausfeld [1991] J. Comp. Physiol. 169:395-411). Supported by a grant from the National Center for Research Resources (RR08688).

NEURAL ARRANGEMENTS ARE EVOLUTIONARILY CONSERVED IN OLFACTORY AND SENSORY ASSOCIATION CENTERS OF SEGMENTED INVERTEBRATES. Nicholas J. Strausfeld*. Robert S. Gomez, and Lars Hansen. ARLDN. Univ. Arizona. Tucson, AZ 85721

Comparative studies of arthropods and annelids reveal unexpected levels of conservation of brain structures. Based on the presence or absence of specific neural characters amongst 30 taxa, phylogenetic analysis using parsimony has suggested evolutionary relationships amongst invertebrates that closely match trees obtained by others from both classical morphological observations as well as comparisons of conserved DNA. Two specific neural architectures occur as leitmotivs throughout most of the arthropods, annelids, Onychophora and Platyhelminthes, but not in mollusks. In insects, these architectures are known as the antennal lobes and mushroom bodies: the former being glomerular olfactory neuropils supplying the latter --- paired lobed neuropils comprising thousands of intrinsic neurons derived from extremely small and tightly backed basophilic perikarya ("globuli cells"). The possibility that mushroom bodies might have arisen only once in evolution is supported by their intrinsic architecture which, whether in an annelid, insect, or chelicerate, follows the same organizational rules with respect to detailed arrangements of processes, afferents, and outputs. Even in many crustaceans, where large populations of globuli cells supply folded, rather than lobate, centers just proximal to the optic lobes, these regions (called hemi-ellipsoid bodies) nevertheless have architectures that conform to the general organizational principles of mushroom bodies in other arthropods. The results suggest a high degree of conservation of neural arrangements and hence operational principles in olfactory neuropils and the neuropils to which their interneurons project. Supported by a John D. and Catherine T. MacArthur Foundation Fellowship to NJS.

LOOMING SENSITIVE INTERNEURONS IN THE OPTIC LOBES OF THE HAWK MOTH MANDUCA SEXTA (SPHINGIDAE, LEPIDOPTERA). Martina Wicklein* and Nicholas J. Strausfeld, ARLDN, Univ. Arizona. Tucson, AZ 85721

Hummingbird hawkmoths are rapid and highly maneuverable diurnal insects that use their large compound eyes to maintain exact position in front of a food source (flowers) even if this moves and irrespective of the direction of movement. Similarly, the tobacco hornworm moth M. sexta (a crepuscular American sphingid) performs precise hovering behavior. Electrophysiological investigations show that the optic lobes of M. sexta possess several types of neurons that respond to different looming stimuli. These include expanding objects in front of a contrasting or textured background, turning spirals and moving gratings. Each of these simulations makes it possible to test different properties of the looming stimulus (moving contrast edges, figure-ground stimuli, motion parallax) and thereby reveal which component of the looming stimulus is relevant for an identifiable neuron. Two types of responses can be observed when recording from the lobula plate of M. sexta. Type 1 neurons (looming edge detectors) react to expanding discs in front of a background and to moving spirals. Moving edges are the relevant stimuli for these neurons: Both the turning spiral and the expanding disk provide the cell with edges that move from the periphery to the center or vice versa. Type 2 neurons (looming object detectors) respond only to expanding discs and show no reaction when stimulated with a turning spiral. For Type 2 neurons, components of the looming stimulus other than moving edges must also be relevant. The responses of Type 2 neurons suggest that figure-ground stimuli and/or motion parallax are the crucial components of the looming stimulus for this type of neuron. Supported by a Feodor Lynen Fellowship for MW and a grant from the National Center of Research Resources (NCRR), NIH RR08688 to NJS.

ACTION SPECTRA OF THE BIOLUMINESCENT RESPONSE IN FIREFLY *Photinus pyralis* FEMALES (COLEOPTERA: LAMPRIDAE). <u>K. M. Worthy and A. B. Lall</u>, Department of Biology, Howard University. Washington, D.C.

The action spectra S(\(\lambda\)) of the female-response to the photic stimulation of a simulated bioluminescent (BL) optical signal of the species male were determined in *P. pyralis*. In nature, *P. pyralis* males emit a 500 ms J-flash every 4 to 4.5s. A xenon arc in conjunction with a monochromator and a electromagnetic shutter provided the simulated male-flash whose color varied from 400 to 640nm at 20 nm intervals, intensity controlled by neutral density filters, flash-duration varied from 500ms and delivered every 4s. The intensity of the simulated flash was varied to determine the threshold of the female-response at thirteen stimulus wavelengths. The firefly females respond only to green-yellow stimuli >500 nm and not to stimuli in the near-UV and blue (380-480nm). $S(\lambda)$ functions which had a narrow peak in the yellow-green $(\lambda_{max}~565nm)$ region. The evidence that the a narrow yellow receptor in the female mediates the detection of BL of the conspecific male is based upon the presence of a correspondence in shape and in λ_{max} between species BL emission spectrum (λ_{max} =564nm), the spectral sensitivity of a narrow yellow receptor by electroretinographic S(λ) data (λ_{max}=565nm) and the S(\(\lambda\)) function of an intracellular response from individual retinular cells (\(\lambda_{max} = 565 nm\), in situ absorption spectrum of P. pyralis P545 visual pigment overlaid by species specific screening pigment (λ_{max} 517nm) and the shape and the \(\lambda_{max} \) of S(\(\lambda \) functions of the female-response. Hence the information in the species BL optical signal is processed exclusively by the green/yellow visual receptor in \(P.\) pyralis, and should be taken as evidence for an achromatic detection of the bioluminescent optical signal. NORTHERN BUTTERFLIES ARE THE BRIGHTEST: THE UV-SENSITIVITY AS A FACTOR FOR VISUAL ECOLOGY.
M. Järvilehto* and V.B. Meyer-Rochow, Univ. of Oulu, Dept. of Biol., Unit for Animal Physiol., P.O. Box 333, 90571 Oulu, Finland.

Many butterflies make use of UV-absorbing or -reflecting patches on their wings in courtship, mate recognition, and mate selection (Ohara, Y & Hidaka, T. (1968) Proc. Jap. Acad. 44, 829-832; Rutowski, R. (1981) Z. Tierpsychol. 55, 325-334; Meyer-Rochow, V.B. (1991) J. Roy. Soc. N.Z. 21, 169-177). We examined 28 female butterflies Pieris napi, common in Finland, under UV-light of 366 nm wavelength and found that the pattern in UV-reflectivity on the wings of females show variation, which is correlated with geographic latitude. Photographic cross-correlations show that in ca. 75% of all female specimens from the northern latitudes 66.5° in Finland (near the polar circle) had wing patterns that were more strongly reflecting than those of individuals caught ca. 600 km further south (61°). Seasonal influences were ruled out when the phenomenon was demonstrated in early as well as late summer generations. The sunlight's UV-component at higher latitudes decreases due to the lower angle of the sun and if the differences of UVpatterns in intra- or interspecific communications have a significance for the butterfly, it will either have to increase the sensitivity of UVreceptors or has to generate more powerful UV-signals. It seems that P. napi has more selectional pressure on the second evolutional solution.

STRESS INDUCIBLE 70kDa HEAT SHOCK PROTEIN (HSP72) EXPRESSION IN ADRENAL GLANDS OF FAWN-HOODED RATS WITH CONGENITAL ERROTONIN ABNORMALITIES. S. Mulugeta, B. Tedeschi, C-T Hsu, S.R. Shenoy, T. Coon, J. McCormick, M-T Maa, G.E. Goode & P.E. Atavich. Eastern Virginia Med. School, Norfolk, VA 23501; VAMC, Hampton, VA 23667; Governor's School for Sci. & Tech., Hampton, VA 23666; Christopher Newport Univ., Newport News, VA 23607.

Various stressors activate the hypothalamo-pituitary-adrenal system (HPA) and an intracellular stress-response system related to the 70kDa heat shock protein family. The HSP70 system is thought to play a role in cellular maintenance by "chaperoning" proteins. Several studies demonstrate that acute HPA activation induces stress-inducible HSP72 expression in the adrenal cortex. The purpose of this investigation was to determine if Fawn-Hooded (FH) rats, which have chronic HPA activation, have adrenal stress-inducible HSP72. FH rats have congenital brain and platelet serotonin abnormalities and are an animal model of depression and alcoholism. They have a variety of other behavioral abnormalities (see M-T Maa et al., this meeting) and eventually develop hypertension and glomerulosclerosis. The subjects were female FH rats (n=6, 5-mo. old) and weight-matched Wistar strain controls (n=5). Adrenal glands were homogenized in denaturation buffer and proteins separated by SDS-PAGE. HSP72 expression was assessed by SDS-PAGE immunoblots probed with specific monoclonal antibody (Stressgen). It was found that stress-inducible HSP72 occurred in the adrenal glands of all six FH rats and in none of the five Wistar controls. These data suggest that stress-inducible HSP72 is constitutively expressed in the adrenal glands of Fawn-Hooded rats. Further studies are needed to determine if this is due to increased synthesis or decreased turnover. This research supported by EVMS institutional funds.

REGULATION OF t-[³⁵S]TBPS BINDING IN INESCAPABLY STRESSED RATS WITH LEARNED HELPLESSNESS BEHAVIOR. J. H. Wu, G. L. Kramer, I. L. Crawford* and F. Petty. VAMC and Depts. of Psychiatry and Neurology, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75216.

GABAA receptor complex is postulated to mediate the neurochemical in human depression. in stress and butylbicyclophosphorothionate (TBPS) binding is a sensitive marker to changes in the function of the GABAA receptor complex. We investigated the alteration of [35S]TBPS binding in several mood responsive areas of rat brain by quantitative receptor autoradiography. We found that rats with learned helplessness behavior (LH) after inescapable stress, [35S]TBPS binding was significantly decreased in dorsal hippocampus, hypothalamus and amygdala (P=0.031, P=0.001 and P=0.025, respectively) compared to tested controls or to naive controls. There were no significant differences among experiment groups and control groups in either prefrontal cortex or septal area. Also, no significant differences were found in rats without LH after inescapable stress compared to control groups in any of the investigated brain areas. It is concluded that the function of GABAA receptor complex is regulated differently in various brain areas of learned helpless rats. The decrease of [35S]TBPS binding, concomitant with the decreased release of GABA in learned helpless animals, is therefore related to the learned helplessness behavior.

SEROTONERGIC NEUROTRANSMISSION IN THE PREFRONTAL CORTEX OF ROMAN HIGH-AVOIDANCE (RHA) AND LOW-AVOIDANCE (RLA) RATS: A BRAIN MICRODIALYSIS STUDY.

M.G. Corda *, O. Giorgi, D. Lecca, G. Piras, P. Driscoll ¹ and G. Di Chiara. Department of Toxicology, University of Cagliari, ITALY and ¹ ETH Zentrum, Zurich, Switzerland.

RHA and RLA rats are selected and bred for rapid versus poor acquisition of two-way avoidance behavior in a shuttle box. RHA and RLA rats show multiple behavioral differences related to emotional factors, RLA rats being emotionally more reactive. In addition, a number of differences in dopaminergic, GABAergic and serotonergic (5HTergic) function in the CNS have been reported in these two lines. Given the role of serotonin (5HT) in the regulation of the reactivity to stressors and the above mentioned line-related differences in emotivity, the present study was undertaken to characterize 5HTergic neurotransmission in the prefrontal cortex (PFCX) of RHA and RLA rats using brain microdialysis. The basal release of 5HT (fmol/20 μ l) was significantly lower in the PFCX of RHA rats (5.37 \pm 0.65) than in RLA rats (7.73 \pm 0.60, n = 12 rats per group, p < 0.05). Consistent with recent data indicating that the binding density of l'Hlparoxetine is larger in the PFCX of RHA rats than in their RLA counterparts, the increase in 5HT output produced by the systemic administration of the 5HT uptake inhibitor chlorimipramine (10 mg/kg, IP) was more pronounced in RHA rats than in RLA rats. Thus, the peak effect of chlorimipramine 40 min after treatment was \pm 269 % and \pm 144 % in RHA and RLA rats, respectively. In addition, a 2-way ANOVA revealed a significant difference across rat line (\pm 1,1124 = 46,8; p < 0.001) and across time after treatment (F_{1,2,111} = 4,0; p < 0.001). Taken together, the above results may provide functional significance to the line-related differences in biochemical markers of serotonergic neurotransmission observed under \pm 10 moltons. Studies aimed at comparing the effects of environemental stressors and anxiogenic drugs on 5HTergic neurotransmission in these two lines are underway in our laboratory.

453.4

EFFECTS OF INESCAPABLE AND ESCAPABLE STRESS ON THE RELEASE OF SEROTONIN IN THE VENTRAL HIPPOCAMPUS OF THE RAT. J. Amat. S. Maswood, P. Matus-Amat, J. Barter, L. R. Watkins and S. F. Maier*. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Organisms exposed to inescapable stress show a constellation of behavioral and physiological alterations that do not occur if the stressor is escapable. Both pharmacological and lesion experiments suggest that these effects may occur in part because inescapable stressors produce a more intense activation of serotonergic neurons within the dorsal raphe nucleus (DRN) than do escapable stressors. Here we report experiments using in vivo microdialysis to directly measure serotonin (5-HT) efflux in the ventral hippocampus, a projection region of the DRN. Pairs of male Sprague Dawley rats were exposed to escapable 1.0 mA tailshock (ES) or exactly equal yoked inescapable tailshock (IS). Samples of extracellular fluid were collected at 15 min intervals before, during, and after the treatment. Levels of 5-HT and 5-HIAA were measured by HPLC. Both IS and ES produced increases in 5-HT, but the increase was much larger in IS subjects. Extracellular 5-HIAA decreased in association with the 5-HT increases, and increased after 5-HT returned to near normal levels. Thus stressor controllability does appear to modulate DRN 5-HT activity and 5-HIAA extracellular levels do not reflect 5-HT release, as has been previously reported.

EFFECTS OF CONTROLLABILITY OF STRESS ON HIPPOCAMPAL PHARMACOLOGY. C.L. Wellman*1, M.J. Cullen2, and M.A. Pelleymounter². ¹Dept. Psychology, Indiana University, Bloomington,

IN 47405 and 2Dept. Neurobiol., Amgen, Thousand Oaks, CA 91320.

Previous studies have shown that exposure to uncontrollable shock produces deficits in behaviors mediated by the hippocampus. To begin to correlate these behavioral effects with pharmacological changes in hippocampus, we examined effects of controllable and uncontrollable shock on hippocampal pharmacology. To assess the role of mu opioid snock on nippocampal pharmacology. To assess the role of mu opioid and cholinergic receptors in mediating effects of uncontrollable stress, we trained rats in a controllability paradigm and assessed pharmacological changes in hippocampus. Rats who could terminate shock (N=7) were paired with rats who could not terminate equivalent shock (N=7); a group of control rats did not receive shock (N=7). When rats who could terminate shock responded at an 80% could terminate shock responded at an rate, all brains were removed and sectioned (16 µm), incubated with tritiated ligands and processed with autoradiographic procedures appropriate for visualizing muscarinic, GABAA, and mu opioid receptor binding, as well as serotonergic uptake and noradrenergic reuptake sites. Density of label in hippocampal CA1 and CA3 fields and dentate gyrus was assessed using an image analysis system (MCID). Quantitative densitometry revealed a 14-22% decrease in muscarinic and mu opioid receptor binding in CA3 and dentate gyrus in rats receiving uncontrollable shock relative to rats receiving no shock; no significant changes were observed in rats that could terminate shock. Thus, ability to control shock prevents stressinduced changes in the opiate and cholinergic systems in hippocampus. Supported by ADAMHA grant to MAP.

CIRCLING BEHAVIOR IN EARLY CALLOSOTOMIZED MICE. <u>S.L. Schmidt.</u> Filgueiras, C.C., Krahe, T.E., E.M., Caparelli-Dáquer*, Manhães, A.C. Dep. Fisiologia, Univ. Estado Rio de Janeiro, Brazil, RJ 20551-030.

Adult mice with neonatal section of the corpus callosum or sham lesions were examined for turning preferences in swimming rotation. On the first postnatal day, pups were taken from their mothers, anaesthetized by hypothermia and subjected to a longitudinal transection of the corpus callosum. After recovery from surgery, the animals were returned to their mothers and left undisturbed for 21 days. Sham operated animals were subjected to the same procedures except the callosal section. The normal group consisted of animals were tested in three different days on a free-swim apparatus which consisted of a plastic container of 21 cm diameter, partially filled with water. The animal's free swim rotations were continuously recorded for 5 minutes with a video camera. All clockwise and counterclockwise full rotations (360-) were counted from the video images of the tests. We also measured 50° turns. After behavioral testings all operated animals and rondom samples of normal and sham operated animals were intracardially perfused with saline followed by a 4° of bornaldehyde solution. The brains were coronally sectioned at 40µm, and stained with cressl-violet. In all animals, the behavioral analysis showed that there was a decline in activity with repeated testing. The highest activity always occurred during the first minute of the first test. For each test there was an overall decline in activity from the first to the second minute. In sham-operated animals, there was a significant effect of sex: handled females had a tendency to be more lateralized and did not show a decline for the preferred side of rotation with repeated testing. In mice with callosal defects, there was a significant interaction between sex and consistency of laterality; acallosal females that were consistent left-rotators did not decline their activity to the preferred side with repeated testing. It is conceivable that testosterone and callosal development may suppress cortical enlargement in the left hemisphere. Thus, this study provides support for t

453.9

ONTOGENY OF BEHAVIORAL AND AUTONOMIC DEFENSIVE RESPONSES FOLLOWING INFUSION OF KAINATE INTO THE DORSAL PERIAQUEDUCTAL GRAY.

G.A. Goodwin* and G. A. Barr .Columbia University and NY State
Psychiatric Institute 722 W. 168th St. New York, NY 10032.

Adult-typical defensive behaviors emerge independently during the
first month of postnatal life in the rat. For example, freezing is seen by about postnatal day 14 (P14), whereas flight in response to a sudden noise does not emerge until around P20. The autonomic control of heart rate is also changing during this period maintained tonically by sympathetic activity during the first postnatal week, with phasic parasympathetic activation occurring in response to stressor exposure. The central systems modulating defensive responses must also undergo dramatic changes during this time. One structure important in the response to stress in the adult is the midbrain periaqueductal gray (PAG). The present study was designed to examine the role of the PAG in the control of defensive responses during early ontogeny. Kainic acid was infused (0.0, 0.03, 0.10, 0.3 nmol) into the dorsal PAG of rats at P7, 14, and 21. Escape like behaviors (running, jumping) were evoked by infusion of the two highest doses at P14 and 21. P7 pups exhibited only a brief (30 sec) increase in activity immediately following drug infusion. A significant increase in heart rate was not observed until P21; respiration rates increased following infusion of kainate at P7 and P14 but not P21. The results suggest that the PAG organizes respiratory, behavioral, and cardiovascular components of defense independently during the first three postnatal weeks in the rat. Supported by grants MH18264, DA05712, and DA07646.

AMYGDALAR SEROTONIN MEDIATES LONG-TERM SOCIAL ROLES FOLLOWING AGGRESSIVE INTERACTION Tangi R. Summers*, Earl T. Larson, Amy L. Hunter, Kenneth J. Renner, Neil Greenberg, and Cliff H. Summers Dept. of Biology, University of South Dakota, Vermillion, SD 57069, Dept. of Zoology, University of Tennessee, Knoxville, TN 37996

Stressful aggressive interaction stimulates, and social roles are distinguishable by, central serotonergic activation in telencephalon as well as brainstem. Pairs of male lizards, Anolis carolinensis, were allowed to fight and form dominant/subordinate relationships. In brainstem, subordinate males have reduced 5-HT, but increased 5-HTP, 5-HIAA and 5-HIAA/5-HT at 1 hour following the fight, gradually decreasing over a week of cohabitation. In micropunched regions of telencephalon, the greatest serotonergic changes also occur in subordinate males. The paleostriatum (medial amyodala), shown to play a role in regulation of aggression, develops serotonergic activity more slowly; greatest following a week of interaction. Turnover, 5-HT and 5-HIAA levels escalate over the first week of interaction in subordinate males, and return to baseline by 1 month. In dominant males. the pattern is accelerated, most extensive 5-HT system activity at 1 h, decreasing over a month. These data are consistent with rapid neuroendocrine stress modulation in dominant individuals, and delayed serotonergic activity in subordinate males. Supported by NIH grant NICHD-1-T32-HDO 7303-01A1, NSF grant OSR-9108773 and HHMI 7195-539501.

ANTIDIURETIC HIPPOCAMPAL/SUBICULAR REGULATION HORMONE FOLLOWING PSYCHOLOGICAL STRESS, K.W. Nettles, D.J. Luchins* and M.B. Goldman. Psychiatric Institute, University of Illinois in Affiliation with the University of Chicago, Chicago, IL, 60612.

The hippocampus/subiculum has been hypothesized to restrain hypothalamicallymediated neuroendocrine responses to psychological stress. To assess if this structure similarly influences antidiuretic hormone (AVP) secretion, we subjected lesioned rats to a standard swim stress (which does not increase plasma AVP in intact animals). Following anesthesia with pentobarbital, 60 d male Long-Evans rats received bilateral aspiration of the hippocampus (H) or just the overlying parietal cortex and corpus callosum (C). Aspiration was performed under direct visualization using a hypodermic needle connected to a suction pump. The lesion transects the subiculum and fimbria but leaves connected to a storon pump. The reson transcess his associating and interior our connected to the ventral hippocampal tip intact. After being individually housed for 3 wk, rats underwent a 45s forced swim (H₂O = 20°C) between 0900 and 1000 h, and were then sacrificed by decapitation at 30 min intervals for 90 min (n = 5 @ ea. time pt).

Immediately following the stressor, AVP levels did not differ (H = 2.8 ± 1.8 pg/ml; C immediately following the stressor, AVP levels did not dimer ($H = 2.8 \pm 1.8$ pg/ml. C = 1.7 ± 0.6), but then rose linearly in H (+ 90 min = 4.7 ± 2.4) to a greater extent than in C (+ 90 min = 2.4 ± 0.9) (MANOVA group X time F (3.32)= 2.63 p = 0.6, linear contrast p <0.2). Plasma osmolality (H = 305.9 ± 4.1 mosm/kg, C = 306.7 ± 3.4), sodium, glucose, creatinine and urea, and hematocrit were similar across groups, suggesting recognized AVP stimuli could not account for the finding. ACTH and corticosterone responses did not differ across groups

While further testing is needed using more discreet lesions, assessing other stressors, and confirming the integrity of recognized regulatory pathways, these preliminary results indicate that hippocampal aspiration is associated with an unexplained increase in plasma AVP following psychological stress. LONG-TERM SENSITIZATION OF ESCAPE BEHAVIOUR AFTER REPETITIVE ELECTRICAL STIMULATION OF THE RAT SUPERIOR COLLICULUS Sheila M King* Dept Exp Psychology, University of Oxford, UK

COLLICULUS Shella M King* Dept Exp Psychology, University of Oxford, UK Life-threatening events generally result in a set of behaviours which include risk assessment, freezing and escape, as well as the concomitant autonomic and endocrine changes which collectively form the 'fight-or-flight' response. However, when the initial stressor is of sufficient duration, intensity or frequency, the defence system may undergo a long-term increase in sensitivity similar to kindling. Consequently, the person may become hypervigilant, and suffer from symptoms of chronic psychophysiological arousal ie be in a persistent 'fight-or-flight' mode. It is known that repeated stimulation of structures in the rodent midbrain defence system ie the superior colliculus [SC] and the cuneiform area, increases the duration and intensity of the defensive responses obtained. So far, however, it has not beestablished whether sensitization of this system results in a long-term alteration of

established whether sensitization of this system results in a long-term alteration of the animal's responses to subsequent stressful events. The purpose of this study was. therefore, to study the behaviour of animals in a threatening environment after direct activation of the midbrain defence circuitry by repetitive electrical stimulation of the SC in both anaesthetized and unanaesthetized animals. 14 days after stimulation, animals were placed on an unstable, elevated and exposed plus maze for 5 mins and

their behaviour recorded. Testing was carried out regularly over a 3 month period.

Throughout the testing period, stimulated animals reliably exhibited a range of behaviours designed to escape the aversive environment. These included visual scanning, preparing to jump, and jumping off the apparatus. Unstimulated control animals and animals which had received footpinch whilst anaesthetized did not in general exhibit these behaviours. In contrast, the experimental animals' performance on standard behavioural tests eg the stable elevated plus maze and hole board, did not differ from the controls. These results demonstrate that kindling of the midbrain defence circuitry can produce a long-term change in an animal's reaction to threat, and may lead to the development of a functional model of extreme anxiety states.

CORTICOSTERONE LEVELS IN RAT BRAIN MICRODIALYSATES FOLLOWING EXPOSURE TO NOISE STRESS OR TO LIPOPOLYSACCHARIDE (LPS). R.W. Bonsall*, M.S. Emery and J.M. Weiss. Department of Psychiatry and Behavioral Sciences, Emory Univ. Sch. of Med., Atlanta, GA 30322.

Microdialysis is widely used to measure the local release of monoamines in specific regions of the brain, but it can also be used to measure hormones that are produced peripherally and cross the blood-brain barrier. Using conventional 4-mm probes constructed with regenerated cellulose membranes (Spectra/Por MWCO 13,000, 200μm i.d.) or 3-channel probes of similar dimensions in which a preservative solution was added to the outflow just distal to the membrane, tissue levels of corticosterone were sampled in hippocampus and prefrontal cortex and then measured in 2.5 µl aliquots of perfusate using a micro-adaptation of a commercially-available radioimmunoassay. Sensitivity was 0.2 pg per tube, with a coefficient of variation of about 5%. At a flow rate of 0.5 µl/min, in vitro recovery rates for corticosterone were 13-14%. Perfusate concentrations of corticosterone showed a circadian variation in the range of 0 to 100 pg/30-min sample with peak levels at the beginning of the dark (active) phase and a nadir 3-4 h after the start of the light phase: this implied tissue levels of 0 to 44 ng/ml. Exposure to a noise stress for 30 min produced elevated perfusate concentrations of corticosterone that lasted for 90 min and peaked at 200 pg/30-min in the sample after the noise stress. To assess the adrenal response to immunostimulation in the absence of other stressors such as handling and injections, LPS (10 µg/kg) was infused from a remote location via an indwelling i.p. cannula. This produced elevated perfusate concentrations of corticosterone starting 1 h after the infusion, peaking at about 60 pg/sample at 2-3 h and lasting for 3.5 h. Monoamines and monoamine metabolites were measured by HPLC-EC simultaneously with the steroid. The technique is sufficiently sensitive to permit serial corticosterone sampling rates of up to twelve per hour which could be maintained for prolonged periods. Supported by USPHS Grant MH 50420.

EFFECTS OF NMDA AMYGDALOID LESIONS ON GASTRIC EROSION FORMATION DURING EXPOSURE TO ACTIVITY-STRESS. N.S. Morrow, C.V. Grijalva, J. Landeira-Fernandez, P.J. Geiselman, T. Garrick. CURE: Digestive Diseases Research Center, Dept. of Veteran Affairs Medical Center, Los Angeles CA 90073, Depts. of Psychology and Psychiatry, UCLA, Los Angeles, CA 90024, Dept. of Psychology and Pennington Biomedical Research Center, S. LSU, Baton Rouge, LA, 70808.

The effects of chemical lesions (N-methyl-Daspartate [NMDA]) of the central (CE) or basolateral amygdaloid (BL) nuclei on gastric erosion formation, wheel running and survival were examined in male rats exposed to activity-stress. As compared to control rats, gastric erosion formation was attenuated in rats with bilateral NMDA lesions in the BL and exacerbated in rats with lesions in the CE, p's < .05. There were no group differences in wheel running, food intake, body weight or length of survival. These results indicate that chemical lesions of CE or BL alter stress-induced gastric erosion formation in a manner opposite to that observed after electrolytic lesions, suggesting that fibers of passage through the amygdaloid nuclei mediate the effects on the viscera during exposure to experimental stressors. **Supported by a Pilot and Feasibility Award from NIH Center Grant DK 41301 (Animal Core), by VA Merit Review funds and by NSF grants BNS 87-09982 and BNS 9196142.

MICROINJECTION OF MUSCIMOL INTO THE DORSOMEDIAL HYPOTHALAMIC NUCLEUS ATTENUATES FOS EXPRESSION IN THE PARAVENTRICULAR NUCLEUS FOLLOWING AIR STRESS IN RATS S.M. Morin*, E.H. Stotz-Potter and J.A. DiMicco. Dept. Pharmacol. & Toxicol. and Prog. in Med. Neurobio., Indiana Univ. Sch. of Med., Indpls, IN 46202

In mammals, acute stress elicits increases in heart rate (HR) and blood pressure (BP) and stimulates the release of adrenocorticotrophic hormone (ACTH). We have shown that microinjection of the GABAA receptor agonist muscimol (MUS) into the dorsomedial hypothalamus (DMH) prior to air stress reduces the cardiovascular changes while similar treatment in the paraventricular nucleus (PVN) has no effect. We have also shown that stress-induced increases in plasma ACTH are attenuated by microinjection of MUS into either the DMH or the PVN. These data suggest a primary role for the DMH in the integration of a multifaceted stress response, including mobilization of the hypothalamic-pituitary-adrenal axis. In this study, we investigated the effect of microinjection of MUS into the DMH on air stressinduced expression of Fos, an immediate-early gene product widely used as a marker of neuronal activation, in other hypothalamic regions. Rats implanted with guide cannulae in the DMH and arterial lines for monitoring HR and BP received 80 pmol/100nL MUS or 100 nL saline prior to being subjected to air stress for 20 minutes. One hour following the beginning of the stress the animals were sacrificed and the brains processed for Fos immunohistochemistry. In saline-treated rats, high levels of Fos expression was processed to the DMH. IN MINIOR was the DMH were evident throughout the hypothalamus, especially in the DMH, PVN, ventromedial nucleus (VMH) and the bed nucleus of the stria terminalis. However, in MUS-treated rats Fos expression was virtually abolished in the PVN and was attenuated to lesser degrees in other hypothalamic areas. These results suggest that activation of neurons in the DMH may be necessary for excitation of neurons in the PVN during stress. IN VIVO DIALYSIS REVEALS RAPID GLUCOCORTICOID STIMULATION OF SEROTONIN FROM HIPPOCAMPAL CORTEX Cliff H. Summers *, Tangi R. Summers, John M. Matter, Jen McKay, Patrick J. Ronan, Earl T. Larson and Kenneth J. Renner. Dept. of Biology, University of South Dakota, Vermillion, SD 57069.

During stressful situations, central serotonin (5-HT) release coincides with glucocorticoid feedback. To test neuromodulatory effects of stress hormones, 5-HT overflow was measured from the medial (hippocampal) cortex of Anolis carolinensis. A concentric dialysis probe (o.d. 250 µm, 1.0 mm length) was inserted a depth of 1.0 mm, 0.6 mm behind the center of the parietal eye. Perfusates were collected at 20 min intervals and analyzed for 5-HT. Probes had 5-HT precalibration recoveries of about 15%. Concentrations of 5-HT stabilized to basal levels after approximately 3.5 h. Tetrodotoxin (1μM) inhibition of approximately 60% of 5-HT overflow suggested that most of the 5-HT signal was neuronally derived. The effect of corticosterone (B) on 5-HT overflow appears to be dose and time dependent: Intracortical infusion of 2 ng/ml evoked transient increases in 5-HT release of approximately 50%, 20 ng/ml B 200%, and 200 ng/ ml B 400%. Duration of corticosterone infusion correlated positively with 5-HT response. Short-lived glucocorticoid stimulation of 5-HT release suggests a possible mechanism for endocrine mediation of continuously changing and transient social behavioral events. HIPPOCAMPAL CHOLINERGIC BLOCKADE INCREASES ANXIETY IN HIPPOCAMPAL CHOLINERGIC BLOCKADE INCREASES ANXIETY IN THE BLACK-WHITE BOX AND SOCIAL INTERACTION TESTS.

J.W. Smythe**, D. Murphy*, S.Bhatnagar*, C. Timothy*, and B. Costall*.

*IDept. of Pharmacology, Univ. of Bradford, Bradford, U.K., BD7 IDP and

*IDept. of Physiology, UCSF, San Francisco, CA 94143-0444, U.S.A.

Hippocampal cholinergic projections mediate attention to arousing stimuli as demonstrated by behavioral, electrophysiological and endocrine studies. We recently reported that peripheral injections of the cholinergic antagonist.

Complaining (SCOP)** increased anxiety-like behaviour. (AI B.) in rats and we seem the complaining (SCOP)** increased anxiety-like behaviour.

scopolamine (SCOP) increased anxiety-like behaviour (ALB) in rats and we sought to investigate if this response might be hippocampally-mediated. Adult male, Lister hooded rats were implanted bilaterally with hippocampal cannulae 3 weeks prior to testing. On the test day, rats were injected with vehicle (VEH; 0.9% saline). Is or 30 µg SCOP, 20 min prior to being placed into the white chamber of the Black-White box (n=7/group). Rats were scored for latencies to exit and re-enter the white chamber. A separate group of rats was injected with VEH (n=12) or 10 μg SCOP (n=18) and tested 20 min later in a social interaction paradigm. Pairs of rats, both injected with VEH or SCOP, were placed into an open field and scored for time spent engaged in interactive behaviours (sniffing, following, physical contact). Data were assessed by ANOVA and Bonferroni corrected t-tests. ANOVA on the black-white box data and the boundary of the state significantly reduced time to exit the white arena (P<.05), while the 15 μ g dose elevated latencies to re-enter the white chamber (P<.01). SCOP also reduced the duration and amount of social behavior compared to VEH rats (P<.02). Loss of hippocampal cholinergic function impairs processing of threatening stimuli that manifests itself as increased ALB and reduced social interaction behavior. Paradoxically, in the absence of cholinergic function, animals exhibit heightened sensitivity to the environment. (Supported by Medical Research Council of Canada and U. of Bradford)

LESIONS OF THE AUDITORY THALAMUS SPECIFICALLY BLOCK CORTICOSTERONE RELEASE AND INDUCTION OF c-fos mrna in the forebrain associated with loud noise stress in rats. $\underline{\textbf{S}}_{\text{c}}$ Campeau*, H. Akil, and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Loud noise reliably elicits the release of corticosterone and the induction of the immediate early gene c-fos in many rat forebrain areas. The paraventricular nucleus of the hypothalamus is thought to be the final relay essential for stress-induced corticosterone release. To begin to determine the putative pathway through which loud noise activates the paraventricular nucleus, the auditory thalamus was chosen for study because of its obligatory role in relaying auditory information to the forebrain. Male Sprague-Dawley rats (n = 48) received either neurotoxic (ibotenic acid) lesions

aimed at the auditory thalamus (n = 18), sham lesions (n = 15) or were unoperated (n = 18) = 11). Four rats served as naive controls. All rats except the naives were handled for 2 min and placed in the experimental cages for 10 min on each of 14 consecutive days following surgery. On Day 15, the rats were placed in the cages for 60 min, and a 105 dBA noise (20 - 20000 Hz) was turned on for the last 30 min. The rats were decapitated immediately upon removal from the cages, their trunk blood collected and processed for corticosterone radioimmunoassay. The brains were rapidly removed, frozen, and processed for c-fos in situ hybridization.

Loud noise produced a reliable increase in plasma corticosterone in the unoperated (21.4 \pm 2.9 μ g/dl) and sham-operated rats (17.2 \pm 3.4 μ g/dl), but not in the rats sustaining relatively complete auditory thalamic lesions (n = 9; $2.8 \pm 1.1 \,\mu$ g/dl). Loud noise induced c-fos mRNA in many forebrain areas of the unoperated and shampoperated rats, but not in the auditory thalamic lesioned rats. The auditory nuclei below the level of the auditory thalamus displayed reliable *c-fos* induction in all groups. Restraint and ether stress elicited similar corticosterone release in all groups. These results indicate that the auditory thalamus is an obligatory relay in the pathway involved in the release of corticosterone by loud noise and suggest the mediation of noise stress by forebrain structures. Supported by MRC of Canada and MH42251.

CRF ALTERS CORTICOSTERONE EFFECTS ON MEDULLARY SENSORIMOTOR INTEGRATION AND NEURAL EXCITABILITY. J. D. Rose^{1*}, Glenn Marrs¹ and F. L. Moore², ¹Dept. of Psychology. Univ. Wyoming, Laramie, WY 82071 and ²Dept. of Zoology, Oregon State Univ., Corvallis, OR 97331.

Previously, we have shown that corticosterone (CORT) rapidly depresses sensorimotor processing and excitability in medullary reticulospinal and non-reticulospinal neurons in the roughskin newt (Taricha granulosa), apparently by an action at a CORT neuronal membrane receptor. In contrast, corticotropin-releasing factor (CRF) increases the activity of medullary neurons as it stimulates locomotion in newts. The present study examined effects of sequential medullary CRF application and medullary or systemic CORT administration in immobilized newts, to simulate the sequential release of these hormones in a natural stress response. CRF caused an immediate increase in firing rate and somatic sensory responsiveness of non-reticulospinal neurons and concurrently enhanced several parameters of excitability of reticulospinal neurons. Subsequent CORT administration, within 5-10 min of CRF, was followed by continued increases in excitability of these same neuronal populations. Thus, the neural action of CORT is modulated by immediately preceding actions of CRF, indicating that the temporal pattern of action of these stress hormones is a critical factor in determining their neuronal effects. Supported by NSF grants IBN-9410284 (J.R.) and IBN-9421175 (F.M.).

MIRRORS REVERSE DISTRESS VOCALIZATIONS BUT NOT STRESS-INDUCED ANALGESIA IN THE CHICK SOCIAL-SEPARATION PROCEDURE. G. S. Watson^{1*} & K. J. Sufka^{1,2}. Departments of Psychology¹ & Pharmacology², The University of Mississippi, Oxford, MS 38677

Chicks separated from social companions displayed an increase in distress vocalizations and a decrease in formalininduced (0.05 ml of 0.10% formalin injected into the plantar surface of the right foot) nociceptive behaviors (i.e., stressinduced analgesia) relative to chicks tested with two social companions during 3 minute test period. Chlordiazepoxide (3.0-10.0 mg/kg/ml, IM 30 min before tests) dose-dependently reversed both distress vocalization and stress-induced analgesia effects. When mirrors were substituted for social companions, stress effects on distress vocalizations but not stress-induced analgesia were reversed. Physical contact with social companions may be necessary for the prevention of stress-induced analgesia whereas a purely visual stimulus (chick's image in a mirror) is sufficient to reverse distress vocalizations. In subsequent mirror studies exploring the effects of chlordiazepoxide on distress vocalizations only. chlordiazepoxide reversed distress vocalizations when injected IM, but not when injected IP.

REGULATION OF CORTICOTROPIN-RELEASING FACTOR (CRF) ACTIONS ON LOCUS COERULEUS (LC) NEURONS: EFFECTS OF ADRENALECTOMY. L.A. Pavcovich and R.J. Valentino*. Dept. of Psychiatry, Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA, 19102

Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA, 19102.

CRF has been hypothesized to act as both a neurohormone and brain neurotransmitter in the coordination of the stress response. The neurohormone actions of CRF are regulated by corticosteroids, as indicated by the effects of adrenalectomy, which include increased CRF synthesis and release (Dallman et al., 1992; Plotsky and Sawchenko, 1987). The present study tested the hypothesis that adrenalectomy also regulates a putative neurotransmitter effect of CRF, ie., its activation of LC neurons. LC spontaneous discharge rates were significantly higher in adrenalectomized (ADX) vs. sham-operated (SHAM) rats. Intracoerulear microinfusion of a CRF antagonist decreased LC discharge rates of ADX rats to rates comparable to those observed in SHAM rats, but had no effect in SHAM rats. The CRF dose-response curve in ADX rats was shifted in a complex manner, suggestive of additivity or that a proportion of CRH receptors were occupied prior to CRF administration. Hypotensive challenge (thought to activate the LC via CRF release) increased LC discharge rate in ADX rats by a magnitude greater than that which would be predicted on the basis of additivity. In contrast, the magnitude of LC activation by carbachol (i.c.v.) and sciation erve stimulation (mediated by an excitatory amino acid input) were similar in both groups. These results suggest that adrenalectomy enhances tonic and stress-induced CRF release within the LC. Thus, the actions of CRF on the pituitary (a neurohormone effect) and on the LC (a neurotransmitter effect) may be regulated in a parallel manner. Such parallel regulated in a parallel manner. Such parallel regulated in a parallel manner. Such parallel regulated in a parallel manner. Such parallel regulated in a parallel manner. Such parallel regulated in a parallel manner. Such parallel regulated in a parallel manner. Such parallel regulated in a parallel manner. Such parallel regulated in a parallel manner.

HORMONAL CONTROL OF REPRODUCTIVE BEHAVIOR IV

454.1

AMYGDALA BUT NOT HIPPOCAMPAL LESIONS DISRUPT OLFACTORY MEMORY INVOLVED IN PREGNANCY BLOCK IN FEMALE PRAIRIE VOLES. G.E. Demas*, J.M. Williams and R.J. Nelson. Department of Psychology, Behavioral Neuroendocrinology Group, The Johns Hopkins University, Baltimore, MD 21218.

Mammalian reproduction is influenced by chemosensory information in many rodent species. The presence of an unfamiliar male results in spontaneous abortion by a pregnant female and a return to an estrous state within 48 h (i.e., the Bruce effect). Disruption of pregnancy does not occur in the presence of a familiar male. Unlike most laboratory species, female prairie voles do not exhibit regular estrous cycles; rather, female prairie voles are induced into estrus by chemosensory stimuli contained in the urine of male conspecifics. Females come into contact with these pheromones while grooming the ano-genital (A-G) region of unfamiliar males. After initial contact with a male, female prairie voles maintain a brief 8-10 day "memory" for their previous mate. Subsequent exposure to the same male within this 8-10 day window does not elicit ano-genital investigation by the female and pregnancy block does not result. The present study is an attempt to elucidate which neuroanatomical area(s) are involved in olfactory memory. Female prairie voles received bilateral electrolytic lesions of either the amygdala or hippocampus; females were subsequently exposed to males for 48 h, separated for 3 days, and then reintroduced to their original mate for 24 h. A greater proportion of females receiving amygdala lesions displayed pregnancy block when re-exposed to their previous mates compared to voles receiving hippocampal or sham lesions. Amygdala-lesioned voles also displayed a greater number of A-G investigations compared to the other groups. Olfactory tests suggest that these results were not due to a basic disruption of the main olfactory or accessory olfactory systems. Taken together, these results suggest that the amygdala plays an important role in olfactory memory or reproductive motivation in prairie voles. Supported by USPHS grant HD22201.

454.2

BRAIN MECHANISMS INVOLVED IN POSTPARTUM ESTRUS IN PRAIRIE VOLES. <u>L.F. Katz, G.F. Ball, and R.J. Nelson</u> *Department of Psychology, Behavioral Neuroendocrinology Group, The Johns Hopkins University, Baltimore, MD 21218.

Female prairie voles (Microtus ochrogaster) do not exhibit spontaneous estrous cycles; rather, estrus is induced by direct contact with chemosensory stimuli from male conspecifics. Female prairie voles also display spontaneous postpartum estrus. Mating probably occurs most commonly during postpartum estrus in nature, yet little is known about its neuroendocrine or neuroanatomical bases. The goal of this study was to determine the neuroanatomical bases of postpartum estrus, and to compare these pathways to those previously found to be involved in male-induced estrus in this species In the present study, perfused brains brains of three experimental treatment groups (0-12 hours, 12-24 hours, and 24-48 hours postpartum) and two control groups (late pregnancy and paired nonpregnant females) were processed using immunocytochem for the fos protein. Digitized images of brain slices (40 µm) were projected from a bright field microscope at 10x and analyzed using a computerized image analysis system (Image 1.4 Mac). A significant increase in the number of fos-ir cells was observed in the accessory olfactory bulb (AOB), medial preoptic area, thalamic paraventricular nucleus, primary somatosensory area, and the bed nucleus of the stria terminalis from brains obtained 0-12 hours postpartum. The neural activation seen in the AOB in the 0-12 hour postpartum group resembles the fos expression observed in the AOB in female prairie voles immediately following exposure to male urine. The origin of the exogenous cue triggering this activity in the AOB may be from contact with a non-volatile stimulus from either the male or the newborn pups. Supported by NIH grants HD22201and MH50388

NEUROPLASTICITY OF THE MATERNAL BRAIN: CHANGES IN SIGNAL TRANSDUCTION AND GLIAL PROTEINS ASSOCIATED WITH POSTPARTUM EXPERIENCE IN RATS. A.S. Fleming*, R. Featherstone, J. Watchus, R. Smyth, M. Lydan, D. O'Dav and G. Ivy, Depts. Psychology and Biology, Erindale Coll., Univ. of Toronto, Mississauga, Ont., CANADA LSL IC6.

When female rats give birth, they adequately care for their offspring with no prior maternal experience. Once females have interacted with young, their maternal responsiveness is sustained past the period of hormonal priming. The long-term retention of responsiveness is mediated by prior experience and learning processes.

A number of neural sites show elevated Fos-like immunoreactivity (Fos-lir) with

experience and in response to pups or pup-associated cues, including the medial preoptic area (MPOA), the basolateral amygdala (BLA) and the parietal cortex (PC). These studies explore the upstream signalling elements associated with experience-based Fos expression, including protein-kinase C (PKC) and calmodulinbinding proteins (CaMBPs), as well as other proteins associated with neuroplasticity (e.g. GFAP in Astrocytes).

In different studies, postpartum females were provided with a brief interactive experience with pups or control experiences. Within each experience condition, animals were either sacrificed immediately (exposure phase) or after an interval (retention), and brains were assessed immunocytochemically for Fos-lir, PKC or GFAP or using gel electrophoresis, for CaMBPs. Brain sites were quantified using

a light microscope with 10 x 15 magnification.

The MPOA and PC showed higher densities of cells showing Fos-lir and PKC and lower concentrations of CaMBPs following the exposure phase and pup stimulation in postpartum animals. The MPOA and PC also showed elevated experience-based PKC and GFAP at retention, in the absence of additional pup-stimulation. No experience effects were seen in BLA or control sites (e.g. VMH, HIPP). These studies show neuroplasticity within the maternal circuit. Supported by the Medical Research Council of Canada awarded to A.S. Fleming

454.5

MATERNAL MOTIVATION: THE EFFECT OF MEDIAL PREOPTIC LESIONS ON OPERANT BEHAVIOR IN FEMALE RATS. A.W. Lee, A.S. Fleming, S. Clancy and M.L. Smith*. Dept. of Psychology, Erindale Coll., Univ. of Toronto, Mississauga, Ont., CANADA L5L 1C6.

The present study consists of four studies, in which the dissociation of maternal motivation and maternal consummatory behaviors in female rats was investigated.

The first study determined the effect of reproductive state on both maternal behavior and instrumental bar press response for pup reinforcement. Groups consisted of maternally experienced impregnated or cycling females. Impregnated females showed a significant increase in both bar press response and the expression of maternal behaviors from pregnancy to Day 1 postpartum. Cycling females showed no changes over a comparable time period. Study 2 compared two groups of cycling maternally experienced females. Half were re-induced to become maternal through continuous pup exposure and half were not induced. Maternal females exhibited a significantly higher pup-reinforced lever pressing rate than did the non-maternal females. Study 3 investigated effects of MPOA lesions on operant behavior. Two groups of cycling maternally-experienced females were induced to become maternal. Groups received bilateral electrolytic medial preoptic area (MPOA) or sham lesions. Pre-surgery, both groups showed a high operant rate for pups and all components on maternal behaviors. After surgery, the bilateral lesioned group showed a decrease in bar press response and did not engage in pup-directed maternal behaviors. Sham subjects did not change their maternal or bar press responses for pups and remained maternal throughout the study. Study 4 investigated the effects of MPOA, nucleus accumbens, and lateral amygdala lesions on postpartum rats. After surgery, the MPOA group showed a decrease in bar press response and did not engage in pup-directed maternal behaviors. No differences were found between sham, nucleus accumbens and lateral amygdala lesioned animals. Supported by the Natural Sciences and Engineering Research Council of Canada awarded to A.S. Fleming.

454.7

INCREASES IN NADPH-DIAPHORASE STAINING IN THE SUPRAOPTIC AND PARAVENTRICULAR NUCLEI DURING LATE PREGNANCY AND EARLY LACTATION IN RATS. N. Popeski*, S. Amir & B. Woodside, Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montréal, Canada.

Among numerous putative functions the gaseous transmitter molecule Nitric Oxide (NO) has been implicated in the modulation of a variety of neuroendocrine events. Recently an increase in staining for NADPH-d, a histochemical marker for Nitric Oxide Synthase has been reported in the paraventricular (PVN) and supraoptic (SON) nuclei of late pregnant rats. In this study, the time course of these changes was examined more closely by comparing NADPH-d staining in the PVN and SON of rats at comparing NADPH-d staining in the PVN and SON of rats at different stages of pregnancy and lactation. Thus, female rats either unmated or on Days 4, 12, 16 or 22 of pregnancy or Days 4, 12 or 20 of lactation were anaesthetized and perfused with ice-cold saline and 4% paraformaldehyde. Brains were removed and processed for NADPH-d histochemistry. Females in early pregnancy showed staining similar to that of virgin animals. Consistent with our earlier study NADPH-d staining was increased in late pregnancy and in some stages of lactation. These data suggest that NO may be involved in the events surrounding parturition and lactation. The role of the hormonal status of the female in producing these effects is presently under investigation. (Supported by Grant # 7938 from NSERC to B.W.)

FFFECTS OF KINDLING-LIKE STIMULATION OF THE MEDIAL PREOPTIC AREA AND THE MEDIAL AMYGDALA ON MATERNAL MOTIVATION IN VIRGIN FEMALE RATS. H.D. Morgan*, J.A. Watchus and A.S. Fleming. Department of Psychology, University of Toronto, Mississauga, Ontario, Canada L5L 1C6.

Ontario, Canada L5L 1C6.

The effects of kindling-like electrical stimulation of the medial preoptic area (MPOA) or the medial amygdala (AME) on maternal and other associated (motivational) behaviors and its interaction with pup exposure were investigated. Previous experiments have shown that kindling the AME and MPOA in pup experienced females enhanced their functional effects. The present study investigated the effects of kindling on the same functional endpoints in virgin animals sustaining a variety of pup experiences. Four conditions of MPOA and AME kindled virgins were used: (1) kindled [K] (and not-kindled [NK] control group) without pup exposure, (2) K (and NK) during pup exposure, (3) K (and NK) 1 week before pup-exposure, and (4) K (and NK) both during pup exposure and 1 week before pup-exposure (16 groups total). Stimulation was applied daily for 2 weeks using 2 second trains of biphasic square wave pulses at 1 ms duration and 400µA. Testing proceeded 1 week after kindling. For groups that had exposure to pups (conditions second trains of biphasic square wave pulses at 1 ms duration and 400µA. Testing proceeded 1 week after kindling. For groups that had exposure to pups (conditions 2,3 and 4) MPOA K animals showed shorter latencies to become maternal than MPOA NK animals and than AME K and NK animals. For measures of maternal 'motivation', in pup-exposed conditions 2 and 4 AME kindled animals showed a decreased attraction to pup odors in a modified hole board test compared to AME NK animals and MPOA NK animals. AME K animals in pup-exposed conditions 3 and 4 showed also showed a decreased attraction to pup odors in the modified hole board when compared to non-pup-exposed AME NK animals. There was no difference between any groups for the hole board test within the non-pup-exposed condition. The above results confirm that the MPOA and the AME are involved in facilitating and attenuing maternal responsiveness and related (precursor?) condition. The above results confirm that the MPOA and the AME are involved in facilitating and attenuating maternal responsiveness and related (precursor?) behaviors, respectively. However, this effect was produced only in interaction with pup exposure. Kindling possibly enhances neural changes during functional reorganization of neural substrates.

COMPARISONS OF ARGININE VASOPRESSIN STAINING IN TWO SPECIES OF PEROMYSCUS WITH DIFFERENT LEVELS OF PARENTAL CARE. J.K. Bester and C.A. Marler*. Dept. of Psychology, University of Wisconsin-Madison, Madison, WI 53706

Previous studies have suggested that arginine vasopressin (AVP), a neuropeptide hormone, is involved in parental and aggressive behavior. In this study, we compared the locations and intensity of AVP immunoreactive staining in the brains of two closely related species, Peromyscus californicus, a monogamous species with high levels of parental care, and Peromyscus leucopus, a promiscuous species with low levels of parental care. We confirmed behavioral differences in parental care between the two species under similar laboratory conditions. Because of these differences, we compared the degree of AVP immunoreactive (AVP-ir) staining using image analysis in brain areas associated with sexual, aggressive, and parental behavior, including the bed nucleus of the stria terminalis, the lateral septum, the amygdala, and the preoptic area. The degree of AVP-ir staining was also compared in brain areas that traditionally have been associated with water balance and non-reproductive functions. These areas include the paraventricular nucleus, the supraoptic nucleus, and the suprachiasmatic nucleus. AVP-ir staining was significantly greater in the medial amygdala of P. californicus and no difference was found in the paraventricular nucleus. Ongoing analyses are being performed to compare other brain areas in the two species. Results of these analyses will be compared to other species comparisons of AVP-ir staining.

DIFFERENTIAL FOS EXPRESSION IN THE BRAINS OF MATERNAL AND NON-MATERNAL VIRGIN FEMALE RATS EXPOSED TO VARIOUS STIMULI. T.P. Sheehan*, E.C. Stack, M.J. Numan, and M. Numan. Psychology Dept., Boston College, Chestnut Hill. MA 02167

Virgin female rats are not spontaneously maternal, but can be sensitized to show maternal behavior after daily exposure to pups Differences in these behavioral states may be reflected in the activity of different brain areas. To investigate this, we exposed both sensitized and naive (non-sensitized) virgin female rats to pups for two hours. Control groups were exposed to marbles as a non-pup stimulus. After exposure, animals were sacrificed and their brains were immunohistochemically processed for detection of the Fos protein, which is used as a marker for neuronal activation. Our initial results indicate that the levels of Fos in the ventral portion of the lateral septum (LSv) and the central nucleus of the amygdala (CNA) are highest in naive virgins exposed to pups when compared to all other groups. All subjects exposed to pups showed higher levels of Fos in the medial preoptic area (MPOA), with sensitized virgins showing a greater Fos response relative to naive virgins. In naive virgins, Fos expression in the LSv and CNA may represent the novelty of pup odors and/or an aversive response to such odors. Enhanced Fos in the MPOA may be a result of both pup exposure and the expression of maternal behavior Results will also be presented on Fos expression in other brain areas such as the bed nucleus of the stria terminalis and the periaqueductal

gray.

SATIETY OF PUPS REGULATES DECLINE OF NURSING DURATION WITH TIME POSTPARTUM IN LACTATING LONG-EVANS RATS. <u>S.E. Keer* and J.M. Stern.</u> Department of Psychology, Rutgers University, New Brunswick, NJ 08855.

Rooting and suckling of rat pups is essential for initiating and maintaining their dams' nursing behavior. During the 2nd week postpartum (PP), there is a normal decline in the duration of time spent nursing, attributed previously to maternal hyperthermia rather than milk transfer. In contrast, we hypothesized that the development of satiety reponsiveness in the 2nd postnatal week contributes to the decline in nursing time. In the 1st study, pups received 0, 4, or 8% of their body weight in half-and-half creamer by stomach gavage on days 7, 12, and 15 PP. Dams nursing 4%- or 8%-gavaged pups showed a decreased number of milk ejections (ME); litter weight gain was also decreased. On days 7 and 12 (4-h dam-litter separation and subsequent observation until 30 min after 1st ME) the 1st ME occurred considerably later. On day 15 (undisturbed 24-h video recording) crouch latency was 10x longer and crouch duration 50% shorter than in dams gavaged with nothing. The 2nd study investigated whether inhibition of milk release would increase nursing duration. Dams underwent mammary duct ligations (MDX) or a control procedure (MDC) on day 6-7 followed by 12-h undisturbed video recordings with foster pups on days 7-8 and 13-14. Weight losses were seen in both day 7 (-7.0 g) and 14 (-4.6 g) litters nursed by MDX dams. On days 7-8, hovering over (without actual nursing) was 40% higher in MDX dams, while passsive (supine) crouching was 35% higher in MDC dams. On days 13-14, kyphotic (upright) crouching lasted 7x longer in MDX than in MDC dams. These experiments suggest that the decline nursing duration in rats is regulated by pup satiety since sating pups decreases while preventing milk transfer to pups increases nursing duration on days 13-14 PP.

CHANGES IN CENTRAL NEUROTENSIN IMMUNOREACTIVITY ASSOCIATED WITH LACTATION AND MATERNAL BEHAVIOR IN RATS. M. Numan*, S.A. Aviles, M.D. Williams, E.C. Stack, T.P. Sheehan, and M.J. Numan. Dept. Psychology, Boston College, Chestnut Hill, MA 02167

Neurotensin is a neuropeptide that is found in high concentrations within the basal forebrain. Since the distribution of Fos-expressing neurons within the basal forebrain of maternal rats approximates the distribution of neurotensin-containing neurons, the present study investigated whether changes in neurotensin systems are associated with maternal behavior and lactation. Virgin female and maternal lactating rats were sacrificed and their brains were processed with standard immunocytochemical procedures for the detection of neurotensin-immunoreactive (NTir) cell bodies and fibers. None of the females was treated with colchicine. An image analysis system was used to measure the density of NTir fibers. Preliminary findings indicate that lactating females have significantly more neuronal cell bodies that contain NTir within the central nucleus of the amygdala (CN) and the oval nucleus of the bed nucleus of the stria terminalis (BST). Lactating females also have a higher density of NTir fibers within the retrorubral field (RRF) of the midbrain. These changes may be due to increased synthesis and/or decreased release of neurotensin in postpartum females. Neurotensin within the CN and BST may be involved in regulating either suckling-induced activation of the adrenocortical system or the adrenocortical stress response. Neurotensin fibers within the RRF may be influencing aspects of maternal behavior

DEFICIENCY IN MOUSE OXYTOCIN PREVENTS LACTATION, BUT NOT DEFICIENCY IN MOUSE OXYTOCIN PREVENTS LACTATION. BUT NOT FERTILITY OR PARTURITION. W. S. Young, III*, E. Shepard, J. Amicoff, M. E. LaMarcat, C. McKinneyt, E. I. Ginnst. Lab. Cell Biology and †Clinical Neuroscience Branch, NIMH, NIH, Bethesda, MD 20892; ¶Div Endocrinol Metab, Univ Pittsburgh, School of Medicine and VA Medical Center, Pittsburgh, PA 15261 To investigate whether oxytocin (OT) is essential for parturition, lactation, various reproductive behaviors, and memory, we eliminated, by homologous recombination, most of the first intron and the last two exons of the mouse OT gene. No gross

most of the first intron and the last two exons of the mouse OT gene. No gross anatomical or behavioral differences were noted between wild-type (WT), heterozygous (HE) or homozygous (HO) mutant pups. Weights of HO mice were not significantly different from WT mice through at least two months (males: 23.1±1.2g (±sdev) and 20.9±0.7; females: 19.3±0.2 and 17.7±0.6). OT has natriuretic and antidiuretic properties and its receptor is present in the rat kidney, so we measured two parameters that could reflect kidney dysfunction. No differences were noted among males in plasma osmolalities (WT: 297±2.4mOSM (±sem), HO: 297±2.1) or abilities to concentrate urines after 24 hours of water deprivation (WT: 2945±151mOsm (±sem), HO: 3045±360). OT transcripts are seen in the PVN and SON of the WT and HE mice using an exon A probe, with greatly reduced levels in the HO PVN. The mRNA levels for the HE and HO PVNs are 53% and 1% of the WT level. Homozygous mutant mice have no detectable neurophysin or processed oxytocin in the paraventricular nucleus, supraoptic nucleus or posterior pituitary. OT RIA of pituitary extracts was 220 ± 20 (mean ± SEM) ng/pituitary in WT mice and <1 ng/pituitary (s00 ± 50 pg/pituitary) in HO mice. Plasma OT levels in the HO mice were undetectable (WT was 15-20pg/ml). VP transcripts are reduced in both nuclei by 30% (p<0.01 in the SON). VP transcripts are reduced in both nuclei by 30% (p<0.01 in the SON). Suprachiasmatic VP expression was unaltered in HO mice arguing against a nonspecific reduction due to disruption of the OT gene which is closely linked to the VP gene. Expression of dynorphin, which is co-expressed with VP, is elevated by 37% in the HO PVN neurons compared to the WT (p<0.01). PVN expression of corticotropin-releasing factor and enkephalin is unaltered. Interestingly, HO males and females are fertile and the HO females are able to deliver their litters. However, they do not lactate and their pups die within 24 hours.

PERIAQUEDUCTAL GRAY LESIONS, PRE- OR POSTPARTUM, SPECIFICALLY IMPAIR KYPHOTIC NURSING BEHAVIOR BUT FACILITATE MATERNAL AGGRESSION IN LONG-EVANS RATS. J.S. Lonstein*, D.A. Simmons, and J.M.

Stern, Department of Psychology, Rutgers University, New Brunswick, NJ 08903. Electrolytic lesions performed on day 7 postpartum (PP) encompassing the lateral and ventrolateral regions of the caudal periaqueductal gray (PAG) at the level of the trochlear nucleus (PAG-X) almost eliminate upright crouched nursing (kyphosis) compared to controls (PAG-C), assessed by continuous 60-min observations after a 3-h mother-litter separation on days 8-13 PP. All dams spent similar amounts of time with their litters, but time spent in other nursing postures was increased in lesioned rats. No deficits were seen in other behaviors including retrieval, nesting time, and pup licking. Though milk ejections and litter weight gains were similar for lesion and control groups during the daily observation periods, 24-h litter weight gains were reduced by 15% after lesioning. Maternal aggression toward an unfamiliar male intruder was tested presurgically on day 5, and on postlesion days 8 and 10 PP. Attack latency was reduced, and attack number and duration were increased, in PAG-X vs. PAG-C dams. When lesions were performed prepartum on gestation days 15-17, and subjects observed for 60 min after a 3-h dam-litter separation on days 1-6 PP, a similar deficit in upright crouched nursing and facilitation of maternal aggression was seen. Deficits in 24-h litter weight gains were larger (~25-30%) after lesioning prepartum. Upright crouched nursing is therefore necessary for normal litter growth, especially during early lactation when pups are small. The present results, along with previous Fos findings (SN '95) and the known medullary, trigeminal, and spinal connections of the PAG, suggest that the PAG may be a component of the pathway by which suckling elicits the postural alterations seen during kyphotic nursing and facilitates maternal aggression. THE ROLE OF LATERAL HABENULA NEURONS IN THE NON-HORMONALLY MEDIATED DISPLAY OF MATERNAL BEHAVIOR IN SENSITIZED VIRGIN FEMALE RATS. T. Matthews-Felton* ¹. J. S. Rosenblatt. ² J.I. Morrell ¹. C.M.B.N. ¹ and I.A.B. ², Rutgers University, Newark, N.J. 07102

Newark, N.J. 0/102
Our previous studies have shown that the Lhb is necessary for the hormonal onset of maternal behavior (Corodimas et al., 1993; Matthews-Felton et al., 1995), but not for the postpartum maintenance of already established maternal behavior in the rat (Corodimas et al., 1992). Although hormones initiate maternal behavior in the naturally parturient female, it is maintained by pup stimulation and is largely non-hormonal. In contrast, the sensitization model of maternal behavior, can occur by

In contrast, the sensitization model of maternal behavior, can occur by direct pup stimulation with no hormonal interaction at all. Sensitization consists of continuously exposing females to pups and results in maternal behavior in 5-7 days even in ovariectomized or hypophysectomized females. Sensitization was used in the present study to examine the effects of Lhb lesions on non-hormonal, pup-mediated maternal behavior. Virgin female rats received bilateral kainic acid-induced lesions of the Lhb, or as a control, the dorsal hippocampus. A third group served as unlesioned controls. All animals were tested for pup retrieval, nest building, and crouching behavior for 15 days. General activity and carrying ability were also tested during this period. A fluorescent retrograde tracer (Fluoro-Gold), along with cresyl violet stained sections were used for histological analysis of the lesions.

Preliminary results indicate that lesions produced in the Lhb do not disrupt the initiation of maternal behavior produced by sensitization.

disrupt the initiation of maternal behavior produced by sensitization. There were no significant differences in pup retrieval, nest building, and crouching behavior between animals with Lhb lesions and either the hippocampal or unlesioned control groups. COMPARISONS OF THE BEHAVIORAL EFFECTS OF OXYTOCIN AND VASOPRESSIN IN MONOGAMOUS PRAIRIE VOLES, M. M. Cho, A. Dharmadhikari, J. R. Williams, & C. S. Carter*. Department of Zoology, University of Maryland, College, Park, MD 20742

Oxytocin (OT) and arginine vasopressin (AVP) have been implicated in pair bonding in prairie voles (Microtus ochrogaster). Earlier studies suggested that males respond most readily AVP, which tends to increase the preference for a familiar partner and aggression to strangers; while females are sensitive to OT, which facilitates partner preferences. In other systems there is evidence that OT and AVP may occupy and affect each other's receptors. In the present study, we have compared the behavioral effects of centrally-administered (icv) OT and AVP on behaviors associated with pair bonding and exploration. At comparatively high doses (100 ng) both OT and AVP can stimulate the rapid development of partner preference in both sexes. Lower doses were less effective. In males, exploratory behavior in an elevated plus maze also tended to increase following both OT and AVP, but the effects of AVP were longer lasting (measured for 3 hours or more) than those of OT (lasting approximately 1 hour). These results suggest that high doses of OT and AVP can have apparently similar behavioral effects in both sexes, although the temporal profiles of the two peptides may not be identical. Sponsored by NIH and NIMH.

ANXIOLYTIC ACTION OF SUBSTANCE P ADMINISTERED SYSTEMICALLY OR INTO THE BASAL FOREBRAIN. R.U. Hasenöhrl¹*, O. Jentjens¹, M.A. De Souza Silva¹, C. Tomaz² and J.P. Huston¹. ¹Inst. Physiol. Psychology, Univ. Düsseldorf, D-40225 Düsseldorf, Germany; ²Dept. Psychobiol., Univ. Sao Paulo, Ribeirao Preto, 14049 Brazil.

Reinforcing and memory-promoting effects of substance P (SP) were found upon injection into several parts of the brain and intraperitoneally. Given the close link between fear/anxiety and memory processes for negative reinforcement learning, the aim of the present study was to gauge the effect of SP in the rat elevated plus-maze (EPM) and social interaction test of anxiety. When given peripherally (IP), SP had a biphasic dose-response effect on the behavior in the EPM with an anxiolytic-like action at 50 μ g/kg, and an anxiogenic-like one at 500 $\mu\mathrm{g/kg}$. After microinjection into the region of the nucleus basalis magnocellularis (NBM), SP (1 ng) was found to exert anxiolytic effects, since SP-treated rats spent more time on the open arms of the EPM and showed an increase in time spent in social interaction. These results show that SP can have anxiolytic-like properties in addition to its known memory-promoting and reinforcing effects, supporting the hypothesis of a close relationship between anxiety, memory and reinforcement processes. Supported by DFG.

ENDOGENOUS NITRIC OXIDE MODULATES SUBSTANCE P-INDUCED ITCH-RELATED BEHAVIOR. <u>T. Andoh, T. Nagasawa, K. Hayashi, Y. Kuraishi*</u>. Dept. of Applied Pharmacol., Res. Inst. for Wakan-yaku, Toyama

Med. & Pharm. Univ., Toyama 930-01, Japan.
Substance P (SP) causes an itch sensation in human subjects when applied to the skin. Recently we have found that an intradermal injection of SP elicits itch-related behavior, that is, scratching of the injected site by the hind paws and that such SP action is inhibited by NK1 antagonist. As stimulation of NK1 receptors activates nitric oxide (NO) synthase in the endothelial cells and macrophages, the present experiments were conducted to determine whether the NO-cyclic GMP pathway was involved in SP-induced scratching. Male ICR mice (5-6 weeks old) were used and SP was intradermally injected into the rostral back in a volume of 50 μ L. Pretreatment with the NO synthesis inhibitor N^G-nitro-L-arginine methyl ester (L-NAME, 0.1-10 mg/kg), significantly suppressed SP (100 nmol)-induced scratching in a dose-dependent manner. Another NO synthesis inhibitor 1-ethyl-2-thiourea (0.1-10 mg/kg, i.v. 5 min before) showed similar inhibitory effects. When injected simultaneously with SP (100 nmol), the NO scavenger hemoglobin (0.01-10 nmol) or the guanylate cyclase inhibitor methylene blue (0.001-0.1 nmol) significantly suppressed SP-induced scratching. Although either L-arginine (300 nmol) or SP (30 nmol) was almost without effects, a concomitant intradermal injection of these agents induced apparent scratching. These results suggest that the NO-cyclic GMP pathway is involved in the SP-induced scratching, probably an itch sensation

EFFECTS OF THE 5HT, ANTAGONIST, ONDANSETRON, ON PENTAGASTRIN-INDUCED ANXIETY IN PATIENTS WITH ANXIETY DISORDERS. U. McCann*, M. Geraci, C. Morgan, S. Slate, R. Post. Biological Psychiatry Branch, NIMH, Bethesda, MD 20892-1272.

Cholecystokinin (CCK) agonists are anxiogenic in animals and humans, and patients with anxiety disorders are more susceptible to the anxiogenic effects of CCK agonists than healthy controls. Preclinical evidence suggests that 5HT₃ receptors may play a role in CCK-induced anxiety. In particular, in rats, 5-HT3 antagonists such as ondansetron have been found to attenuate the anxiogenic effects of CCK agonists. Interestingly, ondansetron has also been reported to be effective in the treatment of panic disorder and social phobia. In an effort to determine the role of 5-HT₃ receptors in pentagastrin-induced anxiety in humans, patients with panic disorder and social phobia underwent three separate pharmacological challenges in random order: 1) Saline pretreatment followed by pentagastrin infusion (0.6 ug/kg over 1 minute); 2) Ondansetron pretreatment (0.15 mg/kg over 15 minutes, followed by pentagastrin (0.6 ug/kg over 1 minute); 3) Saline pretreatment followed by Subjects received pentagastrin (or placebo) while participating in a structured social interaction task, as previously described, and completed repeated measures of anxiety. As previously, intravenous pentagastrin lead to increased anxiety and panic in patients with anxiety disorders. Pretreatment with ondansetron, at a dose that is clinically effective for antiemesis, did not attenuate the anxiogenic effects of pentagastrin. These studies suggest that the anxiogenic effects of pentagastrin are not mediated via 5HT3 receptors.

455 2

THE ROLE OF SUBSTANCE P IN EMETIC AND ANTIEMETIC EFFECTS OF RESINIFERATOXIN ON SUNCUS MURINUS. M. Toyoda*, S. Kakimoto, H. Saito, N. Matsuki, A. J. Woods^a and P. L. R. Andrews^a. Department of Chemical Pharmacology, Faculty of Pharmaceutical Sciences, The University of Tokyo, Tokyo 113, JAPAN and aDepartment of Physiology, St George's Hospital Medical School, London U.K.

To elucidate the role of Substance P (SP) in the emetic response, we examined the effect of resiniferatoxin (RTX) on Suncus murinus. RTX, an ultrapotent analog of capsaicin, is considered to release neuropeptides such as SP mainly from primary afferent C-fibers and then deplete them. Both systemic (1-100 µg/kg, s.c.) and central administration of RTX induced emesis dose-dependently. The Emetic effect of 100 ug/kg (s.c.) RTX was not significantly affected by abdominal vagotomy but was completely blocked by a selective NK1-receptor antagonist, CP-99,994 (30 mg/kg, s.c.). On the other hand, RTX also had antiemetic effect. Pretreatment (- 60 min) with 100 µg/kg RTX reversibly blocked emesis induced by cisplatin, CuSO₄, nicotine or motion. Animals that had treated with capsaicin (100 mg/kg, s.c.), a presumptive depleter of SP, 1-2 days after the birth did not respond to RTX tested when they became 3 months old. However, they responded to cisplatin, CuSO₄, nicotine and motion. These results suggest that RTX causes emesis probably by releasing SP in the brainstem (eg. NTS) and that the depletion of SP and/or the desensitization of SP receptors are likely to cause subsequent antiemetic effects. The results support an important role for SP in emesis. (Supported partly by Grant-in-Aid 07557311 from the Ministry of Education, Culture and Science of Japan. SB Pharmaceuticals. MSD, Phizer INC)

CORTISTATIN MODULATES CORTICAL AND HIPPOCAMPAL ELECTROPHYSIOLOGICAL ACTIVITY AND SLEEP. O. Prospéro-García*1 J. R. Criado¹, L. de Lecea², S. C. Casalman¹, J. G. Sutcliffe², and S. J. Henriksen¹. ¹Dept. Neuropharmacology and ²Molecular Biology, The Scripps Res. Inst. La Jolla, CA.

Cortistatin is a novel peptide with structural similarity with somatostatin but is the product of a different gene. Cortistatin can be found in the brain of rats but not in organs such as adrenal glands, liver, spleen, thymus, ovary, testis or anterior pituitary. The regional distribution of cortistatin in brain suggests that the highest levels are found in the cerebral cortex and the hippocampus. The examination of the cellular distribution of this peptide showed that is synthesized in GABA-ergic interneurons. We have tested in halothane-anesthetized rats, the ability of cortistatin to modify both local electroencephalographic (EEG) activity when it is iontophoretically administered into the cerebral cortex; and evoked population spikes and paired-pulse inhibition-potentiation processes in the hippocampus when it is iontophoretically administered into the hippocampus. In addition, cortistatin was intraventricularly infused into the lateral ventricle of addition, contains was intraventificating influed in the fact a venture of referly moving rats in order to observe changes in the spontaneous behavior, EEG and in the sleep patterns up to four hours following administration. Results demonstrated that locally applied cortistatin does not modify the EEG slow wave activity of anesthetized rats; however, it prevents EEG activation (fast activity) induced by the iontophoretic administration of acetylcholine (ACh). In the hippocampus, cortistatin prevents the ACh-induced paired-pulse disinhibition. In freely-moving rats, cortistatin induces behavioral quiescence and slow wave sleep during normal as well as in reverse light-dark cycle. At the higher dose used (10 µg), cortistatin reduced REM sleep in normal cycle, but 500 ng increased REM sleep in reverse cycle. These facts support cortistatin as a new peptide with anti-ACh antagonist activity and potential sleep modulating properties. This work was supported by grants from GM32355, MH47680and DA08301 to S. J. H. and J. G. S.

EFFECTS OF ONDANSETRON ON PENTAGASTRIN-INDUCED ANXIETY IN PANIC DISORDER PATIENTS

A.W.Goddard*, S.W.Woods, G.M.Banks, G.R.Heninger, D.S.Charney. Dept. of Psychiatry, Yale U. Sch. of Med., New Haven, CT 06519.
There is preclinical evidence that the 5-HT3 blocker, ondansetron (OND).

attenuates fear responses provoked by a mixed cholecystokinin (CCK) receptor agonist. Clinical data implicate dysfunctional CCK neurotransmission in the pathophysiology of human panic disorder (PD). This study examined the effects of acute administration of OND on anxiety induced by the mixed CCK agonist, pentagastrin, in unmedicated PD patients. METHODS: Four PD patients (2 males, 2 females; mean age±SD=33±7 yrs) consented to participate in 2 clinical tests. Test were administered in a randomized, double-blind, cross-over manner and were were administered in a randomized, double-blind, cross-over manner and were separated by approximately 1 week. On one test day patients received an infusion of active OND 2 mg IV, given as an infusion over 20 minutes, followed by a bolus of pentagastrin 0.6 ug/kg IV. On a second test day patients were given placebo OND (PLAC) IV followed by pentagastrin 0.6 ug/kg IV. Within test measures included visual analog scale (VAS) anxiety, DSM-IV somatic panic symptoms, blood pressure, heart rate, and plasma cortisol, ACTH, prolactin, and growth hormone levels. RESULTS: Four of the 4 patients reported panic attacks during the OND test, while 3/4 had full panies during the PLAC test. The mean peak change from baseline anxiety levels on the OND test = 59±35 mm, and for the PLAC test = 63±25 mm (paired t-test t=0.3, df=3, p=0.8). Physiological and neuroendocrine data will be presented. <u>DISCUSSION</u>: The data from this protocol at present indicate that there is no attenuation of pentagastrin-induced anxiety with the 2 mg IV OND dose. Further testing at higher OND doses is indicated. If also negative this would suggest that there are not clinically significant 5-HT/CCK interactions in PD occurring via 5-HT3 receptors.

Supported in part by NIMH grant MH-45966 to Dr. Woods.

BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF PERIPHERALLY ADMINISTERED CHOLECYSTOKININ4. A-K. Gilbert* L. Jerabek. M. Bolongo, J.P. Boulenger, A. Cadieux and F.B. Jolicoeur. Depts. of Psychiatry and Pharmacology, Faculty of Medicine, University of Sherbrooke, Sherbrooke, Qc. Canada, J1H 5N4.

Peripheral administration of cholecystokinin4 (CCK4) induces panic-like symptoms in humans. To better understand this phenomenon, we have examined the behavioral and neurochemical effects of peripherally administered CCK4 in animals. After an intraperitoneal injection of CCK4 (5µg), male hooded rats (230-300g) were placed in a standard plus maze and their behaviors, in terms of number of entries and time spent in closed and open sections of the maze, periods of motor immobility, and general motor activity were measured for a period of 15 min. Immediately after, dissection of the following regions was performed: nucleus accumbens, striatum, septum, hypothalamus, hippocampus, amygdala, frontal cortex and prefrontal cortex. In each region, concentrations of dopamine (DA), serotonin (5-HT) ard of the metabolites HVA, DOPAC and 5-HIAA, were measured by HPLC-ECD. In the same regions, concentrations of neuropeptide Y-Like immunoreactivity (NPY-Li) were determined by radioimmunoassay. Results showed that peripheral administration of CCK4 produces behavioral effects associated with anxiety in animals: decreases in general motor activity, increases in periods of motor immobility and reductions in number of entries and time spent in sections of the maze. Analysis of the biochemical data revealed prominent decreases in utilization of both DA and 5-HT in the prefrontal cortex, as estimated by metabolite-transmitter ratios, as well as a marked decrease in NPY-Li concentrations in the nucleus accumbens The results of the present study clearly demonstrate that peripheral administration CCK4 has important central actions as evidenced by the observed anxiety-like behaviors in animals and by selective and region specific neurochemical changes. INTRA-ARCUATE MORPHINE MICROINJECTIONS INDUCE GRF-DEPENDENT AND PROTEIN SELECTIVE FEEDING. M. R. Taube and F. J. Vaccarino*. Dept. of Psychology, University of Toronto, Toronto, Canada, M55 1A1.

Growth-hormone releasing factor (GRF)-induced feeding behavior and GRF-induced growth hormone release (GH) are dependent on opiate actions (Dickson & Vaccarino, 1994; Wehrenberg et al., 1985). Opiates stimulate arcuate nucleus GRF neurons involved in GH release and were hypothesized to activate arcuate GRF neurons mediating appetitive behavior. Further, GRF injections into the suprachiasmatic nucleus/medial preoptic area (SCN/MPOA) during the light period increase protein intake, while carbohydrate and fat intake are unaffected (Dickson & Vaccarino, 1994). The present experiments further investigated the effects of morphine and GRF antibodies on macronutrient food selection, with specific emphasis on the role of the arcuate nucleus.

In both experiments, non-deprived male rats were given a three-choice macronutrient diet (protein, carbohydrate and fat). Experiment 1 was designed to explore the feeding behavior in a macronutrient paradigm resulting from intra-arcuate morphine injections (0, 1, 10, and 20 µg/0.5 µl). Eleven Wistar male rats received all doses and were subsequently tested for overall food intake, water intake, locomotion and feeding activity in four hour testing sessions. Following all three intra-arcuate morphine doses, protein intake was selectively increased. In Experiment 2, 16 Wistar male rats received intra-SCN/MPOA pretreatments (normal rabbit serum or GRF antibodies) followed by intra-arcuate morphine injections (1 µg/0.5µl) or saline injections. Results illustrated GRF antibody blockade attenuated morphine-induced protein selective feeding effect. Together, both studies suggest that an endogenous opioid trigger stimulates complimentary central-peripheral actions of GRF via the arcuate nucleus. (Research sponsored by NSERC grant to F. J.V.).

TYR-PRO-LYS-GLY-NH, (TYR-K-MIF-1) AFFECTS DRINKING BEHAVIOR IN RATS RELATIVE TO A SOLUTION'S PALATABILITY IN A TWO-BOTTLE CHOICE PARADIGM. G. A. Olson* R. L. Bell, W. L. Nores, A. L. Vaccarino, A. J. Kastin, & R. D. Olson. Department of Psychology, University of New Orleans, New Orleans, LA 70148 & VA Medical Center, New Orleans, LA 70146.

We studied the effects of Tyr-K-MIF-1 on drinking behavior

male Sprague-Dawley rats presented with a two-bottle choice paradigm. In both experiments, tap water was available 12 hours per day, and food was available ad libitum throughout the experiment. Intake was measured in four 30-minute test periods during a two-hour test session after 12 hours of water deprivation. Both experiments had one between-subjects factor (doses) and three within-subjects factors (solutions, days, and test periods). In Experiment 1, thirty rats (n = 5) were injected IP for seven days with one of six doess of Tyr-K-MIF-1 (0.00, 001, 0.01, 0.10, 1.00, and 2.50 mg/kg), and twenty minutes after the injections the rats had access to both a 20% sucrose solution and tap water. Although the dose "effects" were not statistically significant, the analysis revealed that the simple effects of dose for the water data approached significance, $\mathbf{p} = .099$, and the simple effects of dose for the sucrose data were clearly not significant, $\mathbf{p} = .990$. In Experiment 2, twenty-five (n = 5) rats were injected IP for four days with one of five doses of Tyr-K-MIF-1 (0.00, 001, 0.01, 0.10, and 1.00 mg/kg). Twenty minutes after the injections, the rats had access to both a 9% ethanol solution (a 9% ethanol solution is aversive to naive animals) and tap water. There was a significant 4-way interaction (Dose x Solution x Day x Test Period): \underline{F} (36, 162) = 1.74, \underline{p} = .011, with an effect size of partial η^2 = .279 and a power of .996. Analyses of the simple effects revealed significant simple effects of dose for the ethanol data: F(4,18) = 2.92, p = .050, with an effect size of partial $\eta^2 = .394$ and a power of .666, but simple effects of dose for the tap water data were not significant (p = .590). Duncan's post hoc analyses revealed that the middle dose groups drank significantly more than the control and the higher dose groups. Tyr-K-MIF-1 was recently isolated from the human brain, and the stimulation of the consumption of less palatable solutions is the first behavioral effect found for this peptide.

455.8

EFFECTS OF INTRAPERITONEAL ADMINISTRATION OF CCK AGONIST AND ANTAGONIST ON ACOUSTICAL STARTLE RESPONSE, AN "ANXIETY" MODEL, IN RATS. Y. Zhou¹, A. I. Arifuzzaman², S. A. Josselyn², P. W. Frankland², J. Bradwejn*¹and F. J. Vaccarino¹¹² Clarke Institute of Psychiatry¹, Toronto Ont. M5T 1R8 and Department of Psychology², University of Toronto, Toronto, Ont. Canada. M5S 3G3,

It is known that systemic administration of CCK or CCK agonists induce panic attacks in humans and that CCK-B antagonists can inhibit this CCK-induced anxiety. Acoustic startle response has been used as an "anxiety" model both in human and in animals. Few studies have been reported on the effects of systemic injection of CCK with this model.

In this study, rats were administered Pentagastrin, a CCK-B agonist, intraperitoneally followed by trials of acoustic startle at 4 different intensities of acoustic stimuli (80, 90, 100, 110 dB). Startle amplitude was measured and analyzed. Pentagastrin (0.1 mg/kg), resulted in a significant increase of startle response at higher intensities of acoustic stimuli (100 dB, 110 dB); pretreatment of L-365,260 (0.1 mg/kg, i.p.), a CCK-B antagonist, significantly blocked Pentagastrin induced startle response increases.

These results provide more evidence that CCK is involved in the process of anxiety and demonstrate the usefulness of the startle model as a tool for anxiety research.

MICROINJECTIONS OF NEUROTENSIN-(8-13) IN THE MEDIAL PREFRONTAL CORTEX STIMULATE MIDBRAIN DOPAMINE CELL FIRING. M.D. Fatigati, R.M. Anderson and P.-P. Rompré* Département de Psychiatrie, Université de Montréal, Montréal(Québec), Canada.

Psychiatrie, Université de Montréal, Montréal(Québec), Canada. In a previous study, we showed that microinjections of neurotensin-(1-13), but not neurotensin-(1-8), into the medial prefrontal cortex (mPFC) stimulate midbrain dopamine (DA) cell firing. These findings suggest that the release of endogenous neurotensin (NT) in the mPFC activates an excitatory input to midbrain DA cells and that this effect is mediated by the high-affinity NT receptor. In this experiment, we further characterized the role of the physiologically-relevant NT receptor by studying the effectiveness of neurotensin-(8-13), the shortest active fragment. Experiments were performed on male rats anesthetized with urethane (1.2 g/kg). Dopamine cells were recorded with a single micropipette (2M NaCl, 0.1% Chicago Blue) and identified according to the previously described classical criteria. Rate of firing was recorded at least 5 min before, and 20 min after, the injection of 0.3 or 3 nmol/0.5 µl of NT-(8-13) or its vehicle; in some cells the sensitivity to the D2-like agonist, quinpirole (100 µg/kg, sc) was tested. A total of 26 cells were recorded, eight before/after vehicle microinjection and 18 before/after NT-(8-13) microinjection (0.3 nmol, n=9; 3 nmol, n=9). Eleven out of 18 cells were stimulated by NT-(8-13), and the increase in firing rate observed after 20 min ranged from 16 to 742% and from 43 to 380% with 0.3 and 3 nmol respectively. At each dose, the percentage increase in firing was inversely related to the basal firing rate. These findings further support a role for the high-affinity NT receptor in the activation of an excitatory input from the mPFC to midbrain dopamine cells.

ROLE OF BRAIN AMINES IN THE BEHAVIORAL RESPONSES ELICITED BY THYROTROPIN-RELEASING HORMONE IN RATS. <u>D. Funk*, F.S. Hall, R.M. Post and A. Pert.</u> Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.

The systemic or intrathecal administration of thyrotropin-releasing hormone (TRH) in rats elicits behaviors including wet dog shakes, jaw movements, tail rattle and locomotion. The neural substrates underlying these effects are not known. Since amine-containing pathways in the CNS, such as the dopamine (DA) and 5-hydroxytryptamine (5-HT) systems mediate the activational effects of many drugs, it was hypothesized that the behaviors elicited by TRH may also result from effects on brain amine function. To address this issue, experiments were carried out assessing the effects of lesions of the DAergic or 5-HTergic systems made via the microinjection of 6-hydroxydopamine or 5,7-dihydroxytryptamine, respectively, on the behavioral responses elicited by TRH. Lesions of the DAergic innervation of the NAC did not affect the behavioral responses to TRH (10 and 20 mg/kg i.p.), a finding in agreement with our observation in an in vivo microdialysis study that TRH (20 mg/kg i.p.) did not alter the release of DA in the NAC. Neither did lesions of the 5-HTergic projections ascending from the dorsal and median raphe nuclei affect the behavioral responses to TRH. In contrast, lesions of 5-HTergic neurons in the raphe magnus that project to the spinal cord reduced the numbers of wet dog shakes and jaw movements elicited by TRH. Taken together, these results suggest that changes in the activity of the 5-HTergic projections to the spinal cord, but not to the forebrain mediate some of the behavioral responses elicited by the systemic administration of TRH. They further suggest that changes in the release of DA in at least the NAC do not underlie the behavioral effects of TRH. Funded by NIMH.

BEHAVIORAL EFFECTS PRODUCED BY INJECTING A NEUROKININ-1 AGONIST INTO THE PERIAQUEDUCTAL GRAY OF THE RAT.

R. Mongeau* and C.A. Marsden. Dept. of Physiology and Pharmacology, Queen's Medical Centre, Univ. of Nottingham, U.K., NG7 2UH.

Substance P, a neurokinin-1 agonist abundant in the periaqueductal gray

Substance P, a neurokinin-1 agonist abundant in the periaqueductal gray area (PAG), is a potent analgesic when infused into this region, while the excitatory D.L homocysteic acid (DLH) injected into the ventral and the dorsal PAG produces freezing and flight behaviors, respectively. A recent study indicated that infusion of the neurokinin-1 agonist GR73632 into the dorsal raphe (DR), a serotonergic nucleus located in the ventral PAG, produces behavioral freezing. It was thus of interest to investigate the behavioral effect of injecting GR73632 into subregions of the PAG. Rats were implanted with a guide cannula placed above the PAG One week after, behaviors were monitored with a video camera and subsequently analyzed by computer. Behavioral freezing was produced when DLH (5 nmol) was injected into the ventral PAG situated rostrally to the DR, but infusion of GR73632 (10 pmol) into this region did not change the behavioral activity. Furthermore, the flight response elicited by stimulating the dorsal PAG with DLH (5 nmol) was not changed by this prior drug administration. In contrast, injection of GR73632 (10 pmol) into the dorsal PAG decreased the amplitude of the DLH-induced flight response (maximum speed: saline=0.80 ± 0.14 m/s; GR=0.42 ± 0.14 m/s; N=6), though this change was not found significant with this number of animals. Although the behavioral freezing that usually follow the DLH-induced flight response appeared prolonged, GR73632 injected into the dorsal PAG did not produce by itself behavioral freezing. Taken together these data suggest that neurokinin-1 receptors located outside the DR subdivision of the ventral PAG do not mediate by themselves behavioral freezing. The possibility that neurokinin-1 receptors in the dorsal PAG modulate the DLH-induced defense responses will be further assessed.

NEUROKININ NK-1 AND NK-3 RECEPTOR AGONISTS IN THE VENTRAL TEGMENTAL AREA (VTA) AND NUCLEUS ACCUMBENS (NAS) INDUCE ANALGESIA IN THE FORMALIN-TEST. N. Altier* and J. Stewart. Center for Studies in Behavioral Neurobiology. Concordia University. Montreal. Canada.

ACCUMBEIS (NAS) (NAS) (NDOCE ANALOGEAIN THE FORMALIN TEST. N. Altier* and J. Stewart. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Canada. We have shown previously that intra-VTA infusions of the SP analogue, DiMe-C7, cause analgesia in the formalin test for tonic pain. Here we report on the role of NK-1 and NK-3 receptor agonists injected into either the VTA or NAS on analgesia using this test. Rats were tested in the formalin test following an injection of 0.05 ml of 2.5 % formalin into one hind paw immediately after bilateral intra-VTA infusions of either the NK-1 agonist, GR-73632 (0.01, 0.1, or 1.0 nmol/rat), the NK-3 agonist, senktide (0.01, 1.0, or 3.0 nmol/rat) or saline. Two weeks later, the same rats were assessed in the tail-flick test for phasic pain. Tail-flick latencies were recorded following immersion of the tail in 55 C hot water at 10 min intervals for one hour immediately after intra-VTA infusions of either GR-73632 (1.0 nmol/rat), senktide (3.0 nmol/rat), or saline. In a second group of rats the effects of these compounds were test in the NAS. In both the VTA and NAS, the NK-1 and the NK-3 agonists caused dose-dependent analgesia in the formalin test, although the NK-1 agonist was more effective. Neither compound was effective in the tail-flick test. These findings support our earlier ideas that activation of SP during stress and pain may play a role in pain suppression. Furthermore, they suggest that SP systems in the forebrain, and particularly those that interact with the mesolimbic DA system, play an important role in the inhibition of tonic pain. MUSCIMOL IN THE VENTRAL PALLIDUM DOES NOT BLOCK OPIOID-INDUCED LOCOMOTION IN THE DOPAMINE-DEPLETED NUCLEUS ACCUMBENS. L. Churchill* and P. W. Kalivas. Dept. of Veterinary & Comparative Anatomy, Pharmacology & Physiology, Washington State University, Pullman, WA 99164-6520.

The output of the nucleus accumbens to the ventral pallidum is critical in mediating locomotion induced by opioids or dopamine in the nucleus accumbens, since locomotion is blocked by stimulating GABA_A receptors in the ventral pallidum (Austin and Kalivas, Japan J Pharmacol **50**:487). To evaluate the role of this pathway in opioid-induced locomotion, male rats were dopamine lesioned bilaterally with 6-hydroxydopamine (4 μgm/3 μl/side over 12 min) in the nucleus accumbens 10 days prior to the start of the behavioral testing. The GABA_A agonist, muscimol (0.02 nmol/side) was microinjected in the ventral pallidum 5 min prior to the μ-opioid agonist, Tyr-D-Ala-Gly-NmePhe-Gly-OH (DAMGO) (0.33 nmol/side) into the nucleus accumbens. Locomotion was measured as horizontal photocell counts for a maximum of 6 trials with a minimum intertrial interval of 3 days. Muscimol did not block DAMGO-induced augmentation of horizontal photocell activity in the dopamine-lesioned rats. In contrast, the motor stimulation produced by dopamine (53 nmol/side) microinjections into the nucleus accumbens of dopamine-depleted rats was significantly blocked by muscimol into the ventral pallidum. These results suggest that dopamine depletion in the nucleus accumbens changes the circuitry for DAMGO-induced motor activity by removing involvement of the GABAergic projection from the nucleus accumbens to the ventral pallidum. This work was supported in part by USPHS grants #DA06612 (LC) and #MH40817, #DA03906, #DA00158 (PWK).

CENTRAL EFFECTS OF TACHYKININ NK RECEPTOR AGONISTS AND ANTAGONISTS ON THE PLUS-MAZE BEHAVIOR IN RATS. T. C. de Lima* and S. J. Ribeiro. Department of Pharmacology, CCB, Universidade Federal de Santa Catarina, Florianópolis, SC, 88040-900, Brazil.

Federal de Santa Catarina, Florianópolis, SC, 88040-900, Brazil.

Previous results (Teixeira et al., 1996, Eur. J. Pharmacol., in press) had shown that the i.c.v. injection of agonists for NK, neurokinin receptors substance P (SP) and SP methyl ester (SPME) promoted anxiogenic effects in mice observed on a plus-maze. On the other hand, the central administration of the specific NK, receptor antagonist, FK 888, produced an anxiolitic profile of action. In the present study we investigated the influence of these treatments on rat behavior in the plus-maze, trying to determine the central site(s) involved in these effects. Cannulas were stereotaxically implanted in the lateral ventricles (AP=-0.8 mm, ML=±1.5 mm, DV=-3.5 mm) of adult Wistar rats under Equitesin® anaesthesia. After a recovery period the animals were injected i.c.v. with SP (10 pmol), SPME (10 pmol), FK 888 (100 pmol) or the control solution (PBS). Five min later they were tested on an elevated plus-maze for 5 min. SP caused an significant reduction of frequency and time spent on open arms (P<0.05), whereas SPME only reduced the time spent on these arms, when compared to the PBS values. FK 888 treatment did not modify frequency of entries or time spent on open arms. All the other parameters on the plus-maze test were not changed by the different treatments. Other animals were implanted with cannulas directed to the bed nucleus of the stria terminalis (BNST; AP=-0.8 mm, ML=±1.4 mm, DV=-7.8 mm) or basolateral nucleus of the amygdala (BLA; AP=-20 mm, ML=±3.8 mm, DV=-7.6 mm) and both received 10 pmol of SP i.c.v. SP decreased the number of entries on open arms when injected into the amygdala, showing that the NK₁ receptor activation promotes an anxiogenic effect in the rat which seems to involve both nuclei.

A COMPARISON OF THE DISTRIBUTION OF μ- OPIOID AND NMDA-RI RECEPTORS IN THE PERIAQUEDUCTAL GRAY OF THE CAT. K. Schubert-Reilly*, M.B. Shaikh, E. Faber, T.A. Teran and A. Siegel. Lab. of Limbic Syst. & Behav., Depts. of Neurosciences & Psychiatry, NJ Medical School, UMDNJ, Newark, NJ 07103 and Dept. of Biology, Kean College, Union, NJ 07983.

The midbrain periaqueductal gray (PAG) constitutes the lowest region of the neuraxis of the brain for the integration of defensive rage behavior (DR) in the cat. The PAG receives inputs from the medial hypothalamus that facilitate DR and from the central nucleus of amygdala that suppress DR. The functions of these pathways are mediated by μ -enkephalin and NMDA receptors, respectively. This study sought to identify and characterize the distributions of these receptors within the PAG. Immunohistochemical techniques were used to identify u-enkephalin and NMDA-R1 receptors in the PAG of the cat. The results indicate that both types of receptors are located throughout the dorsal PAG--the critical region for DR. The distribution of these receptors display significant overlap within the rostral half of the dorsal PAG. However, μ -enkephalin receptors are much more prevalent within the ventral aspect of the rostral half of the PAG as well as in the caudal PAG. These results provide further support for the role of these receptor subtypes in regulating DR. [Supported by NIH Grant NS 07941-26].

CONTENT OF β-ENDORPHIN, ENKEPHALIN AND DYNORPHIN AND THEIR SPECIFIC mRNAs IN DISTINCT BRAIN REGIONS OF THE ALCOHOL-PREFERRING C57BL/6 AND ALCOHOL-AVOIDING DBA/2 MICE. N.T. Jamensky and C. Gianoulakis. Douglas Hospital Research Centre, McGill University, Verdun, PQ, Canada H4H 1R3.

The endogenous opioid system, which consists of neuropeptides and receptors, is believed to be implicated in the reinforcing effects of alcohol consumption. Genetically determined differences in this system have been observed between animals who have a preference or aversion to ethanol solutions. The objective of the present studies was to compare the content of endorphins, enkephalins and dynorphins in distinct brain regions using specific radioimmunoassays as well as the content of their specific mRNAs (proopiomelanocortin, proenkephalin, and prodynorphin, respectively) using in situ hybridization techniques in animals demonstrating a preference (C57BL/6) or aversion (DBA/2) towards ethanol consumption. Results indicated some differences in the brain. 8endorphin and enkephalin systems between the C57BL/6 and DBA/2 mice. The most significant differences were observed in the dynorphin system where significantly higher levels of both peptide and mRNA were observed in the DBA/2 mice. Notably, the DBA/2 mice had higher levels of both dynorphin immunoreactivity and prodynorphin mRNA content in the nucleus accumbens. Interestingly, the release of dynorphin peptides in the nucleus accumbens has been shown to decrease dopamine release, and therefore may be acting as a negative reinforcer. It is possible then that the higher dynorphin and prodynorphin content observed in the DBA/2 mice compared to the C57BL/6 mice may be important in determining their low alcohol consumption. Supported by a grant from NSERC of Canada.

INDIVIDUAL DIFFERENCES IN LIMITED ACCESS, ORAL SELF-ADMINISTRATION OF ETOH BY RANDOMLY BRED RATS, M. J. Cichelli* and M. J. Lewis, Neurobehavior Lab, Temple University, Dept. of Psychology, Philadelphia., PA 19122

Consumption patterns in randomly bred rats trained to orally self-administer EtOH exhibit markedly bimodal distributions. Ethanol-naive, male Sprague-Dawley rats (with ad lib access to food and water) were presented for 30 minutes each weekday with two drinking tubes, one containing tap water and the other containing water mixed with ethanol. The initial ethanol concentration was 2%; this was gradually increased in 2% increments as each animal reached EtOH preference and consumption criteria. The rate of progression to higher ethanol concentrations, the highest concentration consumed and the amount of ethanol consumed appeared to be neither normally nor randomly distributed. By the end of 30 sessions, two quite distinct subpopulations were identified - one of animals which quickly acquired the ethanol drinking response and drank relatively large amounts of a 10% ethanol solution and another of animals which drank only small amounts of lower concentration ethanol solutions. After 60 exposure slowly acquired ethanol drinking behavior and were beginning to consume larger amounts. These results should be considered in future research using oral self-administration models in randomly bred rats. DIFFERENTIAL EFFECTS OF INTRACEREBRAL μ- AND δ-OPIOID RECEPTOR ANTAGONISTS ON ALCOHOL SELF-ADMINISTRATION IN RATS. P. Hyytiä* and K. Kiianmaa. Department of Alcohol Research, National Public Health Institute, Helsinki, Finland.

Systemically administered μ - and δ -opioid receptor antagonists have previously been shown to suppress alcohol drinking in rats. However, limited information is available on the specific neuroanatomical locations of μ - and δ opioid receptors relevant for alcohol reinforcement. The purpose of the present experiments was to assess the contribution of μ - and δ -opioid receptors in the nucleus accumbens (NAC), the basolateral amygdaloid nucleus (BLA), and the ventral tegmental area (VTA) to the regulation of alcohol self-administration. Wistar rats were trained to respond operantly for oral alcohol (10% w/v) during daily 30-min sessions using a saccharin fading procedure. Following the establishment of reliable baseline alcohol responding, the rats were implanted stereotaxically with bilateral guide cannulae either above the NAC, the BLA, or the VTA. After postoperative recovery, the rats were given intracerebral microinjections of a μ -opioid receptor antagonist CTOP (0-0.5 μg) or a δ -opioid receptor antagonist naltrindole (0-0.5 µg) and then tested for alcohol responding. Injections of naltrindole into both the NAC and the BLA significantly decreased alcohol-reinforced responding, whereas CTOP suppressed alcohol responding only when injected into the BLA. When injected into the VTA, neither CTOP nor naltrindole had significant effects on alcohol responding at the particular doses used. These findings suggest that opioid receptors at least in the NAC and the BLA are involved in the regulation of alcohol self-administration and that the contribution of μ - and δ -opioid receptors may differ from one brain area to

456.2

SEX DIFFERENCES IN THE PTZ-LIKE STIMULUS PRODUCED BY ETHANOL WITHDRAWAL AND NICOTINE.

M. E. Jung, H. Lal and C. J. Wallis*, Department of Pharmacology and Substance Abuse Institute of North Texas, University of North Texas Health Science Center, Fort Worth, TX 76107

An animal model of anxiety [pentylenetetrazol (PTZ) discrimination] was used to compare the anxiogenic stimuli induced by ethanol withdrawal (EW) and nicotine (NIC) in male and female rats. Rats were trained to discriminate a neutral stimulus (saline) from the PTZ stimulus (16 mg/kg, IP) under a FR 10 schedule of food reinforcement. Rats were tested for their dose response to PTZ and NIC prior to treatment with a nutritionally balanced liquid diet (4.5% ethanol) for 10 days. Presence of an endogenous PTZ-like cue was tested 12-24 hr after EW (saline, IP). Challenge with nicotine at 36h was used to demonstrate protracted EW (PEW). At 12-24h EW more male rats (82%) responded on the PTZ lever than female rats (65%) after saline injection and the stimulus persisted longer in males than females. NIC (0.16 -2.5 mg/kg, IP) partially substituted for the PTZ cue in males (70%) and females (40%) and this effect was potentiated by PEW (males, 100% and females, 50%). These data suggest that female rats are less sensitive to the anxiogenic stimuli induced by EW and NIC in the PTZ paradigm Supported by NIAAA # AA09567 and #AA10545.

PERIODIC NALTREXONE AND INTAKE OF ALCOHOLIC BEVERAGE L. D. Reid*, L. R. Gardell and C.L. Hubbell, Lab. for Psychopharm., Rensselaer, Troy, NY 12180.

For over 2 months, 45 male Sprague-Dawley rats were on a daily regimen of presentation of alcoholic beverage designed to achieve moderately high levels of intake of ethanol. That regimen involved presentation for 2 hr a day of a palatable 12% ethanol-solution and water. After 3 weeks, rats took, on average, over 2.0 g/kg of ethanol during 2 hr a day. Then, the daily regimen was suspended and the rats had no opportunity to take ethanol for 30 days (abstinence). After abstinence and for an additional 45 days, the regimen was reinstated. Considering the rats' intakes before abstinence, three groups of rats were selected and one of three dosing regimens instituted. For one group, placebos were given daily for the first 35 days of reinstatement. For one group, naltrexone (NTX), 10 mg/kg, was given for the same 35 days. For the other group, NTX was given on Days 1-5, 11-15, 21-25 and 31-35 and placebos on the other days. NTX, as expected, reduced rats' intakes of alcohol when given daily without apparent decrement in its effectiveness. The effects of abstinence also reduced rats' intakes of alcohol and interacted favorably with NTX's effects to reduce markedly alcohol-intake. The group that received NTX periodically behaved as the group getting NTX when they received NTX. These results have implications for the use of NTX as a pharmacotherapy for alcoholism. One implication, for example, is that NTX may not have effects that endure beyond NTX's administration and, to achieve enduring effects, abstinence and NTX-therapy should be combined.

456.6

OPIOID ANTAGONISTS SUPPRESS THE ETHANOL-INDUCED INCREASE IN EXTRACELLULAR DOPAMINE IN THE NUCLEUS ACCUMBENS OF AA RATS. K. Kiianmaa* and P. Hyytiä. Department of Alcohol Research, National Public Health Institute, Helsinki, Finland.

Our previous studies have shown that opioid antagonists administered icy suppress ethanol intake by alcohol-preferring AA (Alko Alcohol) rats. The purpose of the present study was to examine whether this could be related to the effect of opioid antagonists on ethanolstimulated dopamine release in the nucleus accumbens. Ethanol naive AA rats were injected icv with CTOP (1 µg), a µ-receptor antagonist; naltrindole (1 μg), a δ-receptor antagonist; or naloxone (1 μg), a mixed opiate receptor antagonist, followed by an ip injection of ethanol (1 g/kg) 20 min later. The extracellular levels of monoamines in the nucleus accumbens were examined with in vivo microdialysis. Samples were collected from freely moving animals every 10 minutes, and the concentrations of the monoamines and their metabolites were determined in the dialysate with small pore HPLC. Ethanol significantly increased the extracellular levels of dopamine and DOPAC. This effect of ethanol was attenuated by the particular dose of CTOP and naltrindole examined but not naloxone. These results may have implications concerning whether the suppressive effect of opioid antagonists on ethanol intake may be mediated via the blockade of the ethanol-induced increase in dopamine release in the nucleus accumbens.

THE EFFECTS OF NALTREXONE ON A MULTIPLE SCHEDULE OF ETHANOL AND SACCHARIN SELF-ADMINISTRATION. K.L. Shelton* P.M. Beardsley and R.L. Balster Dept. of Pharmacology/Toxicology, Medical College of Virginia, Richmond, VA 23298-0310

College of Virginia, Richmond, VA 23298-0310

Because naltrexone has show efficacy for the treatment of alcoholism, its effects in animal models of alcohol self-administration are of interest to determine the predictive validity of these procedures. We tested naltrexone using a multiple schedule of ethanol and saccharin self-administration in which selective drug effects on ethanol-reinforced responding could be assessed. Adult male Long-Evans rats were trained to lever press during daily 60-min sessions for 0.05 ml deliveries of 10% ethanol (w/v) and 0.1% saccharin solutions under an alternating fixed-ratio 4 multiple schedule. Doses of 0.3, 1.0 and 3.0 mg/kg naltrexone were then administered, i.p. 30 minutes prior to the experimental session for six consecutive days. Six-day blocks of pre-session saline injections intervened between each naltrexone oses. All three doses of naltrexone significantly (p < 0.05) suppressed ethanol self-administration in a dose-related manner. The 3.0 0.05) suppressed ethanol self-administration in a dose-related manner. The 3.0 mg/kg dose of naltrexone also significantly suppressed saccharin self-administration. These results indicate that systemic administration of naltrexone can selectively suppress ethanol self-administration at doses and time points that can serectively suppress entanties seri-auministration at doses and time points into do not decrease saccharin self-administration. We are currently testing morphine in the same multiple schedule model to determine if opposite effects are produced by an opiate agonist. (Research supported by NIAAA grants AA-08473, AA-05357 and NIDA grant DA-01442)

ACUTE NALTREXONE TREATMENT REDUCES ALCOHOL CONSUMPTION AND PALATABILITY IN RATS. K.G. Hill* and S.W. Kiefer. Dept. of Psychology, Kansas State Univ., Manhattan, KS 66506-5302.

Naltrexone, an opiate antagonist, has been shown to reduce alcohol consumption in rats. The presumed mechanism of this effect is that alcohol intake, which would normally produce opiate activity, is blocked and thus no longer reinforcing. In the present experiment, it was hypothesized that naltrexone treatment may also alter the palatability of alcohol. To test this idea, rats were treated with naltrexone (groups were given either 0, 0.5, 1.0, or 3.0 mg/kg, ip) and then tested 30 min and 60 min later for their taste reactivity responses to 10% alcohol. After four, daily reactivity tests, the rats were then tested for 10% alcohol consumption during restricted, 60 min, fluid access periods over four consecutive days. Rats received the same naltrexone dose as previously. Finally, four days of alcohol tests were then done without drug treatment. The results indicated that the 1.0 and 3.0 mg dose clearly decreased ingestive responding and increased aversive responding to 10% alcohol, thus supporting the hypothesis that naltrexone treatment alters the palatability of alcohol by making it more aversive. Naltrexone treatment, regardless of dose, also reduced alcohol consumption across the four test days although alcohol intake immediately returned to control levels once the drug treatments ceased The present data are consistent with previous findings that naltrexone treatment can reduce alcohol intake in rats and that a contributing factor in this decrease may be reflected by the reduced palatability of the alcohol solutions Research supported by the Department of Psychology, Kansas State University

I.V. ETHANOL SELF-ADMINISTRATION IN β -ENDORPHIN

I.V. ETHANOL SELF-ADMINISTRATION IN β-ENDORPHIN KNOCK-OUT MICE. N.J. Grahame*, C.C. Fjeld, M.J. Low, and C.L. Cunningham. Dept. of Behavioral Neuroscience and VIABR, Oregon Health Sciences University, Portland, OR 97201.

The endogenous opioid peptide, β-endorphin, has been implicated in the reinforcing effects of ethanol (e.g., Gianoulakis, 1993). In order to study the importance of this peptide in ethanol reinforcement, while ruling out effects arising from differences in ethanol taste receptivity, we assessed i.v. ethanol self-administration in β-endorphin knock-out and wild-tyne mice. β-endorphin knock-outs were developed by introducing wild-type mice. β-endorphin knock-outs were developed by introducing a premature translational stop codon into the proopiomelancortin (POMC) gene through targeted mutagenesis. The mutant allele was then backcrossed for 7 generations onto a C57BL/6J background. Homozygous mice expressing the mutated POMC allele have normal expression of ACTH and melanocyte-stimulating hormones, but completely lack β -endorphin. Male mice were allowed to nosepoke for 75 mg/kg ethanol in 5ul jugular vein infusions during 2-h daily freeoperant sessions. Two nosepoke holes were present, only one of which was active. Animals were reinforced on an FR-3 schedule with a 2-s time-out period after each infusion. During 9 sessions, knock-out animals acquired ethanol-reinforced responding, preferentially nosepoking in the active hole, and taking an average of 1.4 g/kg of ethanol per session by Day 9. Wild-type mice, however, did not preferentially respond on the ethanol-reinforced side, and took only 0.6 g/kg ethanol by Day 9, indicating that i.v. ethanol served as a reinforcer only for knock-out mice. Thus, in the absence of taste factors, β – endorphin is not necessary for ethanol reward. AA10760; HD 30236.

EFFECT OF A SINGLE DOSE OF DMI ON VOLUNTARY ETHANOL DRINKING AND LATERALIZED MONOAMINE LEVELS IN RATS. W. J. Shoemaker*, A. W. Deckel and D. M. Hebert. Alcohol Research Center, Dept. of Psychiatry, Univ. of Connecticut Health Center, Farmington, CT 06030.

Prior studies indicate that a single large dose of Desmethylimipramine (DMI; 25 mg/kg, i.p.) produces large increases in voluntary ethanol ingestion in Wistar rats. Using a sucrose-fading paradigm, the increased drinking was seen at all levels of ethanol and sucrose solutions. Furthermore, following the 8 weeks of drink testing, DMI-treated rats demonstrated decreases in serotonin and 5-HIAA in the raphe nuclei. The current study confirms a 15% increase in voluntary ethanol intake after 10 mg/kg DMI. In addition, a group of rats were given 25 mg/kg DMI for the first time following completion of the sucrose-fading regimen and stabilization on the 5% sucrose:10% ethanol solution. Again, DMI produced a 17% increase in ethanol intake over 7 days of testing Brain analysis using HPLC and electrochemical detection revealed that DMI produced large decreases in the serotonin metabolite 5-HIAA in the raphe region. In addition, DMI produced increases in dopamine and DOPAC in the right, but not the left, nucleus accumbens. (This work supported by NIAAA grant #P50-AA3510)

ETHANOL SELF-ADMINISTRATION IN CONSTANT DARKNESS ALITERS AMPLITUDE AND PHASE OF CIRCADIAN AND ULTRADIAN RHYTHMS. D.G. Harper, W. Tornatzky, and K. Dept. of Psychology, Tufts University, Medford, MA 02155.

Chronic ethanol self-administration disturbs homeostatic rhythms which are relevant to the drug's physiological and behavioral effects. The purpose of the present experiment was to investigate further the emergence of ultradian rhythms during chronic ethanol selfadministration in the absence of a light zeitgeber. We also compare these rhythmic changes to our previous findings (NS 485.6, 1995) in animals under a light-dark cycle. Subjects were 8, adult male Long-Evans rats implanted with a telemetry sender (Data Sciences) which Evans rats implanted with a telemetry sender (Data Sciences) which monitored temperature, heart rate and activity. Subjects were studied under 4 basic conditions; 1) light schedule - free feeding, 2) constant darkness - free feeding, 3) constant darkness - free feeding, 3) constant darkness - restricted feeding and 4) constant darkness - restricted feeding - EtOH drinking. Animals were studied for 18-21 days during each treatment condition. Animals self-administered 10% ethanol at 10:30 for 30 min/day for 3 weeks and then were presented with ethanol at differing concentrations (5%, 10% and 20%) for 5 days at each concentration. Animals were then returned to 10% concentration before withdrawal. During freerunning conditions circadian acrophase of temperature and heart rate advanced. Ethanol self-administration was characterized by significant delays in circadian acrophase of temperature and heart rate followed by significant increases in the hemicircadian (2 cycle/day) amplitude of temperature and heart rate that were not seen during constant darkness and food restriction. These changes were complete at the end of three weeks of ethanol selfadministration, and are similar to changes observed under a light schedule. Additionally, the phase times of 2,3,4 and 5 cycle/day rhythms changed to coincide with the time of ethanol availability Supported by USPHS R37AA05122 and R01DA02632.

ALPHA-MELANOCYTE STIMULATING HORMONE (α-MSH) AFFECTS ETHANOL INTAKE IN A TWO-BOTTLE CHOICE PARADIGM. R. L. Bell*, W. L. Nores, R. D. Olson, G. A. Olson, & A. J. Kastin. Department of Psychology, University of New Orleans, New Orleans, LA 70148 & V.A. Medical Center, New Orleans, LA 70146.

We previously showed that α-MSH reduced ethanol intake dose-dependently in rats (Nores et al., 1995). Further, Krishnan et al. (1991) showed that an α-MSH fragment (ACTH₄₋₁₀) reduced ethanol intake in rats. α -MSH has been shown to affect attention and learning (Sandman et al., 1980). Consequently, we investigated the role of aversive learning in α-MSH's effects on ethanol intake. Eighteen male Sprague-Dawley rats had access to both tap water and an ethanol solution, in a limited access (1 hour/ day) two-bottle choice paradigm, for nine days. The ethanol solution was 5% (v/v) for the first five days, and 10% (v/v) for the next four days. In naive rats, 5% ethanol is subthreshold aversive and 10% ethanol is aversive. Water and food were available *ad libitum* throughout the experiment. Measures of food intake, 23 hour water intake, and body weight were taken before the treatments. There were two treatment groups (n = 9) Treatment involved an IP injection of either 1.00 mg/kg α-MSH or an equivolume injection of diluent. Injections were made twenty minutes before the one-hour test period (9:20 a.m. to 10:20 a.m.). A 2 x 9 (Treatment x Days) mixed analysis of variance was performed, with treatment as the between-subjects factor and days as the within-subjects factor. Statistical analyses revealed a significant Treatment x Days interaction: \underline{F} (8, 128) = 2.11, \underline{p} = .039, with an effect size of partial η^2 = .117 and a power of .827. The simple effects of treatment within each day were analyzed, with only that for day nine being significant: F(1, 16) = 5.27, p = .036, with an effect size of partial $\eta^2 = .248$ and a power of .576. No other significant results were obtained. Thus, while there were no significant differences in group intakes for the first eight days, a-MSH decreased intake of the aversive 10% ethanol solution after repeated administration.

AMPEROZIDE, A 5-HT-2A RECEPTOR ANTAGONIST, IS MORE EFFECTIVE IN REDUCING ALCOHOL INTAKE THAN FLUOXETINE OR DULOXETINE Amir H. Rezvani. D.H. Overstreet, and R.A. McArthur, Skipper Bowles Center for Alcohol Studies, Univ. North Carolina, Chapel Hill, NC 27599-7178 and CNS Research, Pharmacia & Upjohn, Nerviano (MI), Italy.
Voluntary consumption of large amounts of alcohol has been demonstrated in several strains of rats, including Fawn-Hooded (FH) rats and the selectively bred alcohol-preferring (P), high alcohol drinking (HAD) and alcohol-accepting (AA) rats. Previously, we showed that these strains exhibit differential responses to a number of serotonergic drugs, including the releaser fenfluramine. The present communication compares the 5-HT-2A receptor antagonist, amperozide (1, 2.5, 5, 10 mg/kg), with the 5-HT reuptake inhibitor, fluoxetine (5, 10, 15 mg/kg). After establishment of stable baselines, rats were injected subcutaneously with amperozide or intraperitoneally with fluoxetine or duloxetine. The 24-hr intakes of food, water and alcohol were recorded. All drugs dose-dependently reduced alcohol intake, but only amperozide was selective, inhibiting alcohol intake at doses which did not affect food or water intake. Unlike findings with other agents, the AA rats were relatively more sensitive to the effects of amperozide, while the HAD rats tended to be more resistant to the effects of all three agents. These findings indicate that although alcohol-preferring rat strains are differentially sensitive to several serotonergic drugs which suppress alcohol intake, amperozide selectively suppresses alcohol intake in a dose-dependent manner in all strains tested. Therefore, it is a more effective suppressor of alcohol intake than is fluoxetine or duloxetine.

QUANTITATIVE EEG PREDICTS RELAPSE IN PATIENTS WITH CHRONIC ALCOHOLISM G. Winterer, B. Klöppel, A. Heinz, M. Ziller, L.G. Schmidt, W.M. Herrmann and H. Rommelspacher* Department of Psychiatry, Free University of

Objectives: In clarifying the potential use of Quantitative Electroencephalography (OEEG) for the prediction of relapse, we investigated 29 abstainers and 49 relapsers. Methods: Electrode positions according to the 10/20 system. Time constant 0.3 s, 70 Hz low-pass filter, 167 Hz sampling rate. One representative 30 s artefact-free EEGsegment was analysed of each patient. For quantitative analysis (pre-processing) we chose spectral as well as Hjorth's parameters and the correlation dimension of Grassberger-Procacia. On the basis of these parameters, we first created a discriminant function (approximated F-test for Wilk's lambda) with random and stepwise introduction of variables, first comparing 24 relapsers and 14 abstainers. Afterwards, the best fitting discriminant function was applied to the remaining 25 relapsers and 15 abstainers. For comparison, we analysed the 2x2 groups with an artificial neural network approach (feed-forward multilayer perceptron): Variable input vector, hidden layer (2-20 neurons), two output units. Various input selection methods. Results: Independent testing of the discriminant function (5 variable model), gained from the first groups of relapsers and abstainers, resulted in an overall correct classification of 75% (sensitivity: 88%, specifity 54%) and especially showed a frontally pronounced EEG-desynchronization with decreased absolute frontocentral alpha-activity, relative left frontal theta-activity and an increased left frontal correlation dimension in relapsers. The neural network approach (9 variable model) correlation dimension in relapsers. The neural network approach (9 variable model) increased the overall correct classification rate up to 85% for the independent test-set (sensitivity 100%, specifity 60%). Conclusions: QEEG seems to be highly sensitive in the detection of relapsers. Neural network approaches may enhance the discrimination power, when compared with linear statistics. Compared with the abstainers, relapsers obviously show a frontally pronounced functional disturbance. DOES MENSTRUAL PHASE OR PREMENSTRUAL SYMPTOMS AFFECT ALCOHOL CRAVING OR RELAPSE IN WOMEN SEEKING TREATMENT FOR ALCOHOL DEPENDENCE? L. Williams-Hemby*, A.R. Childress, L. Spaulding, J. Volpicelli and C.P. O'Brien Treatment Research Center, University of Pennsylvania, Philadelphia, PA 19104

Numerous studies suggest that women increase their alcohol consumption at particular phases of the menstrual cycle. Specifically, several reports indicate that women with premenstrual symptoms increase their alcohol consumption during the late luteal phase of the cycle when premenstrual symptoms are most severe. Additional studies suggest that women with moderate to severe premenstrual symptoms are at greater risk for developing alcohol dependence. Taken together, these findings suggest that the late luteal phase of the menstrual cycle may be a vulnerable time for relapse in women seeking treatment for their alcohol abuse, particularly in those women who have moderate to severe premenstrual symptoms. The goal of the present study is to investigate the effect of menstrual cycle phase and symptom severity on the course of treatment in women enrolled in a double-blind, placebo-controlled naltrexone clinical trial for alcohol dependence. Women will be asked to complete a daily symptom rating which will track cycle phase, emotional and physical symptom severity, intensity of alcohol craving and the amount of alcohol use. This instrument will allow us to determine if alcohol craving or relapse occur more frequently during a particular menstrual phase, as well as to determine whether particular menstrual symptoms might be a risk factor leading to excess alcohol craving and/or relapse. ETHANOL SELF-ADMINISTRATION BY MALE AND FEMALE C57BL/6 MICE: A COMPARISON OF LIMITED ACCESS AND OPERANT PROCEDURES. B.M. Kelley, A.L. Bandy, W.O. Boggan* and L.D. Middaugh. Dept. of Psychiatry, CDAP, Med. Univ. of S.C., Charleston, S.C. 29425.

The present study compared ethanol intake in a limited access paradigm with its intake and reinforcing effect in an operant self-administration paradigm. Aside from the operant component the methodologies were identical for the two experiments. Amounts of ethanol consumed (0, 3, 6, 9, 12, and 15%) by mice maintained at reduced body weight during 30 min tests were determined after and before daily feeding as well as when water was present or absent during limited access testing. In both experiments mice consumed large amounts of ethanol (9-13 g/kg, operant; 6-11 g/kg, limited access) and consumed more when fed before rather than after feeding. During limited access testing they consumed more ethanol when water was present than when absent. Under most conditions females consumed more ethanol than males in the limited access experiment, but less than males in the operant experiment. Both male and female mice lever-pressed for ethanol at all concentrations and increased lever-responses as demands increased on FR and PR schedules of reinforcement. The results indicate that ethanol is a positive reinforcer for both male and female C57 mice, that its reinforcing effects are not simply related to caloric value, and that gender differences in ethanol consumption are influenced by the associated response requirements. EFFECTS OF CHRONIC ETHANOL INGESTION ON MID-LATENCY AUDITORY EVOKED POTENTIALS DEPEND ON LENGTH OF EXPOSURE E.A. Floyd' J.D. Reasor, E.L. Moore, and H.K. Rucker, Dept. of Physiology & Pharmacology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27157 and the Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

We hypothesized that chronic ethanol ingestion is associated with modifications in components of mid-latency auditory evoked potentials (MAEPs). To test this, male Long-Evans rats were administered 10% ethanol in drinking water as the sole fluid source for three, six, or nine months. MAEPs were obtained and compared to age-matched control groups. MAEPs were obtained from additional rats after four weeks of abstinence. Three months of ethanol exposure was associated with increased latencies and amplitudes of Na and Pa. MAEP components recovered and returned to control values after four weeks abstinence following three months of EtOH exposure. Few significant differences were observed in the ethanol-treated or abstinent group after six months exposure. However, nine months of ethanol exposure revealed a significant increase in latencies and decrease in amplitudes of both Na and Pa components. After 4 weeks abstinence, the Na and Pa component peak latencies appeared earlier than controls. Na and Pa peak amplitudes were slightly greater than the ethanol-treated group, however, they did not recover to control values. These findings suggest that chronic ethanol consumption may produce time-dependent structural and/or neurochemical alterations in substrates for cortical information processing which may be irreversible. In the present paradigm, this irreversibility may occur after 6 or more months of ethanol intake, and may be detected with the use of MAEPs.
