Society for Neuroscience Policies on the Use of Animals and Humans in Neuroscience Research

Policy on the Use of Animals in Neuroscience Research

The Policy on the Use of Animals in Neuroscience Research affects a number of the Society's functions that involve making decisions about animal research conducted by individual members. These include the scheduling of scientific presentations at the Annual Meeting, the review and publication of original research papers in *The Journal of Neuroscience*, and the defense of members whose ethical use of animals in research is questioned by antivivisectionists. The responsibility for implementing the policy in each of these areas will rest with the relevant administrative body (Program Committee, Publications Committee, Editorial Board, and Committee on Animals in Research, respectively), in consultation with Council.

Introduction

The Society for Neuroscience, as a professional society for basic and clinical researchers in neuroscience, endorses and supports the appropriate and responsible use of animals as experimental subjects. Knowledge generated by neuroscience research on animals has led to important advances in the understanding of diseases and disorders that affect the nervous system and in the development of better treatments that reduce suffering in humans and animals. This knowledge also makes a critical contribution to our understanding of ourselves, the complexities of our brains, and what makes us human. Continued progress in understanding how the brain works and further advances in treating and curing disorders of the nervous system require investigation of complex functions at all levels in the living nervous system. Because no adequate alternatives exist, much of this research must be done on animal subjects. The Society takes the position that neuroscientists have an obligation to contribute to this progress through responsible and humane research on animals.

Several functions of the Society are related to the use of animals in research. A number of these involve decisions about research conducted by individual members of the Society, including the scheduling of scientific presentations at the Annual Meeting, the review and publication of original research papers in *The Journal of Neuroscience*, and the defense of members whose ethical use of animals in research is questioned by antivivisectionists. Each of these functions, by establishing explicit support of the Society for the research of individual members, defines a relationship between the Society and its members. The purpose of this document is to outline the policy that guides that relationship. Compliance with the following policy will be an important factor in determining the suitability of research for presentation at the Annual Meeting or for publication in *The Journal of Neuroscience*, and in situations where the Society is asked to provide public and active support for a member whose use of animals in research has been questioned.

General Policy

Neuroscience research uses complicated, often invasive methods, each of which is associated with different problems, risks, and specific technical considerations. An experimental method that would be deemed inappropriate for one kind of research may be the method of choice for another kind of research. It is therefore impossible for the Society to define specific policies and procedures for the care and use of all research animals and for the design and conduct of every neuroscience experiment.

The U.S. *Public Health Service Policy on Humane Care and Use of Laboratory Animals* (PHS Policy) and the *Guide for the Care and Use of Laboratory Animals* (the Guide) describe a set of general policies and procedures designed to ensure the humane and appropriate use of live vertebrate animals in all forms of biomedical research. The Society finds the policies and procedures set forth in the PHS Policy and the Guide to be both necessary and sufficient to ensure a high standard of animal care and use and adopts them as its official "Policy on the Use of Animals in Neuroscience Research" (Society Policy). All Society members are expected to conduct their animal research in compliance with the Society Policy and are required to verify that they have done so when submitting abstracts for presentation at the Annual Meeting or manuscripts for publication in *The Journal of Neuroscience*. Adherence to the Society Policy is also an important step toward receiving help from the Society in responding to questions about a member's use of animals in research. A complete description of the Society's policy and procedures for defending members whose research comes under attack is given in the Society's *Handbook for the Use of Animals in Neuroscience Research.*

Local Committee Review

An important element of the Society Policy is the establishment of a local committee that is charged with reviewing and approving all proposed animal care and use procedures. In addition to scientists experienced in research involving animals and a veterinarian, the membership of this local committee should include an individual who is not affiliated with the member's institution in any other way. In reviewing a proposed use of animals, the committee should evaluate the adequacy of institutional policies, animal husbandry, veterinary care, and the physical plant. Specific attention should be paid to proposed procedures for animal procurement, quarantine and stabilization, separation by species, disease diagnosis and treatment, anesthesia and analgesia, surgery and postsurgical care, and euthanasia. The review committee also should ensure that procedures involving live vertebrate animals are designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society. This review and approval of a member's use of live vertebrate animals in research by a local committee is an essential component of the Society Policy. Assistance in developing appropriate animal care and use procedures and establishing a local review committee can be obtained from the documents listed below and from the Society.

Other Laws, Regulations, and Policies

In addition to complying with the policy described above, Regular Members (i.e., North American residents) of the Society must also adhere to all relevant national, state, or local laws and/or regulations that govern their use of animals in neuroscience research. Thus, U.S. members must observe the U.S. Animal Welfare Act (as amended in 1985) and its implementing regulations from the U.S. Department of

Agriculture. Canadian members must abide by the *Guide to the Care and Use of Experimental Animals*, and members in Mexico must comply with the *Reglamento de la Ley General de Salud en Materia de Investigacion para la Salud of the Secretaria de Salud* (published on Jan. 6, 1987). Similarly, in addition to complying with the laws and regulations of their home countries, Foreign Members of the Society should adhere to the official Society Policy outlined here.

The following principles, based largely on the PHS *Policy on Humane Care and Use of Laboratory Animals*, can be a useful guide in the design and implementation of experimental procedures involving laboratory animals.

Animals selected for a procedure should be of an appropriate species and quality and the minimum number required to obtain valid results.

Proper use of animals, including the avoidance or minimization of discomfort, distress, and pain, when consistent with sound scientific practices, is imperative.

Procedures with animals that may cause more than momentary or slight pain or distress should be performed with appropriate sedation, analgesia, or anesthesia. Surgical or other painful procedures should not be performed on unanesthetized animals paralyzed by chemical agents.

Postoperative care of animals shall be such as to minimize discomfort and pain and, in any case, shall be equivalent to accepted practices in schools of veterinary medicine.

Animals that would otherwise suffer severe or chronic pain or distress that cannot be relieved should be painlessly killed at the end of the procedure or, if appropriate, during the procedure. If the study requires the death of the animal, the animal must be killed in a humane manner.

Living conditions should be appropriate for the species and contribute to the animals' health and comfort. Normally, the housing, feeding, and care of all animals used for biomedical purposes must be directed by a veterinarian or other scientist trained and experienced in the proper care, handling, and use of the species being maintained or studied. In any case, appropriate veterinary care shall be provided.

Exceptions to these principles require careful consideration and should only be made by an appropriate review group such as an institutional animal care and use committee.

Policy on the Use of Human Subjects in Neuroscience Research

Experimental procedures involving human subjects must have been conducted in conformance with the policies and principles contained in the Federal Policy for the Protection of Human Subjects (United States Office of Science and Technology Policy) and in the Declaration of Helsinki. When publishing a paper in *The Journal of Neuroscience* or submitting an abstract for presentation at the Annual Meeting, authors must sign a statement of compliance with this policy.

POLICY ON ETHICS

It is expected that authors submitting papers or abstracts will have conducted their work in strict accordance with the following statement on ethics approved by the Society for Neuroscience in November 1989 and amended in November 1993.

The Society for Neuroscience believes that progress in understanding the nervous system materially benefits human welfare. It recognizes that such progress depends on the honest pursuit of scientific research and the truthful representation of findings. While recognizing that both scientific error and differences of interpretation are a natural part of the creative process, the Society affirms that misconduct, in the form of fabrication, falsification, or plagiarism, jeopardizes the success of the entire scientific endeavor. Members of the Society assume an obligation to maintain the highest level of integrity in all scientific activities.

The primary responsibility for considering and resolving allegations of scientific misconduct lies within the individual academic communities and institutions where scientific work is carried out. The Society for Neuroscience therefore supports the principle that academic institutions should develop and have in place procedures to deal with allegations of scientific misconduct. However, the Society has a special responsibility and interest surrounding those scientific activities for which it is directly responsible, e.g., publication of *The Journal of Neuroscience* and the presentations at the Annual Meeting.

Every author of articles or abstracts submitted for publication in *The Journal of Neuroscience* or the neuroscience *Abstracts* agrees to assume full responsibility, within the limits of his or her professional competence, for the accuracy of the report. In the case of multiple-authored papers, each author should have made a significant intellectual or practical contribution to the scientific work; "honorary authorship," i.e., the granting of authorship to persons who have made no substantive contribution to a scientific report, is not appropriate.

Scientists must have access to their original research results. The retention of accurately recorded and retrievable results is essential for the progress of scientific inquiry. Moreover, errors may be mistaken for misconduct when primary results are unavailable. Primary data should remain in the laboratory and should be preserved as long as there may be a reasonable need to refer to them.

Authors submitting articles or abstracts do so with the understanding that reports have not been submitted elsewhere. An abstract is a proper forum for rapid communication of work that will subsequently appear as a full-length article. However, submission of abstracts reporting already published work or publication of multiple similar manuscripts or abstracts, i.e., duplicate publication, is improper. When previously published data are presented as part of a new manuscript or abstract, as in a gradually developing longitudinal data set, or if a subject group or condition is included again for comparison purposes, citations to the previously published work should appear explicitly in the new report.

Scientific publication is an important part of the process by which priority is established for experimental work and ideas. Duplicating without citation of text previously published by others or expropriating the experimental findings of others without attribution, i.e., plagiarism, is unethical. When authors of articles or abstracts have prepublication access to related work of others, as in a review process, care must be taken to avoid the appearance that priority is being claimed for work already done by others.

It is the responsibility of the authors, therefore, and not of the Society or the Editorial Board of *The Journal of Neuroscience*, to ensure that relevant prior discoveries are appropriately acknowledged in manuscripts that are submitted to the *Journal* for publication.

Questions raised about the conduct of experiments or their presentation will be evaluated preliminarily by the Editor of *The Journal of Neuroscience* (in the case of an article in the *Journal*) or by the Chair of the Program Committee (in the case of an abstract), in consultation with the Chair of the Publications Committee and the Secretary of the Society. If possible, the matter may be resolved informally at this level. However, if deemed appropriate, the matter will be referred to the institution where the scientific work in question was done. There, it would be expected that the matter would be reviewed in accordance with institutional procedures for handling allegations of misconduct. At all stages, every effort should be made to ensure that the process is fair and just, both for those who are accused of misconduct and for those who have raised the issue of scientific misconduct.

Based on their own findings or those of the institution, the *Journal* Editor or the Chair of the Program Committee, in consultation with the Chair of the Publications Committee and the Secretary of the Society, may recommend action to the Publications Committee. The Publications Committee will then decide on appropriate action, including, for example, retracting a published report. The Council of the Society and the relevant institution will be informed of any action that is taken. Council retains the right to consider additional action. In accordance with the Bylaws, this action could include, for example, expulsion from the Society. If it is found that allegations were not made in good faith, or were maliciously motivated, action may be recommended for those responsible.

In the event that a published article or abstract is to be retracted, a statement of retraction will be published in *The Journal of Neuroscience* or in the *Abstracts* for the next Annual Meeting.

596.	Long-term potentiation: physiology IV	Poster				Wed AM	
597.	Long-term potentiation: physiology V	Poster				Wed AM	
598.	Long-term potentiation: physiology VI	Poster				Wed AM	

Session Number	Session Title	Type	Day and Time: Sun.	Mon.	Tue.	Wed.	Thu.
599.	Long-term potentiation: physiology VII	Poster				Wed AM	
600.	Long-term potentiation: physiology VIII	Poster				Wed AM	
601.	Long-term potentiation: physiology IX	Poster				Wed AM	
310.	Mechanisms of neurotransmitter release I	Poster		Mon PM			
311.	Mechanisms of neurotransmitter release II	Poster		Mon PM			
780.	Mechanisms of neurotransmitter release III	Poster					Thu AM
408.	Other ion channels I	Poster			Tue AM		
409.	Other ion channels II	Poster			Tue AM		
313.	Postsynaptic mechanisms: Ach, ATP and peptide signal	Poster		Mon PM			
316.	Postsynaptic mechanisms: Ca^{2+} signalling	Poster		Mon PM			
314.	Postsynaptic mechanisms: GABA signals	Poster		Mon PM			
200.	Postsynaptic mechanisms: chemical excitability	Slide		Mon AM			
315.	Postsynaptic mechanisms: dendritic functions	Poster		Mon PM			
387.	Postsynaptic mechanisms: electrical excitability and Ca^{2+} signalling	Slide			Tue AM		
317.	Postsynaptic mechanisms: glutamate signals	Poster		Mon PM			
312.	Postsynaptic mechanisms: morphological and molecular correlates	Poster		Mon PM			
687.	Postsynaptic mechanisms: network activity and models	Poster				Wed PM	
691.	Potassium channels: expression	Poster				Wed PM	
473.	Potassium channels: function and expression	Slide			Tue PM		
497.	Potassium channels: modulation I	Poster			Tue PM		
498.	Potassium channels: modulation II	Poster			Tue PM		
142.	Potassium channels: pharmacology	Poster	Sun PM				
141.	Potassium channels: physiology	Poster	Sun PM				
572.	Potassium channels: physiology, pharmacology, and modulation	Slide				Wed AM	
496.	Potassium channels: structure and function	Poster			Tue PM		
31.	Presynaptic mechanisms I	Poster	Sun AM				
206.	Presynaptic mechanisms II	Slide		Mon AM			
686.	Presynaptic mechanisms III	Poster				Wed PM	
779.	Presynaptic mechanisms IV	Poster					Thu AM
494.	Presynaptic mechanisms: calcium and release	Poster			Tue PM		
134.	Presynaptic mechanisms: modulation—plasticity	Poster	Sun PM				
309.	Presynaptic mechanisms: neuromuscular junction	Poster		Mon PM			
595.	Presynaptic mechanisms: release and recycling	Poster				Wed AM	
32.	Sodium channels: expression and cloning	Poster	Sun AM				
33.	Sodium channels: pharmacology	Poster	Sun AM				
34.	Sodium channels: physiology, structure, and function	Poster	Sun AM				
483.	Sodium channels: synaptic transmission and disease	Slide			Tue PM		

THEME D: NEUROTRANSMITTERS, MODULATORS, TRANSPORTERS, AND RECEPTORS

526.	5-HT_{1A} receptors: binding	Poster			Tue PM		
527.	5-HT_{1A} receptors: pharmacology	Poster			Tue PM		
528.	5-HT_{1B}, 5-HT_{1D}, 5-HT_{1F} receptors	Poster			Tue PM		
500.	Acetylcholine receptors: muscarinic—structure/function I	Poster			Tue PM		
692.	Acetylcholine receptors: muscarinic—structure/function II	Poster				Wed PM	
110.	Acetylcholine receptors: nicotinic	Slide	Sun PM				
504.	Acetylcholine receptors: nicotinic—binding	Poster			Tue PM		
501.	Acetylcholine receptors: nicotinic—molecular biology and knock-out	Poster			Tue PM		

Session Number	Session Title	Type	Day and Time: Sun.	Mon.	Tue.	Wed.	Thu.
502.	Acetylcholine receptors: nicotinic—pharmacology I	Poster			Tue PM		
602.	Acetylcholine receptors: nicotinic—pharmacology II	Poster				Wed AM	
503.	Acetylcholine receptors: nicotinic—physiology	Poster			Tue PM		
603.	Acetylcholine receptors: nicotinic—recombinant	Poster				Wed AM	
411.	Acetylcholine receptors: nicotinic—regulation of gene expression	Poster			Tue AM		
410.	Acetylcholine: structure/function I	Poster			Tue AM		
499.	Acetylcholine: structure/function II	Poster			Tue PM		
617.	Adenosine and ATP as neurotransmitters	Poster				Wed AM	
530.	Behavioral pharmacology	Poster			Tue PM		
622.	Behavioral pharmacology: drugs of abuse	Poster				Wed AM	
623.	Behavioral pharmacology: serotonin	Poster				Wed AM	
609.	CRF receptors: structure and function	Poster				Wed AM	
202.	Catecholamine receptors	Slide		Mon AM			
697.	Catecholamine receptors: anti-psychotic/ nervous system disorders	Poster				Wed PM	
523.	Catecholamine receptors: knock-outs and behavior	Poster			Tue PM		
329.	Catecholamine receptors: localization and structure	Poster		Mon PM			
330.	Catecholamine receptors: molecular biology and receptor binding	Poster		Mon PM			
696.	Catecholamine receptors: pharmacology	Poster				Wed PM	
788.	Catecholamine receptors: regulation of gene expression	Poster					Thu AM
522.	Catecholamine receptors: second messenger signal transduction	Poster			Tue PM		
614.	Catecholamines: biosynthetic enzymes	Poster				Wed AM	
145.	Catecholamines: dopamine I	Poster	Sun PM				
331.	Catecholamines: dopamine II	Poster		Mon PM			
524.	Catecholamines: dopamine III	Poster			Tue PM		
240.	Catecholamines: norepinephrine	Poster		Mon AM			
620.	Dopamine transporters	Poster				Wed AM	
35.	Excitatory amino acid receptors: physiology, pharmacology, and modulation—NMDA I	Poster	Sun AM				
36.	Excitatory amino acid receptors: physiology, pharmacology, and modulation—NMDA II	Poster	Sun AM				
693.	Excitatory amino acid receptors: physiology, pharmacology, and modulation—NMDA III	Poster				Wed PM	
239.	Excitatory amino acid receptors: physiology, pharmacology, and modulation—mGluR I	Poster		Mon AM			
322.	Excitatory amino acid receptors: physiology, pharmacology, and modulation—mGluR II	Poster		Mon PM			
606.	Excitatory amino acid receptors: physiology, pharmacology, and modulation I	Poster				Wed AM	
607.	Excitatory amino acid receptors: physiology, pharmacology, and modulation II	Poster				Wed AM	
608.	Excitatory amino acid receptors: physiology, pharmacology, and modulation III	Poster				Wed AM	
671.	Excitatory amino acid receptors: physiology, pharmacology, and modulation IV	Slide				Wed PM	
236.	Excitatory amino acid receptors: structure, function, and expression—functional properties	Poster		Mon AM			
413.	Excitatory amino acid receptors: structure, function, and expression—metabotropic glutamate receptor	Poster			Tue AM		
237.	Excitatory amino acid receptors: structure, function, and expression—receptor assembly	Poster		Mon AM			
238.	Excitatory amino acid receptors: structure, function, and expression—regulation of expression	Poster		Mon AM			

Session Number	Session Title	Type	Day and Time: Sun.	Mon.	Tue.	Wed.	Thu.
292.	Excitatory amino acid receptors: structure, function, and expression I	Slide		Mon PM			
782.	Excitatory amino acid receptors: structure, function, and expression II	Poster					Thu AM
143.	Excitatory amino acids: anatomy and physiology I	Poster	Sun PM				
144.	Excitatory amino acids: anatomy and physiology II	Poster	Sun PM				
318.	Excitatory amino acids: excitotoxicity I	Poster		Mon PM			
319.	Excitatory amino acids: excitotoxicity II	Poster		Mon PM			
320.	Excitatory amino acids: excitotoxicity III	Poster		Mon PM			
321.	Excitatory amino acids: excitotoxicity IV	Poster		Mon PM			
478.	Excitatory amino acids: excitotoxicity V	Slide			Tue PM		
505.	Excitatory amino acids: excitotoxicity VI	Poster			Tue PM		
506.	Excitatory amino acids: excitotoxicity VII	Poster			Tue PM		
604.	Excitatory amino acids: pharmacology I	Poster				Wed AM	
605.	Excitatory amino acids: pharmacology II	Poster				Wed AM	
412.	Excitatory amino acids: pharmacology—metabotropic receptors	Poster			Tue AM		
507.	Excitatory amino acids: pharmacology—modulation	Poster			Tue PM		
508.	Excitatory amino acids: pharmacology—synaptic receptors	Poster			Tue PM		
514.	GABA: GAD, GAT and GABA studies	Poster			Tue PM		
511.	$GABA_A$ receptors: anesthetics	Poster			Tue PM		
509.	$GABA_A$ receptors: benzodiazepines	Poster			Tue PM		
762.	$GABA_A$ receptors: cellular and molecular studies	Slide					Thu AM
510.	$GABA_A$ receptors: ethanol	Poster			Tue PM		
327.	$GABA_A$ receptors: knock-outs and knock-downs	Poster		Mon PM			
325.	$GABA_A$ receptors: microanatomy	Poster		Mon PM			
323.	$GABA_A$ receptors: native functions	Poster		Mon PM			
324.	$GABA_A$ receptors: native modulation studies	Poster		Mon PM			
326.	$GABA_A$ receptors: recombinant studies and molecular mapping	Poster		Mon PM			
512.	$GABA_A$ receptors: steroids	Poster			Tue PM		
513.	$GABA_B$ and $GABA_C$ receptors	Poster			Tue PM		
618.	Glutamate transporters I	Poster				Wed AM	
619.	Glutamate transporters II	Poster				Wed AM	
470.	**Glutamatergic Transmission: A View from the Dendrite**	SYMP			**Tue PM**		
789.	Histamine	Poster					Thu AM
610.	NPY-like receptors	Poster				Wed AM	
38.	Neurotransmitter interactions I	Poster	Sun AM				
39.	Neurotransmitter interactions II	Poster	Sun AM				
40.	Neurotransmitter interactions III	Poster	Sun AM				
616.	Nitric oxide and other modulators	Poster				Wed AM	
701.	Novel 5HT receptors: $5HT_6$, $5HT_7$, and others	Poster				Wed PM	
37.	Opioid receptors I	Poster	Sun AM				
328.	Opioid receptors II	Poster		Mon PM			
380.	Opioid receptors III	Slide			Tue AM		
695.	Opioid receptors IV	Poster				Wed PM	
786.	Opioid receptors V	Poster					Thu AM
787.	Opioid receptors: sigma receptors	Poster					Thu AM
519.	Opioids: anatomy, physiology, and behavior—anatomy	Poster			Tue PM		
521.	Opioids: anatomy, physiology, and behavior—behavior	Poster			Tue PM		

Session Number	Session Title	Type	Day and Time: Sun.	Mon.	Tue.	Wed.	Thu.
520.	Opioids: anatomy, physiology, and behavior—physiology	Poster			Tue PM		
615.	Other neurotransmitters	Poster				Wed AM	
790.	Other peptide neurotransmitters	Poster					Thu AM
661.	Peptide receptor molecular biology	Slide				Wed PM	
515.	Peptide receptor structure and function I	Poster			Tue PM		
516.	Peptide receptor structure and function II	Poster			Tue PM		
517.	Peptide receptor structure and function III	Poster			Tue PM		
611.	Peptides: anatomy and physiology I	Poster				Wed AM	
612.	Peptides: anatomy and physiology II	Poster				Wed AM	
613.	Peptides: anatomy and physiology III	Poster				Wed AM	
783.	Peptides: anatomy and physiology IV	Poster					Thu AM
784.	Peptides: anatomy and physiology V	Poster					Thu AM
785.	Peptides: anatomy and physiology VI	Poster					Thu AM
518.	Peptides: biosynthesis, metabolism, and biochemical characterization—opiates	Poster			Tue PM		
694.	Peptides: biosynthesis, metabolism, and biochemical characterization I	Poster				Wed PM	
754.	Peptides: biosynthesis, metabolism, and biochemical characterization II	Slide					Thu AM
41.	Receptor modulation: up- and down-regulation I	Poster	Sun AM				
415.	Receptor modulation: up- and down-regulation II	Poster			Tue AM		
531.	Receptor modulation: up- and down-regulation III	Poster			Tue PM		
246.	Regional localization of receptors and transmitters I	Poster		Mon AM			
414.	Regional localization of receptors and transmitters II	Poster			Tue AM		
621.	Regional localization of receptors and transmitters III	Poster				Wed AM	
107.	Second messengers and phosphorylation I	Slide	Sun PM				
152.	Second messengers and phosphorylation II	Poster	Sun PM				
153.	Second messengers and phosphorylation III	Poster	Sun PM				
247.	Second messengers and phosphorylation IV	Poster		Mon AM			
151.	Second messengers: cAMP	Poster	Sun PM				
150.	Second messengers: kinases	Poster	Sun PM				
385.	Serotonin receptors	Slide			Tue AM		
699.	Serotonin receptors: $5HT_2$ I	Poster				Wed PM	
700.	Serotonin receptors: $5HT_2$ II	Poster				Wed PM	
698.	Serotonin receptors: $5HT_2$—anatomy and behavior	Poster				Wed PM	
525.	Serotonin receptors: electrophysiology	Poster			Tue PM		
245.	Serotonin transporters	Poster		Mon AM			
334.	Serotonin/catecholamine interactions	Poster		Mon PM			
243.	Serotonin: behavior	Poster		Mon AM			
242.	Serotonin: general	Poster		Mon AM			
571.	Serotonin: pharmacology	Slide				Wed AM	
241.	Serotonin: tryptophan hydroxylase	Poster		Mon AM			
244.	Serotonin: uptake and release	Poster		Mon AM			
154.	Signal transduction I	Poster	Sun PM				
155.	Signal transduction II	Poster	Sun PM				
372.	**The Synaptic Vescile Neurotransmitter Transporters: Chemical Coding at Central and Peripheral Synapses**	SYMP			**Tue AM**		
529.	Transmitters in invertebrates	Poster			Tue PM		
146.	Transmitters in invertebrates: monoamines	Poster	Sun PM				
332.	Transmitters in invertebrates: neuropeptides I	Poster		Mon PM			
333.	Transmitters in invertebrates: neuropeptides II	Poster		Mon PM			
147.	Transmitters in invertebrates: nitric oxide	Poster	Sun PM				
148.	Transporters I	Poster	Sun PM				
207.	Transporters II	Slide		Mon AM			
295.	Transporters III	Slide		Mon PM			

Session Number	Session Title	Type	Day and Time: Sun.	Mon.	Tue.	Wed.	Thu.
702.	Transporters IV	Poster				Wed PM	
703.	Transporters V	Poster				Wed PM	
149.	Transporters: structure/activity	Poster	Sun PM				
	THEME E: ENDOCRINE AND AUTONOMIC REGULATION						
338.	Cardiovascular regulation: blood pressure regulation	Poster		Mon PM			
44.	Cardiovascular regulation: brainstem mechanisms	Poster	Sun AM				
157.	Cardiovascular regulation: forebrain mechanisms	Poster	Sun PM				
251.	Cardiovascular regulation: nucleus tractus solitarius	Poster		Mon AM			
416.	Cardiovascular regulation: peripheral autonomic control	Poster			Tue AM		
158.	Cardiovascular regulation: sympathetic preganglionic neurons	Poster	Sun PM				
337.	Cardiovascular regulation: ventral medulla I	Poster		Mon PM			
377.	Cardiovascular regulation: ventral medulla II	Slide			Tue AM		
159.	Gastrointestinal regulation: CNS control	Poster	Sun PM				
417.	Gastrointestinal regulation: peripheral mechanism	Poster			Tue AM		
201.	Hypothalamic-pituitary-adrenal regulation I	Slide		Mon AM			
335.	Hypothalamic-pituitary-adrenal regulation II	Poster		Mon PM			
532.	Hypothalamic-pituitary-adrenal regulation III	Poster			Tue PM		
791.	Hypothalamic-pituitary-adrenal regulation IV	Poster					Thu AM
42.	Hypothalamic-pituitary-gonadal regulation I	Poster	Sun AM				
379.	Hypothalamic-pituitary-gonadal regulation II	Slide			Tue AM		
533.	Hypothalamic-pituitary-gonadal regulation III	Poster			Tue PM		
624.	Hypothalamic-pituitary-gonadal regulation IV	Poster				Wed AM	
704.	Hypothalamic-pituitary-gonadal regulation V	Poster				Wed PM	
43.	Neural-immune interactions: CNS mechanisms	Poster	Sun AM				
336.	Neural-immune interactions: cytokines I	Poster		Mon PM			
537.	Neural-immune interactions: cytokines II	Poster			Tue PM		
536.	Neural-immune interactions: depression and stress	Poster			Tue PM		
706.	Neural-immune interactions: inflammation	Poster				Wed PM	
578.	Neural-immune interactions: other	Slide				Wed AM	
705.	Neural-immune interactions: pathology	Poster				Wed PM	
626.	Neuroendocrine regulation: estrogen	Poster				Wed AM	
534.	Neuroendocrine regulation: growth hormone and somatostatin	Poster			Tue PM		
625.	Neuroendocrine regulation: other	Poster				Wed AM	
156.	Neuroendocrine regulation: paraventricular hypothalamic nucleus	Poster	Sun PM				
535.	Neuroendocrine regulation: prolactin	Poster			Tue PM		
250.	Neuroendocrine regulation: supraoptic nucleus	Poster		Mon AM			
249.	Osmotic regulation	Poster		Mon AM			
101.	**Pain and the Cerebral Cortex**	SYMP	**Sun PM**				
628.	Respiratory regulation: chemoreception and hypoxic responses	Poster				Wed AM	
629.	Respiratory regulation: integrative mechanisms	Poster				Wed AM	
627.	Respiratory regulation: pattern generation and motoneuron	Poster				Wed AM	
248.	Thermal regulation	Poster		Mon AM			
45.	Urogenital regulation: bladder	Poster	Sun AM				
418.	Urogenital regulation: sexual organs	Poster			Tue AM		
	THEME F: SENSORY SYSTEMS						
425.	Auditory systems: central anatomy—forebrain	Poster			Tue AM		
57.	Auditory systems: central anatomy—hindbrain	Poster	Sun AM				

Session Number	Session Title	Type	Day and Time: Sun.	Mon.	Tue.	Wed.	Thu.
161.	Auditory systems: central physiology—birds and bats	Poster	Sun PM				
256.	Auditory systems: central physiology—brainstem	Poster		Mon AM			
424.	Auditory systems: central physiology—forebrain	Poster			Tue AM		
716.	Auditory systems: central physiology—hearing loss	Poster				Wed PM	
350.	Auditory systems: central physiology—midbrain	Poster		Mon PM			
637.	Auditory systems: central physiology—primate cortex	Poster				Wed AM	
636.	Auditory, vestibular, and lateral line: development and regeneration	Poster				Wed AM	
423.	Auditory, vestibular, and lateral line: hair cell properties	Poster			Tue AM		
715.	Auditory, vestibular, and lateral line: integration	Poster				Wed PM	
106.	Chemical senses	Slide	Sun PM				
718.	Gustatory sensation	Poster				Wed PM	
373.	**Molecular Biology of Perception**	SYMP			**Tue AM**		
257.	Olfactory receptors: cell physiology	Poster		Mon AM			
258.	Olfactory receptors: development and specificity	Poster		Mon AM			
427.	Olfactory systems: invertebrates	Poster			Tue AM		
426.	Olfactory systems: olfactory bulb anatomy	Poster			Tue AM		
794.	Olfactory systems: olfactory bulb pharmacology	Poster					Thu AM
793.	Olfactory systems: olfactory bulb physiology	Poster					Thu AM
717.	Olfactory systems: olfactory responses	Poster				Wed PM	
208.	Pain modulation	Slide		Mon AM			
55.	Pain modulation: anatomy and physiology—behavior	Poster	Sun AM				
53.	Pain modulation: anatomy and physiology—higher centers I	Poster	Sun AM				
54.	Pain modulation: anatomy and physiology—higher centers II	Poster	Sun AM				
342.	Pain modulation: anatomy and physiology—neuropathic pain	Poster		Mon PM			
711.	Pain modulation: anatomy and physiology—receptors and nerves	Poster				Wed PM	
343.	Pain modulation: anatomy and physiology—spinal cord I	Poster		Mon PM			
344.	Pain modulation: anatomy and physiology—spinal cord II	Poster		Mon PM			
539.	Pain modulation: pharmacology—GABA and NMDA receptors	Poster			Tue PM		
346.	Pain modulation: pharmacology—amines, purines, cannabinoids	Poster		Mon PM			
542.	Pain modulation: pharmacology—amino acids, anesthetics, antidepressants	Poster			Tue PM		
712.	Pain modulation: pharmacology—inflammation and hyperalgesia	Poster				Wed PM	
345.	Pain modulation: pharmacology—neuropeptides and capsaicin	Poster		Mon PM			
540.	Pain modulation: pharmacology—opiates I	Poster			Tue PM		
541.	Pain modulation: pharmacology—opiates II	Poster			Tue PM		
383.	Pain pathways	Slide			Tue AM		
52.	Pain pathways: behavior	Poster	Sun AM				
51.	Pain pathways: higher centers	Poster	Sun AM				
341.	Pain pathways: spinal cord and brainstem	Poster		Mon PM			
199.	Retina and photoreceptors I	Slide		Mon AM			
792.	Retina and photoreceptors II	Poster					Thu AM
630.	Retinal anatomy	Poster				Wed AM	
713.	Retinal intracellular signalling	Poster				Wed PM	
56.	Retinal physiology	Poster	Sun AM				
347.	Retinal receptors and channels	Poster		Mon PM			

Session Number	Session Title	Type	Day and Time: Sun.	Mon.	Tue.	Wed.	Thu.
4.	**Sensorimotor Integration in Superior Colliculus: What Does the Colliculus Control?**	SYMP	Sun AM				
339.	Sensory systems: spinal cord I	Poster		Mon PM			
340.	Sensory systems: spinal cord II	Poster		Mon PM			
707.	Somatic and visceral afferents—visceral afferents I	Poster				Wed PM	
708.	Somatic and visceral afferents—visceral afferents II	Poster				Wed PM	
710.	Somatic and visceral afferents: mechanoreceptors	Poster				Wed PM	
709.	Somatic and visceral afferents: nociceptors	Poster				Wed PM	
16.	Somatosensory cortex and thalamocortical relationships I	Slide	Sun AM				
48.	Somatosensory cortex and thalamocortical relationships II	Poster	Sun AM				
49.	Somatosensory cortex and thalamocortical relationships III	Poster	Sun AM				
50.	Somatosensory cortex and thalamocortical relationships IV	Poster	Sun AM

DIFFERENTIAL EXPRESSION OF GLUTAMIC ACID DECARBOXYLASE mRNA IN CEREBELLAR PURKINJE CELLS AND DEEP CEREBELLAR NUCLEI OF THE GENETICALLY DYSTONIC RAT. L. Naudon*, N. Clavel, J.M. Delfs, J.F. Lorden, and M.-F. Chesselet. Dept. Pharmacol., Univ. Pennsylvania, Philadelphia PA 19104, and Dept. Psychol. U. of Alabama, Birmingham, AL 35294.

The genetically dystonic (dt) rat exhibits a motor syndrome that closely resembles the human disease, generalized idiopathic dystonia. Pharmacological and neurochemical studies have indicated that alteration in GABA-mediated neurotransmission might be critically involved in the pathophysiology of this type of dystonia. The activity of the enzyme glutamic acid decarboxylase (GAD), the synthetic enzyme for GABA, is increased in the deep cerebellar nuclei (DCN) of the dystonic rats in comparison with littermate controls suggesting enhanced Purkinje cell activity. In the current study, *in situ* hybridization histochemistry, with a probe specific for mRNA encoding GAD (Mr 67,000, GAD67) and emulsion autoradiography was used to determine the relative levels of GAD67 mRNA in the cerebellar Purkinje cell soma and in the neurons of the DCN of dystonic rats and littermate controls. Moreover, GAD67 and enkephalin mRNA levels were measured in the globus pallidus and the striatum, respectively. In Purkinje cells, GAD67 mRNA levels were significantly increased in dystonic rats compared to controls (+ 32%). In the DCN, GAD mRNA levels were significantly decreased (- 29%), without modification of the number of labelled neurons. Levels of GAD67 mRNA in the globus pallidus and of enkephalin mRNA in the striatum were similar in dystonic rats and littermates. The data confirm that the cerebellum, in contrast to the basal ganglia, is a site of significant functional abnormality in the dystonic rat. The opposite changes in GAD67 mRNA expression in cerebellar Purkinje cells and DCN are consistent with an increased GABA-ergic transmission in Purkinje cells, resulting in a decreased GABA synthesis in their GABA-ergic target neurons in the DCN. Supported by MH-44894 (MFC) and the Dystonia Medical Found. (JL)

ANTIDYSTONIC EFFECTS OF INHIBITORS OF NITRIC OXIDE SYNTHASE IN GENETICALLY DYSTONIC HAMSTERS (dt^{sz}). A. Richter*[1], P.-A. Löschmann[2] and W. Löscher[1]. [1]Dept. of Pharmacology, Toxicology and Pharmacy, School of Veterinary Medicine, Hannover; [2] Dept. of Neurology, University of Tübingen, Tübingen, Germany. Nitric oxide (NO) formation through activation of NO synthase (NOS), has been implicated in many neuronal processes. Although NO may regulate neuronal function within the striatum its role in basal ganglia diseases, such as dystonia, is largly unknown. NO, generated upon glutamate receptor activation, increases cyclic GMP and stimulates glutamate release. In mutant dystonic (dt^{sz}) hamsters previous studies indicated that an overactivity of the glutamatergic system may be pathogenetically involved in dystonia. Therefore, the effects of NOS inhibitors and of the precursor L-arginine on severity of dystonia were investigated in dt^{sz} hamsters, a model of idiopathic paroxysmal dystonia in which dystonic attacks, characterized by twisting movements and postures, can be induced by mild stress. Two inhibitors of the peripheral and central NOS, N^G-nitro-L-arginine (L-NNA) and N^G-nitro-L-arginine methyl ester (L-NAME), and 7-nitro indazole (7-NI), considered as a selective inhibitor of neuronal NOS, were examined. L-NNA (50 and 75 mg/kg) significantly reduced the severity of dystonia. At a dose of 50 mg/kg L-NAME was more potent and longer acting than L-NNA. At antidystonic effective doses neither L-NNA nor L-NAME caused any side effects, whereas 7-NI exerted at antidystonic effective (50 and 75 mg/kg)doses moderate sedation and reduction of locomotor activity. In order to examine wether an increase of NO would result in prodystonic effects, the precursor L-arginine was administered at doses of 300, 450 and 600 mg/kg. Even at high doses L-arginine did not exert any effect on severity of dystonia. Further examinations of the cGMP levels in brain regions of dt^{sz} hamsters in comparison to non-dystonic control hamsters, both under basal condition and after administration of 7-NI are under way in order to clarify if the present finding of antidystonic effects of NOS inhibitors is related to pathogenetically abnormal increases of NO synthesis and of cGMP in mutant hamsters. *Supported by grants from the Deutsche Forschungsgemeinschaft (Lo 271/4-2)*

RESPONSIVENESS OF CEREBELLAR NUCLEI NEURONS IN THE DYSTONIC RAT TO EXCITATORY AMINO ACIDS. **J.J. Fu* and J.F. Lorden. Department of Psychology, University of Alabama at Birmingham, AL 35294.**

In the genetically dystonic (dt) rats, the average spontaneous activity of neurons in the deep cerebellar nuclei (DCN) is higher than normal. Quantitative autoradiography showed a significant reduction in GABA receptor density, and microiontophoresis revealed a decreased response to GABA in the DCN cells of dt rats in comparison with normal rats. The reduced inhibitory control in the dt DCN might underlie the increased DCN activity, but the response to excitatory input is not known. This study used extracellular single unit recording and microiontophoresis to test both NMDA and non-NMDA type responsiveness in DCN neurons. Under urethane anesthesia, NMDA (0.2M, pH 7.0) and quisqualic acid (20 mM, pH 8.5) were applied to DCN neurons in dt rats and their unaffected littermate controls, aged 18-26 days. NMDA and non-NMDA receptor antagonists AP-3 (50mM, pH 7.5) and DNQX (5mM, pH 8.5) were tested as well. An excitatory effect was defined as increase in firing rate of at least 15% at an ejection current of 90 nA or less. In normal littermates, NMDA produced an excitatory effect in 89% of the cells tested (n=29), and quisqualic acid, in 92% (n=24). In the dt rats, all DCN cells tested displayed an excitatory effect to NMDA (n=12), and 89% (n=9) to quisqualic acid. However, responsive cells in dt rats were less sensitive to both NMDA and quisqualic acid at all ejection currents tested in comparison with normal littermates. DNQX produced an average of 30% inhibition of firing rate in all normal cells at 90 nA current, and an average of 5% inhibition in 50% of the dt cells (n=4, for both). These results suggest that increased DCN cell activity in dt rats is the result of reduced inhibitory control and not increased excitatory input. USE OF REAGGREGATE TISSUE CULTURE FOR EXAMINATION OF *WEAVER* GENE ACTION ON THE NIGROSTRIATAL DOPAMINERGIC PROJECTION. L. Won*, B. Ghetti[1] and A. Heller. Dept. of Pharmacol. & Physiol. Sci., The University of Chicago, Chicago, IL 60637, and [1]Dept. of Pathology and Laboratory Medicine, Indiana University School of Medicine, Indianapolis, IN 46223.

The murine *weaver* (*wv*) mutation is characterized by a loss of nigrostriatal dopaminergic (DA) neurons in both homozygous and heterozygous (*wv*/+) mice. The loss of DA neurons could be due to a direct action of the mutant gene on the dopaminergic neuron, or, secondary to an effect of the gene on striatal dopaminergic target cells. A possible role for striatal cells in DA cell loss in *wv* heterozygote mice was addressed using three-dimensional reaggregate tissue cultures in which cells from embryonic mesencephalon and striatum from *wv*/+ and wild type (+/+) brains were dissociated and recombined into four mesencephalic-striatal aggregate combinations: 1) (+/+)mesencephalon/(+/+)striatum; 2) (*wv*/+)mesencephalon/(*wv*/+)striatum; 3) (*wv*/+)mesencephalon\(+/+)striatum;and 4) (+/+)mesencephalon/(*wv*/+)striatum. Following 29 and 57 days of culture, aggregates containing *wv*/+ mesencephalon coaggregated with either *wv*/+ or +/+ striatum contained fewer DA neurons (10-34% less) than mesencephalic-striatal cultures composed of only +/+ cells. Coaggregation of +/+ mesencephalon with *wv*/+ striatum did not reduce DA cell numbers. Since +/+ striatum does not rescue *wv*/+ DA neurons and the presence of *wv*/+ striatum does not affect the number of +/+ DA neurons, the loss of DA neurons in the *wv*/+ mutation must be due to a direct effect of the *weaver* gene on the DA neurons, themselves. Supported by NS 14426 and MH 28942.

PARVALBUMIN INCREASES SELECTIVELY IN DENERVATED AREAS OF THE DEEP CEREBELLAR NUCLEI: A STUDY IN CEREBELLAR MUTANTS. U. Grüsser-Cornehls, M. Hoshi and J. Bäurle (SPON: European Neuroscience Association) Freie Univ. Berlin, UKBF, Dept. Physiol., Arnimallee 22, 14195 Berlin, Germany

To further investigate a possible interdependence between the extent of Purkinje-cell (PC) loss and the increase in Parv in the PC-target neurons, which was found recently in Purkinje cell degeneration (pcd) mutants, we examined other cerebellar mutants that offered differing grades and chronologies of PC-loss: lurcher (*lc*), nervous (*nr*), staggerer (*sg*), leaner (tg^{la}) and weaver (*wv*). Brains of at least five mice of each mutant strain and the corresponding wildtypes were incubated for Parv-immunocytochemistry. In addition antibodies against Calbindin D-28k were used on alternate sections to visualize the degree of denervation produced in the DCN by the PC-loss.

In *lc*, as in *pcd* mutants, the somatal Parv is elevated in all three subdivisions of the DCN. In *nr* and tg^{la} mutants with only a partial loss of PCs, elevated somatal Parv is restricted to more or less denervated nuclear areas, whereas areas with a residual PC-input are spared. Throughout the interposed (INT) and dentate (DENT) nuclei of *nr* and in the ventral part of the posterior fastigial (FAST) nucleus Parv is increased but not in the anterior FAST. In tg^{la} Parv is elevated in the dorsal part of the FAST and throughout the INT except for its lateral posterior part. Parv+ somata were never found in the DCN of *sg* and *wv*.

In conclusion, elevation of somatal Parv in neurons of the DCN is a common mechanism dependent on the topography and severeness of PC-input loss.

INTRODUCTION OF THE *WEAVER* GENE INTO THE BALB/cJ STRAIN. S.R. Dlouhy*, J. Richter, C. Stauss, J. Wei, M.E. Hodes, B. Ghetti. Ind. Univ. Sch. of Medicine, Indianapolis, IN 46202.

Effects of the *weaver* (*wv*) mutation in mice include loss of cerebellar granule cells and of dopaminergic cells of the substantia nigra. *Wv* arose in the C57BL/6 strain and has been maintained in a B6CBA (mixed genetic background) strain. To explore effects of the mutation in the context of different genetic backgrounds, we have crossed *wv* into the BALB/cJ strain. Fifteen backcross (BC) generations have been completed. These animals should have a genetic background greater than 99% BALB/cJ ("BALB"). As the series has progressed, *wv*/+ females have retained fertility, however, the *wv*/+ males have become more difficult to breed. A fortuitous mating (between BC12 *wv*/+ sibs) resulted in a viable *wv*/*wv* "BALB" male that lived till sacrifice at 90 days of age. Future breeding will be aided by direct DNA genotyping. In a related project, we have crossed "BALB" *wv*/+ mice with CBA/J +/+ mice. When the F1 *wv*/+ hybrids (50% CBA/J, 50% "BALB") are backcrossed to CBA/J, the progeny (75% CBA/J, 25% "BALB") appear to be more prone to early death caused by seizures than the progeny (25% CBA/J, 75% "BALB") produced when F1 the hybrid mice are backcrossed to BALB/cJ. Thus, at this stage of our analysis, genetic background effects on *wv* expression include decreased fertility in male *wv*/+ heterozygotes (BALB background) and increased susceptibility to seizures (CBA background). (Supported by P01 NS27613 and R01 NS14426)

AN ELECTRON MICROSCOPIC STUDY OF PURKINJE CELL AND PARALLEL FIBER SYNAPSES IN THE CEREBELLAR MOLECULAR LAYER OF TOTTERING (*tg/tg*), LEANER (*tg^{la}/tg^{la}*) AND COMPOUND HETEROZYGOUS, TOTTERING/LEANER (*tg/tg^{la}*) MICE.

L.C. Abbott*[1], I.J. Rhyu[1], D. Walker[1] and C. Sotelo[2] [1]Vet. Anat. & Public Hlth., Texas A&M Univ., College Station,TX, USA and [2]INSERM U.106, 47 Blvd. de l'Hopital, 75651 Paris, FRANCE

Tottering (*tg/tg*), leaner (*tg^{la}/tg^{la}*) and compound heterozygous, tottering/leaner (*tg/tg^{la}*) mutant mice exhibit juvenile onset of three abnormal neurologic phenotypes including *Petit-mal*-like epilepsy, ataxia and an intermittent myoclonus-like movement disorder. Recent work has revealed a decrease in the volume of molecular layer per Purkinje cell (Pc) in cerebella of adult *tg/tg* and *tg/tg^{la}* mice, but with no accompanying loss of PCs. Conversely, significant cerebellar Pc and granule cell loss is observed in *tg^{la}/tg^{la}* mice. The ultrastructural morphology of the cerebellar molecular layer was examined from *tg/tg*, *tg/tg^{la}* and *tg^{la}/tg^{la}* mice. In adult mice of all three genotypes, many parallel fiber varicosities (pfvs) were observed to make multiple contacts with Pc dendritic spines (dss). These multiple synaptic units were observed in both vermis and hemispheres and ranged from 2 dss/pfv to 7 dss/pfv. The existence of increased numbers of Pc dss/pfv for some pfvs has also been observed in juvenile mutant mice (postnatal days 20-30), suggesting that onset of the neurologic phenotype is not a primary cause of multiple ds-pfv synaptic units in these mice. **(Supported by NINDS grant NS01681 to LCA.)**

647.10

AGE-RELATED CHANGES IN CORTICAL NEUROCHEMICALS AND WATER CONTENT IN CONGENITALLY HYDROCEPHALIC RATS.

H.C. Jones*, N.G. Harris and R.W. Andersohn. Dept. Pharmacol., Univ. of Florida, Gainesville, FL 32610.

We have previously shown by *in vitro* NMR spectroscopy that in H-Tx rats with advanced hydrocephalus at 21 days of age, there are 50 -60% reductions in the concentration of many cortical metabolites (inositol, creatine, N-acetyl aspartate or NAA, choline compounds, and the amino acids: taurine, aspartate, glutamate and alanine). Treatment with shunt surgery at 4 days prevents these changes, whereas treatment at 10 days of age is less effective. In the present study, the same *in vitro* NMR technique has been used to examine metabolite concentrations in rats at the age of shunt placement, 4 and 10 days (n = 7 or 8 per group). At 4 days of age, the same trend of metabolite reduction was present in hydrocephalic rats but it was much less than at 21 days (25-35%) and was significant only for inositol, taurine, choline compounds and NAA. At 10 days there were larger reductions (30-45%) and six were statistically significant. Since tissue water content may increase in hydrocephalus and the concentrations were related to tissue wet weight, we measured cortical water content in new groups of control and hydrocephalic rats at 21, 10, and 4 days by wet/dry weight ratios. A small but highly significant 1% increase in cortical water content occurred with hydrocephalus at all ages, and hence the relative dry weights decreased. Calculation of metabolite concentration as a function of dry weight, partially reduced the magnitude of the changes in hydrocephalic rats but did not change the significance at 21 days. At the younger ages the significance level was reduced or abolished for a number of metabolites, particularly at 4 days. It is concluded that brain tissue water content is increased at all stages of hydrocephalus but that the changes in metabolites are much smaller in the early stages. This may explain the better outcome for shunt treatment at 4 days. *Supported by Johnson & Johnson Focused Giving and Children's Miracle Network, Telethon awards.*

647.11

MOUSE STRAIN DIFFERENCES IN A SENSORIMOTOR GATING MODEL OF SCHIZOPHRENIA.

R. Paylor*, and J.N. Crawley. National Institute of Mental Health, Bethesda, MD, 20892.

Prepulse inhibition (PPI) is the normal suppression of a startle response when the startle stimulus is preceded by a weak prepulse. Patients with schizophrenia have impaired PPI which is thought to reflect dysfunctional sensorimotor gating mechanisms. To investigate the potential genetic basis for differences in sensorimotor gating, the responses of 11 inbred strains of mice were evaluated using the PPI paradigm.

Ten male mice from each strain were tested for PPI using the acoustic prepulse + tactile startle (AP + TS) test followed by the acoustic prepulse + acoustic startle (AP + AS) test. The TS stimulus was an air puff and the AS was a 120 dB sound. The AP stimuli were 74, 78, 82, 86, and 90 dB sounds. For each test, mice were presented startle stimulus alone trials, prepulse + startle stimulus trials, and no stimulus trials. The background noise was 70 dB.

There was a wide range of responses to both the TS and AS. Using maximal startle response data, the following rank order was found for the TS: C57BL/10J > FVB/NJ > BALB/cByJ = C3H/HeJ = 129/SvEv = C57BL/6J = AKR/J = A/J > DBA/2J = 129/J = 129/SvJ, and for AS: C57BL/10J = FVB/NJ = BALB/cByJ > C57BL/6J = A/J = 129/SvEv = AKR/J = C3H/HeJ > DBA/2J = 129/SvJ = 129/SvJ. There was also a range of PPI for both the AP + TS test and the AP + AS test. Using the amount of PPI observed with the 90 dB prepulse, the following rank order was found for the AP + TS test: 129/SvEv = AKR/J = 129/SvJ = A/J = 129/J > DBA/2J = FVB/NJ = BALB/cByJ = C3H/HeJ = C57BL/10J = C57BL/6J, and for the AP + AS test: 129/SvEv = AKR/J > 129/J = 129/SvJ = DBA/2J = FVB/NJ = A/J > BALB/cByJ = C3H/HeJ = C57BL/10J = C57BL/6J.

These findings confirm and extend a previous report (Bullock, et al, 1995) indicating that inbred strains of mice will be a useful tool to study the genetic basis of sensorimotor gating.

This research was supported by the IRP of the NIMH.

D-1 AND D-2 RECEPTORS IN THE TARGET SITES OF DOPAMINE SYSTEMS IN AN ANIMAL MODEL OF ADHD: DIFFERENTIAL DISTRIBUTION AND RESPONSE TO SUBCHRONIC METHYLPHENIDATE TREATMENT.

M.P.Carey, L.M.Diewald, M.Papa[1], F.Esposito, U.A. Gironi Carnevale, T.Sagvolden[2], J.A.Sergeant[3], and A.G.Sadile. (SPONSORED BY THE EUROPEAN BRAIN AND BEHAVIOUR SOCIETY). Lab. Neurophysiol. Behav. & Neural Networks, and [1]Inst. Human Anat., SUN, Naples, I; [2]Dept. Neurophysiol., Univ. Oslo, N; [3]Inst.Clin.Psychol., UVA, Amsterdam, NL.

The aim of this study was to explore the involvement of D-1 and D-2 dopamine (DA) receptor subfamilies in an animal model of Attention-Deficit Hyperactivity Disorder (ADHD), the Spontaneously Hypertensive rat (SHR), using *in vitro* quantitative autoradiography. Six-wk old male SHR and Wistar-Kyoto (WKY) controls were given the DA re-uptake blocker methylphenidate (MP; 3 mg/kg, i.p.), or vehicle, daily during a 15-day period. Rats were sacrificed 24 h after the last injection. Coronal sections across the caudate-putamen (CPU), nucleus accumbens (ACB), olfactory tubercle (OT), globus pallidus (GP), and the ventral pallidum (VP) were used for a saturation analysis of D-1/D-5 receptors using 0.1-5.0 nM of [^{3}H]-SCH23390 and two competition studies using 4 nM ^{3}H-raclopride and 5 nM ^{3}H-quinpirole with cold spiperone and 7-OH-DPAT (0.1 nM - 10 µM) as cold displacers. Vehicle-treated SHR showed a higher level of D-1/D-5 in the CPU, pole, core and shell of ACB and OT, which was normalized by subchronic MP to control levels in the SHR. In addition, MP-treatment "down-regulated" D-2/D-4 DA subtypes in the CPU, ACB and OT, and "up-regulated" mostly D-3 subtype in CPU, ACB, OT in both strains, and in the GP and VP in WKY-rats only. In contrast, D-3 receptors were "down-regulated" in the islands of Calleja in both strains. Thus, the differential distribution and regulation of DA receptors in the target sites of DA systems after subchronic administration of a DA re-uptake blocker supports the DA hypothesis of ADHD in children. **(Supported by EC grant ERBCHRXCT930303).**

QUANTITATIVE CYTOCHROME OXIDASE MAPPING STUDY, CROSS-REGIONAL AND NEUROBEHAVIORAL CORRELATIVE ANALYSES IN THE ANTERIOR FOREBRAIN OF AN ANIMAL MODEL OF ADHD.

A.G.Sadile[1]*, M.Papa, D.F.Berger[2], T.Sagvolden[2], and J.A.Sergeant[3]. Inst. Human Anat., and [1]Lab. Neurophysiol. Behav. & Neural Networks, SUN, Naples, I; [2]Dept. Neurophysiol., Univ. Oslo, Oslo, N; [3]Inst. Clin. Psychol., UVA, Amsterdam, NL.

A quantitative cytochrome oxidase (COase) histochemical study has been carried out in the anterior forebrain of an animal model of Attention-Deficit Hyperactivity Disorder (ADHD), the Spontaneously Hypertensive Rat (SHR). In fact, SHR feature some of the aspects of ADHD, i.e. attention deficits and hyperactivity. Adult male (Exp. 1) or male and female (Exp. 2) SHR and WKY rats were used. In Exp. 2 rats were trained for 3-mo on a multiple 120-sec fixed interval 5-min extinction schedule. The rats were sacrificed 6-mo after training. Twenty-µm thick coronal cryostat sections were processed for COase histochemistry. Optical density values were transformed in actual enzyme activity units by using calibrated tissue standards. Non-trained SHR showed a lower COase activity in the medial and lateral prefrontal cortices, and in the most rostral portions of the caudate-putamen and in the rostral pole of the n.accumbens. No SHR/WKY difference was demonstrated in trained rats. Regional correlations revealed that (i) under basal conditions, SHR were more "synchronized" than WKY-rats, and (ii) the training that "desynchronizes" COase activity in WKY rats, further "synchronizes" it and increases the cross-talk between hemispheres in male SHR only. Neurobehavioral covariations between behavioral scores and metabolic capacity in the anterior forebrain revealed significant gender differences with effects in male SHR only. Thus, the results lend support to the involvement of the cortico-striato-pallidal system in ADHD which affects mostly male children. **(Supported by EC grant ERBCHRXCT930303).**

647.14

CENTRAL NERVOUS SYSTEM INVOLVEMENT IN LONG-EVANS CINNAMON RATS AS A MODEL OF WILSON'S DISEASE.

A. Hori[1, 2], G. Hirose[2], H. Matsuno[3], S. Fujii[4], C. Sugawara[5], C.E. Stafstrom[1], G.L.Holmes[1], P. Tandon*[1] [1] Dept. of Neurology, Children's Hospital, Harvard Med. School, Boston, MA 02115, [2] Dept. of Neurology and [3] Pathology, Kanazawa Med. Univ., Ishikawa, [4] Dept. of Pathology, Hokkaido Univ. School of Med. [5] Dept. of Public Health, Sapporo Med. Univ., Japan.

Long-Evans Cinnamon (LEC) rats have a mutation causing hereditary hepatic injury based on excessive accumulation of hepatic copper. Here we studied the neurological manifestations and the effect of treatment with trientine dihydrochloride, a copper chelating agent used clinically for Wilson's disease.

Three month old LEC rats were divided into 3 groups. Group 1 (n=19) received continuous trientine (150 - 200 mg per day, p.o.) for one year. Group 2 (n=11) were treated intermittently for one year with the same dose, on a 7-days on / 7-days off schedule. Group 3 (n=76) were not treated.

Mortality within 12 months in the three groups was 0%, 10%, and 57%, respectively. Serum transaminases and bilirubin were greatly elevated in group 3, mildly elevated in group 2 and normal or minimally elevated in group 1. No extrapyramidal symptoms were seen in any group. Spontaneous movements were slightly decreased in group 3; group 1 had normal spontaneous movements. On EEG, spikes, sharp waves and slow bursts were seen in group 3 only.

Liver copper staining was strongly positive in group 3 and negative in group 1. There was no brain copper staining detected (including lenticular nucleus) at any age, in any group of LEC or LEA rats.

LEC rats had liver copper accumulation and CNS disturbances (paroxysmal EEG changes and decreased spontaneous movements), but no abnormalities of brain copper accumulation or pathology were detected, as opposed to that seen in human Wilson's disease. Therefore, the neurological abnormalities in Wilson's disease might be caused by some factor other than long-term exposure to copper. The pathogenesis of the hepatic and neurologic forms of Wilson's disease may be different.

THE BEHAVIOUR OF CHILDREN WITH ATTENTION DEFICIT HYPERACTIVITY DISORDER AND THAT OF AN ANIMAL MODEL SHOW ALTERED REINFORCEMENT MECHANISMS. Terje Sagvolden[1], David F. Berger[2], Heidi Aase[1], and Pål Zeiner[3] [1]Department of Neurophysiology, University of Oslo, Norway; [2]Department of Psychology, State University College at Cortland, Cortland, N.Y., USA; [3]Norwegian State Centre of Child and Adolescent Psychiatry, University of Oslo, Oslo, Norway

SPON: European Brain and Behaviour Society

In the **clinical study**, we used 8 boys with Attention Deficit Hyperactivity Disorder (ADHD) and 12 control boys, all aged 7 to 12 years, to investigate the hypothesis that there are altered delay-of-reinforcement gradients in ADHD. In the **animal study,** we used male and female spontaneously hypertensive rats (SHR), an animal model of Attention Deficit Hyperactivity Disorder (ADHD) and male and female WKY comparison rats, 8 rats in each group. Both children' and model's behaviour was trained and maintained in lever-press response apparatuses operating according to a multiple fixed interval extinction schedule of reinforcement. Trinkets were used as reinforcers for the childrens' behaviour and drops of water for the animals' behaviour. The **results** showed strikingly similar behaviour in ADHD subjects and SHR rats: the hyperactive behaviour was acquired, with high frequency responding during both schedule components, development of short interresponse times (response bursts, "impulsiveness") and a sustained-attention deficit in the extinction component. Both control children and the control group ceased responding in extinction and did not develop response bursts. The behavioural characteristics of the ADHD boys and the male SHRs may be due to a combination of impaired sustained attention and altered reinforcement mechanisms. The results strengthen the position that SHR is a useful model of ADHD which can be used for investigating neurobiological and other factors underlying ADHD. Factors which cannot be investigated in humans.

CANINE MULTIPLE SYSTEMS ATROPHY: A MODEL OF DOMINANTLY INHERITED NEURODEGENERATIVE DISEASE. DP O'Brien*, GC Johnson, GS Johnson. Comparative Neurology Program, College of Veterinary Medicine, University of Missouri, Columbia, MO 65211.

In this study, we characterized the phenotype of a family of Chinese crested dogs with a hereditary multiple systems atrophy. Six dogs of both sexes presented for progressive ataxia and extrapyramidal signs. Affected dogs came from 4 litters all with a common sire suggesting dominant inheritance; 37% of the pups in the litters were affected. The dogs were normal at birth, but began developing dysmetria at about 3 months of age. The dysmetria became maximal at about 6 months. Progressive weakness and spasticity then became evident culminating in recumbency by 15 months of age in one dog allowed to survive that long. Necropsies have been performed on 4 dogs. The earliest histologic change seen was a marked decrease in cerebellar Purkinje cell numbers to <10% of controls with "empty baskets" on Bielschowsky's stain. Older dogs also showed dramatic degeneration of the caudate nucleus and substantia nigra. This disease could be a model of dominantly inherited neurodegenerative diseases of man. Linkage analysis has ruled out a mutation of the canine Huntington's gene, and investigation of other candidate genes is underway.

647.17

CLASSIFICATION OF REDUCED NEURON POPULATION IN SPF MICE. K.H. Hopkins*†, M.B. Robinson+, M.L. Oster-Granite†, †Div. of Biomed. Sci., Univ. of California, Riverside, CA 92521 and +Dept. of Ped., Univ. of PA Sch. Med., Philadelphia, PA 19104.

Ornithine carbamoyltransferase deficiency (OCTD), a urea cycle enzyme defect, occurs in 1:40,000 to 1:80,000 live births resulting in hyperammonemia. The gene for the ornithine carbamoyltransferase (OCT) enzyme is located on the X-chromosome. Males with one Y-chromosome and one mutated X-chromosome often have less than 5% OCT enzyme activity in their liver and are severely affected. The male *Sparse fur* mouse (*Spf/Y*), a model for OCTD, is also hyperammonemic as a result of a defect in the OCT gene. Though changes in neurobehavior and neurochemistry have been reported, no changes in neuropathology of *Spf/Y* brains have been reported prior to our demonstration of loss of a specific population of neurons in the striatum. Immunocytochemical techniques utilizing calbindin and parvalbumin antibodies, which label specific neuron populations in the striatum, were used to further classify the neuronal loss in these animals. Calbindin is localized to the matrix compartment of the striatum where it is present in medium sized striatal spiny efferent neurons projecting to the substantia nigra and to the globus pallidus. Parvalbumin is localized in medium sized aspiny striatal interneurons localized in the lateral striatum. Supported by HD19932 and LLNL B291424, B291833.

THE MOTOR NEURON DEGENERATION (mnd) GENE ACTS INTRINSICALLY IN MOTOR NEURONS AND PERIPHERAL FIBROBLASTS. A.Messer*J.C.Porter and A.Peterson. Wadsworth Ctr. for Labs and Research, N.Y. State Dept. of Health and Dept. of Biomed. Sci., SUNY, P.O. Box 509, Albany, NY 12201-0509; Albany Medical College; and Dept. of Neurology and Neurosurgery, McGill Univ., Montreal, Canada.

The *mnd* mutation produces abnormal ubiquitous accumulation of autofluorescent lipopigment, with retinal degeneration and late-onset motor neuron degeneration. Abnormal accumulations also include immunoreactive mitochondrial ATP synthase subunit *c* (sub *c*). Neurons containing large perinuclear accumulations show margination of neurofilaments. In order to determine whether the gene acts intrinsically or via a circulating factor, motor neurons were examined morphologically in genetic chimeras, while neonatal fibroblasts were passaged in vitro and assayed for sub *c*. The spinal cord of a mouse resulting from the fusion of a wild-type embryo carrying the human neurofilament L transgene (hNF-L) with an *mnd* embryo clearly shows a mixture of abnormal mutant motor neurons containing inclusions and marginated NFs with normal motor neurons. The hNF-L is found only in the normal cells. Control experiments prove that the hNF-L can integrate into the marginated NF complex if the gene is present in mutant cells from a genetic cross. Fibroblasts from *mnd* neonates can show substantial levels of immunoreactive sub *c*, even after being passaged in vitro for >10 weeks. Cultures of cells from wild-type mice do not show this abnormal immunoreactivity. These experiments demonstrate that the action of the *mnd* gene is intrinsic within disparate cell types, and has implications for both pathogenic mechanisms and therapies.

ZITTER MUTANT RAT AS AN AGING RAT MODEL: MORPHOMETRIC AND IMMUNOHISTOCHEMICAL STUDIES.

M.Aikawa, S.Yamaoka* and S.Ueda. Dept. of Histology and Neurobiology, and Physiology, Dokkyo Univ. Sch. of Med., Mibu, Tochigi 321-02, Japan.

Zitter mutant rat derived from Sprague-Dawley strain is characterized by body tremor and vacuolation in the brain. Several physiological indicators for aging have been demonstrated in the young adult Zitter rat. In the present experiments, availability of Zitter rat as an aging rat model was morphologically examined using the morphometric analysis and immunohistochemistry, and compared with age matched SD rats. Morphometric analysis indicated the reduction of the cerebral cortex and ventricular enlargement in the Zitter rat. In the cerebral cortex, the number of calbindin-immunoreactive neurons were significantly decreased in the mutant rat. Furthermore, the abnormal serotonergic fibers were observed in the several brain regions of Zitter rat. These changings were usually seen in the senescent SD rat. The present results indicate the usefulness of Zitter rat as an aging model.

HUMAN GLIOMA MALIGNANCY IS ENHANCED BY SCATTER FACTOR GENE TRANSFER. M.J. Nam*, P. Johnston, E.M. Rosen, and J. Laterra Dept. Neurology Kennedy Krieger Inst. & Johns Hopkins Sch. Med., Balt. MD

Scatter factor/hepatocyte growth factor (SF) is induced by tissue injury and plays roles in differentiation, maturation, and angiogenesis. Malignant gliomas express SF and its receptor but SF's roles in glioma malignancy are not known. We examined the effects of SF expression on human U373 glioma. U373 cells that do not produce SF were transfected with pMEX-SF containing human SF cDNA under the control of MSV-LTR promoter. SF was detected by ELISA in conditioned medium (CM) of U373-SF cells but not in control transfected cells (U373-neo). Proliferation of U373-SF and control cells were similar. Invasion of matrix by U373-SF cells was enhanced *in vitro* ($P<0.05$). CM from U373-SF lines stimulated endothelial cell DNA synthesis 2-fold. CM from endothelial cells exposed to recombinant SF (10 ng/ml) promoted the U373-SF cell proliferation. Tumor formation in SCID mice following the subcutaneous implantation of U373-SF cells was markedly enhanced when compared to U373-neo control (100% vs 0%, respectively). Human SF gene expression *in vivo* was detected by RT-PCR in tumors resulting from the U373-SF but not U373-neo cells. These findings demonstrate that SF can increase the malignancy of human gliomas via autocrine or/and paracrine mechanism *in vivo*. Supported by NS 01329 (JL) and CA64869 (EMR).

DAMAGE TO MYELINATED FIBERS OF PERIPHERAL NERVE AND SPINAL CORD IN AGED PRION PROTEIN GENE-KNOCKOUT MICE.

S Shirabe*, S Katamine, N Nishida, T Miyamoto, K Iwanaga, H Itoh, T Nakamura, K Shigematsu, T Yoshimura, S Nagataki, and T Noda First Department of Internal Medicine and Bacteriology, Nagasaki University School of Medicine, 1-7-1, Sakamoto, Nagasaki 852 Japan, Cancer Institute, Tokyo Japan

Prion protein (PrP), which is the putative etiological agent in human prion diseases such as Creutzfeldt-Jakob Disease and Gerstmann-Sträussler Syndrome, is mainly expressed on neuronal cell surfaces. The physiological role of PrP is still unknown. We have recently reported loss of cerebellar Purkinje cells(PK) in aged PrP gene-knockout mice, suggesting that PrP is necessary for long-survival of PK (Nature, 1996). The ataxic homozygous ($PrP^{-/-}$) mouse also shows paresis in the lower extremities. Morphometric analysis disclosed demyelination of large myelinated fibers in sciatic nerve and spongiform degeneration in the white matter of spinal cord in aged mice. The morphometric analysis, which included nerve fiber density, thickness of myelin, and diameter of axons, was carried out in 4 week, 15 week, 31 week and 80-week-old animals by optical and electron microscopy. Changes were observed in 80-week-old mice, but not younger ages. PrP protein may therefore play a role in long-term maintenance of myelination in the spinal cord and peripheral nerve.

ATAXIC GAIT AND MEMORY DISTURBANCE IN AGED *PrP*-NULL MICE.

N. Nishida [1], S. Katamine[1], K. Shigematsu[2]*, S. Shirabe[3], T. Noda[4]. Dept. [1]Bacteriology, [2]Pathology, [3]Internal Medicine, Nagasaki Uni. Sch. of Med., Nagasaki 852, Japan; Dept. [4]Cell Biology, Cancer Institute, Tokyo, Japan.

Host-encoded prion protein (PrP^C) is a sialoglycoprotein constitutively expressed on the neuronal cell surface and its protease-resistant isoform is implicated in the pathogenesis of the prion diseases. The physiological function of PrP^C, however, remains unknown. We developed a line of mice homozygous ($PrP^{-/-}$) for a disrupted *PrP* gene by homologous recombination using a targeting construct in which the whole PrP-coding region was replaced by a neo-casette, and subsequently analyzed the behavior and motor function of these mice. At 50 weeks after birth, the $PrP^{-/-}$ mice began to show mild hindquarter tremor when evaluated on an elevated runway. Pathological examination revealed that cerebellar Purkinje cells started to show focal loss at 20 weeks of age which gradually progressed as the ataxia become obvious. In a time-course analysis, the long-term memory and latent learning ability were found to be impaired in the $PrP^{-/-}$ mice at 25 weeks of age, but the short term memory was unaffected. These findings strongly suggest that PrP^C plays a key role in the long-term survival of Purkinje cells and is required for hippocampal function.

648.3

NEURONAL TRANSBILAYER DISTRIBUTION OF CHOLESTEROL IS MODIFIED IN "KNOCKOUT" MICE DEFICIENT IN THE LOW DENSITY LIPOPROTEIN RECEPTOR OR APOLIPOPROTEIN E. U.Igbavboa, N.A. Avdulov, S.V. Chochina and W.G. Wood*. Geriatric Research, Education, and Clinical Center, VA Medical Center and Dept. Pharmacology, Univ. Minnesota, Minneapolis, MN 55417.

Cholesterol in plasma membranes including brain synaptic plasma membranes (SPM) is asymmetrically distributed in the two leaflets of the membrane. In SPM, the cytofacial leaflet contains substantially more cholesterol than the exofacial leaflet, 85% vs 15%, respectively. SPM cholesterol asymmetry has been shown to be altered by increasing age and chronic ethanol consumption. Factors involved in regulation of transbilayer cholesterol distribution are not well-understood. We have examined the role of apolipoprotein E (ApoE) and low density lipoprotein receptor (LDLR) in regulating the transbilayer distribution of cholesterol. Knockout mice deficient in either ApoE or LDLR were used. Cholesterol in the exofacial leaflet and the cytofacial leaflet was determined using the fluorescent sterol dehydroergosterol (DHE) and trinitrobenzenesulfonic acid quenching techniques. Cholesterol asymmetry was reduced in SPM of the knockout mice. The percent distribution of cholesterol in the exofacial leaflet was significantly higher ($p<0.01$) in the ApoE and LDLR deficient mice as compared to their appropriate control mice, C57BL/6J and B6129, respectively. There was a significant reduction of cholesterol in the cytofacial leaflets of the knockout mice ($p<0.01$). Total SPM cholesterol (exofacial + cytofacial) was significantly lower in ApoE deficient than C57BL/6J mice ($p<0.002$). Expression of ApoE and LDLR are necessary for the normal transbilayer distribution of cholesterol in neurons. Supported by AG 11056 and Dept. of Veterans Affairs.

MICE LACKING α- AND β-SUBUNITS OF β-HEXOSAMINIDASE DISPLAY MUCOPOLYSACCHARIDOSIS AND GANGLIOSIDOSIS.

K. Sango*[1], M. McDonald[2], J. N. Crawley[2], M. L. Mack[1], C. J. Tifft[1], E. Skop[3], C. M. Starr[3], A. Hoffmann[4], K. Sandhoff[4], K. Suzuki[5] and R. L. Proia[1]. [1]GBB, NIDDK; [2]ETB, NIMH; NIH, Bethesda, MD 20892, [3]Glyko Inc., Novato, CA 94949, USA, [4]Institut für Organische Chemie und Biochemie der Universität, Bonn, Germany and [5]Dept. of Pathol., Univ. of North Carolina, Chapel Hill, NC 27599-7525, USA.

The G_{M2} gangliosidoses, Tay-Sachs and Sandhoff diseases, are caused by mutations in the *HEXA* (α-subunit) and *HEXB* (β-subunit) genes, respectively. Each gene encodes a subunit for the lysosomal enzyme, β-hex A(αβ), as well as for β-hex B(ββ) and S(αα). We have produced mice with both genes disrupted that are totally deficient in β-hex A, B and S. These double knockout mice displayed facial and physical dysmorphia and severe movement difficulties, and had a shorter life span (1-4 months) than each of the single knockout mice. In addition to gangliosidosis, the double knockout mice showed pathologic and biochemical features of mucopolysaccharidosis. The novel phenotype of the totally β-hex deficient mice shows that GAGs like gangliosides are critical substrates for β-hex and that their lack of storage in Tay-Sachs and Sandhoff diseases is due to functional redundancy in the β-hex system (supported in part by U.S.P.H.S., NS-24453 & HD-03110, and DFG, SFB284).

PHENOTYPIC VARIATION IN PRIMARY NEURONAL CULTURES DERIVED FROM ß-AMYLOID PRECURSOR PROTEIN (ßPP) DEFICIENT TRANSGENIC MICE.

R.G. Perez[1]*, H. Zheng[2], L.H.T. Van der Ploeg[2], and E.H. Koo[1]. Brigham and Women's Hospital and Harvard Medical School[1], Boston, MA 02115 and Merck Research Laboratories[2], Rahway, NJ 07065.

The *in vivo* physiological role of ßPP, a type I integral membrane protein, remains unclear. Cell surface ßPP may function as a receptor especially in light of our findings that ßPP colocalizes with α1, α5, and ß1 integrins in cultured primary neurons. A line of transgenic null (TG^0) mice deficient in ßPP show muscle weakness and brain gliosis, consistent with a hypothesized functional role of ßPP in the nervous system. In this study we characterized neuronal survival and neurite outgrowth of primary hippocampal cultures from embryonic day 16 (E16) TG^0 and control mice. Cells plated at the same density onto polylysine coated tissue culture plastic were evaluated at 4 hours and at 3 days after plating. At 3 days *in vitro* total neurite outgrowth, axon length, axonal branching, number of minor processes, and ratios of axon/minor processes were measured. TG^0 neurons plated down as efficiently as controls by 4 hours. However, TG^0 neurons may have diminished viability compared to controls because we observed ~25% fewer neurons in TG^0 cultures at 3 days, although we have yet to determine if TG^0 mice have an unexpected increase in hippocampal glia at E16. TG^0 neurons showed a trend toward greater neurite outgrowth, axon length and number of axonal branchings. Increased branching of minor process was significantly greater for TG^0 neurons compared to controls ($p < .02$). These preliminary data suggest that TG^0 neurons grow similarly to controls in the absence of extracellular matrix (ECM) proteins. Future analyses will assess neurite outgrowth on a number of ECM proteins including laminin, fibronectin, and collagen.

NEUROCHEMICAL MARKERS OF VULNERABILITY AND PROTECTION IN MUTANT SUPEROXIDE DISMUTASE TRANSGENIC MICE.

B.M. Morrison*[1], J.W. Gordon[2], and J.H. Morrison[1]. [1]Fishberg Res. Ctr. for Neurobiol., and [2]Dept. of Obs/Gyn and Reproductive Sci., Mt. Sinai School of Medicine, New York, NY 10029.

Transgenic mice with a point mutation in the mouse superoxide dismutase (SOD-1) gene that results in a Gly86→Arg substitution, corresponding to a mutation observed in familial amyotrophic lateral sclerosis (ALS), display progressive loss of motor function and provide a valuable model of ALS (Ripps et al., 1995). In previous experiments, immunocytochemically-defined neurons in the spinal cord of control and SOD-1 transgenic mice were counted using the optical fractionator and custom-made data analysis software (NeuroZoom: Young et al., Neurosci. Abstr. '96). Neurofilament (NFP)-, choline acetyltransferase (ChAT)-, and calretinin (CR)-containing neurons were all vulnerable to degeneration in SOD-1 transgenic mice. In contrast, calbindin-containing neurons did not degenerate significantly, and represent a protected population of neurons. The neurochemical markers of vulnerability (i.e. NFP, ChAT, and CR) do not define exclusive populations of neurons, however, and additional experiments were designed to determine whether the patterns of colocalization provided additional insight into the key marker(s) of vulnerability. Both ChAT-containing neurons, which are motoneurons, and CR-containing neurons, which are interneurons, are highly colocalized with NFP in control mice (86% and 74%, respectively). From the severe loss of NFP-containing neurons in SOD-1 transgenic mice and the high percentage colocalization of NFP with the other markers of vulnerability (i.e. ChAT and CR), we hypothesized that NFP is the true marker of vulnerable neurons in the spinal cord of transgenic mice. This was supported by the accurate prediction of neuron loss in these vulnerable neuronal populations by the percentage of neurons that contained NFP. In contrast, ChAT immunoreactivity was not an accurate predictor of cell loss, suggesting that NFP content is a better predicter of vulnerability than whether or not a cell is a motoneuron. In addition, we are investigating the patterns of neurodegeneration in pre-symptomatic SOD-1 transgenic mice to determine the timecourse of degeneration of these vulnerable neuronal populations. Supported by NIH grants AG06647 (JHM) and AG10520 (JWG).

ALTERATIONS IN NITROGEN MONOXIDE-SYNTHESIZING NEURONS IN MICE EXPRESSING A SUPEROXIDE DISMUTASE MUTATION ASSOCIATED WITH FAMILIAL AMYOTROPHIC LATERAL SCLEROSIS.

Rodrigo O. Kuljis* and Katina Chatzipanteli. Neurology Service and Geriatric Center, Department of Veterans Affairs Medical Center and Department of Neurology, University of Miami School of Medicine, Miami, Florida 33136.

Nitrogen monoxide (NO; a.k.a. "nitric oxide") synthesizing neurons (NOSN) have been found to develop degenerative changes in some patients with sporadic amyotrophic lateral sclerosis (ALS; Kuljis & Schelper, J. Neuropathol. Exp. Neurol. 55: 25). We hypothesized that a mutation in the Cu/Zn superoxide dismutase gene (G93A) associated with familial ALS (Rosen et al., Nature 362:59) may result in a similar involvement of NOS in trangenic mice that express this mutation and develop ALS-like condition (Gurney et al., Science 264:1772). Expression of the transgene was verified by a reverse transcriptase/polymerase chain reaction in five specimens. After fixation by systemic perfusion with paraformaldehyde, the brains were sectioned and labeled histo- and immunocytochemically for NADPH diaphorase (NADPH-d) and NO synthase (NOS). Transgenic mice exhibit numerous distended or shrunken, dysmorphic NOS- and NADPH-d containing perikarya with deranged internal structure and degenerating neurites throughout the cerebral cortex. These dystrophic neurons are situated predominantly in the deep layers and in the interface between the grey and white matter. They are not confined to motor regions and clearly occur non-motor regions as well. These findings suggest that both sporadic as well as genetic ALS target some types of NOSN, and apparently independently of the insult to motor neurons. The involvement of NOSN in ALS may mediate the non-motor manifestations of the disease, such as cognitive impairment, which may therefore be susceptible of pharmacological palliation. Support: DVA Merit Review 5065.01.

648.8

CEREBRAL GLUCOSE UTILIZATION IN A TRANSGENIC MOUSE MODEL OF FAMILIAL AYOTROPHIC LATERAL SCLEROSIS.

S.E. Browne*, T. Siddique and M.F. Beal. Neurology Research, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

A number of biochemical and imaging studies in human brain suggest that energy metabolism is impaired in cerebral regions targeted by the disease process in amyotrophic lateral sclerosis (ALS). A defect in Cu/Zn superoxide dismutase (SOD1), which regulates intracellular free radical levels, has also been found in some familial ALS (FALS) patients. It has been proposed that neurodegeneration in FALS may result from a defect in mitochondrial energy metabolism, due to excessive oxidative damage. However, reports that transgenic mice overexpressing human mutant SOD1 develop a disease paradigm closely resembling FALS have led to the alternative hypothesis that cell death may arise from the gain of an adverse function associated with SOD1 mutations.

To determine whether a metabolic defect is intrinsically involved in the etiology of cell death in ALS, we have investigated the temporal profile of functional cerebral metabolic events associated with the onset and progression of motor neuron disease in a transgenic mouse model of FALS. Local cerebral glucose utilization was measured in conscious G93A transgenic mice overexpressing SOD1, using [^{14}C]-2-deoxyglucose autoradiography. Initial studies in aged mice (124-130d) with motor abnormalities (tremor and hindlimb paralysis) indicate that glucose use is decreased in cerebral cortex, relative to littermate controls. Further, a marked increase in glucose use was evident in the fornix/perifornicular region of the hypothalamus in SOD1 mice (SOD = 67±7; control = 34±3 µmol/100g/min, $p<0.05$). Results demonstrate that integrated functional energy metabolism is altered in this transgenic mouse model of FALS.

REPETITIVE-COMPULSIVE DISORDER IN MICE CAUSED BY A D1-NEUROMODULATORY TRANSGENE.

K. M. Campbell, D. M. Severynse*, L. deLecea, R. M. Rohland, L. Y. Sun, S. B. Sparber, M. G. Caron, J. G. Sutcliffe and F. H. Burton. Dept. of Pharmacology, Univ. of Minnesota, Minneapolis MN 55455.

In order to examine the physiological and behavioral role of D1 dopaminoceptive neurons, transgenic mice which express an intracellular form of cholera toxin (CT) from the promoter for the human D1A dopamine receptor were studied. This promoter was previously shown to target lacZ reporter expression to subsets of D1 receptor-positive CNS regions in mice. RT-PCR analysis of brain mRNA showed expression of the D1CT transgene in affected D1CT mice. In the only fertile expressing lineage, combined D1CT *in situ* hybridization and D1 receptor immunocytochemistry showed D1CT expression was restricted to four D1 receptor-positive areas — somatosensory, piriform and entorhinal cortex, and intercalated nucleus of the amygdala.

Ethological monitoring of these D1CT mice showed the presence of abnormally long durations of typical behaviors, as well as extreme stereotypic locomotion, leaping and gnawing. Also, D1CT mice exhibited repetitive biting while grooming other mice, often leading to the loss of entire ears and tails of cagemates. Interestingly, this behavior was seen in both genders, and resident-intruder assays of aggression showed that D1CT mice were less, not more, aggressive than non-transgenic controls. This suggests the biting may be compulsive.

This study suggests that amygdalocortical D1 neurons are involved in the etiology or expression of repetitive and compulsive behavior. This use of a dopaminergic neuromodulatory transgene to model a psychomotor abnormality illustrates the potential of this "psychoengineering" approach as a way to both study behavior and potentially treat behavioral disorders.

TARGETING *Hdh* TO MODEL HUNTINGTON'S DISEASE IN THE MOUSE

J.K. White[1], T. Calzonetti[1], W. Auerbach[2], M.P. Duyao[1], A.B. Auerbach[2], A. Ryan[1], V. Vrbanacs[1], J-P. Vonsattel[3], J.F. Gusella[1], A.L. Joyner[2] and M.E. MacDonald[1]*. [1]Molecular Neurogenetics Unit, [3]Laboratory of Molecular Neuropathology, Massachusetts General Hospital East, Charlestown MA 02129, [2]Developmental Genetics Program, Skirball Institute for Biomolecular Medicine, N.Y.U. Medical Center, New York, NY 10016.

The clinical symptoms of Huntington's disease, a triad of motor, behavioral and cognitive abnormalities, stem from the progressive and graded loss of neurons in the basal ganglia triggered by an unstable, expanded CAG trinucleotide repeat in a novel 4p16.3 gene. The defect is autosomal dominant and appears to act at the level of huntingtin, a ~350kDa protein of unknown function which is expressed in the cytoplasm of cells in the brain and periphery. The CAG segment is translated into a stretch of polyglutamine near the N-terminus of huntingtin that exceeds 38 residues in cases of HD. To explore the defect's mode of action and to investigate huntingtin's function we are using ES cell technology to generate mice with targeted mutations in the mouse HD homologue, *Hdh*. First, mice in which *Hdh* was inactivated were generated. Homozygosity for *Hdh* inactivation results in lethality at embryonic day 7.5. This is prior to emergence of the nervous system and indicates a critical role for huntingtin early in normal development. This role is currently being addressed by generating chimeric embryos through aggregation of wild type embryos with ES cells homozygous for *Hdh* inactivation. Observations from these "knock-out" animals do not support a dominant negative mode of action in HD. Thus, a dominant gain of function that confers a novel property on huntingtin without eliminating its own activity is likely. To test this hypothesis, homologous recombination has been used to introduced expanded CAG repeat arrays into the endogenous *Hdh* gene in ES cells with the expectation that production of the mutant isoform of huntingtin with an extended N-terminal polyglutamine segment may accurately model the disorder. This work was funded by grants from the HDSA, HDF and NIH NS32765.

PREPARATION AND BEHAVIORAL STUDIES OF TRANSGENIC MICE WITH CALRETININ UNDER THE CONTROL OF A TALPHA-TUBULIN-1 PROMOTER.

I. Kuznicki, K. R. Isaacs*, S. Okabe, T. L. Sills, J. N. Crawley and D. M. Jacobowitz, NIMH, IRP, LCS, Bethesda, MD, 20892

A construct containing calretinin (CR) cDNA under the control of three tandem repeats of Talpha-1 tubulin promotor (Gloster et al., J. Neurosci, 4:7319,1994) was made to over-express CR in CNS neurons during development. Transgenic mice lines were produced by injecting this DNA fragment into the pronuclei of fertilized one-cell eggs from F1 hybrids of C57BL/6 and C3H mice. Six offspring were identified by PCR analysis of genomic DNA to be transgenic (4 males and 2 females). An F1 generation was created by mating transgenic mice with normal C57BL/6xC3H mice. In dark period open field tests used to evaluate locomotor activity, adult transgenic mice traveled a significantly greater total distance and made a significantly higher number of movements over the 60 min testing period as compared to littermate controls. Male transgenics also had a longer latency to groom when placed in the open field as compared to male controls. This change in behavior suggests that there may be a disruption in dopaminergic functioning due to an over-expression of CR during development.

LONGITUDINAL CHARACTERIZATION OF MOTOR DISEASE IN INTERLEUKIN-3 (IL-3) TRANSGENIC MICE.

R. J. Ralph*[1], F. Dellu, A.J. Roberts, C-S. Chiang, I. L. Campbell and L. H. Gold. [1]Department of Neurosciences, University of California, San Diego and Department of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Transgenic mice with chronic CNS and astrocyte specific expression of low levels of a macrophage/microglia activation cytokine, IL-3, exhibit a phenotypic motor disorder with features (i.e., gait abnormality, tremor, ataxia, quadriplegia) similar to those observed in human inflammatory demyelinating diseases (J. Clin. Invest., 1996, 97: 1512-1524). In symptomatic mice, white matter lesions in cerebellum and brainstem are present showing extensive primary demyelination and remyelination. The onset and development of motor impairment in IL-3 transgenic mice were characterized starting at 8 weeks of age, twice per week on a forward-rotating rota-rod apparatus and once every two weeks under a forward/reverse-oscillating condition. Abnormal motor behaviors were also noted. Mild motor impairment in transgenic mice was observed after 4.5 months of age in the forward-rotating condition, whereas the forward/reverse condition revealed group differences at the start of testing. The progression of rota-rod impairment will be followed until all transgenic subjects manifest significant deficits. This transgenic mouse may serve as a valuable model for investigating potential therapeutic agents to treat the pathological manifestations of demyelinating diseases. For example, 4-aminopyridine (4-AP), a potassium channel blocking drug that prolongs the duration of action potentials, has been reported to improve symptoms in patients with multiple sclerosis. While 4-AP (1, 3 mg/kg, IP) produced a dose-related impairment in rota-rod performance in control animals, the effects of 4-AP on performance in IL-3 transgenic mice remain to be determined. These studies are aimed at understanding the pathogenic effects of cytokines in the CNS, and their role in neurological disease. Supported by P.H.S. grants MH50426 and MH47680.

TRANSGENIC MICE FOR INTERLEUKIN-3 RESULT IN BRAIN AND SPINAL CORD NEURONAL DEGENERATION. C. Chavany⊕, C. Vicario-Abejón#, G. Miller∞, P. Rajan#*, R.D.G. McKay# and M. Jendoubi.⊕
⊕NEI, Lab. of Immunology, Genetics & Molecular Immunology section; #NINDS, Lab. of Molecular Biology; ∞NCRR, VRP, Lab. Sciences Section, Pathology unit, National Institute of Health, Bethesda MD 20892, USA.

Interleukin-3 (IL-3) is a growth factor for a variety of hematopoietic progenitor cells. Recently, it has been shown that IL-3 was expressed by murine neuronal cells in the central nervous system (CNS) and acted as a neurotrophic factor for cholinergic neurons *in vivo* and *in vitro*. These facts suggest that IL-3 plays an important role in the CNS. In order to examine the function of IL-3 in the CNS, we developped a model of transgenic mice overexpressing the mouse IL-3 cDNA under the control of a CMV promoter. RT-PCR analysis of mRNA from various tissues prepared from transgenic mice showed the presence of the IL-3 transgene in liver, kidney, heart, spleen and brain but it was not detectable in control mice tissues. At the age of 8-9 month, IL-3 transgenic mice showed severe neurological symptoms characterized by progressive paralysis of hindlimbs. Histopathological analysis revealed a degeneration of brainstem and spinal cord neurons in most transgenic animals. Moreover, immunohistochemical analysis of brain sections showed a marked decrease of MAP-2, a marker of neuronal dendritic processes in the CA1 layer of hippocampus. To examine the mechanism underlying this neurodegenerative process, we analyzed by western blot protein extracts from IL-3 transgene and control brains. A dramatic increase in the levels of cyclin B1and P53 was only observed in IL-3 transgenic mice. These results suggest a putative role of IL-3 in cellular cycle deregulation.

TRANSFECTION OF NEURONES *IN VIVO* AND *IN VITRO* WITH HSP70I USING AN ADENOVIRAL VECTOR. T.C. Harding*, B.J. Geddes, D. S.Hughes, and J.B. Uney. Dept. of Medicine Laboratories, Univ. of Bristol, Bristol UK, BS2 8HW.

Studies have shown that adenoviral (Ad) vectors can be used to target and infect discrete populations of neuronal cells *in vivo* and express reporter genes for up to 3-6 months. Furthermore, *in vivo* studies have shown that primary neuronal cultures can be transfected with one hundred per cent efficiency. We have therefore chosen to use Ad vectors to study the function(s) and neuroprotective effects of hsp70i. Heat shock proteins are induced rapidly in the mammalian brain following exposure to excitotoxins and ischaemia, and evidence suggests that they may play a role in enhancing neuronal survival during and after stress. The induction of a heat shock response has also been shown to prevent neuronal cells destined to undergo apoptosis from dying and it has been suggested that hsp70i or hsp90 may be involved in modulating this process.

We have made a replication defective Ad hsp70i construct and investigated its ability to: (i) protect primary neuronal cell cultures from various stressors; (ii) reverse apoptotic induced cell death. Studies have also been conducted *in vivo* with an Ad -beta-gal construct and the Ad-hsp70i construct. Prior to assessing the neuroprotective effects of the Ad-hsp70i construct *in vivo* we have also completed studies which characterised the immune response elicited in the CNS following the sterotaxic injection of Ad vectors.
This work was supported by grants from the Wellcome Trust and Medical Research Council of the UK.

648.15

TARGETED EXPRESSION OF HEAT SHOCK PROTEIN 70i IN HIPPOCAMPAL CA1 AND CA2 NEURONS D.S.Hughes, B.J.Geddes, T.C.Harding and J.B.Uney spon: Brain Research Association. Department of Medicine Laboratories, University of Bristol, Bristol, UK.

Cells respond to a sub-lethal heat shock and other traumas by exhibiting an inhibition of normal cellular transcription and translation and an induction of a set of genes encoding heat shock proteins (hsps) which play important roles in cellular repair and protective mechanisms. Evidence from several studies has suggested that the induction of hsp70i plays a role in neuronal survival during and after stress. In the hippocampus, cells in the dentate gyrus and CA3 pyramidal neurons show increases in hsp70i following an ischemic insult and survive, while vulnerable CA1 neurons show minimal accumulation of hsp70i. Transgenic mice overexpressing the human hsp70i under the control of the human LMO-1 promoter (previously been shown to direct expression of reporter genes to post-mitotic neurons in the CA1 and CA2 regions of the hippocampus) were produced and their response to cellular injury examined. Presence of the human transgene in CA1 and CA2 regions was determined by RT-PCR analysis using primers which distinguish between human and mouse hsp70i, and immunohistochemical analysis. Western blotting was also employed to show constitutive expression of hsp70i in hippocampus CA1 and CA2 neurons. Using primary neuronal cultures derived from CA1 and CA2 neurons, cells were exposed to glutamate agonists, free-radical generators and hypoxia at levels which were toxic to 50% of control cells. CA1 and CA2 derived neurons showed significant increases in the level of survival when compared to non-transgenic controls. Glutamate agonists have also been stereotaxically injected into the hippocampus of transgenic and control animals, and the excitotoxin-induced damage to the CA1 and CA2 regions compared.

PROGRAMMED CELL DEATH OF OLIGODENDROCYTES IN C-MYC TRANSGENIC MICE. N.A. Jensen and Mark J. West*. Depts. of Medical Biochemistry and Neurobiology, Univ. of Aarhus, 8000 Aarhus, C. Denmark

Cell loss-related decline in central nervous system (CNS) functions may be mediated by the misexpression of dominant regulatory genes. Numerous *in vitro* studies have shown that the forced expression of the transcription factor, c-myc, under growth limiting conditions may trigger programmed cell death. However, little is known about the potential of c-myc to trigger pathological cell loss in the intact CNS. We have taken a transgenic approach to specifically misexpress a human c-myc locus in myelin forming glia. Transgenic mice were generated that contained an activated c-myc gene under transcriptional control of the myelin basic protein (MBP) promotor. The MBP/c-myc transgenic mice developed severe action tremors and tonic seizures that correlated with the lack of central myelin.TUNEL staining of CNS sections from transgenic mice showed degenerating nuclei mainly in regions that corresponded to white matter in normal animals and ultrastructural examination revealed the presence of rod-shaped microglia containing myelin debris. The bulk of oligodendrocyte death in the transgenic mice occurred during the second and third post-natal weeks, when threshold levels of the transgene are most likely encountered. These data show that the different oligodendrocytes are highly sensitive to aberrant levels of c-myc *in vivo* and that misexpression of c-myc could play a role in myelin-degenerative disorders. This transgenic model should serve as a valuable preparation for studying various structural and molecular aspects of the programmed cell death of myelin-froming cells in the CNS.

REDUCED NEOCORTICAL DENDRITIC BRANCHING IN TRANSGENIC MICE OVEREXPRESSING HUMAN ACETYL-CHOLINESTERASE. **R.F. Mervis[1], L. Coudsi[1] , R. Dvorak[1] ,G. Glaser[1,2], R. Beeri[3] and H. Soreq[3] * [1]NeuroMetrix Research, Inc., Columbus, OH 43212; [2]Capital University, Columbus, OH 43209; [3]Dept. Biological Chemistry, Hebrew University, Jerusalem, 91904 Israel**

Alzheimer's disease (AD) is characterized by impaired cognition and a dysfunctional cholinergic system: there is an imbalance with reduced levels of ACh and a relative excess of AChE. Development of valid animal models of AD is essential for gaining greater understanding of the nature of the disorder as well as for development of drug treatment strategies. Transgenic mice were therefore created that overexpress human AChE in brain neurons (Beeri et al, 1995). Previously, it had been reported that 4 mon-old transgenics had impaired spatial learning and memory (Beeri et al, 1995). To ascertain possible neuroanatomical correlates of AChE-overexpression, quantitative assessment of dendritic branching of Golgi-impregnated cortical neurons from transgenics and from age-matched controls was carried out. Using coded slides, the basilar tree of randomly-selected layer V pyramids (at least five from each subject) from the fronto-parietal cortex of 7-mon-old mice were evaluated. Sholl analysis revealed that the extent of the dendritic domain of neurons from the transgenics were significantly smaller than that of the controls. Preliminary studies with a smaller number of 5 week-old transgenics and controls mice suggest that dendritic branching in these younger transgenics is also compromised. These findings suggest that transgenic mice overexpressing human AChE have diminished cortical circuitry, changes which could be attributed to the hypocholinergic environment. The results lend support to the use of these transgenic mice as a viable mammalian model of Alzheimer's disease. (Support provided by USAMRDC grant 17-94-C-4031 [to H.S.]).

PURKINJE CELL MIGRATION DISORDER IN ATF-2 KNOCKOUT MOUSE CEREBELLUM. B. Kosaras*, A. M. Reimold and R. L. Sidman. Div. of Neurogenetics, NERPRC, Harvard Medical School, Southborough, MA 01772.

Activating transcription factor-2 (ATF-2) is a basic zipper transcription factor that binds to the widely distributed cAMP response element. Highest expression is in the brain. ATF-2 knockout (ko) mice show reduced body size, and skeletal and neurological abnormalities (Nature 1996 379:262-265). We have now examined serial sagittal Vibratome sections immunostained with anti-Calbindin-D28K (Sigma) and thick Epon sections stained with alkaline toluidine blue. Purkinje cell number and molecular layer height were reduced focally in adult ko mice, most severely in the posterior vermis. Purkinje cell axon concentrations were irregularly reduced in the cerebellar white matter compared to their uniform high density in the controls. Strongly immunopositive boutons enveloped the cell bodies of deep nuclear neurons in the controls, but were more sparse in the ko specimens. Many (2-13/section) Purkinje cells, identified by shape, size and calbindin staining, had their cell bodies in the granular layer; some extended a thick primary dendrite outward that branched further upon entering the molecular layer. Some Purkinje somas were displaced into the molecular layer. Many ectopic Purkinje cells were located in clusters and singly in the white matter of the cerebellum close to the deep nuclei or in the white matter of the folia. Dendrites of some of these white matter cells were highly branched in the sagittal plane. Several calbindin-positive cells without stained branches were identified within the deep nuclei of the ko mice. Only rare ectopic cells were seen in any location in control specimens. The dramatic ectopia, particularly the positioning of Purkinje cells in the deeper regions, indicates that ATF-2 affects development of the cerebellum during the prenatal phase of Purkinje cell migration.

ELECTROPHYSIOLOGICAL PROPERTIES OF PERIPHERAL NERVES FROM MICE EXPRESSING A NEUROFILAMENT-β-GALACTOSIDASE FUSION PROTEIN. J. Kriz*, J.A. Falchetto, J. Eyer, A. Peterson and A.L. Padjen, Department of Pharmacology & Therapeutics and Department of Neurobiology and Neurosurgery at Royal Victoria Hospital, McGill University, Montreal, QC, Canada

The purpose of this study was to examine physiological properties of myelinated axons with radically different morphology. Peripheral nerves of transgenic mice, in which a fusion protein gene was added to the NF-H gene resulted in myelinated fibres with smaller axon diameter relative to myelin sheet thickness (line A44, Eyer & Peterson, 1995).

Compound action potentials (CAP) were measured on isolated sciatic nerves *in vitro* using either suction electrodes or sucrose gap technique. Transgenic animals showed several deficits in physiological properties of low threshold myelinated fibres: conduction velocity (CV) of A44 fibers was 50% slower than control (14 ± 2 m/s vs. 27 ± 3 m/s; $p < 0.01$; $n = 12$; 22°C), CAP amplitude of transgenic mice was 30 - 50% of control animals; absolute refractory period was 50% longer. Similar results were obtained by intra-axonal recording from large myelinated axons. Post-tetanic hyperpolarization (presumably result of electrogenic pump activation) had 50% smaller rate in fibers of A44 mice.

These results suggest that in addition to reduction in CV, explainable by morphological changes (thinner axons, thicker myelin), line A44 mice may possibly have dysfunctional Na^+ channels. What remains to be explained is an apparent normal behavior of these animals in spite of profound changes in physiology of peripheral (and presumably central) myelinated axons.

AGE-DEPENDENT SPATIAL MEMORY DEFICITS IN TRANSGENIC MICE EXPRESSING THE HUMAN MID-SIZED NEUROFILAMENT GENE. Y. Zhou, V. Haroutunian, G. Elder, C. Li, P.J. Knott*, and R.. Lazzarini Dept. of Psychiatry and Brookdale Center for Molecular Biology, Mount Sinai School of Medicine, New York, NY 10029.

Previous studies have revealed that the transgenic mouse line expressing the human neurofilament-mid-sized (NF-M) gene evidences age-dependent and cell-specific pathological neurofibrillary accumulation in the central nerve system. We investigated the learning and memory processes of NF-M transgenic mice (Ns=8-11) at three, eight, and fourteen months of age in a modified Morris Water Maze using a series of tasks including those primarily related to reference memory (i.e., spatial learning, reversal learning and probe trials) and to working memory (i.e., matching to sample tasks with or without delays). At three months of age, NF-M transgenic mice were indistinguishable from age and litter matched non-transgenic wild-type controls on any of the tests of reference and working memory. At eight and fourteen months of age, however, the NF-M transgenic mice exhibited significantly poorer performance than the age and litter matched wild-type control mice on both reference and working memory tasks ($ps<0.05$). Immunohistological study of the brains of the eight months old NF-M transgenic mice revealed spherical and tangle-like neurofilamentous accumulation in their cerebral cortices. These results suggest that NF-M transgenic mice express both age-related histopathological changes and age-dependent learning and memory deficits. Whether NF-M transgenic mice exhibit even more severe behavioral impairments when they become aged is currently under study. Support AG05138 to V.H.

TARGETING HUMAN CuZnSOD GENE EXPRESSION IN MOUSE CENTRAL NERVOUS SYSTEM. Y. Li*, E. Carlson, T.-T. Huang, S. Chen, J.-C. Copin, R. Luche, C.J. Epstein and P.H. Chan. Departments of Neurosurgery, Neurology, and Pediatrics, University of California, San Francisco CA 94143

CuZn superoxide dismutase (SOD-1) is an important enzyme for the detoxification of oxygen-derived free radicals, especially in central nervous system (CNS), that are often associated with acute brain injuries and chronic neurodegeneration. Mutations in the*SOD-1* gene have been found in about 20% of familial amyotrophic lateral sclerosis (FALS) cases. A dominant, "gain of adverse function" of FALS-associated *SOD-1* mutations resulting in motor neuron degeneration is supported by FALS *SOD-1* transgenic mouse models. In a mouse model of focal cerebral ischemia and reperfusion, we have documented that there is an inverse correlation between SOD-1 activity and brain infarction and neurological deficits. Our hypothesis is that the increased SOD-1 activity may prevent the formation of the strong oxidant peroxynitrite ($ONOO^-$) from superoxide (O_2^-) and nitric oxide ($NO\cdot$) under ischemic and traumatic conditions. It has been demonstrated that under those conditions excessive activation of NMDA receptors cause abnormal Ca^{++} influx followed by increased O_2^- production and aggravates neuronal injury. To elucidate the neuronal specificity and protective mechanism of SOD-1 in brain injury, we have made a chimeric human *SOD-1* gene for targeted expression only in neurons. This was obtained by using a neuronal specific enolase (NSE) promoter and enhancer to drive *SOD-1* gene. The construct was tested in cultured neurons (GT1 line). Thus far, we have generated a mouse line containing the NSE/*SOD-1* transgene. By gel electrophoresis and SOD activity staining, human and mouse CuZnSOD heterodimer are detected in CNS but not in other tissues in five week old progeny from this founder mouse. Human CuZnSOD homodimer can also be detected in spinal cord, brainstem and cerebrum, indicating higher transgene expression in these regions. The NSE/*SOD-1* transgenic mice will be a useful tool for studying the role of O_2^- in acute brain injuries and neurodegeneration involving CNS neurons. EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS—LIMBIC SEIZURES II

649.1

DELAYED SEIZURE-INDUCED DAMAGE TO THE HIPPOCAMPUS IS PREVENTED BY MODULATION OF THE GABAERGIC SYSTEM. J. Jolkkonen*[1,2], T. Halonen[1], E. Jolkkonen[2], J. Nissinen[1] and A. Pitkänen[1]. A.I.Virtanen Institute[1] and Department of Neurology[2], University of Kuopio, 70211 Kuopio, Finland.

Acute cerebral insults such as status epilepticus, head trauma, and stroke induce damage to selective neuronal populations in the hippocampus. Somatostatin immunoreactive (SOM-ir) neurons in the dentate hilus are one of the most vulnerable cell types. Hilar SOM-ir neurons are innervated by glutamatergic granule cells which in turn are under a powerful control of subcortical afferent pathways via inhibitory interneurons. To investigate, whether the loss of SOM-ir neurons is regulated by the particular subcortical afferent pathway to the hippocampus, we selectively lesioned cholinergic (192-IgG-saporin, 4.1 μg/10 μl i.c.v.), serotonergic (5,7-DHT, 15 μg intracerebrally) or noradrenergic (DSP-4, 50 mg/kg i.p.) fibers 2 days after kainic acid induced seizures (9 mg/kg, i.p.). The effect of increased GABAergic activity on neuronal damage was studied by chronically infusing γ-vinyl GABA (GVG, 75 mg/kg/day via osmotic minipump), a drug that produces a several-fold increase in the brain GABA levels. Kainate-induced seizures resulted in a significant loss of SOM-ir neurons in the dentate gyrus (63% of hilar SOM-ir neurons remaining, $p<0.01$). The augmentation of hippocampal GABAergic inhibition by GVG prevented the delayed seizure-induced damage to hilar SOM-ir neurons. In contrast, selective lesions of the cholinergic, serotonergic, or noradrenergic pathways to the hippocampus did not affect the seizure-induced loss of SOM-ir neurons. Therefore, it is the intrahippocampal GABAergic circuitries, rather than the selective subcortical pathways, that are critical for neuroprotection after seizures. Enhanced GABAergic inhibition prevented damage to hilar SOM-ir neurons, even when started two days after status epilepticus, thus GABAergic agents may provide an alternative treatment for delayed neuronal damage caused by cerebral insults.

649.2

SEIZURE SUPPRESSION IN KINDLING EPILEPSY BY GRAFTS OF FETAL GABAERGIC NEURONS IN RAT SUBSTANTIA NIGRA. W. Löscher[1], U. Ebert[1]*, H. Lehmann[1], C. Rosenthal[2], and G. Nikkhah[2], Department of Pharmacology, Toxicology and Pharmacy, School of Veterinary Medicine, and [2]Neurosurgical Clinic, Nordstadt Hospital, D-30559 Hannover, Germany.

Compared with studies on models of neurodegenerative diseases, considerably less work has been done with neural grafts in experimental epilepsy. The potential value of this approach, however, is already shown by evidence that noradrenergic grafts implanted bilaterally into the hippocampus or amygdala-piriform cortex can suppress seizure development in the kindling model of temporal lobe epilepsy. We have previously demonstrated that amygdala-kindling results in a significant decrease of GABA and its synthesizing enzyme glutamate decarboxylase in substantia nigra (SN), i.e. a region thought to be critically involved in seizure propagation in various models of epilepsy. Thus, transplantation of fetal GABAergic neurons into SN might be an effective means of blocking seizure generalization in kindling epilepsy and probably also other types of epilepsy. In order to test this hypothesis, 3 groups of female Wistar rats ($n = 10$ per group) were kindled by electrical stimulation via a bipolar electrode in the basolateral amygdala. After all rats were fully kindled, one group was implanted with GABA-rich cells prepared from the striatal eminence of Wistar rat fetuses at embryonic day 14. The striatal neurons were bilaterally microinjected at various sites over the anterior-posterior axis of the SN, aimed at the pars reticulata. The second group received microinjections of spinal cord cell preparations, while the third group received microinjections of medium. In all rats, the threshold for focal discharges (afterdischarge threshold, ADT) as well as afterdischarge duration and severity and duration of seizures occurring at ADT current were determined once weekly before and after implantation. Eleven weeks following implantation, the rats were sacrificed, and location and integration of grafts were examined by immunohistological methods. Rats with GABAergic grafts in SN exhibited a significant reduction in seizure severity compared to preimplantation values, while no such alteration was seen in the other groups. However, the seizure-suppressing effect of GABAergic grafts was not permanent, but slowly disappeared over the weeks after transplantation.

649.3

LOSS OF ENTORHINAL CORTEX NEURONS AFTER FOCAL MICRO-INJECTION OF γ-ACETYLENIC GABA IN THE RAT. H.-Q. Wu* and R. Schwarcz. Maryland Psych. Res. Center, Baltimore, Maryland 21228.

Neuronal loss in layer III of the entorhinal cortex (EC) occurs in patients with temporal lobe epilepsy. This lesion can be reproduced in rats by focal injection of the indirect excitotoxin aminooxyacetic acid into the EC (Neurosci. Lett. 147:185,1992). We now report that γ-acetylenic GABA (GAG), a more potent indirect excitotoxin, also causes preferential neuronal loss of layer III neurons in the rat EC. GAG was stereotaxically injected into the EC at a dose of 4 μg/0.8 μl/10 min. As assessed by both Nissl and silver staining two days later, GAG produced a lesion which was detectable preferentially in layer III of the EC but did not appear to affect the hilar region of the ventral hippocampus. This lesion was completely prevented by MK-801 (4 mg/kg, given i.p. 10 min before and 12 hrs after GAG treatment). Examination of the temporal evolution of the EC lesion following the focal injection of 4 μg GAG revealed neuronal loss at and after but not before 24 hrs. A modest increase in the dose of GAG (to 5 μg) resulted in far more extensive neuronal loss in the EC, as well as in the hilus and areas CA1 and CA3 of the ipsilateral hippocampus, and occasionally also in EC layer III and hippocampal structures of the contralateral hemisphere (3/13). Rats treated with 4 μg of GAG were also inspected visually and monitored continuously for 48 hrs electroencephalographically. Behavioral changes indicative of seizure activity accompanied EEG seizures following a latency period of 150 min. These changes were seen in all animals and lasted 3 hrs. EEG abnormalities lasted over 24 hrs. Stage 5 convulsions with spasms and salivation were also observed (3/13). These data confirm the vulnerability of layer III of the EC to excitotoxic and convulsant insults and suggest that intra-entorhinal GAG injections provide a valuable model for the study of seizure-related neuronal degeneration.

CHEMICAL KINDLING IS ASSOCIATED WITH A SELECTIVE DECREASE IN HIPPOCAMPAL ACETYLCHOLINE RELEASE IN RATS. M.Serra*, L. Dazzi, F.M. Chessa, E. Cagetti and G. Biggio. Dept. Experimental Biology, University of Cagliari, 09123 Cagliari, Italy.

The function of septohippocampal cholinergic neurons in pentylenetetrazole (PTZ)-induced kindling was investigated with the microdialysis technique in freely moving rats. Basal extracellular concentration of acetylcholine (ACh) in the hippocampus of rats chronically treated with PTZ (kindled animals) was significantly reduced (- 50%; $P<0.01$) relative to that of vehicle-treated rats. The release of ACh was more sensitive to the effect of a challenge injection of PTZ (20 mg/kg, i.p.) in kindled rats than in rats treated with vehicle. The anticonvulsant drug abecarnil (1 mg/kg, i.p.) administered before each PTZ injection neither antagonized the decrease in basal ACh release nor prevented the development of kindling. In contrast, abecarnil prevented the chronic PTZ-induced increase in the sensitivity of ACh release to a challenge dose of PTZ. Kindling-induced reduction on basal ACh release in the hippocampus was significant (-25%) as early as at 4 weeks after the beginning of the treatment, while were not longer present at 4 weeks after the last PTZ injection. The effect of kindling on ACh release is specific for the hippocampus, infact basal release in the prefrontal cortex and striatum of kindled animals was unchanged compared to vehicle-treated rats. Accordingly, binding of [^{3}H]QNB was significantly increased in the hippocampus (+25%) but not in the cerebral cortex and in the striatum. These results indicate that hippocampal ACh function is reduced in PTZ kindled rats. Moreover, although the mechanism of kindling development does not primaly involve a failure of $GABA_A$ mediated transmission, a GABAergic mechanism seems to play a functional role in the modulation of intrinsic properties of septohippocampal cholinergic neurons as indicated by the lack of supersensitivity to a challenge dose of PTZ in animals chronically treated with abecarnil and PTZ .

A SILVER STUDY OF NEURONAL DAMAGE AFTER THE INJECTION OF AMINOOXYACETIC ACID INTO THE RAT ENTORHINAL CORTEX. F. Du* and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, Maryland 21228.

The injection of 75 μg aminooxyacetic acid (AOAA; Neurosci. Lett., 147: 185, 1992) into the rat entorhinal cortex (EC) causes acute behavioral seizures and neurodegeneration in layer III of the medial EC and in the hippocampus. Neuronal death in these regions was previously observed by Nissl stain and by the *in situ* DNA nick end labeling technique, mainly beyond 48 hrs following an AOAA injection. To test whether neuronal damage occurs at earlier stages as well, we have now used a sensitive silver method (Gallyas et al., Acta Neuropathol., 79:620, 1990) to study neurodegeneration at various timepoints following AOAA treatment. After 3 hrs, numerous silver-stained neurons were readily detectable in the hippocampus ipsilateral to the injection. These neurons were seen especially in the transition zone between the subiculum proper and the CA1 subfield of the hippocampus. A few silver-stained neurons were also frequently noticed in the presubiculum, perirhinal cortex and the lateral amygdaloid nuclei. This distribution pattern of silver-stained neurons remained similar 6 and 12 hrs after the AOAA injection, but at these timepoints many silver-stained neurons were also observed in layer III of the medial EC. Silver-stained neurons apparently decreased in number after 24 hrs and mostly disappeared by 5 days after the AOAA injection. Our results indicate that a subpopulation of hippocampal neurons is damaged, possibly by intensive seizure activity, as early as 3 hrs following an intra-entorhinal AOAA injection. Our data also confirm that the silver method used here is of value in the study of the early neurodegeneration in experimental seizure models.

SEIZURE PROPAGATION PATTERN IN RATS STIMULATED EVERY 5 MINUTES IN VENTRAL HIPPOCAMPUS. O.A. Timofeeva* and G.M. Peterson. Dept Anat & Cell Biology, East Carolina Univ Sch Med, Greenville, NC 27858.

The rate and pattern of seizure-spread from an epileptic focus to other structures is poorly understood. The present study examined the seizure propagation pattern from left ventral hippocampus (lVH) to the contralateral VH and dorsal hippocampus (DH) on either side. Six adult rats with electrodes implanted bilaterally in DH and VH were stimulated in lVH every 5 min at after-discharge (AD) threshold (1 s, 60 Hz) over 6 hr. This protocol provides an opportunity for examining AD propagation in response to weak stimulation applied at different levels of seizure susceptibility. Stimulation produced periodical development of ictal events of different severity being expressed in the number of structures involved and in the duration of AD. ① Seizure activity evoked in lVH propagated first to rVH and then to DH. This order of involvement (lVH→rVH→DH) was constant in all rats and was consistently repeated in each animal over the course of stimulation. The involvement of rVH occurred either simultaneously with lVH or after a delay of 6-10 s. The involvement of DH occurred either simultaneously with rVH or after a delay of 3-40 s. The involvement of l and rDH was simultaneous or with a time difference of 1-4 s. In some animals lDH was involved before rDH, in others rDH was first. Seizure activity spread to DH only after involvement of both VH. The difference in the time of involvement of contralateral VH (0-10 s) and both DH (0-40 s) may reflect the intensity of the post-seizure inhibition (PSI) which develops after each ictal event. ② PSI altered the time of involvement of different regions in seizure but not the order of involvement. No direct relationship was found between AD duration in stimulated lVH and the involvement of contralateral VH or between AD duration in both VH and involvement of DH. ③ These data suggest that inhibitory mechanisms which terminate seizure and those which prevent its propagation to other regions are different. *Supported by NINDS/Fogarty (F05 TW/NS05128)*

DEVELOPMENT OF SPONTANEOUS RECURRENT SEIZURES AFTER ELECTRICAL STIMULATION OF AMYGDALA. T. Halonen*[1], J. Nissinen[1], E. Koivisto[2] and A. Pitkänen[1]. [1]A. I. Virtanen Institute and [2]Department of Neurology, University of Kuopio, P.O. Box 1627, FIN-70211 Kuopio, Finland.

The hallmark of human epilepsy is the appearance of spontaneous epileptic seizures. We undertook a project that aims at developing a focal epilepsy model that mimics different aspects of the human temporal lobe epilepsy, including the expression of electrographic and behavioral spontaneous seizures. Two weeks after the implantation of electrodes in 24 male Sprague-Dawley rats (320-390 g), a 100-ms train of 1-ms, 60 Hz of bipolar pulses at 400 μA intensity (peak to peak) was administered every 0.5 s for 20-30 min to the left amygdala to generate self-sustained status epilepticus. The stimulated rats (N=16) were monitored 24 h/day with combined EEG and video recording system every other day for 12 weeks. At 12-weeks follow-up point, spontaneous epileptic seizures were detected in 14 of the 16 animals (88%). Most (57%) of the seizures occured during the daytime. The severity of behavioral seizures varied from score 1 (eye blinking, head nodding) to score 5 (rearing and falling). Non-convulsive electrographic seizures were also detected. The number of seizures varied between the animals from 0 to 62 seizures/day. In animals with highest seizure frequency, we observed a clear progression of seizure frequency over a first 8-weeks follow-up. Once the highest seizure frequency was attained, the appearance of seizures has remained stable. Our results show that the focal pulsed-train stimulation of the amygdala initiates a cascade of events which leads to the development of spontaneous epileptic seizures in rats. This model provides a new tool to investigate the pathogenesis of temporal lobe epilepsy or the effects of new antiepileptic agents on epileptogenesis and spontaneous seizures. (Supported by Vaajasalo Foundation.)

649.8

CHARACTERIZATION OF THE DEFENSIVE NATURE OF EMOTIONAL BEHAVIOR IN LONG-TERM AMYGDALA KINDLED RATS. L.E. Kalynchuk*, J.P.J. Pinel, & D. Treit[1]. Dept. of Psychology, Univ. of British Columbia, Vancouver B.C., V6T 1Z4 and [1]Dept. of Psychology, Univ. of Alberta, Edmonton, Alberta, T6G 2E9.

We have previously reported that long-term amygdala kindling results in significant changes in emotional behavior in rats, such as thigmotaxia, freezing in an open field, extreme resistance to capture, and jumping from an elevated plus maze (Kalynchuk et al., in press). These behaviors model the increased emotionality often seen in human temporal lobe epileptics. However, controversy exists about whether the increased emotionality in temporal lobe epileptics is aggressive or defensive in nature. The purpose of this experiment was to address this controversy by characterizing the fundamental nature of amygdala-kindling-induced emotionality. A bipolar electrode was implanted in the basolateral amygdala of each of 26 male Long Evans rats. Then, half the rats received 99 convulsive stimulations (kindled) and half received sham stimulations (controls). One day after the last stimulation, each rat was tested as an intruder in a resident-intruder paradigm. The next day, each rat's resistance to capture from its home cage was assessed. Finally, for the next 5 consecutive days, each rat was placed into an open field for 5 min and its resistance to capture was recorded. In the resident-intruder paradigm, the kindled rats displayed significantly more defensive and less aggressive behavior than did the controls. Moreover, the kindled rats were significantly more resistant to capture from the novel open field--an effect that dissipated over subsequent exposures to the open field. There were no significant differences between the groups in resistance to capture from the home cage. These results demonstrate that the emotional behavior resulting from long-term amygdala kindling is fundamentally defensive in nature. Accordingly, the label "temporal lobe aggression" may be a misleading misnomer. (supported by NSERC grants to D.T. and J.P.J.P., and an MRC doctoral scholarship to L.E.K.)

NON-NMDA BLOCKADE BUT NOT NMDA BLOCKADE AT DEEP PREPIRIFORM CORTEX PROTECTS AGAINST HIPPOCAMPAL CELL DEATH IN STATUS EPILEPTICUS. K. Kawaguchi, T. Lowry and R.P. Simon*. Department of Neurology, University of Pittsburgh, Pittsburgh, PA 15261.

Deep prepiriform cortex (area tempestas, AT) is a brain region which modulates seizure activity through the limbic system. We have previously demonstrated that pharmacologic blockade of excitatory amino acid neurotransmission bilaterally at AT, with the competitive NMDA antagonist AP7, decreases neuronal injury during kainate induced status epilepticus, and that this effect occurs in the absence of attenuation of electrographic seizure activity (Neurosci 61:817-822, 1994). We therefore extended this observation to compare the neuroprotectant properties of equimolar concentrations (10 nmol/μl) of a non NMDA (NBQX) versus an NMDA (AP7) glutamate antagonist infused unilaterally at AT (total volume 0.5 μl). Status epilepticus was induced by intravenous kainate and quantified by the duration of high frequency, high voltage polyspike activity. After 50 minutes of status, lorazepam (6 mg/kg) was infused to stop seizures. The number of surviving CA3 neurons was then assessed 72 hours later. Surviving cells in the CA3 sector ipsilateral to that injected with NBQX at AT were significantly greater than in the contralateral saline injected side. In the animals treated with AP7 at AT, no significant differences between the AP7 injected and saline injected sides were found. These results indicate that excitatory amino acid neurotransmission at AT via non-NMDA receptors is more important than that via NMDA receptors in neuroprotection during kainate induced status epilepticus. 649.10

A ROLE FOR THE BILATERAL INVOLVEMENT OF PERIRHINAL CORTEX IN CLONIC SEIZURE EXPRESSION IN RAT. R. J. Ferland*, J. Nierenberg, J. L. Burchfiel and C. D. Applegate. Program in Neuroscience, University of Rochester School of Medicine & Dentistry, Rochester, NY 14642.

The perirhinal cortex (PRh) has been implicated in the production of late stage kindled seizures in rat. The present experiments evaluated the neural activity in the PRh region using Fos immunocytochemistry following electrical stimulation. Eight rats were implanted with chronic indwelling unipolar electrodes in the PRh and allowed to recover for one week. After recovery, rats were habituated to their environment for one week before PRh stimulation in order to eliminate non-specific Fos immunoreactivity (Fos-IR). PRh stimulation consisted of 3 trains per second of 50 ms trains of 0.2 ms square waves delivered at 400 Hz at subthreshold currents (100 μA below afterdischarge (AD) threshold). These stimulus parameters elicited stimulus-locked behaviors, without AD, consisting of rearing and bilateral forelimb clonus which were terminated upon stimulus offset in the majority of rats. Fos-IR in the ipsilateral hemisphere was dispersed throughout neocortical and subcortical structures. By contrast, Fos-IR in the contralateral hemisphere was localized exclusively in the dorsal PRh and in the frontal motor cortex. Similar ipsilateral and contralateral Fos patterns were seen in rats kindled to one stage 5 generalized clonic seizure from septal nucleus, olfactory bulb and amygdala. The above evidence suggests that the PRh is critical in producing the bilateral behaviors associated with generalized clonic seizure expression. Furthermore, administration of KCl (3.0 mM) directly into the contralateral PRh of amygdala kindled rats reverted a stage 5 seizure to a stage 3 seizure in 3 out of 4 animals. Lucifer Yellow injections into the PRh demonstrated a robust reciprocal interconnectivity with the contralateral PRh as well as an anterograde projection to the frontal motor cortex. Taken together, these data suggest a role for the bilateral involvement of PRh in clonic generalized seizure expression whether elicited from the naive or kindled state. NS20351

NEURONAL DEATH IN A CELL CULTURE MODEL OF SEIZURE ACTIVITY: PARADOXICAL EFFECTS OF BLOCKING ACTIVITY WITH ELEVATED MAGNESIUM. B. Murray* and E.J. Furshpan. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Cultured hippocampal neurons grown with agents that block excitatory synaptic transmission undergo seizure-like activity upon removal of the blockers. We have been studying the neuronal death that occurs after sustained seizure activity. Cultures of hippocampal cells, dissociated from newborn rats, were grown for 6-7 weeks with the blockers kynurenate (1 mM) and elevated Mg^{2+} (11.3 mM). Cultures were then transferred to a salt solution lacking these blockers for 2-3 h before the addition of various blocking agents. Lactate dehydrogenase (LDH) activity of the medium and the percentage of Trypan Blue-positive neurons were assessed 24 h later. The apparent LDH release was substantially greater when the seizure activity was terminated by Mg^{2+} than by other blockers, and often exceeded that induced by maximally toxic glutamate (500 μM). In contrast, the percentage of Trypan Blue-positive cell bodies was not increased. We are currently investigating whether blocking seizure activity with elevated Mg^{2+} damages neuropil. EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS—ALTERATIONS IN GLUTAMATE RECEPTORS

650.1

ULTRASTRUCTURAL LOCALIZATION OF GLU-R1 IN HUMAN TEMPORAL LOBE EPILEPSY. T. Eid[1], C. Meredith, I. Kovacs, N.C. de Lanerolle*, Neurosurgery, Yale Univ. Sch. Med., New Haven, CT. 06520,

Glutamate receptor-mediated hyperexcitation may be involved in the pathogenesis of temporal lobe epilepsy (TLE). Immunocytochemical localization of GluR1 revealed different staining patterns in the hippocampi surgically removed from patients with mass lesion related TLE (MaTLE) compared to patients with mesial temporal sclerosis (MTLE). In MaTLE, immunostaining was expressed diffusely over the dendrites in all areas of the hippocampus. By contrast, in MTLE, immunoreactivity was seen in surviving hilar neurons, and in punctate and fibrous elements near or extending from the proximal dendrites and cell bodies of hilar neurons and CA3 pyramidal cells. Ultrastructural examination of the immunoreactivity in MTLE revealed that it was contained within neuronal somata and in dendritic profiles. Many of the fibrous extensions observed by light microscopy were fine dendritic branches. Numerous boutons resembling mossy fiber terminals made asymmetric synapses often onto immunoreactive dendrites and dendritic spines, both in the hilus and CA3, and more infrequently onto hilar cell bodies. Dense immunoreactivity was often seen on the postsynaptic membrane of the synapse. Some of the mossy fiber-like terminals synapsing onto labeled dendrites had a few dense core vesicles suggesting the presence of a peptide, probably dynorphin, in these terminals. These findings suggest that the enhanced GluR1 expression in MTLE-patients may result in more effective glutamate mediated synaptic transmission through the remainder of the trisynaptic pathway in the hippocampus. Such enhanced transmission could produce the hippocampal hyperexcitability and neuronal degeneration seen in MTLE patients. [Supported by NS27081 & NS30619 from NIH]

650.2

POSTSYNAPTIC GLUTAMATE AMPA RECEPTOR IN THE FASCIA DENTATA OF HUMAN HIPPOCAMPAL EPILEPSY Z. Ying*, T. L. Babb, Y. G. Comair#, R. M. Bushey, K. Touhalisky. Depts. of Neurosciences and Neurosurgery#, The Cleveland Clinic Foundation, Cleveland, OH 44195

In human hippocampal epilepsy there is a consistent pathology of cell loss and reactive synaptic reorganization of "excitatory" mossy fibers (MF) into the inner molecular layer (ML) of the fascia dentata (FD). We hypothesized that the densities of glutamate AMPA receptor sub-unit which modulates the fast glutamate synaptic transmission would be related to the glutamate-secreting MFs. The present study examined the relationships between the altered density of postsynaptic glutamate receptor subunit GluR1 in the ML of FD, aberrant MF neoinnervation and hilar cell loss in human hippocampal epilepsy. In the hippocampi from the patients who underwent partial temporal lobectomies to control intractable epilepsy, the densities of GluR1 receptor labeled by immunocytochemistry (ICC) and amount of MF neoinnervation processed with Timms histochemistry were quantified using computer image analysis. In both sclerotic (HS) and non-sclerotic (Non-HS) hippocampi, GluR1 receptor densities in the inner and outer ML were not significantly different. Visual observation confirmed increased GluR1 immunoreactivity in the ML of HS. Because ICC staining of the receptor did not allow true quantitative densitometry of the dendritic trees due to the severe GC loss in HS, the gray value of the GluR1 immunoreactivity and the Timm's staining in the ML were corrected for the extent of GC loss determined by cell counts. Compared to the non-HS, corrected GluR1 receptor densities in the ML of HS were significant higher ($p< 0.05$). Amounts of MF synaptic reorganization in the supragranular ML correlated with normalized GluR1 receptor densities in the ML ($R^2=.88$). Hilar cell loss was found to be related to both corrected densities of MF and GluR1($P<0.05$ respectively). These results support the notion that in the human epileptic fascia dentata there are significantly increased AMPA receptors associated with aberrant MF synaptic reorganization. These pre- and post-synaptic changes are significantly related to loss of hilar neurons, which normally innervate the FD ML. Supported by NIH grant NS 31655.

MOSSY FIBER SPROUTING IS ASSOCIATED WITH INCREASED NMDAR2 IMMUNORREACTIVITY IN HUMAN AND RAT EPILEPTIC FASCIA DENTATA. J.P. Leite[1*], G.W. Mathern[2], T.L. Babb[1], J.K. Pretorius[2], P.A. Kuhlman[2], D. Mendoza[2], I. Fried[2], A.C. Sakamoto[1], J.A. Assirati[1], P.D. Adelson and W.J. Peacock[2]. [1]Ribeirão Preto School of Medicine USP, São Paulo, Brazil; [2]UCLA School of Medicine, Los Angeles, California and [3]Clevelan Clinic Foundation, Cleveland, Ohio.

Recent studies have shown abnormal reorganization of excitatory and inhibitory circuits in epileptic patients with hippocampal sclerosis (HS). Experimental studies have suggested that mossy fiber (MF) sprouting might contribute to hippocampal excitability, however, it is not known whether MF sprouting is associated with increases in NMDAR2 immunorreactivity (IR). Patients with HS (n=11) were compared with those with extrahippocampal mass lesions (n=7) and autopsy cases (n=4); and unilateral KA-injected hippocampi (n=7) were compared with contralateral saline-injected side and age matched controls (n=7). Hippocampi were studied for neo-Timm's MF sprouting and NMDAR2 IR and staining was quantified using computer image analysis. Compared with autopsies and patients with mass lesions, HS patients had greater inner molecular layer (IML) neo-Timm's (p=0.0018) and NMDAR2 staining (p=0.0063). KA-injected hippocampi also showed greater IML MF sprouting and NMDAR2 IR when compared to controls and saline-injected hippocampi (p=0.0001). In addition, IML sprouting positively correlated with greater IML NMDAR2 staining in human and experimental rat groups (p<0.0099). These results indicate that increased NMDAR2 staining is toppographically related to the aberrant MF sprouting in the epileptic hippocampus, however, further studies need to be performed in order to resolve the ultrastructural location of these receptors. THE RELATIONSHIP OF GLUTAMATE RECEPTOR DENSITY WITH CELL LOSS AND PAROXYSMAL DISCHARGES IN THE EPILEPTIC HUMAN DENTATE GYRUS, L.M. Masukawa*, K. Uruno, H. Wang, W. O'Connor, M. O'Connor, and P. McGonigle. The Depts. of Neurology, Pharmacology and Surgery, Univ. of Penn. Med. Sch. and The Graduate Hospital, Phila., PA 19146.

The density of NMDA and non-NMDA glutamate receptors in the dentate gyrus of epileptic patients has been reported either to be unchanged or to be increased when compared to autopsy control tissue. We have found, in surgical specimens from temporal epileptic patients, that NMDA receptor density varies over a wide range but increases as dentate granule cell loss increases in two studies using [^{3}H] MK-801 autoradiography. The increase in NMDA receptor density was greatest proximal to the cell body layer and extended throughout the molecular layer. We corrected [^{3}H] MK-801 receptor binding for differences in granule cell density. Tissue from the same specimen was also examined electrophysiologically using in vitro brain slices of the dentate gyrus. The paroxysmal discharge, a prolonged, synaptically mediated hyperexcitable response, was greater in tissue that showed an increased NMDA receptor density. We suggest that increased glutamate receptor density in dentate granule cells may contribute to hyperexcitability in epileptic patients. Supported by NIH grants NS-23077 to LMM and NS-08803 to PM.

EXPRESSION OF AMPA/KA RECEPTOR SUBUNIT mRNAs IN SURGICALLY EXCISED CORTICAL AND HIPPOCAMPAL TISSUES OF EPILEPTIC PATIENTS. E. V. Grigorenko*[1], W. Bell[2,3], C. O'Donovan[2], S. Glazier[3], T. Pons[3], D. Woodward[1] and S. Deadwyler[1]. Dept. Physiology & Pharmacology[1], Dept. Neurology[2], Dept. Neurosurgery[3], Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27157.

Abnormal gluatamatergic neurotransmission has been implicated in the pathogenesis of epilepsy. Although expression level of a-amino-3-hydroxy-5-methyl-4-isoxazole (AMPA) and kainate (KA) glutamate receptor subunits are altered in animal models of epilepsy, the overall evaluation and changes in AMPA/KA receptor subunit profiles in human tissue remain to be analyzed. We examined the expression profile of AMPA/KA receptor subunits in surgically excised human cortical and hippocampal tissues from individuals with intractable temporal lobe seizures (n=15). RT-PCR with subsequent Southern blot analysis was employed to quantitate relative changes in mRNA level. Surgically-excised nonepileptic human (2 cases) and monkey (*Macaca fasicularis*) cortex and hippocampus were pooled. All tested (GluR1-7, KA1-2) AMPA/KA receptor subunit transcripts were found to be expressed in analyzed control tissues and the expression pattern of AMPA/KA receptor in control human tissue was similar to that of monkey. Messages for GluR2>GluR1>GLuR3>GluR6 were abundant in control hippocampus, while that of GluR4 and GluR5 were also present, but in lower amounts. The GluR1 subunit mRNA level was found to decrease by 35% in hippocampus of all tested epileptic specimens while a reduction of only 28% was detected in cortical tissue. The level of Glur2 was slightly elevated in both structures, 115 % relatively to control. No noticeable change in GluR3 expression was found in cortex while in hippocampus the level of GluR3 transcript was diminished to 68% of control tissue. The level of KA1 transcript was found to be slightly elevated in temporal cortex, but it is significantly reduced to 65% in epileptic hippocampus. The changes in mRNA gene expression were restricted to specific neuronal populations in hippocampus which suggests conspicuous alteration for functional excitatory transmission in epileptic tissue.

PERINATAL HYPOXIA IS ASSOCIATED WITH AN ACUTE DOWNREGULATION IN GLUR2 mRNA IN HIPPOCAMPUS. C. Wang*, ED Lamperti, D Sharma, L Villa-Komaroff, and FE Jensen. Neurology, Children's Hosp., Harvard Medical School, Boston, MA 02115.

We have previously demonstrated that perinatal hypoxia in rats (postnatal day (P) 10-12) results in acute seizures and permanently decreased seizure thresholds in adulthood. The AMPA antagonist NBQX suppresses the acute and long term epileptogenic effects of perinatal hypoxia. To determine whether there is a molecular correlate to the hyperexcitable effect of hypoxia, we evaluated changes in GluR2 AMPA subunit mRNA in cortex and hippocampus from P10 rats at 10 minutes, 2 hours, 6 hours, 24 hours, and 48 hours after a brief exposure to global hypoxia (3%O_2) versus controls. Five μg of RNA was used for each tissue and 3 rats pooled at each time point and examined by northern-blot hybridization using radiolabeled GluR 2 cDNA as probe; probes prepared from NMDA receptor subunit cDNAs and from GAPDH cDNA were used as controls in subsequent hybridizations with the same blots (courtesy Boulter). At short intervals between hypoxia and sacrifice there were no significant changes in any signal, but in the hippocampus GluR2 message showed a selective, progressive, and significant ($p < 0.05$, ANOVA) decline with increasing interval, to a maximum of 50% of the level in age-matched control at 48 hours post-hypoxia. We observed an apparent slight but not statistically significant decline in GluR2 mRNA in cerebral cortex at the same interval. These observations suggest that the hypoxic treatment in our model causes a downregulation in the AMPA receptor subunit that has been implicated in controlling Ca^{++}permeability at the receptor. A downregulation of the GluR2 receptor could increase Ca^{++} influx at the receptor which could contribute to the increased neuronal excitability seen in this model. (Hearst Fdn, NS31718, NS32570)

IMMUNOCYTOCHEMICAL LOCALIZATION OF SELECTIVE GLUTAMATE RECEPTOR SUBUNITS IN KAINIC ACID TREATED RATS

Adnan H. Siddiqui*, David Vago, Eileen Lynd-Balta, Shirley A. Joseph Division of Neurosurgery & Neuroscience Grad. Prog., Univ. of Rochester Sch. of Med., Rochester NY 14642.

Kainic acid is one of the most potent excitatory glutamate analogs and has been used extensively to induce limbic seizures in the rat. Kainic acid induced status epilepticus is an immediate response which resolves in a few hours. This phenomenon is followed by the development of spontaneous recurrent seizures. Additionally, the status results in specific brain pathology highly reminiscent of human temporal lobe epilepsy, the etiology of which is unknown. Although the exact mechanisms of kainic acid induced seizures and the associated pathologies are unknown, it is believed that these effects are mediated through the family of ionotropic glutamate receptors and the associated excitotoxicity. Our previous studies on the hippocampus from temporal lobe epileptic patients suggests that in addition to the reorganization of cellular elements, the hallmark of hippocampal sclerosis, a distinct alteration of glutamate receptor morphology is also apparent. These rat studies were performed to map the precise distribution pattern of glutamate receptor subunit proteins in the hippocampal formation and associated cortices, in the kainic acid model of limbic epilepsy to elucidate the temporal transformation of glutamate receptor morphology and correlate findings with those in human epilepsy. Following the induction of status epilepticus rats were perfused at survival times ranging from 6 hours to 120 days. Rat brains were then processed with immunocytochemical techniques utilizing recently developed antisera against the AMPA receptor subunits GluR-1 and GluR-2/3, and the NMDA receptor subunit NR-1. Each glutamate receptor subunit had a unique immunocytochemical profile. Furthermore, the localizational changes identified in the kainic acid treated rats were subunit specific. Our data revealed that patterns of subunit immunoreactivity correlated with the distribution of seizure-induced cell loss. Knowledge of the distribution of selective glutamate receptor subunits can help elucidate the anatomical substrate through which excitotoxic injury becomes manifest. NIH NS21323 (SAJ)

DIFFERENTIAL MODULATION OF GABA AND GLUTAMATE TRANSPORTER EXPRESSION AT DISTINCT TIMES AFTER KINDLING. T.D. Hernandez*(1), A.E. Kline (1), H.A. Bradley (1), M. Nakashita (2), N. Sakai (2) and N. Saito (2). Dept. of Psychology (1), Univ. Colorado, Boulder, CO 80309, and Laboratory of Molecular Pharmacol. (2), Biosignal Research Center, Kobe Univ., Kobe 657, Japan.

We previously reported that the expression of GABA and glutamate transporter subtypes are differentially modulated 1 week following amygdala kindled seizures in rats (Hernandez, Kline, Nakashita, Obata, & Saito, *Soc. Neurosci. Abstr., 21*:2115, 1995). The specific aim of this study was to examine an earlier time point (24 hrs) because there is a possibility that transporters are altered by the seizure, itself, and not by the kindling process. To achieve this goal, male Long-Evans rats were implanted with an electrode in the amygdala and kindled once daily until each responded on 4 days with a Stage 5 seizure. Twenty-four hrs later, animals were sacrificed and prepared for immunoblot analyses of the GABA and glutamate transporter subtypes, GAT1, GAT2, GAT3, and GLT1, respectively. The results revealed a significant increase in GAT1 in the parietal cortex of kindled, compared to non-kindled, rats. The increase in GAT1 was similar to that observed in rats sacrificed 1 week after the last Stage 5 seizure. Additionally, significant decreases in GLT1 transporters were found at 24 hrs in the parietal and piriform cortex compared to non-kindled controls. This finding is contrary to that of animals sacrificed 1 week following Stage 5 seizures where GLT1 was found to be within a basal range. These data suggest that while GABA and glutamate transporters may contribute to the enhanced seizure susceptibility observed in kindled animals, GLT1 appears to be most affected by recent seizure activity.

THE EFFECTS OF PHENOBARBITAL AND KINDLING ON BEHAVIORAL RECOVERY FOLLOWING BRAIN DAMAGE IN RATS. S.M. Montanez*, T Gasser, A.E. Kline, A. Wallace, and T.D. Hernandez. Department of Psychology, University of Colorado, Boulder, CO 80309.

Previous data from our laboratory has shown that phenobarbital (PHB) delays functional recovery in cortex lesioned rats and that partially kindled seizures during the critical period (i.e., 12-96 hrs after injury) have distinct effects on recovery: Stage 1 seizures block recovery, while Stage 0 seizures have no detrimental effect. Taken together, the aforementioned studies suggest that individually, certain types of seizure activity and PHB administration are detrimental following brain injury. However, because PHB is often administered to brain injured patients to prevent posttraumatic epilepsy, we examined the effects of this drug in combination with kindled seizures and assessed functional recovery. Male Long-Evans hooded rats sustained unilateral anteromedial cortex lesions and were implanted with an electrode in the ipsilateral amygdala. Forty-eight hours after surgery, a 7 day regimen of PHB (30 mg/kg a.m. & 15 mg/kg p.m.) or saline was initiated. Within each PHB or saline group, rats were further divided into kindled (1 hr prior or post a.m. treatment) or nonkindled groups. Functional recovery was assessed via the bilateral tactile stimulation tests. The results of the kindled (Stage 0) and non-kindled saline groups replicate our earlier finding in that both recovered within 35 days. In contrast, administration of PHB prior to kindling prevented recovery, whereas post-kindling PHB only delayed it. Because partial kindling is associated with increased receptor sensitivity to GABA, we hypothesize that administration of PHB prior to kindling potentiates this effect. This enhanced inhibition may explain the differences in recovery between rats kindled prior to PHB versus those kindled after.

ALTERATION IN LEVELS OF METABOTROPIC GLUTAMATE RECEPTOR TRANSCRIPTS IN HUMAN EPILEPTIC TISSUE. S.Glazier*[1], W.Bell[1,2], C.O'Donovan[2], S.Deadwyler[3], T.Pons[1] and E.V.Grigorenko[3]. [1]Dept.Neurosurgery, [2]Dept. Neurology, [3]Dept. Physiology & Pharmacology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27157.

Metabotropic glutamate receptors (mGluRs) are a subfamily of receptors initiating G-protein-mediated signal cascade. The activation of mGluRs has been implicated in modulation of synaptic efficacy in the hippocampus by generation of epileptoform discharges (mGluR1, mGluR5) whereas mGluR2-4 and mGluR7 appear to exert a protective effect by activating an inhibitory cAMP cascade. However, direct investigation of expression of these receptors in human epilepsy has been lacking.

RT-PCR with subsequent Southern blot analysis was employed to quantitate relative changes in mRNA levels in hippocampal and temporal cortex tissues removed from individuals with intractible temporal lobe seizures (n=15). Surgically-excised non-epileptic human and monkey (*Macaca fasicularis*) control hippocampus and cortex were pooled. All tested mGluRs transcripts (1-8, except mGluR6) are found to be expressed in normal human and monkey hippocampus. The expression pattern of mGLuRs mRNAs was similar to that of monkey. A decrease of mGluR1 level to 61% of controls level was found in cortex and hippocampus of epileptic specimens. Changes in mGluR2 and mGluR7 were more distinct in hippocampal tissue than in temporal cortex. The mGluR7 receptor mRNA was reduced by 52% in hippocampus, while the decrease in cortex was estimated as 15% relative to control level. The level of mGluR2 was reduced to 56% and 78% of that in hippocampus and cortex, respectively of normal human and monkey samples. However, the level of mGlur3 transcript was elevated in both tissues, averaged 135% of control level. A novel mGluR8 receptor was found to be expressed in hippocampal and cortical tissue, but its expression level did not differ from control specimens. Our results indicate that the altered pattern of mGluR mRNA expression in epileptic tissues may represent a functional reorganization in these structures directed to reduce Ca2+ influx and the degree of excitability in the hippocampal formation.

DEGENERATIVE DISEASE: ALZHEIMER'S-BETA-AMYLOID—THERAPEUTIC APPROACHES I

BIOCHEMICAL AND BIOLOGICAL CHARACTERIZATION OF PPI-368, A POTENT INHIBITOR OF AMYLOID β-PEPTIDE POLYMERIZATION. S. M. Molineaux, J. Chin, J. J. Lee, M. Kelley, W. Kubasek, J. Wakefield, M. H. Zhang, X. Zhang, C. J. Molineaux*, G. F. Musso, M. A. Findeis. Pharmaceutical Peptides Inc., Cambridge, MA 02139

PPI-368, a low molecular weight peptido-organic compound, is a potent, selective inhibitor of Aβ polymerization that blocks the formation of all neurotoxic species of Aβ oligomers. In a nucleation-dependent polymerization assay of a 50 μM Aβ(1-40) peptide solution, equimolar concentrations of PPI-368 block polymerization and submolar doses significantly delay fibril formation. Electron microscopy confirms that fibril formation does not occur in the presence of PPI-368. In nucleation assays performed at lower peptide concentrations (0.2-25 μM Aβ peptide), where formation of β-sheet polymers is monitored by thioflavin-T binding, high potency and dose-dependent inhibition by PPI-368 are observed. The organic modifier present in PPI-368 has no inhibitory activity by itself in this assay, nor does an analog of PPI-368 in which all amino acyl residues are replaced by alanine. The ability of PPI-368 to inhibit the polymerization of monomeric Aβ suggests that it binds directly to monomers or soluble oligomers. In addition, trace amounts of radiolabeled PPI-368 are incorporated into fibrils during polymerization, demonstrating that the inhibitor can also bind to Aβ peptide within a fibrillar structure. PPI-368 is selective in that it does not inhibit the polymerization of other amyloid proteins such as transthyretin (TTR) or islet amyloid polypeptide [IAPP(20-29)].

In a polymerization extension assay seeded with pre-formed Aβ polymer, similar inhibition and dose-dependency phenomena are observed with PPI-368. Gel-filtration studies show progressive disappearance of the monomer and the concomitant appearance of soluble large molecular weight oligomers. In the presence of submolar concentrations of PPI-368, monomeric Aβ is still present and oligomers do not form. This suggests that PPI-368 would be effective at blocking the deposition of Aβ peptide onto pre-formed Aβ fibrils or plaque.

Monomeric Aβ(1–40) or Aβ(1-42) is non-toxic when incubated with neuronal cell lines, but both peptides become neurotoxic during polymerization. PPI-368 coordinately delays both the onset of polymerization and the formation of all neurotoxic Aβ species for both peptides. This work was supported by PPI.

β-PEPTIDE-PROTEIN INTERACTIONS ACCOMPANIED BY INHIBITION OF FIBRIL FORMATION: EFFECT ON Aβ-INDUCED CYTOTOXICITY. M.Y.Aksenov, M.V.Aksenova, D.A. Butterfield, and J.M.Carney*. Dept. of Pharmacology, Dept. of Chemistry and Center of Membrane Sci., UK, Lexington, KY, 40536.

The β-Amyloid peptide (βA4), a main constituent in both senile and diffuse plaques in Alzheimer's diseased brains, was previously shown to be able to interact with several macromolecular components of brain tissue. Production of beta-peptides, formation of amyloid deposits and neurodegeneration caused by βA4 take place in protein-containing microenvironments. Minor plaque protein components and even proteins which temporarily interact with beta-amyloid potentially can play an important role in the aggregation, toxicity and resistance to proteolysis shown by βA4. In the present study we demonstrate that alpha-1-antichymotrypsin (ACT), a glial-derived protein associated with senile plaques in the Alzheimer's brain, inhibits Aβ (1-40) aggregation into fibrils, but is unable to inhibit the toxicity of Aβ (1-40) in primary rat hippocampal cell cultures. We also demonstrate that the cross-linking of Aβ(1-40) by tissue transglutaminase (tTG) more likely prevents the formation of fibrils than stabilizes insoluble fibrillar aggregates of Aβ(1-40). Co-incubation of Aβ(1-40) with tTG neither could increase the existing toxicity of the peptide nor protect the cells against βA4. We also demonstrate that the interaction of Aβ(1-40) with glutamine synthetase (GS), which is resulted in abrogation of fibril formation, partial fragmentation of Aβ(1-40) and inactivation of GS, leads to the increase of β-peptide cytotoxicity. The results of our experiments suggest that the toxicity of βA4 does not necessarily require fibril formation. Interactions of βA4 with different brain proteins may not only contribute to the deposition of insoluble amyloid, but cause the formation of "soluble" βA4 complexes and/or fragments able to induce neuronal cell damage.

DRUGS THAT INCREASE NEURONAL ACTIVITY AS TREATMENT FOR ALZHEIMER'S DISEASE. S.N. Dijk and P.T. Francis. (SPON: Brain Research Association) UMDS, Div. Biochem. & Mol. Biol., Guy's Campus, St Thomas Street, London SE1 9RT, UK.

Hypoactivity of cortical pyramidal neurones has been hypothesised to underlie both the cognitive symptoms of Alzheimer's disease, and to accelerate the formation of the histological hallmarks of the disease. Recent studies indicate that while the partial M_1 agonist (1-Azabicyclo [2.2.1] heptan-3-one O-[3-(3-methoxyphenyl)-2-propynyl/oxime, Z-(=+/)-, ethanedioate (PD 142505-0028), when topically applied to the rat frontal cortex, increases glutamate (GLU) concentration in the rat striatum by 264 ± 85 % (Mean ± SD) from baseline and the selective 5-HT_{1A} antagonist (N-*tert*-butyl 3-4(2-methoxyphenyl) piperazin 1-yl-2 phenylpropanamidedihydrochloride (WAY100135) by 149 ± 61% from baseline, the combination of these drugs increased GLU concentration in the striatum by 582 ± 164 % from baseline ($P < 0.05$, combination of PD 142505-0028 + WAY100135 different from PD142505-0028 effect when tested by Kruskal Wallis ANOVA followed by Mann Whitney U test). If the parameter tested in this study predicts efficacy of treatment for Alzheimer's disease, combining a partial M_1 agonist with a selective 5-HT_{1A} antagonist may be a promising approach.

Ongoing research focuses on whether cholinomimetics affect amyloid precursor protein secretion *in vivo*, and whether this is accompanied by a change in the concentration of βA4 in the extracellular space.

PHENSERINE REDUCES THE SECRETION OF β-AMYLOID PRECURSOR PROTEIN IN CULTURED CELLS: DUAL THERAPEUTIC APPROACH FOR ALZHEIMER'S DISEASE (AD). N.H. Greig[1], T.T. Soncrant[2]*, A. Brossi[3], D.K. Ingram[1], H.W. Holloway[1], Q.S. Yu[1], M. Farlow[4], and D.K. Lahiri[4]. [1]Lab. Cellular & Mol. Biol., GRC/NIA/NIH, Baltimore, MD 21224; [2]Cure Inc., Silver Spring, MD 20906; [3]Sch. Pharmacy, Univ. N. Carolina, Chapel Hill, NC 27599; [4]Dept. Psychiatry & Neurology, Indiana Univ. Sch. Med., Indianapolis, IN 46202;

The amyloid β-peptide (Aβ) that aggregates to form the core of senile plaques in AD derives from a family of large integral membrane glycoproteins, β-amyloid precursor protein (β-APP). Secreted derivatives of β-APP are the proteolytic cleavage products of full length protein. Cultured cells also secrete Aβ during normal metabolism. Cell culture studies have recently shown that the cholinesterase (ChE) inhibitor tacrine, used to improve cognitive performance in AD, reduces secretion of β-APP in the conditioned media (Lahiri, 1994). Here we report the effects on β-APP secretion of a new class of reversible ChE inhibitors. Phenserine, a 75-fold acetyl- vs butyrylcholinesterase selective inhibitor, was administered to neuroblastoma (SK-N-SH) cells and β-APP levels in cell lysates and conditioned media were analyzed by Western blotting with different antibodies. Phenserine and analogs, like tacrine, reduced secretion of β-APP in the conditioned media and levels in cell lysates, without damage to cell integrity or viability. Phenserine is long-acting ($t_{1/2}$ 8 h) and readily enters brain (brain/plasma ratio of 10) when administered to rodents. It dramatically improves cognition in scopolamine impaired and elderly rats over a wide dose range, increases brain levels of acetylcholine, and has demonstrated favorable toxicity in preclinical toxicological studies. In summary, phenserine and analogs show promise on two levels as therapeutics for AD. First they demonstrate immediate action to improve cognitive function in rodent partial models of AD. Second, they appear to interact with and inhibit primary molecular processes likely involved in the development of AD. Phenserine is progressing toward clinical trials.

AMINOPEPTIDASE HYPOTHESIS FOR β-AMYLOID (Aβ) CATABOLISM IN BRAIN. T.C. Saido* Department of Molecular Biology, Tokyo Metropolitan Institute of Medical Science, 3-18-22 Honkomagome, Bunkyo-ku, Tokyo, JAPAN.

Aβ is constitutively secreted from cells even under the normal conditions. Therefore, senile plaque-free brains should retain the capacity to fully catabolize Aβ peptides before they form irreversible aggregates. However, the post-secretory catabolism of Aβ in brain remains yet unclear. Identification of the *in vivo* metabolic process(es) responsible for Aβ catabolism would found new basis for possible preventive and therapeutic measures against brain aging and Alzheimer's disease (AD).

I and collaborators described previously that the major Aβ species invariantly deposited in brain is Aβx-42 (x = 1(D-Asp) and 3(pyroGlu) and/or 11(pyroGlu)**. This observation was confirmed with familial/sporadic AD and Down's syndrome brains. Because these structures, presumably representing the metabolic intermediates toward degradation, render the Aβ peptide resistant to proteolysis catalyzed by major aminopeptidases and could result from a decrease in aminopeptidase activity, I propose a working hypothesis that proteolysis of Aβ from the amino terminus constitutes a rate-limiting step in Aβ catabolism. The hypothesis predicts that reduction of a specific aminopeptidase activity results in incomplete clearance of secreted Aβ from brain and thus in facilitated deposition leading to senile plaque formation. This hypothesis is not biologically unusual since degradation of a number of peptide hormones including neuropeptides is initiated by aminopeptidase action. Analytical and experimental data supporting this hypothesis will be presented and discussed. Also, possible preventive and diagnostic applications will be proposed.

EFFECTS OF IODODOXORUBICIN AND FCE 29084A ON BEHAVIOURAL CHANGES IN EXPERIMENTAL SCRAPIE. R.A. McArthur*, P. Cassutti, M.A. Cervini, T. Bandiera, M. Varasi, G. Forloni[1], F. Tagliavini[2], C. Post and J. Lansen. Pharmacia & Upjohn CNS Research, Nerviano, (MI), [1]Istituto Mario Negri, via Eritrea, 62, Milan, and [2]Istituto Neurologico, Carlo Besta, via Celoria, 11, Milan, Italy.

Syrian hamsters inoculated intracerebrally with the 263K scrapie strain accumulate PrP^{Sc} scrapie, develop amyloid plaque deposits and display neurological dysfunctions similar to human prion-related encephalopathies (Kimberlin and Walker, *J Gen Virol.*, 1977, **34**, 295). Iododoxorubicin (IDOX), a cytotoxic anthracycline, induces amyloid deposit resorption in peripheral amyloidosis (Gianni *et al., Blood*, 1995, **86**, 855). FCE 29084A is an anthracyclinone derivative devoid of cytotoxicity, but maintains the ability to alter the aggregation state of amyloid fibrils. This study characterises the behavioural changes induced by scrapie infection and examines possible ameliorative effects of both IDOX and FCE 29084A. Hamsters were infected with 30 µl of brain homogenate of previously infected animals. IDOX (2.9 mM) and FCE 29084A (15.4 mM) were pre-incubated for 1 hour with this homogenate before inoculation. Survival time was recorded and detailed behavioural observations recorded the onset time of scrapie symptoms such as tactile and acoustic-induced reactivity, ataxia, loss of righting reflex, and changes in the latency to leave an enclosed area. Infected hamsters were initially hyper-reactive to acoustic and tactile stimuli and then became hypo-reactive. This hypoactivity was related to a progressive loss in balance and inability to escape from an enclosed area. Death occurred at a mean of 109 (± 2.4) days. IDOX and FCE 29084A delayed the onset time of the behavioural symptoms of the infection and prolonged survival time (126 ± 3.1 and 118 ± 2.8 days respectively). However, once infection took hold, the progression of the behavioural symptoms were similar in all groups.

ANTHRACYCLINES DELAY PrP ACCUMULATION AND BRAIN LESIONS IN EXPERIMENTAL SCRAPIE. F. Tagliavini[1], R.A. McArthur[2], B. Canciani[1], G. Giaccone[1], M. Porro[1], M. Bugiani[1], E. Peri[3], P. Dall'Ara[3], M. Rocchi[3], J. Lansen[2], M. Varasi[2], T. Bandiera[2], A. Suarato[2], A.W. Kozak*[2], P. Cassutti[2], M. Salmona[4], G. Poli[3], C. Post[2] and G. Forloni[4]. [1]Istituto Neurologico C. Besta, via Celoria, 11, Milan, [2]Pharmacia & Upjohn CNS Research, Nerviano, (MI), [3]Istituto di Microbiologia Veterinaria, Università di Milano, via Celoria, 10, and [4]Istituto Mario Negri, via Eritrea, 62, Milan, Italy.

Prion diseases are characterised by the accumulation of abnormal isoforms of the prion protein (PrP^{Sc}) in the brain. Unlike the normal PrP, PrP^{Sc} has a high content of β-sheet secondary structure and a high tendency to aggregate into amyloid fibrils. The observation that the anthracycline iododoxorubicin (IDOX) binds to amyloid fibrils and induces amyloid resorption in patients with peripheral amyloidosis prompted us to investigate the effects of this drug and the anthracyclinone derivative, FCE 29084A on experimental scrapie. Syrian hamsters were inoculated intracerebrally with brain homogenate of hamsters infected with the 263K scrapie strain. In two sets of animals, the brain homogenate was incubated for 1 h with 2.9 mM IDOX or 15.4 mM FCE 29084A before inoculation. Both IDOX and FCE 29084A delayed the onset of clinical signs of disease and prolonged the survival time significantly. Neuropathological examination showed a parallel delay in the appearance of spongiosis and astrogliosis as well as in the accumulation of PrP^{Sc} and PrP amyloid. This was revealed both by immunocytochemistry and immunoblot analysis of brain homogenates with anti-PrP antibodies. In the terminal stages of the disease, brain changes and PrP^{Sc} levels were similar in all groups. These data suggest that IDOX and FCE 29084A are able to interact with abnormal PrP isoforms interfering with the development of the disease.

651.8

ANTI-AMYLOIDOGENIC ACTIVITY OF 4'-IODO-4'-DEOXYDOXORUBICIN. G.Forloni*[1], M.Salmona[1], L.De Gioia[1], B.Canciani[3], J.Lansen[2], F.Della Vedova[2], A.Molinari[2], A.Suarato[2], M.Varasi[2], C.Post[2], F.Tagliavini[3], [1]Ist. "Mario Negri", Milano; [2]Pharmacia & Upjohn, CNS Research, Nerviano, (MI); [3]Ist. Neurologico "Carlo Besta", 11 Milano, Italy

β-amyloid (Aβ) plays a central role in the pathogenesis of Alzheimer's Disease (AD). Accordingly, compounds able to interfere with assembly and aggregation of Aβ protein into soluble fibrils are regarded as candidates for AD treatment. The anthracycline, iododoxorubicin (IDOX), induced amyloid resorption in patients with immunoglobulin light-chain amyloidosis (Gianni et al., Blood, 1995, 86, 855). IDOX also has a substantial affinity for biochemically-distinct native amyloid fibrils *in vitro*, and reduces the amount of splenic amyloid deposition in a murine model of peripheral amyloidosis (Merlini G.P. et al., PNAS (USA) 1995, 92, 2959). Thus, the *in vitro* binding of IDOX to cerebral amyloids (namely Aβ and PrP), and the hinderance of Aβ and PrP peptide polymerization were studied. Brain sections of patients with AD and Creutzfeldt-Jakob disease with Kuru plaques were examined by fluorescence microscopy after incubation with IDOX (0.1-10 nM). The drug labeled both Aβ and PrP amyloid deposits with an affinity similar to that of thioflavine-S. The effects of IDOX on the assembly and aggregation of the synthetic peptide homologous to residues 25-35 of Aβ was studied by HPLC. Aβ (25-35) was incubated for 24 hours in 1 mM phosphate buffer, pH 7.4, in the absence or presence of equimolar concentration of IDOX. The peptide suspensions were centrifuged and the soluble Aβ 25-35 was measured. IDOX completely prevented peptide aggregation. This finding was confirmed by light scattering analysis. Similar results were obtained when IDOX was incubated with a synthetic peptide homologous to residues 106-126 of PrP. These data support the relevance of IDOX for studying Aβ and PrP amyloidogenesis and its prevention.

651.9

ANTHRACYCLINES AND AMYLOIDOSIS: STUDIES WITH A DEGLYCOSILATED DERIVATIVE. J.Lansen[1], A.Molinari[1], F.Della Vedova*[1], T.Bandiera[1], C.Caccia[1], M.Colombo[1], M.Caruso[1], F.Tagliavini[2], S.Gorla[3], N.Angeretti[3], L.De Gioia[3], C.Post[1], G.Forloni[3], M.Salmona[3], [1]Pharmacia & Upjohn, CNS Research, Nerviano, (MI); [2]Ist. Neurologico "Carlo Besta", Milano; [3]Ist."Mario Negri", Milano, Italy.

The anti-amyloidogenic activity of 4'-iodo-4'deoxydoxorubicin (IDOX) has been shown clinically (Gianni et al., *Blood*, 1995, **86**, 855); stimulating the development of anthracyclines with low level of cytotoxicity, good blood brain barrier passage with therapeutic efficacy in Alzheimer's Disease. FCE 29084A, a deglycosilated derivative of doxorubicin, showed no cytotoxicity when exposed chronically to primary neuronal cell cultures, except at concentrations over 10 µM, (3-4 orders of magnitude higher than IDOX). The maximal tolerated dose in Syrian hamsters of FCE 29084A was 500 mg/kg; *ip* (vs IDOX <10 mg/kg; *ip*). The brain/plasma ratio was about 0.3. The effect of FCE 29084A on self-aggregation activity of a synthetic peptide homologous to β amyloid fragment (Aβ 25-35) was investigated by light scattering. Light scattering of Aβ 25-35 dissolved in a 200 µM phosphate buffer solution pH 5 was reduced in the presence of FCE 29084A, indicating a decrease of peptide aggregation. Accordingly, an increase in soluble Aβ 25-35 concentrations was observed by HPLC in the supernatant of the peptide solution. This was incubated for 24 hours with FCE 29084A and centrifuged at 10,000 x g. In separate studies, a solution of Thioflavin-T (3 µM) was mixed with Aβ 25-35 fibrils (0.5 mg/ml) and the fluorescence of the solution measured. In these conditions, FCE 29084A incubated at equimolar concentration with Aβ 25-35 reduced the fluorescence signal of about 80%. In conclusion, FCE 29084A could be a useful tool to investigate the structural requirements for the anti-amyloidogenic activity of the anthracyclines/anthracyclinones.

651.10

EFFECTS OF MICROTUBULE STABILIZING AGENTS ON β-AMYLOID-INDUCED TOXICITY IN PRIMARY NEURONS. N. R. Ranciat, R. E. Ragan, G. Georg, L. Rocha, E.K. Michaelis*, and M.L. Michaelis. Dept. of Pharmacology/Toxicology and Ctr. Neurobiol./Immunol. Res., Univ. of Kansas, Lawrence KS 66045

Alzheimer's disease(AD) is a neurodegenerative disorder with no pharmacological treatments to stop or slow progression of the disease. AD neuropathology includes extracellular deposits of β-amyloid and intracellular accumulation of paired helical filaments (PHF's) that form neurofibrillary tangles (NFT's). PHF's contain an abnormally phosphorylated microtubule associated protein τ that may diminish axonal transport, leading to damage or death of neurons. The use of microtubule stabilizing drugs was recently proposed as a potential intervention for slowing the degeneration (*Neurobiol. Aging* 15:S85, 1994). The role of β-amyloid in AD neuropathology is not well understood but β-amyloid was recently shown to induce τ phosphorylation and loss of microtubule binding (*Neuron* 14: 879, 1995). These studies were undertaken to determine whether microtubule-stabilizing drugs such as taxol and related congeners that we have synthesized protect neurons against Aβ-induced toxicity. Primary cortical neuronal cultures exposed to the toxic Aβ peptide 25-35 (10 µM) were pretreated initially with the microtubule stabilizing drug taxol. Neuronal damage was estimated by observation of morphological changes under phase contrast microscopy. Cell counts in several cultures revealed that taxol/Aβ-treated cultures had an average 97% survival rate compared to controls, whereas the Aβ only cells had a 61% survival rate, 24 hours after addition of Aβ. We are currently estimating viability using two biochemical assays (MTT and LDH) to obtain more quantitative data regarding the potential protective effect of taxol and analogs more likely to cross the blood-brain barrier.(Supported by Alz. Dis. Assoc., PHS grants GM 07775, AA04732, and Higuchi Biosciences Ctr., U. of Kansas.)

GLYCOXIDATION AND AGE-INHIBITORS IN NUCLEATION DEPENDENT POLYMERIZATION OF ß-AMYLOID PEPTIDE

G. Munch *, R. Schinzel, P. Riederer Physiological Chemistry I and Clinical Neurochemistry, University of Wuerzburg; Germany

Advanced Glycosylation Endproducts (AGEs) are major components of amyloid plaques, which accumulate in the brain of patients with Alzheimer's disease. Our studies show, that nucleation dependent polymerization of ß-amyloid peptide, the major component of amyloid plaques in patients with Alzheimer's disease, is significantly accelerated by crosslinking through AGEs *in vitro*. Both steps of the polymerization process, the formation of the nucleus and the growth of the aggregate, are accelerated by AGE-mediated crosslinking. In addition, the transition metals copper and iron accelerate this process further, suggesting glycoxidation as the predominant mechanism. Formation of the AGE-crosslinked amyloid peptide aggregates can be attenuated by several AGE-inhibitors such as tenilsetam, aminoguanidine and carnosine. Clinical trials with tenilsetam in Alzheimer's disease have shown marked improvement in cognition and memory in the majority of patients. Our data and this clinical correlate support our hypothesis that AGEs might play an important role in etiology or progression of the disease and hence new AGE-inhibitors could prove promising therapeutic agents.

MODULATION OF COMPLEMENT C1Q SECRETION BY DIFFERENT CLASSES OF ANTI-INFLAMMATORY AND CHOLINERGIC DRUGS.

D.G. Walker*, E.G. McGeer and P.L. McGeer. Kinsmen Laboratory of Neurological Research, Department of Psychiatry, University of British Columbia, Vancouver, B.C. Canada, V6T1Z3.

Studies of brains from Alzheimer Disease (AD) cases have shown evidence of inflammatory changes in affected tissue, as demonstrated by the presence of reactive microglia and activated complement proteins. One of the key events in this process is believed to be the activation of the classical complement pathway by the direct interaction of C1q with the β amyloid peptide. C1q secretion is known to be increased in response to inflammatory stimuli, and increased amounts have been detected in AD brains. The majority of C1q present in the brain is probably synthesized locally by brain microglia. Drugs that are effective in inhibiting C1q production may be useful for treating AD.

An in-vitro ELISA based assay system has been developed, using differentiated THP-1 cells (a transformed human monocytic-like cell line) to represent brain microglia, to test the effectiveness of different classes of drugs on C1q secretion. In this assay, as THP-1 cells secreted detectable amounts of C1q only upon stimulation, each drug was tested on cells stimulated with γ interferon (50 U/ml). Our results showed that dexamethasone (steroid) caused a large induction in C1q secretion (approximately 7 fold). Interestingly, dexamethasone alone caused the induction of significant amounts of C1q in THP-1 cells. Tacrine (acetylcholinesterase inhibitor), which is being used to treat AD, caused a small decrease in C1q secretion, while phorbol myristate acetate (protein kinase C activator) caused a large decrease. In comparison, indomethacin (non-steroidal cyclooxygenase inhibitor) and PK11195 (peripheral benzodiazepine receptor antagonist) did not appear to have significant effects.

Supported by a grant from the Jack Brown and Family AD research fund.

EXPRESSION OF HUMAN APP *IN VITRO* AND *IN VIVO* IN RODENT BRAIN VIA ADENO-ASSOCIATED VIRUS (AAV) VECTORS.

G. Gouras*[1], H. Makimura[4], J. Jovanovic[3], J. Smith[4], S. Sisodia[5], R. Tanzi[6], P. Greengard[3], N. Relkin[1], S. Gandy[1] and M. G. Kaplitt[2,4]. [1]Dept. of Neurology & Neuroscience and [2]Div. Neurosurgery, Cornell Univ. Med. College, and Laboratories of [3]Molecular and Cellular Neuroscience and [4]Biochemical Genetics and Metabolism, Rockefeller Univ., New York, NY 10021, [5]Neuropathology Laboratory, Johns Hopkins Univ. Sch. of Med., Baltimore, MD, and [6]Genetics and Aging Unit, MGH, Boston, MA.

We have previously used AAV vectors for expression of human apolipoprotein E (apo E) in rodent brain. Now we demonstrate expression of human APP both in cultured neuronal cell lines and in primary neuronal cultures, and in rodent brain.

Wild type (wt) and Swedish mutant (Sw) APP genes were cloned into defective AAVs under the control of the CMV promoter. Infections were performed in rat cortical cultures and in N2A neuroblastoma cells, and by stereotactic injection into rat hippocampus. AAV containing the bacterial lac Z gene was used for control infections. Proteins expressed by the inserted genes were analyzed by immunocytochemistry (ICC) at various time points following infection. Wt and Sw APP transgene expression and protein processing were further analyzed by pulse-chase labeling with [^{35}S]methionine and immunoprecipitation or by Western blotting.

ICC using the human specific antibody 6E10 (Senetek) showed staining of primary cortical cultures and N2A cell cultures following infection with either wt or Sw APP. Pulse-chase labeling of wt and Sw APP in N2A cell cultures indicated production of APP and proteolytic fragments. ICC with 6E10 also showed staining around the injection sites in animals sacrificed 3 days after infusion of AAV wt or Sw APP. Extended time points of *in vivo* studies with wt and Sw APP are currently in progress.

These findings, in conjunction with related work with apo E and presenilin 2, demonstrate that transfer and expression of human genes relevant to Alzheimer disease (AD) can be accomplished in neuronal cultures and in normal adult rat brain using AAV vectors. These results suggest the possibility of new approaches for modeling pathology and /or gene therapy in AD.

ALZHEIMER'S DISEASE: PRESENILIN GENE EXPRESION

652.1

IMMUNOHISTOCHEMICAL ANALYSIS OF PRESENILIN 1 AND PRESENILIN 2 EXPRESSION IN THE MOUSE BRAIN.

S. Moussaoui, V. Blanchard, C. Czech, L. Pradier, B. Bonici, M. Gohin, J. C.R. Randle* and A. Imperato. CNS Programme, Rhône-Poulenc Rorer, Vitry sur Seine Cedex, France.

Different mutations associated with early-onset familial Alzheimer's disease (AD) in various kindreds have been reported in a recently identified gene on chromosome 14, called presenilin 1 (PS-1). Other mutations have been reported in a closely related gene found on chromosome 1, called presenilin 2 (PS-2). PS-1 protein has already been reported to be present in senile plaques in postmortem brains from patients with AD.

We used specific antibodies against PS-1 (peptide fragment 340-356 or 50-66) and PS-2 (peptide fragment 7-24) to examine the distribution and the subcellular localization of these two proteins within the mouse brain.

PS-1 and PS-2 proteins have a similar broad distribution throughout the brain. PS-1 and PS-2 immunostaining is concentrated in neuronal somata and extends into proximal dendrites as thick granules resembling post-golgi vesicles.

652.2

QUANTITATIVE DISTRIBUTION OF PRESENILIN-1 IN THE BRAINS OF ELDERLY PEOPLE.

C. Bouras*[1,2], P. Giannakopoulos[1], E. Kövari[1], P.R. Hof[2], P.G. Vallet[1], J. Shioi[3], N. Tezapsidis[3], and N.K. Robakis[3]. [1]Dept of Psychiatry, Univ. of Geneva Sch. Med., HUG Belle-Idée, 1225 Geneva, Switzerland, Depts of [2]Neurobiol. and [3]Psychiatry, Mount Sinai Sch. Med., New York, NY 10029.

Recent evidence suggests that presenilin-1 (PS-1) protein is involved in Alzheimer's disease (AD) pathogenesis. To investigate the distribution of PS-1 protein in the cerebral cortex of elderly people, we performed a quantitative immunocytochemical analysis of PS-1 localization in neurofibrillary tangle (NFT)-free and NFT-bearing neurons and senile plaques (SP) in 12 non-demented (ND) cases and 8 cases with neuropathologically confirmed AD. In both ND (mean age: 78.2 ± 2.4 years) and AD cases (mean age: 87.4 ± 4.6 years), PS-1 was intensely concentrated in the cytoplasm of neurons. In ND cases, the percentages of NFT-free neurons displaying PS-1 expression were 55.7 ± 4.8 in the CA1 field, 57.7 ± 3.8 in the subiculum, 63.5 ± 3.9 in layer II and 52.8 ± 4.6 in layer V of the entorhinal cortex, 62.9 ± 3.7 in layers II-III and 53.5 ± 4.4 in layers V-VI of area 20, and 72.7 ± 3.6 in layers II-III and 59.6 ± 4.0 in layers V-VI of area 9. An increase in PS-1 prevalence with age was observed in this diagnosis group. In AD cases, these percentages were 54.7 ± 7.6 in the CA1 field, 76.0 ± 3.3 in the subiculum, 71.0 ± 4.7 in layer II and 63.3 ± 2.8 in layer V of the entorhinal cortex, 63.9 ± 5.0 in layers II-III and 43.1 ± 8.2 in layers V-VI of area 20, and 64.9 ± 7.1 in layers II-III, and 52.4 ± 4.7 in layers V-VI of area 9. In the subiculum, AD cases displayed significantly higher PS-1 frequency in NFT-free neurons compared to ND cases ($p < 0.005$). Furthermore, the prevalence of PS-1 was significantly lower in NFT-bearing compared to NFT-free neurons ($p < 0.01$ -0.001). The percentages of PS-1-immunoreactive SP averaged 20 to 30% in the cerebral cortex of AD cases. These data suggest that neurons expressing PS-1 may be resistant in the course of the degenerative process. Moreover, they show that PS-1 is not a major constituent of SP. Supported by NIH AG05138 and FNRS.

652.3

Missense Mutations of the *Presenilin 1 (PS1/S182)* Gene in German Early-Onset Alzheimer's Disease Patients

R. Sandbrink[1], D. Zhang[1], S. Lichtenthaler[1]*, S. Schaeffer[2], J. Bauer[2], R. Zerfaß[3], H. Förstl[3], F. Henn[3], C. L. Masters[4] and K. Beyreuther[1]. [1]Center for Molecular Biology Heidelberg (ZMBH), Univ. of Heidelberg, INF 282, D-69120 Heidelberg, Germany; [2]Dept. of Psy-chiatry, Univ. of Freiburg, Germany; [3]Central Institute for Mental Health, Mannheim, Germany; and [4]Dept. of Pathology, Univ. of Melbourne, Parkville, Australia (R. S. and D. Z. contributed equally)

Recently the cloning of a gene on chromosome 14 bearing missense mutations in early-onset familial Alzheimer's disease (FAD) was reported. This *Presenilin 1 (PS1* or *S182*) gene represents the *AD3* locus responsible for up to 70 to 80 % of early-onset FAD. *PS1* missense mutations in early onset FAD have also been reported by several other groups, and, additionally, there are rare FAD mutations in a homologous gene located on chromosome 1, called *PS2 (STM2/E5-1)*.

We studied 21 unrelated German early-onset AD patients (onset age 38-56 years), three of these presenting as FAD. Using cDNA from total RNA extracted from cultivated mononuclear blood cells, we first assessed the presence of the initially described *PS1* missense mutations by PCR and restriction digestion analysis. No mutations were detected. For 14 patients in our group, including 2 of the FAD cases, we then searched for any other missense mutation by PCR amplification and thermal cycle sequencing of the full *PS1* coding region. Two *PS1* mutations were detected. One substitution (M139V), meanwhile also described in an American pedigree, was found in a FAD patient with an age of onset of dementia at approx. 40 years, associated with an early onset of myoclonus. The other substitution (E318G) occurred in a patient with an age of onset of approx. 47 years, but without a known familial background of dementia.

While our results support the role of *PS1* missense mutations in early-onset FAD, we observed only a low frequency of these in our representative group of all early-onset AD patients. This supports the notion that most of the sporadic early-onset AD cases are multifactorially caused by genetic and non-hereditary risk factors, but not by autosomal dominant missense mutations of the *PS1* gene as they are responsible for the majority of early onset FAD. However, in addition to the APOE ε4 allele, *PS1* itself may act as a susceptibility gene due to mutations outside the coding region as recently suggested.

652.4

QUANTIFICATION OF PRESENILIN 1 mRNA IN ALZHEIMER'S DISEASE CEREBRAL CORTEX

J. A. Johnston*, S. Froelich, L. Lannfelt and R. F. Cowburn.
Karolinska Institute, Geriatric Medicine Section, Novum, 141 86 Huddinge, Sweden

A novel gene on chromosome 14, S182 or Presenilin 1, was recently identified and shown to carry missense mutations which cosegregate with early onset familial Alzheimer's disease. The role of Presenilin 1 in the aetiology of this disease is as yet unknown. In the present study, we quantified Presenilin 1 mRNA in post mortem mid-temporal and superior frontal cortices from 14 sporadic Alzheimer's disease, 9 non-demented, and 5 positive disease control subjects. Tissue was provided by the Netherlands Brain Bank and all subjects were Apolipoprotein E-genotyped. We recently reported that amyloid precursor protein (APP) and amyloid precursor-like protein 2 mRNA levels were significantly reduced in the mid-temporal cortices of this group of Alzheimer's disease subjects, as compared to non-demented controls. Presenilin 1 mRNA levels were determined by quantitative solution hybridisation-RNase protection assay using a radiolabelled cRNA probe complimentary to positions 384-554 of this gene.

No significant differences were seen in mid-temporal or superior frontal cortical Presenilin 1 mRNA levels in the Alzheimer's disease, as compared to non-demented and positive disease control groups, when the results were expressed as specific RNA copies per pg total RNA. No differences in Presenilin 1 mRNA levels were detected between individuals carrying different APOE genotypes. Presenilin 1 mRNA was present at relatively low levels, equivalent to approximately 10% of total APP mRNA and 30% of APLP2 mRNA levels in both cortical regions.

These findings suggest that total Presenilin 1 expression is not invariably altered in Alzheimer's disease cerebral cortex, although further investigation is required to determine whether expression of different splice variants is altered in the disease and whether the pathogenic mutations affect Presenilin 1 mRNA levels.

We thank the Gamla Tjänarinnor and Swedish Alzheimer Foundations for their generous financial support.

652.5

GENE EXPRESSION OF ALZHEIMER-ASSOCIATED PRESENILIN-2 IN ALZHEIMER AND AGE CONTROL BRAIN

G. Deng*, J.H. Su and C.W. Cotman. *Institute for Brain Aging and Dementia, University of California, Irvine, Irvine, CA 92697-4540 USA*

Two mutations in the presenilin-2 (PS2) gene have been identified and appear to be genetically linked to early-onset familial AD (Levy-Lahad 1995). To clarify roles of PS-2 in AD, we employed in situ hybridization in combination with immunohistochemical techniques to investigate PS2 gene expression pattern in AD brain. A digoxigenin-labeled antisense riboprobe synthesized from a human full length PS2 cDNA was used to examine PS2 mRNA expression in the frontal cortex from 6 sporadic patients and 4 control cases. Message for PS2 was primarily detectable in neurons and was located in neuronal cytoplasm by antisense probe, whereas sense probe did not give any significant signal. Strong staining signal was most commonly found in large pyramidal neurons, whereas moderate or faint expression signal was usually present in smaller neurons. The pattern of gene expression throughout the cerebral cortex hybridized with antisense probe displayed a laminar distribution profile. The while matter and layer I region of the cerebral cortex appeared mostly devoid of any major hybridization signal, whereas layers II, III and V regions of the cerebral cortex exhibited stronger signal in expression neurons compared with layer IV. Furthermore, higher PS2 mRNA expression was correlated to a higher degree with lipofuscin autoflurescence in a large subset of neurons in both AD and control cases. In addition, a small subset of tangle-bearing neurons also displayed PS2 hybridization signal in AD. Our findings suggested that this gene may play an important role in AD pathogenesis. Supported by NIA AG13007.

652.6

EFFECTS OF ALZHEIMER MUTATIONS ON PRESENILIN 1

A. Takashima*, M. Mercken, H. Takahashi, T. Honda, K. Sato, M. Murayama, K. Noguchi, Y. Nakazato
Mitsubishi Kasei Institute of Life Sciences, 11 Minamiooya, Machida-shi, Tokyo 194, Japan

Alzheimer's disease is a progressive neurological disorder, chraracterized by the accumulation of amyloid ß (Aß) protein in senile plaques and paired helical filaments (PHF) composed of hyper phosphorylated tau in neurofibrillary tangles (NFT). The pathogenesis of AD is not well understood in spite of great efforts. From genetic linkage studies of familial Alzheimer's disease (FAD), presenilin 1(PS1) on chromosome 14 was cloned recently, which is a member of an evolutionary well conserved gene family. Sequence analysis predicts integral membrane proteins, that contain seven putative transmembrane domains. The majority of cases of early-onset familial Alzheimer's disease are caused by mutations in PS 1. We first produced 7 monoclonal antibodies that react with 3 non-overlapping epitopes on the N-terminal hydrophilic tail of PS 1. The monoclonal antibodies can detect the full size PS 1 at Mr 47,000 (47K) and a more abundant Mr 28,000 (28K) product in membrane extracts from human brain and human cell lines. To understand the effects of Alzheimer mutations on PS 1, cells transiently transfected with PS 1 constructs containing different Alzheimer mutations were examined.

652.7

GENETIC DISSECTION OF PRESENILIN FUNCTIONS IN A NEURONAL PRECURSOR CELL LINE.

Chang-Sook Hong and Edward H. Koo*, Harvard Medical School, Center for Neurologic Diseases and Brigham and Women's Hospital, Boston, MA 02115

A number of missense mutations of Presenilin-1 and 2 genes (PS1 and PS2) have been identified from the familial form of Alzheimer's disease (AD). Based on their autosomal dominant transmission trait, an abnormal gain-of-function has been suggested to be the mechanism by which these mutations result in AD. However, the normal biological role of PS gene products are unclear. To understand the physiological functions of PS1 gene, we have used molecular and genetic approaches in a human neuronal precursor cell line (NT2) by expression of PS1 antisense construct in stably transfected cells. The NT2 cell line differentiates into postmitotic neurons by retinoic acid. Following antibiotic selection, the transfected NT2 cell lines showed apparently normal growing characteristics in the undifferentiated state. However, several cell lines expressing the antisense PS1 construct have increased cell death during the early period of retinoic acid induction. After two weeks, there are few, if any, differentiated neurons and all surviving cells share an epithelial type morphology. In addition, the cells showed higher amount of DNA laddering in both uninduced and induced states, suggesting an apoptotic mechanism. In normal NT2 cells, PS1 mRNA levels are increased during early retinoic acid induction, indicating that PS1 have functions for neuronal differentiation and/or cell survival. We are currently studying the critical differentiation stage in which PS1 gene expression is required by using an inducible promoter system and whether the defective phenotype can be rescued by overexpression of PS2 or other genes that have been known to affect the programmed cell death. Supported by grants from AFAR (Beeson Award) and Alzheimer's Association

652.8

TRANSCRIPTIONAL REGULATION OF THE PRESENILIN GENES.

K. R. Pennypacker* Dept. of Pharmacology, Univ. of S. Florida, Tampa, FL 33612.

The presenilin (PS) genes 1 and 2 have been linked to the onset of Alzheimer's disease, although their exact role is unknown. The genetic mutations within these genes suggest translation of an errant amino acid sequence alters the protein's structure to produce negative consequences. Other factors, such as aberrant regulation at the genomic level, may contribute to the etiology of this disease. We have identified the putative promoter of the PS-2 gene and it contains several GC-rich recognition sites (AP-2 and SP1) indicative of a GC box promoter within the first 100 bases upstream from the putative start site. Computer analysis has revealed several other potential regulatory sites, such as AP-1, whose function will be determined by deletional analysis. Electrophoretic mobility shift assay and DNA footprinting will be used to characterize the transcription factor binding sites. A better understanding of the regulation of the PS-2 and eventually the PS-1 gene will give us insight into the function of these proteins and their role in Alzheimer's disease.

652.9

THE MOLECULAR BIOLOGY OF THE PRESENILINS. J. Pérez-Tur*, M. Hutton, J. Hardy and the Alzheimer's Disease Collaborative Group. Suncoast Alzheimer Disease Research Laboratories. University of South Florida. TAMPA (USA)

Three genes cause familial early onset Alzheimer's disease when mutated. Of these genes, APP mutations acounts for less than 5% of familial cases whereas the importance of the other two genes, Presenilin-1 and Presenilin-2, is not estimated at present, PS-1 mutations will be responsible for most cases with an age at onset below 45. In order to investigate our own series of early-onset AD families for mutations we first elucidated the intron/exon structure of both Presenilin genes.

Intronic primers were designed that flanked the coding exons in both PS-1 and PS-2 to allow each exon to be amplified from patient genomic DNA. By direct sequencing of the amplified exons we have now identified a total of 10 mutations in PS-1 in 12 families. These mutations include 9 missense mutations and a unique splice acceptor site mutation that results in the deletion of exon 9 from the mutant mRNA. A total of 6 families, in our dataset, with early-onset AD do not have mutations in the PS-1 gene and these are currently being screened for mutations in the PS-2 gene.

In addition we examined each gene for alternate splicing events. PS-1 and PS-2 are both subjected to alternate splicing although to a different extent. PS-1 shows the alternative use of two splice donor sites at the end of exon 3, resulting in the presence or absence of four residues in the final protein (residues 26-29). PS2 shows two other transcripts in addition to the full-length. mRNA One of these forms splices out exons 3 and 4 and thus lack the start Methionine and part of TM-1. In addition, the new start for the protein should be placed in the middle of TM-2, after the site affected by the Volgan-German mutation. The last splice event observed was the splicing out of exon 8.

652.10

GENETIC RISK FACTORS FOR LATE-ONSET ALZHEIMER'S DISEASE. F. Wavrant-De Vrièze[1], J. Pérez-Tur[1,2], J.-C. Lambert[1], M.-J. Dupire[1], B. Frigard[3], P. Vermersch[1,4], H. Petit[4], F. Pasquier[4], A. Delacourte[1] and M.-C. Chartier-Harlin[1]*. 1 Unité INSERM 422, F 59045 Lille CEDEX.; 2 Suncoast AD lab., University of South Florida, Tampa F 33613-4788 USA; 3 Centre de Gériatrie, Wasquehal F 59 290; 4 Clinique Neurologique, CHRU F 59037 Lille Cedex.

Most of the Alzheimer's patients develop the disease after 60 years old (late-onset Alzheimer's disease, LOAD). To date, associations between LOAD and polymorphisms in 4 genes have been described : 1) the ε4 allele of apolipoprotein E influences at least 40% of the LOAD cases. 2) the presenilin -1 gene, gene responsible for at least 60% of early-onset FAD, also presents an intronic polymorphism involved to a much lesser extent in LOAD. 3) the alpha-1 antichymotrypsin and 4) the VLDL receptor polymorphisms are also suspected to modulate the development of LOAD.

We are comparing the allele frequencies of these polymorphisms in a French LOAD population of 147 cases (mean age of onset 73 years) to 78 controls (mean age 71) using the same primers and conditions described in the original reports. We have performed the analyses of the apolipoprotein E and the presenilin 1 polymorphisms. The analysis of the alpha-1 antichymotrypsin polymorphism is under investigation and the VLDL receptor will be next carried out.

Our findings indicate that the ε4 allele is an important risk factor for this French LOAD population, but do not support a role of the intronic PS-1 polymorphism as risk factor. It is possible that this polymorphism affects some population while in others the disease could be the result of interaction between different risk factors. Analyses of the other polymorphisms will help to elucidate this hypothesis.

Alzheimer's disease (AD) is the most common cause of dementia. Several factors including genetic factors have been identified that may initiate or accelerate AD pathogenesis. Among genetic factors, S182 (presenilin-1) harbours an estimated 70% of the disease-causing mutations of familial early onset form of AD (estimate 10% of all AD cases). To analyze the function(s) of this gene, we have cloned rat S182.

Rat S182 cDNA encoded 468 amino acids (aa) and the deduced aa sequence was highly homologous to those of the human (88.4%) and mouse (92.7%). Moreover, all amino acids, substitutions of which have been reported to cause familial early onset form of AD in humans were conserved in rats. Northern blot analysis of the rat S182 cDNA revealed two mRNA species in rat neural and glial cell lines (PC-12 and C6, respectively) and one mRNA in mouse fibroblast cell lines (NIH3T3 and Swiss3T3). RT-PCR analysis showed ubiquitous expression of S182 in rat organs examined (such as brain, liver, spleen, kidney, lung, heart, thyroid, thymus and testis).

The cloned rat S182 cDNA should provide an atractive system to clarify the function(s) of S182.

Transgenic mice expressing human PS-1 transgenes.

C. Zehr, M. Gordon and K. Duff* Departments of Psychiatry, Pharmacology and Biochemistry, University of South Florida Tampa, Fla. 33613.
Email: kduff@com1.med.usf.edu, Tel. 813 979 3553

Several lines of transgenic mice have been created which carry cDNA constructs for presenilin 1 (PS-1). Expression of the transgene is under the control of the PDGF βII promoter which directs high level expression to neurons in the brain. cDNAs carrying a range of pathogenic mutations (M146V, M146L, E120K, exon 9 deletion) have been generated. To increase expression levels, two different introns have been included in some constructs. These include a chimeric globin intron inserted into the 5' UTR and the PS-1 intron 5 located between exons 4 and 5. The importance of these introns will be discussed. The mice have been engineered by standard pronuclear microinjection into single cell embryos from the hybrid strain Swiss Webster x B6D2F1. The first lines of mice carrying a basic PDGF/wild type PS-1 cDNA (no introns) shows levels of transgene mRNA expression greater than endogenous. Lines of mice carrying mutant APP cDNA constructs under the control of the PDGF promoter with and without introns are also underway. Progress towards analysis of these mice will be discussed.

ALZHEIMER'S DISEASE: PRESENILIN CELL BIOLOGY II

653.1

A NOVEL TRANSCRIPT OF THE ALZHEIMER'S DISEASE PRESENILIN 1 GENE (S182) CODING FOR A PROTEIN WITH A VARIANT N-TERMINUS

J.C. Chisholm*, B. Drache, G. König, and J.N. Davis II Inst. for Dementia Research, Bayer Corp., 400 Morgan Lane, West Haven, CT, 06516.

Several missense mutations of the presenilin 1 gene (PS1), located on chromosome 14q24.3, have been identified which are sufficient to cause an early-onset autosomal dominant form of Alzheimer's disease. Initial analysis of transcripts of this gene indicated that the longest open reading frame coded for a protein 467 amino acids in length ($PS1_{467}$)[1] , however a number of alternatively spliced transcripts have subsequently been reported which code for shorter proteins[2,3,4]. We have identified a novel transcript of PS1 from an aged human brain cDNA library, which codes for a 429 amino acid protein ($PS1_{429}$). $PS1_{429}$ differs from the $PS1_{467}$ protein in that the N-terminal 57 amino acids of $PS1_{467}$ have been "replaced" by 19 alternative amino acids in $PS1_{429}$. RT-PCR analysis of RNA using $PS1_{429}$ splice specific primers indicates that this transcript exists in polyadenylated RNA from all tissues tested, including brain, lung, kidney, and testis. This suggests that $PS1_{429}$ like $PS1_{467}$ is "ubiquitously" expressed. A homology search of protein N-termini using FASTA found a weak homology between the 19 N-terminal amino acids of $PS1_{429}$ and a number of other N-termini which included the cytochrome c oxidase subunit III from *Leishmania tarentolae* and the neuroendocrine convertase 2 precursor (EC 3.4.21.61) from both mouse and human.

THE ~30kDa PUTATIVE N-TERMINAL FRAGMENT OF THE PRESENILIN 1 PROTEIN IS A MAJOR PRESENILIN 1 SPECIES IN CLATHRIN COATED AND SMALL SYNAPTIC VESICLE PREPARATIONS.

S. Gandy,*[1,2] M. Seeger,[2] S. Hilfiker,[2] A. Czernik,[2] G. Thinakaran,[4] J.Ghiso,[5] D. Kovacs,[3] C. Nordstedt,[7] W. Wasco,[3] B. Frangione,[5] P. Fraser,[6] P. St. G. Hyslop,[6] R. Tanzi,[3] S. Sisodia,[4] P. Greengard,[2] and S. Petanceska[2]; [1]Cornell Univ. Med. Coll., [2]Rockefeller Univ., [3]Harvard Med. Sch., [4]Johns Hopkins Univ. Med. Sch., [5]NYU Med. Ctr., USA, [6]Univ. of Toronto, Canada and [7]Karolinska Institute, Sweden.

The majority of cases of early onset familial Alzheimer's disease associates with mutations in the presenilin 1 (PS1) gene. Using a highly specific polyclonal antibody (α14), raised against the N-terminus of the human PS1 protein, we determined the relative levels of PS1 protein in fractions from a standard small synaptic vesicle (SSV) preparation from rat brain cortex and in bovine clathrin coated vesicles (CCV). By Western blot analysis, the antibody specifically recognizes two immunoreactive species of ~45kDa and ~30kDa in both preparations. The ~30kDa immunoreactive species represents a putative N-terminal fragment of the PS1 holoprotein. This is a preponderant PS1 species as compared with the ~45kDa putative PS1 holoprotein. The ~30kDa N-terminal PS1 fragment segregates with the membranous fractions of the preparations and cannot be detected in high speed supernatants. After treatment of membranous fractions with proteinase K in the absence of detergent, we failed to detect either the ~30kDa or the ~45 kDa species suggesting that the N-terminus of the PS1 protein is cytoplasmic. The cofractionation of the ~30kDa PS1 N-terminal fragment with the amyloid precursor protein, synaptophysin and/or BiP, as well as the relevance of the putative PKC, PKA and casein kinase II phosphorylation sites in PS1, are under investigation.

653.3

ALZHEIMER'S PS-1 L286V MUTATION INCREASES NEURONAL VULNERABILITY TO Aβ TOXICITY AND TROPHIC FACTOR WITHDRAWAL-INDUCED APOPTOSIS. Q. Guo*, B.L. Sopher, K. Furukawa, N. Robinson, G.M. Martin, and M.P. Mattson. Sanders-Brown Research Center on Aging, Univ. of Kentucky, Lexington KY 40536. Dept. of Pathology, Univ. of Washington, Seattle, WA 98195.

Two presenilin genes (PS-1, S182) and presenilin-2(PS-2, STM2) linked to early onset inherited forms of Alzheimer's disease were recently identified on chromosomes 14 and 1, respectively. Sequence predictions and hydropathy analyses suggest that both PS-1 and PS-2 are integral membrane proteins with 7-9 transmembrane domains; proteins with such structure may function as receptors and ion channels, or in protein trafficking within cells. It was recently shown that the PS1 and PS2 are localized to intracellular compartments (endoplasmic reticulum and Golgi complex). The mechanism by which PS-1 mutations promote neuronal degeneration in AD are unknown. One possibility being examined in other labs is that the PS mutations promote production of amyloidogenic Aβ isoforms. Here we show that expression of a mutant PS-1 gene (L286V) in neuronal cells results in a marked increase in cell vulnerability to amyloid β–peptide (Aβ) toxicity and apoptosis induced by withdrawal of trophic factors. The mechanism underlying the endangering actions of PS-1 L286V involves increased oxidative stress and disruption of calcium homeostasis. Thus, Aβ induced greater increases of intracellular hydrogen peroxide and Ca^{2+} levels in L286V-expressing cells than in untransfected and vector-transfected cells. Antioxidants and calcium channel blockers counteracted the adverse consequences of the PS-1 mutation. Immunolocalization studies indicate that PS-1 protein is concentrated in subcellular compartments in a perinuclear distribution. We are currently attempting to localize the site at which the L286V mutation disrupts calcium homeostasis (i.e., influx, uptake/release from ER, or mitochondrial regulation) (supported by the NIH and the Alzheimer's Association).

IMMUNOLOGICAL CHARACTERIZATION OF *PRESENILIN-1* IN BRAIN EXTRACTS AND NEURON SPECIFIC EXPRESSION IN CELL CULTURES. J.M.Johnston*[1], N.Tezapsidis, J.Shioi, H.-C.Li[2], G.A.Elder, and N.K. Robakis. Departments of Psychiatry and Biochemistry[2], Mt Sinai School of Medicine, New York, NY 10029 and Neurosurgery[1], Montefiore Medical Center, A.Einstein College of Medicine, Bronx, NY 10461

We studied the expression of PS-1 by Western blotting and immunocytochemistry using affinity purified polyclonal antibodies. Specificity of the antibodies was confirmed by their ability to recognize recombinant PS-1 expressed as a fusion protein in *E. Coli* and competition of the signal by the antigenic peptide. In human brain, PS-1 with an apparent molecular weight of 50-52 kDa was expressed in all regions examined as a membrane protein with no substantial regional differences. A similar band was detected by W.B. in adult and embryonic rat brain. PS-1 was abundant in E14 embryonic rat mesencephalic extracts. Primary neural cultures derived from that region stained with the anti-PS-1 antibody in a neuron-specific manner. GFAP-positive cells (astrocytes) failed to stain markedly for PS-1. The subcellular distribution of PS-1 immunoreactivity in neurons, resembled that of MAP2, a marker for dendrites and to a lesser extent that of tau. In agreement, cell lines of neuronal origin (N2A, SY5Y, and NGF-induced PC12 cells) stained with the anti-PS-1 antibody, whereas non-neuronal cell-lines (COS, 293 or CHO) stained very poorly (see also other abstracts from the same authors). These findings are consistent with the suggestion that the FAD mutations on PS-1 may have a direct effect on neurons during the development of the disease. (Supported by NIH grants AG08200 and AG05138).

653.5

EXPRESSION OF VARIOUS FORMS OF PRESENILIN-1 IN PRIMARY NEURONS USING SEMLIKI FOREST VIRUS. J.C. Richardson, L. Harrington, P.M. Taylor, K. Lundstrom, G. Higgins*, J.C. Barnes and H.T.R. Rupniak. Neuroscience Unit, GlaxoWellcome Medicines Research Centre, Stevenage, Herts., SG1 2NY, England, U.K.

Mutations of the presenilin-1 (PS-1) gene at the Familial Alzheimer's Disease 3 (FAD3) locus on chromosome 14q24.3 are responsible for the majority of familial early-onset AD. To aid in localisation studies and overexpression studies in primary neurons several variants of the PS-1 gene have been genetically engineered to incorporate a haemagglutinin (HA) epitope tag at the very end of the C-terminus of the PS-1 protein.

These clones, which include the two alternatively spliced forms (+/- VRSQ motif) and mutations in (M146V) and out (H163R) of the transmembrane region, have been subsequently cloned into the Semliki forest virus (SFV) vector and recombinant SFV particles generated. Chinese hamster ovary (CHO) cells and primary neurons were infected with SFV-PS-1 virus stocks and subsequent Western blot analysis demonstrated the presence of a 50kD protein (which corresponds to the predicted molecular weight of the translated open reading frame) identified by an antibody (12CA5) to the HA epitope tag. The SFV system will thus be useful in studying the immunolocalisation of PS-1 in primary neuronal cells. In view of Younkin's observations (Scheuner et al., 1995: Soc. Neurosci. Abstr. **21**, 1500), who showed that certain mutations in PS-1 lead to increased production of amyloid β-protein 42 (Aβ42) in fibroblasts and plasma from affected and at-risk carriers, the SFV system could also be used to determine the effect of overexpressing mutant PS-1 on APP processing.

653.6

WILD TYPE AND MUTANT PRESENILIN-1 EXPRESSION IN A CNS-DERIVED NEURONAL CELL LINE Y. Sun and D. M. Holtzman*. Dept. of Neurology, Molecular Biology & Pharmacology, and Center for the Study of Nervous System Injury, Washington University School of Medicine, St. Louis, MO 63110.

Mutations in the presenilin-1 (PS-1) gene, initially termed S182, are associated with an early onset form of familial Alzheimer's disease. There is evidence to suggest that PS-1 is expressed in many cell types including neurons. In order to better understand the potential function of normal and mutant PS-1 protein in neurons, we have begun to establish stable clones of GT1-7 cells expressing wild type and mutant human PS-1 proteins. GT1-7 cells are an immortalized murine hypothalamic neuronal cell line. We have found that GT1 cells express endogenous PS-1 mRNA and protein and that increased neuronal differentiation appears to increase expression of endogenous PS-1. Our evidence also suggests that wild type and mutant human PS-1 protein can be stably overexpressed in these cells. This should allow us to examine the effect of PS-1 expression on a variety of neuronal properties as well as on cell survival. 653.7

EXPRESSION OF PRESENILIN mRNAs IN THE CELL LINE NTera2 S. K. Green[1]*, S. M. Bowes[2], P. R. Heath[1], D. Parkinson[2] and R. C. A. Pearson[1]. [1]Dept. of Biomedical Science, University of Sheffield, S10 2TN, UK. and [2]Dept. of Biomedical Science, Sheffield Hallam University, S1 1WB, UK.

Mutations in the presenilin genes (PS1 and PS2, formerly S182 and STM2) are responsible for a large percentage of cases of familial Alzheimer's disease. Hence, the presenilins are implicated in the pathology of Alzheimer's disease, possibly by interaction with amyloid precursor protein (APP).

The NT2 cell line can be differentiated into a neuronal phenotype by treatment with retinoic acid (NT2N). Previous work has shown that expression of APP isoforms changes during differentiation. The expression of APP and presenilins was studied in NT2 stem cells, at different stages of differentiation, and in pure neuronal cultures. Cells were cultured and harvested at various stages during differentiation. Total RNA was isolated using Trizol reagent (Gibco-BRL) and specific mRNAs detected by Northern analysis and S1 Nuclease Protection Assays. Probes were designed to detect PS1, PS2 and differentially spliced APP mRNAs.

During stem cell differentiation, there was a change in expression of APP isoforms: APP_{695} and APP_{751} mRNAs were increased. PS1 mRNA was detected in NT2 stem cells and increased in differentiated cells and pure neuronal cultures. PS2 mRNA was of very low abundance. These changes in APP and PS1 expression suggest that both genes may be under similar control and regulated by similar factors. Furthermore, NT2 stem cells and NT2N neurones are suitable for the study of the presenilins and their interaction with APP and APP processing. *Supported* by The Wellcome Trust.

653.8

EXPRESSION OF PRESENILINS IN TRANSFECTED CELLS. L. Pradier*, C. Czech, L. Delalonde, J. Le Guern, N. Clavel, L. Mercken, F.Revah and B. Tocqué. Rhône-Poulenc Rorer, 94400 Vitry, France

Mutations in S182 and STM2 (presenilins, PS) genes have been recently discovered in familial forms of early-onset Alzheimer's Disease. Along with APP and ApoE, elucidating the role of these two new genes should shed new light on the pathophysiological mechanism of AD. In order to study the function of presenilins, we recloned both genes and introduced the mutations observed in FAD patients. Following results of initial in vitro translation studies, the coding sequences for both proteins were further subcloned between the 5' and 3' untranslated regions (UTR) of the β-globin gene. COS1 cells were transfected with these constructs. Expression of both proteins was detected by immunoprecipitation with antibodies generated against specific peptides (Moussaoui et al.,1996, *FEBS Letters* **383**: 219). Both S182 and STM2 proteins had the same molecular weight (50 and 55kD respectively) as for in vitro translated material suggesting the absence of posttranslational modifications. Heat-denaturation of proteins leads to the presence of a smear of large molecular weight indicating aggregation. We are currently analyzing the impact of PS expression on protein sorting in transient and stable transfected cells, using vaious reporter proteins targetted to different cellular compartments and APP. Source of support: internal Rhône-Poulenc Rorer program.

653.9

PRESENILINS IN CULTURED CELLS AND ALZHEIMER'S DISEASE BRAIN. T.Y. Chu, F. Yang, B.X. Carlson*, S.A. Frautschy and G.M. Cole. Sepulveda VAMC, GRECC 11E, Sepulveda, CA 91343 and Depts of Medicine and Neurology, UCLA, Los Angeles, CA 90095

The recently discovered presenilins (PS 1 and PS 2) contain mutations in 60% of early Alzheimer's disease (AD) cases. These proteins appear to span the membrane seven times, but their function(s) and distribution are unknown. We have developed polyclonal antisera to three different epitopes of PS: the N-terminus, the large loop domain, and the C-terminus and characterized them on cultured cells and AD brain. In Western blot analysis of AD brain, the C-terminus antibody specifically labeled 43 kD and 17 kD bands. Only the 43 kD band was present in human synaptosome preparations. Immunohistochemical analysis showed that this C-terminal antibody immunolocalized to cell processes of selected neuritic plaques of AD hippocampus. The antibody against N-terminal and large loop domains detected 43 and 28 kD bands in immunoprecipitates of ^{35}S labeled-differentiated human neuroblastoma cells in culture, but immunohistochemically did not label specific structures in AD brain. The antibodies to N-terminus and large loop domain immunoprecipitated a 43-45 kD doublet and showed ER, Golgi and possible lysosomal staining in PS-1 transfected COS cells. In alcohol-fixed mixed cultures from human fetal brain the antibodies labeled both neurons and glia, but this staining was not found in routine formalin fixed human brain.

We are investigating the functions of presenilins and the presenilin response to drug treatments in cultured cells. We have developed sensitive amyloid ß protein (Aß) 40 and 42 sandwich ELISAs to characterize the modulation of Aß release by PS in PS-1 transfected cells. Our earlier immunoprecipitation data that indicated no increase in total Aß from presenilin-linked AD fibroblast disagreed with the recently reported hypersecretion of Aß40 and Aß42 in presenilin-linked familial AD. We will further investigate the secretion of Aß40 and 42 in presenilin-linked familial AD.

653.10

EXPRESSION OF THE ALZHEIMER'S DISEASE RELATED PRESENILIN-1 cDNA VARIANTS IN HUMAN NEUROBLASTOMA CELLS. L. Hendriks [1], C. De Jonghe[1], U. Lübke[2], S. Woodrow[1], I. Vanderhoeven[1], J.J. Martin[2], C. Van Broeckhoven*. Laboratory of Neurogenetics[1], Flanders Interuniversity Institute for Biotechnology, Laboratory of Neuropathology[2], Born-Bunge Foundation[1,2], University of Antwerp (UIA), Antwerp, Belgium.

Alzheimer's disease (AD) is a neurodegenerative disease, pathologically characterized by the presence of neurofibrillary tangles and senile plaques in the brain of AD patients. Until now, 3 genes for early-onset AD (EOAD) have been identified: the amyloid precursor protein (APP) gene on chromosome 21, the presenilin-1 (PS-1) on chromosome 14 and a homologous presenilin-2 (PS-2) gene on chromosome 1. In 2 extended Belgium EOAD pedigrees, AD/A and AD/B, an Ile143Thr and a Gly348Ala substitution respectively have been identified in the PS-1 gene (Cruts et al, 1995, Hum. Molec. Genet, 4, 2363-2371).

We have cloned the wild-type PS-1 cDNA splicing variants, both with and without the VRSQ coding sequence, from an escapee of family AD/B. In addition, two "Belgium mutations" were introduced into the wild-type cDNA by oligo-mediated site-directed mutagenesis. Polyclonal antibodies were raised in rabbits against 3 different PS-1 epitopes. Immunocytochemistry on non-transfected human neuroblastoma SHSY-5Y cells localised PS-1 to the perinuclear zone. Transfected cells were also studied for the subcellular localisation of PS-1, as well as that of other AD-associated proteins. The protein expression levels of the different PS-1 cDNA variants was measured by metabolic labelling of cells and by western blotting. Preliminary studies showed that, although the PS-1 mRNA level was significantly higher in PS-1 cDNA transfected cells compared to mock transfected cells, as measured by a semi-quantitative RT-PCR assay, no upregulation of PS-1 protein expression was observed in transfected cells.

PRESENILIN-1 PROTEIN PROCESSING IN TRANSFECTED CELL LINES. J. Zhang, W. Xia, D. C. Anthony*, D. J. Selkoe, E. H. Koo. Center for Neurologic Diseases, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115.

The mutations in the presenilin-1 gene (PS1) located on chromosome 14 are the major cause of early onset familial Alzheimer's disease. The biological function of PS1 protein is unknown. PS1 is believed to be an endoplasmic reticulum (ER) localized membrane protein. In Chinese hamster ovary (CHO) cells stably transfected with full length PS1 cDNA, PS1 protein is expressed as a 43-45 kDa doublet on SDS-PAGE by immunoprecipitation and Western blotting with both N- and C-terminal specific antibodies. Interestingly, both species of the doublet appeared coincidentally in pulse chase studies and begin at the first methionine residue by radio-sequencing, as reported in a companion abstract. PS1 protein expressed in CHO stables showed no evidence of glycosylation or sulfation as determined by tunicamycin and glycosidase treatments, and sulfate labeling. The half-life of full length PS1 protein in stably transfected CHO cells was less than 1 hour. Brefeldin A treatment did not alter this rapid turnover rate. There was no difference in half-life between wildtype and mutant (M146L, C410Y) PS1 proteins. Ammonium chloride and leupeptin treatment did not change the short half-life of full length PS1, indicating that an acidic compartment is not involved in the rapid turnover of PS1. There was little to no detectable full length endogenous PS1 in CHO, NT2, Hela, and COS cell lines. However, stable fragments of PS1 were seen in these cells as ~30 kDa N-terminal and ~18 kDa C-terminal species. These polypeptides were also found in higher levels in PS1 transfected CHO cells. Our data suggest that PS1 proteins do not undergo further Golgi processing and may be degraded in the ER to stable fragments. Finally, the turnover rate of amyloid precursor protein (APP) was not affected by overexpression of wild type or mutant PS1 in CHO cells stably transfected with both APP and PS1. Supported by AG12376 (EHK).

DETECTION OF CLEAVED PRESENILIN-1 (PS-1) IN PS-1 TRANSFECTED AND NON-TRANSFECTED NEUROBLASTOMA CELLS.

R.V.Ward, C.W.Gray, J.B.Davis*, M.Caivano, L.Bresciani, M.Hutton°, K. Duff °, J.Hardy°, G.W.Roberts, E.H.Karran

Molecular Neuropathology, SmithKline Beecham, Harlow, Essex CM19 5AW, UK; °Suncoast Alzheimer's Disease Laboratories, University of South Florida, Tampa, FL33613,USA.

A number of point mutations in the presenilin-1 gene on chromosome 14 currently accounts for greater than 75% of cases of familial Alzheimer's disease (AD). Post mortem examination of brains of these cases reveals very similar pathology to sporadic AD brains. Western blot analysis of the neuroblastoma cell line SHSY5Y with polyclonal antibodies raised to the N-terminal region and the C-terminal region of PS-1 has revealed that the full length PS-1 (43-46kDa) is cleaved to lower molecular weight forms. The N-terminal specific antibody detects a 28kDa form, whereas the C-terminal specific antibody detects an 18kDa form. Transfection of SHSY5Y cells with PS-1 resulted in the detection of a 46kDa band that was absent in the control cells and an increase in the intensity of the 28kDa and 18kDa bands. Western blot analysis of a number of non-transfected neuroblastoma cell lines reveals that the majority of PS-1 detected was in these lower molecular weight forms. These data suggest that PS-1 is cleaved by an as yet unidentified proteolytic activity (Presenilinase).

This work was funded by SmithKline Beecham Plc.

Presenilin-1 A/E mutation alters calcium signaling in cultured cell lines. V.P.Bindokas*, S.S.Sisodia[†], M.K.Lee[†], I.Trowbridge[‡], A.Lai[‡], G.D.Ghadge[‡‡], R.P.Roos[‡‡], J.Jordán, and R.J.Miller. Dept. Pharmacol. and Physiol. Sci., [‡‡]Dept. Neurology; Univ. Chicago, 947 E. 58th St. Chicago IL 60637; [‡]Salk Institute; [†]Dept. Pathology, Johns Hopkins Univ.

Mutations in presenilin (PS) proteins have been linked to Alzheimer's disease. As PS is associated with intracellular membranes, we examined the possibility that mutated PS might disturb cellular Ca homeostasis and contribute to neurodegeneration. MDCK and N2A neuroblastoma cells were stably transfected to express wild-type (WT PS1) or A/E mutant presenilin-1 (A/E PS1). Transfected cells displayed no gross differences in viability or morphology. However, A/E PS1 cells often tended to have distended nuclei. Mitochondrial potential assessed by tetramethylrhodamine methyl ester fluorescence was similar in parental, WT and A/E PS1 lines. [Ca^{2+}]i was monitored by digital imaging microfluorimetry of fura-2AM loaded cells. A/E PS1 MDCK and N2A cells displayed significantly increased [Ca]i elevations following bradykinin and FCCP applications compared to WT cells. WT PS1 cells were statistically similar to parental lines. The increased amplitude of the [Ca]i transients suggested that intracellular Ca release was enhanced in A/E PS1 cells. However, the Ca released from stores by thapsigargin was not significantly different. We have also transfected rat hippocampal neurons with WT and A/E PS1 by means of adenoviral vectors and are presently examining the effects on [Ca]i signaling. These preliminary observations suggest that PS1 mutations may disrupt cellular Ca homeostasis and thereby lead to neurodegeneration. Support via grants NIH DA-02575, DA-02121, MH-40165, and NS-33502 to RJM.

LOSS OF BDNF PRECEDES APOPTOSIS OF CA1 NEURONS AFTER HYPOXIA-ISCHEMIA. M. Dragunow,* M Walton, Q Yan, D Young, P Lawlor, B Connor, E Sirimanne, C Williams, and P Gluckman. Department of Pharmacology and Research Center for Developmental Medicine and Biology, University of Auckland, Auckland, New Zealand, and Amgen, Thousand Oaks, California, USA.

We analysed the expression of BDNF protein in rat hippocampus at different times following hypoxia-ischemia (HI). We have previously demonstrated that CA1 neurons undergo apoptosis whereas dentate granule cells survive this insult (Mol Brain Res 29, 1, 1995). Additionally, CA1 neurons dying through apoptosis express c-Jun starting at 24 hrs after HI (Mol Brain Res 25, 19, 1994), and this might be critical in causing apoptotic nerve cell death (Brain Res Revs 21, 1, 1995). In the present study we found that levels of BDNF fell in CA1 neurons by 12 hrs after HI whereas BDNF levels increased in dentate granule cells. TrkB full-length levels also fell in CA1 neurons suggesting that loss of BDNF and its receptor might trigger Jun-mediated apoptosis in CA1 neurons after HI. Furthermore, increased BDNF production might be responsible for the survival of dentate granule cells after HI.

654.2

DEPOLARIZATION THRESHOLD FOR BDNF mRNA INDUCTION AFTER ISCHEMIA. T. Sorimachi, H. Abe and T. S. Nowak, Jr.* Dept. of Neurology, University of Tennessee, Memphis, TN 38163.

Brain-derived neurotrophic factor (BDNF) is reported to be neuroprotective in models of cerebral ischemia. Levels of BDNF mRNA are also increased after ischemic insults, suggesting that BDNF could contribute to the protection observed in models of induced ischemic tolerance. Previous studies used DC potential recording to demonstrate that several immediate-early genes are induced at depolarization thresholds identical to that observed for induction of tolerance. In the present study we evaluated the depolarization threshold for BDNF mRNA induction. Ischemia was produced by bilateral carotid artery occlusion in halothane-anesthetized gerbils fixed in a stereotaxic frame, and bilateral hippocampal DC potentials were recorded via glass microelectrodes. Depolarizations of 50-330 sec were produced. Induced mRNAs were evaluated by in situ hybridization at 3 h recirculation. BDNF mRNA was present in control dentate granule cells and showed near-maximal induction at the shortest depolarizations studied. In contrast, BDNF was not induced in CA1 neurons after any depolarization interval evaluated. Ischemic tolerance is only observed after depolarizations longer than 90 sec, with maximal protection after priming insults of 150-200 sec. These results indicate that tolerance is not associated with prior BDNF induction in vulnerable neurons, and conversely that maximal BDNF expression in dentate gyrus occurs after insults insufficient to induce tolerance. Further, these studies demonstrate the utility of such threshold studies in evaluating candidate genes that may be involved in tolerance mechanisms.

SPREADING DEPRESSION MAY PROTECT FROM SUBSEQUENT ISCHEMIC DAMAGE BY INCREASING EXPRESSION OF NEUROTROPHIC FACTORS, K. Matsushima, R. Schmidt-Kastner and A.M.Hakim.* Neuroscience Research Institute, University of Ottawa, Ottawa, Ontario, Canada, K1H 8M5

Spreading depression (SD) applied to rat brain prior to the imposition of cerebral ischemia has been reported to be neuroprotective (Matsushima et al.: J.Cereb Blood Flow Metab. 16:221-226, 1996). As part of an extensive program to investigate the mechanisms by which this is accomplished, we determined the timing and cerebral distribution of neurotrophic mRNAs in normal rats following SD.

SD was generated by placing on the occipital dura a cotton wedge soaked in 0.3 M KCl for 2 hours. We have shown this to result in recurrent waves of cortical depolarization. The intervals after this procedure at which mRNAs for BDNF and bFGF were determined were: 0,3,12,24,72,and 196 hours. In situ hybridization with antisense oligonucleotide probes to BDNF mRNA and bFGF mRNA was used on coronal brain sections at three representative levels. Autoradiograms were evaluated for side-to-side differences of cortical signals using video-based image analysis.

Our data showed an increase in the expression of both neurotrophic factor mRNAs after KCl application with the following characteristics:1.BDNF mRNA signals increased with a maximum at 0 and declined to reach background level by 12 hours. 2. bFGF mRNA reached its peak at 24 hours and returned to background level by 72. 3. The cortical distribution of both mRNA species largely coincided with the brain region that is protected when focal ischemia is imposed on rat brain previously exposed to SD.

We conclude that upregulating the expression of neurotrophic factors may be one mechanism by which SD renders the brain more resistant to ischemic damage.

PATTERNS OF BDNF mRNA AND bFGF mRNA EXPRESSION IN GLOBAL OR FOCAL BRAIN ISCHEMIA IN RAT. R.Schmidt-Kastner *, N.Duggal, A.M.Hakim. Neuroscience Research Institute, Univ. of Ottawa, Ottawa, K1H 8M5, Ontario, Canada.

In brain ischemia, upregulation of trophic factor expression may indicate the activation of autoprotective mechanisms. Multiple trophic signals by neurons and glial cells may be needed for successful protection.

Global brain ischemia (GI) was induced by 20 min of four-vessel occlusion in halothane-anesthetized rats (survival from 1 h to 7 d). Focal ischemia (FI) was elicited in the middle cerebral artery territory using an intravascular filament, either transiently for 2 h (survival 0 h to 7 d) or permanently for 5 h to 1 d. In situ hybridization was carried with antisense oligonucleotide probes for BDNF and bFGF mRNAs on coronal sections.

In GI, BDNF mRNA increased strongly in granule cells, moderately in CA3 to CA1 of hippocampus and mildly in parietal cortex. bFGF mRNA increased first in the CA1 pyramidal cells and granule cells and then in glial cells. In transient FI, some increased BDNF mRNA signals were seen in the cingulate gyrus at 0 and 3 h recirculation. After permanent FI, strong induction of BDNF mRNA was initially seen in parietal and cingulate cortex at 5 h, and then became restricted to cingulate cortex at later stages. bFGF mRNA hybridization decreased in ischemic tissue.

CA1 neurons are capable of upregulating trophic factor expression after GI which may prolong their survival. FI induced BDNF mRNA expression outside the ischemic cortical area suggests a role for perifocal depolarization. Thus, energy deprivation alone may not be a sufficient stimulus for increased BDNF mRNA expression, and enhanced excitation and repeated depolarizations are required.

BASIC FIBROBLAST GROWTH FACTOR (bFGF) PROTECTS FOCAL ISCHEMIA BY BLOOD FLOW INDEPENDENT MECHANISM IN MICE. Z. Huang, S.P. Finklestein, P.L. Huang, G. Bove*, K. Chen and M.A. Moskowitz. Depts. Neurology, Neurosurgery and Medicine, Massachusetts General Hosp. and Harvard Medical School, Charlestown, MA 02129

We previously showed that bFGF administration reduced infarct volume after middle cerebral artery (MCA) occlusion, as well as dilated cerebral blood vessels by nitro-L-arginine reversible mechanisms. To test the hypothesis that bFGF might directly protect neurons without affecting regional cerebral blood flow (rCBF) during ischemia, we examined blood flow and infarct volume in mice dificient in endothelial nitric oxide synthase (eNOS) gene expression. Halothane - anesthetized eNOS knockout and wild type mice were subjected to MCA occlusion by intraluminal filament for 24 hrs. bFGF (100 µg/kg/hr) was infused intravenously for 2 hr, beginning at 15 min after the onset of ischemia. Infarct volume was reduced from 119 ± 8 to 93 ± 4 mm^3 ($p<0.05$) or from 102 ± 9 to 77 ± 6 mm^3 ($p<0.05$) in eNOS knockout or wild type mice respectively, as compared to vehicle treated animals (n=10 in each group). Neurological deficits were also significantly reduced after bFGF administration in both groups. While bFGF showed a 27% rCBF increase and 17% resistance reduction in the infarct margin of wild type animals (laser Doppler flowmetry), bFGF did not enhance blood flow in the ischemic zone of eNOS mutant mice. There were no differences in blood pressure, blood gases or core temperature between groups. These data indicate that bFGF affords protection in brain ischemia in mice primarily by blood flow-independent mechanisms.

Studies were supported by the Massachusetts General Hospital Interdepartmental Stroke Program Project NS10828 (MAM).

aFGF AND bFGF ARE EQUIPOTENT IN PREVENTING HIPPOCAMPAL ISCHEMIC CELL DEATH. C. S. Melton and J. N. Davis*. Northport VA Medical Center, Northport, NY and the Dept. of Neurology, SUNY at Stony Brook, Stony Brook, NY 11794.

Both acidic and basic fibroblast growth factor (aFGF and bFGF) protect neurons from hypoxic or hypoglycemic insults *in vitro* and from ischemia *in vivo*. We compared the abilities of these two factors to prevent CA_1 ischemic cell death in gerbils. Male Mongolian gerbils had osmotic pumps surgically implanted and either aFGF, bFGF, or artificial CSF continuously infused into the left lateral ventricle at rates of 0.3, 1, 3, 10, 30, or 100 ng/hr. Body temperature was monitored in the alert, freely-moving animal using an implanted thermistor. The following day, gerbils underwent 5 minutes of bilateral carotid occlusion under halothane anesthesia and were sacrificed by intracardiac perfusion with paraformaldehyde 5 days later. Paraffin-embedded sections of brain were stained for Nissl substance and CA_1 neurons were manually counted. CA_1 length was measured using an image analysis system (JAVA).

Both aFGF and bFGF prevented approximately 25% of the cell death seen in animals infused with CSF at all rates of infusion ($p<0.05$; ANOVA). There was no difference in the amount of protection as the rate was increased. In addition to preventing cell death, both FGF's reversed a behavioral measure of ischemic damage. These results show that both aFGF and bFGF are extraordinarily potent and could explain why intravenous infusions of bFGF are effective even though only small amounts of the factor cross the blood-brain barrier. (Supported by the Department of Veterans Affairs)

ICV PRETREATMENT WITH GDNF REDUCES INFARCT VOLUME IN A RAT MODEL OF TRANSIENT MIDDLE CEREBRAL ARTERY OCCLUSION, L.R. Williams*, G. Inouye, V. Cummins, and C. Du. Dept. Neurosci., Amgen, Inc., Thousand Oaks, CA 91360, and The Center for the Study of Nervous System Injury, Washington Univ., St. Louis, MO.

GDNF is a recently discovered protein identified and purified based upon its neurotrophic efficacy for mesencephalic dopaminergic neurons. Recent in vitro experiments have indicated that GDNF is also neurotrophic for cerebral cortical neurons, and protective against ischemia-related stress. In the present experiments, we tested the ability of GDNF to protect cortical neurons in vivo and to reduce infarct volume in a model of transient cerebral ischemia. Long Evans male rats were pretreated icv with vehicle (n = 12) or GDNF (10 µg/day for 3-5 days, n = 14) through a cannula connected to an Alzet pump. Non-fasted animals received an occlusion of the MCA using a microaneurysm clip in a procedure modified from Du et al. Blood pressure, gases, and glucose were monitored throughout the procedure. Body temperature was maintained at 37°C with a recirculating pad and heat lamp controlled by an intrarectal thermocouple. After 90 min. of MCA occlusion, the clip was removed and the MCA allowed to reperfuse. After 24 hrs of reperfusion, the rats were sacrificed, and the brains were processed for TTC histochemistry and indirect measurement of infarct volume using computer assisted morphometry. GDNF pretreatment resulted in a significant 30% reduction in infarct volume ($\rho<0.01$). The GDNF icv pretreatment affected animal physiology: animals lost weight, had elevated blood pressure (105 versus 93 mm Hg in controls), and were less responsive to the surgical stress - induced elevation in plasma glucose observed in the vehicle-treated rats.

NEUROPROTECTIVE EFFECTS OF K252a IN CEREBRAL ISCHEMIA: THE NAIP CONNECTION. G.S. Robertson*[1], D.G. Xu[1], J.-P. Doucet[1], S.J. Crocker[1], M. St- Jean[1], M.S. Saporito[2], A.M. Hakim[3], J.-E. Ikeda[4], R.G. Korneluk[5] and A. MacKenzie[5]. Department of Pharmacology[1], Neuroscience Research Institute[3], University of Ottawa, Ottawa, Ontario, K1H 8M5, Canada. Cephalon, Inc.[2], 145 Brandywine Parkway, West Chester, PA 19380-4245, USA. The Institute of Medical Science[3], Tokai University, Kanagawa 259-11, Japan. Molecular Genetics Research Laboratory[4], Children's Hospital of Eastern Ontario, Ottawa, Ontario K1H 8L1, Canada.

K252a, a glycosylated indolocarbazole, has been shown to possess neurotrophin-like activity in several models of excitotoxic death suggesting that this compound may also reduce ischemic damage. Consistent with this hypothesis, subcutaneous injection of K252a (0.1 mg/kg/day) for seven days prior to four-vessel occlusion (4-VO) and each day afterwards (5 days) significantly reduced the loss of hippocampal CA1 neurons produced by 10 minutes of transient forebrain ischemia. One interpretation of this finding is that K252a pretreatment elevates expression of protective protein(s) which renders CA1 neurons more resistant to the injurious effects of transient cerebral ischemia. Indeed, we observed that K252a administration (0.1 mg/kg, s.c.) elevated both mRNA and protein levels of neuronal apoptotic inhibitory protein (NAIP) in the hippocampus. It is therefore possible that the ability of K252a to increase NAIP levels contributes to its neuroprotective actions. In keeping with this proposal, striatal cholinergic neurons which are known to be resistant to the damaging effects of transient forebrain ischemia displayed a marked increase in NAIP-like immunoreactivity 1.5 - 3 hr after 20 min of 4-VO. In contrast, CA1 neurons demonstrated only marginal increases in NAIP-like immunoreactivity 1.5 - 48 hr after 20 min of 4-VO. Taken together, these findings suggest that elevated NAIP expression is (A) associated with resistance to ischemic cell death and (B) may contribute to the neuroprotective effects of K252a.

DYNORPHIN 1-13 CROSSES THE BLOOD-BRAIN BARRIER FOLLOWING CEREBRAL ISCHEMIA IN CATS. D.S. Baskin,* J.L. Browning and M.A. Widmayer. Dept. of Neurosurgery, VAMC and Baylor College of Medicine, Houston, Texas 77030

Previously we reported that the κ-opioid peptide, ([^{3}H]-pro^{10})-dynorphin 1-13 (DYN) crossed the blood-brain barrier (BBB) in cats following 6h of focal cerebral ischemia (fci) (SFN 18:991, 1992). This assertion was based on calculations of the amount of ^{3}H found in the parenchyma of the brain. It was not determined, however, whether the ^{3}H which crossed the BBB was intact DYN.

In the current study, 3 cats were injected with ([^{3}H]-pro^{10})-dynorphin 1-13, 6h following induction of fci. Tissue samples were dissected from 7 areas of the brain. To determine whether the intact ^{3}H DYN peptide crossed the BBB, HPLC was performed on each tissue sample. A peak of ^{3}H eluted at the retention time of intact Dyn in each tissue sample. This demonstrated not only that DYN crossed from the blood into the parenchyma, but also that DYN penetration into the brain was widespread following fci. This research was supported by a VA Merit Review Grant.

BEHAVIORAL DEFICITS INDUCED BY INTRATHECAL DYNORPHIN AND ENDOTHELIN IN THE MOUSE.
Marilyn A. Knowles, Carrie L. Cramer, Thomas H. Lanthorn, and Gene C. Palmer*
Astra Arcus USA, P.O. Box 20890, Rochester, NY 14602.

An important goal in the study of compounds which can protect against ischemic insult-induced damage is the development of in vivo models which are technically relatively easy and rapid. In addition, models which induce a quantifiable behavioral deficit which is specific for the lesion are needed. In the rat spinal cord, dynorphin induces vasoconstriction which may mimic vasospasm or transient occlusive stroke. Injected into the lumbar spinal cord, dynorphin can lead to neuronal damage and behavioral deficits ranging from total hindlimb paralysis to selective loss of the tail-flick (nociceptive) reflex. These behavioral deficits have been prevented by the vasodilator, hydralazine, and compounds which block activity at the NMDA receptor complex. Since the tail-flick assay is a commonly-used, technically simple, quantifiable and objective measure of neuronal activity, we believe that this can be an excellent assay for the detection of neuroprotective compounds. However, in the rat, intrathecal injection of dynorphin is done through a cannula threaded down the spinal cord to the lumbar area. On the other hand, intrathecal injections in mice can be done directly through the spinal column under transient anesthesia. This procedure can be very rapid. The purpose of this work is to investigate whether this assay can be carried out using mice for the detection of neuroprotective agents. Dynorphin does not produce long-lasting loss of the tail-flick reflex in mice. On the other hand, endothelin-1 does produce long-lasting behavioral deficits. The protective effects of hydralazine (vasodilator) and NMDA antagonists will be presented. Behavioral deficits induced by intrathecal injections of endothelin-1 may be a rapid and straightforward assay for the detection of potential neuroprotective agents.

CHARACTERIZATION OF A RIBOZYME AGAINST ENDOTHELIN-1 IN HUMAN BRAIN ENDOTHELIAL CELLS. G.A. Mashour*,[1,2], A. Kurtz[2,3], K. McGrail[2], and A. Wellstein[3]. [1]Interdisciplinary Program in Neuroscience, [2]Department of Neurosurgery, [3]Department of Pharmacology, Georgetown University School of Medicine, Washington, D.C. 20007.

Endothelin-1 (ET-1) is a potent vasoconstrictor expressed by endothelial cells that mediates vascular tone and chemoregulation in the brain. ET-1 has been found to be involved in the pathogenesis of cerebral vasospasm after subarachnoid hemorrhage (SAH), as well as other forms of stroke. Cerebral vasospasm is the most common cause of morbidity and mortality after SAH, and is refractory to most pharmacological and surgical interventions. Although ET-1 antagonists have shown promise in ameliorating experimental forms of cerebral vasospasm, these drugs are poorly characterized and may have unwanted systemic effects. Because cerebral vasospasm is well localized in space and time, the use of gene therapy to reduce ET-1 levels may be a more efficacious approach. Ribozymes are enzymatic RNA molecules whose activity is the specific cleavage of other RNA molecules. We have designed, synthesized, and cloned a ribozyme against the human ET-1 mRNA. Furthermore, we have a sensitive assay with which we can detect expression of ET-1 in human endothelial cell culture systems. We are currently optimizing the transfer and activity of the ET-1 ribozyme in human brain endothelial cells (HBEC). HBEC are isolated and cultured from normal human brain tissue resected during the course of neurosurgery. Optimizing gene transfer in these cells will be essential to this and any further attempts of gene therapy for cerebrovascular disorders. The long term goal of this project is to develop a ribozyme-mediated gene therapy for cerebral vasospasm.

INHIBITION OF ISCHEMIC DAMAGE BY PREINJECTION OF IL-1β IN THE RAT. R.P. Stroemer and N.J. Rothwell. School of Biol. Sciences., Univ. of Manchester, Manchester, M13 9PT, UK.

IL-1 exacerbates ischemic brain damage when administered at the onset of stroke. Pretreatment, however, may reduce damage through the induction of endogenous neuroprotectants. We tested the hypothesis that administration of IL-1β in the rat two days before ischemia, would reduce infarct volume.

Male, Sprague-Dawley rats (250-300g) were implanted with guide cannulae to inject IL-1β (2.5ng/1µl) or vehicle (saline) into either the lateral ventricle (i.c.v) or striatum, 2 days before ischemia (n=9). Permanent middle cerebral artery occlusion was induced using the method of Tamura (1981). After 24 hours, animals were sacrificed, fresh brain slices (500µm) stained with TTC and stroke volumes evaluated using Students' t-test for significance.

I.c.v. injections of IL-1β caused a 40% reduction in cortical damage (118.9±16.1mm^3 IL-1ra vs 53.0±13.9mm^3 veh, $p<0.001$) and a 32% reduction in striatal damage (30.1±3.7mm^3 IL-1ra vs 22.0±6.3mm^3 veh, $p<0.01$). Striatal injections of IL-1β caused a 36% reduction in cortical damage (90.1±4.9mm^3 IL-1ra vs 57.6±3.9mm^3 veh, $p<0.001$) and a 41% reduction in striatal damage (31.6±3.1mm^3 IL-1ra vs 18.7±3.2mm^3 veh, $p<0.001$).

Preinjection of IL-1β significantly reduces infarct volume, perhaps through the induction of endogenous protective elements (eg IL-1ra, NGF) or down-regulation of IL-1 receptors.

INTERLEUKIN-1 RECEPTOR ANTAGONIST GENE TRANSFER IN THE MOUSE BRAIN REDUCES ISCHEMIC BRAIN INJURY

G-Y Yang*, YJ Zhao, JZ Wu, AL Betz Depts. of Surgery, Neurology, and Pediatrics, University of Michigan, Ann Arbor, MI 48109

It has been reported that middle cerebral artery occlusion in rats causes overexpression of interleukin-1, and that administration of the interleukin-1 receptor antagonist protein (IL-1ra) reduces ischemic brain injury. The aim of the present study is to determined whether a recombinant adenovirus vector carrying human interleukin-1 receptor antagonist cDNA (Ad.RSVIL-1ra) could be used to overexpress IL-1ra in mouse brain and to evaluate its effect on brain edema formation and infarction after permanent focal ischemia in mice.

Ad.RSVIL-1ra, control adenovirus containing the lacZ gene (Ad.RSVlacZ), or saline was injected into the right cerebral ventricle in mice. Brain IL-1ra concentrations were measured 1 to 13 days later. On the fifth day after virus injection, the middle cerebral artery was occluded for 24 hours. Brain water content was determined and a histological technique was used to measure the infarction size.

Overexpression of human IL-1ra protein in whole brain was confirmed by immunoassay in the Ad.RSVIL-1ra injected mice. It began on the first day, peaked at 5-7 days, and was sustained for 13 days. Brain edema and cerebral infarct volume were significantly reduced following 24 hours of permanent middle cerebral artery occlusion in mice transfected with Ad.RSVIL-1ra compared to Ad.RSVlacZ or saline 5 days earlier.

These studies demonstrate that adenoviral vectors can be used to deliver genes to small animals such as mice and also suggest the feasibility of gene therapy for stroke and other neurological diseases. Overexpression of human IL-1ra attenuated ischemic brain injury, suggesting that IL-1 may play an important role in cerebral ischemia.

INTRACISTERNAL OSTEOGENIC PROTEIN-1 (OP-1) ENHANCES FUNCTIONAL RECOVERY FOLLOWING FOCAL CEREBRAL INFARCTION IN THE RAT. T. Kawamata[1,3], M. Charette[4], T. Chan[4], and S.P. Finklestein[1,2,*] [1]CNS Growth Factor Research Laboratory, Departments of [2]Neurology and [3]Neurosurgery, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114; and [4]Creative Biomolecules, Inc., Hopkinton, MA 01748

Behavioral recovery following focal cerebral infarction may depend on new neuronal outgrowth and synapse formation in the intact (uninjured) brain. Osteogenic protein-1 (OP-1) is a member of the bone morphogenic protein (BMP) subfamily of the transforming growth factor-ß (TGF-ß) superfamily that is found in the developing brain and promotes dendritic outgrowth of cultured neurons. We tested the effects of exogenously administered OP-1 on functional recovery in a model of focal cerebral infarction in the rat.

OP-1 (10 µg/injection, N=11) or vehicle (N=7) were administered by percutaneous injection into the cisterna magna biweekly for four weeks beginning at 24 h after unilateral proximal middle cerebral artery occlusion (MCAO) in mature male Sprague-Dawley rats. Four standard tests of sensorimotor function of the contralateral limbs and of balance and reflex function were administered every other day. After four weeks, animals were sacrificed, brains were removed and stained, and infarct volume was determined by computerized image analysis.

There was no difference in infarct volume among OP-1 vs. vehicle-treated animals (26.3±2.5 vs. 28.0±2.0 % of total hemispheric volume [mean ± SEM], respectively; p-n.s.). By contrast OP-1 treatment was associated with a marked enhancement of recovery of contralateral limb function as assessed by forelimb and hindlimb placing tests (p=0.0001 by two-way repeated measures ANOVA). A less pronounced enhancement of recovery was found on beam balance and postural reflex tests. OP-1 may enhance behavioral recovery through stimulation of dendritic sprouting in undamaged brain following focal infarction.

BRAIN RENIN-ANGIOTENSIN SYSTEM (RAS) IS INVOLVED IN CEREBRAL ISCHEMIA. B. Li, S. Galli, N. Rowland*, M.I.Phillips. Department of Physiology, College of Medicine, University of Florida Gainesville, FL 32610.

The roles ascribed to the brain RAS include blood pressure regulation, body fluid homeostasis and possibly memory. We hypothesized that the brain RAS is involved in cerebral ischemia. In this study, bilateral carotid artery occlusion (BCAO) was performed to induce cerebral ischemia in SHR and WKY rats. Sham operations were used as controls. After the operation, blood pressure (BP) and mortality rate were recorded and the brain angiotensin activities were measured by RIA and receptor binding assay. There was a higher mortality in the SHR rats (53%) compared to age-matched WKY rats (15%) after BCAO. The rats that died within 24 hr showed a significant higher BP at 4 hr after BCAO than sham operated controls. In the WKY rats, angiotensin II (Ang II) levels in the frontal lobe and hypothalamus were depressed compared to the control. In the SHR rats, the Ang II levels did not differ from the control. However, there was a significant increase in AT_1 receptors in the brain stem (30%) and frontal lobe (21%) in SHR rats after BCAO, while no change in AT_1 receptors was found in WKY rats. Scatchard analysis indicated that there was elevated receptor number without change in affinity. The receptor autoradiography indicated elevated AT_1 receptors in NTS and AV3V region. This study provided direct evidence that brain RAS may be involved in cerebral ischemia in rat model. (NIH)

CORTICOSTERONE EXACERBATES THE OVERFLOW OF EXTRACELLULAR [^{3}H]D-ASPARTATE IN HIPPOCAMPAL CULTURES DURING CYANIDE-INDUCED ISCHEMIA. Y.-C. Chou and S. Yu*. Inst. of Physiology, Natl. Yang-Ming Univ., Natl. Res. Inst. of Chinese Medicine, Taipei, Taiwan, ROC.

In hippocampal cultures, corticosterone (CORT) aggravates cell death during cyanide (CN)-induced ischemia. Using [^{3}H]D-aspartate ([^{3}H]D-Asp) as a tracer, CN increased the accumulation of extracellular [^{3}H]D-Asp in astrocyte cultures. However, similar effect was not observed in neuronal cultures, suggesting the failure of [^{3}H]D-Asp release from cells upon energy deprivation. CORT exacerbated the overflow of [^{3}H]D-Asp in neuronal, astrocyte and neuron/glia mixed cultures during CN -induced ischemia. Moreover, CORT potentiated the reduction of [^{3}H]D-Asp uptake in all three cultures treated with CN. It is likely that, during CN-induced ischemia, CORT decreases [^{3}H]D-Asp uptake which, in turn, enhances its overflow, thus endangering neurons. As noted, when compared with mixed cultures, astrocyte cultures appear to be more susceptible to all the treatments tested. It is conceivable that, via an unknown mechanism, neurons may interact with glia and thus provide a way to offset some of the actions observed in astrocyte glial. ESTROGEN INCREASES cGMP IN SELECTED BRAIN REGIONS. S.C.Palmon, L.K.Gorman, M.J. Williams, P.D.Hurn*. Johns Hopkins Med Inst, Baltimore, MD 21287.

We have previously reported that elevating *in vivo* plasma estrogen level increases residual hemispheric blood flow during experimental global cerebral ischemia. Because estrogen has been linked to both endothelial and neuronal nitric oxide/cGMP signaling in non-cerebral tissue, we tested the hypothesis that chronic 17β-estradiol treatment amplifies basal cGMP in brain homogenates from the female rabbit. We also determined if there are gender-specific differences in regional cGMP. Sexually mature, female rabbits were implanted with either placebo (F, n=19) or 17β-estradiol pellets, 10 mg (F10, n=10) or 50 mg (F50, n=12) and compared to untreated, age matched males (M, n=10). After 14 days, plasma estradiol was 1±0 pg/ml in M, 5±1 in F, 134±19 in F10, 286±57 in F50. Brains were harvested under pentobarbital anesthesia, subdissected into 9 regions, and assayed for cGMP via radioimmunoassay (Amersham). Basal cGMP was higher in F vs M in numerous brain regions and increased in F10, but not F50. Increases were prominent in ventral hippocampus (M=4±1, F=12±3, F10=31±6, F50=38±10 fmol/100ml); dorsal hippocampus (M=7±1, F=17±3, F10=32±5, F50=32±5 fmol/100ml); and posterio-lateral cortex (M=23±7, F=104±26, F10=114±14, F50=105±20 fmol/100ml). Therefore, 17β-estradiol increases cGMP in a gender-linked and dose-dependent manner in areas which are known to be selectively vulnerable to ischemic injury. Supported by NS3368.

FOCAL CEREBRAL ISCHEMIC MODEL USING MIDDLE CEREBRAL ARTERY OCCLUSION IN OVARIECTOMIZED RATS. Y. Q. Zhang[1], A. L. Day[1], J. Shi[2], G. Rajakumar[2], W. J. Millard[2]* and J. W. Simpkins[2]. Departments of Neurosurgery[1] and Pharmacodynamics[2], University of Florida, Gainesville, FL 32610.

In the present study, we developed a new focal ischemia model using ovary intact (normal) and ovariectomized (OVX) female rats. The focal ischemia was achieved by unilateral middle cerebral artery (MCA) occlusion with a nylon surgical suture inserted through the ipsilateral internal carotid artery (ICA). The purpose of developing this model was to investigate the effect of estrogens against brain ischemia. Methods: Adult female rats (Charles Rivers Inc., 3 months old, 200-220 g) were ovariectomized for one week. Rats were anesthetized with ketamine and xylazine *i.p.*. Rectal temperature was monitored and kept at 36.5-37.0 °C with a heating lamp during the operating procedures. A 3-0 monofilament nylon suture was introduced into the ICA and advanced it intracranially to block blood flow into the MCA. The suture was removed to allow recirculation after 40 minutes. At 24 hours after the onset of occlusion, neurologic deficit, mortality rate, gross pathology and serum level of estradiol were evaluated in all surviving rats. Results: Mortality was 23.5% for the OVX rats but was reduced to 12.5% for the normal rats ($p<0.05$). The cerebral ischemic area in the OVX rats was 15.8% vs 9.5% in the normal rats ($p<0.05$). Conclusions: This study demonstrated the protective effect of endogenous estrogens in the focal ischemic female rats. As such, MCA occlusion in OVX rats should be a useful model in various investigations of the efficacy of estrogens against ischemic brain injury. (Supported by NIH AG 10485)

EFFECT OF PINEALECTOMY ON BRAIN INJURY INDUCED IN RATS BY REVERSIBLE MIDDLE CEREBRAL ARTERY OCCLUSION. J.-Y. Joo[2], T. Uz, A. Kharlamov[1]* and H. Manev[1], ASRI and Departments of Psychiatry[1] and Neurosurgery[2], Medical College of Pennsylvania and Hahnemann University, Allegheny Campus, Pittsburgh, PA, 15212.

Recently, we reported that melatonin injections into rats reduce excitotoxic brain damage triggered by the activation of glutamate receptors. We have investigated the role of endogenous melatonin in neuroprotection by using models of changed levels of endogenous melatonin, i.e., diurnal rhythm and pinealectomy (see Manev et al., this meeting). In the work presented here, we tested the hypothesis that pinealectomy and the melatonin deficiency that results from it will put the brain into a state of greater susceptibility to neurodegeneration and thus result in greater damage after reversible middle cerebral artery occlusion (MCAo). We induced MCAo in male rats 15 days after pinealectomy or sham pinealectomy. Pinealectomized rats showed no detectable melatonin in the plasma (measured with an RIA kit). After anesthesia, both common carotid arteries (CCAs) were isolated and the left MCA exposed. Microvascular clips (Roboz) and the microsurgical mini-clip (Codman) were used to occlude the CCAs and the MCA, respectively. After 1 hr of occlusion, the clips were removed and the restoration of blood flow was observed under a microscope. During the surgical procedure and until recovery from anesthesia, body temperature was maintained at 37-38°C. The animals were sacrificed at different times, i.e., 3-24 hr after starting the recirculation. The brains were processed for Nissl staining and the in-situ TUNEL assay of DNA damage. The number of TUNEL-positive cells and the volume of the lesion were assessed using a computer-assisted imaging system. With the above-noted assays we observed a gradual time-dependent development of brain damage in the frontoparietal cortex. The extent of damage was significantly greater in pinealectomized rats. Our results support the proposition that the pineal gland and its hormone melatonin could be considered part of an endogenous neuroprotective system. Impairment of this system, which normally occurs with aging, may increase the risk of neurodegeneration.

TRH CHANGES HIPPOCAMPAL FASTIPSPs DURING HYPOXIA

M.Barbieri, L.Beani* and A.Nistri#. Inst. Pharmacol., Univ. Ferrara, 44100, Ferrara, Italy. # Int. Sch. Adv. Studies (SISSA), 34013 Trieste, Italy.

The neuropeptide TRH is suggested to improve brain recovery from ischaemia. Our lab has recently shown that TRH modulates GABAergic transmission which is known to be an early target for hypoxia. During transient hypoxia (33 Co) the modulatory action of TRH (10 mM) on fast IPSPs of intracellularly recorded CA1 pyramidal neurones (n=13) of the adult rat hippocampal slice preparation was thus investigated. Monosynaptic IPSPs were evoked by focal electrical stimulation of stratum radiatum, in the presence of kynurenic acid (1 mM), and CGP 35348 (1 mM). TRH (210 s) per se slightly hyperpolarized cells (-4.7 mV) and decreased their input resistance (-26%) and IPSPs (-73%). Hypoxia (150 s) reversely hyperpolarized by 8.3mV and decreased IPSPs and input resistance (-90%, -38%, respectively). In the presence of TRH (applied 60 s prior to hypoxia) hypoxic IPSP peak amplitude, input resistance fall and cell hyperpolarization were the same as during hypoxia alone. However, on return to oxygenated control medium, recovery of membrane potential was accelerated by TRH (from 540 to 360 s) while the recovery of IPSP amplitude was greatly delayed (from 480 to 700 s) and never complete (70% of control). Conversely, TRH did not influence recovery of input resistance. TRH did not change IPSP reversal which was depolarized by anoxia. TRH plus hypoxia did not further change IPSP reversal; despite incomplete and slow recovery of IPSPs their reversal returned to control value. These data suggest that during hypoxia the action of TRH consisted in delaying recovery of GABAergic transmission, while the cell returned more rapidly to resting membrane potential. INCLUSION OF HYPOXIA RESPONSIVE ELEMENTS CONFERS REGULATED GENE EXPRESSION IN THE HSV AMPLICON SYSTEM. M.W. Halterman[1,2],N. Panahian[2], H.J. Federoff[2]*. Department. of Microbiology & Immunology[1]; Division of Molecular Medicine, Department of Neurology[2]; University of Rochester School of Medicine, Rochester, NY 14642.

The development of physiologically responsive gene transfer vectors offers the possibility of entraining gene expression to the *in situ* demands of the target organ. To this end, we asked whether *cis* DNA elements that confer hypoxia inducible transcription on the erythropoietin gene could be used to develop an HSV amplicon vector. This would be regulated by oxygen levels and may be useful for gene therapy of chronic ischemia. We constructed HSVepolac which contains a synthetic hypoxia responsive promoter/enhancer sequence which was transfected into Hep3B cultures, a cell line previously shown to manifest a hypoxia response. Cells transfected with HSVepolac displayed a five fold induction in transcription when treated with an agent (100μM $CoCl_2$) that mimics hypoxia. Levels of expression when fully induced were 15x below that observed with a vector using a comparable backbone driven by the CMV promoter. These studies suggest that hypoxia responsive amplicon vectors can be made to regulate gene expression in a physiologically relevant manner. Ongoing studies will investigate transcriptional properties of this vector in *in vivo* models of ischemia. (This work was supported by NIH grant #HD31300).

UPREGULATION OF PLEIOTROPHIN (Ptn) GENE EXPRESSION IN MICROVASCULATURE, MACROPHAGES AND ASTROCYTES IN ISCHEMIC BRAIN OF RAT, H.-J. Yeh*, Y.Y. He, J. Xu, C.Y. Hsu, and T.F. Deuel. Washington University, Departments of Medicine, Neurology, and Biochemistry and Molecular Biophysics, St. Louis, MO 63110

The pleiotrophin (Ptn) gene encodes a heparin binding, 18 kD secretory protein (PTN) that induces mitogenesis, angiogenesis, and transformation in vitro. The Ptn gene is highly expressed in the central nervous system in glia and neurons at different times during development and thus its expression is highly regulated. We now have used a focal ischemic model that results from occlusion of the middle cerebral artery in rat to study the regulation of the Ptn gene expression in response to injury by in situ hybridization with ^{35}S-labeled Ptn cRNA probes and immunohistochemistry with both polyclonal and monoclonal anti-PTN antibodies. Expression of the Ptn gene in cortical neurons of the ischemic brain was dramatically decreased 6 hrs. and 24 hrs. after occlusion. At day 3, Ptn transcripts were undetectable in degenerating neurons. However, levels of the Ptn mRNA and the PTN protein were strikingly increased in microvasculature, OX_{42}-positive macrophages, and in astrocytes in the area of the infarct. Seven days after the ischemic injury, the infarct contained large numbers of PTN-positive macrophages and numerous hyperplastic blood vessels. The results demonstrate that in areas of proximity to and within an ischemic brain injury there is upregulation of expression of the Ptn gene in activated macrophages, microvasculature, and astrocytes, suggesting a potential role of PTN in development of post-ischemic angiogenesis and perhaps in reactive astrocytosis as well. (Supported by NIH Grant HL14147)

ADAPTIVE MECHANISMS IN DEVELOPING BRAIN: HYPOXIC INDUCTION OF ANGIOGENESIS, L.R.Ment*, W.B.Stewart, R. Fronc, C.Seashore, S.Mahooti, and J.B.Madri. Dept.Peds, Path, & Surg, Yale Univ. Sch. Med., New Haven, CT 06510.

Although chronic sublethal hypoxia has been shown to promote angiogenesis in the developing brain, the pathogenesis of this response is unknown. We hypothesized that this response may be mediated in part by vascular endothelial growth factor (VEGF). We reared newborn rats (P2) in a chamber with FIO_2 of 9.5 ± 1% (exposed, E). At P32, the animals were removed from the chamber and the brains prepared for mRNA or horseradish peroxidase (HRP) permeability studies. We also isolated beagle brain germinal matrix endothelial cells from PND 1 beagle pups and placed them in 3-D coculture with PND 1 rat forebrain astrocytes. Cultures were grown for 6 days in 11% O_2 (H, hypoxic) and compared to control (C) 3-D cocultures. Compared to controls, VEGF mRNA from E pups was increased 3-fold. Permeability to HRP was significantly increased over controls. As reported for the newborn rat, when compared to controls, H cocultures demonstrated significant increase in tubelike structures representing in vitro angiogenesis. Astrocyte mRNA levels for VEGF were increased 2-fold in H compared to C cocultures, and VEGF protein levels increased 3-fold in H cocultures compared to controls. These data suggest that VEGF mediates increases in angiogenesis in response to chronic hypoxia in the developing brain. (supp by NS 32578)

IDENTIFICATION OF HIPPOCAMPAL GENE INDUCTION IN GLOBAL CEREBRAL ISCHEMIA: mRNA FINGERPRINTING USING DIFFERENTIAL DISPLAY. D. A. Wigle, Jee Ching Hsu, J. H. Eubanks, J. Francis* and M. C. Wallace. Cerebrovascular Laboratories, Playfair Neuroscience Institute, Division of Neurosurgery, Toronto Hospital, Toronto, Canada, M5T 2S8; and Chang-Gung Memorial Hospital, Kweishan, Taiwan.

Accumulating evidence indicates that neuronal damage following ischemic insult involves an over-stimulation of Ca^{2+} permeant glutamate receptors. It is unclear however, how Ca^{2+} ions initiate neurodegeneration in specific vulnerable neurons. To investigate the hypothesis that global cerebral ischemia inadvertently activates the expression of detrimental gene products we have evaluated mRNA fingerprints of hippocampal tissue after a global ischemic insult using differential mRNA display. Total RNA was prepared 24 h after 15 min of global cerebral ischemia using the rat 4-vessel occlusion model. Reverse transcription of RNA was performed using poly-T_{12}MN anchoring primers, and the resulting cDNA's were amplified by PCR using arbitrary decamers as 5' primers and the corresponding T_{12}MN 3' primer. An initial screen of approximately 2000 putative mRNA transcripts yielded 10 fragments that appeared to be significantly upregulated in duplicate animal evaluations. Isolated fragments were reamplified, subcloned and sequenced. Interesting sequences isolated to date include p21 ras, an aspartyl-tRNA synthetase, and ME2, a helix-loop-helix transcription factor known to be neuronally expressed. We have also identified a novel gene sequence previously tagged from both fetal brain and aortic cDNA libraries. Given the known associations in stroke and other cell systems between Ca^{2+} fluxes and cell death, ras activation by Ca^{2+}, and the induction of apoptosis via ras-mediated pathways, we are particularly interested in the hypothesis of Ca^{2+} influx inducing ras activation and leading to apoptotic induction in stroke. The mechanisms associated with this hypothesis in addition to the characterization of further upregulated genes are currently being pursued.

ISOLATION OF A NOVEL DISPERSED REPETITIVE IDENTIFIER GENE INDUCED BY CEREBRAL ISCHEMIA FROM THE RAT BRAIN USING COMBINED SUBTRACTIVE HYBRIDIZATION AND DIFFERENTIAL SCREENING. KL Jin*, J Chen, M Nakayama, RL Zhu, RA Stetler, RP Simon, SH Graham, Department of Neurology, University of Pittsburgh, Pittsburgh, PA 15261

We used a modified strategy that combines subtractive hybridization (SH) and differential screening (DS) to identify genes induced in the rat brain following cerebral ischemia. Messenger RNA isolated from rat brains subjected to transient global ischemia was hybridized with excess cDNA reverse-transcripted from non-ischemic brain mRNA. The subtracted ischemia-inducible containing mRNA was used to construct a cDNA library. The isolated clones from this library were processed for duplicate Southern blots using 32P-labeled cDNA from ischemic and non-ischemic brains as probes.

A total of 1015 positive clones were isolated from the cDNA library. DS was performed in 86 of these clones and 34 of them were found to be upregulated in ischemia. Subsequently, Northern blot analysis of 12 cDNA confirmed that 9 of them are ischemia-inducible genes. Partial sequencing showed that about 50% of them are identical or highly homologous to known rat genes including hsp70, hsp10, nucleic acid binding protein, and carboxypeptidase.

Among the unknown genes, one gene referred to as GIIG11 (global ischemia-inducible gene) has been fully sequenced. Sequence analysis suggests that the GIIG11 gene encodes a 32 amino acid peptide and contains a 107-bp sequence at its 5'-untranslation region that is nearly identical (>95%) to the known dispersed repetitive identifier (ID). Thus GIIG11 is a novel rat ID gene. Northern blot performed using a GIIG11 ID sequence-containing cDNA fragment as a probe detected increased mRNA expression of the "brain specific" ID-homologue gene BC1 at 160bp and several other larger species, suggesting that multiple ID-homologue genes are upregulated in ischemia. Northern blot performed using a GIIG11 cDNA fragment not containing the ID sequence revealed a single transcript at 1.5 kb that is upregulated in ischemic brains, indicating the specific GIIG11 transcript. In situ hybridization demonstrated that GIIG11 mRNA was overexpressed in the brain with the highest levels in the vulnerable hippocampal CA1 pyramidal neurons following global ischemia.

Since the ID-sequence presents in a large number of copies in the rat genome and is considered to play a important role in governing "organ specific" gene expression, the cloning of GIIG11 and other ID-homologue genes from ischemic brains may further elucidate the molecular mechanisms of transcriptional regulation in the brain following ischemia and other CNS injuries.

The Expression of the Proliferating Cell Nuclear Antigen mRNA and Protein Is Upregulated in the Rat hippocampus Following Global Ischemia. R.A. Stetler, K.Kawaguchi, KL Jin, R.L. Zhu, S. H. Graham, D.A. Greenberg*, and J. Chen, Department of Neurology, University of Pittsburgh School of Medicine, Pittsburgh, PA

The proliferating cell nuclear antigen (PCNA) is a 36 kd nuclear protein that plays an important role in DNA replication in mammalian cells. It has recently been found that PCNA relocates from sites of DNA replication to sites of DNA damage following DNA injury and is essential for DNA excision repair. To investigate the molecular mechanisms for DNA damage and repair in acute CNS injuries, we studied the expression of the PCNA gene in a rat model of global ischemia and reperfusion.

Adult male Sprague-Dawley rats were anesthetized using 1.5% isoflurane and subjected to 15 min of 4-vessel occlusion followed by reperfusion. PCNA mRNA expression in the brain was studied at 0.5, 2, 4, 8, 16, 24, and 72 h following ischemia using a constructed 40-mer antisense oligodeoxynucleotide by means of in situ hybridization and Northern blot analysis. PCNA protein expression was studied using Western blot analysis at 2, 4, 16, 24, and 72 h after ischemia. TUNEL staining and histology were performed to study DNA damage and neuronal cell loss 24-72 h following ischemia.

In normal control rats, PCNA mRNA was expressed at a low level in hippocampal neurons. At 0.5 h following ischemia, a striking increase in PCNA mRNA level was first detected in dentate granule cells. At 8 h, mRNA was moderately increased in CA1-3 pyramidal neurons and further increased in dentate granule cells. At 24 h and thereafter, mRNA was remarkably increased in CA1 neurons but subsided in CA2-3 neurons. At 72 h, mRNA was also detected in a large number of glial cells in the hippocampus. Western blot analysis revealed that the PCNA protein was 1.8-4.5-fold increased at 2-72 h after ischemia with the highest level at 72 h. TUNEL staining detected DNA damage at 72 h exclusively in CA1 neurons and in some hilar cells.

This study demonstrates that PCNA mRNA and protein in the rat hippocampus are upregulated following transient global ischemia. The expression of PCNA in glial cells is consistent with its known biological function in DNA replication. Since oxidative stress induced by cerebral ischemia may produce DNA damage, the observation that PCNA was also induced in injured non-dividing neurons following ischemia suggests that DNA excision repair may be involved in the neuronal recovery process following oxidative stress. The precise role of PCNA in this process remains to be determined. (NIH/NINDS)

CYCLOOXYGENASE 2 PROMOTES NEURONAL CELL DEATH AFTER GLOBAL ISCHEMIA IN RAT CA1 HIPPOCAMPUS. M. Nakayama*, K. Uchimura, L. Zhu, K. Kadota, T. Asakura, J. Chen, and S.H. Graham, Dept. of Neurosurgery, Univ. of Kagoshima, Sch. of Medicine, Japan and Dept. of Neurology, Univ. of Pitsburgh, Sch. of Medicine, PA 15261

Two forms of cyclooxygenase (COX) , the enzyme that catalyzes the conversion of arachidonic acid (AA) into prostaglandins, have recently been cloned. The second form, COX2, is the predominant form expressed in brain and is an immediate early gene that is induced by neuronal activity. COX produces an oxygen free radical as a byproduct of its AA metabolism; therefore, COX2 expression could have an important role in ischemic neuronal injury. To address this hypothesis, we studied COX2 mRNA and protein expression after global cerebral ischemia in rats and determined the effects of inhibition of COX2 upon neuronal death in CA1 hippocampus. Global cerebral ischemia was induced by the four vessel occlusion method in isoflurane anesthetized rats. Rats were given 0, 3 or 30 mg/kg of the highly selective COX2 inhibitor SC58125, p.o., at 0, 24, and 48 hr after ischemia. Neuronal death was assessed by counting surviving neurons in cresyl violet stained sections obtained 72 hr and 14 d after ischemia. COX2 mRNA expression was induced in CA1 at 8 and 24 hr after ischemia. COX2 protein was expressed in CA1 at 24 hr after ischemia, while there was no expression of HSP72 in this region. Most neurons in CA1 TUNEL labeled, consistent with apoptotic death in this region. There was increased survival of CA1 neurons in drug treated rats at 72 hr and 14 d after ischemia. There was no effect of drug treatment on brain temperature during ischemia nor upon rectal temperatures at 1, 2, 3 and 14 d after ischemia. These results suggest that COX2 expression may play an important role in ischemic neuronal injury and that selective COX2 inhibitors could be effective neuroprotective agents.

PERMANENT MIDDLE CEREBRAL ARTERY OCCLUSION IN AMPA GLU R2 (FLIP) TRANSGENIC MICE PRODUCES INCREASED INFARCTION COMPARED TO WILD TYPE LITTERMATES. Dean Le[1], Frank Wang[2], Yasunory Sasaki[3], Saumya Das[3,4], Mari Takasu[3], Stuart A. Lipton[2,4], and Nobuki Nakanishi[3,4]*. Depts. of Neurology, [1]Massachusetts General Hospital and [2]Children's Hospital; [3]Dept. of Neurobiology and [4]Program in Neuroscience, Harvard Medical School, Boston, MA 02115.

Excitatory amino acid neurotransmitters play an important role in neuronal cell death in the acute injury state of cerebral ischemia. Blocking the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) subtype of glutamate receptor with AMPA antagonists has been shown to attenuate infarct volume in both focal ischemia and transient global ischemia, at least in some animal models (Buchan et al. 1991, Bullock et al. 1994, Smith et al. 1992). In the present study, we subjected transgenic mice that overexpress AMPA GluR2 (flip) receptors and their wild type littermates to permanent focal ischemia by introducing a filament via the common carotid artery into the middle cerebral artery. After 24 hours, brain sections were stained with triphenyltetrazolium chloride (TTC) and infarct volume calculated. We found that transgenic mice sustained larger infarctions compared to controls [87.4 ± 32.8 mm^3 vs. 54.3 ± 14.5 mm^3 (mean ± s.d., n = 21; p = 0.01)]. This study is thus complimentary to and consistent with the above pharmacologic studies in supporting the important role of AMPA receptors in neuronal damage during ischemia.

THE EXPRESSION AND REGULATION OF POLY(ADP-RIBOSE) POLYMERASE (PARP) DURING CEREBRAL ISCHEMIA J. Liu*, K. Solway, M. T. Murrell, G. G. Poirier, and F. R. Sharp Dept. of Neurology, University of California at San Francisco and SFVAMC.

To elucidate the molecular mechanism of CNS injury and cell death, we searched for genes that are expressed during cerebral ischemia and kainate induced seizure. By homology cloning with an oligonucleotide corresponding to the conserved region in the DNA binding domain within the fos family, we have isolated a cDNA clone encoding the rat poly(ADP-ribose) polymerase (PARP), a zinc finger DNA binding protein which is involved in maintaining chromatin architecture and DNA repair.

In situ hybridization showed an up-regulation of PARP message in the dentate gyrus (DG) region one hour post kainate injection in rat. PARP mRNA is also induced in DG during transient global ischemia in gerbils. Western blotting of brain tissue from both ischemic and kainate treated samples did not reveal significant change in the quantity of protein detected by monoclonal antibody c-2-10. Consistent with the evidence from other laboratory, c-2-10 recognized the 115 KD PARP protein in HL-60 human lymphoma cells by Western, and a cleaved form (85 KD) of PARP during apoptosis upon etoposide treatment. Western analysis of human postmortem brain samples from patients died of cerebral ischemia revealed a large molecule (150 KD) detected by c-2-10. This protein species is also predominantly present in rodent ischemic brain samples. The origin and nature of this brain specific protein species is under further investigation.

This work is supported by NIH (NS14543) Brain edema program project.

EXPRESSION OF ZINC FINGER IMMEDIATE EARLY GENES FOLLOWING PERMANENT MIDDLE CEREBRAL ARTERY OCCLUSION. J.S. Zhang*, J. Honkaniemi, B. States, P.R. Weinstein, J. Espinoza and F.R. Sharp. Departments of Neurology and Neurological Surgery and Neurology, University of California, Department of Veterans Affairs Medical Center, San Francisco, CA 94121.

The prolonged expression of the *fos*/*jun* immediate-early gene (IEG) families have been suggested to participate in the neuronal death program after prolonged seizures and cerebral ischemia. In the present study we applied in situ hybridization to investigate the effect of permanent middle cerebral artery occlusion (MCAO) on the expression of zinc finger IEGs NGFI-A, NGFI-B, NGFI-C, egr-2, egr-3 and Nurr1. One hour after MCAO all the genes were induced in the dentate granule cells of the hippocampus, cingular cortex, and in the MCA/ACA transition zone of the parietal cortex. In striatum, in which the core of the infarct is localized, no induction was observed. By 12 h the induction continued in the MCA/ACA transition zone and cingular cortex. In contrast, the expression declined below control values in the striatum. By 1 d, only *egr*-3 showed an increased expression, which was localized in the MCA/ACA transition zone. In other brain areas the expression of all the IEGs studied had returned to control levels except in the infarcted striatum and cortex, consistent with histology showing severe cell loss. The acute induction is most likely due to the ischemia induced spreading depression. The prolonged IEG expression at 12 and 24 h was localized in areas that are outside the MCA territory and therefore survive the ischemic insult. Supported by NS28167, NS14543, VA Merit Review, the Finnish Academy of Sciences and the Finnish Neurology Association.

655.11

HEME OXYGENASE-1 (HSP32) INDUCTION FOLLOWING FOCAL BRAIN ISCHEMIA INVOLVES SPREADING DEPRESSION. J. Koistinaho*[1], S. Miettinen[1], R. Keinänen[1], N. Vartiainen[1], R. Roivainen[1] and J.T. Laitinen[2]. [1]A.I. Virtanen Institute, [2]Department of Physiology, University of Kuopio, Finland.

Heme oxygenase-1 (HO-1) is a stress protein and a rate-limiting enzyme in heme degradation generating ferrous iron, carbon monoxide and bile pigments. HO-1 has been suggested to be protective against oxidative stress. Here we studied HO-1 expression in the rat brain following transient focal ischemia produced by intraluminal nylon thread introduction.

Northern blotting and *in situ* hybridisation showed increased levels of HO-1 mRNA in the ischemic region from 4 h through 7 days following 90 min of ischemia. The mRNA levels peaked at 12 h being localized perifocally. Immunohistochemical double-labeling experiments with GFAP (an astrocyte marker) or OX-42 (a microglia/macrophage marker) antibodies revealed HO-1 immunoreactivity to be localized in astrocytes, microglia and a few neurons in the perifocal region and in macrophages in the infarct core. Occasionally hippocampal non-neuronal cells also expressed HO-1 protein. A microassay measuring conversion of ^{14}C-heme to ^{14}C-bilirubin showed a two-fold increase in HO activity in the ischemic region when measured at 2 days, indicating a long-term HO-1 induction following focal brain ischemia. When MK801 (3 mg/kg), an NMDA receptor antagonist, was given 30 min prior to ischemia, HO-1 mRNA induction was inhibited perifocally, but not in the thin rim surrounding the infarct core, suggesting that spreading depression (SD) is involved in the HO-1 induction. We next produced unilateral cortical SD by topical application of 3M KCl and found HO-1 mRNA to be upregulated 4 and 8 h following stimulation.

SD is thought to be initiated and propagated by massive presynaptic release of glutamate and activation of NMDA receptors. Since SD produced 24 h prior to brain ischemia has been reported to exacerbate ischemic injury, HO-1 induction may have a neuroprotective role in brain ischemia.

655.12

OVEREXPRESSION OF PROTOONCOGENES AND NEUROTROPHINS mRNA IN THE BRAIN OF STROKE-PRONE SPONTANEOUSLY HYPERTENSIVE RATS. T.Ueyama*, [1]K. Nemoto, [2]Y.Nara, [2]Y.Yamori, E.Senba Dept.of Anat.& Neurobiol., Wakayama Med.Coll ,Wakayama,640,[1]Lab.of Health Sci.,Univ.of Shizuoka, Shizuoka,422, [2]Graduate Sch.of Human and Environmental Studies,Kyoto Univ.,Kyoto,606,Japan

Stroke-prone spontaneously hypertensive rats(SHRSP) are unique animal models which develop stroke (cerebral hemorrhage and/or softening) spontaneously with high incidence and are regarded as good pathogenetic models for studies on stroke in humans. Brain insults such as seizure and ischemia induce marked transient changes of gene expression for neurotrophins such as nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF). In this study, we investigated the mRNA expression of protooncogenes such as c-*fos* and zif268/NGFI-A and neurotrophin such as NGF and BDNF in stroke-affected SHRSP brain using *in situ* hybridization histochemistry. We found the mRNA levels for c-*fos*, zif268, NGF and BDNF were augmented in the hippocampus and cortex not only ipsilaterally but contralateraly to the lesion site, whereas mRNA for cytokines such as IL-1 β was not observed. These changes are considered as the compensatory response for the survival and functional maintenance of the residual neurons.

655.13

ELEVATED CLUSTERIN GENE EXPRESSION IN THE IMMATURE RAT BRAIN FOLLOWING HYPOXIC-ISCHEMIC INJURY. M. Walton*, D. Young, E. Sirimanne, J. Dodd, D. Christie, C. Williams, P. Gluckman and M. Dragunow. Departments of Pharmacology, Biochemistry, and Research Centre for Developmental Medicine and Biology, Faculty of Medicine and Health Science, University of Auckland, Auckland, New Zealand.

The role of clusterin in nerve cell death has been assessed using a moderate (15 min) and severe (60 min) unilateral hypoxic-ischemic (HI) insult in the 21 day old Wistar rat. The severe HI insult lead primarily to necrotic neuronal death and showed very little, if any clusterin mRNA and protein induction on the ligated side of the brain. Following the moderate HI insult there was a dramatic time-dependent accumulation of clusterin protein in regions undergoing delayed neuronal death, especially within the CA1-CA2 pyramidal cell layers in the hippocampus and cortical layers 3-5. In contrast, clusterin mRNA expression appeared to be glial in origin (probably astrocytes) which supports the hypothesis that the clusterin protein is synthesised in the astrocytes, secreted and then taken up by dying neurons. A double label for clusterin immunoreactivity and in situ DNA end-labelling revealed that clusterin was accumulating in neurons destined to die by programmed cell death. However the relative time-courses of DNA fragmentation and clusterin immunoreactivity suggest that clusterin production was a result of the selective delayed neuronal death rather than being involved in the biochemical cascade of events that cause it.

This research was funded by the New Zealand Health Research Council, the New Zealand Neurological Foundation and the New Zealand Lottery Board. M. Walton is a New Zealand Neurological Foundation, WB Miller Scholar.

INHIBITION OF TUMOR NECROSIS FACTOR TYPE II RECEPTOR BY ANTISENSEOLIGONUCLEOTIDES ENHANCES ß-AMYLOID TOXICITY AND HYPOXIA-INDUCED NEURONAL INJURY. Y. Shen[1]*, R. Li[2] and K. Shiosaki[1] [1]Department of Neuroscience, Abbott Laboratories, Abbott Park, Illinois 60064, USA, [2]Department of Psychiatry, University of Louisville School of Medicine, Louisville, Kentucky 40292, USA

The deposition of ß-amyloid peptide (Aß) in Alzheimer's disease and hypoxic episodes in stroke may be involved in neuronal cell death. Recent evidence also indicates the potential involvement of tumor necrosis factor α (TNFα), an inflammatory cytokine, in neurodegenerative disorders. TNFα elicits multiple biological effects through two distinct TNF receptor subtypes: TNFRI (p55) and TNFRII (p75). Studies have demonstrated that TNFRI contributes to cell death, but the function of TNFRII in neuronal cells is unclear, although it shares homology with the NGF receptor, which provides a protective effect in neural injury. To study the involvement of TNFRII in neuronal cell death, we treated human neuronal cells (differentiated SH-SY5Y) with phosphorothioate-modified antisense oligonucleotides (ASO) for TNFRII and found that ASO inhibited TNFRII protein expression. Co-treatment with ASO and Aß(1-42) in SH-SY5Y cells enhanced cell death (25.8% increased LDH release) at 48 hours compared to treatment of Aß(1-42) or ASO alone or co-treatment of Aß and sense oligo controls. Exposure of SH-SY5Y cells to oxygen deprivation for 6 hours produced cell death (16% LDH release). Moreover, co-treatment with ASO and 6 hours of hypoxic exposure increased significantly cell death (30.3% LDH release from cells) compared to hypoxia alone or hypoxia in the presence of sense oligo. These results indicate that inhibition of TNFRII increases neuronal cell vulnerability to Aß toxicity and hypoxia-induced injury, and suggest that TNFRII plays a trophic role in neuronal survival.

ISCHEMIA: TOLERANCE AND STRESS PROTEINS

656.1

INCREASED HYPOXIC TOLERANCE BY PRECEDING CHEMICAL HYPOXIA IS ABOLISHED BY ANTAGONISTS AT NMDA RECEPTORS. K. Kasischke *, M. W. Riepe. Department of Neurology, Humboldt University (Charité), 10098 Berlin, Germany.

Hypoxic tolerance in rat hippocampal slice is increased by preceding mild, clinically inapparent, chemical hypoxia *in vivo*.

The amplitude of the population spike (psap; stimulation of Schaffer collaterals at 0.1 Hz, recording in hippocampal region CA1) at the end of 15 min hypoxia is reduced to about 10 % of onset. Upon 45 min of recovery from hypoxia, psap is 31 ± 9 % (mean ± SE) in slices prepared from untreated control animals ("c-slices") and 107 ± 7 % ($p < 0.01$) in slices prepared from animals pretreated *in vivo* by a single i.p. injection of 3-nitropropionic acid ("p-slices"; 24 hour time interval between *in vivo* treatment and preparation of slices). Increased hypoxic tolerance can be reversed dose-dependently with application of NMDA antagonists. When p-slices are treated for 5 min with 20 µM APV 45 min prior to hypoxia, recovery of posthypoxic psap declines to 73 ± 12 % ($p < 0.05$ to control) after 45 min of posthypoxic recovery. Similar treatment with 100 µM APV 45 min prior to hypoxia results in a decline of recovery of posthypoxic psap to 35 ± 10 % ($p < 0.01$ to preconditioning alone, $p < 0.05$ to treatment with 20 µM APV) after 45 min of recovery from hypoxia. In contrast, similar treatment of p-slices with 10 µM CNQX does not affect psap upon recovery from hypoxia (93 ± 15 %).

We conclude that increased hypoxic tolerance by 'chemical preconditioning' is abolished by NMDA-antagonists but not non-NMDA-antagonists.

Supported by a grant from the Deutsche Forschungsgemeinschaft to MWR.

656.2

LONG-TERM POTENTIATION IN HIPPOCAMPUS IS PRESERVED IN GERBIL MODEL OF ISCHEMIC TOLERANCE. K.Kawai, T.Nakagomi, H.Kanemitsu*, T.Kirino, A.Tamura, N.Kawai. Dept. of Neurosurgery, Teikyo Univ., Itabashi, Tokyo 173 Japan, Dept. of Neurosurgery, Univ. of Tokyo, Bunkyo, Tokyo 113 Japan, and Dept. of Physiology, Jichi Medical School, Tochigi 329-04 Japan.

After 5 min forebrain ischemia, capacity for long-term potentiation (LTP) in CA1 pyramidal neurons of the gerbil hippocampus is progressively decreased followed by loss of CA1 neurons a few days later. Although preconditioning ischemia (PI) has been known to reduce the morphological damage in CA1 neurons, it is not known if surviving neurons function properly.

We produced PI in adult male gerbils by bilateral carotid occlusion for 2 min. Double ischemia (DI) was produced by 5 min ischemia 2-3 days after PI. Hippocampal slices were prepared from these gerbils. Field excitatory postsynaptic potentials (fEPSPs) were recorded from the stratum radiatum of the CA1 sector by stimulation to Schaffer collateral/commissural fibers (0.05-0.08 Hz). Capacity for LTP was compared by measuring the maximal slope of fEPSP before and after brief tetanic stimulation to the input fibers (100 Hz, 1 sec x 2).

The percentages of slices which exhibited robust LTP were 85.7%, 76.2%, 15.0% and 67.6% in normal control gerbils, gerbils 2-3 days after PI, gerbils 1-2 days after DI and gerbils 7-8 days after DI, respectively. Thus, capacity for LTP was transiently inhibited after DI but it recovered by 7-8 days. These results suggest that: 1) protection by PI is not only morphological but also functional, 2) PI does not affect LTP during the period when it protects neurons from subsequent ischemia. PROTECTIVE EFFECT OF INTRAUTERINE HYPOXIA-ISCHEMIA ON BRAIN INFARCT SIZE INDUCED BY A SECONDARY HYPOXIC-ISCHEMIC INSULT IN NEONATAL RATS. Z. Cai*, J. Fratkin[§] and P. G. Rhodes. Dept. of Pediatrics/Newborn Medicine, [§]Dept. of Pathology, Univ. of Miss. Med. Ctr., Jackson, MS 39216

In a neonatal model of hypoxia-ischemia (HI), brain damage was assessed in rat pups which had or had not previously experienced an intrauterine insult. Initial HI conditions were achieved by surgically ligating the uterine arteries for 30 min on gestation day 17. A sham operation (SH) was performed in the control group. After surgery, the uterine horns were returned to the dam's abdomen to let the pups deliver naturally. One-week-old pups from both groups were subjected to right carotid artery ligation followed by an exposure to 8% O_2/92% N_2 for 3 h (LH). Animals were sacrificed 24 h after the secondary HI insult. Brain slices were stained with 2,3,5-triphenyltetrazolium chloride (TTC) or hematoxylin and eosin (H&E) for assessment of tissue damage. Intrauterine HI alone did not result in any apparent tissue damage. The average size of the TTC-stained infraction area was 26.3 ± 3.1% (mean±S.E., N=10), in the coronal brain sections of pups which had not experienced the initial intrauterine HI (SH+LH). The corresponding value in pups which had experienced a 30-min intrauterine HI (HI+LH) was 13 ± 3.2% (N=10). H&E sections indicated that secondary HI decreased neuronal density in the ipsilateral CA1 subfield of the hippocampus. In the HI+LH group this was less than in the SH+LH group. Induction of heat shock protein 70 (HSP70) was detectable in both SH+LH and HI+LH groups. To determine whether intrauterine HI has a protective effect, reducing brain damage caused by a secondary HI via HSP70 synthesis, will require further experiments. ISCHEMIC PRECONDITIONING CONVEYS DIMINISHING HISTOLOGICAL PROTECTION CONCURRENT WITH RECOVERY OF FUNCTION. P. Dooley*, S. J. Evans, J. Wells and D. Corbett. Basic Med.Sciences, Fac. Med., Memorial Univ., St. John's, NF, Canada A1B 3V6.

Exposure to brief periods (e.g. 1.5 min) of ischemia protects CA1 neurons from a subsequent, severe ischemic insult (e.g. 5 min) several days later. We have found that this ischemic "tolerance" translates into a limited functional preservation 3-10 days after the final ischemia even though ~ 70% of CA1 neurons appear "histologically normal." Here we sought to determine if this histological protection continues to decline and whether functional recovery occurs with longer survival times.

Gerbils were exposed to 2 x 1.5 min episodes of global ischemia (24 hr apart) followed 3 days later by a 5 min occlusion that typically destroys >95% of CA1 neurons. Open field habituation tests were conducted 3, 7, 10 and 30 days after the last ischemia while CA1 dendritic field potentials (fEPSP's)were recorded from hippocampal slices on days 3, 10 and 30.

Preconditioning resulted in ~88, 77 and 67% preservation of CA1 neurons at 3, 10 and 30 days survival respectively. Nonetheless, preconditioned gerbils had habituation deficits comparable to ischemic gerbils. Similarly, CA1 fEPSP's at 3 days were ~ 50% of those recorded in sham animals, with recovery to ~ 80% in gerbils surviving 30 days. These data show that while the histological protection provided by ischemic preconditioning declines over time, the remaining neurons exhibit considerable capacity for functional recovery. Similar studies in aged animals will be reported on at the meeting.

RAPID PRECONDITIONING PROTECTS RATS FROM ACUTE NEURONAL INJURY FOLLOWING GLOBAL CEREBRAL ISCHEMIA. M. A. Pérez-Pinzón*, Guang-Ping Xu, W.D. Dietrich, M. Rosenthal and T.J. Sick. Dept. of Neurology, U. of Miami Sch. of Medicine, Miami, Fl. 33101

Earlier studies indicated that sublethal ischemic insults separated by many hours may 'precondition' and thereby protect tissues from subsequent insults. In Wistar rats, we examined the hypothesis that ischemic preconditioning (IPC) can improve histopathological outcome even if the 'conditioning' and 'test' ischemic insults are separated by only 30 min. Normothermic (36.5-37 °C) global cerebral ischemia was produced by bilateral carotid artery ligation after lowering mean systemic blood pressure to 40-50 mm Hg. The 'conditioning' ischemic insult lasted 2 min which was associated with a time sufficient to provoke 'anoxic depolarization' (i.e. the abrupt maximal increase in extracellular potassium ion activity), following 30 min of reperfusion, a 10 min 'test' ischemia was produced, and histopathology was assessed 3 days later. Neuroprotection was most robust in the left lateral, middle and medial subsectors of the hippocampal CA1 subfield and in the cortex, where protection was 91, 76, 70 and 86%, respectively. IPC also protected the right lateral, middle and medial subsectors of the hippocampal CA1 region, by 67, 57 and 39%, respectively. These data demonstrate that neuroprotection can be achieved by 'conditioning' insults followed by only short (30 min) periods of reperfusion. These studies were supported by PHS grant NS 14325, NS 32167, NS 05820 and Grant in Aid from AHA.

INTRAISCHEMIC MILD HYPOTHERMIA DURING PRETREATMENT WITH SUBLETHAL ISCHEMIA REDUCES THE INDUCTION OF ISCHEMIC TOLERANCE IN THE GERBIL HIPPOCAMPUS. T. Miyazawa*, K. Wada, H. Kato, K. Shima, H. Chigasaki. Dept. of Neurosurgery, National Defense Medical College, Tokorozawa, Saitama, 359 Japan

Pretreatment with sublethal ischemia has been shown to induce tolerance to subsequent lethal ischemic injury in hippocampal neurons, although the influence of brain temperature during pretreatment on induce tolerance has not been demonstrated. We examined whether mild brain hypothermia during pretreatment with sublethal ischemia affected the tolerance to subsequent lethal ischemic insults. Male Mongolian gerbils were subjected to 2 min of ischemia at mild brain hypothermia (n=8), or normothermia (n=8). The animals were then subjected to a second 5-min ischemia interval of 2 days following the first ischemic insult. Seven days after the second ischemia, the neuronal densities in the hippocampal CA1 sectors of the gerbils in the mild brain hypothermia subgroup (32% of normal) were significantly lower than those in gerbils in the brain normothermia subgroup (70% of normal). Immunohistochemical staining analysis using a monoclonal antibody raised against 72-kDa heat-shock protein (HSP-72), in the CA1 sector 2 days following pretreatment, revealed that intraischemic mild hypothermia reduced HSP-72 synthesis compared with that in the brain normothermia subgroup.

ISCHEMIC PRECONDITIONING DECREASE TYROSINE PHOSPHORYLATION AND LEVELS OF NMDA RECEPTOR 2 A/B FOLLOWING TRANSIENT CEREBRAL ISCHEMIA IN THE RAT NEOCORTEX T.Wieloch* and M. Shamloo. Lab. for Exp. Brain Research, 221 85 Lund, Sweden

We have previously shown that tyrosine phosphorylation of NMDA receptor 2 (NR2 A/B) increases in the recovery phase following reversible cerebral ischemia. This increase in tyrosine phosphorylation may be due to inhibition of phosphatases or activation of tyrosine kinases in neurons exposed to ischemia. In this study we have investigated the changes in tyrosine phosphorylation in rat exposed to 9 min ischemia with and without 3 minutes preconditioning. We demonstrate that tyrosine phosphorylation of the NMDA receptor 2A/B (NR2A/B) following preconditioning ischemia normalizes to control level at 24 h of recovery. Since the phosphorylation state of NR2 reflect the balance between protein tyrosine kinase and phosphatase, we concluded that decrease in tyrosine phosphorylation of NR2 can be due to activation of a protein tyrosine phosphatase or inhibitor of protein tyrosine kinases. We also investigated the levels of NR2A and NR2B proteins using Immuno blotting techniques in crude postsynaptic densities (PSDs). We show that the levels of both NR2A and NR2B proteins decrease below control levels at 24 h rec. We conclude that both downregulation of NR2A/B proteins and normalization of tyrosine phosphorylation of NR2A/B may contribute to a neuronal survival in preconditioned animals. We speculate that this stabilizes the $[Ca^{++}]_i$ following reversible cerebral ischemia. This work was supported by the Swedish Medical Research Council (grant no. 08644) and NIH (NS07838).

INDUCTION OF IMMEDIATE EARLY GENES AND ISCHEMIC TOLERANCE IN THE IPSILATERAL GERBIL HIPPOCAMPUS BY DISTAL MIDDLE CEREBRAL ARTERY OCCLUSION. H. Abe* and T.S. Nowak, Jr. Dept. of Neurosurgery, Niigata University, Niigata 951, Japan, Dept. of Neurology, University of Tennessee, Memphis, TN 38163

Middle cerebral artery occlusion (MCAO) induces expression of immediate early genes (IEGs) in the ipsilateral hippocampus and other regions remote from the MCA territory. We have previously demonstrated a close association of prior IEG induction with ischemic tolerance after global ischemia in gerbil hippocampus, identifying comparable threshold depolarization intervals for tolerance induction and changes in gene expression.

In this study we investigated expression of c-fos, junB, junD, c-jun and hsp72 mRNAs in the ipsilateral hippocampus of the gerbil after permanent distal MCAO, and examined tolerance of CA1 neurons to transient forebrain ischemia produced by bilateral carotid artery occlusion (BCAO) following pretreatment with MCAO. Induced mRNAs were evaluated by in situ hybridization after 1, 3, 6, 24 and 48 h MCAO. Histological evaluation of CA1 was done 7 d after 5 min BCAO produced 6 h, 1 d or 2 d after MCAO pretreatment. In other animals DC potential was recorded in the ipsilateral cingulate cortex and hippocampus for 1 h after MCAO. All procedures were done under halothane anesthesia.

c-fos, junB, junD and c-jun were induced 1-6 h following MCAO in the ipsilateral hippocampus. No increase in hsp72 mRNA was detected at any time point. Protection of ipsilateral CA1 neurons was observed in all groups with MCAO pretreatment 6 h, 1 d or 2 d prior to 5 min BCAO with 47±39, 48±25 and 41±28% control neuron density vs. 11±8, 6±3 and 11±6% survival in contralateral hippocampus. One or two brief depolarizations (50-100 sec) were recorded in hippocampus during 1h MCAO, while several events were detected in the cingulate cortex. These results demonstrate that focal cortical ischemia produces depolarizations in the ipsilateral hippocampus associated with subsequent IEG expression and neuroprotection.

ISCHEMIC TOLERANCE AND REGIONAL EXPRESSION OF C-FOS AND HEAT-SHOCK GENES FOLLOWING FOCAL CEREBRAL ISCHEMIA IN RATS

L. Belayev,* M.D. Ginsberg, J.T. Singer, O.F. Alonso, W.Zhao, R. Busto, S. Kraydieh and I.Klatzo. Cerebral Vascular Disease Research Center, Department of Neurology (D4-5), University of Miami School of Medicine, P.O. Box 016960, Miami, FL 33101.

The objective of this study was to determine whether focal ischemia induces ischemic tolerance in hippocampal CA1 neurons when transient bilateral forebrain ischemia is carried out 3 days later; and to explore the effects of focal ischemia on the regional expression of c-fos and hsp70 mRNA. Male Sprague-Dawley rats received 120 min of temporary middle cerebral artery occlusion (MCAo) by retrograde insertion of an intraluminal nylon suture coated with poly-L-lysine. Three days later, the animals were subjected to 10 min of 2-vessel occlusion (2VO). Group I underwent MCAo and 2VO, and Group II underwent sham-MCAo and 2VO. Rats were sacrificed 4 days after 2VO, and normal-appearing neurons in CA1 subregions were counted. Rats with MCAo + 2VO had significant protection of CA1 neurons in ***both*** hippocampi, whereas rats with sham MCAo + 2VO typically had severe destruction of CA1 neurons (**Ipsilateral**, mean±SE, *medial*: 59.8±7.2 vs 16.6±7.8; *middle*: 50.0±4.7 vs 16.0±8.8; *lateral*: 43.5±5.7 vs 13.8±6.3;**Contralateral**, *medial*: 52.3±6.3 vs 17.0±6.4; *middle*: 43.3±4.7 vs 19.8±8.1; *lateral*: 45.5±4.6 vs 26.0±10.3, respectively). *In situ* hybridization for c-fos and hsp70 30 min post-MCAo revealed a conspicuous expression in the cortex and striatum ipsilateral to MCAo. Marked increases of c-fos expression were also observed *bilaterally* in both hippocampi. These results show that antecedent severe unilateral ischemia may confer neuronal protection on distant contralateral regions connected by neuronal circuitry. This neuronal tolerance was preceded by the early induction of c-fos and hsp70 mRNA, which may in turn lead to expression of critical target genes that promote cell recovery.

EARLY ACQUISITION OF ISCHEMIC TOLERANCE AFTER CORTICAL SPREADING DEPRESSION IN GERBIL CEREBRAL CORTEX. T. Kumagai*, H. Abe, S. Takeuchi and R. Tanaka. Dept. of Neurosurgery, Brain Res. Inst., Niigata University, Niigata 951, Japan

We revealed the acquisition of ischemic tolerance in gerbil cerebral cortex after cortical spreading depression (CSD) and investigated the relevance to gene expression and its products. CSD was evoked by application of 2M-KCl to left parietal cortex for 30 minutes in anesthetized Mongolian gerbils. 2M-NaCl was applied to animals of control group. Saline was applied to right parietal cortex in both groups. Six or 24 h later animals were subjected to 15 min of global ischemia (GI). The animals were decapitated 5 days after GI and injured cortical neurons were counted bilaterally in H&E stained coronal sections 1.5 mm rostral, 1.0 mm caudal and 3 mm caudal to the bregma respectively. c-fos, jun B and hsp72 mRNA and products were examined using in situ hybridization and immunocytochemistry. Mean number of injured neurons in CSD hemispheres was significantly less than opposite side in both 6 h and 24 h groups. No significant difference between both hemispheres was seen in control group (Table). c-fos and junB mRNA were widely expressed in the cortex ipsilateral to the KCl application reaching the peak 1 or 3 h after CSD. C-FOS immunoreactivity in ipsilateral cortex peaked 3 or 6 h and disappeared 24 h following CSD. In contrast hsp72 mRNA was not detected in the cortex except small region around the burr hole.

These results demonstrate that ischemic tolerance induced by CSD is associated with c-fos gene expression because of the correspondence of time course of c-fos induction with that of tolerance acquisition.

	KCl side	Saline side	NaCl side	Saline side
6 h group	143.8±30.0	284.3±108.5	214.7±46.1	189.7±5.1

DEPOLARIZATION-INDUCED "ISCHEMIC TOLERANCE" IN CORTICAL CELL CULTURES. M.C. Grabb* and D.W. Choi. Center for the Study of Nervous System Injury and Dept. of Neurology, Washington Univ. School of Medicine, St. Louis, MO 63110.

Two in vivo studies have recently demonstrated that KCl-induced spreading depression 24 hrs prior to global ischemia, can mimic sublethal ischemia in reducing brain vulnerability to subsequent ischemic insults, a phenomenon called "ischemic tolerance" (Kobayashi et al., *J. Cereb. Blood Flow Metab.* 15: 721-27, 1995; Kawahara, et al., *Neurol. Res.* 17: 9-16, 1995). We have developed an in vitro model of cerebral tolerance in murine cortical cell cultures (Grabb and Choi, Soc. Neurosci. Abstr. 675.13, 1995). The goal of the present study was to determine if transient exposure to high K^+ is sufficient to induce a state of "ischemic tolerance" in this model.

Mixed cultures containing both neurons and glia (DIV 13-14) were exposed to sham wash, or 45 mM KCl, for 5-15 min. 24 hrs later, these cultures were exposed to a 50-60 min period of oxygen-glucose deprivation, sufficient to induce intermediate levels of neuronal death without glial death in control cultures (as assessed 24 hrs later by morphological examination and LDH efflux to the bathing medium). Cultures previously exposed to high KCl exhibited approximately half as much neuronal death as sister cultures exposed to sham wash preconditioning. Application of the NMDA antagonist D-CPP (100 μM) during 45 mM KCl stimulation, blocked the induction of tolerance, indicating that it requires NMDA receptor activation. However surprisingly, a 30 min sublethal pretreatment of cultures with NMDA (5-10 μM) did not induce tolerance. These data encourage us to continue investigation into the mechanisms underlying "ischemic tolerance" in this simplified model system.

IMMEDIATE EARLY GENE CHANGES AFTER REVERSIBLE FOCAL PHOTOTHROMBOTIC BRAIN ISCHEMIA IN RATS. I-M. Johansson, T. Olsson*, M Hakova, W Gu, J.R. Seckl[1] and P. Wester. Dept Med, Umeå University Hospital, Sweden and [1]Dept Med, Western Gen Hosp, Edinburgh, Scotland.

This study aimed at exploration of ipsilateral cortical effects as well as remote effects on immediate early gene (IEG) expression following induction of a photothrombotic stroke with reperfusion. The exposed crania of erythrosin B-injected adult male Wistar rats were irradiated with a 514.5 nm laser beam (0.92 watts/cm^2) configured as a ring, 5 mm in diameter and 0.35 mm thick, to yield a ring-shaped thrombotic lesion surrounding a central "area at risk". This resulted in a delayed gradual impairment of cortical vasculature patency at 48 hrs with reperfusion at 72 hrs. Rats (n=3-5 for each time-point) were decapitated after 0, 60, 120, 240 mins; 10 and 24 hours; 3, 5 and 7 days post-irradiation. mRNA expression as well as protein levels for the IEGs NGFI-A and c-fos were studied by Northern blots, in situ hybridization, Western blots and immunohistochemistry. A strong induction of NGFI-A and c-fos gene and protein expression developed in the ipsilateral cortex with peak gene/protein expression within 2 hours of ischemia induction, persisting for 10 hours with return to baseline levels after 24 hours. In the contralateral cortex and in the hippocampus temporary profound decreases in NGFI-A gene and protein levels were seen. Focal photothrombotic cortical brain ischemia is associated with major changes in IEG expression. This concerns both changes near the injury and remote abnormalities in cortical and hippocampal areas. These changes may have profound effects on neuronal function and selective neuronal vulnerability.

HEAT-SHOCK PROTEIN (HSP70) INVOLVEMENT IN GLUTAMATE NEUROTOXICITY AND FOCAL CEREBRAL ISCHEMIA: A TRANSGENIC MOUSE STRAIN OVEREXPRESSING THE RAT INDUCIBLE HSP70. P. Britton, J.R Dave, X.-C.M Lu, J.P. Ray*, [1]R. Mestril, [1]W.H. Dillman, H.S. Ved and F.C. Tortella. Div. Neurosci., Walter Reed Army Inst. of Res., Washington, DC 20307 and [1]UCSD, La Jolla, CA 92093.

HSP70 is induced by a variety of stimuli, including heat and CNS ischemia and is suggested to demonstrate neuroprotective actions. In the present study we have examined (1) the effect of a heat-shock episode on glutamate-induced toxicity in neurons cultured from anatomically distinct brain regions and (2) the outcome of focal cerebral ischemia in a transgenic mouse strain overexpressing hsp70. Primary neuronal cultures from embryonic rat cortex, cerebellum, or hippocampus were exposed to 37°C (control) or 42°C (heat-shock) for 15 min and returned to 37°C for 4 hr before treating with either vehicle or glutamate (75 μM) for 45 min. Morphological and cell viability assessments were made at 24 hr post-injury. Permanent middle cerebral artery occlusion (MCAO) was produced in transgene negative (-) and transgene positive (+) CB6 F1 mice. Infarct analysis was performed 24 hr post-occlusion. In vitro, glutamate neurotoxicity was maximum in neurons derived from the cerebellum and minimum in those obtained from the cerebral cortex. Heat-shock provided neuroprotection of approximately 15-40% in cortical and 40-60% in cerebellar and hippocampal neurons. In vivo, no significant difference was observed between infarct volumes in (-) (10.0 ± 4.2 mm^3) and (+) (13.2 ± 4.6 mm^3) mice. However, 40% of injured (+) mice (n=10) failed to show signs of infarction. These results demonstrate that heat-shock treatment has differential neuroprotetive effects on neurons derived from distinct brain regions. Also, we conclude that the CB6 F1 transgenic mouse strain may be an appropriate model to study the role of hsp70 in ischemic injuries.

SAPK/ JNK ACTIVATION IN RAT BRAIN BY ANISOMYCIN: POSSIBLE NEUROPROTECTIVE ROLE IN CEREBRAL ISCHEMIA E. Bettini, R. Carletti, L. Carboni, F. Ferraguti, S. Tacconi*. Dept. of Pharmacology, Glaxo Wellcome S.p.A., Medicines Research Center, 37135 Verona, Italy

Rat Stress Activated Protein Kinase (SAPK) or the human homologue Jun-N terminal Kinase (JNK) constitute a family of serine/threonine protein kinases which share the unique feature of being activated by double phosphorylation on threonine and tyrosine residues at Thr-Pro-Tyr site. Stress extracellular stimuli (including pro-inflammatory cytokines, protein synthesis inhibitors and UV rays) have been shown to activate SAPK/JNK in a variety of cell types. SAPK/JNK activation is able to modify gene expression, phosphorylating transcription factors like c-jun, ATF-2 and elk-1. mRNA levels for c-jun itself increase as a consequence of SAPK activation. Recently, we could demonstrate (Neuroscience 69, 1103-1110, 1995) that SAPK mRNA is expressed at high level in rat brain. However, the mechanism of regulation of SAPK activity and the physiologic role of SAPK activation in CNS neurons has never been addressed. SAPK activity was measured in rat brain areas of naive animals and at different times after anisomycin (30mg/kg, i.p.) injection, by solid phase kinase assay. This dose of anisomycin was able to induce a significant increase in SAPK activity in cortex and hippocampus 15 minutes following drug administration. This dose of anisomycin increased also c-jun mRNA expression in cortex and hippocampus, at 4 hours.No obvious morphological changes were observed in rat brain of anisomycin injected animals. Because anisomycin has been shown ro reduce delayed death of CA1 neurons in gerbil model of global cerebral ischemia (Shigheno et al., Neurosci. Lett, 1990), we tested anisomycin effect in rat MCAo. 30mg/kg, i.p. anisomycin induced neuroprotection in this model of cerebral ischemia, when administered for 3 days before ischemia. Our results suggest that activation of SAPK pathway could play a neuroprotective role in rat MCAo.

DETECTION OF MDM2 IMMUNOREACTIVITY DURING ISCHEMIC NEURONAL DEATH FOLLOWING MIDDLE CEREBRAL ARTERY OCCLUSION. Y.Tu, Z.Huang[1], G.S.Robertson[1], A.M.Buchan*[2] and J.P.MacManus. Institute for Biological Sciences, National Research Council, Ottawa, Canada K1A 0R6; [1] Ottawa University; [2] University of Calgary, Canada.

After insult cells produce a cascade of stress response proteins both immediately or over a long period after the insult has ceased. Transcriptional activators such as p53 may play an important role in neuronal damage following cerebral ischemic insult. The p53 factor in turn activates many other downstream genes such as mdm2 and p21. In this study, MDM2 protein in ischemically damaged brain has been investigated.

The focal model of brain ischemia produced by transient middle cerebral artery occlusion for 90 minutes (MCAO) was used. The samples of brain tissue were obtained from sham operation and at 1, 8, 24 and 48 h of reperfusion after MCAO. Immunohistochemical staining of MDM2 reveals that the protein is expressed in the fifth layer of pyramidal neurons in the cortex in the infarcted hemisphere. In the same coronal section, no MDM2 positive staining was visible in the contralateral non-occluded side. The appearance of MDM2 protein in the damaged hemisphere appears to be time-related, since by one hour of reperfusion, no positive MDM2 was detected. By 8 h of reperfusion, there was some MDM2 staining, but less than that in the 24 h samples. Western blotting using Colo357 or T3M4 cells as positive controls showed MDM2 antibody staining at 75, 97 and 105 kDa. The 75 and 97 kDa proteins were also detected in brain, but the 105 kDa band apparently shifted to approximately 115 kDa. The majority of MDM2 positive pyramidal cells appeared to be eosinophilic, and had partial loss of hematoxylin staining which left a ghostlike nucleus. In contrast to MDM2, no difference in p21 staining was observed between the occluded and contralateral hemispheres. The results suggest a selective increase in some p53 controlled genes in the pyramidal neurons of the cortex following an ischemic insult.

NEUROPSYCHIATRIC DISORDERS: SCHIZOPHRENIA II

657.1

[^{3}H]MK-801 BINDING IS NOT ALTERED IN PREFRONTAL CORTEX OR NUCLEUS ACCUMBENS OF RATS WITH NEONATAL HIPPOCAMPAL DAMAGE. Hassen A. Al-Amin*, Barbara K. Lipska, Sonja M. Lillrank, and Daniel R. Weinberger. Clinical Brain Disorders Branch, IRP, NIMH, Neuroscience Center at St. Elizabeths, Washington, DC 20032.

We have previously shown that the neonatal ibotenic acid lesion of the ventral hippocampus in the rat results in a variety of hyperdopaminergic behavioral changes that can be used as an animal model of schizophrenia. Glutamatergic neurotransmission may also be altered in schizophrenia as it has been shown that the non-competitive NMDA antagonist, ketamine, exacerbates psychotic symptoms. We found that the rats with neonatal hippocampal lesions were behaviorally hyperresponsive to glutamatergic blockade (MK-801, 0.2 mg/kg). In the present study, we examined the effects of these neonatal lesions on binding of [^{3}H]MK-801 to NMDA receptors in the medial prefrontal cortex (mPFC) and shell of nucleus accumbens (NAC) in the lesioned and control rats after continuous footshock (20 min) or without stress. Rats were lesioned with ibotenic acid (3 µg/0.3 µl) on postnatal day 7 (PD7). They were sacrificed at PD56. The total binding was performed using quantitative autoradiography with 16nM [^{3}H]MK-801; and non-speciifc binding was done in the presence of ketamine (200µM) on 20 µm brain sections. The preliminary results showed no significant changes in binding of the ligand to NMDA receptors in the brain regions studied either after footshock or without stress. In view of the known glutamaterigic projections from the hippocampus to these brain regions, the lack of change in NMDA receptors may suggest either an upregulation of receptors to compensate for the loss of glutamaterigic input, or that these projections are minimal compared to other glutamaterigic projections in mPFC and NAC.

657.2

$5HT_{2A}$ AGONISTS PREVENT NMDA ANTAGONIST NEUROTOXICITY. N.B. Farber* and J.W. Olney. Dept. Of Psychiatry, Washington University, St. Louis, MO 63110.

Antagonists of the NMDA receptor reversibly injure or kill neurons in rodent brain and produce psychotic "emergence reactions" in humans. Previousy we have proposed that both of these adverse CNS side-effects might represent different manifestations of the same toxic process and that NMDA receptor hypofunction (NRH) might occur in patients with schizophrenia. Here we report that the neurotoxicity induced in rat brain by the potent and specific NMDA antagonist, MK-801, is prevented by $5HT_{2A}$ agonists. The dose of MK-801 used (0.5 mg/kg sc) causes a reversible neurotoxic reaction ("vacuole reaction") in specific cerebrocortical neurons in 100% of treated rats. The ED_{50}s (dose that reduced the mean number of vacuolated neurons by 50%) for the agents tested were DOB (0.36 mg/kg), LSD (0.67 mg/kg), DOM (0.81 mg/kg), and DOI (1.05 mg/kg). While all these agents are agonists at both the $5HT_{2A}$ and $5HT_{2C}$ receptor, the ability of lisuride, which is a $5HT_{2A}$ agonist but a $5HT_{2C}$ **antagonist**, to also prevent the vacuole reaction (ED_{50} = 0.17 mg/kg) suggests that it is agonist activity at the $5HT_{2A}$ receptor that is critical for these agents' protection against NMDA antagonist neurotoxicity. If a common mechanism does underlie the neurotoxic and psychotomimetic effects of NMDA antagonists, then co-adminstration of a selective $5HT_{2A}$ agonist with an NMDA antagonist might prevent the NMDA antagonist from inducing either of these adverse side effects. It will be important to develop specific and selective $5HT_{2A}$ agonists prior to testing this hypothesis in humans since agonism at the $5HT_{2C}$ receptor has been linked to the hallucinogenic action of LSD, DOB, DOM, and DOI.

POSITIVE MODULATORS OF AMPA RECEPTORS INCREASE NEURONAL ACTIVITY IN NEOCORTEX RELATIVE TO STRIATUM: AN ADJUNCT TREATMENT FOR SCHIZOPHRENIA? L.C. Palmer[1], U.S. Hess[2], J. Larson[3], C.M. Gall[2*], and G. Lynch[3] Depts. of Philosophy[1], Anat. & Neurobiol.[2], and Psychobiol.[3], Univ. of CA, Irvine, 92717.

Certain aspects of schizophrenia may reflect an imbalance in the relative activities of functionally antagonistic glutamatergic / dopaminergic systems; or more specifically, a hypoglutamatergic condition in cortex and excessive activity in ascending dopaminergic (DA) projections. In agreement with this idea, drugs that facilitate AMPA-type glutamate receptors ("ampakines"), reduce certain behaviors elicited in rats by methamphetamine (AMPH). The present study used *in situ* hybridization to c-*fos* mRNA to test the prediction that ampakines and AMPH cause opposing changes in the balance of neuronal activity in cortex vs. striatum. AMPH (n=8) induced a marked increase in c-*fos* in the dorsomedial quadrant of striatum and a 3-fold smaller but reliable increase in the ventrolateral quadrant. The drug also elevated c-*fos* mRNA in ventral and medial orbitofrontal cortex (area VO/MO) but had no detectable effects in premotor and parietal neocortices. The ampakine (n=8) caused a near inverse pattern of changes; i.e., no alterations in either striatal zone, no significant effects in VO/MO, but a sizable increase in premotor and parietal cortices. Within-rat cortical and striatal values were correlated in both the vehicle (n=8) and ampakine groups and it was established that the drug caused a 30-40% increase in the ratio of cortical to striatal activity. These results support the idea that facilitation of glutamatergic transmission has "network level" effects that are opposite to those resulting from enhanced DA transmission. The potential relevance of ampakines alone or in conjunction with DA antagonists for the treatment of schizophrenia will be discussed. (BNS9024143, MH00974, and Cortex Pharmaceuticals).

EARLY POSTNATAL MK-801 EXPOSURE ALTERS LOCOMOTOR RESPONSE TO SUBSEQUENT ADMINISTRATION IN ADULT RATS. P. J. Kruzich*, J. W. Grimm, and R. E. See. Department of Psychology, Washington State University, Pullman, WA 99164

N-Methy-D-Aspartate (NMDA) receptor antagonists have been well characterized as producing psychotic-like symptoms in humans and a variety of behaviors in rats which may be predictive of psychosis. The present study investigated the developmental effects of early exposure to the NMDA antagonist MK-801 in rats. Three litters of Sprague-Dawley rats (n= 47) served as subjects. Two litters (n= 30) were injected daily from postnatal day 2 (pd 2) through postnatal day 5 (pd 5) with either a high dose of MK-801 (0.1 mg/kg), a low dose of MK-801 (.033mg/kg), or saline vehicle. The third litter (n= 17) was not injected or handled until weaning at pd 21. At pd 21, initial screening revealed no overt ataxia, locomotor deficits, or physical abnormalities in any groups. From pd 55 through pd 63, all rats underwent behavioral measurement. On pd 55, locomotor activity was measured in a photobeam activity chamber. At pd 56 and pd 63, responses to a novel environment were assessed with an open field apparatus. During the pd 63 open field trial, all rats were injected with MK-801 thirty minutes before the trial began. Passive avoidance was measured at pd 58-6. Females in all groups showed significantly higher activity in the photobeam activity chamber than males. Females in all groups also displayed higher activity levels than males across both open field trials. During the MK-801 challenged open field trial, male rats with early postnatal exposure to 0.1mg/kg MK-801 displayed significantly less activity than all female groups, and approached significantly lower levels of activity compared to the male early postnatal saline treated rats ($p = .056$) and the male control rats with no early postnatal treatment ($p = .074$). The data suggest that male rats injected with high dose MK-801 at pd 2-5 acquire higher sensitivity to the behavioral locomotor effects of a subsequent exposure to MK-801 as adults than all other groups. This research was supported by USPHS Grant DE-09678(RES) and the state of Washington.

BEHAVIORAL ASSESSMENT OF MK-801 INDUCED NEUROPATHOLOGY AS A MODEL OF SCHIZOPHRENIA. M. J. Walter* and J. Panksepp. Dept. of Psychology, Bowling Green State University, Bowling Green, Ohio 43402

It has been suggested that N-methyl-D-aspartate (NMDA) glutamate receptor hypofunction represents a critical mechanism for the major aspects of schizophrenia. Multiple doses of MK-801, a NMDA receptor antagonist, have also produced neural damage in animal models resembling that observed in human schizophrenia patients (Olney & Farber, Arch gen psychiat, 52:998-1007). Accordingly, MK-801 was used to investigate the behaviors associated with this brain damage. Female rats approximately eighty-five days old received injections of MK-801 (0.5 mg/kg/day) for three consecutive days. After the three injections, the rats were severely debilitated and exhibited a substantial weight loss. Although weight was slowly regained, the MK-801 rats remained chronically below the weight of controls. At least twenty days after the last injection when the rats were restored to health, behavioral changes were evaluated in a foraging task and elevated plus-maze. The foraging task consisted of a 60 cm by 60 cm chamber with 36-2 cm diameter holes drilled in the floor and treats hidden in four of the wells. Number of errors and latency to find the treat were recorded. MK-801 rats demonstrated 16% fewer errors and a 25% decrease in latency on the foraging task relative to controls. In the elevated plus maze entries and duration in each type of arm were recorded for five minutes. MK-801 rats exhibited a 48% decrease in open arm frequency and a 64% decrease in duration, suggesting a heightened anxiety/inhibition on the elevated plus-maze for MK-801 rats relative to controls. These findings suggest an increase in both positive and negative emotions in MK-801 damaged animals, which may be congruent with some of the symptoms of schizophrenia. MICRODIALYSIS STUDIES OF EXCITATORY AMINO ACID TRANSMITTERS IN A RAT MODEL OF SCHIZOPHRENIA. C.D. Stine*, C.-J. Xue and M.E. Wolf. Department of Neuroscience, Finch University of Health Sciences/The Chicago Medical School, North Chicago, IL 60064.

Considerable evidence points to a role for excitatory amino acids in both the pathological processes underlying schizophrenia and the mechanism of action of antipsychotic drugs. In vivo microdialysis studies were performed in medial prefrontal cortex (mPFC) to further characterize EAA involvement in schizophrenia using a novel rat model of schizophrenia in which excitotoxic lesions of ventral hippocampus (VH) are produced on postnatal day (PD) 7 (Lipska et al., Neuropsychopharmacol. 9:67-75, 1993). The neonatal VH lesion model reproduces several features of schizophrenia, including postpubertal emergence of symptoms, functional impairment of mPFC, dysregulation of subcortical DA systems, stress-induced exacerbation of symptoms, and altered responsiveness to antipsychotic drugs. This model is also in accord with clinical findings of structural abnormalities in the hippocampal formation of schizophrenic brains and with evidence that such abnormalities result from early developmental injury. The aim of the present study is to characterize basal and K^+-stimulated efflux of glutamate and aspartate in mPFC of sham and VH lesioned rats at both prepubertal (PD35) and postpubertal (PD60) time points. Preliminary studies conducted on PD35 have not revealed robust differences in basal or K^+-stimulated efflux of glutamate or aspartate between sham and lesioned groups, perhaps in keeping with the lack of behavioral abnormalities in VH lesioned rats at prepubertal time points, although a tendency towards lower basal glutamate efflux was observed in the lesioned group. Our results should provide information about the possibility that developmentally-induced abnormalities in EAA transmission in mPFC contribute to schizophrenia. Supported by USPHS grant DA07735.

CHRONIC NEUROLEPTIC TREATMENT DOWN-REGULATES D1A AND D5 DOPAMINE RECEPTOR mRNAs IN THE PRIMATE PREFRONTAL CORTEX BUT NOT IN THE STRIATUM

M.S. Lidow[1]*, J.D. Elsworth[2], Y Cao[1] and P.S. Goldman-Rakic[1]. *Section of Neurobiology[1] and Department of Pharmacology[2], Yale University, School of Medicine, New Haven, CT 06510*

The regulation of D1A and D5 dopamine receptor mRNAs in the monkey prefrontal cortex and the striatum by chronic treatment with eight different neuroleptics, representing most of the structural and pharmacological spectrum of these drugs, was investigated using ribonuclease protection assay. The drugs tested were chlorpromazine, clozapine, haloperidol, molindone, olanzepine, pimozide, remoxipride, and risperidone. They were administered orally, in fruit treats, for 6 months, twice a day at doses which fall within the therapeutic range recommended for human patients. On the next day after the last treatment, animals were sacrificed and their brains dissected for the ribonuclease protection assay and HPLC analysis of dopamine and its metabolite, homovanilic acid (HVA). We found that, while none of the drugs used in the present study affected the levels of either D1A or D5 mRNAs in the striatum, they all significantly down-regulated both mRNAs in the prefrontal cortex. The HPLC analysis showed that neuroleptics did not produce consistent changes in the levels of dopamine or HVA either in the striatum or in the prefrontal cortex. Therefore, the down-regulation of the cortical D1A and D5 receptors probably was not a compensatory reaction of these receptors to an increase in dopamine release resulting from blockade of D2 sites. Our observations suggest that reduction in the levels of prefrontal cortical dopamine receptors of the D1 class is one of the common results of the chronic neuroleptic treatment in primates.

MEDIAL PREFRONTAL CORTICAL LESION IN THE NEONATAL RAT RESULTS IN POSTPUBERTAL EMERGENCE OF HYPERLOCOMOTION: COMPARISON WITH OTHER CORTICAL LESIONS. Barbara K. Lipska* and Daniel R. Weinberger. Clinical Brain Disorders Branch, IRP, NIMH, Neuroscience Center at St. Elizabeths, Washington, DC 20032.

We have previously shown that the neonatal ibotenic acid lesion of the ventral hippocampus in the rat results in postpubertal emergence of a number of behavioral abnormalities, such as hyperlocomotor responsiveness to stress and amphetamine, and deficits in prepulse inhibition of startle. Some of the changes associated with this neonatal hippocampal lesion at the behavioral and molecular level suggested that it may adversely affect development of the medial prefrontal cortex (mPFC), the target of glutamatergic ventral hippocampal projections. In the present study, we examined the effects of the neonatal lesions of the mPFC on dopamine-related behaviors and compared with the lesions of the entorhinal and parietal cortices. All rats were lesioned with ibotenic acid (3 µg/0.3 µl) on postnatal day 7 (PD7). Spontaneous locomotion in response to novelty and amphetamine-induced hyperactivity (1.5 mg/kg) were measured on PD35 and PD56. Only the mPFC lesions resulted in the delayed emergence of amphetamine-induced hyperlocomotion. The pattern of the lesion-induced behavioral changes was similar in some respects to that seen previously in animals with neonatal hippocampal damage, but very different from what has previously been reported for the adult mPFC lesion (Jaskiw et al. 1990). These data suggest that maldevelopment of the mPFC occurring at an early age may be responsible for the postpubertal appearance of hyperdopaminergic behaviors in the rat.

NEONATAL LESIONS OF THE RAT VENTRAL HIPPOCAMPUS RESULT IN HYPERLOCOMOTION AND DEFICITS IN THE SOCIAL BEHAVIOR IN ADULTHOOD. Frank Sams-Dodd*[1], Barbara K. Lipska[2], Daniel R. Weinberger[2]. [1]H. Lundbeck A/S, Ottiliavej 9, DK-2500 Copenhagen - Valby, Denmark; [2]Clinical Brain Disorders Branch, IRP, NIMH, Neuroscience Center at St. Elizabeths, Washington, DC 20032.

The neonatal ibotenic acid lesion of the ventral hippocampus in the rat is an animal model of several aspects of schizophrenia. This lesion produces a number of behavioral abnormalities, such as hyperlocomotion and deficits in prepulse inhibition of startle that present themselves relatively late in development, i.e. after puberty. Some of these abnormalities, which are thought to model the positive symptoms of schizophrenia, can be normalized by chronic treatment with neuroleptics. In the present study, we examined the effects of the neonatal hippocampal lesion on social behavior. Social withdrawal and isolation are key components of the negative symptoms of schizophrenia that have not been previously addressed in this model. Rats were lesioned on postnatal day 7 (PD7) and tested for social interaction on PD35 and PD65. They were then treated with clozapine (0.63; 2.5 mg/kg) for 21 days and retested. The results show that although, as previously reported, spontaneous hyperlocomotion emerged in the lesioned rats only after puberty (PD65), social interaction deficits were present at both PD35 and PD65. Treatment with clozapine normalized locomotion, but worsened the deficits in social behavior. These data suggest that the neonatal hippocampal lesion in the rat models some positive as well as negative aspects of schizophrenia and that the onset of these symptoms closely resembles the clinical pattern. However, in contrast to clinical findings, the negative symptoms in this animal model are not ameliorated by clozapine.

EXTRACELLULAR LEVELS OF DOPAMINE AND 5-HIAA ARE DECREASED IN RATS WITH A NEONATAL VENTRAL HIPPOCAMPAL LESION

Lillrank S.M*., Lipska B.K., Kolachana B.S., and Weinberger D.R.
Clinical Brain Disorders Branch, IRP, NIMH, Neuroscience Center at St Elizabeths, Washington D.C. 20032.

The effects of restraint stress and amphetamine (AMPH 5 mg/kg i.p.) treatment on the extracellular levels of dopamine (DA) its metabolites, and the 5-HT metabolite 5-HIAA in the nucleus accumbens (NA) and prefrontal cortex (PFC) in rats with a neonatal ventral hippocampal (VH) lesion were studied using *in vivo* microdialysis. This neonatal (day 7 after birth, PD7) ibotenic acid VH lesion results in postpubertal (PD56) onset of a variety of abnormal behaviors related to corticolimbic and striatal dopaminergic dysfunction. To monitor neurotransmitter levels in these freely moving rats, microdialysis probes were implanted in the NA and PFC of adult (PD56) rats one day prior to the experiment. The basal extracellular levels of 5-HIAA but not DA were significantly reduced in the lesioned as compared to sham operated rats in both NA and PFC. Restraint stress for 30 minutes resulted in a 20 % increase of the extracellular levels of DA and its metabolites DOPAC and HVA in the sham operated rats in both NA and PC but no change in the lesioned rats. 5-HIAA was reduced in the PFC after stress in the lesioned as compared to the sham operated rats. A significant increase in the extracellular levels of DA after AMPH challenge in both lesioned and sham operated rats was seen in both NA and PFC. DA release was however, attenuated in the lesioned as compared to sham operated rats after AMPH in both NA and PFC. AMPH treatment had no effect on the extracellular levels of 5-HIAA. These data show that the neonatal VH lesion alters serotonergic functioning and extracellular DA levels in response to AMPH challenge but not short restraint stress in adult rats.

TWO NONHUMAN PRIMATE MODELS OF PSYCHOSIS: FETAL X-IRRADIATION AND AMPHETAMINE SENSITIZATION. S. A. Castner*, O. Algan, P. Rakic and P.S. Goldman-Rakic. Yale University School of Medicine, Section of Neurobiology, 333 Cedar Street, New Haven, Connecticut, 06510.

A high incidence of schizophrenia has been reported in offspring subjected to irradiation during the second trimester of gestation (Mednick et al., Arch. Gen. Psych.; 1988). The present study addresses (1) whether irradiation exposure to nonhuman primates during critical stages of fetal life also produces behavioral abnormalities associated with psychosis and (2) whether these abnormalities resemble those produced by amphetamine (AMPH) sensitization in this species. If both behavioral models represent second order approximations of schizophrenia, it is possible that nonhuman primates subjected to one treatment paradigm or the other will reveal similarities in behavioral outcome indicative of a possible common underlying mechanism of abnormal behavior.

The behavior of singly-housed young adult male and female rhesus monkeys that had undergone fetal irradiation (N=4), AMPH sensitization (N=4) or controls (N=10) was examined. Baseline observations of home cage behavior were made using a focal sampling procedure. Behaviors such as stereotypic pacing and circling, self-biting and saluting, indicators of stress responses, were measured and quantified.

All features of this aberrant behavioral profile were observed in irradiated monkeys and in monkeys undergoing chronic AMPH treatment or sensitized monkeys after a low dose AMPH challenge. Interestingly, hallucinatory-like behaviors were observed under baseline conditions in irradiated monkeys and were shown by AMPH sensitized animals after withdrawal. The aforementioned similarities between X-irradiated animals and AMPH sensitized monkeys suggest a possible common underlying mechanism. ANTAGONISM OF METHAMPHETAMINE-INDUCED HYPERACTIVITY IN RATS BY SPECIFIC FACILITATION OF AMPA-RECEPTOR-MEDIATED GLUTAMATERGIC TRANSMISSION. S.A. Johnson*[1], J. Larson[2], N.T. Luu[1], D.L. Lutz[1], G. Rogers[1] and G. Lynch[2]. [1]Cortex Pharmaceuticals, Inc., Irvine, CA 92718 and [2]Center for the Neurobiology of Learning and Memory, Univ. of California, Irvine, CA 92717.

Certain evidence suggests that schizophrenia may in part be caused by reduced cortical glutamatergic transmission. This has led to the hypothesis that positive modulators of AMPA-type glutamate receptors could be useful in treating psychoses, and to the demonstration that a compound of this type attenuates abberant behaviors induced in rats by methamphetamine (METH) treatment - a standard animal model of schizophrenia (Larson et al., submitted). We now have extended these results using a drug (CX516) that has been tested in animal and human studies, and show that it antagonizes METH-induced behavioral hyperactivity and also enhances the effects of typical neuroleptic drugs in the METH model.

Exploratory activity (locomotion and rearings) of naive, male Sprague-Dawley rats was measured during a 30-minute acclimation period before and for 90 minutes after i.p. injection of saline, METH (2 mg/kg), CX516 (10 mg/kg) and METH+CX516. A second series of experiments tested whether CX516 would enhance the effects of the typical neuroleptic drugs haloperidol (HAL; 0.12 mg/kg) and fluphenazine (FLU; 0.2 mg/kg).

CX516 significantly antagonized METH-induced locomotor (-40%, $p=0.001$, $n=19$) or rearing (-41%, $p=0.004$, $n=19$) activity throughout the 90-minute test period, with no effect on normal exploratory activity. CX516 also enhanced, in an additive manner, the antagonistic effects of either HAL or FLU on METH-induced locomotor or rearing activity ($p<0.005$).

These results provide further evidence that AMPA receptor modulators are potentially useful in the treatment of schizophrenia. Supported by Cortex Pharmaceuticals, Inc.

EFFECTS OF PREFRONTAL CORTICAL LESIONS ON NEUROPEPTIDE AND DOPAMINE RECEPTOR GENE EXPRESSION IN THE STRIATUM-ACCUMBENS COMPLEX. S. M. Baca, M. F. Egan, S. E. Bachus, B. K. Lipska, J. N. Ferguson, and T. M. Hyde*. Clinical Brain Disorders Branch, IRP, NIMH, Neuroscience Center at St. Elizabeths, Washington, DC 20032.

Alterations in prefrontal cortical regulation of the basal ganglia have been implicated in the pathophysiology of schizophrenia. To understand how cortical dysfunction in schizophrenia might alter subcortical activity, *in situ* hybridization histochemistry was used to assess changes in subcortical gene expression following bilateral excitotoxic lesions to the rat medial prefrontal cortex. Using S^{35}-labeled oligonucleotide probes (as previously described, Young, 1989), mRNA levels for D1, D2, Substance P (Sub P), dynorphin (DYN), and enkephalin (ENK) were assessed in regions of the striatum-accumbens complex three weeks after mPFC lesions. The mPFC lesions were produced by bilateral injections of ibotenic acid (IA). No differences were found between sham and lesion groups for D1 receptor, Sub P, DYN, or ENK mRNA levels in any region of the striatum or nucleus accumbens. D2 receptor mRNA levels were, however, significantly higher in the dorsomedial striatum and in the core area of the nucleus accumbens in lesioned rats. Although the functional significance of increased D2 message is unclear, these findings demonstrate that the mPFC modulates gene expression in regionally localized, subcortical neuronal populations that normally receive considerable glutamatergic input from the mPFC. Funding for this research was provided by the Intramural Research Program at NIMH.

NEONATAL HIPPOCAMPAL LESION (NHL) MODEL OF SCHIZOPHRENIA IN RATS: SEX DIFFERENCES AND PERSISTENCE OF EFFECTS INTO MATURITY. M.D. Black, J.M. Hitchcock & S.M. Sorensen*, Hoechst Marion Roussel, Department of Pharmacology, 16 rue d'Ankara, Strasbourg, France.

The neonatal hippocampal lesion model of schizophrenia (Lipska *et al.*, Neuropsychopharm., 9, 67-75, 1993) appears to have behavioural elements which only fully reveal themselves in adulthood, consistent with the time of onset of schizophrenia. We wished to extend these studies using female as well as male rats and to invetsigate whether these effects persist past early adulthood.

Rat pups, postnatal day (PD) 7, were injected with ibotenic acid (3 μg) or saline vehicle into the hippocampus. Behavioural testing (spontaneous, saline- and amphetamine- stimulated locomotor (LMA) activity) was performed on PD35, 56, and 100.

In male rats, at the PD35 timepoint (prepubertal) only amphetamine-stimulated LMA was enhanced in lesion vs sham. At the postpubertal timepoint PD56, significant enhancement of both amphetamine-stimulated and spontaneous LMA was seen in lesion vs sham. Saline injection failed to stimulate LMA in lesion or sham. The lesion effects on spontaneous and amphetamine-stimulated LMA were still apparent at the PD100 timepoint. In contrast to these results, the lesion had very little effect in female rats. The only significant differences between lesion and sham were in LMA after the saline injection at the PD35 timepoint and spontaneous activity at the PD100 timepoint.

The results indicate that the effects of NHL in male rats develop at early adulthood and persist in the mature rat. These results are consistent with the clinical development sequence seen in schizophrenia, which usually manifests after puberty and persists throughout life. In female rats, there was no persistent change produced by NHL. The fact that sex differences were seen with the NHL model is interesting, given that sex differences can also be seen in the clinical course of schizophrenia. Studies are ongoing to assess the validity of the NHL model as a test for potential antipsychotic drugs.

INDUCTION OF PSYCHOSIS-LIKE BEHAVIORAL SIGNS IN RATS AFTER S.C. IMPLANTATION OF PHENCYCLIDINE-LOADED POLYMERS. U. Schroeder, H. Schroeder and B.A. Sabel*. Inst. of Med. Psychology, Otto-v.-Guericke Univ., Magdeburg, Germany.

Phencyclidine (PCP) can induce a model psychosis and exacerbate the symptoms of chronic schizophrenic patients. We developed drug loaded subcutaneously implantable controlled release polymers which are capable to release drug continuously in vitro and in vivo. PCP loaded polymers were characterized in vitro for a period of about 100 days and release was found to be linear. Motor activity, latent inhibition and elevated plus maze performance were tested in vivo after 1mg/kg or 5 mg/kg of PCP applied continuously by polymer implants or by pulsatile injections over a period of 5 days in adult rats (n=10/group). This was compared to acute application of 5 mg/kg PCP or to saline treated controls. 48 hrs after completion of the behavioral experiments the brains were removed and specific 3H-TCP (thienylcyclohexylpiperidine) binding to striatal synaptic membranes was evaluated. The pulsatile application of both doses led to enhanced motor activity and to reduced number of changes and reduced length of stay in the bright arms of the elevated plus maze. The rats which received PCP by polymer implantation showed no changes in motor activity or elevated plus maze performance compared to saline controls. The lower dose of repeated pulsatile PCP (1.0 mg/kg) and the acute dose of 5.0 mg/kg did not modify latent inhibition. In contrast, the continuous application of 5.0 mg/kg by polymers but not the repeated pulsatile treatment disrupted latent inhibition. The 3H-TCP binding to striatal membranes was reduced in both, repeated pulsatil and continuous, cases of the chronic treatment but not after the acute application. Our findings suggest that continuously applied PCP is a useful tool to simulate psychosis-like behavioral signs in rats. This study was supported by the DFG Sa 433/5-2.

EFFECTS OF THE SEROTONIN AGONIST (±)-DOI HCl ON PREPULSE INHIBITION OF ACOUSTIC STARTLE REFLEX AND CAUDATE CELLULAR ACTIVITY. W.E. Cannon and M.D. Kelland*. Department of Psychology, St. Anselm College, Manchester, NH 03102.

The inhibitory effect that serotonin has on neurons in the prefrontal cortex (PFC), subsequently leading to reduced glutamate transmission to the caudate, has been postulated to be a contributing factor in the etiology of schizophrenia. The present study examined the behavioral and physiological effects of acute administration of DOI, a serotonin (5HT-2/5HT-1C) agonist. The prepulse inhibition of acoustic startle reflex model of schizophrenia was used to determine if DOI would disrupt prepulse inhibition in the rat. Doses of 0.1 and 1 mg/kg did not have a significant effect, while a dose of 0.5 mg/kg significantly disrupted prepulse inhibition as compared to a saline-treated control group. Standard, extracellular single-unit recording techniques were also used to assess the basal activity of caudate neurons in rats having received 0.5 mg/kg of DOI. DOI did not significantly alter either the firing rate or pattern of activity of Type I caudate neurons. However, preliminary results suggest that acute administration of 0.5 mg/kg of DOI may decrease the firing rate and increase the firing variability (i.e., increased coefficient of variation) of Type II cells. Thus, serotonergic pathways appear relevant to the responsiveness of rats in acoustic startle paradigms. Further studies will be necessary to confirm whether the prefrontal cortex is the site of these effects. (MDK is supported by PHS Grant MH51706)

657.17

THE EFFECTS OF ATYPICAL AND NOVEL ANTIPSYCHOTIC DRUGS ON PHENCYCLIDINE-INDUCED DISRUPTION OF PREPULSE INHIBITION IN RATS. D.C. Hoffman*, H. Donovan, M.R. Gates, C.A. Bankoski and J.V. Cassella. Neurogen Corporation, Branford, CT 06405.

The amplitude of the acoustic startle response in rats is decreased if the startle stimulus is preceded by a nonstartle-eliciting auditory stimulus. This sensory gating phenomenon, known as prepulse inhibition, is diminished in schizophrenic individuals. In rats, the noncompetitive NMDA antagonist phencyclidine (PCP) disrupts prepulse inhibition. The present study examined whether the disruption by PCP is reversible in rats pretreated with the classical antipsychotic haloperidol, the atypical antipsychotic clozapine or the novel antipsychotics olanzapine, remoxipride and seroquel. Male Sprague-Dawley rats were placed into a startle chamber and presented with auditory stimuli consisting of either 95 or 105 dB noise bursts presented alone or preceded by a 75 dB noise burst. Rats treated with 2.0 mg/kg PCP demonstrated a significant disruption of prepulse inhibition. Neither haloperidol (0.125, 0.25, 0.5 mg/kg SC) nor olanzapine (1.0, 2.0, 4.0, 8.0, 16.0 mg/kg SC) antagonized the PCP-induced disruption of prepulse inhibition. In contrast, clozapine (1.0, 5.0, 10.0, 20.0 mg/kg SC), remoxipride (8.0, 16.0, 32.0 mg/kg SC) and seroquel (2.0, 4.0, 8.0, 16.0 mg/kg SC) significantly attenuated the effects of PCP. These observations raise the possibility that the attenuation of the disruptive effects of PCP on prepulse inhibition may provide a useful rodent model for screening potential atypical antipsychotic drugs. (Funded by Neurogen Corporation)

EFFECTS OF MODULATION OF NITRIC OXIDE ON ACOUSTIC STARTLE AND PREPULSE INHIBITION IN RATS. J.L. Wiley*, K.M. Golden, and S.E. Bowen. Dept. of Pharmacology & Toxicology, Virginia Commonwealth University, Richmond, VA 23298-0613.

The nitric oxide (NO)-arginine pathway is intimately connected to the release of dopamine and glutamate, two neurotransmitter systems that may be dysfunctional in schizophrenia. In addition, NO synthase (NOS) inhibitors share many behavioral effects with the psychotomimetic drug, phencyclidine (PCP). Previous research has found that PCP-like drugs disrupt prepulse inhibition of the acoustic startle response, an animal model of sensorimotor gating, an attentional process that is disrupted in schizophrenia. The purpose of the present study was to examine the effects of NO modulators in this model. Following injection with a NO modulator, rats were placed in startle chambers in which they were exposed to acoustic pulses presented alone or preceded by a prepulse. The NOS inhibitors, L-NOARG and L-NAME, dose-dependently decreased startle during pulse alone trials, but neither drug affected prepulse inhibition (as previously reported). A substrate of the NOS-arginine reaction, L-arginine, produced similar results. The combination of L-NOARG and PCP decreased startle at higher doses of L-NOARG and produced variable effects on prepulse inhibition. The present results suggest that modulation of NO synthesis does not affect sensorimotor gating of the acoustic startle response. (Supported by the Grant-In-Aid Program for Faculty of VCU and by NIDA grant DA-01442.)

SEROQUEL REVERSES PCP-INDUCED HYPERACTIVITY AND PARTIALLY ANTAGONIZES PCP-MEDIATED DISRUPTION OF PREPULSE INHIBITION IN THE RAT

W.P. Jordan* and R.T. Bohan
Psychology, St. Mary's College of Maryland, St. Mary's City, MD 20686

Schizophrenics are unable to inhibit a startle response when a startle-eliciting stimulus is preceded by a shorter, less intense prepulse. This disruption of prepulse inhibition (PPI) can be modeled in rats injected with the NMDA antagonist phencyclidine (PCP). PCP produces psychomimetic symptoms in humans. In rats, PCP causes hyperlocomotion as well as disrupts PPI. These effects are blocked by the atypical antipsychotics clozapine and olanzapine, but not drugs with more specific dopaminergic inhibition. The present study examined the ability of seroquel, a dopamine/serotonin antagonist with preclinical similarities to clozapine, to block PCP-induced effects.

Male rats were tested under four counterbalanced conditions: saline, seroquel (5 mg/kg i.p.), PCP (1.35 mg/kg s.c.), or seroquel/PCP. Sessions were separated by at least 72 hr.

PCP caused a significant increase in locomotion that was blocked by pretreatment with seroquel. Seroquel alone had no effect on activity. PCP also produced deficits in PPI that were partially reversed by seroquel. These findings suggest that seroquel functions similarly to the other atypical antipsychotics clozapine and olanzapine in the animal model and may predict therapeutic effectiveness for seroquel.

ATTENTIONAL ABNORMALITIES IN AN ANIMAL MODEL FOR DEVELOPMENTAL DISORDERS OF THE ENTORHINAL CORTEX. L.M. Talamini, S. Knollema* and J. Korf. Psychiatry, Academic Hospital of Groningen, P.O. Box 30.001, 9700 RB Groningen, The Netherlands.

Post mortem investigations in schizophrenic subjects show entorhinal cortex (EC) abnormalities, which appear to be of prenatal origin. Abnormal developement of the EC was modelled in the rat. Effects on attention, which is typically abnormal in schizophrenics, were investigated. To induce a developmental insult methylazoxy methanol acetate (MAM) was used, which destroys cells undergoing mitosis. Four groups of gestating dams were injected with MAM around the time when the entorhinal cortex is expected to originate, namely on E9, E10, E11, or E12. A control group was injected with saline. In adult, male offspring the behavioural response to a sudden reduction in background noise was measured. During the test various behavioural elements were registrated, amongst others the element 'alert'.

All MAM treated groups displayed increased amounts of 'alert' during the noise-off period, compared to controls ($p<0.05$). The increase was largest in the E9 group and progressively decreased in later treated groups; in group E12 statistical significance only reached trend level ($p<0.1$). Remarcably, E11 rats showed a significantly increased percentage of 'alert' during the noise-on period, as well as during noise-off ($p<0.05$).

The results suggest that an abnormal orientation-attention response can result from an insult at the time of EC formation in the foetus. The overall increased orientation-attention response in E11 rats, may reflect an over-sensitivity to auditive stimuli, possibly extending to environmental stimuli in general. The latter observation may be related to our previous finding that normal habituation to an auditive startle stimulus is deficient in this group, and is in fact replaced by a sensitizing reaction.

NEUROPSYCHIATRIC DISORDERS: POSTMORTEM II

658.1

ALTERATIONS IN PHOSPHOINOSITIDE SIGNALING AND G-PROTEIN LEVELS IN DEPRESSED SUICIDE BRAIN. M. A. Pacheco*, C. Stockmeier, H. Y. Meltzer, J. C. Overholser, G. E. Dilley, and R. S. Jope. Dept. of Psychiatry, Univ. of Alabama at Birmingham, Birmingham, AL 35294-0017. Dept. of Psychiatry, Case Western Reserve Univ., Cleveland, OH 44106.

The function of the phosphoinositide signal transduction system was examined in postmortem prefrontal cortex regions (8/9) and (10) from suicide victims with major depression and matched control subjects without psychiatric illness. [^{3}H]Phosphatidylinositol (PI) hydrolysis stimulated by phospholipase C, GTP-γ-S, NaF, and neurotransmitter receptor agonists was measured in membrane preparations from both groups. Phospholipase C-β activity was similar in both groups in both regions. In prefrontal cortex (10), but not in (8/9), the GTP-γ-S concentration-dependent stimulation of [^{3}H]PI hydrolysis was significantly lower (30%) in the depressed suicide group. Receptor-coupled, G-protein-mediated [^{3}H]PI hydrolysis induced with agonists in the presence of GTP-γ-S stimulated equivalent responses in the two groups of subjects in each brain region. In prefrontal cortex (10) there was a 68% increase in the level of the 45kD subtype of Gαs and in prefrontal cortex (8/9) there was a significant decrease (21%) in the level of Gαi2 in the depressed suicide group compared to the control group. Levels of other heterotrimeric G-protein α-subunits (Gαq/11, Gαil, and Gαo) were not different. There were no differences in the levels of phospholipase C-β or protein kinase C-α. These results provide direct evidence in human brain that in the prefrontal cortex of suicide victims with major depression there is a region-specific alteration of G-protein-induced activation of the phosphoinositide signal transduction system and in the levels of G-protein α-subunits involved in cyclic AMP synthesis. REDUCED LEVELS OF SYNAPTIC PROTEINS IN THE PREFRONTAL CORTEX IN SCHIZOPHRENIA C.N. Karson*, W.S. Griffin, R.E. Mrak, W.Q. Sturner, S. Shillcutt, F.G. Guggenheim John L. McClellan VAMC 4300 West 7th St., Little Rock, AR 72205-5484, Univ of Arkansas Medical Sciences, Little Rock, AR 72114.

Recent studies of post mortem brains from patients with schizophrenia suggest that there are neuropil changes in the prefrontal cortex but no clear reduction in neuronal number. Using post mortem brain tissue obtained from schizophrenic and age matched control subjects, we measured the concentration of synaptophysin, a structural protein of synaptic vesicles, and a presynaptic 25-kD synaptosomal protein (SNAP-25). Schizophrenics (N = 14), had decreases in the relative concentration of both synaptophysin and SNAP-25 in Brodmann's area 10 (for synaptophysin, 0.63 ± 0.24 absorbance units or AI versus 0.82 ± 0.24 AI, $p < 0.05$; for SNAP-25, 0.24 ± 0.11 AI versus 0.37 ± 0.09 AI, $p < 0.002$) when compared with controls (N = 12). These data could support the notion of a neuron sparing neurodevelopmental process leading to "hypofrontality".

Supported by MH Grant #45729-03 and an award from the Theodore & Vada Stanley Foundation.

GENE EXPRESSION FOR CALBINDIN-D28K IN THE PREFRONTAL CORTEX OF SCHIZOPHRENICS AND CONTROLS. T.Takahashi*[1)2)], H.Arai[1)], R.Inoue[1)], P.J.McKenna[3)] and P.C.Emson[2)] 1)Dept. of Psychiatry, Juntendo Univ. Sch. of Medicine, Hongo, Tokyo 113, Japan 2)MRC Molec. Neurosci. Group, Dept. of Neurobiology, The Babraham Institute, Babraham, Cambridge CB2 4AT, UK 3)Dept. of Psychiatry, Univ. of Cambridge, Cambridge CB2 2QQ, UK

The findings of an increasing number and variety of studies have implicated the prefrontal cortex as a site of dysfunction in schizophrenia. Recent studies suggest that this dysfunction may be related to abnormalities in GABAergic neurotransmission. Understanding the functional consequences of these abnormalities depends upon a knowledge of which populations of GABA neurons are affected in this disorder. Calbindin-D28K(CB) immunoreactive neurons mostly belongs to subpopulation of GABAergic interneurons in the human cerebral cortex. Previous studies suggest that the prefrontal cortical area of schizophrenics show an increase of CB immunoreactive local circuit neurons. In this study we have used in situ hybridization technique with an antisense oligonucleotide probe specific for CB mRNA to detect sites of gene expression in postmortem human prefrontal cortex (Brodmann areas 9, 10 and 11). The distribution and CB mRNA levels have been determined using computer assisted image analysis in brains from schizophrenics and from matched normal controls. CB mRNA was expressed with similar pattern in all cases. This distribution pattern revealed a dense band of strongly labeled CB mRNA containing neurons in superficial layers. On film autoradiography there was no significant differences in amounts of CB mRNA between schizophrenics and controls, however that of schizophrenics tended to be increased than controls. They are consistent with hypothesis that the function of a specific population of GABA neurons may be altered in this disorder.

VIRAL AND VIRUS-RELATED RNAS ARE DIFFERENTIALLY EXPRESSED IN THE BRAINS OF INDIVIDUALS WITH SCHIZOPHRENIA. F. Yee*, N.L. Johnston, F. Leister, S. Li, C.A. Ross#, E.F. Torrey and R.H. Yolken. *Stanley Neurovirology Laboratory, #Depts. of Psychiatry and Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21287.

The etiology and pathogenesis of schizophrenia is not yet known. In this study, we have examined the hypothesis that the expression of brain RNAs may be altered in schizophrenia. A modified version of the arbitrarily primed-polymerase chain reaction (AP-PCR) method (Welsh et al, Nucl. Acids Res. 20:4965, 1992) was used to determine whether RNAs are differentially expressed in cortical regions obtained postmortem from individuals with schizophrenia and normal controls.

Several RNA transcripts had higher expression levels in the frontal cortex of an individual with schizophrenia compared to the normal control. One of the candidate RNAs displayed 77% amino acid homology to the Pol polyprotein of simian retrovirus (SRV-2), which is a primate type-D retrovirus. A second transcript was nearly identical to the DB1 zinc finger protein (>99% predicted amino acid similarity), which interacts with the tax protein of human T-cell leukemia virus to increase interleukin-3 transcription.

These candidate clones were then screened for disease association using semi-quantitative reverse transcription-PCR on brain RNAs extracted postmortem from individuals with schizophrenia (n=21), bipolar disorder (n=19) and controls without history of psychiatric illness (n=10). Initial evaluation of the DB1 transcript indicates that there are significant differences between the cases and controls ($p<0.03$ by ANOVA). Northern blots, ribonuclease protection assays and analysis of other brain regions will be used to confirm the differential expression of these candidate RNAs. Our preliminary findings indicate that viral and viral-associated RNA transcripts are expressed in the brain of some individuals with schizophrenia and may play an important role in disease pathogenesis.

N-CAM AND L-1 ANTIGEN IN THE HIPPOCAMPUS OF NEUROPSYCHIATRIC DISORDERS. M.P.Vawter, H.E. Cannon-Spoor*, J.J.Hemperly[1], D. Vander Putten, T.M. Hyde, A.M. Murray, J.E. Kleinman, and W.J. Freed. NIMH Neuroscience Center at St. Elizabeths, Washington D.C.20032. [1] Becton Dickinson, *Neurobiology Section, P.O. Box 12016, Research Triangle Park, NC* 27709.

Cell recognition molecules are thought to be involved in neuronal migration, synaptogenesis, and hippocampal long-term potentiation. Concentrations of the neuronal cell adhesion molecule (N-CAM) were increased in CSF in schizophrenics, bipolar type I and unipolar depressed patients, while L1 concentrations were decreased in schizophrenia (Poltorak et al, J. Neurochem 66,1532,1996) Evidence from imaging and post-mortem studies suggest hippocampal abnormalities in schizophrenia. We have measured levels of soluble- and detergent-extracted adhesion molecules in whole hippocampi of schizophrenics (16), bipolar disorders (5), suicides (7), and normal controls (13) by Western immunoblots. Detergent-extracted levels of specific isoforms of N-CAM and L1 were increased in suicides versus other groups. Concentrations of soluble adhesion molecules showed a dissimilar pattern. Schizophrenics showed an increase in soluble N-CAM hippocampal concentrations as compared to normal controls ($p=.04$) and to the bipolar subjects ($p=.05$). Soluble L1 concentrations were the same in hippocampi from all four groups. Western immunoblots from additional regions implicated in these disorders will also be presented.

^{3}H-NEMONAPRIDE BINDING IN SCHIZOPHRENIA: DECREASE IN σ BUT NO D_4 DIFFERENTIALS. S.W. Tang, D.M. Helmeste, W.E. Bunney, Jr.*, S.G. Potkin and E.G. Jones, Departments of Psychiatry and Anatomy and Neurobiology, University of California, Irvine, CA 92717.

The ^{3}H-nemonapride (D_2, D_3 and D_4)/^{3}H-raclopride (D_2, D_3) subtraction method was proposed by Seeman et al. (1993) to label dopamine D_4 receptors in postmortem schizophrenic brains. Attempts to replicate the elevated D_4 differentials in postmortem schizophrenic brains have not been consistently successful. In recognizing that ^{3}H-nemonapride labels σ sites in addition to dopaminergic sites, we proceeded to quantify both D_4 differential and σ sites in postmortem schizophrenic brains, using ^{3}H-nemonapride with sulpiride (dopamine) and PPAP (σ) baselines. All six schizophrenic brains showed a marked decrease in σ sites (caudate, cerebellum and frontal cortex) and an increase in the caudate dopamine component in comparison with controls matched for age, sex and autolysis time. Scatchard analysis using ^{3}H-nemonapride and ^{3}H-raclopride did not yield a D_4 differential in the caudate. The results suggest a negative correlation between σ and dopamine sites but do not support a striatal dopamine D_4 differential increase in schizophrenia.

FURTHER EVIDENCE OF CYTOARCHITECTURAL DISTURBANCE IN THE ROSTRAL ENTROHINAL CORTEX IN SCHIZOPHRENIA USING SPATIAL POINT PATTERN ANALYSES. D.R. Ruscheinsky, L.-Y. Han, G.S. Smutzer*, S.E. Arnold. Center for Neurobiology and Behavior, Dept of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104

Previous studies have reported cytoarchitectural abnormalities in superficial laminae of rostral portions of the entorhinal cortex including decreased densities of neurons, poorly formed layer II neuron islands, and apparent displacement of layer II-type neurons deep into layer III. However, findings have been controversial given the qualitative nature of the descriptions and the normal heterogeneity of cytoarchitecture of the region. In this preliminary investigation employing quantitative methods of cytoarchitectural analysis, Nissl stained neurons were mapped in layers II, III, and V of subdivision ER of the entorhinal cortex in 8 prospectively accrued and assessed patients with schizophrenia and 8 age compatible normal controls. Quadrat count methods for measuring neuron dispersion indicated abnormal clustering of neurons in layer III in schizophrenics compared to controls accompanied by a trend towards reduced neuron effective radius ("dead space"). Analyses of layer II found a non-signficant decrease in the normally expected clustering of neurons in schizophrenia, but an increased effective radius and packing factor. No between group differences were noted in layer V for any variable nor were there any significant differences in total neuron numbers or in other indices of neuronal arrangement in any layer. These data provide further evidence for subtle aberrant cytoarchitecture in superficial laminae of the entorhinal cortex in schizophrenia and are consistent with neurodevelopmental models of abnormal neuronal migration, pruning, and/or "miswiring" in the illness. Supported by NIH grants MH00978, MH55199, MH43880.

THE INVESTIGATION OR BORNA DISEASE VIRUS ANTIBODIES AND ANTIGEN IN SCHIZOPHRENIC PATIENTS *S. Iritani*[1], N. Kuroki[1], T. Horimoto[2], S. Haga[3], M. Tashiro[2], K. Ikeda[3] and H. Kazamatsuri[1]* 1 Dept. of Psy. Tokyo Metropolitan Matsuzawa Hosp., Setagaya Tokyo 156 Japan. 2 Dept. of Virology 1., National Institute of Health, Shinjyuku Tokyo 162 Japan. 3 Dept. of Ultrastructure Tokyo Institute of Psychiatry, Setagaya Tokyo 156 Japan.

Borna disease (BD) virus is a partially characterized neurotropic agent, and natural infections are widely spread among horses, sheep, even cats. In 1985, BD virus antibodies were detected in human peripheral blood, there was possibility that this virus could infect even human being. Furthermore, it was declared that the ratio of the positive in serum antibody was remarkably high in schizophrenic patients statistically compared to that in healthy normal control. In the present study, we investigate BD virus-reactive antibodies in blood serum of schizophrenic patients using the technique of ELISA method, and detect BD virus antigen in blood mononuclear cells using the technique of RT-PCR method. As the results, BD virus reactive antibodies against 40Kd or/and 24Kd proteins were high frequently find in serum of schizophrenic patients compared to normal controls without neurological or mental disorder. Virus-specific nucleic acid were found in the blood of some schizophrenic patients, but there was not found in the blood of normal controls without mental disorder. This facts indicates that BD virus infection could be one of origin for schizophrenic disorder.

THE DISTRIBUTION OF NEURONS CONTAINING NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE IN SCHIZOPHRENIA. N. Kuroki [1], S. Iritani [1], K. Ikeda [2], K. Uéda*[3] and H. Kazamatsuri [1]. 1 Dept. of Psy. Tokyo Metropolitan Matsuzawa Hosp., Setagaya-ku Tokyo 156 Japan, 2 Dept. of Neuropathology, Tokyo Institute of Psychiatry, Setagaya-ku Tokyo 156 Japan, 3 Tokyo Institute of Psychiatry, Setagaya-ku Tokyo 156 Japan.

Nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) staining often correlates with nitric oxide (NO) synthase immunoreactivity in fixed brain tissues. NO is associated with synaptic plasticity and other functions in the central nervous system. In the present study, the distribution of neurons expressing the enzyme NADPH-d in the right prefrontal cortex (Brodmann area 10) and the temporal cortex (area 21) of 5 schizophrenic and 3 control brains was investigated. Schizophrenic patients had significantly lower density of NADPH-d positive neurons in almost all layers of the prefrontal cortex and the temporal cortex than controls. The low density of NADPH-d positive neurons, which may be explained by neurodevelopmental disturbances, may cause dysfunction of NO which contributes to some symptoms of schizophrenia.

ELEVATED NEURONAL DENSITY IN PREFRONTAL AREA 46 OF THE HUMAN SCHIZOPHRENIC CORTEX. L.D. Selemon*, G. Rajkowska and P.S. Goldman-Rakic. Section of Neurobiology, Yale University School of Medicine, New Haven, CT 06510 .

Our recent morphometric analysis of prefrontal area 9 in schizophrenic brains revealed a pattern of higher than normal neuronal density coupled with a slight reduction in cortical thickness (Selemon et al., 1995). We have now examined a cytoarchitectonically distinct (Rajkowska and Goldman-Rakic, 1995) region, area 46, which mediates working memory-dependent behavior in the spatial domain. Formalin fixed blocks of area 46 were obtained from 9 neurologically normal and 7 schizophrenic brains. Normal and schizophrenic brains were well matched for age (46.67 ± 4.76 yrs., 37.14 ± 5.66 yrs.), postmortem interval (15.46 ± 2.51 hrs., 15.52 ± 3.30 hrs.), and storage time in formalin (12.41 ± 14.85 mo., 14.85 ± 6.12 mo.), respectively. The blocks were celloidin-embedded and cut at 40 um. Neuronal and glial density, as well as cortical thickness, were measured using the direct 3-dimensional counting protocol of Williams and Rakic (1988). Mean neuronal density was 13% (p=.054) higher in the schizophrenic cohort relative to normal control brains; mean glial density was 10% higher although this difference was not significant. There was a trend decrease (5%) in cortical thickness in area 46 as well. These results support previous findings in areas 9 and 17 and extend the evidence for elevated cell packing density to an additional area, area 46, thus increasing the possibility that this may be the predominant abnormality in the schizophrenic cerebral cortex.
Supported by CNS grant #44866.

REDUCED DOPAMINE INNERVATION OF THE PREFRONTAL CORTEX IN SCHIZOPHRENIA. M. Akil*, D. A. Lewis. Departments of Psychiatry and Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15213.

The prefrontal cortex (PFC) has been implicated in the pathophysiology of schizophrenia, and the dopamine (DA) innervation of this region has been suggested to be altered in this disorder. We used immunocytochemical methods and an antiserum against tyrosine hydroxylase (TH), previously shown to visualize primarily DA axons in human neocortex, to examine the DA innervation of the PFC in schizophrenic (S) and control (C) subjects. We compared area 9 of the PFC in postmortem specimens from 7 S each matched to 1-3 C for age, sex, race and postmortem interval. TH-containing axons were reconstructed in layers I, III and VI using the Eutectics Neuron Tracing System. Quantitative analysis of these reconstructions revealed a reduction in two measures of innervation density, total axon length and number of varicosities, in the S. Compared to C, total axon length in S was decreased in layers I, III, and VI by 42%, 47% and 65%, respectively. Similarly, the number of fiber swellings was reduced in the S by 37% in layer I, 43% in layer III, and 75% in layer VI. Most of this decrease was accounted for by 4 of the 7 S. To determine whether these findings reflected a decrease in TH levels or a reduced number of DA afferents, we examined the same specimens with an antibody against the DA transporter. Preliminary studies also revealed a reduction in the density of axons containing the DA transporter in S. These findings are consistent with a decrease in the DA innervation of the PFC in schizophrenia, and given the critical role of DA in the normal function of the PFC, may provide insight into the pathophysiological basis for PFC dysfunction in this disorder. Supported by a NARSAD Young Investigator Award and MH43784.

658.12

AXON TERMINAL CARTRIDGES OF CHANDELIER NEURONS IN THE PREFRONTAL CORTEX IN SCHIZOPHRENIA. T.-U. Woo*, R. E. Whitehead, and D. A. Lewis. Departments of Psychiatry and Neuroscience, University of Pittsburgh, PA 15213.

GABAergic dysfunction in the prefrontal cortex (PFC) has been implicated in the pathophysiology of schizophrenia. Among the inhibitory local circuit neurons in the PFC, chandelier cells are of particular interest because their axon terminals, which are arranged in cartridge-like arrays, target the axon initial segment of pyramidal cells. This synaptic arrangement suggests that chandelier neurons could directly regulate the output of pyramidal cells and thereby the activation of PFC circuitry. Thus, alterations in the inhibitory circuitry of chandelier neurons could contribute to PFC dysfunction in schizophrenia.

The calcium-binding protein parvalbumin is often used as an immunohistochemical marker for chandelier neurons, but it fails to identify chandelier axon cartridges in human tissue. In this study, an antibody (Chemicon) raised against the high-affinity GABA plasma membrane transporter, GAT-1, was used to label GABAergic axon terminals, including axon cartridges of chandelier neurons, in postmortem human PFC (areas 9 and 46). Examinations of GAT-1-stained tissue revealed punctate labeling of neuropil across all cortical layers, with intensity of labeling greater in the supra- than in the infragranular layers. Chandelier axon cartridges were morphologically distinct, as they were comprised of intensely immunoreactive varicosities arranged in rod-like arrays. Not uncommonly, cartridges were found immediately below the outline of unlabeled, presumably pyramidal cell soma. The laminar pattern of distribution of cartridges was also distinct; they tended to be concentrated in superficial and deep bands. Quantitative blind comparisons of 15 pairs of schizophrenic and control subjects, matched on the basis of age, sex and postmortem interval, are in progress to test the hypothesis that the density of these axon cartridges is altered in schizophrenia. Supported by NIMH grant MH45156.

PARVALBUMIN-IMMUNOREACTIVE LOCAL CIRCUIT NEURONS IN THE PREFRONTAL CORTEX IN SCHIZOPHRENIA. J. L. Miller, T.-U. Woo, R. E. Whitehead,* and D. A. Lewis. Departments of Psychiatry and Neuroscience, University of Pittsburgh, Pittsburgh, PA 15213.

The excitatory circuitry of the prefrontal cortex (PFC), furnished by layer III pyramidal neurons, has been implicated in the pathophysiology of schizophrenia. Two classes of inhibitory local circuit neurons, both of which express the calcium-binding protein parvalbumin (PV), could powerfully modulate the activity of PFC circuitry through synaptic input to the soma (basket cells) or axon initial segment (chandelier cells) of pyramidal neurons. Thus, PFC dysfunction in schizophrenia could be reflected in alterations in the inhibitory circuitry involving PV-immunoreactive (IR) neurons. To examine whether the density of PV-IR neurons was altered in schizophrenia, postmortem prefrontal (areas 9 and 46) and occipital (area 17) cortical tissue from 10 pairs of schizophrenic and control subjects, matched on the basis of age, sex and postmortem interval, were processed for PV immunohistochemistry. The density of PV-IR neurons in the schizophrenic subjects was not different from controls in any of the three areas. The average somal area of PV-IR neurons in schizophrenic subjects also did not differ from the controls. Measurements from Nissl-stained sections revealed a slight (approximately 5%) decrease in cortical thickness in each region of the schizophrenic subjects, though statistical significance was not achieved. These results suggest that alterations in inhibitory circuitry in schizophrenia might involve local circuit neurons that do not express PV. Alternatively, functional alterations in basket and/or chandelier neurons might not be reflected in levels of PV expression. Supported by NIMH grant MH45156.

SPECIFICITY OF DECREASED SPINE DENSITY ON LAYER III PYRAMIDAL CELLS IN SCHIZOPHRENIA. L.A. Glantz* and D.A. Lewis. Departments of Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

A decreased number of synaptic contacts in the prefrontal cortex (PFC) has been suggested to contribute to the dysfunction of this region in schizophrenia. Because dendritic spines are the major site of excitatory synaptic inputs to pyramidal neurons, decreased synapse number in schizophrenia may be associated with alterations in spine density. Layer III pyramidal neurons are of particular interest in this regard, given their role in both intra- and inter-areal cortical connectivity. The Rapid Golgi procedure was used to impregnate neurons in the PFC (area 46) and primary visual cortex (area 17) from eleven schizophrenic, ten normal control, and eleven non-schizophrenic psychiatric subjects with diagnoses of major depression, bipolar disorder and/or alcoholism. In both areas 46 and 17, spine density on layer III pyramidal neurons was decreased in the schizophrenic subjects compared to both the normal control and non-schizophrenic psychiatric subjects. Other parameters, such as somal area, total dendritic length, number of branch segments, maximum branch order, and ratio of natural ends to artificial ends, did not differ across the three groups in either region. These findings indicate that decreased spine density on layer III pyramidal neurons is not a common characteristic of individuals with psychiatric disorders, suggesting that it may be specific to schizophrenia. This decrease in spine density is consistent with the hypothesis that alterations in the integrity of cortical synaptic structures may contribute to the pathophysiology of schizophrenia. DECREASED NEURON-SPECIFIC EXCITATORY AMINO ACID TRANSPORTER 3 (EAAT3) IN SCHIZOPHRENIC HIPPOCAMPUS. A.M. Murray*, C. Shannon Weickert, P. Shashidharan#, T.M. Hyde, J.E. Kleinman Clinical Brain Disorders Branch, IRP, NIMH, St. Elizabeths Hospital, Washington, DC 20032, #Dept. of Neurology, Mount Sinai School of Medicine, New York, NY 10029.

Glutamate abnormalities have been implicated in the pathophysiology of schizophrenia. One focus of these abnormalities may involve the hippocampus, a site implicated in the neuropathology of schizophrenia in a number of neuroimaging and postmortem studies.

In order to evaluate alterations in glutamatergic neurotransmission, mRNA encoding the neuronal EAAT3 (Shashidharan et al., 1994) was measured using a quantitative nuclease protection assay in hippocampal homegenates of schizophrenics (n = 19), suicides (n = 15) and normal controls (n = 19). A 50% decrease in EAAT3 mRNA was observed in schizophrenics (p=0. 0005) and a 20% decrease in suicide (p=0.1227) compared to normal controls.

These data support an increasing body of findings implicating the hippocampus in the neuropathology of schizophrenia. They also suggest that at least part of this pathology may be related to decreased glutamate reuptake. Alterations in the glutamate/aspartate transporter in the schizophrenic hippocampus could reflect neuronal loss, decreased transport function resulting in rebound excess glutamate in the synapse or hypofunction of glutamatergic neurons. These questions require a number of further studies.

Supported by funding from the NIMH-IRP.

Localization and Quantitative Studies of Synaptic Markers in the Hippocampal Formation of Schizophrenic and Control Subjects. M.J. Webster*, C. Shannon Weickert, A.M. Murray, T.M. Hyde, M.M. Herman, L.B. Bigelow, J.E. Kleinman. Clinical Brain Disorders Branch, NIMH Neuroscience Center, Washington, DC 20032.

Growth-associated protein 43 (GAP-43) and synaptophysin are proteins involved in regulating synaptic plasticity and/or transmitter release and are colocalized to the presynaptic terminal. Recent studies have proposed a possible alteration in the number of synapses in the brains of schizophrenic patients. We therefore hypothesized that there may be an alteration in the level of mRNAs that code for synaptic proteins in diseased brains. However, we found no significant alteration in levels of GAP-43 mRNA analyzed by RNase protection assay performed on cytoplasmic mRNA extracted from whole hippocampal homogenates of schizophrenic (N=19) and control (N-19) subjects. *In situ* hybridization with additional schizophrenic (N=9) and control (N=7) subjects also failed to detect any alterations in either GAP-43 or synaptophysin mRNA in hippocampal subfields. Neurons expressing highest levels of mRNA were found in layers II/III of entorhinal cortex, in granule cells of the dentate gyrus and in CA3 pyramidal cells. Immunohisto-chemical localization of the proteins revealed that both GAP-43 and synaptophysin were concentrated in the molecular layer of the hippocampal formation while the granule and pyramidal cell layers were devoid of immunoreactivity. There were no apparent differences in localization or intensity of immunoreactive staining between schizophrenic and controls. Supported by the Stanley Foundation and NIMH-IRP.

658.17

REDUCED LEVEL OF EXCITATORY AMINO ACID TRANSPORTER 3 mRNA IN HIPPOCAMPUS OF SCHIZOPHRENICS.

S. E. Bachus*, T.M. Hyde, C. Shannon Weickert, P. Shashidharan+, M.M. Herman & J.E. Kleinman. CBDB, NIMH Neuroscience Center at St. Elizabeths, Wash., DC, 20032; & +Dept. Neurology, Mt. Sinai Sch. Med., NY, NY 10029.

A number of diverse findings suggest that a neural circuit involving striatum/nucleus accumbens, hippocampus/parahippocampal cortex and prefrontal cortex may be involved in the pathophysiology of schizophrenia. As these regions are connected by glutamatergic neurons, a study of these neurons in the hippocampus/parahippocampal cortex seemed indicated.

In situ hybridization histochemistry was performed with an [^{35}S]-labelled ribonucleotide probe for mRNA for the human excitatory amino acid transporter 3, which has been shown to be expressed in human hippocampus (Shashidharan et al., Brain Res. 662:245, 1994), using 14 μ-thick fresh frozen sections containing parahippocampal gyrus, hippocampus, presubiculum and subiculum from schizophrenics (n=9) and normal controls (n=7).

A two-way ANOVA (group by region) indicated that there was a reduction in glutamate transporter mRNA in schizophrenics ($p<.0001$). Post-hoc comparisons for each region indicated that this difference attained statistical significance ($p\leq.05$) in dentate, CA1, and subiculum, where levels were 69, 67 and 61 %, respectively, of normal levels, and approached significance ($.08 \geq p > .05$) in CA4, presubiculum and parahippocampal layers ii/iii.

Our results are consistent with those found by an RNase protection assay in a separate cohort by A.M. Murray et al. (Neuroscience Abstracts, 1996). While the human excitatory amino acid transporter 3 is not entirely specific to glutamate neurons, these results are consistent with the hypothesis that glutamatergic hypofunction in hippocampus might contribute to the neuropathological basis of schizophrenia.

Sponsored by the Theodore and Vada Stanley Foundation, & by IRP, NIMH.

658.18

DECREASE IN GAP-43 mRNA IN THE SCHIZOPHRENIC PREFRONTAL CORTEX. S.Geethabali*, C.Shannon Weickert, T.M.Hyde, A.M.Murray, A.K.Brouha, M.M.Herman, D.R.Weinberger and J.E.Kleinman. Clinical Brain Disorders Branch, IRP, NIMH Neuroscience Center at St.Elizabeths, Washington, D.C. 20032

Several studies have shown that there is a decrease in the cortical volume in the brains of schizophrenic patients compared to normal controls. Neuropathological studies suggest that neuronal loss and/or reduction in neuropil may be contributing to this decrease. It is possible that there is a decrease in the number of synapses in the schizophrenic brain. GAP-43 is a presynaptic membrane phosphoprotein associated with growth and modulation of neuronal connections. The level of mRNA for GAP-43 is highest in the association areas in the adult human brain, and the nerve terminals with high GAP-43 levels may be highly plastic, changing in response to physiological activity and environmental factors. We hypothesized that there may be a decrease in the mRNA coding for GAP-43 in the prefrontal cortex of the schizophrenic brain. GAP-43 mRNA levels were measured by performing RNase protection assays on cytoplasmic RNA extracted from homogenates of the dorsolateral prefrontal cortex from schizophrenics (n=19) and age, sex and postmortem interval matched normal controls (n=19). GAP-43 mRNA was found to be significantly lower (55% of controls, p=0.01) in the prefrontal cortex of schizophrenics as compared to controls. These studies support the hypothesis that there is a reduction in the number of synapses in the prefrontal cortex of schizophrenics. Another possible interpretation of this finding is that the synapses that are present are less malleable.

REDUCTIONS IN BRAIN DERIVED NEUROTROPHIC FACTOR mRNA IN THE HIPPOCAMPUS OF PATIENTS WITH SCHIZOPHRENIA. A. K. Brouha*, C. Shannon Weickert, T. M. Hyde, M. M. Herman, A. M. Murray, L. B. Bigelow, D. R. Weinberger and J. E. Kleinman. Clinical Brain Disorders Branch, IRP, NIMH Neuroscience Center at St. Elizabeths, Washington, DC 20032

Brain Derived Neurotrophic Factor (BDNF) has been shown to help sustain many types of central nervous system neurons. Previous studies have suggested that hippocampal pathology is involved in schizophrenia. BDNF mRNA has been found in the human hippocampus, and may be acting as a neurotrophic agent for neurons in and around the hippocampus. To explore the hypothesis that compromised neuronal circuits cause symptoms of schizophrenia, levels of BDNF mRNA were analyzed in the schizophrenic and normal hippocampus. Messenger RNA was measured using riboprobe in situ hybridization on sections of postmortem human hippocampus, from eight subjects with schizophrenia and seven controls. A 1.6 kb human BDNF cDNA clone was used as a template for in vitro transcription of a riboprobe. Preliminary data show BDNF mRNA levels are reduced by 20-30% in schizophrenics in granular cells of the dentate gyrus, and in the pyramidal cell layer of CA1 and CA4. In all subjects, mRNA levels were highest in granular cells of the dentate gyrus. A decrease in BDNF expression in the hippocampus of schizophrenics may signify a primary pathological process intrinsic to the hippocampus, or pathology in sites projecting into the hippocampus. Because BDNF gene expression has been shown to be affected by glutamate receptor activation, a reduction in BDNF mRNA may be the result of a previously reported decrease in glutamate concentration in the schizophrenic hippocampus. Conversely, a decrease in BDNF may lead to a decrease in glutamate activity. The observation of reduced hippocampal BDNF gene expression augments previous neuroimaging, neuropsychology and neuropathology studies suggesting pathology of the hippocampus in schizophrenia. Supported by the IRP of NIMH.

SYMPOSIUM. THE CELLULAR BASES OF FUNCTIONAL BRAIN IMAGING. P.J. Magistretti, Univ. of Lausanne, (Chairperson); M.E. Raichle, Washington Univ.; T.A. Woolsey, Washington Univ., A. Grinvald, Weizmann Institute; R.G. Shulman, Yale Univ.; P.J. Magistretti, Univ. of Lausanne.

Functional brain imaging has become an increasingly important element in the investigative armamentarium of neuroscience research. The signals detected by PET, fMRI, MR spectroscopy and optical imaging are based on activity-dependent localized changes in blood flow, oxygenation and metabolism. The symposium will review new insights into the cellular mechanisms and localization of the coupling between neuronal activity, vascular events and metabolism, focusing on their relevance to functional brain imaging. After a brief introduction by M.E. Raichle, T.A. Woolsey will present data on the direct imaging of dynamic blood flow regulation in response to somatosensory (whisker) stimulation in the barrel cortex, focusing on the biological limits to spatial, temporal and magnitude resolution in flow-based imaging studies. A. Grinvald will review new developments in the analysis of activity-related intrinsic optical signals which provide the means to map the spatial and temporal relationships between electrical activity and the response of cortical microcirculation. Quantitative data on glucose metabolism obtained with in vivo MR spectroscopy using ^{13}C labels will be reviewed by R.G. Shulman to illustrate the occurrence of a transient glycolysis during activation; this activation-induced glycolysis, which results in a transient production of lactate, is followed by a stoichiometric recoupling of glucose utilization and oxygen consumption during sustained stimulation. P.J. Magistretti will present data on the structural and functional characteristics of astrocytes which indicate that this cell type plays a key role in coupling neuronal activity to energy metabolism, making astrocytes a prevalent site of glucose uptake and metabolism during activation and a likely source of the signal detected in ^{18}F-deoxyglucose PET activation studies.

SYMPOSIUM. NEUROTROPHINS AND SYNAPTIC PLASTICITY. B. Lu NIH-NICHD (Chairperson); M.-M Poo, UC San Diego; I. B. Black, RWJ Med. Sch.; H. Thoenen, Max-Planck Inst.; C. J. Shatz UC Berkeley.

Neurotrophins (NTs) have traditionally been viewed as trophic factors for neuronal survival and differentiation. Recent studies suggest that NTs may also play an important role in synapse development and plasticity. This symposium will summarize progress in this emerging field. **Bai Lu** will introduce several important issues, using data primarily from his lab: 1) Comparison of NT action at neuromuscular junctions (NMJ) and in the CNS. 2) NTs' effects on developing versus mature synapses. 3) Acute as well as long-term regulation of synaptic function by NTs. 4) Do NTs act pre- or postsynaptically? 5) Can NTs serve as retrograde messages? **Mu-ming Poo** will describe the effects of NTs on growth cone motility and chemotactic turning of spinal neurons. He will also discuss how NTs acutely regulate transmitter secretion at NMJ, and whether cell body or nerve terminals are responsible for this regulation. **Ira Black** will review the acute enhancement of neuronal activity and synaptic transmission by NTs in cultured hippocampal neurons, and its possible mechanism through postsynaptic tyrosine phosphorylation. **Hans Thoenen** will present data supporting the hypothesis that NTs serve as retrograde messengers for activity-dependent modulation of synaptic efficacy. He will describe activity-dependent secretion of NTs, and the defects in hippocampal LTP in the BDNF knockout mice. **Carla Shatz** will review the role of NTs in synaptic competition during visual cortex development. She will present evidence that BDNF is present in the visual cortex while its receptor TrkB is expressed in LGN neurons. Infusion of BDNF into the visual cortex prevented the formation of ocular dominance column.

CONSTITUTIVE SIGNALLING OF GLUCAGON/VIP/CALCITONIN-RECEPTORS - TRANSMEMBRANE vs. LIGAND-BINDING DOMAIN. S. A. Hjorth *, C. Ørskov, and T. W. Schwartz , Laboratory for Molecular Pharmacology, Rigshospitalet 6321, DK-2100 Copenhagen, Denmark.

Background: The glucagon/VIP/calcitonin family of receptors can hypothetically be considered as two-domain structures, composed of an N-terminal ligand-binding domain and a predominantly transmembrane (TM) signaltransducing domain. **Results:** Analysis of chimeraes between the glucagon and the homologous GLP-1 receptor has demonstrated the need for epitopes from both receptor domain for high affinity peptide binding. Activation of the receptors may however occur following mutational exchange at a single position deep in the TM domain. Thus, substitution of a highly conserved residue in the glucagon receptor, $His^{178} \rightarrow Arg^{178}$, was accompanied by elevated, ligand-independent cAMP accumulation. In contrast, exchange of His^{178} into Lys^{178}/Ala^{178} or Glu^{178} had no effect. Previously, substitution of the corresponding residue in the PTH receptor from this family was observed in a naturally occurring constitutively active receptor. A truncated glucagon receptor, deleted for the N-terminal domain, which no longer binds the peptide, and which includes the Arg^{178} substitution, similarly caused an elevated cAMP level. **Conclusions:** It is suggested that 1) the N-terminal and the TM domains of the glucagon/VIP /calcitonin receptors are both required for selective, high affinity peptide binding, and involve an interaction between the N-terminal part of the peptide and the TM domain of the receptor, and 2) that the exchange of a single residue, His^{178} - specifically into arginine - confers constitutive activity upon the TM domain of the receptor independently of the presence of the ligand-binding domain.

Cloning, Characterization and Functional Studies of a Guinea Pig Diencephalic Calcitonin Receptor. A.Sarkar* and I.M.Dickerson, Dept. of Phys. and Biophys., Univ. of Miami School of Medicine, Miami, FL 33101.

We have cloned the guinea pig calcitonin receptor to gain insights into the functionof seven transmembrane G-protein coupled receptors. Calcitonin receptors present in renal and skeletal tissues function to alter calcium homeostasis as a hypocalcemic agent. The binding of calcitonin to its receptor in the CNS elicits diverse behavioral modifications ranging from analgesia to anorexia.

A degenerate reverse transcription/ polymerase chain reaction (RT/PCR) strategy was employed to clone the guinea pig calcitonin receptor. The amino acid sequences from pig, human and rat calcitonin receptors were aligned to identify conserved regions for the design of degenerate oligonucleotide primers flanking the first to seventh transmembrane domains. Messenger RNA from guinea pig kidney and total brain used as template for RT/PCR reactions generated a 1.0 kb amplimer from both tissues. Cloning and sequencing the amplimers revealed ≥79% deduced amino acid similarity to previously cloned calcitonin receptors. To obtain a full length guinea pig calcitonin receptor, 5' and 3' rapid amplification of cDNA ends (RACE) was performed on guinea pig diencephalic mRNA. The 5' and 3' RACE clones were ligated to the 1.0 kb RT/PCR amplimer to reconstruct a full length, 478 amino acid, seven transmembrane guinea pig calcitonin receptor, which was ligated into a CMV driven eukaryotic expression plasmid (pcDNA3). Transient transfection studies of the guinea pig calcitonin receptor in COS 1 cells to evaluate cAMP activation and radioligand binding demonstrate that the cloned guinea pig diencephalic receptor is a high affinity calcitonin receptor. This work was supported in part by AHA/FL.Affiliated Grant in Aid #9401236 to I.M.D.

STRUCTURAL DETERMINANTS OF ANGIOTENSIN II RECEPTOR RECOGNITION FOR THE BALANCED AFFINITY AT_1/AT_2 NONPEPTIDE LIGAND, L163017 Diane C Clarke, Renuka Sothinathan, Vaneet Nirula, Thomas G Sherman* & Kathryn Sandberg Div of Nephrology & Hypertension, Dept of Medicine, Georgetown Univ Med Ctr, Washington, DC 20007

Angiotensin II (Ang II), a potent modulator of cardiovascular homeostasis, mediates its effects through two Ang II receptor (AT R) subtypes (AT_1 and AT_2) which share less than 30% amino acid (aa) homology and can be differentiated by specific nonpeptide (NP) antagonists. Using site-directed interspecies aa exchange, we previously transferred a mammalian AT_1-selective NP (Losartan) binding site to an unresponsive amphibian AT R (xAT) by substituting 13 residues in the xAT R for corresponding aas in the rat AT_1 R (rAT_1) to create a frog R (xM46) which bound Losartan (IC_{50} in nM: rAT_1, 2.2; xAT, >50,000; xM46, 2.0). To determine the extent of overlap in binding sites on the rAT_1 R for Losartan and the balanced affinity AT_1/AT_2 NP ligand, L163017, we measured NP affinities in radioreceptor binding assays in membranes from COS cells transfected with xM46 and rAT_1 R cDNAs. The xM46 combinatorial mutant recognized L163017 with an affinity (IC_{50} = 10nM) that was only 2-fold lower than for rAT_1 R (IC_{50} = 5nM) suggesting significant overlap exists between determinants of Losartan and L163017 binding. Analysis of corollary single point rAT_1 R mutants in which individual mammalian residues were replaced by the corresponding frog aas, however, also revealed distinct differences in ligand binding interactions. Some point mutants (S109T) which reduced Losartan binding in the rAT_1 R by 2-200 fold had no effect on L163017 binding while other exchanges (V108I,S252C,N295S) reduced both Losartan and L163017 binding affinities. These data in conjunction with molecular modeling of NP binding sites on AT Rs suggests that Losartan and L163017 share overlapping but distinct binding pockets on the AT_1 R. These findings provide a focus for detailing the exact sites of L163017 binding on AT Rs and thus a foundation for greater understanding of the interactions between *NP* ligands and *peptidergic* Rs which may facilitate development of novel ligands acting on this large class of Rs. This work was supported by AHA Grant-in-Aid #DC95GS25.

ORGANIZATION AND CHARACTERIZATION OF THE HUMAN NEUROTENSIN RECEPTOR GENE AND ITS PROMOTER REGION. F. Le*, X. P. Zeng, K. Groshan, and E. Richelson. Lab. of Neuropsychopharmacology, Mayo Clinic Jacksonville, 4500 San Pablo Road, Jacksonville, FL32224, USA

The neurotensin receptor is a member of the superfamily of G-protein-coupled receptors. Growing evidence suggests that neurotensin and the neurotensin receptor play roles in the etiology of some neurological and psychiatric disorders. To understand transcriptional and translational regulation of the human neurotensin receptor (NTR) gene and identify possible microsatellite genetic marker(s) existing or flanking in this gene for genetic analysis of association between the NTR and neuropsychiatric disorders, we have isolated genomic clones spanning the entire gene locus. Except for introns the entire sequence of the NTR gene (~7.2 kb) was sequenced, including 5'- and 3'-untranslated regions, the coding region, exon-intron boundaries, and the promoter region. The gene contained four exons and three introns. All three introns were in the coding region. The sizes of the introns, determined by polymerase chain reaction, were approximately 0.3 kb, 4.1 kb, and 1.8 kb, respectively. Comparison of the genomic sequence to the cDNA sequence of the NTR revealed several different nucleotides between the two sequences, among which three were in coding region. The transcription start site, determined by primer extension experiments, was 438 base pairs 5' of the methionine initiation codon. The 5'-flanking region was rich in G+C content and lacked a typical TATA box, but contained several potential Sp1 binding sites around the transcription start site. It also had consensus sequences for other transcription factors including AP2, GRE, CREB, GATA motif, and others. Southern blot analyses demonstrated a single copy gene for the NTR. Additionally, genome mapping revealed a CA repeat microsatellite that flanked the NTR receptor gene. This microsatellite might serve as a marker for genetic analysis of association between the NTR and neuropsychiatric disorders. (Supported by grant MH27692 from N.I.M.H. and the Mayo Fdn. for Medical Education and Research).

A POTENTIAL ROLE FOR NF-κB/Rel PROTEINS IN THE REGULATION OF MOUSE NPY-Y1 RECEPTOR GENE TRANSCRIPTION. Carola Eva*, Rita Musso, Alessandra Oberto, Rossella Brusa and Mariagrazia Grilli[a]. Section of Pharmacology, Dept. Anatomy, Pharmacology and Forensic Medicine, Pharmacology Section, University of Torino, Torino, Italy, and [a]Division of Pharmacology, Dept. Biomedical Sciences and Biotechnology, University of Brescia, Brescia, Italy.

The murine gene encoding the Y1 receptor for NPY contains a 1.3 kb promoter region which drives a tissue-specific expression of heterologous reporter genes both in cultured cells and in transgenic mice. Sequence analysis of this genomic fragment identified two decameric sequences corresponding to consensus binding sites for NF-κB/Rel proteins. Gel shift analysis indicates that a 29 bp oligonucleotide comprising the two putative κB sites, which we refer to as Y1-κB sequence, specifically binds κB-related complexes in nuclear extracts from rat brain areas, NG108-15 cells and the murine T cell clone A.E7. In nuclear extracts from A.E7 and NG108-15 cells, the Y1-κB sequence specifically binds an additional complex whose molecular nature remains to be elucidated. Transient transfection studies demonstrated that the Y1-κB sequence acts as an enhancer element, inferring its potential role in regulating the Y1 receptor gene expression. We also identified a 70 bp region lying between nucleotides -1029 and -959, relative to the ATG, which may contain a negative regulatory element able to suppress the enhancer activity of Y1-κB sequence in NG108-15 cells.

MOLECULAR CLONING AND PHARMACOLOGICAL CHARACTERIZATION OF A NEW HUMAN NEUROPEPTIDE Y RECEPTOR SUBTYPE. C. Gerald*, M.W. Walker, T.M. Laz, P.J.-J. Vaysse, D.L. Linemeyer, T.A. Branchek and R.L. Weinshank. Synaptic Pharmaceutical Corporation, 215 College Road, Paramus, NJ 07652.

Neuropeptide Y (NPY) and related peptides PYY and PP elicit a broad range of physiological effects on appetite, pain, blood pressure, anxiety and circadian rhythm. These effects are thought to be mediated through activation of at least six G protein-coupled receptor subtypes known as Y1, "atypical" Y1, Y2, Y3, Y4 (PP1) and PYY-preferring. The cDNAs encoding three subtypes (Y1, Y2 and Y4) from various species have already been isolated. The existence of an "atypical" Y1 receptor has been proposed following *in vivo* feeding studies where the peptide rank order of potency was: $NPY_{2-36} \geq NPY$, $[Leu^{31}, Pro^{34}]NPY > NPY_{13-36}$. The Y3 receptor has been reported on bovine adrenal chromaffin cells and is preferentially activated by NPY over PYY. Expression of a PYY-preferring receptor has been reported on intestinal and renal epithelial cells.

We recently isolated a new rat NPY/PYY/PP receptor. We now report the identification of a human homolog from a hippocampal cDNA library. The deduced amino acid sequences are 87.2% identical between the two species. All putative transmembrane domains and extra cellular loop regions are highly conserved. The human receptor is one amino acid shorter at the very end of both amino and carboxy tails and its 5-6 loop is one amino acid longer than the rat homolog. Even though the 5-6 loops show significant differences between the rat and human homologs, all of the protein motifs found in the rat receptor are present in the human homolog. The molecular biology, including chromosomal localization and the pharmacology of this new human NPY/PYY/PP receptor subtype will be discussed.

PHARMACOLOGY OF A NOVEL CLONED Y-TYPE RECEPTOR FOR NEUROPEPTIDE Y, PEPTIDE YY OR PANCREATIC POLYPEPTIDE. M.W. Walker*, C. Gerald, K.E. Smith, J.A. Bard, P.J.-J. Vaysse, Z. Shaposhnik, N. Rogacki, L. Criscione†, C.B. Hartmann†, A.O. Schaffhauser†, S. Whitebread†, K.G. Hofbauer†, R.L. Weinshank and T.A. Branchek. Synaptic Pharmaceutical Corp., Paramus, NJ 07652 and †Ciba-Geigy Ltd., CH-4002 Basle, Switzerland.

Pancreatic polypeptide family members neuropeptide Y (NPY), peptide YY (PYY) and pancreatic polypeptide (PP) function as neurotransmitters or hormones through activation of membrane bound receptors. The three receptor subtypes (Y1, Y2 and Y4 or PP1) cloned previously from human and other species share a seven transmembrane spanning topology typical of G protein-coupled receptors. Y1, Y2 and Y4 receptor clones can be expressed in mammalian cells for analysis by radioligand binding assays using ^{125}I-PYY and related peptides. Y1 binds NPY, PYY, $[Leu^{31},Pro^{34}]NPY > NPY_{13-36}$. Y2 binds NPY, PYY, $NPY_{13-36} > [Leu^{31},Pro^{34}]NPY$. Y4 binds PP > $[Leu^{31},Pro^{34}]NPY$ > NPY, PYY. Y1, Y2 and Y4 receptor clones can also be analyzed in functional assays based on $[Ca^{++}]$ mobilization or on the inhibition of forskolin-stimulated [cAMP], in which case the rank order of peptide potency is consistent with the rank order of affinity in radioligand binding assays. Pharmacological studies support the existence of additional subtypes. The putative Y3 is characterized in rat colon and elsewhere as a target for NPY > PYY. A putative Y1-like receptor was proposed based on the ability of peptides to stimulate food intake with a unique rank order when injected into rat hypothalamus: $NPY_{2-36} > NPY$, $[Leu^{31},Pro^{34}]NPY > NPY_{13-36}$. A putative PYY-preferring receptor in dog adipocytes and elsewhere is suggested by functional studies in which peptides were ranked for activity: PYY > NPY > NPY_{13-36} > $[Leu^{31},Pro^{34}]NPY$. A potentially unique receptor subtype in a human colonic cell line is suggested by peptide-dependent inhibition of ion transport with the following rank order: PYY > NPY > $[Leu^{31},Pro^{34}]NPY$ > PP > NPY_{2-36}. We have recently isolated a unique G protein-coupled receptor with homology to Y-type receptors. The pharmacology will be compared with cloned and proposed receptor subtypes in this family.

LOCALIZATION OF THE mRNA ENCODING A NOVEL NPY RECEPTOR SUBTYPE IN RAT BRAIN. E.L. Gustafson*, C. Gerald, M.M. Durkin, K.E. Smith, M.W. Walker, A. Moralishvilli, P.J.-J. Vaysse, R.W. Weinshank, and T.A. Branchek. Synaptic Pharmaceutical Corp., 215 College Rd., Paramus, NJ 07652.

Using an expression cloning strategy, we have recently isolated a novel G-protein coupled receptor cDNA with marked similarities to the family of Y-type receptors (Gerald et al., 1996). The distribution of the mRNA encoding this receptor has been elucidated in rat brain employing oligonucleotide probes and *in situ* hybridization histochemistry.

No hybridization signal was observed with the radiolabled sense probe. With the radiolabeled antisense probe, hybridization signals were widely distributed in rat brain. In the telencephalon, the most intense hybridization signals were observed over the dentate gyrus and region CA3 of the hippocampus, over cingulate cortex, and over the central amygdaloid nucleus and anterior cortical amygdaloid nucleus. In the diencephalon, substantial accumulations of silver grains were seen over the midline thalamic nuclei, including the paraventricular, rhomboid, and centromedial thalamic nuclei. Most regions of the hypothalamus contained hybridization signals, including the lateral hypothalamus, paraventricular nucleus, and suprachiasmatic nucleus. In the mesencephalon, hybridization signals were observed over neurons in the anterior and olivary pretectal nuclei, periaqueductal gray, rostral linear raphe, dorsal raphe, superior colliculus, substantia nigra, and pontine nuclei. In the medulla and pons, the medial vestibular nucleus was moderately labeled, as was the parvocellular reticular nucleus and the gigantocellular reticular nucleus.

The distribution of the mRNA encoding this new Y type receptor is intriguing, and suggests a function in homeostatic mechanisms or in sensory integration.

CORRELATIONS BETWEEN SENSITIVITY TO CHAOTROPIC AGENTS AND DOWNREGULATION BY NEUROPEPTIDE Y (NPY) FOR NPY Y_1 AND Y_2 SUBTYPE RECEPTORS OF RAT BRAIN, S.L. Parker[1/], M.S. Parker[2/], and W.R. Crowley*[1/], Department of Pharmacology, University of Tennessee College of Medicine[1/], and Department of Biology[2/], The University of Memphis, Memphis, TN 38163.

We have shown before (Abstract 402.1, 25th Annual Meeting of the Society for Neuroscience, San Diego 1995), as well as on this Meeting, that ligand binding to rat brain Y_2 subtype NPY receptors is much less sensitive to ions and chaotropic agents than the binding to Y_1 subtype receptors. In this work, the Y_2 sites were also found to be much more resistant to inactivation by alkylating agents (e.g. N-ethylmaleimide and phenoxybenzamine), with IC_{50}'s about one order of magnitude above the corresponding values for the Y_1 sites. This led us to believe that the Y_2 receptors could also be more resistant to *in vivo* down-regulation by NPY. Indeed, third-ventricle injection of human/rat NPY (2-5 mg) after 180 min (a post-injection interval at which all of the injected peptide was eliminated) resulted in circumventricular hypothalamic areas (CHA), in a 70% or larger down-regulation of the Y_1 receptor, and only a 40% decrease of the Y_2 complement. After extraction of particulates with 0.8 M KCl to remove NPY bound to receptors, it was possible to show an almost 90% downregulation of the CHA Y_1 subtype at 20 min post-injection, while the CHA Y_2 binding was only about 50% less than in controls receiving saline only. Thus, in vivo internalization appears to be much more difficult to force by exogenous NPY for CHA Y_2 receptors relative to CHA Y_1 subtype. The CHA Y_2 receptors could be largely aggregated and immobile at their (presumably presynaptic) membrane sites, as indicated by their much lower sensitivity toward all classes of ions and chaotropes, and also by an affinity much larger than found for the Y_1 subtype, regardless of the ligand used. The regulation of Y_2 density could depend on a disaggregation initiated by agents other than the agonist peptides, e.g. by steroids (SL Parker, BL Carroll, SP Kalra, S St-Pierre, A Fournier & WR Crowley, *Endocrinology* **137**, in press). Supported by HD-13703.

661.10

IDENTIFICATION AND MOLECULAR CLONING OF A NOVEL GALANIN RECEPTOR (GALR-2) IN RAT SENSORY NEURONS.

S. Ahmad[1,2], S.H.Shen[2], P. Walker [1] and C. Wahlestedt*[1] [1]Astra Pain Research Unit and [2]Pharmaceutical Sector, Biotechnology Research Institute, Montreal, Quebec, H4P 2R2, Canada.

The antinociceptive actions of galanin as well as changes in its expression levels in animal models of pain have generated much interest.. Based on the pharmacological profile of galanin and its analogs in various tissues, we have previously hypothesised galanin receptor heterogeneity. To date, only one galanin receptor (GALR-1) has been cloned. In the present studies we have identified, cloned and characterized a novel rat galanin receptor from rat dorsal root ganglia and spinal cord. A partial cDNA was obtained by reverse transcriptase-polymerase chain reaction with dorsal root ganglia cDNA and degenerate primers in transmembrane regions that had high degree of homology with GALR-1. This partial cDNA was used to screen rat brain stem/spinal cord library, several overlapping clones were obtained and a full length clone was constructed that we have termed GALR-2. Sequence analysis of GALR-2 revealed that the predicted protein has a typical profile of G-protein-coupled receptor with an overall identity of 35.5% with rat GALR-1. HEK 293 cells transfected with a recombinant plasmid containing GALR-2 cDNA express saturable ^{125}I-galanin binding with an affinity (Kd) of of 1.68 ± 0.43 nM and the Bmax of 1-2 pmoles/mg. Rat galanin and galanin related peptides effectively competed for binding at GALR-2 receptors with the rank order of potency galanin > M40 > $galanin_{1-16}$ > M15 > C7. In GALR-2 expressing HEK 293 cells, galanin attenuated the forskolin-stimulated accumulation of cAMP with half-maximal response seen at nanomolar range. *In situ* hybridization studies demonstrated expression of GALR-2 in discrete brain areas, spinal cord and dorsal root ganglia (see O'Donnell *et al.* this meeting).

HUMAN SUBSTANCE P RECEPTOR EXPRESSED IN SF9 CELLS COUPLES WITH MULTIPLE ENDOGENOUS G PROTEINS.

J. Frederick, K. Nishimura, and M.M. Kwatra*. Departments of Anesthesiology and Pharmacology, Duke University Medical Center, Durham, NC 27710

In order to study the function and regulation of the human substance P receptor (hSPR) at the protein level, we expressed the receptor in Sf9 cells using the baculovirus system. The expression of the hSPR in Sf9 cells was high (>60 pmol/mg membrane protein), and its pharmacology was similar to that of naturally occurring receptor. The binding of agonist radioligand ^{125}I-BHSP to the receptor in Sf9 membranes was sensitive to guanine nucleotides, indicating that the receptor is coupled to endogenous G protein(s). To identify these G proteins, the membranes were photoaffinity labeled with [^{32}P]-azidoanilido GTP ([^{32}P]-AAGTP) in the presence and absence of substance P, followed by immunoprecipitation with antibodies specific for various Gα-subunits. We found that G proteins immunoprecipitated with antibodies against Go, Gq/11, and Gs exhibited increased incorporation of [^{32}P]-AAGTP upon receptor activation. These results suggest functional interaction between hSPR and Go-like, Gq/11-like, and Gs-like G proteins. This is the first demonstration of hSPR's coupling to multiple G proteins. These findings greatly enhance our understanding of signal transduction through hSPR, and provide a molecular basis for the known activation of multiple effectors by hSPR. Supported by grants from the NIH (#NS 33405) and the American Lung Society.

DRUGS OF ABUSE: OTHER II

DECREASED MONOAMINE OXIDASE A (MAO A) IN SMOKERS.

J. S. Fowler, N. D. Volkow, G-J Wang, N. Pappas, C. Shea, D. Alexoff, R. MacGregor, D. Schlyer, I. Zelzukova., R. Hitzemann* Brookhaven National Laboratory, Upton, NY 11973-5000; SUNYSB, Stony Brook, NY 11794-8101

Cigarette smoke inhibits MAO A and B in vitro and in animals (Yu, 1987; Pavlin, 1993) and peripheral measures indicate reduced levels of MAO A and B in heavy smokers (Berlin, 1995). Our recent observation that smokers have reduced brain MAO B (Fowler, 1996), stimulated this study to compare brain MAO A in smokers and non-smokers. MAO A was measured in 16 non-smokers and 16 smokers with [^{11}C]clorgyline and positron emission tomography (PET). Four non-smokers were treated with the non-selective MAO inhibitor tranylcypromine (10 mg/day for 3 days) after the baseline PET scan and then re-scanned to assess the sensitivity of [^{11}C]clorgyline binding to MAO. MAO A levels were quantified using the model term λk_3 which is a function of brain MAO A concentration. Smokers had significantly lower brain MAO A than non-smokers in all brain regions examined (average reduction: 28%). The mean λk_3's for the whole brain were 0.185 ± 0.35 and 0.133 ± 0.03 cc brain ml plasma min-1 for non-smokers and smokers respectively ($p<0.0002$). The plasma to brain transfer constant did not differ between non-smokers and smokers (0.29 ± 0.052 vs 0.26 ± 0.045 for the global value). Treatment with tranylcypromine reduced λk_3 by an average of 58%. In summary, smokers had a marked reduction in brain MAO A relative to non-smokers and this reduction is about half of that produced by brief treatment with the non-selective MAO inhibitor tranylcypromine. Thus MAO A inhibition by cigarette smoke needs to be considered as a variable in smoking behavior and epidemiology including the strong association between smoking and psychiatric disorders and addiction. DIFFERENTIAL CONDITIONING PRODUCED WITH CIGARETTE SMOKING AS THE UCS

R. F. Mucha*, P. Pauli and A. Angrilli. Inst. of Medical Psychology and Behavioral Neurobiology, U. of Tuebingen, 72074 Tuebingen, Germany and Depart. General Psychology, U. of Padova, 35100 Padova, Italy.

The animal literature indicates that signals for a self-administered drug may elicit conditioned drug similar, drug compensatory and/or incentive effects. To test for the occurrence of these in the human, we examined mildly-deprived smokers in a differential conditioning paradigm using 2 acoustic stimuli as the CSs and cigarette smoking as the UCS. On at least 3 sessions the 16 smokers smoked a normal cigarette in the presence of the CS+ and on a comparable number of sessions they did nothing in the presence of the CS-. Psychophysiological recordings during and after conditioning examined the acute and conditioned effects of smoking.

Following training, it was seen that subjects spent significantly more time listening to the CS+ than to the CS-, indicating that preference effects were acquired. However, no parameters of peripheral psychophysiological or spontaneous EEG activity were changed significantly in response to the CS+, as compared to the CS-, except for EMG activity; moreover, these were only seen long after the onset of the CS and when smoking should have occurred. Whereas it was confirmed that conditioning had occurred, the data were not consistent with a simple model of conditioning of drug similar or opposite effects. Our data suggest that a signal for smoking may play a role as an incentive and/or discriminative stimulus

CAFFEINE DIFFERENTIALLY ALTERS THE STIMULUS PROPERTIES AND LOCOMOTOR ACTIVITY PRODUCED BY NICOTINE IN RATS

M.Shoaib, M. Gasior, S. R. Goldberg & S.Yasar*. Preclinical Pharmacology Laboratory, National Institute on Drug Abuse, D.I.R., N.I.H. Baltimore, MD 21224.

Epidemiological reports indicate a correlation between coffee drinking and tobacco smoking. The pharmacological basis for this interaction remains unclear, however simple behavioral observations suggest that these two heavily used licit drugs interact additively. The aim of the present experiments was to examine exposure to caffeine on stimulus properties and locomotor activity produced by nicotine, standard measures that closely relate to drug-seeking behaviors. Using an acquisition paradigm we have previously described, rats learn to self-administer infusions of nicotine over 14 days. Sprague-Dawley rats consuming caffeine (50mg/day) in their drinking water for 7 days prior to the beginning and throughout behavioral testing acquired intravenous nicotine self-administration (0.03 mg/kg/inj) much faster than did controls. In a cross-over design, exclusion of caffeine decreased intake of nicotine, although rates remained high, while supplementing caffeine to water-drinking controls facilitated nicotine self-administration. The same regimen of caffeine potentiated nicotine-induced locomotor activity (0.1-0.8 mg/kg SC) resulting in an upward shift of the dose-response curve, and this sensitization waned when caffeine was removed from the drinking water. In contrast, the same caffeine regimen failed to potentiate the acquisition of a nicotine discrimination (0.1 and 0.4 mg/kg SC), rather, there was a trend for discrimination to be retarded with the lower training dose. These results demonstrate that caffeine potentiates both the reinforcing and locomotor activating effects of nicotine, while the cueing properties are not modified. Since both the reinforcing and locomotor activating effects are mediated via the same neural circuitry, it is possible that caffeine may exert it's effect on the mesolimbic dopamine system, rather than reticulo-hippocampal regions, brain sites which mediate the cueing properties of nicotine. EFFECTS OF PRENATAL Δ^9-THC ON MOTHER-PUP INTERACTIONS AND CB_1 RECEPTORS

E. Fride*, S. Ben Shabat and R. Mechoulam. *Dept. Natural Products, Hebrew Univ. Faculty of Medicine, Jerusalem, Israel.*

Effects of maternal marijuana use during pregnancy have been studied with equivocal results. However, in an ongoing study, Fried and colleagues have pointed at subtle behavioral deviations in these offspring. In the present series of experiments we examined a number of parameters in offspring of mice which had been injected (*i.p.*) with 20 mg/kg Δ^9-THC (tetrahydrocannabinol,T, the main active constituent in marijuana) or vehicle (V) on five days during the the last half of gestation. Four sets of findings are presented: *A*. Except for a delay in eye opening on postnatal day 13, no developmental differences were detected between V- and T-treated pups, including litter size, righting response and postnatal body weights. *B*. The density of "central" cannabinoid receptors (CB_1) was higher in the brains of prenatal T offspring at adulthood. *C*. In a series of tests which are commonly used to assess cannabinoid receptor activation, we observed significantly lower body temperature (BT) and motor activity, and higher immobility on a ring (catalepsy) in the adult offspring of T-treated dams. *D*. In a cross-foster study we found that offspring which were born to V-treated mothers but reared by T-treated dams, as well as in offspring from T mothers raised by V dams displayed similar or intermediate differences with nonfostered T pups. *E*. Next, we investigated whether 1) changes in maternal behavior and/or 2) the role of the pup in maternal retrieval could explain the deviations in cross-fostered offspring. We found that 1) T mothers took more time to contact and retrieve pups, than it took V mothers. and that 2) T pups were retrieved at a slower rate than V pups irrespective of whether they were exposed to a T or V mother.

In conclusion, prenatal treatment with T resulted in increased concentrations of CB_1 receptors in the brains of T offspring, accompanied by "T-like" behaviors. Control offspring, reared by T mothers also showed differences compared to controls. We suggest that some of these prenatal and postnatal effects of T may be related to abnormal mother-pup interactions.

NEUROBEHAVIORAL SPECIFICITY OF GENES ENCODING CANNABINOID RECEPTORS. E. S. Onaivi* and A. Charkrabarti, Dept of Pharmacology, Meharry Medical College, Nashville, TN 37208.

Studies in our laboratory indicate that anandamide, the putative endogenous cannabinoid ligand produces a myriad of neurobehavioral changes similar but less potent than Δ^9-THC, the major psychoactive constituent in the marijuana plant. We have also cloned, sequenced, constructed the 3D helical structure and localized the murine cannabinoid receptor, *Cnr*, gene to chromosome 4. There is extensive nucleotide and protein sequence homology between the mammalian *Cnr*, CB1 that are distinct from the *Cnr* CB2 known to be localized in the PNS. To study the molecular bases of the neurobehavioral effects produced by cannabinoids, the C57BL/6, DBA/2 and ICR mouse strains were used. The Northern blot analysis data using the CB1 cDNA probe indicate that the CB1 gene is not only differentially expressed in the naive mouse strains but also following the sub-acute treatment with anandamide. We are continuing these studies with specific CB1 antisense probes to inhibit the *in vivo* expression of CB1 genes to determine the contribution of the CB1 *Cnr* in the expression of cannabinoid induced behaviors. To determine what CNS genes are influenced by cannabinoids, the differential display of genes in the brains of anandamide treated and non-treated mice are being analyzed. It is unlikely that the CB1 *Cnr* mediates all the cannabinomimetic effects. Thus, the neurobehavioral specificity of genes that code for the *Cnrs* may require the creation and careful analysis of targeted mutations in mice. IN VITRO RELEASE OF DOPAMINE BY THE STRIATUM AND NUCLEUS ACCUMBENS IS DIMINISHED IN BOTH SPONTANEOUS AND NALOXONE-PRECIPITATED OPIATE WITHDRAWAL Kenneth Grasing* and Suchandra Ghosh, Department of Medicine, Division of Clinical Pharmacology, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, New Jersey 08901

We compared different strategies for stimulating dopamine release in slices obtained from the striatum and nucleus accumbens of rats undergoing either naloxone precipitated or spontaneous opiate withdrawal. For naloxone precipitated withdrawal, tissue was obtained immediately after a 1.0 mg/kg injection of naloxone, given 7 days following subcutaneous implantation of placebo or morphine pellets. For spontaneous withdrawal, tissue was obtained at least 3 days following cessation of morphine treatment (saline or morphine sulfate was subcutaneously injected 3 times per day, an initial dose of 6.0 mg/kg was gradually increased to 120 mg/kg). For slices obtained from the nucleus accumbens, dopamine fractional release after exposure to separate treatments with 320 and 1000 μM 4-aminopyridine was significantly diminished in tissue obtained from animals undergoing either spontaneous (8.78 ± 2.28 and 6.59 ± 0.99 % for control and withdrawal conditions) or naloxone precipitated withdrawal (8.96 ± 1.36 and 6.56 ± 1.09 % for control and withdrawal conditions). Similar effects were observed for striatal tissue. An alternate strategy in which slices were continuously exposed to four treatments with 1000 μM 4-aminopyridine was ineffective in showing differences between tissue from control and morphine withdrawn animals. Treatment with two separate exposures to 1000 μM cocaine was also effective in showing diminished dopamine release in tissue obtained from the nucleus accumbens of animals undergoing naloxone precipitated withdrawal. In conclusion, opiate withdrawal diminishes *in vitro* release of dopamine by the striatum and nucleus accumbens, when release is stimulated by two discrete exposures to relatively high doses of 4-aminopyridine or cocaine. Support by a grant from the National Institute on Drug Abuse, at the NIH.

REGULATION OF NITROBENZYLTHIOINOSINE-LABELLED ADENOSINE TRANSPORTER SITES IN BRAIN REGIONS OF OPIATE TOLERANT MICE. G.B. Kaplan*, K.A. Leite-Morris, Department of Psychiatry & Human Behavior, Brown University School of Medicine and Veterans Affairs Medical Center, Providence, RI 02908.

Alterations in brain extracellular adenosine levels and adenosine receptors have been demonstrated during morphine treatment and may mediate opiate effects. The effects of chronic morphine treatment on central adenosine transporter site binding was examined in mice. Implantation of morphine or placebo pellets in CD-1 mice for 72 hours significantly ($P<.05$) reduced acute stimulant effects of morphine injections at doses of 40 and 50 mg/kg, suggestive of opiate tolerance. Saturation binding studies were performed in brain regions of pellet-implanted mice using radiolabelled nitrobenzylthioinosine, or [^{3}H]NBTI. Non-linear curve-fitting of saturation studies provided measures of maximal binding capacity (B_{max}) and binding affinity (K_d). In hypothalamus (single point studies), chronic morphine treatment significantly increased maximal binding concentrations, 23(+/-2; SEM) vs 16(2) fmol/mg (vehicle treatment). In cerebellum, morphine treatment signficantly reduced B_{max} values, 8.4 (0.5) vs 9.8 (0.5) fmol/mg without altering Kd values (1.2 vs 1.6 nM). In initial studies in cortex, chronic morphine treatment reduced B_{max} values in cortex by 10% without altering Kd values. Initial saturation studies showed no effects of chronic morphine treatment on saturation binding values in striatum, hippocampus and brainstem. Chronic morphine treatment created a state of tolerance and produced differential regulation of adenosine transporter sites in brain regions, providing a potential cellular mechanism for altering extracellular adenosine levels and mediating opiate effects.

MORPHINE DECREASES AND NALOXONE INCREASES GLUTAMATE AND ASPARTATE IN THE NUCLEUS ACCUMBENS IN RATS. Jacqueline Sepulveda, Luis Hernandez*, Sonia Tucci, Pedro Rada and Enrique Contreras. Department of Physiology, Apartado de correos # 109, Mérida, Venezuela and Department of Pharmacology, Casilla 152-C, Concepción University, Chile.

The role of Glutamate and Aspartate in Morphine tolerance was studied by microdialysis and capillary zone electrophoresis with laser induced fluorescence detection in rats. Microdialysis probes were inserted into the nucleus accumbens and microdialysis samples were collected every 30 seconds. After 5 samples the rats received a subcutaneous injection of 20 mg/Kg of morphine. Samples were collected every 30 seconds for 5 minutes and then 7 more samples were collected 30 minutes after the injection. Acute morphine decreased Glutamate and Aspartate significantly. Then the microdialysis probes were withdrawn and the animals received 20 mg/Kg of morphine for two days after which the dose was increased to 30 mg/Kg for days 3rd and 4th and to 40 mg/Kg for days 5th and 6th. A microdialysis session was repeated on day 7th. A morphine injection at the dose of 40 mg/Kg did not change either glutamate or aspartate suggesting tolerance. The same day the animals received an intraperitoneal injection of 5 mg/Kg of Naloxone. Glutamate and Aspartate increased during the first 5 minutes after naloxone injection and the animals showed the behavioral symptoms of the withdrawal syndrome. Then Glutamate and Aspartate decreased although the animals still showed the withdrawal syndrome. Since NMDA receptor blockers suppress the withdrawal syndrome, our experiments suggest that Glutamate and Aspartate trigger the withdrawal syndrome but do not cause the symptoms.

OPIOID RECEPTOR ANTAGONISTS ALTER AMPHETAMINE-INDUCED CIRCLING IN RATS WITH UNILATERAL NIGRAL LESIONS. H.L. Kimmel* and S.G. Holtzman. Dept. of Pharmacology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

In a previous study in rats, the general opioid antagonist naloxone (NX) and the delta-opioid receptor antagonist naltrindole (NTI) attenuated amphetamine (AMPH)-induced striatal dopamine release and locomotor activity. However, treatment with mu- and kappa- opioid antagonists did not affect locomotor activity or dopamine release. To investigate further this relationship between brain opioid and dopaminergic systems, rats with a unilateral lesion of the nigrostriatal tract were used in the rotational model of behavior. Direct dopamine agonists, such as AMPH, induce ipsilateral turning in these animals. Treatment with 1.0 mg/kg NX decreased circling induced by 3.2 mg/kg AMPH, but 5.0 mg/kg NX had no effect. In contrast, naltrexone (NTX) (0.1-10 mg/kg), another general opioid receptor antagonist, dose-dependently increased turning induced by 1.0 mg/kg AMPH. NTI (10 μg) and the kappa-opioid receptor antagonist nor-binaltorphimine (10 μg) significantly decreased turning induced by 3.0 mg/kg AMPH, but not by 1.0 mg/kg AMPH. The mu-opioid receptor antagonist, β-funaltrexamine (10 μg) enhanced turning induced by 1.0 mg/kg AMPH but not by 3.0 mg/kg AMPH. Thus the effects of opioid antagonists on amphetamine-induced turning were not always the same as their effects on other amphetamine-induced effects, and appeared to dependent upon the specific dose of amphetamine.

U69,593, a κ-opioid receptor agonist, potentiates the antinociceptive effects of cocaine in the hot-plate assay. A.B. Patterson and S.G. Holtzman*, Emory School of Medicine, Atlanta, GA 30322.

The purpose of this study was to determine the effect of combinations of the kappa-opioid receptor agonist U69,593 and cocaine in the hot-plate and paw-pressure tests of nociception. Male Sprague-Dawley rats received cumulative injections of cocaine (0, 5.6, 10, 17.5, 30 mg/kg intraperitoneally) and were tested 10 min after each injection in the hot-plate (51° ± 2° C) and paw-pressure tests. Cocaine produced a dose dependent increase in latency to respond in the hot-plate test ($p< 0.05$) and no effect in the paw-pressure test. In subsequent experiments, subjects were pretreated with U69,593 (0, 0.1, 1.0, or 3.0mg/kg subcutaneously) 15 min. before the first dose of cocaine was administered. The lowest dose of U69,593 (0.1 mg/kg) had no significant effect by itself in the hot-plate and paw-pressure tests; however, it potentiated the analgesic effect of cocaine in the hot-plate ($p<0.05$) , but not paw-pressure test. The 1.0 and 3.0 mg/kg doses of U69,593 produced significant analgesic effects in both tests. There were no significant differences between the combinations of cocaine and U69,593 versus U69,593 alone in the hot-plate test. However, in the paw-pressure test, the effect of the combination of 3.0 U69,593 and cocaine was significantly reduced compared to 3.0 U69,593 alone ($p<0.05$). Depending upon the doses of drug and analgesic assay used, the combination of U69,593 and cocaine can produce superadditive or subadditive effects. CHANGES IN HYPOTHALAMIC GLUTAMATE DURING FEEDING IN FREELY MOVING RATS.

P. Rada*, S., Tucci and L. Hernandez. Laboratory of Behavioral Physiology. Medical School, Los Andes University, Mérida, Venezuela.

Involvement of the lateral hypothalamus (LH) in feeding behavior is well known. Lesion or stimulation of this region induces aphagia or hyperphagia, respectively. Recently, Stanley et al (1) have shown that glutamate injections in the LH induces a strong feeding effect suggesting that this amino acid might be involved in eating behavior. However, there is no *in vivo* neurochemical evidence supporting this hypothesis.

In the following experiments a combination of brain microdialysis and capillary zone electrophoresis with laser induced fluorescence (CZE-LIFD) was used to monitor extracellular levels of glutamate in the LH of freely moving rats. The nucleus accumbens (NAC) was used as a control site. Microdialysis probes were inserted 18 hr before experimentation at which time food pellets were removed from the dialysis cage. Samples were taken every 30 sec in microcollectors made of capillary glass. Five control samples were followed by 2 min of free access to rat chow (4 samples) and 4 post feeding samples.

Rats with LH and NAc probes ate 0.52 ± .03 g and 0.525 ± .17 g respectively. In this period glutamate increased to 372 ± 139% ($F(0,10)=3.182$; $p<.01$) in the LH while it decreased to 41 ± 5.6 % ($F(0,10)=3.252$;$p<.01$) in the NAc. These results confirm earlier behavioral and pharmacological research which suggests that LH glutamate could be involved in feeding behavior.

HISTOCHEMISTRY OF NEUROPEPTIDE Y (NPY) IN THE ARCUATE NUCLEUS OF THE ANORECTIC (anx) MOUSE.

C. Broberger*, J. Johansen#, M. Schalling# and T. Hökfelt. Department of Neuroscience and #Clinical Genetics, Karolinska Institutet, 171 77 Stockholm, Sweden.

NPY, when injected into the paraventricular nucleus (PVN) of the hypothalamus, has been shown to act as a powerful orexigenic signal. The NPY-expressing cell population in the ventromedial portion of the arcuate nucleus (Arc) has been implicated as the source for endogenous NPY in the PVN, and NPY levels in this pathway show alterations with feeding status and in models of nutrient depletion. We have studied mice with the *anorexia* mutation (anx), a recessive mutation that causes decreased food intake and starvation leading to death 22 days after birth. The aim of this study was to compare hypothalamic NPY histochemistry of anx and control mice, to see if alterations there could be correlated to this anorexia. Using fluorescence immunohistochemistry, the intensity of NPY-like immunoreactivity was markedly increased in Arc cell bodies and decreased in terminals in Arc and PVN in anx as compared to normal littermates. *In situ* hybridization for NPY mRNA in the Arc, however, showed no significant difference in gene expression between anx and normal mice, suggesting that synthesis is not affected. In addition, immunoreactivities for acetylcholinesterase and aspartate in the Arc were decreased, suggesting that somatic accumulation is not a generalized phenomenon for neurones in the anx Arc. Also, for cholecystokinin, no difference in hypothalamic immunoreactivity could be seen. These data suggest that an NPY signalling impairment in the Arc-PVN pathway contributes to the failure-to-thrive of anx mice. (Supported by Swedish MRC 04X-2887.)

LEPTIN RECEPTOR EXPRESSION IN THE BRAIN OF GENETICALLY OBESE *ob/ob* AND *db/db* MICE: LOCALIZATION OF mRNA BY IN SITU HYBRIDIZATION.

D.G. Baskin*, J.L. Kuijper[1], S. Lok[1], R.J. Seeley, S.C. Woods and M.W. Schwartz. V.A. Medical Center and University of Washington, Seattle WA 98108, and [1]ZymoGenetics Inc., Seattle WA 98102

Leptin, a hormone secreted by adipose cells, reduces food intake in the obese *ob/ob* mouse, which has an ineffective mutant form of leptin, but not in the *db/db* mouse, which develops obesity due to mutation of the intracellular signaling domain of the leptin receptor (LR) and consequently exhibits leptin resistance. Since the extracellular domain of LR variants is identical in *ob/ob* and *db/db* genotypes, expression of mRNA for the extracellular domain should be similar in *ob/ob* and *db/db* mice unless the LR gene is regulated by high circulating levels of leptin (as found in *db/db*) or the absence of leptin signaling (as found in *ob/ob* and *db/db*). To test this hypothesis, we did in situ hybridization (ISH) on brain slices of *ob/ob*, *db/db*, and lean wild type mice, using a 330 base ^{33}P riboprobe complementary to the extracellular domain that is present in all known LR splice variants (amino acids 786-894 upstream from the stop codon of the *db* form of the receptor), prepared from a linearized DNA template (GenBank MMU42467). The location and relative intensity of LR mRNA ISH signal were visually similar in *ob/ob* (leptin-deficient; no LR binding or signaling), *db/db* (LR binding but no signaling), and lean wild type mice (normal LR binding and signaling). The ISH signal was strongest in the hypothalamic arcuate nucleus, but strong ISH signal was also present in the ventromedial and dorsomedial nuclei of the hypothalamus, choroid plexus, and pyriform cortex. In comparison, the cerebral cortex, thalamus, hippocampus, and paraventricular nucleus showed less ISH for LR mRNA. The finding of relatively normal levels of leptin receptor mRNA in *db/db* and *ob/ob* brains indicates that neither elevated leptin levels nor the obesity syndrome associated with disorders of leptin receptor signaling regulate expression of brain leptin receptor transcripts that contain the extracellular domain of the receptor. (Supported by Dept. of Veterans Affairs, NIDDK, and ZymoGenetics)

663.4

HYPOTHALAMIC EXPRESSION OF GALANIN VARIES WITH THE PREFERENTIAL CONSUMPTION OF FAT.

A. Burlet*, M. Odorisis, B. Beck, JP Max, B. Fernette, E. Angel, JP Nicolas and C. Burlet. MRCA, INSERM U308, Nancy-54000-France.

Galanin (GAL) stimulates food intake when injected into the rat brain. Some data showed that it preferentially increased the consumption of fat but others did not agree. Brattleboro rat (DI) suffers of a genetic defect in the central synthesis of vasopressin (AVP), a peptide co-synthezised with GAL in magnocellular neurons of the hypothalamus. We compared the central expression of GAL and the selection of macronutrients, in adult DI and Long Evans rats.

Three pure diets were given ad libitum to LE and DI males rats for two weeks (training period). Their consumption was then measured for the light period and at different moments (2h, 4h and 6h after light off) of the dark period. Ten days later, the expression of GAL was studied by in situ hybridization of GAL mRNA, immunocytochemistry and measurements of immunoreactive content of GAL in discrete micropunched areas of brain.

In DI rats, the daily consumption of carbohydrates (CHO) is significantly reduced (60%, $p<0.02$), that of fat increased (40%, $p<0.001$) whereas that of proteins does not change. Both diurnal and nocturnal consumption of CHO decreases but only the nocturnal consumption of fat increases for the first 6h in the night.

The in situ hybridized mRNA of GAL is the highest in arcuate and paraventricular nuclei of DI rats. On the contrary, the immunoreactive contents of all micropunched areas are strongly reduced (30-50% less, except in arcuate and dorsomedian nuclei).

We performed the same studies in DI rats centrally or peripherally treated with AVP.

Under basal conditions, the hypothalamic expression of GAL varied with the consumption of fat in DI rats. The GAL turn-over strongly increased as proved by mRNA increased and immuoreactive content decreased. This participates in the central disregulations of peptidergic networks in DI rats.

FOOD RESTRICTION UPREGULATES HYPOTHALAMIC NPY GENE EXPRESSION: LOSS OF DAILY RHYTHM

B. Xu*, P.S. Kalra and S.P. Kalra Depts. Neuroscience and Physiology, Univ. Fla. Col. Med., Gainesville, FL 32610

Neuropeptide Y (NPY) is an important peptidergic signal in the hypothalamic circuitry that regulates feeding and neuroendocrine control of pituitary function. Food restriction (dieting) has been shown to increase lifespan in rats and monkeys. Therefore, we investigated the dynamic relationship in NPY synthesis with daily *ad libitum* intake pattern and intake reduction by 30% in male rats. Hypothalamic preproNPY mRNA was measured by solution hybridization/RNase protection assay at 4 h intervals in *ad lib* rats and rats maintained on diet restriction for 4 weeks. The *ad lib* rats displayed a daily rhythm in NPY gene expression; preproNPY mRNA increased abruptly ($p < 0.05$) soon after lights on (0500 h) and stayed elevated until 1100 h. Thereafter, NPY gene expression decreased to a nadir at 1500 h and remained at that level during the dark phase (1900-0500 h) in conjunction with robust feeding. Importantly, 30% reduction in intake prevented the normal rate of increase in body weight and abolished the daily rhythm in NPY gene expression. In fact, preproNPY mRNA levels were maintained at significantly high levels during the 24 h period in restricted diet animals. Thus, we show that (1) NPY gene expression is at its lowest during nighttime feeding, (2) food restriction by 30% maintains body weight, but upregulates NPY gene expression leading to a loss of daily rhythm in preproNPY mRNA and (3) this high NPY activity may sustain enhanced appetite in rats on restricted intake. (Supported by NIH DK37273).

ICV LEPTIN (OB PROTEIN) SUPPRESSES FOOD INTAKE AND FASTING-INDUCED CHANGES IN HYPOTHALAMIC GENE EXPRESSION FOR CORTICOTROPIN RELEASING FACTOR (CRF) AND NEUROPEPTIDE Y (NPY) IN LEAN BUT NOT OBESE ZUCKER RATS.

R.J. Seeley1*, D.G. Baskin2, E.M. Bernstein1, M.H. Wonner1, L.A. Campfield4, and M.W. Schwartz3. Depts of Psychology1, Biological Structure2 and Medicine3, University of Washington and Seattle VA Medical Center, Seattle, WA 98195 and Metabolic Diseases4, Hoffmann-LaRoche Inc.

The adipocyte hormone, leptin, is implicated in the negative feedback regulation of food intake and body weight. The current work tested the hypothesis that reduction of leptin levels during fasting is critical to the behavioral and hypothalamic responses to fasting. In the first study, recombinant human leptin (3.5 ug) or its vehicle was administered into the third ventricle of male Long-Evans rats at the onset of a 24 h period of fasting. After 24 h without access to food, each animal received a second injection identical to the first, and animals were given access to food 1 h later. Food intake in leptin-treated rats was reduced by 70% over the subsequent 4 h compared to vehicle. In a second study, we used *in situ* hybridization to measure hypothalamic levels of NPY and CRH mRNA in rats that received the identical leptin treatment as described in the first study and were sacrificed after a 40 h period of food deprivation. In leptin-treated rats, arcuate nucleus NPY mRNA were reduced by 24%, whereas CRH mRNA levels were elevated by 38% (both $p<0.05$). In contrast, obese Zucker rats, which have a mutation in the gene coding for the leptin receptor (*fa/fa*), showed no effect of icv leptin on either food intake or in NPY and CRH mRNA levels. These data show that central leptin administration can ameliorate behavioral and hypothalamic changes induced by fasting. This work was supported by NIDDK, VA and Hoffmann-LaRoche Inc.

DECREASED ARCUATE N. DOPAMINE TURNOVER AND INCREASED NPY EXPRESSION IN OBESITY-PRONE RATS. B.E. Levin*, K. Brown and A.A. Dunn-Meynell. Neurol. Svc., DVA Med. Ctr., E.Orange, NJ 07018 and Dept. Neurosci., NJ Med. Sch., Newark, NJ 07103

NPY has been implicated in the regulation of energy balance by the brain. Dopamine (DA) inhibits NPY mRNA expression in the arcuate n. (ARC) of the hypothalamus and both ARC DA metabolism and NPY expression are abnormal in the genetically obese rat. We used a model of diet-induced obesity (DIO) to study the interactions of DA and NPY in rats with a propensity to develop DIO (DIO-prone). Male, chow-fed Sprague-Dawley DIO-prone rats were separated from those which resist DIO (DR-prone), when later placed on a high energy diet, by their high (1.46±0.10 ug) vs. low (0.83±0.03 ug; P=0.01) 24 h urine norepinephrine levels, respectively. DA turnover was measured by synthesis inhibition with α-methyl-p-tyrosine in 18 rats per group and expression of NPY mRNA was assessed by in situ hybridization using a riboprobe for preproNPY in 11 rats per group. Endogenous ARC/median eminence DA levels were 14% higher (36.6±1.1 vs. 32.2±1.3 ng/mg protein; P=0.05) but half-life was 175% longer (3.40±1.1 vs. 1.23±0.26 h; P=0.05) and turnover rate was decreased by 60% (7.5±0.1 vs. 18.1±0.7 ng/mg protein/h; P=0.01) in DIO- compared DR-prone rats. In association with this decreased DA turnover, the area of largest ARC NPY mRNA expression was increased by 25% in DIO- (0.427±0.040 mm^2) vs. DR-prone rats (0.342±0.042 mm^2; P=0.022). Thus, diminished ARC DA release may permit increased NPY expression which may, in turn, predispose DIO-prone rats to develop the increased metabolic efficiency which is seen when they are fed a high energy diet.

INDEPENDENCY OF HYPOTHALAMIC AND PLASMA INSULIN. S. Nicolaïdis*, M. Orosco and K. Gerozissis, CNRS UPR 9054, Collège de France, 11 place Marcelin Berthelot, 75231 Paris Cedex 05, FRANCE

The presence of hypothalamic (H) insulin and its involvement in the control of food intake are well admitted but the question of its dependency on plasma (P) insulin is unsolved. For that purpose, hypothalamic (PVN-VMH) and extrahypothalamic insulin were assessed by RIA in samples obtained by brain microdialysis in freely behaving normal rats and compared with P immunoreactive insulin (IRI) during and around various situations affecting insulin secretion. - A standard chow meal resulted in a four to sixfold P IRI versus a 2.5fold (H) IRI increase. - Furthermore, expectation of a scheduled standard meal in rats accustomed to this meal for one or two days, increased significantly (60%) H IRI and did not modify P IRI (Orosco et al., 1995). - An exclusively carbohydrate meal increased by ten to fifteenfold P and twofold H IRI; the profiles of IRI changes were totally different from those induced by standard meals - An exclusively lipid (lard) meal reduced by 60% H IRI and did not affect significantly P IRI. - i.v. injection of a huge amount of insulin (0.5 IU), corresponding to concentrations more than a hundredfold than basal P IRI, did not change significantly H IRI levels (Gerozissis et al., 1993). The above data suggest that the profile of H IRI changes is independent from that of P IRI changes. In rats bearing two microdialysis probes the basal H IRI level was twofold that of the cerebellum (0.65±0.09 and 0.30±0.05 µU/ml, respectively) and, interestingly, the carbohydrate meal did not affect cerebellar insulin. This additional observation confirms the role of insulin in feeding-related areas only and, taken together with the above data and molecular biology studies, is in favor of some local origin or disposal, independent from pancreatic insulin.

HYPOTHALAMIC GALANIN IN RATS WITH MARKED DIETARY PREFERENCES. B. Beck*, A. Stricker-Krongrad[1], A. Burlet, C. Burlet. INSERM U.308 - 38 rue Lionnois - 54000 NANCY (France) and [1] Ciba-Geigy, Basel (Switzerland)

Galanin (GAL) is a 29AA peptide which stimulates food intake when it is injected in the hypothalamic paraventricular nucleus (PVN). It might promote fat intake but this effect is actually discussed. In the present experiment, we tried to determine the hypothalamic galanin status of rats with marked dietary preference either for carbohydrates or for fats. The rats were selected among a population of 72 Long-Evans rats which could freely choose between a high-fat (HF) diet and a high-carbohydrate (HC) diet. The carbohydrate-preferring (CP) rats ate 13.1 ± 0.6 g HC diet per day and 6.0 ± 0.3 g HF diet per day. An inverse distribution in diet intakes was observed in fat-preferring (FP) rats. GAL was measured by a specific radioimmunoassay in several brain nuclei involved in the regulation of feeding behavior. It only varied in the magnocellular part of the PVN where its concentration was 25 % higher in CP rats than in FP rats (p=0.035). It was not significantly different in the ventromedian and dorsomedian nuclei and in the lateral hypothalamus. As we previously showed that CP rats have lower NPY concentrations in the parvocellular part of the PVN, we can conclude that rats with a marked dietary preference have a specific neuropeptide profile and that their preferences result of a balance between these peptides distributed in different areas of the brain.

DIFFERENTIAL C-FOS INDUCTION IN THE CNS OF SODIUM DEPLETED RATS BY NaCl INTAKE, BOMBESIN OR THE COMBINATION OF NaCl INTAKE AND BOMBESIN.

Frankmann*, S.P.[1] and T.A. Houpt[2].
[1]Dept. of Psychology, University of Southern Colorado, Pueblo. CO 81001 and [2]E.W. Bourne Behavioral Research Lab., Dept. Psychiatry, Cornell University Medical College, White Plains, NY 10605.

The sodium depleted rat rapidly initiates intake of NaCl (salt) solutions when offered and satiates within 30-60 minutes. Exogenous administration of the peptide bombesin (BN), which binds at neuromedin B and gastrin releasing peptide receptors, hastens the onset of satiety. c-Fos immunoreactivity (c-Fos) in the Nucleus Tractus Solitarius (NTS) is increased 1) following salt intake in the sodium depleted rat and 2) following BN administration in the non-sodium depleted rat. In the current study we examined c-Fos positive cells in the NTS, area postrema (AP), parabrachial nucleus (PBN) and other forebrain taste-related nuclei of sodium depleted rats at 90 min after: 1) access to 0.3M NaCl, 2) BN administration (8 µg/kg, ip) or 3) combined BN and 0.3M NaCl intake. Preliminary data suggest that either salt intake alone or BN alone induce c-Fos in the NTS but very little in the AP. The combination induces increased c-Fos in both the NTS and in the AP. The PBN and forebrain nuclei await quantification. These data suggest that not only is the behavior of salt intake reduced by BN administration, but also that the pattern of c-Fos induction in the NTS and AP is altered. Thus, there is a neuronal correlate of the behavioral change produced by BN administration in the sodium depleted rat.

STIMULATION OF FEEDING BY AGENTS THAT INCREASE ENDOGENOUS CYCLIC AMP IN THE PERIFORNICAL HYPOTHALAMUS (PFH) OF THE RAT. E.R. Gillard*, B. Mouradi, R.S. Grewal, A.M. Khan, T. Yau, and B.G. Stanley. Departments of Neuroscience and Psychology, University of California, Riverside, CA 92521.

Several neurotransmitters are known to affect eating by acting in the PFH. However, little is known about which signal transduction pathways mediate their effects on eating. We have recently shown that PFH injection of the cAMP analogue 8-br-cAMP stimulates eating in the satiated rat, and that this effect is dependent on intracellular access. To determine whether increases in endogenous cAMP in the PFH can also stimulate eating, we have microinjected satiated adult male rats (n=10) with the phosphodiesterase inhibitor IBMX (300 nmol) followed 10 minutes later by the adenylyl cyclase activator MPB forskolin (300 nmol) unilaterally in the PFH. Compared to vehicle or either compound alone, combined PFH administration of IBMX and MPB forskolin significantly stimulated eating (10.9 ± 2.0 g in 2 hrs). In a separate group of animals (n=10), bilateral PFH injection of MPB forskolin elicited intense eating (15.7 ± 2.3 g in 2 hrs). In contrast, bilateral PFH injection of the inactive forskolin analogue 1,9-dideoxyforskolin at the same dose was ineffective. To determine whether the stimulation of eating by agents that increase endogenous cAMP might be mediated by cAMP-dependent protein kinase (PKA), these animals were also received bilateral PFH injections of the PKA inhibitor H-89 (100 nmol) followed 30 min. later by injection of MPB forskolin. H-89 suppressed MPB-forskolin induced eating by 50%. Collectively, these results suggest that increases in endogenous cAMP in the PFH can stimulate eating dramatically, and that this effect is dependent on modulation of PKA activity. HINDBRAIN ADMINISTRATION OF ANTISENSE OLIGONUCLEOTIDES FOR THE TWO BOMBESIN RECEPTOR SUBTYPES DIFFERENTIALLY AFFECT THE SATIETY ACTIONS OF CENTRAL AND PERIPHERAL BOMBESIN. E.E. Ladenheim*, A. Wohn and T.H. Moran. Dept. of Psychiatry & Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The suppression of food intake produced by bombesin (BN)-like peptides in rats is mediated by two receptor subtypes; gastrin-releasing pepide (GRP) and neuromedin B (NMB) preferring. To evaluate a role for these receptor subtypes in feeding suppression produced by centrally and peripherally administered BN, rats were divided into groups and treated for five days with 1) GRP or NMB receptor antisense oligonucleotides 2) oligonucleotide controls for each receptor subtype or 3) 0.9% saline. Prior to treatment, rats were assessed for suppression of 0.5 kcal/ml glucose intake in a short term feeding test following BN injected into either the fourth cerebral ventricle (10 pmol) or intraperitoneally (3.2 nmol/kg). Following the 5 day treatment regimen, rats were re-evaluated for feeding suppression after central or peripheral BN. Treatment with 0.9 % saline or the control oligonucleotides had no effect on the ability of rats to suppress glucose intake after central or peripheral BN administration. However, pretreatment with NMB receptor antisense oligonucleotides abolished the suppression of glucose intake produced by fourth ventricular BN administration but did not affect suppression elicited by peripherally injected BN. In contrast, GRP receptor antisense oligonucleotide pretreatment eliminated suppression of glucose intake by both peripheral and fourth ventricular BN administration. These results demonstrate that 1) hindbrain GRP receptors are required for the suppression of glucose intake produced by peripherally administered BN and 2) both hindbrain GRP and NMB preferring receptors are required for the satiety action of fourth ventricularly administered BN. The differential effects of GRP and NMB receptor antisense oligonucleotides on the satiety action of BN suggest that different mechanisms are involved in BN's ability to suppress glucose intake depending upon the route of adminstration. Supported by NIH grant DK46448.

CONTRIBUTION OF CAUDAL BRAINSTEM 5-HT RECEPTORS TO MEAL SIZE CONTROL IN THE RAT. H. J. Grill*, J.C.K. Donahey and J. M. Kaplan, Psychol. and Neurosci., Univ. of Pennsylvania, Phila., PA 19104.

Of the central receptors that may mediate the anorexic actions of systemically administered serotonergic compounds such as d-fenfluramine [d-FEN] and mCPP, those in the forebrain have received the greatest attention. As a counterpoint to this forebrain focus, we evaluated the contribution of caudal brainstem (CBS) 5-HT receptors to the anorexic action of d-FEN and mCPP. Two paradigms were employed. [1] We compared the feeding response [intraoral intake of 12.5% glucose] of intact and chronic supracollicular decerebrate rats (CD) to systemic administration of these two agents. [2] The two agents were administered via 4th i.c.v. injection to determine whether dose-related suppression of intraoral intake could be obtained. Results: A dose-dependent suppression of intraoral intake was obtained in the chronic decerebrate rat treated with either d-FEN or mCPP (0 - 8 mg/kg, delivered i.p. 20 min before testing). For d-FEN, the threshold dose was somewhat higher in CD rats than in their intact controls. However, (a) intake suppression was obtained over approximately the same supra- threshold d-FEN dose range, (b) there was a comparable degree of maximal intake suppression (~ 80%) in the two groups, and (c) a comparable slope for the dose range from threshold to highest dose was obtained. Fourth i.c.v. administration of each agent in the intact rat yielded a dose-related suppression of intraoral intake. Preliminary data indicate that the reduced intake following 4th i.c.v. d-FEN treatment is attenuated by i.p. administration of metergoline. The CD results demonstrate the sufficiency of CBS receptors in mediating intake suppressive responses to these model serotonergic compounds. The 4th i.c.v. results suggest, further, that 5-HT receptors in the CBS play a significant role in normal meal size control in the neurologically intact rat. Supported by NIH DK21397.

ACTIVATION OF THE HYPOTHALAMO-PITUITARY-ADRENAL (HPA) AXIS BY 2DG AND 8-OH-DPAT IN RATS WITH LESIONS OF THE DORSOMEDIAL MEDULLA. Gaylen L. Edwards*, Brenda K. Edmonds and Joyce D. Power. Dept. of Physiol. and Pharmacol., Coll. of Vet. Med., Univ. of Georgia, Athens, GA 30602, USA.

Lesions centered on the area postrema (AP) are reported to disrupt ingestive responses to 2-deoxy-D-glucose (2DG) and 8-hydroxy-dipropylaminotetralin (8-OH-DPAT) (Am. J. Physiol. 258: R1395, 1990; Brain Res. 628: 321, 1993). This lesion also disrupts conditioned taste aversions produced by some circulating toxins such as paraquat (Tox. Appl. Pharm. 87: 212, 1987). We have recently found that lesions centered on the AP disrupt the ability of paraquat to activate the HPA axis, suggesting the AP may be a common neural substrate for behavioral and neuroendocrine responses to certain chemical agents. In the present study, we have evaluated the effect of treatment with 2DG and 8-OH-DPAT on activation of the HPA axis in rats with lesions centered on the AP. We have found, as previously reported, lesions centered on the AP attenuate the ingestive responses to 2DG and 8-OH-DPAT. Interestingly, both 2DG and 8-OH-DPAT activate the HPA axis in rats with lesions centered on the AP. These data suggest that the neural substrates mediating the behavioral effects of 2DG and 8-OH-DPAT are different from those that activate the HPA axis. Current studies are aimed at identifying the neural substrates involved in these responses. (Supported in part by NIH DK42533)

OCULOMOTOR SYSTEM: HUMAN STUDIES

664.1

THE PRECISION OF OCULAR FIXATIONS TO SIMPLE FEATURES. SJ Hamstra* & PE Hallett. Dept of Physiology, University of Toronto, Toronto, Canada, M5S 1A8.

Visual judgements of a complex image, such as a textured material, require the processing of spatially localized image elements ("features"). To discriminate between two textured images, one must somehow compare the two sets of features and their spacing. To provide a baseline of performance for interpreting free-viewing data, we determined the best precision of ocular fixations to simple sinusoidal bar features.

Fixation position was measured in 3 human subjects with a magnetic search coil, allowing accuracy in the image plane to within 1 arc min. Head position was fixed with a dental bite. Stimuli consisted of stationary sine gratings, isolated bars and maltese crosses. Subjects were asked to fixate alternately a pair of targets as accurately as possible.

We found that repeated voluntary fixation can be extremely precise (better than 3 arc min). Also, fixation precision varies directly with the duration of fixation and inversely with target size over a range of bar widths from 2 deg to 2 arc min, with an asymptote observed at a bar width of 10-20 arc min.

These results specify the minimum error in a voluntary fixation task and provide a standard of performance to be used in further experiments involving complex textured images (ie, combinations of sine gratings).

VOLUNTARY SACCADIC EYE MOVEMENTS : EFFECTS OF TASK REPETITION. A PET STUDY.

S. Dejardin, S. Dubois, J-M. Bodart, C. Schiltz, C. Michel[1], A. Roucoux and M. Crommelinck*. Lab. of Neurophysiology, U.C.L., Brussels; [1] PET Unit, U.C.L., Louvain-la-Neuve, Belgium.

Using ^{15}O-water PETscan, regional cerebral blood flow (rCBF) was measured in five normal subjects performing large horizontal saccadic eye movements in darkness. Eight scans were acquired alternatively during saccades and rest (eyes open). Data were analysed using Statistical Parametric Mapping (Friston et al., 1995). Both the task effect (comparing saccades to rest) and the interaction between task effect and time (repetition of the conditions during the scanning session) were investigated.

Subtracting rCBF during rest from rCBF during saccadic eye movements (task effect), activations were found bilaterally in precentral gyrus (frontal eye field), supplementary motor area, anterior calcarine sulcus and lingual gyrus, right caudate nucleus and cerebellum (vermis) (corrected p-value <0.05). Furthermore activations in the left caudate nucleus and bilaterally in putamen and thalamus were observed at an uncorrected p-value < 0.001. These results are for a large part consistent with a previous study of saccadic eye movements in darkness (Petit et al, 1993). However, unlike the previous study, we found no activation in the medial cingulate cortex, but rather a deactivation ($p < 0.001$, uncorrected).

When activations throughout repetitions of the same saccadic task are compared, right supplementary motor area showed a time-dependent increase of activation. On the contrary, activation in the cerebellum decreased during the experiment. The time-dependent effects suggest a specific physiological adaptation to task repetition.

fMRI STUDIES OF VISUAL FIXATION IN HUMANS. **B. Luna*, R.A. Berman, B.J. McCurtain, M.H. Strojwas, J.T. Voyvodic, K.R. Thulborn, and J.A. Sweeney. MR Research Center, University of Pittsburgh Medical Center, Pittsburgh, PA 15213.**

Single-cell recording studies of nonhuman primates provide evidence that dorsolateral prefrontal cortex (DLPFC), supplementary motor area (SMA), frontal eye fields (FEF), posterior parietal cortex (PPC) and pulvinar are involved in maintaining visual fixation. Despite the fundamental role of visual fixation in visuomotor control and spatial attention, its functional neuroanatomy remains to be clarified in human subjects.

fMRI studies were conducted while healthy young adults performed two tasks: visual fixation (vs. eyes-closed) and visually guided saccades (vs. fixation) in a high field (3.0 Tesla) scanner using gradient-echo echo-planar imaging. Results indicated increased activity in multiple cortical areas (FEF, SMA, DLPFC, and PPC) during visual fixation, consistent with a homology with nonhuman primates. Activation in FEF, SMA and PPC was further increased when subjects performed a saccadic eye movement task. Activations in medial anterior parietal cortex, the middle frontal gyrus (DLPFC), and caudate nucleus were observed to show activation only during fixation (but not saccades). These results provide new *in vivo* evidence that activity in cortico-cortical and cortico-striatal pathways function to sustain attention and suppress saccadic eye movements that would divert the eyes from a target of interest. Supported by NIMH R01 MH42969 (to J.A.S), NIMH P50 MH45156 (to D.A. Lewis).

fMRI STUDIES OF HUMAN FRONTAL EYE FIELDS. **R.A. Berman*, B. Luna, B.J. McCurtain, M.H. Strojwas, J.T. Voyvodic, K.R. Thulborn, and J.A. Sweeney. MR Research Center, University of Pittsburgh Medical Center, Pittsburgh, PA 15213**

While subregions of the frontal eye fields (FEF) - such as those associated with pursuit and saccadic eye movements - have been delineated in non-human primates, the anatomic localization and functional properties of the human FEF have not been well characterized. In fact, the precise localization of the frontal eye fields in humans remains a matter of some controversy.

We conducted functional magnetic resonance imaging (fMRI) studies to localize and characterize the frontal eye fields in individual subjects. High resolution (3x3x3 mm voxels) gradient-echo echo-planar images were acquired at high field (3.0 Tesla) in the coronal plane from healthy individuals performing pursuit and saccade tasks. Both tasks elicited activity in the supplementary motor area and FEF, consistent with observations from single-cell recording studies in behaving monkeys. The region of activity in frontal cortex that comprised the FEF was highly uniform across subjects, having a medial extent on the surface of the precentral gyrus, and a lateral extent primarily in the bank of the precentral sulcus, where it also included limited adjacent areas of middle frontal gyrus. Smooth pursuit and saccade tasks elicited activation in similar areas of FEF, suggesting that the FEF regions subserving these eye movements are largely overlapping in human brain. Supported by NIMH R01 MH42969 (to J.A.S.), NIMH P50 MH45156 (to D.A. Lewis).

664.5

FRONTAL EYE FIELDS ACTIVATION DURING VISUALLY GUIDED SACCADES AND SMOOTH PURSUIT IN HEALTHY HUMANS STUDIED WITH FMRI. L. Petit*, V. Clark, J. Ingeholm, S. Courtney, K. Keil, J. Maisog and J.V. Haxby. Section on Functional Brain Imaging, LPP, NIMH, Bethesda MD 20892.

The location of the human frontal eye fields (FEF) underlying horizontal visually guided saccades and sinusoidal smooth pursuit was investigated using functional magnetic resonance imaging (fMRI) in four healthy humans. Gradient echo echoplanar fMRI scans were obtained while subjects alternately performed a baseline task and one of the oculomotor tasks. Volumes of 20 to 26 contiguous axial images, each 5 mm thick, were obtained in 4 to 8 series of 70 scans each (TE 40 ms, TR 3 sec, flip angle 90°) on a GE Signa 1.5 Tesla magnet. Data for each subject were analyzed with ANCOVA, and the statistical significance ($p < 0.05$) of a region of activation (voxels exceeding a Z threshold of 3.09) was determined based on its spatial extent. All subjects showed bilateral FEF activation in the precentral gyrus that was correlated with the execution of visually guided saccades. Saccadic FEF activation extended from +35 to +55 mm above the AC-PC plane and was centered in the medial-caudal precentral sulcus. Bilateral FEF activation was also observed in two subjects during smooth pursuit performance. Pursuit FEF activation extended from +35 to +50 mm above the AC-PC plane and was centered in the lateral precentral gyrus. These findings confirm previous results on the location of the human FEF and suggest, in addition, a medial-to-lateral organization that is related to the type of eye movements.

fMRI STUDIES OF SPATIAL WORKING MEMORY. **J.A. Sweeney,* B. Luna, R.A. Berman, B.J. McCurtain, M.H. Strojwas, J.T. Voyvodic, C.R. Genovese, and K.R. Thulborn. MR Research Center, University of Pittsburgh Medical Center, Pittsburgh, PA 15213.**

Increased single-cell activity in several cortical areas has been demonstrated during performance of oculomotor spatial working memory tasks in behaving monkeys. We conducted fMRI studies to provide a detailed characterization of the functional anatomy of brain circuitry subserving spatial working memory in humans. Gradient-echo echo planar images were acquired in the axial plane at 1.5 or 3.0 Tesla.

Activation maps from individual subjects documented increased activity in multiple cortical regions during an oculomotor delayed response task relative to a visually guided saccade task (sensorimotor control). Significant task-related activation was seen in middle frontal gyrus (dorsolateral prefrontal cortex), precentral gyrus and sulcus (frontal eye fields), supplementary motor area (primarily within the interhemispheric fissure) and along the intraparietal sulcus (posterior parietal cortex). A high level of coherence in the activation across these cortical regions is consistent with the view that ongoing reciprocal activity in this circuitry may maintain visual representations in working memory over brief periods of time. Supported by NIMH R01 MH42969, NIMH P50 MH45156 (to D.A. Lewis).

664.7

INVOLVEMENT OF THE ANTERIOR CINGULATE CORTEX IN EYE MOVEMENT CONTROL. B. Gaymard, S. Rivaud, J.F. Cassarini, A.I. Vermersch, C. Pierrot-Deseilligny*. INSERM 289, Hôpital de la Salpêtrière, 47 bd de l'Hôpital, 75651 Paris Cedex 13, France.

Recent experimental data suggest that the anterior cingulate cortex (ACC) is involved in somatic motor control. A clear somatotopy exists in the cingulate motor areas with face and limb areas. Although no specific ocular motor areas have yet been experimentally identified in the ACC, cerebral blood flow studies in humans suggest that the ACC could also be involved in eye movement control. In two patients with a lesion involving the right ACC and 10 control subjects, we have tested several saccadic eye movement paradigms: reflexive saccades (peripheral targets randomly presented with a 200 ms gap), voluntary saccades (right or left targets continuously presented), antisaccades (saccades performed contralaterally to either a 5° or 25° lateral target), memory-guided saccades with a short (1 s) or a long (7 s) delay, and sequences of memory-guided saccades (4 visual targets presented successively and remaining illuminated). Compared to controls, patients had normal latency in the reflexive saccade paradigm but increased latency in all the other tasks. The gain of memory-guided saccades was markedly decreased, bilaterally, whether the delay was short or long. The patients made more errors than controls in the antisaccade task when the 5° lateral target was used, and a higher percentage of chronological errors in sequences of saccades. These results suggest that the right ACC plays an important role in eye movement control, and that its role could be exerted through an activation of the frontal ocular motor areas which are involved in intentional saccades.

664.8

AGE-RELATED PERFORMANCE OF HUMAN SUBJECTS ON PRO- and ANTI-SACCADE TASKS. **D.P. Munoz*, J. E. Goldring, K. A. Hampton, K. D. Moore. MRC Group in Sensory-Motor Neuroscience, Queen's Univ., Kingston, ON, Canada.**

Performance in saccadic eye movement tasks is frequently compared between human subjects with various pathologies or disabilities and controls. It is likely that among control subjects there may be significant age-dependent factors that also influence subject performance. To determine the extent of these influences, we studied control subjects from the ages of 6 to 80 years on several oculomotor tasks. Subjects initially fixated a central visual stimulus (fixation point: FP). A second visual stimulus (target: T) then appeared randomly 20° to the right or left of the FP. The T was presented while the FP remained on (overlap condition), or 200 ms after it was turned off (gap condition). In each block of trials, subjects were instructed to look to (pro-saccade task) or away from (anti-saccade task) the T; gap and overlap conditions were interleaved randomly. For each subject in each condition, we computed the mean saccadic reaction time (SRT), the coefficient of variation (CV), the percentage of express saccades (SRT 90-140 ms), and the percentage of misdirected saccades. The shortest mean SRTs in all tasks and conditions were generated by subjects aged 15-40. Younger and older subjects tended to have longer mean SRTs. The CV was greatest for subjects under 20 years of age. Express saccades were generated almost exclusively in the pro-saccade gap condition and occurred most often in subjects less than 30 years old. Direction errors in the anti-saccade task (i.e., saccades made toward the T instead of away) occurred most often in children, but there was a dramatic improvement in task performance between ages 6 to 15 years. Despite the large percentage of direction errors produced by many children in the anti-saccade task, they understood the instructions of the task because immediately following a direction error, they often generated a corrective saccade away from the T. Thus, the anti-saccade task may serve as a useful tool to study the development of brain structures involved in the control of impulsivity and saccade suppression. *Supported by the MRC of Canada and the EJLB Foundation*

PREDICTIVE SACCADIC AND SMOOTH PURSUIT RESPONSES IN NORMAL AND SCHIZOPHRENIC SUBJECTS G.K. Thaker*, D.R. Ross, and C. E.Kim Maryland Psychiatric Research Center, University of Maryland School of Medicine, Baltimore, MD 21228.

The aim of the current set of studies was to evaluate accuracies of saccadic and smooth pursuit responses to retinal and extraretinal motion information in normal and schizophrenic subjects. Studies in normal subjects suggested that (1) saccades to moving targets were significantly more accurate in response to extraretinal motion (e.g., during pursuit maintenance) than to retinal motion information (e.g., during pursuit initiation); and (2) the latter were more accurate than when target motion information was not available. In contrast to the previous studies, resampling of position error was not a confound because the target was masked during the planning and execution of the saccade. The results were unchanged even after experimentally controlling for the smooth eye motion just prior to the saccade. Smooth pursuit gain in response to just extraretinal motion information was about 0.60 in normal subjects. In this task the target was unexpectedly masked for up to 500 msec. Performance of schizophrenic patients (n=36) was generally normal in response to the retinal velocity error. However, compared to normal subjects (n=23), saccadic and pursuit gain in response to only extraretinal information was significantly low in schizophrenic patients. These results suggest that schizophrenic patients are able to normally respond to retinal velocity error, but, they have deficits in processing and/or utilizing extraretinal motion information (i.e., internal representation of the previous target motion).

EXTRAOCULAR PROPRIOCEPTION IS REQUIRED FOR SPATIAL LOCALIZATION IN MAN

Jocelyne Ventre-Dominey [1]*, Peter F. Dominey [1] and Marc Sindou [2]
[1] INSERM, Vision et Motricité, 69500 Bron, France- [2] Hôpital Neurologique P. Wertheimer, Neurosurgery Clinic, 69003 Lyon, France.

We investigated the role of extraocular proprioception on the performance of open loop manual pointing to visual targets, in human. As a treatment for their idiopathic trigeminal neuralgia, five patients underwent a unilateral percutaneous thermocoagulation of the trigeminal nerve. These patients were tested, before and after surgery, for their accuracy in pointing to foveated visual targets at different craniotopic locations (10 and 20 degrees right and left, and center). Deficits in accuracy of pointing were found only in patients that had an involvement of the ophthalmic branch and consequently of the extraocular proprioceptive fibers (demonstrated by a postsurgical anesthesia of the cornea and of the ophthalmic territory). In these patients with unilateral extraocular deafferentation, the position of initial and final pointing was significantly shifted 2 and 2.4 degrees, respectively, toward the lesioned side. This shift in initial and final position was predominant when the patients were pointing in the ipsilateral hemispace. These data support a model in which balanced extraocular proprioceptive inputs are required for accuracy of visually oriented movements in egocentric space.

COMBINATION OF OCULAR ECCENTRICITY AND SACCADIC AMPLITUDE AFFECT GAZE LATENCY IN HEAD-FREE HUMANS

James H. Fuller* Oral Anatomy University of Illinois m/c 829 Chicago, IL 60612

It has been recently reported (Fuller, Exp. Brain Res. 1996) that starting an ocular saccade from the contraversive side of the orbit shortens the reaction time latency. For example, with the head fixed and aligned with the body, the subject fixates a small light at -40° or -20° horizontal; after an unpredictable interval a second saccade target light appears at +20° or at +40°, respectively. The saccade starting at -40° will have a shorter latency than that starting at -20°. This effect is in addition to the increase in latency which occurs with increase in saccadic amplitude. The orbital effect and amplitude effect combined logically in head-free conditions; in the following three examples ocular saccadic latency is expressed relative to head saccadic onset. 1) Ocular saccadic onset is expedited if the eye is contraversive in the orbit; otherwise a long latency could allow the head to lead the saccade, and thus allow the VOR to drag the eyes over to the orbital limit. 2) Conversely, the two effects will delay ocular saccadic onset if the eyes are centered in the orbit, and if a large ipsiversive saccade will exceed the orbital limits at the end of the saccade. In this case the longer latency allows the VOR to move the eyes contraversively as the head leads the gaze saccade, thus allowing a larger ocular saccadic amplitude. 3) Alternatively, or even concomitantly, slowing the ocular saccade allows a more synchronous eye-head onset, which combined with a reduced VOR near the onset of head movement, will again assure that the ocular saccadic amplitude will not exceed the ipsiversive orbital limit before the gaze saccade is completed. Each of these conditions was examined with the head starting from different positions on the trunk. The head movement latency effect logically augments the orbital and amplitude effects.

ROLES OF *DROSOPHILA* SYNAPTIC INTEGRINS DURING AXON PATHFINDING AND SYNAPSE MATURATION B. Hoang, H. Kose, & A. Chiba* Dept. of Cell & Struct. Biol., Univ. of Illinois, Urbana, IL 61801

Integrins, a family of heterodimeric cell surface receptor proteins, play major roles in many developing tissues by mediating cellular signal transduction and promoting cell adhesion. However, their roles in neural tissues remain poorly characterized. We report the presence of both PS1 (laminin specific) and PS2 (RGD-dependent) Integrins in *Drosophila* larval neuromuscular synapses and present evidence supporting specific roles for "synaptic Integrins" during pathfinding and synaptic maturation. First, analysis of null mutants of various subunits (βPS, αPS1 and αPS2) using neural specific antibodies during motoneuron pathway recognition revealed a significant percentage of motoneurons behaving abnormally, either taking the wrong path, failing to extend growth cones or lacking a normal branch extension. This suggests that Integrins may be involved in axon pathway recognition as signal transducers and/or adhesive recognition molecules. Second, immunocytochemistry revealed the presence of PS1 and PS2 Integrins at the mature neuromuscular synapses, with protein expression restricted to only one type of boutons (type I). In a given muscle, where different types of boutons may be present, this specific subcellular distribution of Integrins suggests a role in defining bouton identity through their interactions with a network of cytoplasmic proteins. We propose that Integrins may be involved during neural pathfinding and synapse stabilization. The powerful genetics of *Drosophila* will allow for further in vivo studies of the molecular mechanism underlying the functions of the synaptic Integrins. Supported by NIH and NSF.

665.2

BOTH MOTOR NEURONS AND SCHWANN CELLS CAN DISTINGUISH BETWEEN DIFFERENT FORMS OF LAMININ.

S. I. Cho, J. Ko, and A. Y. Chiu* Division of Neuroscience, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

Although laminin is present in all basement membranes, its composition is variable because there are numerous isoforms of each of the three chains (α, ß and γ) that make up this heterotrimeric molecule. Since motor neurons and Schwann cells encounter several forms of laminin within the peripheral nervous system *in vivo*, the response of these cells to different laminin substrates was examined in primary cultures. Three substrates were examined: rodent *laminin*, consisting of α1, ß1 and γ1 subunits, and two other preparations enriched for either α2 (*merosin*) or for ß2 (*s-laminin*) chains. Schwann cells attached best to the *merosin* preparation and showed the weakest adhesion on an *s-laminin* substrate. Interestingly, no such difference was seen with motor neurons; all three substrates promoted neuronal adhesion and survival equally well. However, with longer time in culture, motor neurons extended extremely long processes on *merosin* and *laminin* substrates, while those on *s-laminin* bore shorter neurites with unusually large, flattened growth cones. These results show that the behavior of Schwann cells and motor neurons can be regulated directly by the local laminin composition. The precise geometric relationship of these cells at the neuromuscular junction may therefore reflect the unique composition of laminin at this synapse. (Supported by a grant from NSF)

NEURAL AGRIN INDUCES AGGREGATION OF MUSCLE-DERIVED ARIA , AND ITS RECEPTORS *erb*B 2 AND 3, IN ADULT RAT SOLEUS MUSCLE.

M.Rimer*[1], I.Cohen[1], T.Lomo[2], S.J.Burden[3] and U.J.McMahan[1]. [1] Dep.of Neurobiol., Stanford Univ. Sch.of Med.,Stanford,CA 94305. [2] Dep.of Neurophysiol.,Univ.of Oslo, Norway. [3] Skirball Inst.of Bio.Med.,New York Univ.Med.Ctr.,New York, NY 10016.

Several lines of evidence suggest that ARIA released by axon terminals of developing motor neurons activates acetylcholine receptor (AChR) subunit gene expression in myotubes during formation of the neuromuscular junction (NMJ). Myotubes, themselves,also synthesize ARIA. Since motor neuron agrin is thought to induce aggregation of AChRs and other proteins at developing NMJs, we determined whether neural agrin induces aggregation of muscle ARIA and ARIA receptors. We used a preparation in which extrajunctional regions of denervated adult rat soleus muscles are transfected with a CMV-vector carrying rat neural agrin cDNA. By 1 wk posttransfection, the neural agrin is expressed in ~1% of muscle fibers and agrin-induced AChR aggregates form on these fibers and on those surrounding them. Regions of the myofiber surface having ectopic AChR clusters develop features of the mature postsynaptic apparatus and persist for at least 6 wk. Using antibodies specific for the ARIA receptors *erb*B 2 and 3, we observed that these receptors aggregated at agrin-induced AChR aggregates. We also observed co-localized staining for ARIA at agrin-induced AChR aggregates with a variety of antibodies including a serum against a cytoplasmic epitope shared by ARIA isoforms α, β1 and β2. Expression of ARIA isoforms encoding both α- and β-EGF domains in denervated and normal adult soleus muscle was confirmed by RT-PCR and immunostaining. Motor neurons are known to synthesize EGF-β ARIA isoforms. These results raise the possibility that AChR synthesis at the developing NMJ is regulated at least in part by an autocrine pathway involving muscle ARIA and its receptors which is in turn, directed by neural agrin by virtue of its ability to aggregate those proteins. Supported by NIH. M.R. held a Myasthenia Gravis Foundation postdoctoral fellowship.

THE ROLE OF AGRIN IN NEUROMUSCULAR SYNAPTOGENESIS: ANALYSIS OF AGRIN-DEFICIENT MICE.

Medha Gautam, Peter G. Noakes[1], Lisa Moscoso[1], Fabio Rupp[2], Richard Scheller[2], John P. Merlie and Joshua R. Sanes[1]*. Dept. of Molecular Biology and Pharmacology and [1]Dept. Anatomy and Neurobiology, WashingtonUniversity Medical School, St. Louis, MO 63110 and [2]Howard Hughes Medical Institute, Dept. of Molecular and Cellular Physiology, Stanford Medical School, Stanford, CA 94305.

During neuromuscular synapse formation, motor axons induce clustering of acetylcholine receptors (AChRs) in the muscle fiber membrane. The protein agrin, originally isolated from the synaptic basal lamina, is synthesized and secreted by motoneurons, and triggers the formation of AChR clusters on cultured myotubes. These results suggested the hypothesis that agrin plays crucial roles in synaptic differentiation at the neuromuscular junction (U.J. McMahan, CSHSQB 50:407-418). Two alternatively spliced exons that occupy the 'z' site (in rat agrin) are required for high clustering activity in recombinant forms of agrin. To assess the role of agrin *in vivo*, we generated agrin-deficient mice by targeted deletion of the genomic region containing these two exons. In these mice, the z-exon containing forms were absent and levels of all agrin isoforms were markedly reduced. Our main finding was that the spatial relationship between pre- and postsynaptic structures was disrupted in homozygous mutants. Postsynaptic AChR clusters are reduced in number, size and staining intensity. However, some nerve-asociated AChR clusters were present, suggesting the existence of a second, nerve derived synapse organizing signal. In addition, intramuscular nerve branching and presynaptic differentiation was abnormal, which may be a direct effect of agrin-deficiency or impaired retrograde signalling from a defective postsynaptic apparatus. To distinguish between these possibilites, and to determine the natureof agrin-independent interactions between nerve and muscle, we have derived immortalized muscle cell lines from agrin-deficient mice and control littermates. We will now culture these cells with motoneurons to ask whether muscle agrin is required for proper innervation. (Supported by NIH and Myasthenia Gravis Foundation)

665.5

ALTERED ARIA/NEUREGULIN EXPRESSION AFFECTS BOTH PRE- AND POST-SYNAPTIC COMPONENTS OF NEUROMUSCULAR TRANSMISSION A.W. Sandrock*, S.E. Dryer†, L.E. Theill‡, & G.D. Fischbach *Dept. Neurobiol., Harvard Medical School, Boston, MA 02115; †Prog. Neurosci., Florida State University, Tallahassee, FL 32306; ‡Amgen, Inc., Thousand Oaks, CA 91320*

At the vertebrate neuromuscular junction (nmj), motoneurons regulate the accumulation of acetylcholine receptors (AChRs) in the postynaptic membrane in part by stimulating subsynaptic nuclei to increase AChR subunit synthesis. ARIA, a product of the neuregulin gene, is concentrated at nmjs and stimulates AChR synthesis *in vitro*. To test the role of ARIA in the mainenance of postsynaptic AChRs *in vivo*, we studied neuromuscular transmission in mice in which the exon encoding the immunoglobulin-like domain of the ARIA/neuregulin gene has been disrupted by homologous recombination. Homozygous knockout mice die on or before embryonic day 10. In heterozygous mice, compound muscle action potentials during repetitive nerve stimulation showed a decremental response with lower D-tubocurarine concentrations than in wildtype controls. Consistent with this, the amplitudes of spontaneous miniature endplate potentials (m.e.p.p.s) recorded in an isolated phrenic nerve-diaphragm preparation were significantly reduced in the ARIA-deficient mice compared to wild-type controls. However, these mice compensate for reduced postsynaptic sensitivity by increasing quantal content. Heterozygous mice also exhibit a greater presynaptic facilitation and a more rapid rate of fatigue during tetanic stimulation at 25 Hz. In summary, neuregulin-deficient mice are myasthenic, providing strong evidence that ARIA/neuregulin is essential for the development and/or maintenance of normal synaptic transmission at mammalian neuromuscular junctions. THE DYNAMIC PROCESS OF THE DISPERSAL OF ACETYLCHOLINE RECEPTOR CLUSTERS IN CULTURED MUSCLE CELLS. Z. Dai* and H.B. Peng. Department of Cell Biology and Anatomy and Curriculum in Neurobiology, Univ. of North Carolina, Chapel Hill, NC 27599-7090.

The formation of the neuromuscular junction (NMJ) in tissue culture involves a local differentiation of the muscle membrane as shown by the clustering of acetylcholine receptors (AChRs) and a global cellular remodeling as shown by the dispersal of preexisting AChR clusters (hotspots). Both innervation-induced changes can be mimicked in cultured Xenopus myotomal muscle cells by latex beads coated with heparin-binding growth-associated molecule (HB-GAM). Using digital video microscopy, we have examined the dynamic process of the hotspot dispersal in these muscle cells. The hotspot, consisting of smaller aggregates of AChRs, exhibit an intricate pattern as shown by fluorescent α-bungarotoxin (BTX) labeling. The dispersal of the cluster, as evidenced by the decrease in BTX fluorescence, was initiated immediately upon the presentation of beads. Although the density of AChRs decreased with time, the structural feature of the hotspot remained remarkably constant during the dispersal process. To understand this process further, we studied the hotspot-associated cytoskeletal proteins, rapsyn (43K protein), focal adhesion kinase (FAK) and dystrophin, as well as phosphotyrosine (PY) during its dispersal. We found that rapsyn and PY disappeared together with AChRs, while FAK and dystrophin remained at dispersing hotspots. The latter two proteins displayed the same structural features as the original hotspot during the dispersal process. In addition, the rate of hotspot dispersal is inversely dependent on its proximity to the bead-muscle contact. These results thus suggest that the clustering signal, either from the neuron or from the bead, is capable of generating a diffusible signal to cause a destabilization of the hotspot and the dispersal simply involves the disruption of the anchorage of AChRs to their underlying cytoskeleton without the dismantling of the entire apparatus. EVIDENCE OF DYNAMIC BEHAVIOR OF NERVE TERMINALS IN THE VICINITY OF RECEPTOR PLAQUES AT NEONATAL NEUROMUSCULAR JUNCTIONS. W-B Gan* and J.W. Lichtman. Dept. of Anatomy and Neurobiology, Washington Univ. Sch. Of Med., St. Louis, MO 63110

In order to better understand the ways in which synapse formation and elimination give rise to accurate alignment of nerve terminals and postsynaptic specializations, we have simultaneously visualized developing motor nerve terminals and postsynaptic receptor sites. Motor axons innervating rat sternomastoid muscle were labeled by iontophoretically applying lipophilic tracer dyes (DiI and DiO) from a micropipette positioned near nerve bundles within the muscle. Postsynaptic AChRs were labeled with fluorescently tagged alpha-bungarotoxin. At birth, most motor nerve terminals possessed several varicosities which resided over well defined postsynaptic receptor plaques present on each muscle fiber. We estimate that at any given time, one or more axons converging on a plaque only partially occupy it. Interestingly, the labeled nerve terminals were not confined to the region of the plaque, often having processes (sometimes > 20μm) and varicosities that extended onto regions of the muscle fiber where no AChR clusters were evident. Over the next several days, evidence of this dynamism decreased: fewer filopodia extended beyond the receptor region and a greater fraction of the receptor plaque was occupied by nerve terminal processes. However, the terminal regions overlying the receptor plaques still contained many small processes extending from larger swollen regions suggesting a high degree of dynamism more confined to the vicinity of the plaque. By the end of the first postnatal week the morphology of terminals and receptor plaques had changed such that there was often near perfect correlation in area and extent of the remaining axon and receptor regions. Junctions also began to show obvious areas where receptor density had become quite low. At such sites nerve terminals were not present either. Our findings suggest that in early life, nerve terminals are highly dynamic whereas receptor plaques appear relatively stable. Present studies are aimed at observing this dynamism directly. REPEATED *IN VIVO* IMAGING OF TARGET-DEPRIVED FROG MOTOR NERVE TERMINALS. A. Dunaevsky and E. A. Connor*. Dept. of Biology, Univ. of Massachusetts, Amherst, MA 01003.

Precise alignment and maintenance of presynaptic and postsynaptic specializations at synaptic sites are required to ensure fast and focal synaptic transmission. The mechanisms responsible for nerve terminal maintenance are not known. Here we address the role of target muscle in maintenance of frog motor nerve terminals. Target-deprived nerve terminals were generated by selective removal of muscle fibers without damage to the innervation. Individual target-deprived nerve terminals, stained with the dye, FM1-43, were repeatedly imaged *in vivo* over a period of 1-9 months after target removal and compared to controls. Most nerve terminals were relocated 1 month after muscle damage and the pattern and number of nerve branches at these synaptic sites were nearly always maintained. Although some nerve terminals were maintained in total for up to 9 months after muscle removal, at a greater percentage of nerve terminals, we observed retraction and loss of nerve terminal branches. This loss was most evident 7-9 months after target removal, although evidence of retraction was detected at synaptic sites at all times. All nerve terminal branches were functional as measured by FM1-43, although at some synaptic sites the pattern of FM1-43 stain was altered as a function of time without target. There was no evidence of growth of target-deprived nerve terminals. We conclude that frog nerve terminals deprived of target muscle undergo slow retraction from synaptic sites over a period of several months. These results support the hypothesis that target muscle plays a role in nerve terminal maintenance as demonstrated in mammalian muscle, although the mechanisms of stabilization may differ. PROTEIN SYNTHESIS INHIBITION IN POSTSYNAPTIC CELLS IS FOLLOWED WITHIN SEVERAL DAYS BY ELIMINATION OF NERVE TERMINALS. H. Santo Neto,* Q.T. Nguyen, J.W. Lichtman. Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110 USA

The role of the postsynaptic cell in synaptic maintenance is unclear. To determine whether or not postsynaptic cells provide ongoing support to established synaptic contacts, we have attempted to inhibit the synthetic capability of postsynaptic cells without interfering with that of presynaptic cells. Muscle fibers in living mice were injected intracellularly with the ribosomal inactivating protein (RIP) known as luffin at the site of their neuromuscular junctions in order to inhibit protein synthesis. We then monitored these junctional sites in the living animals over the next several days. We found that in the absence of protein synthesis by synaptic nuclei (as evidenced by the lack of new acetylcholine receptor insertion) the overlying nerve terminals progressively retracted beginning a few days after injection. This loss began before there were any detectable signs of muscle fiber damage or degeneration. Disengagement of presynaptic nerve terminals was not caused by the intracellular injection of the vehicle buffer alone, indicating that active protein synthesis by the postsynaptic cell is required to maintain junctional contact between cells. To identify the postsynaptic agent(s) whose absence induces nerve terminal withdrawal, ongoing studies include the blockade of exocytosis from muscle fibers and the inhibition of protein insertion into the plasma membrane.

NEURONAL AGRIN INDUCES ACTIVITY RESISTANT ACHR CLUSTERS IN DENERVATED RAT SKELETAL MUSCLES IN VIVO. I. Mathiesen, M. Rimer[1], I. Cohen[1], U.J. McMahan[1] and T. Lømo*. Dep. of Neurophysiol., Univ. of Oslo, 0317 Oslo, Norway; [1]Dep. of Neurobiol., Stanford Univ. Sch. of Med., Stanford CA 94305.

After injection of neuronal rat agrin cDNA into soleus muscles of adult rats some muscle fibers take up the DNA and release neuronal agrin. Subsequently, multiple clusters of AChRs and other postsynaptic molecules form ectopically on single denervated muscle fibers surrounding the transfected ones (Cohen et al., Soc.Neurosci. Abstr., 25: 686, 1995). Transplanted axons induce similar ectopic AChR clusters on denervated fibers, only one (or a few) of which survive on active muscle fibers and become mature neuromuscular junctions, while the others are eliminated. In inactive muscles, such selection for survival and accompanying elimination do not occur.

To determine if agrin-induced AChR clusters show similar activity dependent survival and elimination, we denervated the soleus on day 0, injected agrin cDNA on day 3-4, started direct electrical stimulation on day 6-14, and examined the muscle fibers on day 28-81.

Unlike AChR clusters on control unstimulated muscle fibers, all clusters eventually disappeared except for one per muscle fiber which persisted for at least 2.5 months. On average, the surviving clusters attained nearly the same size as the AChR clusters at original endplates several mm away.

The results show that neuronal agrin and direct muscle stimulation mimic the effect of motor axons in inducing activity resistant AChR expression at surviving AChR clusters and in causing elimination of nearby clusters. Together with our previous observations that AChE, Na-channels, junctional folds and myonuclei accumulate at the agrin-induced AChR aggregates, these findings indicate that agrin and muscle activity are sufficient for the formation of most if not all of the postsynaptic apparatus at developing neuromuscular junctions.

ALTERATION OF GENE EXPRESSION AFFECTS THE DEVELOPING NERVE-MUSCLE SYNAPSE. E.W. Godfrey, H. Tcheurekdjian and R.D. Heathcote*. Dept. of Cell. Biol. & Anat., Med. Col. of Wisconsin, Milwaukee, WI 53226 and Dept. of Biol. Sci., U. of Wisconsin-Milwaukee, Box 413, Milwaukee, WI 53201.

A number of synaptic molecules may play a role in the formation of the neuromuscular junction. To test the role of these proteins in synaptogenesis, we developed a method to alter expression of specific genes at developomg nerve-muscle synapses *in vivo*. RNA encoding specific synaptic proteins was injected into fertilized eggs of the frog *Xenopus laevis* to overexpress that protein during synaptogenesis. Initially, we altered expression of agrin, an extracellular matrix molecule that aggregates postsynaptic acetylcholine receptors (AChRs) on developing muscle cells. Following injection of RNA encoding isoforms of agrin, we assayed AChR aggregation in tadpole myotomal muscles by rhodamine-α-bungarotoxin labeling and image analysis after confocal microscopy. Control experiments using RNA for green fluorescent protein (GFP) showed that this marker diffused throughout the embryo and was expressed in all cells from the beginning of nerve-muscle synapse formation. Overexpression of a neuronal agrin isoform (A_0B_8) caused an increase in ectopic AChR aggregates, away from the ends of myotomal muscle cells, where synapses normally form. The volume of AChR aggregates was significantly greater in embryos injected with agrin RNA than in those injected with GFP RNA or uninjected controls. Thus, agrin increases the size and number of AChR clusters and changes their distribution on developing muscles.

CELLULAR AND MOLECULAR RESPONSES TO DENERVATION IN *DROSOPHILA*. T.N. Chang[1] & H. Keshishian*, Interdepartmental Neuroscience Program[1] and Dept. of Biology, Yale University, New Haven, CT 06511.

We have previously shown that laser ablating motoneurons in the *Drosophila* embryo results in ectopically placed endings by the first larval instar (Keshishian et al, 1993, Soc. Neurosci. Abstr.19:272.11). To see if there was a critical period, we used a microbeam laser to cut abdominal nerves in embryos and larvae, and looked for collateral inputs on the denervated segments. Nerve cuts in the embryo and early first instar resulted in collateral inputs. Segments which had their nerve cut later, remained denervated. Therefore, this type of plasticity may be restricted to the embryo and early first instar stage. Alternatively, older motor endings although severed from their cell bodies, may prevent collateral innervation.

To investigate the response of synapse associated proteins to denervation, we examined various pre and post-synaptic molecules. We used a vertebrate antibody to glutamate receptor and saw glutamate receptor-like immunoreactivity (IR) localized to the sites of synaptic boutons. This IR is evident in embryonic motoneuronal growth cones by stage 17, and is robust and specific to the bouton sites by the first larval instar. Nerve cuts at the 2nd or 3rd instar result in reduced IR in denervated compared to innervated segments evident by one day post operation (1 day p.o.). IR is almost gone by 2 days p.o., but persists as a few dense specks at the former innervation site for several more days. In contrast, the neuronal markers synaptotagmin and 22C10 are completely absent from the terminal by 3 days p.o.. These results suggest that the motoneuron is required to maintain glutamate receptors but that once localized to the bouton, receptors will not disperse through the muscle fiber. Interestingly, another post-synaptic marker, b-integrin, which is involved in adhesion, is not observed at nerve terminals until mid-first instar. It disappears from its localization at synaptic boutons much slower after nerve cut, so that 3 days p.o., staining is reduced but still high. Funded by NIH and NSF.

FASCICLIN II CONTROLS STRUCTURAL PLASTICITY AND REQUIRES CREB ACTIVITY TO INCREASE SYNAPTIC STRENGTH. Graeme W. Davis*, Christoph M. Schuster, Richard Fetter, and Corey S. Goodman. HHMI, Dept. of Molec. and Cell Biology. Univ.of California, Berkeley 94720.

Previous studies have shown that increases in either neuronal activity (in *eag Sh* mutants) or in cAMP (in *dunce* mutants) lead to an increase in both the structure and function of the *Drosophila* neuromuscular junction. We find that these activity-dependent increases in synaptic growth are accompanied by a ~50% decrease in presynaptic Fasciclin II, a cell adhesion molecule that is localized pre- and postsynaptically at each bouton. This decrease in Fas II is both necessary and sufficient for the presynaptic sprouting; *fasII* mutants that decrease Fas II by 50% lead to sprouting, while *fasII* transgenes that maintain presynaptic Fas II levels suppress sprouting in the *dnc* mutant background. However, decreasing Fas II does not lead to an increase in synaptic strength (as is the case in the *dnc* mutant). The quantal content of individual synaptic boutons is reduced in *fasII* mutants, suggesting that the normal synaptic machinery has been distributed throughout the increased number of boutons. Thus, elements downstream from cAMP, but not downstream from Fas II, must be involved in increasing quantal content. An increase in activation of CREB, the cAMP-dependent response element, is required in parallel with the decrease in Fas II in order to achieve an increase in synaptic strength. An increase in a CREB dominant negative in a *dnc* background inhibits the increase in synaptic strength but not the Fas II-mediated increase in synaptic structure; an increase in a CREB activator increases synaptic strength, but only in a *fasII* mutant background which increases synaptic structure. Thus, activity-dependent changes in cAMP appear to initiate two parallel pathways: (1) Fas II-mediated sprouting, and (2) CREB-mediated increase in transmitter release machinery. VISUAL CORTEX: EXTRASTRIATE—DORSAL STREAM III

666.1

DISSOCIATION OF VISUAL FUNCTIONS BOTH BETWEEN AND WITHIN COMPONENTS OF THE VISUAL CEREBRAL NETWORK. S.G. Lomber* and B.R. Payne. Laboratory for Visual Perception and Cognition, Department of Anatomy and Neurobiology, Boston University School of Medicine, Boston, MA, USA.

The purpose of the present study was to test the hypothesis that behavioral functions can be dissociated both between cerebral regions and across cortical laminae within a single region. In earlier studies, we have shown that occipito-parietal cortex of the posterior-middle suprasylvian (pMS) sulcus in the cat contributes to accurate direction-of-motion and differential motion discriminations, and to orienting of the head to look at a novel stimulus introduced into the contralateral visual field. In contrast, occipito-temporal cortex of the ventral-posterior suprasylvian gyrus contributes in a number of ways to the learning and recall of form discriminations. On the basis of previous anatomical and electrophysiological and studies, we suspected that motion-based processing depends primarily on the superficial layers of pMS cortex, whereas visual orienting operations depend primarily on deep layers of pMS cortex. Performance on these tasks was evaluated during different levels of cooling deactivation of pMS cortex. Overall, deactivation limited largely to the superficial layers impaired performance on both motion tasks examined, but had little or no effect on orienting. It was not until deep layers were also deactivated that orienting performance was profoundly impaired. These observations demonstrate that behavioral functions can be dissociated both within and between individual cerebral regions. Supported by NS32137.

VISUAL NEGLECT IN THE CAT: UNILATERAL VERSUS BILATERAL CORTICAL OR COLLICULAR DEACTIVATIONS AND IMPLICATIONS FOR UNDERSTANDING VISUAL NETWORK FUNCTION.

B. R. Payne* and S. G. Lomber. Laboratory for Visual Perception and Cognition, Department of Anatomy and Neurobiology, Boston University School of Medicine, Boston, MA, USA.

We have compared the effects of unilateral versus bilateral cooling deactivation of cortex at the temporo-occipito-parietal (TOP) junction on the cat's ability to redirect attention in an orienting task. Comparable deactivations were made of superior colliculus (SC). Unilateral cooling of either TOP cortex or SC induced a profound neglect of stimuli introduced into the contracooled hemifield. Addition of cooling of contralateral TOP cortex or SC largely reversed the neglect and restored orienting into the previously neglected hemifield. These results show that: 1) it is only under certain circumstances that TOP cortex and SC are *essential* for normal detection and orienting to visual targets; 2) interactions between components in the visual network are dynamic and are influenced by prevailing processing elsewhere in the network, and 3) it is unwise to predict the outcome of two combined deactivations even when the effects of deactivating individual nodes in a network are known. REAL MOVEMENT RESPONSES OF OPTIC FLOW NEURONS IN MST.

C. J. Duffy*. Dept. of Neurology, Univ. of Rochester Med. Ctr., Rochester, NY 14642

Moving observers have access to both visual and non-visual information about their direction of self-movement. MST neurons respond to optic flow stimuli which simulate the visual motion seen during self-movement. We have now recorded MST responses to optic flow and real movement stimuli, finding that many neurons show evidence of both visual and non-visual activation.

We have studied 120 MST neurons from two monkeys, with responses isolated during the presentation of planar, radial and circular optic flow stimuli. In each neuron, we first recorded responses to a standard set of eight optic flow stimuli which simulate the self-movement scene during translation on the horizontal plane (straight ahead and in seven directions at 45 deg intervals). We then presented real movement stimuli in darkness using the same eight directions of self-movement and trapezoidal velocity waveforms (Vm=20-40 cm/sec). Finally, we combined these stimuli to simultaneously present optic flow and the corresponding direction of real movement.

Ninety-eight neurons were studied with real movement, and 49 (50%) showed substantial responses to those stimuli. Sixty neurons were also studied with the combined optic flow and real movement stimuli, yielding a wide spectrum of combination response characteristics: 23% (14/60) reflected the responses evoked by the optic flow stimuli alone, 13% (8/60) reflected the responses evoked by the real movement stimuli alone, and 64% (38/60) showed interaction effects in their combination responses.

These findings suggest that some MST neurons might integrate visual and non-visual signals potentially supporting self-movement perception.

HEADING COMPUTATION DURING PURSUIT EYE MOVEMENTS IN CORTICAL AREA MSTd.

D.C. Bradley*, M. Maxwell, R.A. Andersen, M.S. Banks† and K.V. Shenoy, Division of Biology, Caltech, 216-76, Pasadena, CA 91125, and †School of Optometry, U.C. Berkeley, Berkeley, CA 94720.

As we move through the environment, the visual world appears to expand. The focus of this expansion signals the direction of heading when the eyes are still. However, when the eyes track an object, the retinal expansion focus shifts in the direction of the eye movement. To compute heading during eye movements, we must correct for this focus shift. One way humans do this is by using a pursuit eye movement signal for compensation. We hypothesized that this compensation occurs in MSTd. We trained a rhesus monkey to fixate a stationary spot or pursue a spot moving at 16°/s. While recording from each MSTd cell, we measured responses to 8 pursuit directions; the "preferred" direction elicited the strongest response. Next the cell's preferred optic flow pattern (expansion, contraction, rotation) was determined. Cells preferring expansion (~half the total) were then tested for focus tuning by showing 9 expanding images which differed only in their focus position, which was varied from -40° to 40° along an axis parallel to the preferred pursuit direction. This same procedure was done while the eyes were either fixating or pursuing in the neuron's preferred direction or the opposite direction. Relative to fixation, pursuit caused ~2/3 of the neurons to shift their retinal focus tuning by ≥10° *in the direction of pursuit*, thus compensating at least partly for the 30° retinal focus shift induced by the pursuit. The shift in the entire population averaged 9±2° (n=57; both pursuit directions combined). In control experiments, pursuit was simulated during stationary fixation by moving the entire stimulus (thus producing the same retinal image without the eye movement). In this case shifts averaged only -2±1° (n=57). Therefore, MSTd neurons use an eye movement signal to adjust their retinal focus selectivity in a way that compensates for retinal focus shifts which occur during pursuit. As a result, MSTd cells maintain approximately constant output for a given direction of heading. These findings suggest that MSTd is the neural site of heading perception in the macaque.

666.5

HEADING COMPUTATION DURING HEAD MOVEMENTS IN MACAQUE CORTICAL AREA MSTd.

K.V. Shenoy*, D.C. Bradley and R.A. Andersen, M/C 216-76, Division of Biology, Caltech, Pasadena, CA 91125.

In an accompanying abstract in this volume, we report that area MSTd is tuned for the focus of expansion position and uses an eye-pursuit signal to compensate for the retinal focus shift induced by pursuit. However, gaze changes often involve head as well as eye movements. Does MSTd also use a vestibular signal to compensate for the retinal focus shift induced by head movement? We compared responses to optic flow during eye-pursuit and VOR-cancellation tasks, the latter using full-body rotation in a 3-axis vestibular chair with the animal fixating a target moving in register with the chair. First, responses to eye pursuit and full-body rotation were compared for 8 directions in the fronto-parallel plane. The preferred directions were aligned (within 30°) in 67% of cells and the full-body rotation to eye pursuit response ratio averaged 87% (n=18). Second, the cell's preferred optic flow pattern was determined. Third, focus tuning curves were created for 3 different optic flow viewing conditions: eyes, head and body stationary; eyes pursuing (9.2°/s) with head and body stationary; and eyes fixed in the head with full-body rotation (9.2°/s). Focus tuning curves were generated by showing 9 optic flow motion patterns (fixed in room) which differed only in their focus position (-32° to 32° along an axis parallel to the pursuit/rotation direction). Relative to the stationary condition, eye pursuit and full-body rotation caused 44% and 39% of the neurons, respectively, to shift their retinal focus tuning by ≥ 24° *in the direction of pursuit/rotation*, compensating for the induced 24° retinal focus shift. The remaining cells showed less or no shift. Finally, as a control, we created an identical retinal stimulus by moving only the image. In this case shifts of ≥ 24° occured in only 14% of cells. Thus, MSTd neurons use both eye-pursuit and vestibular signals to compensate for retinal focus shifts produced by gaze changes. These findings further suggest that MSTd is the neural site of heading perception. Supported by NIH and ONR.

666.6

MICROSTIMULATION OF EXTRASTRIATE AREA MST INFLUENCES HEADING JUDGMENTS IN MONKEYS.

K.H. Britten*. Center for Neuroscience, UC Davis, Davis, CA, 95616.

The pattern of optic flow on the retina is a good cue for the direction of self-motion through a static scene. Psychophysical judgments of heading direction from optic flow are very accurate and precise. It is widely hypothesized that neuronal signals in the medial superior temporal (MST) area of macaque extrastriate cortex are involved in such tasks. Neurons in MST have very large receptive fields and are often selective for components of optic flow that occur naturally during self-motion. We have tested this hypothesis by stimulating columns of heading-selective neurons in MST while the animal was performing a threshold heading judgment task.

In our task, the monkey was required to maintain fixation or perform horizontal pursuit while heading displays were presented on a CRT monitor. These displays simulated a cloud of points uniformly distributed in a 3-dimensional volume; a range of headings long the horizontal meridian were shown. On each trial, the monkey indicated whether the simulated heading was left or right of zero (in head coordinates) by making a saccade to a target on the same side. Thresholds (minimal angle from zero) were very similar to those of human observers under the same conditions.

First, we mapped multiunit activity in area MST. This activity was often well tuned for heading direction and the tuning appeared to be columnarly organized. When a region showed consistent heading preferences over a distance of > 250 μ, the electrode was positioned in the center of the region and connected to a constant-current stimulator. In a pseudorandomly sequenced block of trials, half included microstimulation (20 μA, 200 Hz) simultaneous to the visual stimulus motion.

In a preliminary sample of such experiments in one monkey, microstimulation produced significant biases about half the time. These biases were usually in favor of the direction of heading preferred by neurons at the electrode tip. While the effects were typically modest in size, their consistency supports the hypothesis that area MST participates in the computation of heading from motion cues. VISUAL-VESTIBULAR INTERACTION IN THE VENTRAL INTRAPARIETAL AREA (VIP) OF MACAQUE MONKEYS.

W. Graf*, F. Bremmer, S. Ben Hamed and J.-R. Duhamel. CNRS - Collège de France, 75270 Paris Cedex 06, France.

Self-motion detection is the end product of multisensory interactions involving visual, vestibular, somatosensory and other cues. Since the parietal cortex is thought to play an important role in motion analysis, we quantified neuronal responses in the ventral-intraparietal area (VIP) during visual and vestibular stimulation.

Single cell responses were recorded extracellularly in two awake and head-fixed macaque monkeys (Macaca mulatta and Macaca fascicularis) who were trained to perform a fixation task. Visual stimuli and the fixation target were back-projected onto a translucent tangential screen. Vestibular stimuli were delivered by vertical axis (horizontal) rotation of a turntable either in total darkness or in light.

About 40 % of all recorded neurons (n=110) had vestibular sensitivity. Visual receptive fields were large, often covering more than an entire hemifield. Vestibular responses were in phase with head velocity, or could signal position integration. Associated visual responses were always direction selective. However, preferred directions for vestibular and optokinetic activation were always in the same direction, i.e., non-complementary. In essence, this response pattern is geared to generate a sensory conflict situation. Visual and vestibular on-directions were either to ipsilateral (with reference to the recording site), or to contralateral. Sensitivity to vestibular stimulation could be high or low. In the former case, visual-vestibular interaction resulted in a decrease of the response gain reflecting the conflict nature of the two stimuli. In the majority of cases, however, vestibular sensitivity was low, but the conflicting visual input actually resulted in an amplification of the overall response. - These results could be interpreted as signalling overcompensation of an eye or head movement response, or as detecting constant spatial coordinates. A final answer to these questions has to come from recordings in head-free animals.

NON-RETINOCENTRIC CODING OF VISUAL SPACE IN THE MACAQUE VENTRAL INTRAPARIETAL AREA (VIP).

F. Bremmer*, J.-R. Duhamel, S. Ben Hamed and W. Graf. CNRS - Collège de France, F-75270 Paris Cedex 06, France.

Different hypotheses have been suggested about how visual spatial information may be encoded in posterior parietal cortical areas: signals may remain in purely oculocentric coordinates until they reach the effector system, or populations of neurons may encode non-retinocentric coordinates by combining visual signals with eye position signals. In our present study we investigated in detail visual receptive fields (RFs) of neurons in the ventral intraparietal area (VIP) and tested another hypothesis i.e., a non-retinocentric coding of visual space at the *single cell* level.

Single cell responses were recorded extracellularly in two alert monkeys (*Macaca mulatta* and *Macaca fascicularis*) trained on a fixation task. Visual stimuli as well as the fixation target were back-projected onto a translucent screen subtending a stimulation area of 70°x70°. During fixation, visual excitability of recorded neurons was assessed by presenting sequences of bars (10°x1°) moving at constant velocity (100ms, 100°/s) in randomized order across different parts of the screen. This allowed sampling of the full stimulation area by a grid of 49 pixels, each pixel covering 10°x10°. Fixation locations were either the screen center or one of ideally 8 different screen locations. For each fixation location, a complete stimulation grid with at least 6 stimulus responses per grid pixel was recorded.

The majority of investigated neurons revealed visual RFs fixed to the retina i.e., RF locations shifted with respect to the screen for respective fixation locations. However, in about one third of the neurons, the RF locations remained constant with respect to the screen, or they did not shift to the same degree as the underlying gaze shift. Stimulus driven responses of neurons from both groups were often influenced by eye position. Our results thus give evidence for a non-retinocentric encoding of visual space at the single cell level in area VIP of macaques.

BEHAVIORAL MODULATION OF SPEED TUNING FOR NEURONS IN AREA 7a IN THE BEHAVING MACAQUE. R.E. Phinney* and R. M. Siegel. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102.

Area 7a receives input from MT via MST and is involved in motion processing and mapping of environmental space. Since MT and MST both possess speed tuned cells (Cheng, et al., 1994; Celebrini & Newsome, 1994), we wanted to determine whether cells in 7a would exhibit speed tuning. One *Macaca mulatta* was trained to fixate a 0.5° square, pull back a lever, and release it for a juice reward in response to a change in optic flow. The stimulus consisted of 128 limited lifetime dots in a 50° diameter, circular aperture. The points underwent changes in fraction of structure (FOS) via randomly translocating the motion vectors 3.5-6 sec after stimulus onset. Before testing for speed selectivity, the optimal optic flow was determined using translation, radial, and rotation stimuli with an average speed of 12°/sec. The neurons were then tested with a logarithmically scaled set of speeds in the range of [0, 256°/sec] for optimal and non-optimal stimuli. Spike rate was averaged over a 500 msec duration; an ANOVA compared the rate both before/after stimulus onset, and before/after FOS change.

Twenty-four percent of 49 cells tested displayed a speed selectivity at stimulus onset, as might be expected based on the MT/MST projections. The speed selectivity could be different for the *non-optimal* as compared to the *optimal* optic flows. This implies that the optic flow tuning is speed dependent. The speed selectivity also depended on the behavioral state of the animal. At the time the FOS changed, the number of speed selective neurons doubled. Subsequent analyses indicate that many neurons that were non-selective to the onset of the random dots, became selective later in the trial. In contrast, only a few of the neurons that were selective at onset became non-selective at FOS change. The influence of the behavioral events on the response of the neurons is demonstrated by the change in firing rate coincident with the change in FOS (65% of the neurons). These data indicate that area 7a neurons are tuned for the speed of the optic flow and this tuning may (1) modulate optic flow selectivity and (2) be modulated by the behavioral state of the animal. This dynamic allocation of neuronal selectivity at FOS change may underlie increased information processing capacity devoted to strongly attended as opposed to non-attended or lightly attended stimuli. DIRECTION SELECTIVITY OF RESPONSES TO OCCLUDED MOTION IN PRIMATE POSTERIOR PARIETAL CORTEX.

J.A. Assad* and J.H.R. Maunsell. Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

One of the challenges facing the visual system is keeping track of moving objects that become temporarily occluded. We have previously demonstrated that some cells in primate posterior parietal cortex (PP) remain active following the disappearance of a visual stimulus which, from context, could be inferred to be moving behind an occluder. Here we characterize the direction selectivity of these extraretinal signals. A rhesus monkey was trained to maintain fixation while viewing the following stimuli: On all trials, six spots appeared in a circular array around the receptive field under study, with each spot surrounded by a circular target. On visible motion trials, all spots simultaneously disappeared except for one, which moved across to the opposite target. Visible motion trials were randomly interleaved with occluded motion trials in which all spots disappeared, but then one reappeared in motion a few degrees from its target, as if it had been continually moving behind an occluder. Visible and occluded motion trials were repeated for one direction, and then the direction changed, such that all six directions were eventually tested. For all directions, occluded motion trials were identical until the reappearance of the spot; the direction could be inferred only from the direction-blocked organization of the trials. Single unit recordings were made from 85 neurons in the intraparietal and superior temporal sulci of PP cortex. Average spike rates were computed from the disappearance or start of movement of the spot until the time of, or time corresponding to, the reappearance of the spot. 32 of the 66 cells that were direction selective for visible motion trials were also direction selective for occluded motion trials (ANOVA; $p<0.05$), even though no stimulus was visible for any direction on the occluded motion trials. For 71% of these cells the preferred direction was the same for the two trial types. These results suggest that one role of PP may be to create a representation of moving visual stimuli that can resist transient occlusion.

MICROSTIMULATION IN AREA LIP INFLUENCES CHOICES IN A DIRECTION DISCRIMINATION TASK. E Seidemann* and WT Newsome. Dept. of Neurobiology, Stanford University, Stanford, CA 94305.

We trained a rhesus monkey to discriminate the direction of motion in a stochastic dot display and to indicate his psychophysical choices by means of a saccadic eye movement to one of two targets. To perform correctly, the monkey must convert information concerning motion direction into a plan to execute a particular saccade; recent single unit recordings suggest that area LIP may play a role in this conversion. To test whether LIP is directly involved in this task, we measured the effects of electrical microstimulation in LIP on the monkey's psychophysical choices.

In each experiment, we located a cluster of LIP neurons that discharged well in advance of saccades planned to locations within the multi-unit movement field (MF). The motion stimulus was positioned near the center of gaze but outside of the MF; one saccade target was positioned within the MF while the other was placed well outside of the MF. Microstimulation (50μA, 200 Hz) was applied for 800 msec during one of three possible intervals: prior to stimulus presentation, during stimulus presentation, or during a delay period following the stimulus but preceding the saccade. Non-stimulated control trials were included, and all trial types were randomly interleaved.

We have obtained three primary results: 1) in 38% of the experiments microstimulation biased the monkey's choices toward one of the two targets (logistic regression analysis, $P<.05$). In 87% of these cases, the bias was towards the target within the MF of the LIP neurons (mean shift = 4% dots). 2) Somewhat surprisingly, the effects on the monkey's choices were largest and most frequent when microstimulation was applied during the visual stimulus presentation - the interval in which the monkey is likely to reach a decision and choose a target for a saccade. 3) Microstimulation did not elicit saccades directly, but sometimes induced small effects on saccade duration, end-point or peak velocity; these effects, however, were most common when microstimulation was applied in the delay period. Together, our results suggest that LIP plays a direct role in the processes that lead to target selection and saccade planning in the direction discrimination task. Supported by N.E.I.

HEMODYNAMIC AND NEUROMODULATORY EFFECTS OF NOS GENE DELETION: IN VIVO FUNCTIONAL IMAGING AND MICRODIALYSIS STUDIES IN KNOCKOUT MICE. E.H.Lo*, T.Kano, M.Shimizu-Sasamata, H.Hara, J.Rogowska, M.Trocha, A.R. Pierce, P.L.Huang, M.Fishman, G.L.Wolf, M.A.Moskowitz. Ctr for Imaging & Pharm Res, Neurovasc Regulation Lab, and Cardiovasc Res Ctr, Harvard Med Sch, Boston, MA 02129.

After cerebral ischemia, knockout mice lacking expression of the endothelial isoform of NO synthase (eNOS) develop larger infarcts whereas neuronal NOS (nNOS) knockouts develop smaller infarcts compared with wild type mice. These differences may be due to differential hemodynamic vs neuromodulatory effects of NO. In Expt A, focal ischemia was induced by MCA occlusion in eNOS knockouts and SV129 mice. High resolution functional CT scanning was performed to measure the cerebral transit profiles of injected contrast agents. Hemodynamic deficits were more severe in the eNOS knockout than SV129 mouse. When expressed as a percentage of the total lesion, the hemodynamic penumbra was significantly smaller in eNOS knockouts (60.2±3.7%) compared to wild types (71.2±3.4%). In Expt B, in vivo microdialysis was used to evoke K+ depolarization in cortex and basal ganglia. Initial data suggest that this approach produces robust glutamate and GABA release and can be used to examine for possible differences in transmitter response between wild types and NOS knockouts. These studies will provide insight into the differential hemodynamic vs neuromodulatory effects of NO derived from either endothelial or neuronal NOS isoforms. KNOCKOUT MICE LACKING THE INDUCIBLE NITRIC OXIDE SYNTHASE GENE ARE RESISTANT TO CEREBRAL ISCHEMIA

C. Iadecola*, F. Zhang, R. Casey and M. E. Ross, Dept. of Neurology, Univ. of MN, Minneapolis, MN 55455.

Focal cerebral ischemia is followed by expression of the inducible nitric oxide synthase (iNOS) gene in the injured brain (JCBF&M 15:378, 1995). However, the role of iNOS expression in the mechanisms of ischemic damage remains unclear. Although experiments using iNOS inhibitors suggest that iNOS expression may contribute to ischemic brain damage (AJP 268:R286, 1995), these drugs have unrelated pharmacological effects that could also play a role. We therefore used knockout mice with a null mutation of the iNOS gene (Cell 81:641, 1995) to test the hypothesis that iNOS expression contributes to cerebral ischemic damage. The middle cerebral artery (MCA) was occluded in iNOS-kn and in wild-type mice (C57B6). iNOS mRNA was determined by the reverse transcription polymerase chain reaction (RT-PCR). Infarct volume was determined in thionin-stained brain sections 4 days after MCA occlusion. In wild-type mice, iNOS mRNA first appeared at 1 day, peaked at 2 days and then subsided. In iNOS-kn no iNOS signal was observed at any of the time-points studied. Four days after MCA occlusion the infarct was 31% smaller in iNOS-kn (27±2 mm^3; n=5) than in wild-type mice (39±3; n=5; $p<0.01$; t-test). The reduction in stroke size could not be due to alterations in neuronal NOS gene expression because Ca^{++}-dependent NOS activity in cerebellum did not differ between wild-type mice (7948±660 dpm/150μg pro/45 min; n=4) and knockouts (7929±19; n=12; $p>0.05$). We conclude that iNOS-kn do not express the iNOS gene following cerebral ischemia and have significantly smaller infarcts. The data provide evidence that large amounts of NO produced by iNOS contribute to the progression of the brain damage that occurs in the post-ischemic period. Thus, inhibition of iNOS expression or activity could be a valuable tool to specifically target the delayed extension of the infarct that occurs following cerebral ischemia. (Supported by NS 34179)

TISSUE PLASMINOGEN ACTIVATOR KNOCKOUT MICE MANIFEST SMALLER CEREBRAL INFARCTS IN A FOCAL ISCHEMIA/REPERFUSION MODEL. Yanming F. Wang[1]*, Stella E. Tsirka[2], Sidney Strickland[2], and Stuart A. Lipton[1]. [1]Dept. of Neurology, Children's Hospital; Program in Neuroscience, Harvard Medical Schl, Boston, MA 02115, and [2]Dept. of Pharmacology, University Medical Center at Stony Brook, Stony Brook, NY 11794.

Neuronal damage due to intracerebral injections of excitotoxins has been shown to be attenuated in mice lacking the serine protease tissue plasminogen activator (tPA-deficient mice) (Tsirka et al., *Nature* 1995). It has therefore been suggested that tPA, which is produced by both neurons and microglia, might play a role in excitotoxic neuronal cell injury. Here we extend these results by showing that animals undergoing focal cerebral ischemia/reperfusion have smaller infarcts than wild type control mice. A 6.0 nylon filament coated with silicone was threaded into the lumen of the middle cerebral artery to produce transient occlusion for 3 hours, following a modification of the procedure of Longa et al. (*Stroke* 1989). After 3 hours of occlusion, the filament was gently withdrawn to allow tissue reperfusion (Soriano et al., *Ann Neurol* 1996). Animals were then sacrificed 21 hours later. As analyzed by 2,3,5-triphenyltetrazolium (TTC) staining, after accounting for cerebral edema, infarct volume was decreased from 79.5 ± 6.7 mm^3 in controls to 39.2 ± 7.2 mm^3 in tPA-deficient mice (mean ± SEM, n =7 mice in each group). Under these conditions, there is no clot formation at the thrombotic site, so the absence of tPA would not contribute to damage via an enhanced clotting cascade as could otherwise occur. These results suggest that tPA may mediate, at least in part, excitotoxic damage after focal ischemia.

DNA FRAGMENTATION AND HSP70 PROTEIN INDUCTION IN HIPPOCAMPUS AND CORTEX OCCURS IN SEPARATE NEURONS FOLLOWING PERMANENT MIDDLE CEREBRAL ARTERY OCCLUSIONS. B.A. States, J. Honkaniemi, P.R. Weinstein and F.R. Sharp*, Department of Neurology, UCSF and VA Med Ctr, San Francisco, CA 94121.

DNA nick end-labeling (TUNEL) and HSP70 immunocytochemistry were performed on the same sections 1 (n=6), 3 (n=12) and 7 (n=7) days following MCA occlusions produced using the endovascular carotid suture method in adult rats. In cortex at 1 and 3 days following MCA occlusions, HSP70 stained neurons were located outside areas of infarction and showed little evidence of DNA fragmentation. DNA fragmentation occurred in CA1 hippocampal neurons in 39% of the animals at 1 and 3d following ipsilateral MCA occlusion. Bilateral DNA fragmentation occurred in CA1 neurons in one subject. HSP70 protein was expressed in CA1 hippocampal neurons in 50% (9/18) of the animals at 1 and 3 days following MCA occlusions, including all animals that exhibited hippocampal DNA fragmentation. Three animals had bilateral expression of HSP70 in CA1 neurons. Cells that stained for either HSP70 protein or DNA fragmentation existed in close proximity to one another. Approximately 5-7% of the HSP70 stained cells were also TUNEL stained. These data suggest that ischemic cells capable of translating HSP70 protein generally do not undergo DNA fragmentation, and support the concept that most HSP70 immunoreactive neurons survive ischemic injury and are "reversibly injured." CA1 neurons are injured in half the animals.

MITOCHONDORIAL DAMAGE EXACERBATES APOPTOSIS AND EXPRESSION OF hsp70 mRNA AND HSP70 PROTEIN IN BRAIN

S Sato[1]*, GT Gobbel[1], J Honkaniemi[3], Y Li[1], T Kondo[1], K Murakami[1], K Hasegawa[2], FR Sharp[3], and PH Chan[1].

Departments of Neurological Surgery[1] and Anesthesia[2], University of California, San Francisco, CA94143 and Department of Neurology[3] VA Medical Center, San Francisco, CA94121.

Administration of the mitochondrial toxin 3-niitoprppionic acid (3-NP) to rats causes neuronal degeneration in the striatum, a lesion similar to that found with Huntington's disease. We previously reported that intraperitoneal or stereotaxic injection of 3-NP, induced neuronal apoptosis in the striatum. Because there is an increase in heat shock protein 70 (HSP70) synthesis in the brain following a variety of insult, we investigated the effect of 3-NP on the induction of apoptosis and hsp70 mRNA and protein expression in brain. Male Sprague -Dawley rats were stereotactically injected with 1 µl of either 500 nM 3-NP or saline (control) in the striatum under methoxyflurane anesthesia. The rats were killed at 3, 6, 12, 24 h, 3, 5 and 7 d after the injection. The frozen brains were sectioned and stained for Nissl substance (cresyl violet), apoptosis (TUNEL), HSP 70 (immunohistochemistry), and hsp 70 mRNA (in situ hybridization). DNA from the striatum was isolated from some rats 1 d after injection and subject to electrophoresis to detect the laddering pattern associated with apoptosis. Our result demonstrate that cells in the striatum become TUNEL positive by 6h, and continued 7 days. DNA laddering was also present in the 3-NP injected brain. There was an increase in hsp 70 mRNA and HSP 70 protein expression in the center of the striatum at 12 h after injection which persisted expressed at the edges of the striatum at 5 days. The present study demonstrates first time that increased hsp 70 gene expression is induced by mitochondorial dysfunction which is closely associated with apoptosis.

HEAT STRESS-INDUCED OR VIRAL-MEDIATED EXPRESSION OF HSP70 IN MURINE CORTICAL ASTROCYTES REDUCES VULNERABILITY TO LOW pH. B. J. Snider*, D.M. Turetsky and D.W. Choi. Center for the Study of Nervous System Injury and Dept. of Neurology, Washington Univ. School of Medicine, St. Louis, MO 63110.

Heat-induced cytoprotection in many systems has been correlated with the expression of a 70 kDa heat shock protein (hsp70), but we found that exposure of murine cortical cell cultures to heat stress only induced detectable hsp70 in astrocytes, not neurons. Here we examined the ability of such astrocyte hsp70 expression to protect these cells against death induced by exposure to low pH.

A conditioning heat stress (44°C for 1 hr) induced substantial astrocyte hsp70 expression, and reduced astrocyte death induced by 18 hr exposure to low pH (6.2). Protection was seen as early as 3 hrs after heat stress, and was lost by 72 hrs after heat stress. These results are consistent with an earlier study showing that a conditioning heat stress reduced cortical astrocyte death induced by prolonged exposure to oxygen-glucose deprivation, (Giffard et al., Neurosci Abs. 19:1651, 1993). To test the hypothesis that hsp70 expression was at least in part responsible for the observed cytoprotection, we infected astrocytes with an adenovirus encoding human hsp70 (Ad-hsp70). Robust hsp70 expression in astrocytes was achieved, and these infected astrocytes were indeed protected against low pH-induced death.

Supported by NIH NINDS grants NS 01827 (BJS) and NS 30337 (DWC).

DECREASED LEVELS OF CuZn-SUPEROXIDE DISMUTASE (CuZn-SOD) IN GENE KNOCKOUT MUTANT MICE INDUCE EARLY EDEMA FORMATION AND APOPTOTIC NEURONAL CELL DEATH AFTER FOCAL CEREBRAL ISCHEMIA. T. Kondo,* A.G. Reaume, T.-T. Huang, K. Murakami, E. Carlson, S. Chen, R.W. Scott, C.J. Epstein, P.H. Chan. Departments of Neurogical Surgery, Neurology and Pediatrics, University of California, San Francisco, CA 94143 and Cephalon, Inc., West Chester, PA 19380.

Oxygen free radicals are involved in the pathogenesis of a variety of central nervous system disorders, including cerebral ischemia, trauma and many degenerative diseases. Recently developed CuZn-SOD gene (*Sod-1*) knockout mutant mice show decreased levels of CuZn-SOD activity at 0% in homozygous (*Sod-1* -/-) and 50% in heterozygous (*Sod-1* +/-), compared to wild-type (Wt) mice. Although the knockout mutant mice develop normally and have no phenotypic abnormalities, they show high mortality and severe infarction after focal cerebral ischemia and reperfusion. To investigate the mechanism of these effects, we examined the breakdown of the blood-brain barrier and apoptotic neuronal cell death in the ischemic brain of the knockout mutant mice. In the present study, *Sod-1* -/-, *Sod-1* +/- and Wt mice were subjected to various times of reperfusion following 1 h of middle cerebral artery occlusion. Evans blue extravasation indicates early blood-brain barrier breakdown in the knockout mutants at 2 h after the ischemia, depending on their CuZn-SOD activity (Wt, 0.12 ± 0.04; *Sod-1* +/-, 0.49 ± 0.22; *Sod-1* -/-, 1.96 ± 0.51, µg/hemisphere, $p<0.05$, ANOVA). At 24 h after the ischemia, *in situ* nick end labeling of DNA free ends (TUNEL) demonstrates increased apoptotic neuronal cell death in the cortical penumbra and piriform cortex of the knockout mutants compared to Wt mice. These results suggest that superoxide anions are an important factor for the pathogenesis of brain edema and neuronal cell injury, including DNA damage, after focal cerebral ischemia and reperfusion.

667.8

CYCLOOXYGENASE-2 GENE EXPRESSION IN NEURONS FOLLOWING FOCAL CEREBRAL ISCHEMIA S. Nogawa*, F. Zhang, M.E. Ross and C. Iadecola, Dept. of Neurology, Univ. of Minnesota, Minneapolis, MN 55455.

Cyclooxygenase (COX) 1 and 2 are rate-limiting enzymes for prostanoid synthesis. COX1 is constitutively expressed while COX2 is not present in normal tissues, except brain and testis, and is induced during inflammation (Agents & Actions 46: 41, 1995). We investigated whether the COX2 gene is induced following cerebral ischemia and, if so, we sought to identify the cell type in which COX2 is expressed and determine whether COX2 expression is associated with increased synthesis of prostanoids in the post-ischemic brain. The middle cerebral artery was occluded in rats by an intraluminal filament and the ischemic area was dissected 12 hours later. Sham-operated rats served as controls. COX1 and COX2 mRNA were determined by the reverse-transcription polymerase chain reaction. PBD, a ubiquitous sequence, was also amplified and used for normalization. In sham operated rats, low levels of COX1 and COX2 mRNA were observed. 12 hours following ischemia COX2 mRNA was upregulated in the post-ischemic brain but not contralaterally. COX1 mRNA was not increased. 12 hours after ischemia the concentration of the COX product PGE2 was elevated in the postischemic brain (stroke:12±2; contralateral: 6±2ng/g). COX2 immunoreactivity was observed in cells with the morphological features of neurons at the border of the ischemic area and in the surrounding regions. Thus, cerebral ischemia leads to upregulation of COX2 message, protein and reaction products in the post-ischemic brain. Such upregulation is involves COX2, but not COX1, and occurs in neurons in the ischemic hemisphere. The role of COX2 induction in the pathogenesis of ischemic damage is unknown. Increased COX2 activity could contribute to ischemic damage by producing superoxide anion (Circ. Res. 59: 612, 1986) or by generating toxic prostanoids. Thus, COX2 upregulation could play a role in the delayed progression of cerebral ischemic damage.

MICE LACKING TNF RECEPTORS EXHIBIT ALTERED NEURONAL AND MICROGLIAL RESPONSES TO ISCHEMIC AND EXCITOTOXIC BRAIN INJURY. A. J. Bruce*, M. S. Kindy, P. J. Kraemer, F. W. Holtsberg, J. Peschon, M. K. Carpenter, and M. P. Mattson. Sanders-Brown Center on Aging, Dept. of Anatomy & Neurobiology, Dept. of Psychology, Dept. of Biology, Univ. of Kentucky, Lexington, KY 40536. Immunex Corp. Seattle, WA 98101.

The expression of tumor necrosis factor-α (TNF) in neural cells is rapidly increased following ischemic and excitotoxic brain injuries, but its roles in the responses of neurons and glia to injury are unknown. TNF binds two different receptors (p55 and p75) that are widely expressed in neurons, astrocytes, and microglia. Using gene targeting methods we generated mice genetically deficient in both TNF receptors (TNFR-KO) to determine the role of TNF in cellular responses to brain injury. Lack of TNF receptors had no overt con-sequences for brain structure, and no measurable differences were observed in behavioral tests of learning and memory. However, responses of neurons and microglia to ischemic and excitotoxic brain injury were dramatically altered in TNFR-KO mice. Cortical damage induced by focal ischemia and seizure-induced damage to hippocam-pal neurons were both significantly greater in TNFR-KO mice com-pared to wild-type mice indicating that endogenous TNF serves a neuroprotective function. Levels of Mn-SOD were reduced and lipid peroxidation following exposure to kainic acid was increased in hippocampal neurons of TNFR-KO mice, suggesting that TNF protects neurons by enhancing antioxidant pathways. Studies of cultured hippocampal and cortical neurons showed that the transcription factor NFκB plays an important role in mediating Mn-SOD induction and neuroprotective actions of TNF (see Umberger et al., this meeting). Injury-induced microglial activation was suppressed in TNFR-KO mice demonstrating a key role for TNF in microglial activation. Our data indicate TNF plays major roles in brain cell responses to acute injury and that TNF signaling components may be effective targets for development of therapeutic approaches to treating stroke and traumatic brain injury. (supported by NIH and the Kentucky Head Injury and Spinal Cord Trust).

INDUCTION OF PKCδ IS MEDIATED BY NMDA RECEPTORS AND PROPAGATED BY SPREADING DEPRESSION FOLLOWING FOCAL BRAIN ISCHEMIA. S. Miettinen*, R. Keinänen, K. Kurkinen, R. Roivainen and J. Koistinaho. A. I. Virtanen Institute, University of Kuopio, Finland.

Protein kinase C δ (PKCδ) is a Ca-independent member of the PKC family. We have previously shown that from the multiple PKC subspecies expressed in the brain, transient focal brain ischemia induces specifically PKCδ mRNA and protein in perifocal neurons. A likely mechanism for this gene induction is spreading depression (SD), which consists of repeated ionic transients involving the release of K^+ and uptake of Ca^{2+}, Na^+, and Cl^-. SD is thought to be initiated and propagated by presynaptic release of glutamate and activation of NMDA receptors subsequently to local brain injury, including focal brain ischemia. Thus, this study was designed to test the hypothesis.

Transient focal brain ischemia was produced by intraluminal nylon thread introduction. When 3 mg/kg MK801, a NMDA receptor antagonist, was given i.p. 30 min prior to 90 min of MCA occlusion, in situ hybridization and immunocytochemistry showed that both the mRNA and protein induction were inhibited in the perifocal cortical and striatal neurons. Next, unilateral cortical SD was elicited by applying filterpaper pledgets soaked in 3M KCl to exposed parietal cortex for 60 min. The rats were decapitated 4 h, 8 h, 24 h and 2 d following the exposure, and the tissues processed for in situ hybridization, immunocytochemistry and Western blotting. Induction of PKCδ mRNA was observed at 4 h throughout the parietal cortex, peaked at 8 h, and was back to the normal level by 24 h. The gene induction was reflected in increased levels of PKCδ-immunoreactive proteins in cortical neurons. No induction was seen in the contralateral cortex which was exposured to 0.9% NaCl. Preliminary experiments suggest that no other PKC subspecies are induced by SD.

The regulation of PKCδ differs remarkably from the other PKC subspecies expressed in the brain. The PKC member may serve to adapt energy-compromised perifocal tissue to altered requirements of protein phosphorylation during recovery from ischemic insult.

INHIBITION OF INTERLEUKIN-1-β CONVERTING ENZYME-LIKE PROTEASES SELECTIVELY REDUCES THE APOPTOSIS COMPONENT OF OXYGEN-GLUCOSE DEPRIVATION-INDUCED CORTICAL NEURONAL DEATH. F. J. Gottron*, H. S. Ying, and D.W. Choi. Center for the Study of Nervous System Injury and Dept. of Neurology, Washington Univ. School of Medicine, St. Louis, MO 63110.

As the mammalian homologues of Ced-3, a protein required for developmental cell death in *C. elegans*, the interleukin-1-β converting enzyme (ICE) protease family may play an important role in neuronal apoptosis associated neurodegenerative disease or acute insults such as stroke. Cultured mouse cortical neurons undergo apoptosis when exposed for 24 hr to 100 nM staurosporine. The cell permeable ICE-like protease inhibitor Z-val-ala-asp-CH_2F (ZVAD) attenuated this death in a concentration-dependent fashion between 10-100 μM. Unlike cycloheximide, which also blocked staurosporine-triggered death, ZVAD did not alter overall protein synthesis. 100 μM ZVAD also attenuated neuronal apoptosis induced in near pure neuronal cultures by removal of serum for 24 hr.

However, ZVAD did not protect the same cultured neurons against the excitotoxic necrosis induced by 5 min exposure to 100 μM NMDA, 24 hr exposure to 100 μM kainate, or 90 min exposure to combined oxygen-glucose deprivation. If the excitotoxic component of oxygen-glucose deprivation-induced death was blocked by the addition of MK-801 and 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), and the duration of insult was extended to compensate for glutamate antagonist neuroprotection, then neurons underwent apoptosis and ZVAD was again effective in reducing death. These data suggest that ICE-like proteases may play a role in the apoptosis component of oxygen-glucose deprivation-induced death, and that ICE inhibitors may be combined with glutamate antagonists to achieve high levels of neuroprotection against hypoxic or ischemic insults. DAMAGE AND REPAIR OF NUCLEAR GENES AFTER CEREBRAL ISCHEMIA AND REPERFUSION. PK Liu[1*], CY Hsu[2], M Dizdaroglu[3], RA Floyd[4], YW Kow[5], A Karakaya[3,6], LE Rabow[5], and JK Cui[1] [1]Div. of Restorative Neurology and Human Neurobiology, Baylor Coll. of Med., Houston, TX 77030. [2]Dept. of Neurology, Washington Univ., St. Louis, MO 63110. [3]Chemical Science and Technology Lab., Natl. Inst. of Standards and Technology, Gaithersburg, MD 20899. [4]Free Radical Biology and Aging, Oklahoma Medical Research Foundation, Oklahoma City, OK 73104-5046. [5]Dept. of Radiation Oncology, Emory Univ. Sch. of Med., Atlanta, GA 30335

Free radicals of oxygen increase during ischemia and reperfusion in the brain. We had shown a five-fold increase in nuclear gene mutation of the brain in male C57BL/6 mice using a model of forebrain ischemia by transient bilateral occlusion (30-min) of both common carotid arteries (Cui et al., Mutagenesis and Neurodegeneration after Cerebral Ischemia. Abstr. No.394.7, Society for Neuroscience Meeting, 1995, p.1001].). We now report mutagenic lesions (2,6-diamino-4-hydroxy-5-formamidopyrimidine, 8-hydroxyadenine, 5-hydroxycytosine, and 8-hydroxyguanine examined by gas chromatography-mass spectrometry, and one additional nucleoside 8-hydroxy-2'-deoxyguanosine by HPLC-EC method) increased in cortical DNA by 2-4 fold ($p < 0.05$) during 10-20 min of reperfusion; then reduced to the normal level at 6 hr reperfusion. The total level of DNA damage involving measurable G and C lesions increased from 3×10^5 in each cell of the normal brain to approximately 15×10^5 at 10 min reperfusion in this model. The repair of oh^8-dG was detected using the appearance and disappearance of formamidopyrimidine DNA N-glycosylase sensitive sites in actin and DNA polymerase-β genes. We found that sensitive sites were increased at 10-20 min, then reduced to near the normal level at 4-6 hr of reperfusion. We showed that free radicals could damage nuclear genes, and that DNA damage was repaired in the brain. Mutagenesis was detected, nevertheless. [Supported by V.L. Smith Found. for Restorative Neurology; Am. Heart Assoc.(94012700); NIH (NS34810, NS25545, NS28995, NS32636, AG09690, GM37216); ONR (C4114503)].

DEGENERATIVE DISEASE: ALZHEIMER'S-BETA-AMYLOID—ApoE

668.1

Aß IS TRANSPORTED ON LIPOPROTEINS AND ALBUMIN IN HUMAN PLASMA. A.L. Biere*, B.L. Ostaszewski, E.R. Stimson‡, B.T. Hyman, J.E. Maggio‡, and D.J. Selkoe. Departments of Neurology and Biological Chemistry and Molecular Pharmacology, Harvard Med. School, Boston, MA

Soluble Aß is found in CSF and blood of both healthy and AD subjects, but it is unclear whether Aß, once secreted, is free in biological fluids or associated with other proteins and thus transported and metabolized with them. ApoE4, the major genetic risk factor for late-onset AD and a constituent of lipoproteins, could influence Aß transport in brain extracellular fluid. To address the question of Aß distribution in human biological fluids and its possible interaction with ApoE under *in vivo* conditions, we employed density gradient centrifugation for isolation of lipoproteins and lipid-free proteins, and non-denaturing gels and Western blots for further characterization. Fresh human plasma samples were incubated with physiological amounts of iodinated $Aß_{1-40}$ or $Aß_{1-42}$, subjected to continuous NaBr density gradient centrifugation, and the fractions analyzed for protein and iodinated Aß distribution. We have tested a total of 38 plasma samples to date, including 17 ApoE 3/3 and 9 ApoE 4/4 subjects. We found Aß bound to selected lipoproteins [VLDL, LDL, HDL, but not Lp(a)] and principally to albumin; very little Aß was free. Aß distribution on plasma proteins was not significantly influenced by ApoE genotype. In addition, we have begun studies to compare $Aß_{1-40}$ to $Aß_{1-42}$ distribution among plasma proteins. Preliminary results (total of 7 plasmas, including 3 ApoE 3/3 and 2 ApoE 4/4) indicate that a higher percentage of $Aß_{1-42}$ is bound to lipoproteins than of $Aß_{1-40}$. We conclude that Aß is normally bound to and transported by albumin and lipoproteins in human plasma under physiologic conditions. If $Aß_{1-40}$ and $Aß_{1-42}$ are confirmed to be differentially bound to lipoproteins, this could contribute to different clearances and pathogenic potentials of these two peptides. Supported by AG12749.

BETA-AMYLOID, APOLIPOPROTEIN E AND TAU IMMUNO-REACTIVITY IN ALZHEIMER'S DISEASE. N.J.Cairns , Y.Fukutani, A.Chadwick and P.L.Lantos. Dept. Neuropathology, Inst. Psychiatry, London, SE5 8AF, U.K. (Spon: BRA)

Apolipoprotein E (apoE) allele e4 (APOE4 gene) is a major risk factor in both sporadic and late onset familial Alzheimer's disease (AD). Thirty consecutive sporadic cases of AD (10 male, 20 female) were obtained from the Brain Bank, Department of Neuropathology, Institute of Psychiatry, London. DNA was extracted from frozen brain tissue, amplified by the polymerase chain reaction (PCR), restriction digested and genotyped. Immunohistochemistry using antibodies to apoE, beta-amyloid (Aβ) and phosphorylated tau was performed on 7μm paraffin wax sections of the frontal lobe. The density of deposits, plaques, or neurofibrillary tangles was expressed as the number per square mm or area fraction. Data were analysed using SSPS for Windows. APOE4 gene frequency was significantly associated with apoE deposition ($F=10.4$, $df=27$, $p<0.001$) and Aβ deposition ($F=6.30$, $df=26$, $p<0.01$). The APOE4 gene showed a trend for increased neurofibrillary tangle (phosphorylated tau) density but this was not significant ($F=1.86$, $df=28$, $p=0.18$). APOE gene frequency was not correlated with age at onset, duration, age at death, or brain weight. These data indicate that in the AD brain, the APOE4 gene is associated with increased apoE and Aβ deposition and not directly with the phosphorylation of tau. How apoE interacts with Ab remains to be be resolved. Acknowledgement: This work was supported by the Medical Research Council, U.K.

Apolipoprotein E4 Promotes Early β-Amyloid Deposition in the Nondemented Elderly. L.C. Walker*[1,5], R. Warzok[1], S. Dünnewald[1], G. Apel[1], A. Schwarz[1], R. Egensperger[2], D. Schreiber[3], J.C. Troncoso[4] and Ch. Kessler[1]. [1]Ernst-Moritz-Arndt Univ., Greifswald, Germany; [2]Univ. Munich; [3]Erfurt Clinic; [4]The Johns Hopkins Univ.; and Parke-Davis Pharm. Res., Div. of Warner-Lambert Co., Ann Arbor, MI.

Alzheimer patients carrying the ApoE ϵ4 allele may have a greater β-amyloid burden at death than persons without the ϵ4 allele. However, little is known about the age at which amyloid deposits begin to appear as a function of ApoE ϵ4 gene dosage. We analyzed the degree of cerebral β-amyloidosis in cortical area 28 and hippocampus of 97 nondemented persons who had died between the ages of 50 and 93 years, grouped according to ApoE allele type: ϵ2/2, *1*; ϵ2/3, *16*; ϵ2/4, *4*; ϵ3/3, *44*; ϵ3/4, *29*; and ϵ4/4, *3*. We also determined the β-amyloid load in 15 patients who had died of AD, *8* ApoEϵ3/3 and *7* ApoEϵ4/4, matched for age and duration of disease. We found significantly more cerebral amyloid deposition in nondemented persons carrying the ϵ4 allele than in those lacking ϵ4, with deposits becoming common after the age of 60. However, Alzheimer patients homozygous for ApoEϵ4 did not have significantly more amyloid deposition than patients homozygous for ApoEϵ3. We conclude that the ApoEϵ4 allele promotes the early deposition of Aβ, but that the pathological changes in end-stage Alzheimer's disease are largely comparable in subjects matched for age and duration of disease. RELATIVE INVULNERABILITY OF APOE KNOCKOUT MOUSE HIPPOCAMPAL NEURONS TO AMYLOID BETA TOXICITY. Prathibha Nadig, Richard Fine, Ann McKee* GRECC, Bedford VA Medical Center, Bedford MA; Depts Neurology, Pathology, Biochemistry, Boston University School of Medicine, Boston MA.

Allelic forms of apolipoprotein E (ApoE) strongly associate with the risk of Alzheimer's disease. In dorsal root ganglion cultures, ApoE3 enhances neurite outgrowth whereas ApoE4 decreases outgrowth. In vitro and in senile plaques (SP), ApoE binds beta amyloid (Aß), the primary peptide component of SP. Aß is also toxic to rat hippocampal neurons in vitro. We investigated the toxicity of Aß in cultured mouse hippocampal neurons from wild type and ApoE knockout mice and assessed the allelic effects of ApoE on neurite growth and survival. 5 day neurons harvested from C57B6 control and ApoE knockout mice (Jackson Labs) were treated with 20 μM pre-incubated (agg)Aß (1-40, QCB) and non-aggregated (non-agg)Aß. Normal mouse neurons treated with agg Aß showed a significant decline in survival ($p<0.05$) as compared to controls after 48 and 72 hr, whereas no significant toxicity was found with non-agg Aß. ApoE knockout mouse neurons showed no significant toxicity after 24-72 hr treatment with either agg or non-agg Aß. To assess the allelic effects of ApoE, 2 hr cultures were treated with human recombinant ApoE3 & E4 (Calbiochem) in the presence and absence of 40μg VLDL. Initial results showed dose-dependent neurotoxicity of 4-30 μgs E4>E3 with profound inhibition of neurite outgrowth in ApoE knockout and normal mouse cultures. Treatment of neurons with 7.5 μg of human ApoE purified from plasma showed enhanced viability and neuritic growth. These findings suggest that ApoE knockout neurons are relatively less vulnerable to Aß toxicity, perhaps through up regulation of a protective factor. Furthermore, our preliminary findings suggest a toxic effect of recombinant E4>E3 preparations derived from baculovirus plasmids - results that require confirmation with alternative preparations of ApoE. Sponsored by grants from the Departments of Veterans Affairs and NIH.

COMPLEX FORMATION OF APOE PRODUCED BY MAMMALIAN CELLS WITH AMYLOID PEPTIDE B (AB) FOLLOWS THE ORDER APOE2 > APOE3 > > APOE4. S. B. Aleshkov, C.. R. Abraham* and V. I. Zannis. Section of Molecular Genetics, Whitaker Cardiovascular Institute, and Department of Biochemistry, Boston University Medical Center, Boston MA, 02118

Population studies have established that the common apoE4 isoform is a risk factor for late onset Alzheimer's disease (AD). To study the interaction of apoE isoforms with Aβ, we have expressed apoE2, apoE3 and apoE4 in mammalian cells using the Semliki Forest Virus expression system (SFV). Recombinant viral RNA was used to express apoE isoforms in BHK cells and primary astrocytes. ApoE secreted by these cell cultures was analyzed by one- and two-dimensional gel electrophoresis and immunoblotting as well as by density gradient ultracentrifugation. The first analysis showed that the nascent apoE is heavily modified with carbohydrate chains containing sialic acid. The second analysis showed that 45% of apoE is distributed in lipoprotein particles which float in the HDL region (d=1.08-1.20 g/ml), 15% in the lipid-free region (d > 1.33 g/ml), and 40% is found in lipid-poor particles of d=-1.22/1.28 g/ml. Analysis of the interactions of native apoE2, apoE3 and apoE4, produced by mammalian cells, with Aβ under physiological conditions (pH 7.4 and temperature 37°C) showed that complex formation follows the order apoE2 > apoE3 > > apoE4. The findings indicate that apoE produced by astrocyte cultures may have the capacity to bind and remove excess Aβ from the brain, and thus may prevent the deposition of amyloid fibers and the pathogenesis of AD. *In vivo* and *in vitro* studies of the interactions of apoE isoforms with its intra- and extracellular ligands may provide clues and new therapeutic strategies for the treatment and/or prevention of AD. Supported by grant AG12717 from NIH.

TYPE AND AMOUNT OF THE APOLIPOPROTEIN E/AMYLOID β PROTEIN COMPLEX IN ALZHEIMER'S AND CONTROL BRAIN. M. Tabaton*, A. Piccini, D. Dapino, G. Angelini, P. Gambetti, D. Zaccheo. Institute of Human Anatomy, University of Genova, 16132 Genova, Italy; Division of Neuropathology, Case Western Reserve University, Cleveland OH, USA.

We recently showed that Apolipoprotein E (Apo E) forms a 41 kD complex with soluble amyloid β-protein (Aβ) in brains from Alzheimer's (AD) as well as control subjects (Soc. Neurosci. Abstr, 1714, 1995). We further investigated this issue, analyzing type, stability, and amount of the ApoE/Aβ aggregate in soluble fraction of brains from AD and amyloid free normal cases with various Apo E genotype. We found: 1. The 41 kD Apo E/Aβ complex is recognized bt two antibodies specific for Aβ extending to residue 42 (Aβ 42). 2. The native complex comigrates in gels with an Apo E/Aβ 42 aggregate made in vitro, and they are both partially stable in reducing conditions. 3. The complex is undetactable in insoluble fractions of brain tissue, either in AD or control cases. 4. The amount of cerebral unbound Apo E is several folds higher in cases with ε2 and ε3 alleles. Our findings show that Apo E sequestrates soluble Aβ 42 in normal brain. They also suggest that the amount of cerebral Apo E, isoform depending, may be critical in regulating the clearance of soluble Aβ 42 in brain. Supported by grants from Telethon (E.126), CNR (9502450CT04).

APOLIPOPROTEIN E IN PROGRESSIVE SUPRANUCLEAR PALSY IN JAPAN.

A.SAWA*#, N.AMANO and M. MATSUSHITA
Dept. of Neuropsyhciatry, Faculty of Med., Univ. of Tokyo, Tokyo 113, Japan (#present address; Johns Hopkins Univ., Sch. of Med., Baltimore)

We studied the allele frequency of apolipoprotein E (ApoE) in 34 cases of progressive supranuclear palsy (PSP) in Japan.

One of the pathological changes of Alzheimer's disease (AD), neurofibrillary tangles (accumulation of tau), is the hallmark of PSP, but without senile plaques (β-amyloid deposits).

Contrary to AD, there isn't increased ε4 allele frequency in PSP. On the other hand, we found overrepresentation of ε2 compared with Japanese normal controls.

These results suggested that 1) ApoE4 may be related to β-amyloid rather than tau in AD pathogenesis, 2) ApoE2 may be involved in neurodegeneration of PSP.

INTERACTIONS BETWEEN APP AND THE APOE RECEPTOR, LRP. G.W. Rebeck*, M.E. Briggs, S. Mui, N.C. Alonzo, M.Z. Kounnas, R.E. Tanzi, D.K. Strickland, and B.T. Hyman. Dept. of Neurology, Mass. General Hospital, Boston, MA 02129 and American Red Cross, Rockville, MD 20855.

The low density lipoprotein receptor-related protein (LRP) is a prominent apoE receptor in the CNS, present on neurons and activated astrocytes. LRP is also a receptor for KPI-containing forms of APP. We hypothesized that apoE might affect the metabolism of APP by affecting its interaction with LRP. We examined H4-APP751 cells which express high levels of both APP751 and LRP, and secrete APPs into the conditioned media. APPs accumulated in the conditioned media of H4-APP751 cells over 12 hours; in cells treated with the LRP inhibitor RAP over this time, APPs accumulated to levels 5 to 20 fold higher than in untreated cells. We tested whether this accumulation was due to increased production of APPs or decreased uptake of APPs by examining production of APPs over a short period of time (30 minutes) in metabolically labelled cells. RAP-treated and untreated cells secreted similar amounts of APPs as measured by immunoprecipitation, suggesting that RAP acted to block uptake of APPs, not to alter its production. We examined whether apoE-containing lipoproteins affected the levels of APPs in the conditioned media. We purified high density lipoproteins containing apoE by KBr gradient ultracentrifugation of conditioned media from mouse liver cells expressing human apoE3. We treated H4-APP751 cells with doses of apoE-containing lipoproteins ranging from 0.15 to 15 ug/ml; APPs accumulated to levels up to 2-3 fold higher than in untreated cells. We are currently testing whether apoE4 affects APP metabolism to a greater or lesser degree than apoE3, and examining whether apoE alters the metabolism of cell surface APP.

INVOLVEMENT OF ACT, apoE, AD3/PS-1, AD4/PS-2, AND TRISOMY 21 IN ALZHEIMER'S DISEASE. H. Potter*, J. Li, J. Ma, L.N. Geller, H. Zhou, M. Xu, S.-S. Zhang, and P. Nilsson. Department of Neurobiology, Harvard Medical School, 220 Longwood Avenue, Boston, MA 02115, U.S.A.

The clinical and pathological features of Alzheimer's disease arise from a complex series of steps—a pathogenic pathway. Thus far, five gene products—APP, apoE, AD3/PS-1, AD4/PS-2, and ACT have been most clearly implicated by genetic and biochemical evidence as playing a role in the pathogenesis of the disease. We will present evidence that ACT and apoE serve as amyloid accelerators, promoting the polymerization of the $A\beta_{1-42}$ peptide into amyloid filaments, which, in turn, are toxic to human cortical neurons. Small molecules have been identified that block the ACT and apoE-promoted filament formation and neurotoxicity.

Certain amino acid motifs have suggested to us that the AD3/PS-1 and AD4/PS-2 proteins may reside in the nuclear membrane and play a role in the intracellular signaling involved in gene expression and/or chromosome segregation. Progress toward understanding the role of AD3/PS-1 and AD4/PS-2 in normal and Alzheimer physiology will be presented. Studies of fibroblasts from Alzheimer and control individuals will be presented, which suggest that one mechanism by which PS-1 and PS-2 cause Alzheimer's disease may be through the induction of chromosome nondisjunction and the accumulation of trisomy 21 cells.

NICOTINE ADMINISTRATION IMPAIRS SENSORY-GATING IN MALE AND FEMALE LONG-EVANS RATS. M.M. Faraday[1], M.A. Rahman[2], P.M. Scheufele[1], and N.E. Grunberg[1,2]*. [1]Medical and Clinical Psychology, [2]Neuroscience Program, Uniformed Services University of the Health Sciences, Bethesda, MD 20814

Nicotine, the primary active pharmacologic agent in tobacco, has been reported to enhance cognitive and attentional processes in humans, but these findings have been equivocal. We have reported that nicotine enhances sensory-gating in male Sprague-Dawley rats as measured by pre-pulse inhibition (PPI) of the acoustic startle reflex (ASR), and have interpreted these findings as nicotine enhancing attention. The present experiment examined the effects of nicotine on ASR and PPI in male (n=96) and female (n=96) Long-Evans rats. This strain was examined to determine whether effects of nicotine on sensory-gating generalize across rats of markedly different genetic character.

In contrast to previous findings with Sprague-Dawley rats, nicotine impaired PPI in Long-Evans rats. In addition, there was a sex difference in PPI responses, with males showing greater PPI than females. These results indicate that genotype plays an important role in effects of nicotine on sensory-gating and, perhaps, on attention.

SUSTAINED ATTENTION DEFICITS IN PATIENTS WITH LESIONS OF POSTERIOR CORTEX. L. Rueckert*, and J. Grafman. Cognitive Neuroscience section, MNB, NINDS, NIH, Bethesda, MD 20892.

This is a follow-up to a previous study that found sustained attention deficits in humans with lesions to the frontal lobes. Ten Vietnam Veterans who had suffered penetrating head injuries were compared to sixteen normal control subjects. The two groups did not differ in age or education. In all patients the lesions were posterior to the central sulcus. Sustained attention was measured on a Continuous Performance Test that required subjects to monitor a computer screen on which various letters were presented and to press a button whenever the letter "X" appeared. In one ten-minute block of trials one letter was presented every second. In another one letter appeared every 2 seconds. The number of targets did not differ between blocks.

The patients missed more targets than controls, and the difference between the two groups increased significantly with time on task, suggesting that the patients had difficulty sustaining their attention over the entire 10 min. of a block of testing. Whereas control subjects showed a significant increase in targets missed with time on task only for the slow presentation rate, the patients showed a greater increase at the fast presentation rate.

These results suggest that patients with lesions of posterior cortical areas show deficits in sustained attention, but that these deficits may differ from those shown by patients with frontal lesions.

DISTRIBUTED CORTICAL NETWORKS FOR SPATIAL ORIENTATION VISUALIZED BY FUNCTIONAL MAGNETIC RESONANCE IMAGING DR Gitelman*, AC Nobre, JR Meyer, TB Parrish, C Callahan, EJ Russell, M-M Mesulam. Departments of Neurology and Radiology, Northwestern Univ. Med. School; Neurology Service-127, Veterans Admininistration Lakeside Medical Center; Northwestern Memorial Hospital, Chicago, IL, USA; Dept. of Experimental Psychology, Oxford Univ., Oxford, UK.

We used functional magnetic resonance imaging to visualize cortical activity during tasks of covert spatial orientation. Ten right-handed subjects were studied. Three 10 mm contiguous slices were acquired every 2 seconds as a time series using 2D EPI on a 1.5 T Philips Gyroscan unit. Control and active tasks alternated every 20 seconds, 4 times in each experimental run. For the active tasks, either a central arrow, or a brightened peripheral box at 7° eccentricity primed the side for subsequent target discrimination. Subjects' ability to maintain central fixation was confirmed outside the scanner with an infra-red eye tracker. Cue validity was 100% in all tasks, and equivalent numbers of left and right targets were shown.

Regional a priori hypotheses were based on the large-scale network model of spatial attention and results from a preceding PET study with a parallel design. In both tasks, activations were seen bilaterally in premotor cortex (area 6) and adjacent area 8, parietal cortex in the region of the intraparietal sulcus, and the anterior cingulate cortex. In the spatial expectancy task, activation size often appeared greater in the right frontal and parietal regions, while in the spatial priming task, right sided asymmetry was more prominent for the parietal activation.

These findings provide further support for the representation of spatial orientation in the form of a distributed network that displays a pattern of right hemispheric specialization. Our observations also show that the parietal component of this network is located predominantly in the region of the intraparietal sulcus (mostly area 7, but also area 39) and that there may be anatomical differences of activation patterns when attentional shifts are cued by spatial priming versus spatial expectancy. Supported by NIH Grant NS30863.

669.4

CORTICAL NETWORK FOR VISUOSPATIAL ATTENTION IMAGED USING PET AND fMRI AC Nobre*, DR Gitelman, GN Sebestyen, J Meyer, CD Frith, RSJ Frackowiak, and M-M Mesulam. Oxford University, Oxford, UK; University College London, London, UK; Northwestern University, Chicago, IL, USA.

Equivalent studies of visuospatial attention were conducted using PET and fMRI with the aim of localising the cortical regions involved in directing visual attention across extrapersonal space. Six subjects participated in each study. The active condition was a covert spatial cueing task in which brief peripheral cues (100 ms, 7° eccentricity) primed that location in space for subsequent target discrimination (50 ms). The task emphasised reflexive aspects of spatial orientation, but may have also included controlled attentional processes such as spatial expectancy. Behaviour and eye-movements were monitored, and confirmed the behavioural advantages of spatial cueing and the subjects' ability to maintain central fixation.

Neuroimaging data were analysed using statistical parametric mapping (SPM). Comparison of the active condition and a rest control in the PET experiment revealed four main foci of activation: the right posterior parietal cortex, the right anterior cingulate cortex (BA 24), the lateral premotor cortex (BA 6) bilaterally, and the medial premotor cortex (BA 6). Functional anatomical resolution was improved by analysis of the data at the single-subject level. The posterior parietal activation was localised to the intraparietal sulcus. Premotor activation was observed to extend into the right prefrontal cortex in some cases, and was consistent with localisation of frontal eye-fields in previous studies. The fMRI experiment tested the same active task condition in alternation with a rest control. The conditions were alternated every 20 seconds and repeated four times each during one single run. Three 10-mm echoplanar transaxial images were obtained in parallel with the line through the anterior and posterior commissures, centred to span the areas identified in the PET study. The results replicated the PET findings and provided higher spatial resolution with which to resolve the localisation and variability of functional neuroanatomy in individuals. Supported by fellowship from the McDonnell-Pew Centre for Cognitive Neuroscience, and a grant from the Wellcome Trust.

DEVELOPMENT OF EARLY SELECTIVE ATTENTION PROCESSES. M.J. Taylor, S.C. Khan and W.J. Logan*. Div. Neurology, Hosp. Sick Children, Toronto, Canada.

We studied the development of early attentional processes in parallel and serial visual search tasks. Event-related potentials (ERPs) were recorded from children (n=40, 17-12 yr of age), from 25 active electrodes. Pop-out paradigms were used for the two parallel processing tasks and a conjunction of features task was used to study serial processing. In the colour parallel task the standard stimuli were small, blue rectangles and the pop-out stimuli (targets; 20%) were small, red rectangles; in the size task the targets were large blue squares. Non-target pop-out stimuli were also presented (17%). In the serial task the targets were conjunction of features from the parallel task, i.e., large, red squares; the standard stimuli were variously sized and coloured squares and rectangles. Subjects pressed a button to target stimuli.

Reaction times decreased with age and task (colour<size<serial). A posterior P1 and N2 were measured as well as an anterior P2 and N2. In 7-8 yr old children there was very little effect as a function of task for these components. With increasing age the processing associated with the colour targets became faster than that associated with the size or serial tasks. There were age main effects for the P1 and N2a across the three age groups. These data suggest that developmental changes are continuing even in the very early stages of visual selective attentional processing in simple pop-out tasks. The maturational changes are not parallel across the three tasks, with the ERPs from the size task being more similar to the ERPs from the serial than the colour task. These data will be discussed in terms of the Guided Search model of attention.

Research funded by Medical Research Council of Canada (MA12081).

INDEPENDENT COMPONENT ANALYSIS (ICA) OF EVENT-RELATED POTENTIALS DURING SELECTIVE ATTENTION.

S. Makeig*†§, L. Anllo-Vento§, T-P. Jung†‡, A.J Bell‡, T. J. Sejnowski‡§, and S. A. Hillyard§. †Naval Health Research Center; §Dept. Neurosciences, University of California San Diego; ‡Salk Institute for Biological Studies, La Jolla, and Howard Hughes Medical Institute.

Recordings of event-related potentials (ERPs) can reveal the time course of brain events associated with visual perception and selective attention. ERP studies of visual-spatial attention indicate that cortical processing of stimuli appearing in the attended location is augmented as early as 80 ms after stimulus onset. However, separation of the multiple brain processes contributing to the surface-recorded components of ERP waveforms has proven difficult. Recently, an 'infomax' algorithm for the blind separation of linearly mixed inputs has been devised (Bell and Sejnowski, 1995) and applied to EEG and ERP analysis (Makeig et al., 1996). The neural generators of ICA sources are not specified by the algorithm and may be either physically compact or distributed.

Results of applying this Independent Component Analysis (ICA) algorithm to single-subject and group-mean ERPs recorded during a visual selective attention experiment (Anllo-Vento and Hillyard, 1996) suggest that ERP waveforms represent a sum of overlapping, discrete and time-limited brain processing events whose amplitudes are modulated by selective attention without affecting their time course. These source components identified by ICA appear to index independent stages of visual information processing. Spatial attention operates on early source components in a manner similar to a sensory gain-control mechanism, while later components appear to reflect further processing of stimulus features and feature conjunctions.

BILATERAL VISUO-SPATIAL ATTENTION SYSTEMS IN PARTIAL AND TOTAL SPLIT-BRAIN PATIENTS. M. Lassonde[1], M. Arguin[1], J.P. Guillemc*, A. Quattrini[2], M. Del Pesce[2], and L. Papo[2] 1. Groupe de Recherche en Neuropsychologie Expérimentale, Université de Montréal, Canada; 2.Centro dell'epilessia, Ospedale Torrette, Ancona, Italy.

Normal individuals can attend only one visual stimulus at a time on the basis of its localization in the visual field. Since callosotomized patients have divided visual fields, they could also have divided visuo-spatial attention systems and indeed, some studies of split-brain subjects indicate that they can perform concurrent attentional searches of both the left and right visual fields. However, other studies using spatial cuing of attention with the Posner paradigm, have suggested an integrated attention system in split-brains. The discrepancy may be explained by the hypothesis of divided visual attention systems but an integrated response selection mechanism in split-brain subjects. In the present experiment, three patients with a total callosotomy and seven patients with a section of the anterior 50-80% of the corpus callosum produced bimanual (lever pull) simple reaction times to lateralized (left/right) visual targets (X). Targets were preceded (SOA=500 ms) by pairs of spatial cues displayed on the immediate left and right of fixation. Valid cues were pairs of arrows pointing to the upcoming target location while invalid cues pointed in the opposite direction. Ambiguous cues consisted in arrows pointing away from fixation, with the left-sided arrow pointing left and the right-sided arrow pointing right. Neutral cues were equal signs. Subjects with total or anterior callosotomy showed shorter reaction times with valid than invalid cues. Both groups also showed reaction times that were shorter with ambiguous cues than with neutral cues. In fact, reaction times with ambiguous cues were identical to those with valid cues. The advantage for ambiguous cues relative to neutral cues indicates that split-brain subjects directed their attention to each visual half-field in response to ambiguous cues. It is concluded that callosotomy results in divided visuo-spatial attention systems, even with sparing of the splenium. This latter observation suggests that the portion of the corpus callosum that is anterior to its caudal 50% contributes to the integration of lateralized visuo-spatial attentional mechanisms in normals. PASSIVE AND ACTIVE PROCESSING OF FORMANT TRANSITIONS: A PET STUDY. P. Belin, M. Zilbovicius, S. Crozier, M.-C. Masure, Ph. Remy and Y. Samson*. SHFJ, CEA Orsay and SUCV, La Salpêtrière, Paris, France.

We have previously reported that in the normal subject the right temporal auditory cortex is less extensively activated for rapid (40ms) than slow (200ms) formant transitions (FT) during passive listening, whereas activation is similar in both conditions in the left auditory cortex [Belin et al, 95]. In order to extend these findings, we performed a PET-$H_2{}^{15}O$ activation study in 10 normal subjects. Pairs of nonsense consonant-vowel-consonant(CVC)-like stimuli with 200, 80, 40 and 20ms FT were presented in passive and active (discrimination) conditions. Data were analysed with SPM software. Compared to rest, all listening conditions activated both left and right auditory cortex. During *passive* listening, the focus of activation in the *right temporal lobe* progressively shrunk from 480 to 76 voxels when FT duration decreased from 200 to 20 ms. The *left temporal* activation was always associated with a left frontal activation including Broca's area. In all these regions, the general pattern of activations was similar during *active* listening, as evidenced by the lack of significant difference between active and passive conditions. These results confirm that rapid acoustic changes are less efficiently processed by the right than by the left auditory cortex, and support the hypothesis of a temporal processing advantage of the left hemisphere. *Supported by a DRC grant of AP-HP.*

REACTION TIME STUDIES OF DICHOTIC LISTENING TO SPEECH

David L. Woods*, Akira Uno, and E. William Yund, Dept. of Neurology and Neurosciences Center, UC Davis, Northern California System of Clinics, Martinez, CA 94553.

When different consonant-vowel syllables (CVs) are presented simultaneously to the two ears, subjects more accurately report CVs presented to the right ear. The chronometry of this right-ear advantage (REA) and the degree to which it depends on acoustic and phonetic competition were examined in reaction time (RT) experiments in which subjects selectively attended to a designated ear (Experiments 1 and 2) or to a specified voice (male or female, Experiment 3). Their task was to detect occasional targets (CVs or non-speech sounds). The stimuli were presented at normal speech rate (mean 2/sec) and included random dichotic and monaural trials with CV, tone and noise burst stimuli. Although both acoustic and phonetic factors influenced performance, REAs were seen primarily in attend-CV conditions and were enhanced by phonetic competition. *Supported by the NINDS and the VA Research Service.*

SPARSE CODING AND ATTENTIONAL MECHANISMS ENABLE NEURAL SEPARATION OF MULTIPLE INTERFERING INPUT STREAMS: A BIOLOGICALLY PLAUSIBLE "COCKTAIL PARTY" PROCESSOR.

R. Linsker.* IBM Watson Research Center, Yorktown Heights, NY 10598.

What neural information processing principles enable a perceptual or cognitive subsystem to process input (from the environment or other brain regions) that is produced by multiple sources, so that the subsystem can reliably attribute a portion of the input to one source, and attend to that source only? I propose that the following strategy may be used in neural systems: 1. Map the input stream into a representation (a) whose output preserves substantial information about the input signal, and (b) that is sparse -- i.e., large output values are rare, yet carry the bulk of the information. 2. Using some known properties of the input stream, label many of the large output values according to their likely source. 3. Suppress (inattend to) values not corresponding to a selected source. 4. Reconstruct an approximation of the selected source if desired.

A concrete example is the "cocktail party" processing effect: the ability to listen to a superimposed mixture of acoustic sources (e.g., speakers at different locations), attend to one source, and suppress perception of interfering sources. Computational methods typically have been limited to special non-biological cases, e.g., in which there are at least as many receivers as sound sources. I demonstrate a method for inferring each of N (≥ 3) sources, given just two received mixtures, despite the fact that an infinite number of possible sets of N sources can yield the identical pair of mixtures. In experiments, the reconstruction preserved any selected one of three speech sources, with little trace of the interfering sources.

FUNCTIONAL ACTIVATION OF RIGHT PARIETAL AND FRONTAL REGIONS DURING AUDITORY ATTENTION TO SPACE AND FREQUENCY. R.J.Zatorre*[1], T.A. Mondor[2], and A.C. Evans[1]. [1]Montreal Neurological Institute, McGill University, Montreal, QC, and [2]Mt. Alison University, Sackvile, NB, Canada.

The neural mechanisms involved in auditory attention were studied in a group of 8 normal volunteers using H_2O^{15} PET and paired-image subtraction. We examined whether or not similar neural systems would be involved in attending to spectral and to spatial features of sounds. Subjects participated in one silent baseline condition and in four active attention conditions. The stimuli were identical in each of the attention conditions, and consisted of a continuous sequence of 200 msec tones varying randomly in frequency (250, 1000, and 4000 Hz) and location (left, right, or center). In the Low and High conditions, subjects were instructed to respond (by a key press) to either the 250 Hz or 4000 Hz stimuli, respectively, ignoring location. In the Left and Right conditions, subjects responded to stimuli in the appropriate location, regardless of frequency. Subtraction of the baseline scan from each active scan yielded foci of CBF change; PET data were stereotaxically transformed and averaged, and superimposed on MRI for anatomical localization. Apart from the expected CBF increases in primary auditory, motor, and supplementary motor areas, several other areas were consistently recruited in all four subtractions. Notably, a right superior parietal region (Brodmann area 7) was observed, together with foci in the right dorsolateral frontal (area 46/9) and premotor (area 6) regions, and left thalamus. This pattern of activation implies that the deployment of auditory attention engages a specialized network of right-hemisphere cortical regions, consistent with neuropsychological lesion data. Most important, the same attentional network appears to be recruited for either spatial location or tonal frequency. This finding supports a model in which the selection of auditory information is accomplished via an attentional template which normally incorporates both spectral and spatial parameters.

SELECTIVE ATTENTION PARADIGMS TO MAP LANGUAGE FUNCTIONS USING fMRI. M. Dapretto, S. Bookheimer, M. Cohen*, J. Wang. UCLA Brain Mapping Division, UCLA School of Medicine, Los Angeles, CA 90095.

Selective attention paradigms, where subjects attend to different aspects of the same stimuli across experimental conditions, have been successfully used in functional neuroimaging studies to investigate the neural correlates of different aspects of sensory and cognitive processing [1]. We have used functional MRI to map the neural networks involved in key language processes in normal adult volunteers.

In the first series of activation paradigms the subjects first saw a picture of an object followed by the presentation of two written words. In the semantic condition, the subjects had to choose the word that belonged to the same taxonomic category of the presented object; in the phonological condition, the subjects had to choose the word that rhymed with the name of the object; and in the spelling condition they had to choose the correct spelling for the name of the object between two plausible alternatives. In the second series, subjects listened to pairs of sentences and had to judge whether they had the same meaning by relying either on syntactic or semantic cues. MRI images were collected on a GE 1.5 Tesla Signa MR scanner with an SPGR sequence (256x256; TR=70; TE=50; FOV= 24; Flip=45; NEX=.75; imaging time=7 sec.). Activation blocks alternated with rest periods. The data were analyzed using pixel-wise comparisons with Student's T tests. The corresponding maps of statistical significance were superimposed on the co-planar high resolution flow images for localization.

Even though stimuli and task demands were kept constant across activation conditions, reliable differences were observed in the pattern of cortical activity during language tasks emphasizing distinct aspects of language processing. Areas active during all language activation periods were also observed.

CONSTRAINTS ON ANGULAR VELOCITIES IN THE ELBOW AND SHOULDER JOINT DURING TARGET TRACKING ARM MOVEMENTS. J. Laczko*, J. Tihanyi, Hungarian University of Physical Education, H-1123, Budapest, Hungary

A geometric model of 3-dimensional (3D) target tracking movements of a limb with at least two rotating joints (with many degrees of freedom) was developed. The model is applied to reveal if the angular velocity vectors (instantaneous rotational axes) in the elbow and in the shoulder of the human arm are confined to subspaces (planes or lines) of the 3D space. In the model the direction of the instantaneous rotational axis in each joint is assummed while angular changes are predicted. Assuming appropriate rotational axes the model succeeded in predicting the change of intersegmental angles in the shoulder and elbow of healthy subjects. The comparison of measured and simulated angular changes supports that a) the instantaneous axis of rotation in the shoulder is orthogonal to the line that connects the shoulder and the finger; b) the axis of rotation in the elbow is orthogonal to the plane of the shoulder, elbow and wrist.

The problem of redundancy is solved in the simulation by constraining rotational axes to subspaces as stated above. We suppose that natural rotational axes may also be chosen this way due to biomechanical and neural constraints. This choice prevents shoulder torsion around the line that connects the shoulder and the finger, and elbow torsion around the direction of the forarm. The rotational axes assumed are compatible with Listing's law: there is no unnecessary torsion in the joints. Rotating the arm's segments around such axes avoids unnecessary force and the magnitudes of the angular velocities are minimal. The simulated intersegmental angles in the elbow and the shoulder are changing in opposite phase. This is consistent with a property of biarticular muscles: they may cause flexion in one joint and extension in the other one.

LINEAR SYNERGY - COORDINATING HUMAN ARM MOVEMENT AT TWO JOINTS. G. L. Gottlieb*, Q. Song and D. M. Corcos. NeuroMuscular Research Center, Boston Univ., Univ. of Illinois at Chicago, & Rush Medical Center.

Voluntary human movement is performed by the coordination of many muscles and joints, a complex task, the principles of which we poorly understand. Pointing movements with the unrestrained arm, requiring coordination of the shoulder and the elbow, have been found to appear simple at the level of hand motion but complex at the level of joint motions and muscle activity patterns.

We have studied a variety of movements, all made in a sagittal plane under different conditions. These include movements from different initial positions, in different directions, with different inertial loads on the wrist and at different intended speeds. Our results suggest that kinematic simplicity appears to be an emergent property of surprisingly simple rules for the production of dynamic joint torques, separate from the torques necessary to oppose gravity and maintain posture. We hypothesize that torque pattern generators drive our point-to-point movements according to four "rules."

1. The control patterns for muscle activation are biphasic torque pulses of relatively invariant shape, regardless of load, speed, direction or location.

2. The torque pulses are similar in shape at the elbow and shoulder and are generated in close temporal synchrony.

3. The scaling of the torque pulse amplitudes at both joints to control movement speed or distance or to adapt to added loads is the same. Task specific variations in pulse patterns are similar to those seen during single joint movements.

4. The relative amplitudes of the torques at the two joints determine the direction of movement.

These rules represent an example of the synergies, postulated by Bernstein, that enable the CNS to reduce the number of degrees of freedom it must independently control. These synergies may be a combination of learned and innate constrains.

670.3

THE CONTROL OF MULTI-JOINT MOVEMENTS BY FIELD SUMMATION. F.A. Mussa-Ivaldi* and C.J. Lee. Dept. of Physiology, Northwestern University Medical School. Chicago, IL 60611.

The purpose of this work is to investigate to what extent the intersegmental coordination observed in multi-joint limb movement may be carried out by the CNS without any explicit representation of time. Previous studies of reaching arm movements (Morasso, 1981) have shown that these movements tend to occur along straight pathways, characterized by a symmetric, "bell-shaped" profile of the hand's tangential velocity. These reaching movements display a variety of angular joint motion patterns, some of which involve the reversal of direction in one or more joints. These precisely-timed joint reversals are essential to insure that the hand moves along a straight line. Thus, it was suggested that the neural controller must explicitly provide carefully-crafted temporal patterns of intersegmental coordination in order to achieve the observed hand kinematics. Here, we challenge this view by considering the alternative hypothesis that the observed kinematics of reaching movements may be generated by simple time-invariant sets of control parameters. We tested this hypothesis by simulating a controller that generates limb trajectories by combining a set of fixed muscle synergies. Each muscle synergy generates a field of viscoelastic forces acting on the controlled limb. The force fields used in our simulations are similar to those observed after microstimulation of the spinal cord in the frog (Bizzi et al., 1991) and in the rat (Tresch and Bizzi, 1995). These experiments revealed that the focal activation of the spinal cord results in a field of elastic forces converging toward an equilibrium location. Furthermore, the activation of two different spinal sites results in the vector summation of the force fields elicited by each site. Our simulations demonstrate that timeless combinations of such force fields may generate a variety of kinematic patterns including those observed in hand reaching movements. We conclude that the convergent force fields generated by combination of viscoelastic muscles may greatly reduce the need for accurate timing in multi-joint limb control.

INTERCEPTION OF MOVING TARGETS: ONLINE CONTROL OF OVERLAPPING SUBMOVEMENTS. D. Lee*, N. Lindman Port, and A. P. Georgopoulos. Brain Sciences Center, VAMC, Minneapolis, MN 55417

We studied the kinematic characteristics of human arm movements produced to intercept a target moving with a wide range of velocity and acceleration. The target traveled in constant acceleration, constant deceleration, or constant velocity, for 0.5-2 s until it arrived at a location where it was required to be intercepted. For fast moving targets, subjects produced single movements with symmetrical, bell-shaped velocity profiles. In contrast, for slowly moving targets, hand velocity profiles displayed multiple peaks, which suggests a control mechanism that produces a series of discrete submovements. To understand how these submovements are controlled according to the target motion, vertical hand velocity profiles were decomposed into submovements according to the minimum-jerk model (Hogan, *J. Neurosci.* 4:2745, 1984). The average amplitude and duration of all submovements were 4.9 cm and 0.56 s. The number of submovements was roughly proportional to the movement time, resulting in a relatively constant submovement frequency (~2.5 Hz). However, the interval between the onsets of successive submovements increased with the duration of the preceding submovement, thus resulting in a relatively constant overlap between the two submovements (~0.25 s). Examination of submovement amplitude and its relation to target motion revealed that the subjects achieved interception mainly by producing a series of submovements that matched the displacement of the hand and the first-order estimate of target position at the offset of each submovement along the axis of hand movement. Finally, we did not find any evidence that information regarding target acceleration is fully utilized in the production of submovements. (Supported by USPHS grant 1-PSMH48185-01)

A BIOMECHANICAL MODEL FOR THE INVESTIGATION OF INTER-SEGMENTAL COORDINATION IN MULTI-JOINT ARM MOVEMENTS

A.Boose, H.Ruder[1], and H.Topka*. Dept. of Neurology and [1]Dept. of Theoretical Astrophysics, Univ. Tübingen, D-72076 Tübingen, Germany

We examined the role of interactive (motion-dependent) torques for the coordination of multi-joint arm movements by biomechanical modeling and kinematic analyses.

Four healthy volunteers and a patient with cerebellar degeneration were seated comfortably with the shoulders strapped to the back of the chair. They performed unconstrained elbow or shoulder flexions with the instruction to move only one joint (the "focal" joint) and to keep the other "nonfocal" joint fixed. Movements were recorded using an optoelectronic tracking system. Amplitudes and velocities of the "nonfocal" movements were used as kinematic variables that describe the ability of the system to counteract the interactive torques. A biomechanical model of the arm was used (a) to calculate the muscle torque patterns that patients and normals really employed, (b) to calculate the "ideal" torques that would have been necessary in the nonfocal joint to completely eliminate the nonfocal for a given focal movement, and (c) to simulate movements with amplified or reduced nonfocal joint torque patterns.

Neither normals nor the patient could completely avoid movement in the nonfocal joint. In normals, the calculated ideal torque patterns for the nonfocal joint showed a much steeper rise (factor 1.81±0.63SD) and fall (2.38±0.58) and higher amplitude (1.55±0.25) than the real patterns. Ideal focal torque patterns also were steeper and higher (factors 1.34±0.30, 1.22±0.20, and 1.14±0.08, resp.). This effect was less prominent when subjects were allowed to move at comfortable rather than maximum speed. Dynamic simulation of focal elbow movements revealed that an artificial reduction of the compensatory shoulder torque pattern not only had the effect of an increased nonfocal movement, but also yielded a higher focal velocity.

We conclude that normals do not produce muscle torques fast enough to completely abolish the nonfocal movement, i.e., to compensate for the interactive torques of the focal movement. However, as this 'suboptimal' behaviour definitively leads to an improvement of the focal movement, it may be considered part of a global optimization strategy. *(supported by German Science Foundation (DFG) SFB 307 - A3)*

Force control deficits in the proximal joints of cerebellar patients are correlated with abnormal agonist EMG activity

J-S Lou*, L Carusone, W Kananen, Human Motor Control Laboratory, Department of Neurology, University of Rochester, Rochester, NY

Cerebellar patients make errors in planar multijoint arm movements by making inadequate shoulder rotations. We have recently shown that these errors in multijoint coordination may be attributed to greater force control deficits in proximal joints. We therefore designed a study to see if these force control deficits are associated with abnormal EMG activation. Five cerebellar patients and 5 normals performed 5 single joint isometric movements including shoulder abduction and adduction, elbow extension and flexion, and abduction of the second finger. Subjects performed 3 ballistic, stepwise trials [maximum voluntary force (MVF), 50% MVF, 20%MVF] for each single joint movement. Each trial was 10 seconds in duration consisting of a 2s resting period, a 6s activation period, and another 2s resting period. They attempted to match actual force levels with target force traces displayed on a screen. We analyzed maximum force and normalized EMG activity [defined as ratio of (averaged EMG amplitude during the first 0.5 s of the activation period) and (averaged EMG amplitude during the 3s to 7s of the trial)] for the first 0.5s of the activation period (2 to 2.5 s of a trial) in agonist muscles. Maximum force did not differ between the two groups. Cerebellar patients displayed a more gradual build up of EMG activity and smaller normalized EMG activity ($p<0.005$). The difference was more prominent in proximal than in distal joints ($p<0.03$). We conclude that force control deficits displayed by cerebellar patients in proximal joints are associated with reduced EMG activation in agonist muscles.

MOTOR PERFORMANCE BY PATIENTS WITH MILD ALZHEIMER DISEASE AND PARKINSON DISEASE. R. J. Elble*, R. Cousins, K. Leffler, S. Elble, D. Herrmann and S. Hill. So. Illinois Univ. Sch. of Med., Springfield, IL 62794.

Thirty healthy adults (ages 60-92) and groups of 10 patients with mild Alzheimer disease (AD), mild Parkinson disease (PD; Hoehn and Yahr stage 2) and moderate PD (stage 3) pushed or pulled on a rigid horizontal bar while maintaining stable erect stance. Ankle moments of force, body motion, and extremity EMG were measured with a computerized motion analysis system. Preliminary trials (≈3) were conducted to determine the maximum force for each subject, but practice was not allowed for the target forces of 50% and 75% maximum. Three 5-s push trials and three pull trials were then performed for each target force. The target window (target force ± 10% maximum) and bar force were displayed on a video screen, and subjects were asked to place the force cursor within the window for at least 1 s. The Alzheimer patients had slightly lower Mini Mental Status Examination (MMSE) scores (25 ± 2) than the stage 2 and 3 Parkinson patients (29 ± 1 and 27 ± 2). The Alzheimer patients had normal clinical measures of motor function (Tinetti scale = 25.3 ± 1.4), in contrast to the patients with stage 3 PD (Tinetti = 22.9 ± 2.4). The stage 2 patients had a slightly lower Tinetti score (25.5 ± 1.1) than age-matched controls (26.3 ± 1.3). All patients exhibited normal anticipatory postural activity. The Alzheimer patients had prolonged reaction times (0.60 ± 0.39 s) and movement times (1.75 ± 0.72 s) that were similar to those of stage 3 PD (0.53 ± 0.38 and 1.80 ± 0.81). Furthermore, patients with AD and stage 3 PD performed a much lower percentage of trials correctly (46% and 47%) than the controls of ages 75-92 (75%) and ages 60-74 (90%), due to inadequate visually-guided adjustments in force. This effect of mild dementia on quick motor adjustments is relevant to the propensity of these patients to fall. (Supported by NIA AG10837).

KINEMATIC TEST OF MOTOR PROGRAMMING IN APRAXIA.

R.J Caselli*, G.E. Stelmach, D. Timmann, S. Tadikonda. Mayo Clinic, Scottsdale, AZ; Arizona State University, Tempe, AZ

Apraxia may result from spatial and temporal disruption of the motor program. Previous kinematic methods have confirmed spatial disruption, but there is little data regarding temporal control. Patients with asymmetric cortical degeneration (perceptual-motor variant)/corticobasal ganglionic degeneration (CBGD) have disabling progressive apraxia. In such patients, we studied the effects of apraxia on prehension, a stereotypical, two-component, upper limb movement consisting of a transport (proximal limb control), and a grip (distal limb control) component.

Infra-red emitting diodes were affixed to the thumb, index finger, and wrist of each hand of 10 apraxic patients with CBGD and 10 controls. Subjects reached on cue for a target cylinder under four different test conditions. Data was sampled at 100 Hz with an Optotrak camera system to measure absolute kinematic parameters (e.g., peak wrist velocity). Relative, or scaled, parameters (e.g., grip velocity/wrist velocity), and adaptation to altered test conditions were calculated to reflect the motor program.

Across all four test conditions, apraxia was characterized by 1) prolonged duration of transport and manipulation components, 2) reduced transport velocity, and 3) increased grip aperture and closure speed. The most consistently effected portions of the motor program were relative scaling of grip speeds to transport velocity.

We conclude that apraxia is primarily a spatial disorder of movement, but temporal programming of grip kinematics is also impaired.

DYNAMIC INFLUENCE OF A MOVING VISUAL STIMULUS ON POSTURE

T.M.H. Dijkstra*[1,2], G. Schöner[3,4], C.C.A.M. Gielen[1], M.A. Giese[1]. Dept. of Med. Physics & Biophysics, Univ. of Nijmegen, The Netherlands. [2]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia PA 19104. [3]CNRS-LNC, Marseilles, France. [4]Institut für Neuroinformatik, Ruhr-Univ., Bochum, Germany.

Purpose We study the influence of an oscillating visual surround on posture in humans. We set out to verify the predictions of a linear oscillator model of postural control. This model simplifies the dynamics to that of a pendulum driven by the expansion rate of the visual surround. **Methods** We use computer-generated displays where the motion of the subject's head is used to alter the display, a kind of psychologist's virtual reality. The display simulates a wall oscillating around a mean distance. In the *distance* experiment we vary the mean distance between subject and wall, in the *frequency* experiment we vary the frequency of oscillation. We analyse the data by linear systems theory and by extracting the time-series of relative phase and fitting its returnmap. **Results** Varying the distance we find that the fluctuations in relative phase and the relaxation-time after a phase perturbation increase with increasing distance. This decrease of temporal stability with distance is consistent with the linear model. Varying the frequency we observe three types of coordination between sway and visual motion: (1) absolute coordination or one-to-one phase locking, (2) relative coordination, where a preferred phase is prevalent but quick jumps to other phases occur and (3) no coordination, where sway is not locked to the stimulus. In both experiments we find the gain to be constant and around one. The occurrence of relative coordination and no coordination and the constancy of the gain are inconsistent with the linear model with fixed parameters. **Conclusions** We conclude that the postural control system is quite linear for a given dynamical situation but that it adapts its parameters to the dynamics of the surround.

IDENTIFICATION OF STATE SPACE DYNAMICS OF VISUALLY INDUCED POSTURAL SWAY PROVIDES EVIDENCE FOR ACTIVE SWAY GENERATION M.A. Giese, T.M.H. Dijkstra, G. Schöner*, C.C.A.M. Gielen. Inst. Neuroinfo. Ruhr-Univ. Bochum, Germany; University of Pennsylvania, Philadelphia, PA 19104; CRNC-CRNS, Marseille, France; KUN, Nijmegen, Netherlands.

Postural sway in response to small amplitude sinusoidal oscillation of the visual environment was analyzed using system identification techniques. The tight phase locking of sway motion to visual motion was perturbed by phase shifting the visual display. The induced transients were sufficient to identify the system dynamics on the basis of individual trials. The frequency of the visual motion was varied from 0.05 to 0.5 Hz. We found that the parameters both of the visual channel and of the postural control system adapt to the spatio-temporal structure of the visual scene. The eigenfrequency of the postural control system follows closely the visual frequency up to about 0.3 Hz, where it starts to fall behind. Visual input contributes to stabilization. We determined the stabilization of posture generated by the other sensory channels by subtracting the visual contribution. We find negative damping for this contribution. Thus, the postural control system actively generates sway motion in order to achieve posture in the moving visual world.

670.11

SOMATOSENSORY COUPLING TO POSTURAL SWAY VELOCITY J.J. Jeka*[1], K.S. Oie[1], E.M.Henson[1], T.M.H. Dijkstra[2], G. Schöner[3], J.R. Lackner[4], [1]Department of Kinesiology, University of Maryland, College Park, MD 20742,[2]Department of Psychology, University of Pennsylvania, Philadelphia, PA 19104, [3]Laboratoire de Neurosciences Cognitives, CNRS, Marseille, France, [4]Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254

Light touch contact of a fingertip to a stationary surface provides orientation information that enhances control of upright stance. Slight changes in contact force at the fingertip lead to sensory cues about the direction of body sway, allowing attenuation of sway. In the present study, we investigated whether postural sway was coupled to the velocity of a moving contact surface, as previous results suggested. We measured head, center of mass and center of pressure displacement when the contact surface was moving rhythmically at 0.1, 0.2, 0.4, 0.6 and 0.8 Hz. Stimulus amplitude was decreased with frequency to keep peak velocity constant across all stimulus frequencies. Our focus was the temporal relationship between body sway and the contact surface.

Postural sway was highly coherent with contact surface motion at all frequencies except 0.8 Hz, where a dropoff in coherence was observed. Mean frequency of head and center of mass displacement matched the driving stimulus at frequencies up to 0.4 Hz. At higher frequencies, mean frequency was lower than the drive but mean phase was stationary, indicating non-1:1 coupling. Head and center of mass gain response peaked at 0.2 - 0.4 Hz and decreased at higher stimulus frequencies, consistent with our velocity coupling hypothesis. Potential adaptive effects were observed, suggesting that the postural system decreases its damping to match the amplitude of a changing sensory stimulus.

670.12

A dynamical model of the coupling between posture and gait. Bruce A. Kay* and William H. Warren, Jr. Department of Cognitive and Linguistics Sciences, Brown University, Providence, RI 02912.

Subjects walking on a treadmill viewed large-field visual displays of an oscillating hallway (0.1 - 1.0 Hz), and various types of coordination between postural sway and gait were observed. The amplitude of the postural response depended upon the frequency of oscillation, with two main bands -- one in the lower half of frequencies (0.1 - 0.5 Hz), the other centered around the stride frequency (0.7 - 0.9 Hz). We observed 1:1 mode-locking, in which one postural cycle (N) occurred for each gait cycle (M), in all trials at all frequencies in the upper band. In the low frequency band, we observed superharmonic mode-locking (N:M = 1:2, 2:3, ...) in about 30% of trials, whereas in the remaining trials, the two systems operated independently. A coupled oscillator model incorporating both state and parametric coupling captures many, but not all, features of the observed phenomena. Discrepancies between the model and data may indicate that some of the dynamics are operating at different time scales.

DIFFERENTIAL SENSITIVITY OF RECOMBINANT NMDA RECEPTOR SUBTYPES TO ZINC: IMPLICATIONS FOR GLUTAMATE EXCITOTOXICITY. A. Moshaver*, L.A. Raymond. Division of Neurological Sciences, Department of Psychiatry, University of British Columbia, Vancouver, B.C. Canada.

The role of N-methyl-D-aspartate (NMDA) receptors in induction of excitotoxic cell death has been well established. Recent studies indicate that free zinc may be co-released at glutamatergic synapses, and it has been suggested that zinc may play a modulatory role in excitatory transmission as well as in excitotoxicity. To further investigate the modulatory effects of zinc on NMDA receptors of different subunit compositions, we have co-expressed the recombinant subunit NR1 with NR2A or NR2B in human embryonic kidney 293 (HEK 293) cells. We have found that zinc inhibits peak glutamate-evoked current responses and accelerates desensitization in whole-cell patch clamp recordings from these transfected cells, but that NR1/NR2A is ~20-fold more sensitive to zinc inhibition than NR2B, with IC_{50} values of ~0.5 μM and ~10 μM, respectively. Furthermore, in NR1/NR2A-transfected cells zinc reduces the cytotoxicity of NMDA with an IC_{50} similar to that found for current inhibition (i.e., 0.5 μM). These results suggest that even low concentraitons of endogenous zinc may modulate NR1/NR2A function and play an important role in limiting glutamate-induced cell death in neurons expressing this subunit combination. (Supported by the BC Health Research Foundation and the MRC of Canada).

PROPERTIES OF SINGLE NMDA CHANNELS IN HUMAN DENTATE GYRUS GRANULE CELLS. D.N. Lieberman*, M. Isokawa, I. Fried, and I. Mody Dept. of Neurology, UCLA School of Medicine, Los Angeles, CA

To date, NMDA channel openings have been studied mainly in rodent central neurons. Based on the structural homology of NMDA-R subunits in rodents and humans, it may be assumed that human channels have comparable properties. However, this has not yet been shown experimentally. We have now examined single NMDA channels in adult human granule cells acutely dissociated from temporal lobe epilepsy patients following surgical resection of the hippocampal formation.

Following surgery, transverse hippocampal slices (450 μm thick) were prepared from human hippocampi by standard procedures. Slices were incubated at 32°C for 15-20 min in artificial cerebro-spinal fluid containing 1.75 mg/ml pronase-E (Type XIV, Sigma), and a wedge of approximately 1×3 mm containing the granule cell layer was triturated. Cell-attached recordings from visually identified dentate gyrus granule cells were obtained in Mg^{2+}-free medium containing 1.8 mM $CaCl_2$, using L-aspartic acid (500 nM) + glycine (8 μM) as agonists. All points histograms of the open state indicated a main conductance level of 48 ± 3.6 pS, with a subconductance state of 36 ± 2.9 pS. The conductance was linear over a voltage range of 130 mV. The characteristic complex groupings of NMDA channel openings in bursts, clusters and superclusters previously seen in rodent neurons were also observed in human granule cells. In 11 neurons obtained from 7 patients the mean (± s.e.m., in ms) open time, burst, cluster and supercluster durations were 2.94 ± 0.26, 8.54 ± 2.04, 27.89 ± 7.65, and 110.36 ± 24.64 respectively. These values are 50-100% longer than those found in control rat granule cells. Open time histograms could be best fit with 3 exponential distributions and shut times were fit with five exponentials. Adjacent state analysis indicated the preferential association of short closures with long openings and long closures with short open times.

Our study shows the feasibility of recording single ligand-gated channels in human central neurons, and provides a basis for understanding the properties of excitatory neurotransmission in the human brain.

Ca^{2+} FLUX THROUGH THE NMDA CHANNEL AMPLIFIES PKC POTENTIATION OF RECOMBINANT NMDA RECEPTORS. X. Zheng, L. Zhang, R.S. Zukin & M.V.L. Bennett. *Dept. Neurosci., Albert Einstein College of Medicine, Bronx* ***NY 10461***.

Protein kinase C (PKC) potentiates NMDA receptors in hippocampal and trigeminal neurons. The present study shows that Ca^{2+} flux through the NMDA channel amplifies PKC potentiation of recombinant NMDA receptors expressed in *Xenopus* oocytes. Potentiation of NMDA responses by PKC has two components, a Ca^{2+}-independent and a Ca^{2+}-dependent component (Ca^{2+} amplification), particularly evident in NR1 splice variants containing the NH_2-terminal splice cassette ($NR1_{111}$ and $NR1_{100}$). Ca^{2+} amplification increases with extracellular Ca^{2+}; Ca^{2+} is required during opening of the NMDA receptor, but not during activation of PKC by phorbol ester. Mutant NR1 receptors with greatly reduced Ca^{2+} permeability do not exhibit Ca^{2+} amplification. These findings suggest that Ca^{2+} flows through the NMDA channel to act on the cytoplasmic face of the receptor or on a cytoplasmic protein to amplify the NMDA signal. NR1 splice variants containing the NH_2-terminal splice cassette ***N1*** exhibit a greater Ca^{2+}-dependent component of PKC potentiation, possibly due to greater current and therefore greater Ca^{2+} influx per channel. Neutralization of positively charged residues within this cassette reduce Ca^{2+} amplification. NR1 splice variants lacking the COOH-terminal splice cassettes ***C1*** and ***C2*** exhibit a greater Ca^{2+}-independent component of PKC potentiation. These results demonstrate that Ca^{2+} flux through the NMDA channel amplifies PKC potentiation of NR1 receptors in a manner that is regulated by alternative splicing.

PHOSPHORYLATION-DEPENDENT REGULATION OF NMDA RECEPTORS BY CALMODULIN. H. Umemori, C. Hisatsune, T. Inoue, T. Michikawa, K. Kohda, K. Kato*, K. Mikoshiba and T. Yamamoto. Dept. of Oncology and Molecular Neurobiology, Inst. of Med. Sci, Univ. of Tokyo, Tokyo 108, Japan.

The NMDA receptor plays important roles in synaptic plasticity and brain development. The NMDA receptor is composed of two distinct types of subunits, NR1 and NR2A-2D. Both subunits have large intracellular domains at the C-terminus which may interact with signal-transducing proteins. We used the yeast two-hybrid system to identify such targets for NMDA receptors and identified that calmodulin directly interacts with NR1. We found that NR1-calmodulin interaction is regulated by PKC-mediated phosphorylation of serine residues on NR1 C-terminal region. Phosphorylation of NR1 by PKC decreased the amount of calmodulin binding. Single channel recordings from 293T cells expressing NR1 and NR2A showed that application of calmodulin decreased the open probability of NMDA channels. Therefore, binding of calmodulin to NR1 results in inactivation of the NMDA receptor channels, and the phosphorylation of NR1 by PKC prevents the receptor from calmodulin binding to allow the persistent NMDA receptor activation, which may lead to LTP.

Supported by a grant from the Ministry of Education, Science and Culture of Japan.

INVOLVEMENT OF CALCIUM IONS IN THE PROTEIN KINASE C MODULATION OF NMDA RECEPTOR CURRENTS EXPRESSED FROM SPLICE VARIANTS. S.M. Logan* and J.P. Leonard. Department of Biological Sciences, University of Illinois at Chicago, Chicago, Il 60607.

When expressed as homomeric channels in Xenopus oocytes, the NR1 cDNA clones of the natural splice variants produce currents that are potentiated by PKC to varying degrees in a process that is dependent upon the presence or absence of the three alternatively spliced exons. In our studies, we compared current magnitudes before and after a ten minute incubation in 20 nM PDBu, a PKC activating agent. We found that phorbol potentiation of receptor currents obtained when calcium is used as the major divalent cation in the recording solution (COS) is greater than when solutions in which barium replaces calcium (BOS) are used. Comparing the degree of PKC modulation obtained in COS with that found in BOS demonstrates that a group of exon 5 containing variants (NR1-111, -101 and -100) yield a 2-fold greater potentiation in COS. The PKC enhancement of currents expressed from the remainder of the variants is marginally increased in the presence of calcium over that found in BOS. To account for these differences, we examined whether the endogenous calcium dependent chloride channels ($I_{Cl(Ca)}$) were in some way contributing to current potentiation by using COS containing 200μM niflumic acid (NFA), the $I_{Cl(Ca)}$ blocking agent. If the $I_{Cl(Ca)}$ participates, then NFA should reduce the levels of potentiation recorded in COS to those levels seen in BOS. Aside from a considerable decrease in baseline currents, we observed no effect of 200μM NFA on the levels of potentiation recorded in COS. This suggests that calcium plays some other role in the PKC modulation of the NMDA splice variant currents and that exon 5 may somehow participate in this process.

DIFFERENTIAL REGULATION OF SYNAPTIC NMDA AND NON-NMDA CURRENTS IN DORSAL HORN NEURONS BY ENDOGENOUS SRC KINASE ACTIVITY. G.J. Keil II* and M.W. Salter. Div Neurosci, Hospital for Sick Children and Dept Physiology, Univ of Toronto, Toronto, Ontario, Canada.

Our laboratory has demonstrated evoked NMDA currents are modulated by non-receptor protein tyrosine kinases (PTKs) and protein tyrosine phosphatases. The aim of the present study was to investigate possible regulation of synaptic NMDA or non-NMDA currents, as well as which specific PTK(s) might be involved in such a regulation, recorded from rat spinal dorsal horn cultures. Miniature excitatory postsynaptic currents (mEPSCs) were recorded from neurons bathed in extracellular solution (ECS) containing (in mM): NaCl (140), KCl (5.4), glucose (33), $CaCl_2$ (1.3), HEPES (10) and TTX (0.001). ECS also contained bicuculline (0.01) and strychnine (0.01), $GABA_A$ and glycine receptor antagonist, respectively. Patch pipettes contained (in mM): Cs_2SO_4 (90), CsOH (35), $CaCl_2$ (1), EGTA (11), HEPES (10) and MgATP (4).

mEPSCs were characterized by fast currents blocked by DNQX (10 μM), a selective non-NMDA receptor antagonist, and slow currents blocked by APV (100 μM), a selective NMDA receptor antagonist. Bath application of the membrane permeable, non-selective PTK inhibitor, genistein (100μM), but not the inactive analog, daidzein (100μM), significantly reduced the NMDA component of the mEPSCs by 57±6%. Intracellular application with a peptide activator (EPQ(pY)EEIPI) of the *src* family of PTKs, led to an enhancement of the NMDA mEPSC component (158%±13%). The inactive form of the peptide (EPQYEEIPI) did not induce changes in mEPSCs (89±7%). Intracellular perfusion with anti-src 1, a Src-specific function blocking antibody, led to a decrease (76±8%) of NMDA mEPSC levels. Effects on NMDA mEPSC components were not associated with a change in the reversal potential. No changes of the non-NMDA components of the mEPSCs were seen with any of the above treatments.

These results demonstrate that synaptic NMDA, but not non-NMDA, currents are regulated by PTKs. In addition, they indicate that Src in an endogenous PTK regulating synaptic NMDA channels. (Supported by MRC of Canada and The Nicole Fealdman Memorial Fund)

671.8

PHOSPHORYLATION OF AMPA RECEPTORS IN RESPIRATORY NEURONS OF PREBÖTZINGER COMPLEX (PREBÖTC) Q.J. Ge* & J.L. Feldman, Departments of Physiological Science and Neurobiology, UCLA, Los Angeles, CA, 90095-1527

Glutamate (non-NMDA, especially AMPA) receptors are important in respiratory rhythm generation and pattern formation. To investigate the role of phosphorylation in mediating excitatory postsynaptic currents (EPSCs), we patch-clamped respiratory neurons in preBötC of neonatal rat medullary slices generating respiratory rhythm. Microcystin-LR, a membrane-impermeable protein phosphatase inhibitor in the recording pipette altered neuronal properties: in expiratory neurons, spontaneous EPSC amplitude was increased with no change in phasic IPSCs; for inspiratory neurons, phasic inspiratory drive was enhanced (longer duration or increased amplitude), as well as the amplitude of spontaneous EPSCs. Bath application of GYKI 52466 (GYKI), a non-competitive AMPA receptor antagonist, completely and reversibly blocked rhythmic activity and spontaneous EPSCs of all respiratory neurons, as well as the respiratory motor output of the slice. Local application of AMPA over preBötC depolarized respiratory neurons and increased respiratory burst frequency. Following whole-cell dialysis with microcystin solution, the maximum inward current induced by AMPA (in presence of 1μM TTX) increased for both inspiratory and expiratory neurons. Bath application of GYKI completely blocked the AMPA-induced current. We suggest that phosphorylation of AMPA receptors regulates the activity of neurons involved in respiratory rhythm generation, and that the AMPA phosphorylation site is a target of second messengers activated by neuromodulators such as 5-HT. Transient localization of D-serine and NMDA receptors in the cerebellum during postnatal development. M.J. Schell*, R.O. Brady, Jr., and S.H. Snyder. Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

D-Serine is present in many brain regions enriched in NMDA receptors and may act as an endogenous ligand at the receptor's glycine site. Functional NMDA receptor channels are known to be expressed transiently in the rat cerebellum during the first 3 postnatal weeks. We have examined the levels and localization of glycine site agonists during this period. HPLC measurements of D-serine indicate that levels rise during postnatal week 2, reaching a peak of about 250 nmoles/ g wet weight on day 12 (20% of the free serine pool). Levels fall sharply beginning on day 15, reflecting the induction of D-amino acid oxidase. By day 26, only 1% of the free serine is the D-stereoisomer. Glycine levels during this period range between 500 and 700 nmoles/ g. We have compared the immunohistochemical localizations of of D-serine, glycine, and NR2A/B in serial sections of glutaraldehyde-fixed cerebellum. We find that Purkinje cells stain prominently for NR2A/B between days 7-21, with peak staining occurring at day 13. Starting around day 19, staining in Purkinje cells disapears and is replaced by staining in the basket cell pinceau, which is the only labeled structure in the adult. Likewise, D-serine immnoreactivity appears transiently in glial cells of the cerebellum, with highest levels in Bergmann glial processes in the molecular layer and lower levels in astrocytes in the granule cell layer; this staining is almost completely absent in the adult. Glycine immunoreactivity is mainly in Golgi neurons and remains in a constant pattern after week 1. These results suggest that glial-derived D-serine may modulate NMDA receptors on Purkinje cells or migrating granule cells during cerebellar development. (Supported by USPHS DA-00266).

1-AMINOCYCLOPROPANECARBOXYLIC ACID (ACPC) ADMINISTRATION PRODUCES MORE RAPID ADAPTATION OF THE NMDA RECEPTOR COMPLEX THAN IMIPRAMINE IN MICE. G. Nowak[1], D.P. Taylor[2]* and I. A. Paul[1]. Lab. Neurobehav. Pharmacol. & Immunol., Depts. of Psychiatry and Pharmacology, Univ. of Miss. Med. Ctr., Jackson, MS 39216, USA[1] and Symphony Pharmaceuticals, Inc., Malvern, PA. 19355. USA[2].

Administration (10-14 d) of clinically active antidepressants (ADs) such as imipramine (IMI) produces a dose-dependent adaptation of the NMDA receptor complex in rodents. Specifically, chronic AD administration reduces the potency of glycine to displace [^{3}H]5,7-dichlorokynurenic acid (DCKA) from the strychnine-insensitive glycine recognition site of the NMDA receptor complex whereas compounds lacking AD activity do not. NMDA receptor antagonists such as the glycine recognition site antagonist, ACPC, are as efficacious as ADs in preclinical behavioral paradigms sensitive to ADs and in animal models of depression. In addition ACPC acts 2-3 times more rapidly than IMI in the chronic mild stress model of depression (M. Papp, personal communication). We investigated the time-dependency of ACPC's ability to produce adaptation of the NMDA receptor complex in male, NIH Swiss-Webster mice. Mice (n = 8/group) received ACPC (200 mg/kg), IMI (15 mg/kg) or saline i.p. for 1, 3, 5, 10, 14 or 21 d. Twenty-four h after the last treatment mice were decapitated and the cortices dissected and assayed for glycine displacement of [^{3}H]5,7-DCKA. We now report that ACPC administration produced a time-dependent reduction in the potency of glycine to displace [^{3}H]5,7-DCKA with effects observed after 3 ($p < 0.1$) and 5 ($p < 0.05$) d of administration. In contrast, IMI did not produce significant adaptation until at least 10 d administration. Since NMDA receptor adaptation is a reliable marker of AD activity (>95% predictive), these data indicate that ACPC will prove a more rapidly acting AD than current pharmacotherapies.

INCREASED POLYAMINE SENSITIVITY IN PIRIFORM CORTEX PYRAMIDAL CELLS OF AMYGDALA-KINDLED ANIMALS. H. P. Miller*, A. J. Levey, A. V. Tzingounis, P. J. Conn. Depts. Of Pharmacology and Neurology, Emory Univ., Atlanta GA 30322.

We have previously shown a down-regulation of the AMPA receptor subunit GluR2 immunoreactivity in the piriform cortex of animals that have undergone kindling-induced epilepsy (to 30% of control). Here we further characterized the time course and physiological sequelae of kindling induced down regulation of GluR2, using whole-cell patch clamp analysis in piriform cortex slices to determine the effect of kindling on polyamine sensitivity and rectification properties of evoked EPSCs in piriform cortex layer 2 pyramidal cells. Quantitative western blot analysis of GluR2 levels in kindled animals revealed a 30% decrease in GluR2 in limbic forebrain after only 1 stage 5 seizure with no change in the pinform cortex. No changes in GluR2 were seen in either area after 1 stage 3 seizure or after 1 stimulation. Lateral olfatory tract (LOT) evoked EPSCs were recorded from layer 2 pyramidal cells in the presence of DL-AP5 (100 μM) and picrotoxin (100 μM). EPSCs were blocked by 1 μM (n=4 of 6), 3 μM (2 of 2) and 10 μM (4 of 4) hydroxyphenylpropanyl-spermine (HPPS) in kindled animals to 81, 74 and 69% of pre-drug values, respectively. The effect of 10 μM HPPS was statistically significant ($p<0.05$). In control or sham-operated animals, no significant blockade of EPSCs was seen at 1 μM (n=1 of 5; 93% of pre-drug) or 10 μM (0 of 5; 98% of pre-drug). Analysis of I-V plots of evoked EPSCs did not reveal any significant differences between kindled and control animals. The increase in sensitivity to blockade by the polyamine HPPS in piriform cortex pyramidal neurons in kindled animals suggests that the decrease in GluR2 that we previously observed by immunoblotting results in the formation of synaptically activated AMPA receptors that lack the GluR2 subunit. This could result in increased calcium permeability which may contribute to the changes in synaptic plasticity seen with kindling-induced seizures. *This work supported by NINDS grant NS28405. H.P.M. is the recipient of a PhRMAF award.*

672.1

THE DIVERGENCE OF RETINAL GANGLION CELLS ONTO MULTIPLE GENICULATE NEURONS: IMPLICATIONS FOR CORTICAL PROCESSING. R. Clay Reid* and W. Martin Usrey. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

In previous work (Alonso and Reid, Soc. Neurosci. Abs. **20**, 1476), we have found that neurons in the lateral geniculate nucleus (LGN) are often highly correlated when their receptive field centers are overlapped. These correlations are tighter than any correlation seen in the retina; they peak near zero time and have a width of less than 1.0 msec. When the two neurons have nearly identical receptive fields, these correlation are always present and are quite strong (10-40% of the spikes). These neurons with the strongest correlations are very likely to connect to the same simple cells in striate cortex (Reid and Alonso, *Nature*, **378**, 281). Tight correlations are also found when there is only partial overlap of the centers, or even between *on*-center and *off*-center neurons, but these correlations are seen only in a fraction of cell pairs(10-20%) and weaker (1-5% of the spikes).

In order to examine the source and the potential implications of these synchronous events, we have made intra-ocular recordings from single retinal ganglion cells simultaneously with recordings from up to eight neurons in the LGN. The electrodes were spaced closely enough that occasionally the same neuron was recorded on two electrodes and often all receptive fields were partially overlapped.

We have recorded simultaneously from pairs of LGN neurons with nearly identical receptive fields, together with a retinal ganglion cell that provides strong input to these cells. In this case, the LGN cells were clearly being synchronized by the common input from the single ganglion cell. Further, it appeared that the retinal influence on each geniculate cell was itself correlated; if a retinal spike produced a spike in on LGN cell, it was more likely to do so in the other. Potential implications of this correlated transmission of information from retina to visual cortex are being explored.

CODING OF VISUAL INFORMATION BY PRECISELY CORRELATED SPIKES IN THE LGN. Yang Dan[1,2]*, Jose-Manuel Alonso[2], W. Martin Usrey[1,2], and R. Clay Reid[1,2], [1]Department of Neurobiology, Harvard Medical School, Boston, MA, 02115. [2]Laboratory of Neurobiology, The Rockefeller University, New York, NY, 10021.

A recent study has revealed precisely correlated spiking among neighboring geniculate cells with overlapping receptive fields. (Alonso and Reid, Soc. Neurosci. Abs. **20**, 1476). In the present study we have examined whether this temporal correlation, which occurs on the msec time-scale, can carry information about visual input. The spikes of each correlated cell pair were divided into 3 categories: spikes that are correlated between the two spike trains (A&B) and those from either spike train that were not correlated with spikes from the other (A alone and B alone). We then asked the following question: can we extract more information from these three spike trains than from the two original spike trains? In other words, can more be learned about the stimulus if the coincident spikes are considered separately?

The spatiotemporal receptive field of each spike train was measured with white-noise analysis. Mutual information between visual input (white noise) and geniculate response was calculated with the reverse reconstruction technique (Bialek et al., Science **252**:1854 [1991]) and information theoretic analysis. We found that the information carried by the three spike trains (A&B, A alone, and B alone) is often significantly more than that in the two original spike trains, by a factor of up to 20%. This increase in information is not an artifact of dividing the two spike trains into three, since dividing the spike trains randomly did not result in an increase in information. We therefore conclude that precisely correlated spikes between LGN cells could carry additional information. Since the precisely correlated spikes have a greater efficacy in driving the postsynaptic cells in the cortex than isolated spikes (Usrey et al., Soc. Neurosci. Abs. **22**), this information may be available at the next stage of visual processing.

672.3

TEMPORAL DEPENDENCE OF THE INTERACTIONS BETWEEN GENICULATE INPUTS TO SIMPLE CELLS IN CAT VISUAL CORTEX.

W. Martin Usrey[1,2]*, Jose-Manuel Alonso[2], and R. Clay Reid[1,2]. [1]Department of Neurobiology, Harvard Medical School, Boston, MA, 02115. [2]Laboratory of Neurobiology, The Rockefeller University, New York, NY, 10021.

Simple cells in layer 4 of visual cortex receive convergent input from multiple *on* and *off* geniculate cells whose receptive fields overlap the simple cell's *on* and *off* subregions, respectively. Previous work in our laboratory has shown that geniculate inputs which arrive simultaneously act to reinforce each other and are more likely to bring a simple cell to threshold. The present study examines the temporal dependence of this reinforcement. Specifically, we asked how closely timed two inputs need to be in order to interact with each other positively.

To address this question, we recorded simultaneously the responses of several geniculate cells and single simple cells whose receptive fields overlapped in visual space. Geniculate and cortical receptive fields were mapped with a white-noise stimulus and large numbers of spikes were generated for cross-correlation analysis using a grating stimulus or during spontaneous activity.

We recorded from 13 pairs of geniculate cells connected to a common cortical simple cell. Geniculate spikes were divided into several groups which varied in their interspike interval (i.e., <1, 1-2, 2-5, 5-10, 10-20, >20 msec). The *efficacy* (probability that a geniculate spike is followed by a cortical spike, above chance) was then calculated for each group. In nearly all cases, the efficacy of a geniculate cell's input was greatest when it occurred within 1 msec of a spike from the other cell. The efficacy then decreased rapidly with interspike intervals between 2-5 msec and pairs generally displayed only modest interactions at times greater than 10 msec. Ongoing studies are examining the influence of other factors, such as the dependence of the efficacy on the visual stimulus and on the firing rate of the cortical neuron.

SINGULAR VALUE DECOMPOSITION OF SPATIOTEMPORAL RECEPTIVE FIELD STRUCTURE OF NEURONS IN CAT LGN AND STRIATE CORTEX. D.E. Wollman*, J. McLean, J.N. Wolfe and L.A. Palmer. Department of Neuroscience, University of Pennsylvania, Philadelphia, PA 19104

Adelson and Bergen (1985) demonstrated that direction selective responses may be obtained from Cartesian inseparable spatiotemporal (ST) filters. They also showed that a Cartesian inseparable (i.e. direction selective) ST filter may be constructed from the linear combination of quadrature phase Cartesian separable (i.e. direction unselective) ST filters. The resulting theoretical ST filters from this investigation demonstrated close approximation to the ST receptive field (RF) structure of routinely observed direction selective simple cells in cat striate cortex (McLean and Palmer, 1994). Furthermore, recent work from our laboratory has shown that in some cases, inhibitory blockade of these cells reveals underlying separable inputs (Wollman and Palmer, 1996).

We examined the ST receptive field structure (obtained by reverse correlating neuronal responses to ternary white noise stimuli) of cells in LGN and simple cells in cat striate cortex using the singular value decomposition (SVD). This technique decomposes an m x m matrix into a series of m orthogonal vectors with associated weights (the singular values). The first component of the SVD of LGN and separable simple cell RFs accounted for the majority of the underlying RF structure. In contrast, the first and second components of the SVD of simple cells with inseparable RF structure were needed to account for the RF structure seen in this class of cells. In these cases, each component bore striking similarity to the RF structure of simple cells with separable RF structure. These components were separable and form a quadrature pair.

We conclude that the SVD is a useful technique for quantifying Cartesian separability and provides insight into the origin of inseparable RF structure of simple cells in visual cortex by suggesting one possible set of inputs which is in agreement with theoretical models.

SPATIAL-PHASE-INVARIANT SIGNALLING OF CONTRAST, SPATIAL FREQUENCY, AND ORIENTATION IN V1: THE ROLE OF TEMPORAL CODING. J. Victor* and K. Purpura. Dept. of Neurology and Neuroscience, Cornell University Medical College, New York NY 10021.

Responses of neurons in primary visual cortex depend on multiple stimulus attributes, including contrast, spatial frequency, and orientation. Converging evidence indicates that the temporal pattern of a spike train can partially disambiguate these determinants of the response. However, the manner in which the spatial phase of a stimulus interacts with mechanisms of temporal coding is unclear. To address this, we recorded responses of single neurons in cat area 17 and macaque V1 to grating stimuli presented transiently at each of 16 spatial phases, across a range of contrasts, orientations, and/or spatial frequencies. Information transfer was calculated two ways: (i) responses were pooled across spatial phase prior to estimation of transmitted information (H_{pooled}), and (ii) responses to each spatial phase were considered individually, and the resulting information estimates were averaged (H_{indiv}). These calculations were performed via the "spike time" family of metrics and a nonparametric clustering algorithm (Victor and Purpura 1996).

For stimuli which varied in contrast, H_{pooled} usually exceeded H_{indiv}. For stimuli which varied in orientation, H_{indiv} exceeded H_{pooled} for "simple" cells and for most "complex" cells. Spatial frequency experiments gave intermediate results. This shows that for "simple" cells, temporal coding could help to disambiguate contrast and spatial frequency from the confounding effects of spatial phase. For "complex" cells, we have shown not only that (consistent with a subunit structure) responses are qualitatively independent of spatial phase, but also that the informative temporal aspects of the subunit responses are combined in a coherent fashion.

RESPONSES TO VISUAL STIMULI APPEARING ON RECEPTIVE FIELDS OF V1 COMPLEX CELLS DUE TO SACCADES ARE SIMILAR TO RESPONSES ELICITED BY STIMULUS SEQUENCES PRESENTED DURING FIXATION. B.J. Richmond, T.J. Gawne and J.A. Hertz*, Laboratory of Neuropsychology, NIMH, Bethesda, MD and Nordita, Copenhagen.

During normal viewing visual stimuli arrive on V1 receptive fields as a consequence of saccadic eye movements. However, we do not know the effect of the saccadic dynamics on the visual responses that follow the eye movement. We are recording from supragranular complex cells (12 to date) in monkeys as they follow a small fixation target that bounces from one location to another. The monkeys do this well. Oriented grating patches are positioned so that each saccadic eye movement brings a new stimulus onto the receptive field of the neuron. When we synchronize the neuronal responses using the time that the eye enters a 1.5° region around the fixation target the responses show characteristics (i.e., crisp onsets to optimal stimuli, response patterns, and tunings to orientation and spatial frequency) similar to those seen when stationary stimuli are flashed onto the receptive field. The responses induced by saccadic stimulus presentations can not be easily distinguished from those that occur when random sequences of stimuli are presented at rates approximating the frequencies of saccades. Thus, there do not seem to be any signals related to saccadic eye movements that modify the stimulus-elicited responses of V1 complex cells. Support: IRP/NIMH/NIH and Nordita.

OPTICAL IMAGING REVEALS SPATIAL FREQUENCY MAPS IN THE STRIATE CORTEX OF ADULT CATS AND MACAQUES. E.V. O'Brien[1], Prashanth A.K.[2] B. Knight[1], & E. Kaplan[*2], Biophysics Lab, Rockefeller Univ.[1]; Ophthalmology, Physiology & Biophysics, Mt Sinai Med. Sch., NYC[2].

The striate cortex organizes several parameters, including ocular dominance and orientation preference, in a columnar fashion. Cells in the striate cortex are sharply tuned to spatial frequency, and there has been considerable interest in determining how the response to spatial frequency relates to the retinotopic map and orientation domains. Previous investigators, including Maffei & Fiorentini, '73, Tootell *et al.*, '81, '88, Thompson & Tolhurst, '81; and Hubener, *et al.*, '95, reported clustering of cells with similar spatial frequency preference, but the axis of that organization is in dispute. Our aim was to map the anatomical arrangement of spatial frequency responses in the tangential plane of the primary visual cortex of adult cats and macaques.

We imaged intrinsic optical signals from the visual cortex of anaesthetized and paralyzed cats and macaques with a CCD camera (retinal eccentricity: ~ 3 degrees). The animals viewed drifting sinusoidal gratings of various spatial frequencies at a fixed temporal frequency, two orientations and several contrasts, with monocular or binocular stimulation. We generated indicator functions (activity maps) of areas which responded preferentially to low or high spatial frequencies with extensions of Karhunen-Loève principal component analysis developed in our laboratory.

We found clustering of cells with similar spatial frequency preference in the tangential plane of the cortical surface in cat area 17 and macaque V1. We are comparing the optical maps with single unit recordings from the centers of iso-spatial frequency domains, and with known features of the cortical architecture, such as ocular dominance columns and orientation domains. Based on these data, we propose a model for the functional architecture of the striate cortex.

A STATISTICAL PERSPECTIVE ON ORIENTATION SELECTIVITY IN THE PRIMARY VISUAL CORTEX. A. Pouget*[1] and K. Zhang[2]. [1]Georgetown Institute for Computational and Cognitive Sciences, Washington D.C., and [2]The Salk Institute, La Jolla.

Several models suggest that orientation selectivity is the result of an amplification process of the weakly tuned LGN inputs through the cortical lateral connections. These models rely on the intuitive notion that sharpening tuning curves improves the information content of the representation. This intuition is only partially valid. Information content is proportional to the ratio of the tuning curve derivatives to the variance of the noise in the system. For a fixed noise level, sharp tuning curves are better because their derivatives are higher. The amplification of a weakly tuned LGN input, however, will not only sharpen tuning curves but increase the noise as well, keeping the information content constant.

We have developed a simplified model of the LGN-cortex circuitry to investigate this issue more closely and to explore the role of lateral connections. We used standard estimation theory to compute the Fisher information carried by LGN inputs. Our results show that 1- Fisher information increases as the orientation bias of the LGN input increases, i.e. the more pretuned the LGN inputs are, the better, and 2- lateral connections cannot increase information content but can be used to clean up uncorrelated noise between units within a cortical hypercolumn. These results are consistent with the findings of Ferster et al (Nature, 380, 1996) who have recently reported that LGN inputs are as tuned as the cortical cells. (Supported by a training grant from the McDonnell-Pew foundation to A.P.).

CORTICAL CIRCUITRY REVEALED BY REVERSE CORRELATION IN THE ORIENTATION DOMAIN D. L. Ringach*, M. Carandini¶, G. Sapiro# and R. Shapley Center for Neural Science, New York University, New York, NY 10003; ¶Dept. of Neurobiology and Physiology, Northwestern University, 2153 North Campus Drive, Evanston, IL 60208; #Hewlett-Packard Labs., 1501 Page Mill Rd., Palo Alto, CA 94304.

We applied a novel "white-noise"-like stimulation technique to study the neural circuitry underlying the orientation tuning of simple cortical cells in cats and monkeys. We generate an image sequence (the stimulus) by selecting, at each refresh time, a random image from a finite set S of orthonormal images. For simple cells, we have shown that the above stimulus allows one to compute the projection of the receptive field onto the subspace spanned by the vectors in S (Ringach et al, *ARVO Proceedings*, 1996). The calculation is based on the crosscorrelation between the input image sequence and the cell's spike train output. In the present study, we selected S to be the subspace spanned by sinewave gratings having a fixed spatial frequency but different orientations and spatial phases. A finite orthonormal basis for this subspace is a subset of the complete two-dimensional discrete Hartley basis functions. The choice of this "orientation-subspace" allowed us to measure how the orientation tuning of the cells evolved in time at a particular spatial frequency. In addition to a sharp peak of activity at the optimal orientation of the cell, we observed secondary peaks of the orientation tuning curve at off-optimal orientations. Off-peak inhibition was also observed frequently. These results are difficult to reconcile with feedforward models of the neural network that produces orientation tuning, but are consistent with recurrent cortical network models (Carandini and Ringach, *Computation and Neural Systems Conference*, 1996).

VIDEO REFRESH ENTRAINS NEURONS IN MONKEY V1 CORTEX F. Mechler*, R. Shapley, M. J. Hawken and D. L. Ringach. Center for Neural Science, New York University, New York, NY 10003.

We found that a large proportion of neurons in the macaque V1 are entrained by the 60 Hz video refresh rate. Responses of 48 single neurons were recorded to drifting sinusoidal gratings; the tuning properties, contrast sensitivity, and the temporal statistics of the spike trains were studied.

More than 50% of the cells synchronized to the video refresh as evident in the PST histograms and response power spectra. 25% of the cells followed the refresh rate of a uniformly illuminated screen. At least another 25% of cells also showed the entrainment when stimulated with a high contrast grating. High contrast gain, high temporal cut-off frequency and maintained discharge rate were correlated with video synchronization but cell type, chromatic sensitivity and laminar position were not.

We conclude that (1) primate V1 cortical neurons can respond to video raster rates and (2) this can strongly affect the statistical properties of the neurons' spike trains. Differences between neurons in entrainment may be related to magno/parvo input but might also be determined by intracortical processes.

CONTRAST GAIN CONTROL IN NEURONS OF THE CAT PRIMARY VISUAL CORTEX: INPUT-OUTPUT ANALYSIS. J.D. Allison*, B. Ahmed, J.C. Anderson, R.J. Douglas, and K.A.C. Martin. Institut fuer Neuroinformatik, ETH/University of Zurich, Gloriastrasse 32, CH-8006, Zurich, Switzerland.

Cortical neurons exposed to patterns of the same average contrast for extended periods show an elevation in contrast threshold and a reduction in sensitivity to rapid changes in contrast. This phenomenon, called contrast gain control, is not displayed by thalamic relay neurons and is thus a property of cortical circuits. This gain control provides a means of rescaling the input-output relationship of the neuron to keep it within its effective operational range in the face of widely varying average contrasts. It has been proposed that contrast gain control is mediated by a divisive inhibitory mechanism, which has the effect of decreasing the response gain of the neuron as the average contrast increases. We tested this hypothesis by recording intracellularly from neurons (n=6) in the cat's primary visual cortex *in vivo* and measuring their current-voltage curves at two different levels of contrast adaptation (7% vs. 28%). The cats were recorded under barbiturate anaesthesia and N_2O/O_2 analgesia. The visual protocol we used was simplified version of that described by Ohzawa *et al.* (J. Neurophysiol. *54*: 651-667, 1985). Biophysical measurements were conventional and the recordings were made with sharp pipettes filled with a low-molarity KCL or KMeSO4 solution and HRP. All neurons showed clear contrast adaptation both extra- and intracellularly. The neurons exhibited changes in input conductance of up to 30% when the average contrast was increased from 7% to 28%: 5 increased, one decreased in conductance. They did not show the magnitude of change in input conductance (approximately 400%) expected of the applied contrast change. This result does not support the proposal that contrast gain control is mediated by a divisive inhibitory mechanism. Supported by SPP/SNF, The Gatsby Trust, ONR, and HSFP.

ORIENTATION TUNING MAPS IN THE CAT VISUAL CORTEX ARE FUNCTIONALLY CO-DETERMINED. U.T. Eysel, Z.F. Kisvárday*, M. Rausch Department of Neurophysiology, Faculty of Medicine, Ruhr-Universität Bochum, D-44780 Bochum, Germany.

Orientation tuning maps are stable in time and even reorganize very robustly after disturbances during development (Kim and Bonhoeffer, Nature 370, 370, 1994). Here we ask the question whether interactions in the cortical network contribute to the shaping of the orientation tuning maps in the fully developed adult visual cortex. We hypothesize that due to functional co-determination orientation tuning maps should change when a circumscribed region of cortex is acutely destroyed. Orientation tuning maps of the adult cat visual cortex (area 17 and 18) were visualized with optical recording of intrinsic signals (Grinvald et al., Nature 324:361, 1986). The cats were maintained in a stable condition under continuous anesthesia with pentobarbital and artificial respiration. Blood pressure, body temperature, end-expiratory CO_2, and EEG were monitored. Control maps obtained at intervals of several hours proved to be constant in terms of spatial periodicity, topography of orientation domains and singularities. The orientation specificity within domains varied by less than ±15° and the only regions susceptible for variations up to ±90° were the fractures between orientation domains (possibly due to limitations in our aligning procedure).

Local destruction of a region with 2 mm diameter induced changes of the orientation tuning in the surrounding while the spatial periodicity and topography of the orientation maps remained essentially unaffected. Within domains up to two hypercolumns from the border of the lesion preferred orientations displayed substantial shifts larger than ±15° but not exceeding ±60°. These shifts were qualitatively constant over time within given orientation domains. We conclude that spatial periodicity, gross topography and orientation preference of the orientation tuning maps may well be anatomically predetermined. However, the actually preferred orientation at a given point can be significantly modified by intracortical signal processing via horizontal excitatory and inhibitory axonal systems.

ORIENTATION SELECTIVITY OF MACAQUE V1 NEURONS FOR NON-LUMINANCE DEFINED EDGES. V.L. Marcar*, D.-K. Xiao, S.E. Raiguel and G.A. Orban. Lab. Neuro- en Psychofysiologie, KULeuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

We have previously reported that V2 cells can code orientation of Kinetic Edges (KE), made by differences in motion direction, Texture Edges (TE) and Illusory Edges (IE) generated by abutting gratings shifted in spatial phase (Marcar *et al.*, 92, Soc.Neurosci.Abstr. 18:537.5; 94, Soc.Neurosci. Abstr. 20, 710.2). We compared the selectivity of V1 and V2 cells to those these three types of contours. Single cells were recorded from monkeys prepared for acute electrophysiological recording. To be accepted as a cell selective for either non-luminance edge, the cell had to have a tuning, measured by the Selectivity Index, SI > = 15. In addition their preferred orientation for the luminance and nonluminance edge had to be within 40 deg of each other. Selectivity for Texture Edges were found in equal proportions in V1 (14%) and V2 (15%). Fewer V1 neurons were selective for KE (5%) than V2 neurons (12%). Similarly fewer V1 neurons were selective for IE (3%) than V2 neurons (22%), which agrees with previous reports (von der Heydt and Peterhans, 89, J.Neurosci. 9,1731). While V2 neurons responded later to TB than V1 neurons, the reverse was true for KE and IE. When compared with a scintillation edge (Gawne *et al.*, 94, Soc.Neurosci.Abstr. 20,137.10) or edges containing a mean luminance field abutting a linear or circular grating (Grossof *et al.*, 93, Nature, 365, 550), the proportion of selective neurons in V1 for either type of edge was clearly larger than for KE and IE. Our data suggest that while extraction of TE first arrises in V1, that of IE and KE first arrises in V2 and feedback projections relay this information to V1. However different types of dynamic and subjective contours are treated differently by the visual system.

PROTEIN DELIVERY TO NEURONS: TETANUS TOXIN COMPARED TO ITS GANGLIOSIDE BINDING FRAGMENT (FRAGMENT C). P.S. Fishman*, D.A. Parks, A.J. Patwardhan. Neurology Service, Baltimore VAMC, and Dept. of Neurology, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

The non-toxin 50 KD C-terminus peptide of tetanus toxin (C-Fragment or CF) contains the ganglioside binding domain of tetanus toxin (TTX). CF retains much of the capacity of tetanus toxin for binding and transport by neurons. For this reason CF has been studied as a carrier for delivery of therapeutic proteins to neurons. However, other sites on TTX may also be involved in neuronal binding and internalization. We directly compared CF and TTX in the capacity to bind and be internalized by neurons by ELISA. Primary cultures of dissociated fetal cortical neurons were incubated with equimolar amounts of TTX or CF. Neuronal associated tetanus protein was 3-4 fold greater on a molar basis with tetanus toxin compared to CF (1 hr. incubation). This increase in neuronal tetanus protein was evident with incubation in concentrations ranging from 0.1 µM to 2 µM of either TTX or CF. There were greater amounts of TTX delivered to the cultured cells at both 0°C (representing membrane bound tetanus protein) and 37°C (bound and internalized tetanus protein). Unlike CF, TTX showed significant continued accumulation of protein with increasing incubation durations. Neuronal associated TTX increased 2-3 fold over incubation times ranging from 1 to 8 hrs. Tetanus toxin appears to be clearly superior to its ganglioside binding fragment CF in the capacity for neuronal binding and internalization. Atoxic tetanus proteins containing additional molecular domains as well as CF may be more suitable vectors for linkage with therapeutic proteins and delivery to neurons. (Supported by NIA Grant 1PO1-AG12992-01).

THE TYROSINE-KINASE $p56^{lck}$ IS ASSOCIATED WITH CD4 IN MOUSE BRAIN. B. OMRI, P. CRISANTI, M.C. MARTY, F. ALLIOT & B. PESSAC* CNRS UPR 9035, 15 rue de l'Ecole de Médecine, 75270 PARIS cédex 06, FRANCE

We have previously reported that the CD4 molecule is present in subsets of neurons throughout the adult mouse brain as well as in human fetal neurons in culture (1). Since $p56^{lck}$ tyrosine kinase is physically and functionally associated with CD4 in lymphocytes, we investigated if it is also expressed in neurons. RT-PCR and nucleotide sequence analyses showed an authentic LCK mRNA in brain. The $p56^{lck}$ protein, indistinguishable from that in thymus, is present in adult mouse brain. *In situ* hybridization and immunohistochemistry studies show LCK expressing neurons throughout the central nervous system, particularly in the frontal cortex, hippocampus, brain stem and cerebellum where primary dendrites of Purkinje cells are intensely labelled. $p56^{lck}$ is also synthesized in primary cultures from fetal mouse brain. The physical association between CD4 and $p56^{lck}$ was shown by a co-immunoprecipitation assay with a mouse CD4 antiserum followed by an *in vitro* kinase-labelling reaction. This suggests that the CD4-$p56^{lck}$ complex is involved in a new signal tranduction pathway in mouse brain. (Supported by institutional funds from the Centre National de la Recherche Scientifique (CNRS) and a grant from the Agence Nationale de Recherches sur le SIDA (ANRS).

IMMUNOCYTOCHEMICAL LOCALIZATION OF A POSSIBLE AXONAL LIGAND FOR MYELIN ASSOCIATED GLYCOPROTEIN. K.A. Sheikh, G.M. McKhann*, J.W.Griffin. Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD 21287

Recent studies have suggested that the ganglioside GT1b is a neuronal ligand for myelin-associated glycoprotein (MAG), whereas other gangliosides like GM1 do not bind MAG (Yang *et al., PNAS*, 1996;93:814-818). This GT1b-MAG interaction may be an important component of the Schwann cell-axon interaction in normal biology and pathology. We therefore investigated the presence and distribution of this ligand in mature peripheral nerve fibers by immunocytochemistry (ICC).

ICC was performed on cultured rat nerves with HRP-conjugated tetanus toxin C subunit (TTC) and cholera toxin (CT). (TTC binds to B series of gangliosides but predominant binding is to GT1b; CT binds to GM1.) Our results show that CT binds to nodes of Ranvier and paranodal myelin but not to internodal axons, whereas TTC stained nodal and, more importantly, internodal axolemma but not Schwann cells or myelin. Since both toxin-HRP complexes are of approximately equal molecular weight, the different staining patterns seen are not simply the result of differential access of toxin to the periaxonal space but rather represent different epitope distributions. The axolemmal region stained by TTC is normally apposed to adaxonal Schwann cell plasmalemma and is the region which contains MAG.

The axonal distribution of GT1b demonstrated by IHC suggests that GT1b is appropriately located to serve as an axonal ligand for MAG on Schwann cells, and disturbance of this interaction might disrupt normal physiology.

TOPOGRAPHIC DISTRIBUTION OF A CDC2-LIKE KINASE CYTOSKELETAL COMPLEX IN SQUID GIANT NEURONS. P. Grant[1,3], M. Takahashi[2,3], and H.C. Pant*[1,3]. LNC, NINDS, NIH, Bethesda, MD 20892, [2]Dept. of Psychiatry, School of Medicine, Yokohama University, Yokohama, Japan and [3]Marine Biological Laboratory, Woods Hole, MA 02543.

Using $P13^{suc1}$ affinity chromatography, we previously demonstrated that axoplasm from the squid giant axon contains an active complex of kinases and putative regulators that phosphorylate bound cytoskeletal proteins such as neurofilaments and tubulins. The extraction of the complex depended on the high affinity of P13 with a cdc2-like kinase that phosphorylates KSPXK motifs in neurofilaments and other proteins. To further explore the nature of this multimeric complex we examined its distribution within the neurons of the giant fiber system responsible for jet propulsion locomotion. Using the same P13 affinity chromatography procedures we compared the nature of the complexes extracted from giant fiber lobe of the satellite ganglion (the cell bodies of the giant axons in the mantle), the axoplasm of giant fibers and the synaptosomes isolated from optic lobes (a preparation of axon terminals from the visual system). Immunoblot analyses using antibodies to kinases, regulators and cytoskeletal proteins, combined with kinase, a p67 putative regulator, PKA, CK1 and other kinases bound to neurofilaments and tubulins was most abundant in axoplasm, less so in synaptosomes and virtually absent in the perikarya of the giant fiber lobe. Although all components of this large phosphorylating "machine" are synthesized within the cell bodies, its assembly into a functional complex is delayed until the elements are transported into the axon. This work is funded by the NINDS, NIH, Intramural Program.

VISUALIZATION OF CYTOSKELETAL PLASTICITY USING GREEN FLUORESENT PROTEIN-TAGGED MICROTUBULE-ASSOCIATED PROTEINS. S. Kaech, B. Ludin and A. Matus*. Friedrich Miescher Institute, P.O.Box 2543, 4002 Basel, Switzerland.

Existing evidence suggests that changes in morphological plasticity of axons and dendrites during brain development is correlated with changes in expression of two microtubule-associated proteins, tau and MAP2. To assess the influence of these proteins on microtubule behavior we prepared cDNA fusion constructs between several isoforms of MAP2 and tau and autofluorescent jellyfish green fluorescent protein (GFP). These GFP-tagged constructs were expressed by transfection in both fibroblastic cells and hippocampal pyramidal cells. The results show that both MAP2- and tau-GFP bind efficiently to cellular microtubules and induce the same changes in their distribution that have been previously reported using the native unlabelled proteins, including bundle formation and detachment from the microtubule organising center. Short time lapse recordings show a remarkably high level of dynamic behaviour by microtubules containing tau or MAP2, both as individual microtubules and in bundles. Longer recordings further revealed the disappearance and formation of large microtubule bundles which was correlated with significant changes in cell morphology. This behavior was shown by both embryonic and adult forms of tau and MAP2. These results suggest a high degree of dynamism in the neuronal cytoskeleton, where tau and MAP2 are naturally expressed at high levels. This in turn implies that neuronal circuitry in both the developing and adult brain may possess a far higher potential plasticity than has been previously considered.

THE 3' UNTRANSLATED REGION OF CaMKIIα IS A CIS-ACTING SIGNAL FOR THE LOCALIZATION AND TRANSLATION OF mRNA IN DENDRITES. M. Mayford*, D. Baranes, K. Podsypanina, and E.R. Kandel. Ctr. Neurobiol. & Behav., Columbia Univ., HHMI, NY, NY 10032.

The appropriate subcellular localization and regulation of synaptic proteins is a critical determinant of neuronal function. In mammalian neurons, polyribosomes are found in dendrites where they are concentrated within or beneath the dendritic spine. The α subunit of Ca^{2+}-calmodulin-dependent protein kinase II (CaMKIIα) is one of only four mRNAs known to be present within the dendrites as well as in the soma of neurons. This targeted subcellular localization of the mRNA for CaMKIIα provides a possible cell biological mechanism for both controlling the distribution of the cognate protein, and for independently regulating the level of protein expression in individual dendritic spines. To characterize the cis-acting elements involved in the localization of dendritic mRNA, we have produced transgenic mice in which the CaMKIIα promoter is used to drive the expression of a *lacZ* transcript that either contains or lacks the 3' untranslated region (UTR) of the CaMKIIα gene. Whereas both lines of mice show expression in forebrain neurons that parallels the expression of the endogenous CaMKIIα gene, only the *lacZ* transcripts bearing the 3' UTR are localized to dendrites. The β-galactosidase protein shows a variable level of expression. Along the dendritic shaft and within dendritic spines which represents either differential localization of the mRNA or variations in the translation rate at different sites along the dendrite.

CELL CYCLE REGULATION DURING DIFFERENTIATION OF THE CG-4 GLIAL PRECURSOR CELL, R.K.Tikoo[1], M.V.Chao[1]*, and A.Koff[2] Departments of [1]Neurology and Cell Biology, Cornell Univ. Medical Center and, [2]Department of Molecular Biology, Memorial-Sloan-Kettering Cancer Center, NY, NY 10021.

Although differentiation requires withdrawal from the cell cycle, the role of the different cell cycle regulatory molecules during cell fate determination, particularly during glial development, remains unclear. CG-4 precursor cells differentiate into oligodendrocytes or astrocytes, depending on the culture conditions. Serum-free culture of CG-4 cells induces the oligodendrocyte differentiation pathway. High serum culture of CG-4 cells induces the astrocyte differentiation pathway. Because serum has profound effects on cell cycle progression we investigated the changes in cell cycle regulatory molecules during differentiation along both the oligodendrocytic and astrocytic lineages.

We demonstrate that there are both general and lineage-specific changes in the expression of cyclin-dependent kinases (CDK) and the CDK inhibitor $p27^{Kip1}$. During differentiation of CG-4 cells into either oligodendrocytes or astrocytes, we observed a decrease in the amount of both CDK2 and CDK4 proteins. Additionally, p27 protein was increased, but only during astrocyte differentiation. This suggests that p27 may be involved in the determination process of glial differentiation. To begin to address the mechanism by which p27 may affect lineage-specific differentiation, we examined the function of p27 as an inhibitor of CDK2 kinase activity in extracts derived from these cells. We determined that addition of cyclin E to extracts derived from either CG-4 precursors or oligodendrocytes was sufficient to activate the endogenous CDK2 protein. In contrast, addition of cyclin E to extracts derived from astrocytes was unable to activate the CDK2 protein. To confirm that inhibition was due to p27, we depleted p27 from the astrocyte extract and demonstrated that cyclin E could activate the endogenous CDK2. Together these results suggest the involvement of a p27-mediated block of CDK2 activation in astrocyte differentiation. We speculate that oligodendrocyte differentiation proceeds along a separate pathway. Supported by the NIH and the Revson Foundation.

CYCLIN D3 IS ASSOCIATED TO CELL DIVISION AND NEURONAL DIFFERENTIATION IN THE CNS. P. Quaghi, S. Timsit, , B. Allinquant#, E.Tremblay, Y. Ben-Ari and M. Khrestchatisky*.Université René Descartes, ParisV, INSERM U-29, 123, Bd Port-Royal, 75014 Paris France. #Ecole Normale supérieure, CNRS URA 1414, 75230 Cedex 05, France.

Cyclins D play a key role in the G1 phase of the cell cycle. Recently cyclin D2 has been detected in post-mitotic neurons but very little is known about cyclins D expression in the embryonic developing CNS. In situ hybridization revealed for all cyclins D an expression in the germinal layer, a region of neural cell division. Furthermore, cyclin D2 and D3 mRNA were expressed in the cortical plate in a region of post-mitotic neurons. Analysis of cyclin D3 protein revealed a gradient expression toward the cortex and in the spinal cord toward the marginal zone. Expression of cyclin D3 protein was further analyzed *in vitro* in cortical neuronal cultures, it was found in the nucleus as assessed by confocal microscopy, but also in neurites. The distribution of cyclin D3 in neurites was not uniform but scattered in a beading pattern. Double immunolabeling of various cytoskeleton markers and cyclin D3 revealed that it was concentrated at the initiation points of secondary neurites, and was partly superposed with actin and tubulin, but absent from growth cones. Destabilization of microfilaments and microtubules coupled to immunocytochemistry, as well as western blot analysis of cytoskeleton preparation are in progress. Our data shows that cyclin D3 is expressed in regions of cell division but also, unexpectedly, in post-mitotic neurons during neuronal differentiation. This work was supported by INSERM.

674.3

DRG NEURONS, BUT NOT GROWTH-ARRESTED SCHWANN CELLS, ARE RESISTANT TO S-PHASE INDUCTION BY OVEREXPRESSION OF E2F-1/CDK2/CYCLIN E. D.S. Smith*, G. Leone, J. DeGregori and J.R. Nevins. Dept. of Genetics, Duke University Medical Center, Durham NC, 27710.

Terminally differentiated neurons rarely, if ever, undergo proliferation *in vivo*. In contrast, differentiated glial cells often proliferate *in vivo* in response to injury. This is reflected in the behavior of adult neurons and glia removed to tissue culture. For example, Schwann cells from adult rats undergo robust proliferation in serum-containing medium, whereas mature sensory neurons from the same animals do not. This difference in proliferative potential between these cells of common lineage could reflect a simple loss of serum responsiveness in neurons, or a more fundamental difference in processing of a proliferative signal. Both neurons and glia in cultures from adult rat dorsal root ganglia (DRG) can be infected with replication-deficient, recombinant adenovirus vectors. We have used these viruses to overexpress human E2F-1, cyclin E, and Cdk2, either individually or simultaneously, in both cell types, as these proteins are thought to be critical for entry in to the DNA synthesis phase of the cell cycle. At 24 hours post-infection, 70-100% of the cells in DRG cultures dramatically overexpress the proteins encoded by the recombinant viruses. E2F1 overexpression induces DNA-synthesis in serum-starved Schwann cells and fibroblasts, as detected by BrdU incorporation. When E2F-1, cdk2, and cyclin E are overexpressed simultaneously, the effect is more pronounced. In stark contrast, neurons in the same cultures remain resistant to S-phase induction, despite expressing the same proteins at very high levels. The fact that inhibition of DNA synthesis in neurons is not overcome by this battery of proteins points to fundamental distinctions in cell cycle regulation in these cells that exceeds loss of serum responsiveness.

E2F1 TRANSCRIPTION FACTOR AND RETINOBLASTOMA GENE EXPRESSION IN THE OLFACTORY EPITHELIUM. Susan S. Little[1], N.S. Rama Krishna[2] and Thomas V. Getchell[1,2,3]*, [1]Department of Physiology, [2]Department of Surgery, Division of Otolaryngology, and [3]Sanders-Brown Center on Aging, University of Kentucky College of Medicine, Lexington, KY 40536.

The aim of our study was to test the hypothesis that the E2F1 transcription factor acts in conjunction with the retinoblastoma (Rb) gene product in regulating the transition of progenitor cells in mouse olfactory epithelium from the early to late G1 phase of the cell cycle. The presence of E2F1 and Rb transcripts was verified by RT-PCR and protein products were detected using Western blot analysis with ECL as the reporter. Olfactory marker protein (OMP) mRNA and protein were used as positive controls for the identification of olfactory epithelial tissue. Total RNA from mouse olfactory mucosa was reverse transcribed using MuLV reverse transcriptase (RT) and oligo dT primers. The resulting cDNA was amplified with *Taq* DNA polymerase using the following primers for E2F1: sense 5'GGG TTT GGT TGC TGC CAC ATT G3' and anti-sense 5'TTC ACC TTC ATT CCC GGG ACA CG3', and for Rb: sense 5'TGT GCA CGC CTT CTG TCT GAC C3' and anti-sense 5'TGG TGG AGG CAT ACT GT3'. Western blot analysis was performed on protein homogenates from mouse olfactory mucosal tissue using a monoclonal antibody to E2F1 and a polyclonal antibody to Rb protein (pRb). In RT-PCR, expected product sizes of 246 bp for E2F1, 328 bp for Rb and 348 bp for OMP were observed. Western blot analysis showed bands of approximate M_r 60 kDa for E2F1 and 110 kDa for pRb in olfactory epithelial homogenates and positive control kidney homogenates. These results demonstrate that E2F1 and Rb mRNAs and proteins are expressed in mouse olfactory mucosa and support the hypothesis that E2F1 is activated via release from a complex with pRb at the transition of progenitor cells from the quiescent early to the replication-committed late G1 phase of the cell cycle. Supported by NIH grant 5 R01 DC 00159 (TVG) from NIDCD.

DIFFERENTIATION IS SELECTIVELY RESCUED BY bFGF IN MN20/D2 CYCLIN DEFICIENT CEREBELLAR CELLS CJ MacNabb* & ME Ross, Dept of Neurology, Univ of Minnesota, Minneapolis, MN 55455.

The D type cyclins are key regulators of the G1 to S phase transition of the cell cycle, and are an integral part of cell growth and differentiation. We previously cloned from cerebellum a message form, MN20, of the D2 cyclin gene. MN20 has a highly restricted temporal and anatomic expression pattern in brain suggesting a role in the transition of the neuroblast from proliferation to a more mature neuronal morphology (J. Neurosci, 16:210, '96). We used antisense oligodeoxynucleotides (AS-oligos) to investigate the effect of downregulation of MN20/D2 cyclin expression on the proliferation and differentiation of cerebellar granule precursors in culture. The AS1-oligo, targeted near the translation start codon, downregulated MN20/D2 cyclin mRNA between 30 to 80% as measured by semi-quantitative RT-PCR. This oligo inhibited proliferation, as assayed by BrdU staining at 16 hours, and differentiation, as assayed by neurofilament staining at 24 hours. The dose dependent effect of the AS1 oligo did not occur in cultures treated with either sense strand or oligos targeting the 3' end of the message. bFGF but not NGF fully rescued the AS1-oligo effect on cell proliferation and differentiation. To test whether this rescue occurs through the upregulation by bFGF of MN20/D2 cyclin transcription, cerebellar granule precursor cells were isolated from mice on postnatal day 3-5, and plated in serum-free medium in the presence or absence of 10 μM bFGF. After 16 hours, bFGF treated and control cultures were harvested for Northern analysis. MN20/D2 cyclin mRNA levels were equivalent for bFGF and NGF treated cultures, as compared to untreated controls. These results indicate that proper regulation of D2 cyclin expression is required for successful differentiation and survival of cerebellar granule neurons. Furthermore, the data suggest that bFGF may rescue cerebellar granule cells from downregulation of D2 cyclin expression by a postranscriptional mechanism. (Supported by NINDS)

A RELATIONSHIP BETWEEN CIRCUS MOVEMENTS AND NEURONAL DIFFERENTIATION INDICATED BY ECTOPIC EXPRESSION OF NEURO D AND XNOTCH1.

E.C. Olson*, J.L. Dantzker, W.A. Harris and N.C. Spitzer. Department of Biology and Center for Molecular Genetics, UCSD. La Jolla, CA 92093.

We are investigating the molecular mechanisms that govern the expression of circumferential plasma membrane blebbing or circus movements in cells dissociated and cultured from *Xenopus* ectoderm. These circus cells include precursors of primary spinal neurons (E. Olson, Soc. Neur. Abs. 20:242). To investigate molecular control of circus behavior, we injected RNAs encoding neuronal fate-determining molecules into blastomeres of 2- and 4-cell stage embryos. Ectopic expression of NeuroD, a basic helix-loop-helix transcription factor is sufficient to convert cells from ventral ectoderm to neuronal fates (J. Lee et al., Science 268: 836-844). Ventral ectoderm cultures from NeuroD-injected embryos exhibited circus cells and later contained neurons, whereas cultures from uninjected or control-injected embryos (β-gal, GFP) had significantly fewer circus cells and did not contain neurons. Video-timelapse microscopy confirmed that, like neurons in neurectoderm cultures, neurons in these ventral ectoderm cultures exhibited circus movements prior to differentiating. The excitability of these neurons was demonstrated by depolarization-elicited elevations of $[Ca^{2+}]_i$ assayed by increases in fluo-3 fluorescence. In the converse experiment, we targeted RNA encoding the differentiation-inhibiting molecule XNotch1 to blastomeres fated to produce neural ectoderm. The constitutively active, intracellular-domain of XNotch1 (gift from C. Kintner) does not significantly reduce the amount of circus cells in neurectoderm cultures but does prevent the differentiation of morphologically recognizable neurons. One interpretation of these results is that XNotch1 acts on neuronal differentiation subsequent to circus movements. Supported by the McKnight Foundation (WAH) and NS15918 (NCS).

BDNF STIMULATES CHEMOTAXIS OF EMBRYONIC RAT CORTICAL NEURONS *IN VITRO*. T.N. Behar*, M.M. Dugich-Djordjevic[1], Y-X. Li, W. Ma, E. Brown, C.A. Scott, and J.L. Barker. Lab. of Neurophysiology, [1]Lab. of Molecular Biology, NINDS, NIH, Bethesda, Md. 20892

Immunocytochemistry of embryonic cortical sections revealed that Trk B receptor protein is expressed by cortical neuroepithelial cells at E15. By E17, all Trk B+ cortical cells also express the neuronal marker, TUJ1. In situ hybridization confirmed that embryonic cortical cells contain Trk B mRNA. Many Trk B+ cells exhibit the classic morphology of migratory neurons. Thus, we analyzed whether BDNF stimulates cortical cell migration (from E15-E21) using an *in vitro* chemotaxis assay. Peak motility was observed at E18, when 1ng/ml BDNF stimulated maximum migration. At other ages, 10ng/ml evoked maximal motility. BDNF stimulated chemotaxis that was inhibited by K252a or BAPTA-AM. Optical recordings of cells loaded with Ca^{2+} indicator dye demonstrated that BDNF evokes increases in intracellular Ca^{2+}. These results imply that BDNF-induces motility mediated by autophosphorylation of Trk B receptor proteins and involves Ca^{2+}-dependent mechanisms. Thus, signal transduction through the TrkB receptor complex may influence the migration of cortical cells during embryonic development.

RETINOIC ACID (RA) DIFFERENTIATED P19 CELLS DEVELOP MATURE NEURONAL PROPERTIES IN CULTURE. Peter A. Pawson*. Dep't of Physiology, University of Ottawa, Ottawa, Ont. and Dep't of Biology, Utica College of Syracuse University, Utica, NY 13502.

P19 cells, pluripotent cells derived from a murine embryonal carcinoma, differentiate into neuron-like cells after RA treatment (McBurney et al, 1988). The purpose of the present experiments was to compare the properties of P19 cells grown in culture to those of P19 cells transplanted into adult rat striatum (Morassutti et al, 1994).

Neuron-like cells were studied in various aged cultures (from 4 to 63 days post-RA treatment) using whole cell patch clamp recordings. There is the progressive development of a TTX-sensitive neuronal action potential (AP) that continues to mature with time in culture, as evidenced by the fact that the largest amplitude APs are consistently seen in the oldest cultures. Cells grown in a defined medium (i.e. "serum free" conditions) show a significant deficit in the development of electrical excitability. Spontaneous synaptic potentials could be observed from cells as young as 6 days in culture. The complexity of the background spontaneous synaptic activity increases with time in culture. Similarly, depolarizing responses to pressure applied puffs of glutamate increased with time in culture. (Supported by MRC Canada and the Burrstone Award by Utica College of Syracuse University).

ECTOPIC EXPRESSION OF CSK, AN INHIBITORY KINASE OF SRC FAMILY TYROSINE KINASES, CAUSED AN ABNORMAL CELL-CELL INTERACTION DURING NEURONAL DIFFERENTIATION OF P19 EMBRYONIC CARCINOMA CELLS Y.Takayama[1], S.Nada[1], Y.Enokido[2]*, M.Okada[1], H.Nakagawa[1] and K.Nagai[1]. [1] Div. Prot. Metabolism, [2]Div. Prot. Biosynthesis, Inst. Prot. Res., Osaka Univ. Suita, Osaka 565, Japan.

To examine the role of Src family tyrosine kinases in the neuronal differentiation, we established P19 embryonic carcinoma cell lines expressing membrane-targeted variant of Csk(Src/Csk) which had been used as common suppresser of Src family tyrosine kinases. In Src/Csk transfectants, elevation of activities of Src and Fyn during neuronal differentiation was suppressed, and fasciculation of neurites and aggregation of cell bodies were impaired. Inductions of cell adhesion molecule L1 and neurofilament were abrogated in Src/Csk transfectants whereas those of other neuronal markers including MAP2, syntaxin and N-CAM were apparently unimpaired. Addition of anti-L1 antibody to the medium of wild type P19 cells resulted in suppressions of neurite fasciculation and cell aggregation, showing a similar phenotype to that of Src/Csk transfectants. Cross-linking of L1 with specific antibody caused rapid activations of Src and Fyn in control cells, but the activation were delayed in Src/Csk transfectants. These findings suggest that Src family tyrosine kinases act as a transducer of signals originated from cell-cell interaction which is mediated by L1. IDENTIFICATION AND CHARACTERISATION OF STATHMIN RELATED PROTEINS IN RAT BRAIN, S.Ozon, S. El Mestikawy°, T. Byk, R.M. Mege* and A. Sobel, INSERM U440 and °U288, Paris - France

Stathmin is a ubiquitous, 19kDa, cytosoluble phosphoprotein which was previously identified as a relay integrating various intracellular signalling pathways.

Stathmin is the generic member of a protein family which includes neuronal proteins such as SCG10, a protein marker of neuronal differentiation, and XB3, whose cDNA was identified in Xenopus.

Our previous systematic PCR search of stathmin related sequences in rat led to the identification of RB3, the rat homologue of XB3. Moreover, clones containing EST sequences coding for an additional stathmin related protein in rat PC12 cells, or in mouse and human tissues were identified. This new member of the stathmin family possessed a stathmin like domain and an additional N-terminal domain comparable to the SCG10 but not to the RB3 specific domain. The overall domain structure of this novel sequence was comparable to that of SCG10 and we therefore designate the corresponding protein SCLIP, for **SC**G10 **LI**ke **P**rotein.

RB3 and SCLIP mRNAs are expressed only in brain, like SCG10, while stathmin is ubiquitous. On the other hand, whereas SCG10 and stathmin are abundant around birth, RB3 and SCLIP mRNAs are more abundant in adult than in prenatal or newborn brain. We showed that the SCLIP mRNA expression increased, like that of SCG10, in PC12 cells in response to NGF treatment, whereas no RB3 mRNA was detectable in those cells. Comparative *in situ* hybridisation of the four different mRNAs of stathmin, SCG10, RB3 and SCLIP showed differences of localisation in rat brain. We therefore suggest that each member of the stathmin family is playing a specific role in the nervous system, in relation with their own spatial and temporal distribution.

CHARACTERIZATION OF *NG-1*, A NOVEL ZINC FINGER GENE EXPRESSED BY NEWLY POSTMITOTIC NEURONS. J.A. Weiner*, P.D. Shilling, and J. Chun, Department of Pharmacology and Program in Neurosciences, School of Medicine, University of California, San Diego, La Jolla, CA 92093-0636.

Towards identifying molecules contributing to neuronal differentiation, we report the cloning and characterization of *ng-1*. The full-length mouse *ng-1* cDNA contains an open reading frame of approximately 3.6 kb, predicted to encode a protein containing five putative zinc finger domains of the CCHC type, suggesting that it may function as a transcription factor. Northern blot analysis detected a transcript of approximately 6.9 kb, present in fetal and adult brain and absent from other tissues. *In situ* hybridization analysis of an embryonic developmental series confirmed that *ng-1* expression was restricted to the nervous system, and indicated that it may be pan-neuronal: *Ng-1* was detected in every region of the developing CNS and PNS examined. Expression within the nervous system was further restricted to regions containing postmitotic neurons; proliferative regions did not express *ng-1*. This restriction was further analyzed in the embryonic cerebral cortex, where clearly laminar zones of proliferating and postmitotic cells exist. *Ng-1* expression was absent from the telencephalon at E10, before the generation of postmitotic neurons had begun. From E12 to E14, expression was confined to a gradually expanding band of cells near the pial surface, representing the first postmitotic neurons of the cortex. By E16, *ng-1* was expressed throughout the cortical plate, marginal zone, subplate, and intermediate zone. At all ages examined, expression was virtually absent from the proliferative ventricular zone (VZ). Double-labeling experiments in which *in situ* hybridization was combined with BrdU immunohistochemistry, performed to label the superficial margin of the VZ, confirmed that *ng-1* expression was confined to postmitotic cortical regions. Further, *ng-1* expression was induced in P19 cells following neural differentiation with retinoic acid. These data suggest roles for *ng-1* in neuronal differentiation. CHARACTERIZATION OF AN ANTISERA AGAINST THE POU PROTEIN CNS-1 AND EXPRESSION OF CNS-1 PROTEIN IN THE MOUSE BRAIN. H. Cui* and R. F. Bulliet, Dept of Pharmacology Univ. of Maryland Sch. of Med., Baltimore MD 21201

POU/homeodomain proteins encode transcription regulators important in determining the phenotypic properties of cells. RNA encoding Cns-1, a member of the POU/homeodomain protein family, is expressed predominantly but not exclusively in the central nervous system (CNS) of mice. Thus, Cns-1 may be involved in regulating the phenotypic properties of cells within the CNS. Knowledge about spatial and temporal expression patterns of the Cns-1 protein in the adult and developing CNS may provide insight into the function of Cns-1. To initiate these studies we have developed a rabbit polycolonal antiserum against a glutathione-S-transferase (GST)/Cns-1 fusion protein. This antisera is being used for immunohistochemistry to localize cells expressing Cns-1 protein in the adult and developing CNS. The GST/Cns-1 fusion protein was purified from bacterial extracts using glutathione agarose beads and used to immunize rabbits. An ELISA assay showed that immune serum from these rabbits specifically reacted with purified Cns-1 protein. This antisera had low reactivity to BSA or a GST fusion protein with the POU protein Oct-1. In immunohistochemistry experiments, we observed nuclear staining in many regions of the adult CNS, including the cerebral cortex, cerebellum, hippocampus, and thalamus. We focused on the cerebellum, where Cns-1 expression occurs in both the purkinje and granule cell layers. In the postnatal developing cerebellum, Cns-1 protein is expressed in the internal granule cell layer. In the external granule layer it is only expressed in the premigratory zone and not in the proliferative zone. Thus Cns-1 appears to be expressed in developing neurons soon after they exit the cell cycle. (supported by NIH grant NS29792)

LOCALIZATION OF THE TRANSCRIPTION FACTORS PAX 2, PAX 3, EN-1 AND EVX-1 IN THE DEVELOPING VERTEBRATE NEURAL TUBE. J. D. Burrill*, H. Sauceressig, and M. Goulding, MNL-G, Salk Institute, La Jolla, CA. 92037

We have investigated the relationship between expression patterns of the transcription factors en-1, evx-1, pax 2, and pax 3 in both embryonic chick (st. 15-23) and mouse (E9.5-11) neural tube using double label techniques.

Double label *in situ* hybridizations show that pax 3 is expressed in the ventricular zone of the dorsal half of the neural tube and that pax 2 is expressed lateral to the ventricular zone of the neural tube between the dorsal root entry zone and the ventral root exit zone. The cells expressing pax 2 in the ventral third of this zone are themselves ventral and lateral to pax 3 expressing cells, suggesting that this subset of cells is not derived from progenitor cells that express pax 3. Double label *in situ* hybridizations have also shown that both evx-1 and en-1 are expressed in the developing neural tube lateral to the ventricular zone, dorsal to the motorneurons, and ventral to the pax 3 expressing cells. This suggests that cells expressing either en-1 or evx-1 are not derived from pax 3 expressing progenitors. Double label experiments combining antibodies that recognize either en-1 (gift of A. Joyner) or pax 2 (gift of G. Dressler) and *in situ* hybridization show that many of cells that express en-1 also express pax 2. In contrast, very few cells that express evx-1 also express pax 2. We are currently determining if the en-1 expressing cells also express evx-1.

Our results suggest that the transcription factors en-1, evx-1, pax 2, and pax 3 act in a combinatorial fashion to control cell fate in the developing vertebrate neural tube.

REGION-SPECIFIC DIFFERENCES IN THE DEVELOPMENTAL PROFILES OF ACETYLCHOLINESTERASE (AChE) AND BUTYRYLCHOLINESTERASE (BuChE) ACTIVITY IN THE RAT BRAIN. T.L. Lassiter[1], S. Barone, Jr.[2], and S. Padilla[2]*. [1]Curr. in Tox., UNC, Chapel Hill, NC 27514; [2]Neurotox., US EPA, RTP, NC 27711.

Recent investigations suggest that AChE has a role in the coordinated spatiotemporal development of the nervous system. BuChE, a serine hydrolase without a clearly defined endogenous substrate, may also have a developmental function. Considering these potential developmental roles, biochemical characterization of the region-specific profiles of AChE and BuChE activity across developmental time would be informative. Several brain regions were collected across seven developmental time points, (PND 1,4,7,12,17,21,adult; n≥3). AChE and BuChE activity were distinguished by optimization experiments using selective inhibitors and specific substrates: AChE activity was defined as the fraction of total acetylthiocholine hydrolyzing activity removed by the selective AChE inhibitor BW284c51. BuChE activity was defined as the butyrylthiocholine (10 mM final concentration) hydrolyzing activity. All data were normalized according to the amount of Lowry protein. The diencephalon and olfactory bulb were studied first because of the considerable literature on AChE in the developing diencephalon which is in contrast to the paucity of information for AChE in the olfactory bulb and BuChE activity in both regions. Biochemical determination of the developmental AChE and BuChE activity profiles for these two areas presented different time-courses. AChE activity was higher in the diencephalon than the olfactory bulb. During development, AChE in the olfactory bulb increased steadily out to PND 21, as compared to the AChE activity profile in the diencephalon which presented peaks at PND 7 and 21. Diencephalon BuChE activity was also higher as compared to the olfactory bulb. Similar to AChE, the developmental BuChE activity in the diencephalon peaked at PND 7 and 21. Interestingly, in the olfactory bulb, BuChE activity did not follow the AChE profile. These results indicate that the developmental pattern of AChE and BuChE activity varies with respect to brain region and age. (TLL supported by NIEHS Training Grant T32 ES07126)

GAP-43-Like Immunoreactivity in Developing Insect Nervous Tissue. J H Hicks' and D A. O'Dell* Dept. Biol. Sci., Mary Washington College, Fredericksburg, VA 22401.

GAP-43 is a 43KD growth-associated protein that is generated in vertebrate nervous tissue during growth and regeneration. We describe immunocytochemical evidence that a similar protein may be present in the developing invertebrate nervous system.

We have used a commercially raised antibody to vertebrate GAP-43 (Boehinger-Mannheim) and probed adult and developing insect nervous tissue (*Manduca sexta, Apis mellifera*), and non-neuronal insect tissue (*Apis mellifera* oviduct, *Manduca sexta* thoracic muscle) for immunoreactivity. Specimens were fixed with 4% buffered formalin and embedded in paraffin. 10µm serial sections were dewaxed and incubated with the primary antibody. The presence of the primary antibody was detected by the Strepavidin technique using horseradish peroxidase as the marker enzyme and DAB as the chromagen (LAB-SAP kit, Zymed Inc.) Controls consisted of adult and pupal brain sections incubated in the absence of the primary antibody.

Positive staining was observed only in sections of pupal nervous system that were incubated in the presence of the antibody. Wide distribution of the antibody was observed: both soma and processes in all regions of the nervous system were seen to be immunoreactive. Neither non-neuronal tissue (muscle) nor adult neuronal tissue were observed to react to the antibody, and therefore, the protein identified by the antibody is specific to the developing nervous system.

We therefore conclude that the antibody to vertebrate GAP-43 crossreacts with a similar protein in insect nervous systems. Like the vertebrate protein, this protein is present only in developing nervous tissue. The specific cellular distribution and biochemical attributes of the insect protein are unknown at this time.

This work has been supported by an Undergraduate Research Grant and a Faculty Development Grant (DAO) from Mary Washington College.

EMBRYONIC DEVELOPMENT OF THE HUMAN SUBSTANTIA NIGRA (SN) PARS COMPACTA AND PARS RETICULATA VISUALIZED WITH TYROSINE HYDROXYLASE (TH)- AND GABA-IMMUNOREACTIVITIES. C. Verney, S. Vyas*, L. Puelles INSERM U.106, U.289 , Hôpital Salpêtrière, 75651-Paris France, Depart. Morph. Sc., Univ. Murcia, Murcia, 30100, Spain.

The dopaminergic neurons A9-A10 express TH-immunoreactivity as they leave the ventricular zone from the 5th gestational week (g.w.) on, in human embryos. As observed on frontal sections at 6-7 g.w., these neurons are generated in the floor plate and contiguous basal plate of the diencephalic p1,p2 and mesencephalic segments. A contingent of these TH-immunoreactive (IR) neurons -parallel with less numerous calbindin-28D(CaBP)-IR cells- migrates laterally and is likely to correspond to the SN pars compacta anlage. Simultaneously, in the alar plate area contiguous to the basal plate region, a GABA-IR cell population develops superficial to lateral TH-IR neurons, partly intermingling with them. This GABAergic cell population apparently corresponds to the SN pars reticulata, whose primordium had not been identified previously. The TH-IR neurons send efferents via the middle forebrain bundle (MFB) to the lateral ganglionic eminence. Interestingly, a prominent CaBP-IR bundle run in the MFB within and dorsal to the TH-IR bundle invading the superficial striatal TH-IR territory as well as deeper striatal areas. This analysis suggests that the SN is formed by the junction of the floor- basal plate-derived TH-IR cells (pars compacta) with an alar plate-GABA-IR population (pars reticulata) across at least three different brain segments (midbrain,p1 and p2).

DEVELOPMENT OF THE INNER EAR: STUDIES ON MORPHOLOGICAL CHANGES AND DIFFERENTIATION OF CELL TYPES IN EMBRYONIC OTIC EXPLANTS S. M. Fueshko* and S. Wray. Lab of Neurochemistry, NINDS, NIH, Bethesda, MD 20892.

The precursor to the inner ear, the otocyst, gives rise to sensory, non-sensory and ganglionic cells. The ganglionic cell precursors migrate away from the otocyst, forming the acoustic ganglion. However, axons from these neurons must return later in development to innervate the sensory epithelium and establish functional circuits. The mechanisms directing ganglionic cell migration away from the otocyst and the subsequent targeting of these axons back to the sensory cells are not well understood. In the mouse, the otocyst is readily accessible for dissection and culture. This feature makes examination of the development of the auditory system well suited to explant technology. Morphogenesis of the inner ear (development of semi-circular canals, endolymphatic duct and cochlear duct) and migration/formation of the acoustic ganglion occur fairly early in mouse development. Thus, we have concentrated on generating explants from E10.5-E11.5 embryos. After 5-7 days in serum-free, defined media, otic explants show dramatic morphological changes, similar to structural changes which occur *in vivo*. Differentiation of multiple cell types is further supported by immunocytochemical results which suggest that cellular migration occurs to form acoustic ganglion-like structures. Using this model, we are determining to what extent this *in vitro* explant model mimics the development of the otic system *in vivo* . In addition, we are examining the mechanisms underlying the migration of newly differentiated neurons away from the otocyst to form the acoustic ganglion. Supported by NINDS, NIH Intramural Program.

B-50 (GAP-43) INDUCES SPONTANEOUS FORMATION OF FILOPODIA AND FOCAL ADHESION-LIKE COMPLEXES IN RAT1 FIBROBLASTS. L.H.J. Aarts, A.B.Oestreicher, L.H. Schrama, W.H. Gispen and P. Schotman*. Rudolf Magnus Inst. for Neurosci., Depts. for Physiol. Chem. and Med. Pharmacol., Utrecht Univ., Universiteitsweg 100, 3584 CG Utrecht, NL

B-50 (GAP-43) is a neural, calmodulin binding, PKC-substrate that accumulates in growth cones and nerve terminals. The protein has been implicated in growth cone morphology, stability and guidance, presumably by affecting the actin cytoskeleton. The exact mechanism of action, however, is still unknown. We have investigated the morphogenetic effects of B-50 in Rat1 fibroblasts, normally lacking B-50 expression. Transient transfection with B-50 cDNA lead to spontaneous formation of a large number of long filopodia in these cells with strong B-50 immunostaining. This was accompanied by a more diffuse F-actin staining indicating a rearrangement of the actin cytoskeleton. Moreover, B-50 immunoreactivity was found concentrated at specific filopodial sites. At these sites, vinculin and paxillin, markers for focal adhesion points, were concentrated as well. This is an indication that B-50 is a component of focal adhesion complexes and that B-50 expression in nonneuronal cells can induce those complexes. Mutation of the two N-terminal cysteines, critical for directing the protein to the plasma membrane, interfered with the morphogenetic effects of B-50. Recent studies (Nobes and Hall, Cell 81, 1995) have shown that fibroblast cell morphology might be coordinately controlled by several members of the Rho-family of small GTPases. Currently, we are examining the contribution of these GTPases in the morphogenetic effects of B-50. *This work was supported by the Netherlands Organization for Scientific Research MW-NWO grant 903-42-006 and by the Princess Beatrix Fonds, grant 92-3477.*

ADENOVIRAL VECTOR MEDIATED EXPRESSION OF B-50/GAP-43 INDUCES ALTERATIONS IN THE MEMBRANE ORGANIZATION OF OLFACTORY AXON TERMINALS IN-VIVO. A.J.G.D. Holtmaat[1,2], W.T.J.M.C. Hermens[1,2], M.A.F. Sonnemans[1], F.W. Van Leeuwen[1], M.G. Kaplitt[3], A.B. Oestreicher[2], W.H. Gispen[2], J. Verhaagen[1,2]. (SPON: Eur. Neurosci. Ass.)[1]Neth. Inst. Brain. Res., A'dam, NL; [2]Rudolf Magnus Inst., Utrecht, NL; [3]The Rockefeller Univ., NY, USA.

To investigate the effect of overexpression of the growth-associated protein B-50/GAP-43 on axonal growth and morphology *in vivo*, we constructed an adenoviral vector bearing an expression cassette for B-50/GAP-43 (Ad-B-50). Unilateral infusion of Ad-B-50 in the nostrils of mice resulted in numerous B-50/GAP-43 positive mature [olfactory marker protein (OMP)-positive] primary olfactory neurons and sustentacular cells. These cells do not normally express this growth-associated protein. Confocal scanning microscopy performed at 3.5, 5 and 12 days post-infusion of Ad-B-50 revealed transport of B-50/GAP-43 to primary olfactory axons in the glomeruli in the olfactory bulb. At 3.5 days post-infusion B-50/GAP-43 positive primary olfactory fibers and axon terminals were present in a scattered pattern throughout the glomerulus, however, at 5 and 12 days increasing numbers of olfactory axons expressing transgenic B-50/GAP-43 had grown from the glomerular neuropil to the edge of the glomerulus where they formed enlarged terminals. Ultrastructural analysis of the enlarged axon endings revealed the occurrence of "axonal labyrinths", i.e. structures composed of thin sheaths of axoplasm surrounded by excessive amounts of axolemma. No morphological alterations were seen in olfactory axons transduced with an adenoviral vector expressing the bacterial LacZ gene. The occurrence of "axonal labyrinths" was confirmed in transgenic mice expressing B-50/GAP-43 in primary olfactory neurons [Holtmaat et al., J.Neurosci.(1995)15:7953]. In these mice, post-embedding immuno-EM revealed that morphological alterations were exclusively induced in OMP-positive olfactory fibers that expressed transgenic B-50/GAP-43 and were absent in OMP-positive/B-50/GAP-43-negative axon profiles. In conclusion, transgenic expression of B-50/GAP-43 in mature olfactory neurons induces intraglomerular spontaneous axonal growth. The formation of "axonal labyrinths" at the rim of glomeruli suggests that B-50/GAP-43 continued to promote axon membrane addition but that neurite growth inhibitors prevent elaborate extraglomerular growth of axons. Support: grants from NWO/GB-MW (903.52.121, 030.94.142).

675.3

AN RNA-BINDING PROTEIN IMPLICATED IN REGULATING GAP-43 EXPRESSION N. Irwin*, L. Goritchenko, A. Horiuchi, A.C. Nairn, P. Greengard, E. Levine, L.I. Benowitz Dept. Neurosurg., Children's Hosp., Harv. Med. School, Boston MA 02115 and Lab. Molec. and Cell. Neurosci., Rockefeller U., N.Y., NY 10021

The neuronal phosphoprotein GAP-43 is important for the development and plasticity of neuronal connections. Its expression is regulated both by transcriptional mechanisms and by changes in mRNA stability. Regulation of mRNA stability frequently involves the binding of proteins to particular domains of the RNA. In PC12 cells, induction of a neuronal phenotype by NGF is accompanied by upregulation of GAP-43 expression; this is mediated primarily by an increase in the stability of the mRNA. A stability determinant has been identified in GAP-43 mRNA that includes c. 100 nucleotides of coding sequence and 80 nucleotides of 3'UTR (Nishizawa, BBRC, 1994). We have purified a protein, GMBP-3, which shows specific, NGF-regulated binding to this region. Partial amino acid sequence indicates that GMBP-3 coincides with an identified phosphoprotein, and antibodies to the latter cause a supershift in the electrophoretic migration of the protein-RNA complex. Phosphorylation of GMBP-3 affects its binding to GAP-43 mRNA. Preliminary studies suggest that GMBP-3 promotes the formation of a large protein-mRNA complex, and it will be of interest to determine whether this includes GMBP-1 and -2, two proteins which bind to a different region of GAP-43 mRNA (Irwin et al, SNS Abstracts, 1994). The present findings indicate that NGF initiates a cascade of events that regulate GAP-43 expression through phosphorylation of a specific mRNA-binding protein. *Support: NIH EY 05690.*

ROLE OF GAP-43 3' UTR SEQUENCES AS *CIS-* AND *TRANS-*REGULATORS OF GAP-43 mRNA STABILITY AND NEURONAL DIFFERENTIATION. K-C. Tsai*, R.L. Neve and N.I. Perrone-Bizzozero Dept. Biochemistry, Univ. New Mexico Sch. Med., Albuquerque, NM. 87131 and Dept. Genetics, Harvard Medical School, McLean Hospital, Belmont MA, 02178.

We have recently shown that the major determinants for GAP-43 mRNA stability are localized within its highly conserved 3' unstranslated region (3' UTR) (Kohn et al, Mol. Brain Res. 36: 240, 1996; see also Kohn et al, this series). To map the specific *cis*-acting sequences for mRNA stability, we generated several GAP-43 3' UTR deletion mutants and chimeras with the ß-globin gene and measured their half-life in transfected cell lines. In addition, to test the role of these 3'UTR sequences in GAP-43 gene expression and neuronal differentiation, different regions of the GAP-43 3'UTR were overexpressed in cells containing the endogenous mRNA using Herpes simplex virus vectors and other expression systems. Our results indicate that both positive and negative *cis*-acting elements of mRNA stability are present in two distinct regions, called B and C, of the GAP-43 3' UTR. Region B confers mRNA instability in the basal condition and is responsible for the stabilization of this mRNA in response to the phorbol ester TPA. The C-region displays an opposite effect, showing stabilization in the basal condition and destabilization in the presence of TPA. Finally, analysis of the effect of exogenous GAP-43 3' UTR sequences indicates that excess 3' UTR sequences are capable of blocking GAP-43 gene expression and neuronal differentiation. This effect was found to involve primarily sequences in the C-region of the mRNA. In conclusion, our results demonstrate that the GAP-43 3' UTR can act not only as a *cis*-acting element for mRNA stability but also as a negative transregulator of GAP-43 gene expression and neuronal differentiation. DEVELOPMENTAL REGULATION OF GAP-43 mRNA STABILITY *IN VITRO*. D.T. Kohn, K-C.Tsai, V.V. Cansino and N.I. Perrone-Bizzozero*. Dept. Biochem. Univ. New Mexico, Albuq., NM. and Sch. Phys. Ther., Ohio Univ,. Athens. OH .

The expression of GAP-43 (also called B-50, F1 and neuromodulin) coincides primarily with periods of axonal elongation during the development, regeneration and remodeling of synaptic connections. Changes in mRNA stability control GAP-43 gene expression during neuronal differentiation through a mechanism that involves activation of protein kinase C (PKC) but does not require *de novo* protein synthesis. We have recently shown (Kohn et al, Mol. Brain Res. 36, 240, 1996) that the highly conserved 3'UTR of the GAP-43 mRNA can destabilize an otherwise stable mRNA and contains recognition sites for neuronal specific RNA-binding proteins. Using a series of deletion mutants and chimeras, we found that the GAP-43 3' UTR contains both positive and negative determinants for mRNA turnover (see Tsai et al, this series). The interactions of some of these sequences with RNA-binding proteins is also regulated by protein phosphorylation. To evaluate the precise contribution of *cis* and *trans*-acting factors to the control of GAP-43 mRNA turnover, we have set up an *in vitro* decay assay using rat brain polysomes. This system contains not only the GAP-43 mRNA and some of the GAP-43 mRNA-binding proteins but also reproduces the differential decay of the mRNA in neonate and adult brains. Of the major GAP-43 mRNA binding proteins, the lower molecular weight components (35 kDa to 65 kDa) are preferentially enriched in polysomes. Among these polysomal proteins we identified a 40 kDa HuD-like protein that is present both in PC12 cells and rat brain extracts. HuD is a nervous system-specific RNA-binding protein that is related to the *Drosophila* proteins *elav* and *sex-lethal* and the mammalian Hel-N1 protein. Our results support a model in which GAP-43 mRNA stability may be regulated by the association of soluble proteins to the polysomal fraction, a process that is controlled by PKC-dependent protein phosphorylation. Supported by NS30255 and GM08139 (NPB), TSGH-NDMC, (K-C.T.) and Baker Grant, Ohio Univ. (DTK).

REGULATION OF GROWTH-ASSOCIATED GENES IN NGF-INDUCED NEURITE OUTGROWTH IN PC-12 CELLS AND EFFECTS OF ANTISENSE TREATMENT J.P. Cogen*, J.K. Andersen, and T.H. McNeill. Andrus Gerontology Center and Department of Biological Sciences, Univ. of Southern California, Los Angeles, CA 90089.

Previous studies have shown that mRNAs for the growth-associated neuronal proteins SCG-10 and GAP-43 are rapidly upregulated in PC-12 cells in conjunction with NGF-induced differentiation and neurite outgrowth, but few studies have looked at the time course of gene expression during the extended period when these morphological changes are occurring. In an attempt to formulate possible roles for these genes in neurite outgrowth, PC-12 cells were cultured with NGF (50ng/ml) for 6, 12, 24, 48, 72, 120, and 168 hrs. and prepared for Northern analysis.

The pattern of mRNA upregulation after NGF treatment differed for SCG-10 and GAP-43. GAP-43 levels were greatest (550% of control) at 24 hours, whereas SCG-10 levels were largest (400% of control) at 72 hours.

Antisense oligonucleotides were added to PC-12 cells for 3 days to reduce levels of GAP-43 or SCG-10 message, and cultures were fixed and stained with Coomassie blue for morphologic analysis. Total neurite length and branch point number were significantly reduced with GAP-43 antisense treatment, but not with SCG-10 antisense, or sense treatments. In addition, growth cones in GAP-43 antisense-treated cultures had fewer filopodia compared to those given other treatments. These data support the hypothesis that GAP-43 is involved in growth cone pathfinding via formation of filopodia, whereas SCG-10 may be involved in some later process involved in neurite formation. Supported by NIH grants MH-11085 and AG-09793.

GENE EXPRESSION OF GROWTH ASSOCIATED PROTEINS DURING THE POSTNATAL DEVELOPMENT IN THE MACAQUE MOTOR CORTEX. T. Oishi[1], N. Higo[1], Y. Umino[1], K. Matsuda[1] and M. Hayashi[2]*. [1]Neuroscience Sect., Electrotechnical Lab., Tsukuba, Ibaraki 305, Japan, [2]Dept. of Cellular and Molecular Biology, Primate Res. Inst., Kyoto Univ., Inuyama, Aichi 484, Japan.

To study the postnatal development of the motor cortex, we determined the amount of mRNAs of two growth associated proteins, i.e., GAP-43 and SCG10, in the forelimb region and the hind limb region of the primary motor area (FAfl and FAhl, respectively) and the premotor area (FB) of macaque monkeys at postnatal day 8 (P8), P30, P70, P183 and at the adult stage. G3PDH mRNA was used as the internal control for the fluctuation of the electrophoresed total RNA. The amount of GAP-43 mRNA in FAhl did not change from P8 to P30 and then decreased gradually to P70. The amount of GAP-43 mRNA in FAfl and FB decreased from P8 to P30 but was almost constant until P183. Large amounts of GAP-43 mRNA in these regions during P30 and P183 may reflect prolonged development of the corticospinal tract. In contrast, SCG10 mRNA in these three regions of the motor cortex decreased almost exponentially to the adult level. The difference between the developmental patterns of GAP-43 mRNA and that of SCG10 mRNA suggests different roles of these two proteins during postnatal development. In FAfl, the amount of GAP-43 mRNA at the adult stage was as high as in the association areas, suggesting lifelong high plasticity of FAfl. Moreover, developmental pattern of both mRNAs in FAfl was more similar to that in FB than that in FAhl. These results suggest that FAfl seems to share common features with the association areas. (This work was supported by the grants of AIST, MITI, Japan and the Cooperation Research Program of Primate Research Inst., Kyoto Univ. We thank Dr. R. L. Neve and Dr. N. Mori for their generous gift of GAP-43 cDNA clone and SCG10 cDNA clone, respectively.)

ULTRASTRUCTURAL IMMUNOLOCALIZATION OF GAP-43 IN THE DENTATE GYRUS OF KAINIC ACID TREATED RATS. C.Bendotti*[F]. Guglielmetti, S. Baldessari, R. Samanin and S. De Biasi[1] Istituto di Ricerche Farmacologiche "M. Negri", Milano, Italy and [1]Dept. Fisiologia e Biochimica Generali, Università di Milano,Italy.

A systemic injection of kainic acid (KA) in rats evokes a status epilepticus accompanied by hippocampal neuronal loss and sprouting of mossy fibers in the supragranular layer that are typical features of human temporal lobe epilepsy. We have recently shown that the mRNA of GAP-43, an axonal growth associated protein, can be rapidly and transiently upregulated in the granule cells of adult rats after KA administration. In order to further characterize the involvement of this protein in the synaptic reorganization of mossy fibers induced by KA, in the present study we examined the ultrastructural changes and the immunolocalization of GAP-43 induced in the dentate gyrus by KA at different intervals after treatment. At early times (1-4 days) several degenerating terminals are found in the inner molecular layer (IML), intermingled with a few GAP-43 immunoreactive (ir) terminals of small size and making asymmetric synapses, similar to those present in control samples. At longer times(30-90 days) degenerating terminals disappear in the IML and several of the GAP-43ir terminals show ultrastructural characteristics of mossy fiber boutons. These findings provide morphological evidence for the involvement of GAP-43 in the synaptic remodeling induced by KA treatment in the rat dentate gyrus.

The study was supported by Consiglio Nazionale delle Ricerche, Convenzione Psicofarmacologia and Ministero Università Ricerca Scientifica e Tecnologica (40%), Rome, Italy.

THE EFFECT OF AGE AND GONADAL STEROIDS ON THE EXPRESSION OF GROWTH ASSOCIATED PROTEIN 43 IN THE RAT BRAIN FOLLOWING HIPPOCAMPAL LESIONS. BW. DeHart*, JE. Anderson, JR. Day. Department of Biology, The Pennsylvania State University, University Park, PA 16802.

Growth associated proteins play a role in neurite outgrowth during development and regeneration. Growth associated protein 43 (Gap-43) is abundant in growth cones. Phosphorylation of Gap-43 by protein kinase C has been implicated in LTP, signal transduction, and neurotransmitter release. According to Schauwecker et al. (J. Neurosci. 15:2462-70, 1995) Gap-43 mRNA increases in the ipsilateral and contralateral hilar and CA3 pyramidal cells following hippocampal lesions in young adult, but not aged rats. Other studies have shown that glial fibrillary acidic protein (GFAP) expression can be manipulated by altering circulating adrenal and gonadal steroids. The purpose of this study was to examine the effect of gonadal steroid manipulations on Gap-43 expression in aged rat brains following hippocampal lesions. 3 and 24 months male, Fisher 344 rats were castrated and received combined entorhinal cortex/fimbria fornix lesions. Castrated animals were given either testosterone-filled implants or empty implants. Gap-43 message in the hilar and CA3 region of the hippocampus was measured by *in situ* hybridization and compared between hormone treatment groups at 14, 30, and 45 days after lesioning. Our results indicated that Gap-43 mRNA was not significantly different among hormone treatment groups at any time after lesioning. This suggests that gonadal steroids have no effect on Gap-43 mRNA expression following deafferentation. Nevertheless, Gap-43 message decreased bilaterally 14 days after the lesion and increased to control levels 45 days later in the old animals. This suggests that Gap-43 mRNA does change transiently in aged rats following hippocampal deafferentation. This study was funded by AFAR and NSF (IBN 9511864) research grants awarded to JRD.

AXON GUIDANCE IN THE DEVELOPMENT OF MOUSE RETINOFUGAL PATHWAYS - A CONFOCAL MICROSCOPY STUDY. K.F. Wong and S.O. Chan* Department of Anatomy, Chinese University of Hong Kong, Shatin, NT, Hong Kong.

In order to understanding how growth cones of retinal ganglion cell find their way in the chiasm, brain slices of C57 mice aged embryonic day 14 (E14) and E15 were dissected and the ventral temporal retina was labelled with fluorescent dye DiI. The brain slices were maintained in culture medium at 37°C and dynamic growth of labelled axons across the optic chiasm were examined using confocal microscopy.

In E14 and E15 embryos, most axons from the ventral temporal retina were crossed. Most of these crossed axons had simple growth cones, with an elongated tip and a few short filopodia. Some crossed axons, however, showed a complex morphological change and a pause in their course across the chiasm. The uncrossed axons turned at a region 100-200 μm lateral to the midline of the chiasm. All of these turning axons showed a pause in their course. During the pause period, there were complicated remodeling of growth cones. The growth cones which had filopodia and lamellopodia initially extended in all directions had the branch pointing to the ipsilateral tract eventually increased in length while the others retracted, resulted in a change of growth direction. It was also noted in this study that most newly arrived growth cones turned at a position more medial than the already turned axons, suggesting that the uncrossed axons, after reading the local signals at the midline of chiasm and turned, were shifted to a later position by the newly arrived uncrossed axons.

AXON GUIDANCE MECHANISMS AND PATHWAYS: CELL ADHESION MOLECULES

676.1

PETRIN - A NOVEL PHOSPHATASE INVOLVED IN NEURITE GROWTH REGULATION ON CNS MYELIN. M. Labes*[#], J. Roder[#] and A. Roach[+]. Samuel Lunenfeld Research Institute, Toronto, M5G 1X5, Canada, and Allelix Pharmaceuticals Inc., Mississauga, Canada.

Mammalian CNS myelin is known to contain molecules which inhibit neurite extension. We have cloned and characterized a novel rat brain cDNA, designated as petrin, that plays a role in regulating the neuronal response to these myelin-associated inhibitors. The petrin cDNA contains an open reading frame of 1941bp, encoding a protein with a predicted molecular weight of 55kD which shares amino acid identities/similarities of approximately 30/60% with portions of the Ser/Thr phosphatase 2C. Rabbit antiserum raised against the carboxy terminus of Petrin specifically immunoprecipitates a protein of M_r 60,000 and a phosphatase activity with the Mg^{2+} dependence characteristic of 2C phosphatases.

The expression of Petrin appears to be neuron-specific and developmentally regulated, and the sequence was found to be highly conserved in mouse, hamster and human. Introduction of antisense RNA or oligonucleotides which perturb the expression of the petrin protein, conferred on NG108-15 cells the ability to grow neurites on inhibitory CNS myelin substrate. The presented data suggest that the petrin gene product identifies a new phosphatase-dependent signalling pathway which modulates the cellular response to myelin-associated inhibitors.

EXPRESSION OF EZRIN IN A SUBSET OF THE CHICK RETINOTECTAL PROJECTION. M. Yamagata*, M. Takahashi and M. Noda. Div. Molecular Neurobiology, National Inst. for Basic Biology, Okazaki, Aichi 444 Japan.

In the chick retinotectal system, retinal ganglion cell (RGC) axons terminate and arborize in only 3-4 of 15 laminae in the optic tectum. RGCs consist of several subsets which can be defined neurochemically. Axons of each subset choose a single specific lamina among these retinorecipient laminae. To understand the molecules and structures that regulate the lamina-specific neuronal connection, we have generated a series of monoclonal antibodies that specifically stain one of the retinorecipient laminae in the tectum. Among these, TB4 stained not only one retinorecipient lamina named F but also a subpopulation of RGCs, and cell-cell contact area in some epithelia including the intestine. The TB4-positive RGC subset overlapped with an acetylcholine receptor β2 -bearing RGC subset that projects into lamina F. In the tectum, the lamina-selective immunoreactivity for TB4 was not evident in the tectum of the eyeless chick, suggesting that terminal arbors of the RGC subset are responsible for the laminar staining. The antibody recognized a 79 kD protein. cDNA cloning and immunochemical analysis revealed that the antigen is ezrin, a membrane-anchoring microfilament-associated protein. The chick ezrin shared 90% amino acid identity with human and mouse ezrin. Ezrin is a member of the ERM protein family that regulate cell morphology and cell adhesion. We would like to propose that ezrin is involved in the formation and/or maintenance of the lamina-specific neuronal connectivity.

676.3

MOLECULAR CHARACTERIZATION OF TRACTIN AND LeechCAM, TWO NOVEL INTERACTING PROTEINS EXPRESSED ON AXON FASCICLES. Y. Huang*, C. Jie, J. Jellies†, K.M. Johansen, and J. Johansen. Department of Zoology & Genetics, Iowa State University, Ames, IA 50011 and †Department of Biological Sciences, Western Michigan University, Kalamazoo, MI 49008.

The mAb lan3-2 identifies a 130 kD surface glycoprotein which is expressed by a subset of peripheral neurons that tightly fasciculate together and which employ CNS axons for proper navigation during leech development (Jellies et al., Dev. Biol. 171:471). By immunoaffinity chromatography of leech proteins using the lan3-2 antibody we obtained 8 peptide microsequences from the purified protein. New antibodies were made to several of these peptides and were subsequently used to clone two novel proteins. One of these proteins corresponds to the lan3-2 antigen which we have named tractin; the other is an interacting protein which copurified with the lan3-2 antigen and which we have named leechCAM. Each protein was found to contain 4 of the 8 original peptide microsequences. Tractin is a novel member of the Ig-superfamily with a highly unsual structure. It contains 6 Ig-domains, 4 FNIII-domains, an acidic domain, 64 repeats of a novel proline- and glycine-rich motif, a transmembrane domain, and an intracellular tail with an ankyrin binding motif. LeechCAM, which is expressed only by CNS neurons and their projections, has 5 Ig-domains, 2 FNIII-domains, and a transmembrane domain and may be the leech homolog of NCAM, FasII, and ApCAM. Studies are under way to further characterize the interactions of tractin and leechCAM and their possible role in axon guidance and tract formation. Supported by NIH NS28857 (JJo) and NSF 9696018 and a Sloan Fellowship (JJe).

UNC-69, A MOLECULE REQUIRED FOR AXONAL GUIDANCE, IS CONSERVED FROM WORMS TO HUMANS. S. Tharin[1]*, B. Wightman[2], N. Tsung[3], E. Hartwieg[3], G. Garriga[2], H.R. Horvitz[3] and M.O. Hengartner[1]. 1. Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, NY, 11724. 2. Department of Molecular and Cell Biology, 401 Barker Hall, University of California, Berkeley, CA, 94720. 3. Howard Hughes Medical Institute, Department of Biology, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA, 02139.

The *unc-69* gene is required for axonal outgrowth, guidance and fasciculation in *Caenorhabditis elegans* (*C. elegans*). In *unc-69* mutants many axons, including those of the hermaphrodite-specific neurons (HSNs) terminate prematurely. The dorsal and ventral nerve cords are defasciculated in *unc-69* mutants. An *unc-69-lacZ* fusion construct is expressed predominantly in neurons; expression is most prominent in the nerve ring and ventral nerve cord. *unc-69* encodes a 108 amino-acid protein with a predicted coiled-coil motif near its C-terminus. UNC-69 fusions interact with eachother in the yeast two-hybrid assay. UNC-69 is not homologous to any previously characterized protein. However, it shows significant similarity to the predicted product of a previously uncharacterized human gene (tentatively called *hunc-69*), identified by a set of overlapping expressed sequence tags. *hunc-69* mRNA is enriched in human fetal brain, although its expression is not restricted to this tissue. HUNC-69 is also predicted to form a coiled-coil structure near its C-terminus. The two proteins are 77% identical over their predicted coiled-coil regions. The high degree of sequence conservation in this region leads us to predict that homophilic and/or heterophilic interactions, mediated by the coiled-coil domain, are required for UNC-69 function. We have therefore started a two-hybrid screen to identify gene products interacting with UNC-69. (Supported by grants from the American Cancer Society (BW), March of Dimes (GG), Howard Hughes Medical Institute (HRH) and the National Institutes of Health (MOH). GG is a McNight Scholar. HRH is an investigator of the Howard Hughes Medical Institute.)

676.5

L1 EXPRESSION AND LOCALIZATION IN DEVELOPING HAMSTER RETINAL GANGLION CELL (RGC) AXONS. K. L. Moya*, A. W. Lyckman, A.M. Confaloni, K. Redolfo and S. Jhaveri. CNRS URA 2210, INSERM U334, SHFJ, CEA, 91401 Orsay, France; Ist. Sup. Sanità, Rome, Italy; Dept. Brain & Cog. Sci., M.I.T., Cambridge, MA 02139.

Glycoprotein L1 has been implicated in the fasciculation of growing axons, and recently in modulation of synaptic plasticity in mature synapses [Luthi et al., Nature 372: 777, 1994]. We examined changes in axonal transport and localization of L1 during development of the retinofugal pathway. Radiolabeled L1 (separated by 2D gel electrophoresis) transported to the lateral geniculate nucleus (LGN) and superior colliculus (SC) was quantified in P2 to adult hamsters. For L1 localization, hamster brain sections (P0 to P34) were reacted with anti-L1.

Levels of newly synthesized L1 in RGC-axons were highest at P2 and P5, greatly diminished by P12 and declined to adult levels by P17. Correspondingly, the optic tract over the LGN was heavily immunoreactive for L1 in P0 and P2 brain, as were fibers in the superficial SC. The retinal origin of these L1-positive fibers was verified in P1 animals by their disappearance after unilateral eye enucleation at P0. At P5, and more so at P10, a dramatic decrease in the intensity of L1-staining was noted in the optic tract. The few L1-positive fiber bundles detected over the LGN at P10 may correspond to non-retinal afferents. By P34, the retinofugal pathway was devoid of L1.

Changes in levels of L1 synthesis and patterns of localization in maturing RGC-axons correspond to their known growth phases. Thus, expression of L1 in RGC-axons is greatest during their rapid elongation as fasciculated fiber bundles, and greatly dimishes as they defasciculate during arborization/target innervation. Mature axons have the lowest L1-expression and the least growth potential.

We thank C. Lagenaur and M. Schachner for anti-L1 sera. Supported by INSERM, CNRS, CEA, CEE and NIH grant EY05504.

676.6

THE NEURAL CELL ADHESION MOLECULES NG-CAM AND AXONIN-1 INTERACT IN THE PLANE OF THE SAME MEMBRANE.

A. Buchstaller, S. Kunz, P. Berger, U. Ziegler, C. Rader, M. A. Ruegg** and P. Sonderegger. Institute of Biochemistry, University of Zurich, CH-8057 Zurich, Switzerland; *Biocenter, University of Basel, CH-4056 Basel, Switzerland.

The axonal surface glycoproteins NgCAM and axonin-1 promote neurite outgrowth and regulate growth cone guidance. They are spatiotemporally coexpressed in the developing chicken nervous system and colocalized on the growth cones of various neurons. A direct binding between NgCAM and axonin-1 has been demonstrated using isolated molecules conjugated to the surface of fluorescent microspheres (Kuhn et al., *J. Cell Biol.* 115:1113, 1991). To make NgCAM and axonin-1 available for detailed topological studies on the NgCAM/axonin-1 interaction, we expressed both cDNAs heterologously in diverse cells and performed binding studies. We found that NgCAM and axonin-1 can not bind when present at the surface of different cells. In contrast, an association of NgCAM and axonin-1 in the plane of the membrane was revealed by antibody-induced capping/cocapping experiments. Crosslinking studies in DRG neurons showed that NgCAM and axonin-1 tend to form discrete heterodimeric complexes on the surface of non-fasciculated neurons grown on laminin. Suppression of axonin-1 translation in DRG neurons by antisense oligonucleotides impaired neurite outgrowth on NgCAM substratum. The results suggest that axon extension along selected pathways does not involve simple receptor-ligand interactions but functional cooperation of receptor molecules on the growth cone membrane.

676.7

NOVEL GLYCOFORMS OF THE NEURAL CELL ADHESION MOLECULE (N-CAM) ARE INVOLVED IN AXON GUIDANCE WITHIN THE DEVELOPING VERTEBRATE BRAIN.

R.B. Anderson* and B. Key. Laboratory of Molecular Neurodevelopment, Department of Anatomy and Cell Biology, University of Melbourne, Parkville, Victoria, Australia, 3052.

There is increasing evidence to suggest that carbohydrates play an important role in axon guidance, by either modulating the adhesiveness of cell adhesion molecules, or by acting directly as ligands for carbohydrate receptors. We have previously identified two novel cell surface carbohydrates present on N-CAM glycoforms within the developing vertebrate brain. These cell surface carbohydrates are expressed on phenotypically distinct subpopulations of axons within the supra-optic tract (SOT) and the tract of the post-optic commissure (TPOC). SOT axons appear to change direction upon containing axons expressing the same cell surface carbohydrates within the TPOC. Perturbation studies were performed on exposed *Xenopus* brain preparations (stages 28-35) in order to assess the role of these N-CAM glycoforms at the junction of the two tracts. Ablation of axons expressing N-CAM glycoforms within the TPOC resulted in formation of three distinct phenotypes: premature turning; normal turning; and failure to turn of the SOT axons. These results suggest that novel cell surface carbohydrates play an important role in axon guidance within the developing *Xenopus* brain. Supported by NH&MRC Grant #950631.

676.8

NEURITE GUIDANCE BY CARBOHYDRATE RESIDUES OF ASTROCYTE GLYCOPROTEINS. E. M. Powell* and H. M. Geller, Department of Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Astrocytes have been implicated in guiding neurites by forming boundaries during development. We have developed a cell culture astrocyte boundary model to elucidate mechanisms of neurite guidance. The boundary is formed by the juxtaposition of permissive A7 and inhibitory Neu7 astrocyte-derived cell lines. Neurites from dissociated embryonic rat cerebral cortical neurons recognized the A7/Neu7 boundary and >95% turned or stopped. A 50% decrease in neurite turning was observed when cells were pretreated with xylosides or chlorate, which prevent normal proteoglycan synthesis. Previous studies have reported Neu7 cells express higher levels of chondroitin sulfate-6-proteoglycan and dermatan sulfate than A7 cells. However, treatment of the A7/Neu7 boundary with chondroitinase AC, chondroitinase ABC, or heparinase had no effect on neurite turning. Thus, these molecules do not appear to be responsible for neurite guidance by these cells. Lectin cytochemistry of A7 and Neu7 monolayers demonstrated only slight differences in overall carbohydrate expression. However, glycoprotein detection blots of cell extracts revealed that A7 and Neu7 cells have unique expression patterns of glycoproteins which bind to peanut agglutinin (PNA), concanavalin A, and wheat germ agglutinin. In addition, soluble lectins, including PNA, reduced the neurite turning response but did not alter neurite outgrowth. These studies imply that the carbohydrate residues of astrocyte glycoproteins provide directional cues to guide neurites. Supported by NIH R01 NS-24168 to H.M.G. and NIH F31 MH-10815 to E.M.P.

THE ULIPS: A GROWING PROTEIN FAMILY RELATED TO THE AXONAL GUIDANCE ASSOCIATED UNC-33 PROTEIN, T. Byk, S. Ozon, C. Cifuentes-Diaz° and A. Sobel*, INSERM U440 and °U153, 75005 Paris - France

We have recently described a novel phosphoprotein preferentially expressed in the nervous system and strongly regulated during development. We named this protein Ulip for **U**nc-33 **Li**ke **P**hosphoprotein, based on its homology with this axonal guidance associated protein in *C. elegans*. The phosphorylation pattern of Ulip in PC12 cells is changed upon induction of neuronal differentiation with NGF. It is expressed in neurons and can also be detected in oligodendrocytes and Schwann cells.

Ulip is closely related to other unc-33 like proteins identified recently: toad-64, originally identified as a neuronal differentiation marker in the rat, crmp-62, implicated in the collapsin signal transduction in chick. Sequence analysis of these proteins as well as of human EST sequences revealed the existence of a broad Ulip protein family: Ulip1 (Ulip), Ulip2 (crmp-62 and toad-64) and Ulip3 (hcrmp-1) displaying ~75% identity between each other and more than 95% phylogenetic conservation; Ulip4 and Ulip5 displaying ~50% identity with Ulip1-Ulip3. The phylogenetic conservation of this family is emphasized by the identification of several "Ulip" sequences within the recently available *C. elegans* genome sequence.

The Ulip expression patterns during development and neuronal differentiation displayed distinct regulation. Ulip1 is strongly down-regulated in the adult brain and up-regulated in differentiated PC12 cells. Ulip2 is similarly but only weakly regulated in both cases. Ulip3 is strongly down-regulated in the adult brain, but its expression is not induced in differentiating PC12 cells. Ulip4 is down-regulated in the adult brain, but also down-regulated in differentiated PC12 cells. Finally, Ulip2-4 appeared more brain-specific than Ulip1,which was also detected in newborn heart and muscle.

This expression analysis suggests that each of the Ulip proteins might have its specific biological role, particularly in neuronal differentiation and outgrowth.

BIOLOGICAL ROLE OF CONTACTIN STUDIED BY GENE KNOCKOUT

E. O. Berglund* and B. Ranscht. *The* Burnham Institute, La Jolla, CA 92037, USA.

The development of genetic techniques to disrupt gene funtion in developing mouse embryos provides a powerful tool for investigating the biological role of specific proteins. Contactin, a cell adhesion/ recognition molecule of the immunoglobulin gene family, is highly expressed in the developing nervous system and implicated to play a role in axon guidance and fasciculation. A contactin knock-out construct was generated from mouse genomic DNA by insertion of a neomycin casette into a 5'exon; herpes simplex thymidine kinase was used as a negative selection marker. The gene targeting vector was electroporated in R1 embryonic stem cells, and 12 out of 124 G418-resistent clones identified as correctly targeted by PCR and Southern blotting. After karyotyping, three targeted clones were injected into blastocysts and reimplanted in pseudo-pregnant mice. Chimeric founder males were bred with Black Swiss females yielding offspring with agouti coat color. Heterozygous F1 animals were identified to carry the mutated contactin allel by PCR and Southern Blot analysis of tailbiopsies. Heterozygotes are being bred to produce mice homozygous for the contactin null mutation. The mice will be analyzed for developmental defects including axonal pathfinding errors and malformation of neuronal circuitry, and a preliminary assessment of the phenotype will be presented.

CLONING OF RAT POLYSIALYLTRANSFERASE cDNA AND DEVELOPMENTAL EXPRESSION OF ITS mRNA IN THE BRAIN.

G.K. Wood[1]*, J. J. Liang[1], S. Ahmad[2], R. Quirion[1], and L.K. Srivastava[1]. [1]Douglas Hospital Research Centre, Dept. of Psychiatry, McGill Univ., Montreal, Quebec, Canada; [2] Biotechnology Research Institute, Montreal.

Polysialyltransferase (PST) is an enzyme that catalyzes polysialic acid (PSA) synthesis on neural cell adhesion molecule (NCAM), which is critical for neural development and plasticity. Based on the cDNA sequences of recently cloned hamster, mouse, and human PSTs (that are highly homologous to each other), we used a PCR strategy to clone the cDNA of the rat brain PST in order to devise probes for studying expression of the enzyme mRNA in this tissue during development and adulthood. By Northern blotting using an oligonucleotide probe, we observed a prominent band of ~5 Kb in the brain tissue which is consistent with recently reported hamster and mouse PST transcripts. As expected, the message is more abundant in the embryonic than the adult brain. By in situ hybridization, signals for PST were detected abundantly in E15 cortical neuroepithelium, hippocampal formation neuroepithelium, cerebellar neuroepithelium and basal telencephalon. At postnatal stages, PST mRNA was detected in many brain areas including neocortex, hippocampus, some thalamic nuclei, and cerebellum. In adult brain, expression of PST mRNA was observed in the olfactory bulb, cerebral cortex, hippocampus, and cerebellum. The results suggest that the expression of PST mRNA in the rat brain is developmentally regulated and that PST mRNA has more widespread distribution in the rat brain than expected from the known expression pattern of PSA-NCAM. HOMOPHILIC BINDING OF THE NEURAL ADHESION MOLECULE TAX-1 IS MEDIATED THROUGH ITS FIBRONECTIN DOMAINS.

P.C. Tsiotra, K. Theodorakis, J. Papamatheakis, and D. Karagogeos*,[1]. Institute of Molecular. Biology & Biotechnology, and [1]Dept. Basic Sciences, School of Medicine, Univ. of Crete, 71110 Heraklion, Crete, Greece.

Cell adhesion molecules belonging to the immunoglobulin superfamily promote cell aggregation and neurite-outgrowth. These proteins are multidomain molecules comprising a number of distinct modules, notably Ig domains of the C2 class (IgC2) and fibronectin type III repeats (FNIII). Among them, the transient axonal glycoprotein, TAG-1 which engages in homophilic as well as heterophilic interactions with L1 and integrins (Felsenfeld et al., Neuron 12:675-690, 1994). We have isolated the human homolog of TAG-1, named TAX-1, which shares a great degree of similarity at the protein level with the rodent molecule (Tsiotra et al., Genomics 18:562-567, 1993). We set out to determine which domains of TAX-1 are involved in promoting the homophilic, adhesive properties of the molecule. We established stable Schneider's (S2) cell lines expressing equivalent amounts of either the intact molecule, the fibronectin or the immunoglobulin domains. The FNIII domains were necessary and sufficient to mediate homophilic binding and induce cell aggregation, a response also observed with cells expressing the intact TAX-1 molecule. Aggregation was inhibited by the secreted form of the TAG-1 protein. On the other hand, the IgC2 domains by themselves were not able to induce this activity and presumably are required for the neurite outgrowth-promoting function of TAX-1. In addition, TAX-1 was localized in areas of cell contact among aggregating cells, justifying its role as an adhesion molecule.

Involvement of p90rsk in neurite outgrowth mediated by the neural cell adhesion molecule L1. A. W. Schaefer, E. V. Wong, G. Landreth, and V. Lemmon*. Case Western Reserve University, Cleveland, OH 44106.

L1 is an axonal cell adhesion molecule found primarily on projection axons of both the CNS and PNS. L1 is a phosphorylated membrane-spanning glycoprotein which can be immunoprecipitated from rat brain membranes in association with at least two distinct protein kinase activities. Western blot analysis demonstrates that p90rsk (ribosomal S6 kinase) is present in these immunoprecipitates. p90rsk can phosphorylate recombinant L1 cytoplasmic domain (L1CD), which consists of residues 1144 to 1257, as well as one of a series of L1CD-derived synthetic peptides. Both L1CD and this peptide, encompassing aa1144-1158 (KRSKGGKYSVKDKED), are phosphorylated on Ser-1152, as demonstrated by Ser to Ala substitutions in the peptide, and amino acid sequencing of p90rsk-phosphorylated L1CD. Furthermore, this site is phosphorylated in L1 purified from newborn rats. These data show that p90rsk is associated with and able to phosphorylate L1 both in vivo and in vitro. The KRSK peptide described above was introduced into neurons growing on different substrates in culture, and the effect on neurite outgrowth was observed. This peptide specifically inhibited neurite outgrowth on L1, while leaving neurons growing on laminin unaffected. Control peptides containing a Ser/Ala-1152 substitution and a scrambled sequence peptide did not perturb neurite outgrowth on either substrate.

OUTGROWING OLFACTORY AXONS FROM THE OLFACTORY EPITHELIUM SLICE CULTURES EXPRESS NEURAL CELL ADHESION MOLECULE AND L1. W-L. Liu*, T. D. Foster and M. T. Shipley. Dept. of Anat., Univ. of Maryland, Baltimore, MD 21201

Early olfactory axons grow from the olfactory epithelium (OE) to the telencephalon along a specific pathway. Several extracellular matrix and cell surface molecules are present along the developing olfactory nerve pathway *in vivo*, indicating that these molecules might be involved in axonal guidance for early olfactory axons. To investigate potential mechanisms of olfactory axon pathfinding, we used an organotypic olfactory epithelium slice culture to analyze the expression of adhesion molecules (NCAM and L1) in outgrowing olfactory axons.

E13 embryos were taken from timed pregnant rats. Embryonic heads were cut on vibratome. The OE slices were harvested from the sections and placed in the Milicell-CM culture plate inserts. Serum-free Waymouth's medium was added to the insert (0.7 ml) and the culture dish well (1.0 ml). The slices were maintained at 100% humidity in air/5% CO2 at 37°C for 5 days. The medium was changed every two days. GAP43 or neuronal specific tubulin (NST) antibodies were used to identify the outgrowing olfactory axons from the OE slice cultures. A monoclonal antibody against NCAM (1:6) and the rabbit polyclonal antibody against L1 (1:1000) were used for analyzing the expression of NCAM and L1 in the outgrowing olfactory axons. These processes were identified as axons by immunoreactivity with either NST, which is present in all neurons and axons, or with growth associate protein (GAP 43), which shows the growing neurons and axons. NCAM is strongly expressed by both the outgrowing olfactory axons and the olfactory receptor neurons in the OE slices. Some migrating cells also expressed NCAM. The outgrowing olfactory axons strongly expressed L1, and the staining pattern of L1 is similar to that of NCAM. L1 positive axons formed more bundles than NCAM positive axons. This suggests that both NCAM and L1 are associated with the outgrowth of the olfactory axons and that L1 may also play a role in fasciculation of the olfactory axons. FUNCTIONAL CHARACTERIZATION OF TWO CELL ADHESION MOLECULES - THE E587 ANTIGEN AND NEUROLIN - DURING ZEBRAFISH CNS DEVELOPMENT M. Bastmeyer *, H. Ott, U. Laessing and C.A.O. Stuermer. Faculty of Biology, Univ. of Konstanz, 78434 Konstanz, Germany.

The two cell adhesion molecules, E587 antigen and Neurolin are present on many neurons and axons of the developing zebrafish CNS. We have analyzed aspects of their function. The E587 antigen belongs to the L1 family of cell adhesion molecules and is transiently expressed on all developing axons in zebrafish (Giordano et al., 1995, Soc.Neurosci.Abstr. 21: 788). It has been shown to mediate fasciculation of goldfish retinal axons in vitro and in vivo (Bastmeyer et al., 1995, J.Cell Biol. 130: 969). Neurolin is the fish homolog of chick DM-GRASP (Laessing et al., 1994, Differentiation 56: 21). During zebrafish development Neurolin exhibits a restricted spatio-temporal expression pattern on subsets of neuronal cell bodies and their axons, i.e. on secondary motoneurons of the spinal cord and on neurons of cranial nerves.

For functional analysis, Fab fragments of polyclonal sera against E587 antigen and Neurolin, respectively, were injected into the ventricle of 30 hpf zebrafish. Control embryos received injections of nonimmune Fabs. Embryos were fixed 8-10 h later, immunostained with monoclonal antibodies against the corresponding antigens and analysed with a confocal microscope.

Injections of E587 Fabs caused a marked defasciculation of axon bundles in the posterior commissure and in longitudinal tracts and commissures of the hindbrain. Embryos injected with Neurolin Fabs showed a reduction in the number of secondary motoneurons of the spinal cord. Furthermore, trigeminal and facial nerve branches were reduced in length as compared to controls.

We conclude that E587 antigen contributes to the creation of tight and orderly fascicles in the developing CNS. Neurolin is involved in the timely differentiation of secondary motoneurons and the growth of cranial nerve projections.

FAILED MOTONEURON INNERVATION IN *DROSOPHILA* EMBRYONIC TRANSFORMANTS MISEXPRESSING TOLL D. Rose[1], X. Zhu[1], A. Chiba[1], & F. Delcomyn*[2], Dept. of [1]Cell & Struct. Biol., and [2]Entomol., Univ. of Illinois, Urbana, IL 61801

We describe here the use of the *Drosophila* neuromuscular system as a model to study the molecular recognition mechanism underlying growth cone-target interaction. Specifically, we set out to elucidate an in vivo function for the transmembrane receptor molecule Toll, through the examination of both null mutants and transformants heterochronically misexpressing Toll. Expression of Toll is dynamically regulated, with normal protein expression occurring on a small subset of muscles during neuromuscular synaptogenesis. Many motoneuron growth cones, including the RP3 motoneuron, normally grow past these Toll-positive muscles before innervating their appropriate targets. We have found that misexpression of Toll by a muscle-specific promoter (*Mhc*) in the *Drosophila* embryo leads to pathfinding defects in multiple motoneuron pathways, as visualized by a motoneuron-specific antibody, including the RP3 motoneuron pathway. *Mhc*-driven Toll remains expressed in all muscles at high levels during late embryogenesis, when RP3 is navigating though the musculature. We visualized RP3 growth cones in the abdominal segments by injecting the fluorescent dye Lucifer yellow into RP3 cell bodies in the abdominal segments of late stage 16 (hour 14-16) embryos. In wild type embryos, the RP3 growth cone innervates along the cleft between two specific muscles (muscle 6 and 7). Muscles 6 and 7 normally express Toll during early embryogenesis, but no protein is detectable in either muscle beyond hour 12, 2 hours before RP3 reaches them. In *Mhc'-Toll* transformant flies, which continue to express Toll throughout motoneuron outgrowth, RP3 growth cone still reaches the target area normally but fails to innervate the 6/7 cleft in about half of the observed cases. These results suggest that heterochronically misexpressed Toll can act as a cell surface recognition molecule which prevents normal RP3 innervation of the 6/7 cleft. Toll's extracellular domain contains leucine-rich repeats, domains found in other proteins which are thought to mediate protein-protein interaction, providing further support that Toll may directly bind to and signal passing growth cones. We propose that Toll can act locally to affect synaptogenesis and furthermore, temporal regulation of Toll expression is important in shaping *Drosophila* neuroarchitecture. THALAMOCORTICAL AXONS EXPRESS THE MATRIX METALLOPROTEASE MATRILYSIN DURING OUTGROWTH THROUGH THE EXTRACELLULAR MATRIX-RICH SUBPLATE. C. P. Ludwig[1]*, J. E. Brunstrom[2], H. G. Welgus[3], and A. L. Pearlman[1,2]. Depts. of Cell Biology[1], Neurology[2], and Dermatology[3], Washington Univ. Sch. Med., St. Louis, MO, 63110.

Matrix metalloproteases (MMPs) have been shown to play important roles in developmental and pathological invasion of extracellular matrix (ECM) by non-neuronal cells. In the nervous system, PNS neurites use metalloproteases to invade ECM *in vitro*, but a role for MMPs in the developing CNS has not been clearly demonstrated. To determine whether MMPs could be involved in CNS neurite outgrowth, we examined the expression of matrilysin (MMP-7) during CNS development. *In vitro*, matrilysin digests proteoglycans, laminin, and fibronectin, three ECM components that are also found in the developing CNS. Affinity purified antiserum raised against a synthetic peptide corresponding to amino acids 93-108 of human matrilysin (Busiek et al. 1992, J. Biol. Chem. 267: 9087-9092) was applied to cryostat sections of various mouse tissues and detected by immunofluorescence. Matrilysin immunoreactivity is intense along axons in the proteoglycan-rich thalamocortical pathway subjacent to neocortical subplate cells but is not present in cortical efferents that grow outside this pathway. Immunolabeling of these axons is blocked by a synthetic peptide corresponding to the equivalent region of rat matrilysin. Additionally, in agreement with previous reports, immunoreactivity is also present in epithelial cells of the postpartum mouse uterus and epidermal cells of embryonic skin. Finally, anti-matrilysin antiserum raised against the rat sequence synthetic peptide labels bands at the expected molecular weights for matrilysin on western blots of embryonic mouse brain and postpartum uterus. The expression of matrilysin by selected CNS neurons during development suggests that it has a role in the outgrowth of specific fiber tracts. (Supported by NSF Graduate Fellowship, NEI, and NINDS)

AXON GUIDANCE MECHANISMS AND PATHWAYS: OUTGROWTH PATTERNS

677.1

SPECIFIC PROJECTIONS OF SYMPATHETIC PREGANGLIONIC NEURONS ARE NOT INTRINSICALLY DETERMINED AT BIRTH. J. W. Yip*, Y. P. L. Yip and C. Capriotti. Dept. of Neurobiology, University of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261

Sympathetic preganglionic projections of the chick are segmentally-specific. Neurons from the C16 and T1 spinal cord segments project almost exclusively in the rostral direction, while those from the T5 to L1 spinal segments project almost exclusively in the caudal direction. Intervening spinal levels (T2-T4) show rostral as well as caudal projections. There is also a tendency for rostrally-located neurons in each segment to project rostrally, and caudally-located neurons to project caudally.

The majority of chick preganglionic neurons are born between stages 16 and 24. In this study, neural tube segments were transplanted in embryos at stages 24-26 - after preganglionic cell birth and just before axon outgrowth. When the T1 neural tube segment was replaced with the T5 neural tube segment, the transplanted T5 preganglionic neurons, now in the T1 position, projected rostrally. Conversely, when the T5 neural tube segment was replaced with the T1 neural tube, the transplanted T1 preganglionic neurons projected caudally. In addition, individual T2 or T3 spinal cord segments were rotated 180^0 along the A-P axis. Neurons which were originally in the caudal part of the segment, now project rostrally, whereas neurons originally from the rostral part of the segment project caudally. These results show that the direction of preganglionic projections is not intrinsically determined at birth. Since translocated neurons encounter novel environments and project in directions appropriate to their new locations, these results also suggest that preganglionic projections are influenced by factors in the tissue environment outside of the spinal cord. (Supported by NS 23916)

677.2

EARLY OUTGROWTH OF SYMPATHETIC PREGANGLIONIC AXONS IN THE CHICK Y. P. L. Yip*, J. W. Yip and C. Capriotti. Dept. of Neurobiology, University of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261

Preganglionic neurons in the chick embryo are located from the C16 spinal level through the L1 spinal level. The projection pattern of these neurons is segmentally specific. Preganglionic neurons from rostral levels (C16 and T1) project predominantly rostrally in the sympathetic chain, whereas preganglionic neurons from caudal levels (T6-L1) project predominantly caudally. Intervening spinal levels (T2-T5) show rostral as well as caudal projections. Moreover, within each of these segments, rostrally-located neurons tend to project rostrally and caudally located-neurons tend to project caudally. To gain some insight into the mechanisms underlying the formation of this specific projection pattern, preganglionic axon behavior during early outgrowth was studied.

The spatio-temporal pattern of preganglionic projections from multiple spinal cord segments of the same embryo was examined by retrograde labeling with various lypophilic dyes. Projections from a small number of neurons were further examined by orthograde labeling with HRP. The number of rostral and caudal projecting neurons from single spinal cord segments at early developmental stages was determined by retrograde labeling with fluorescent dextran amines.

Our results show that initial outgrowth of preganglionic neurons into the sympathetic trunk proceeds in a rostral to caudal sequence. In addition, within individual segments, initial axon outgrowth into the sympathetic trunk tends to be in the rostral direction - even in caudal segments. Subsequent development shows that neurons from the rostral (C16&T1) and caudal (T7&L1) ends of the preganglionic cell column project at rates and distances considerably greater than their counterparts from midthoracic segments. These results are important for the identification of guidance mechanisms. (Supported by NS 23916)

677.3

THE ROLE OF CHONDROITIN SULFATE PROTEOGLYCANS IN THE AVOIDANCE OF EPIDERMIS BY CHICK DORSAL ROOT GANGLIA *IN VITRO*. S.M. Cahoon, G.C. Schoenwolf*, and S.A. Scott. Dept. of Neurobiology & Anatomy, University of Utah School of Medicine, Salt Lake City, UT 84132.

During embryonic development in chick embryos, sensory neurons innervate the dermis of the skin but not the epidermis. It has been suggested that axons are inhibited from invading epidermis by a diffusible molecule, most likely a chondroitin sulfate proteoglycan (CS-PG) (Fichard et al., '91; see also Honig & Zou, '95). Epidermis expresses CS-PG *in vivo* and *in vitro* (Hemming et al., '94), and releases CS-PG *in vitro* (Fichard et al., '91). Moreover, CS-PG inhibits sensory neurite outgrowth in culture (Snow et al., '90). In previous studies using trigeminal sensory neurons, we seldom saw neurites turn away from epidermis at a distance, as expected for a diffusible chemorepellant, although they often retracted upon contacting epidermis (Woodbury & Scott, '95). Therefore, we began to examine whether secreted CS-PG alone is responsible for failure of sensory neurons to innervate epidermis. In control co-cultures of E7 (St. 27-28) chick epidermis and dorsal root ganglia (DRG), neurites usually, but not always, failed to grow onto epidermis. Similarly, neurites did not grow onto epidermis that had been killed by fixation. Other treatments, such as killing the epidermis with UV irradiation, air drying or freezing, allowed some growth of neurites onto the explant, but not as much as expected if inhibition were completely eliminated. Thus, diffusible factors are not essential for avoidance of chick epidermis by DRG neurites *in vitro*. Additionally, neurites failed to grow onto epidermis in the presence of function blocking anti-CS antibody (CS-56) or chondroitinase ABC (Sigma C2905). Together these results suggest that, in addition to secreted CS-PG, other factors contribute to the avoidance of epidermis by DRG neurites. A likely possibility is that epidermis may lack factors that are attractive or permissive for neurite growth. Supported by NS16067 to SAS.

TISSUE INTERACTIONS AFFECTING THE NEURITE GROWTH FROM THE EARLY DEVELOPING DORSAL ROOT GANGLION. T.Shiga* and K.Nakamoto. Dept. of Anat., Inst. of Basic Med. Sci., Univ. of Tsukuba, Tsukuba 305, Japan.

To elucidate the mechanism regulating the ingrowth of primary afferent axons into the entry zone of the spinal cord, we examined tissue interactions which affect the neurite growth from dorsal root ganglion (DRG). Using three dimensional collagen gels, we cocultured DRG of embryonic day 3.5 (E3.5) chick embryos with E3 spinal cord, E3 notochord or E3 dermamyotome. The ventral spinal cord, notochord, and dermamyotome, to none of which early developing primary afferents project, repelled DRG neurites. In contrast, the dorsal spinal cord which includes the entry zone faintly repelled DRG neurites. The putative repellent may be diffusible, because the repelling activity was observed without direct contacts between DRG neurites and other tissues. The heterochronic culture showed that E3 notochord repelled E9 DRG neurites, whereas E3 ventral spinal cord did not, suggesting that E3 notochord and ventral spinal cord secrete different repellents. Supported by Grant-in-aid from Japanese Ministry of Education, Science, Sports and Culture.

PERIPHERAL TARGET SELECTIVITY AND PATTERNING OF PRIMARY SENSORY AXONS IN HETEROTYPIC COCULTURES. E. Ulupinar* and R.S. Erzurumlu. Dept. of Anatomy, LSU Medical Center, New Orleans, LA 70112.

Primary sensory neurons of the dorsal root ganglia (DRG) and their cranial homologues innervate appropriate peripheral target fields from the onset in development. We used explant cocultures to examine target preference and target-derived influences on axonal patterning. Embryonic day15 rat trigeminal ganglion (TG) and cervical DRG explants were cocultured with the same age whisker pad (trigeminal field), fore paw (DRG field) and heart (foreign tissue) explants in serum free medium. After 5 days *in vitro* the cultures were fixed and labeled with the lipophilic tracer DiI to analyze axon growth patterns.

Given a choice of two cutaneous and a foreign target DRG and TG axons grow into the whisker pad > fore paw > heart explants. In the whisker pad both DRG and TG axons heavily fasciculate between follicle rows and form distinct arboreal patterns around follicles. Sensory axons enter the fore paw explants in thick fascicles then emit short but dense arbors. Very little or no axon growth is present in the heart tissue. Often axon bundles go around the heart without entering it. Occasionally thin fascicles of axons extend into the heart and form sparse arbors. When TG or DRG explant is placed between a central (brainstem) and any of the three peripheral targets, axon growth vigor and patterns are the same as that seen in 3-choice cocultures. Thus, DRG and TG axons are equally capable of growing into each others' target fields regardless of the presence of a central neural target. They also show limited growth capacity into noncutaneous tissue. Our results also suggest that target-derived trophic influences and cues regulate sensory axon density and patterning. *Supported by NIH (NS32195)*

677.6

SELECTIVE FASCICULATION OF MOTOR AXONS INNERVATING FAST AND SLOW REGIONS OF INDIVIDUAL CHICK MUSCLES. L.D.Milner, V.F.Rafuse*, L.T.Landmesser. Department of Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

While it is well established that fast and slow muscle fibers are innervated by their appropriate class of motoneurons, it is not understood how this specificity is established. Recent evidence in the chick hindlimb suggests that fast/slow matching occurs early in development as ingrowing motor axons first innervate their targets. To further elucidate the mechanisms regulating this selectivity we took advantage of the fact that chick fast and slow myofibers are segregated into discrete muscle regions. Lipophilic dyes were used to retrogradely label the axons projecting to the fast and slow regions of the iliofibularis (IFIB) muscle between stages 30-36. We found that, as IFIB axons from different spinal nerves first converge in the plexus to form a muscle-specific fascicle, those projecting to the fast and slow regions segregate from one another. These fascicles remain distinct in the sciatic nerve until they branch to selectively innervate the fast or slow muscle regions. This data strongly suggests that from early stages of outgrowth axons possess distinctive cell surface cues which enable them to selectively fasciculate. We are currently exploring whether innervation to other muscles is similarly organized and whether this selective fasciculation plays a critical role in ensuring proper motoneuron pathfinding and target selection.

Supported by NINDS grant NS 19640; V.F.R. is funded by the Rick Hansen Man in Motion Legacy Foundation.

677.7

SPINAL AXON PATHS IN TAIL-TO-TAIL GRAFTS IN XENOPUS EMBRYOS SUGGEST THAT AXONS RECOGNIZE EACH OTHER'S PROXIMODISTAL POLARITY. S-X. Liu and R.H. Nordlander*. Dept. Oral Biol., Ohio State Univ. Columbus, OH 43210.

Experiments in our laboratory (J.Neurobiol., 4:490-502) have indicated that in young Xenopus embryos (st.22-24) with implanted spinal cord grafts of reversed A-P polarity, axons of one identified ascending neuron, the KA cell, are able to realign so that their courses match those of the host. KA axons make U-turns near graft-host interfaces, but these turns rarely involve direct contact between KA axons. To begin sorting out factors influenc-ing KA axon behavior, we made tail-to-tail grafts in the early embryo so that we could assess the behavior of KA axons as they approach and enter tissue which is identical except for its A-P polarity.

Nearly half of the KA axons of these grafts passed from one tail to the other without deviation, entering the opposite tail in the usual position. However, in others, KA axons from one side seemed to deflect those of the other just before they met at the graft seam, or, where the axons from one tail were more advanced than those of the other, the faster-growing axons approached and deflected axons of their slower counterparts in the tail. The patterns of these deflections suggest that KA axons from one tail are able to sense the proximodistal polarity of KA axons of the other, and that axons often make wide turns taking parallel, but ectopic pathways, even if this takes them out of their usual pathway.

Supported by NIH NS18773 to RHN.

677.8

MUSCLE SENSORY INNERVATION PATTERNS IN EMBRYONIC CHICK HINDLIMBS FOLLOWING DORSAL ROOT GANGLIA REVERSAL. GY. Wang* and S. A. Scott. Dept. of Neurobiology & Anatomy, University of Utah School of Medicine, Salt Lake City, UT 84132.

During embryonic development sensory and motor innervation patterns are established precisely from the outset. Previous studies suggest that sensory innervation of muscle may be patterned by the motor innervation. Muscle afferents require, and appear to follow, motor axons in the limb, mimicking motor projections after several types of surgical manipulations. It is not known, however, whether muscle afferents are specified with respect to the corresponding motoneurons or target muscles. To investigate these possibilities we created mismatches between the rostrocaudal origin of hindlimb dorsal root ganglia (DRG) and motoneurons at the same segmental level by rotating 3-4 segments of neural crest and dorsal neural tube in St.15-17 chick embryos, leaving motoneurons intact. This reversed the rostrocaudal order of DRG T7/LS1-LS3, causing sensory neurons derived from one segmental level to grow into the limb with motor axons from a different level. In some embryos we confirmed the origin of DRG from rotated neural crest by labeling crest with DiI prior to rotation. Innervation patterns were mapped at St. 30-37, by injecting DiI and DiA into the sartorius and femorotibialis muscles, or into the spinal cord and DRG. In most operated embryos muscle afferents grew to muscles in accord with their new position, following motor axons from the same segment. These results suggest that neural crest cells are not specified with respect to motoneurons or target muscles prior to aggregation into DRG. We are now testing whether specification occurs later, after DRG coalescence, by rotating the entire neural tube including the motoneurons at St. 20-21, when most neural crest migration is complete. In these embryos, DRG develop in their usual positions, but encounter motor axons derived from a different segmental level. Supported by NS16067 to SAS.

677.9

INTERACTIONS OF SENSORY NEURONS IN THE EMBRYONIC AVIAN TRIGEMINAL SYSTEM WITH HINDBRAIN MOTONEURONS. S. A. Scott*. Dept. of Neurobiology & Anatomy, University of Utah School of Medicine, Salt Lake City, UT 84132.

During embryonic development muscle afferents from the trigeminal mesencephalic nucleus (TMN, mesV) grow to the periphery with trigeminal (V) motoneurons, and not with other sensory axons from the trigeminal ganglion (TG) (Covell & Noden, '89). TG afferents, in contrast to TMN axons, do not directly contact V motoneurons. TG neurons do, however, affect the lateral migration and early outgrowth of V motoneurons (Moody and Heaton, '83). We have begun to investigate whether these patterns of outgrowth observed *in vivo* reflect selective affinities between TMN neurons and V motoneurons that can be detected *in vitro*. As a first approach, explants of rhombomeres 2 and 3 (r2/3) from St.21-22 chick embryos, containing V motoneurons that have not yet migrated laterally, were grown *in vitro*. The next day we added explants of TMN or dorsomedial TG (DM-TG) from St.26 embryos, a stage when DM-TG neurons are withdrawing from the cell cycle (D'Amico-Martel & Noden, '80) and when most TMN neurons have not yet reached their peripheral targets (von Bartheld & Bothwell, '93). One day later cultures were fixed and explants were labeled with DiI and/or DiA. In most cultures both TMN and DM-TG neurites appeared to intermix freely with neurites from r2/3, with little evidence of selective fasciculation or avoidance. There were no obvious differences in the length or density of sensory neurites that mingled with neurites from r2/3, and those that grew on the substrate, away from the r2/3 explants. Nor were there differences between the growth of TMN or DM-TG neurites on neurites from r2/3 compared with their growth on neurites from r4/5, which give rise to facial motoneurons. These preliminary results, if supported by other assays, suggest that the selective association of TMN axons with V motoneurons *in vivo* may be brought about more by spatial constraints or diffusible signals, rather than selective fasciculation. Supported by NS16067.

677.10

DEVELOPMENTAL PATTERN OF ROHON-BEARD CELL PERIPHERAL ARBOR OUTGROWTH IN THE ZEBRAFISH. Beth A. Sipple and Paul Z. Myers*, Dept. of Biology, Temple University, Philadelphia, PA 19122

The Rohon-Beard cell of the zebrafish embryo is a primary sensory neuron that sends out peripheral axons which form an elaborate network. This peripheral arbor is formed by the crossing and branching of numerous neurites. The zn-12 antibody, which selectively stains for Rohon-Beard cells and trigeminal ganglion at early developmental stages, has allowed us to measure a standard timecourse for growth cone outgrowth and the development of complexity. There is no evidence of a rostro-caudal gradient of outgrowth; however, there are at least three general regions with different timecourses of outgrowth. Between 19 and 20 hours of development, outgrowth is seen rostrally (between somites 1 and 8) with scattered outgrowth along the trunk. The majority of outgrowth along the trunk (between somites 9 and 20) occurs between 20 and 23 hours. Within the tail (somites >20), growth cones emerge after 24 hours. Live fluorescent labeling with lineage tracer dyes allows time lapse microscopy of the developmental events described above, as well as growth cone behaviors at the ventral midline.

The sensory function of the Rohon-Beard cell is taken over by the dorsal root ganglia at approximately 3-4 days of development. Observations of DRG development allow us to draw comparisons with Rohon-Beard development and function.

As zebrafish embryos develop they begin to express a spontaneous twitching behavior. We have been using a motion analysis program to form a standard map of this early behavior from 19 to 48 hours of development. The twitch rate increases between 19 and 20 hours, when it reaches a plateau. At 29 to 30 hours, the rate decreases drastically and levels off to 3-4 twitches/min. This occurrence is most likely due to inhibitory influences coming from interneurons and reticulospinal neurons. Using this standard model for normal behavior in conjunction with tactile stimulation, we can determine at what stage during development the Rohon-Beard peripheral arbor becomes a functional sensory system.

677.11

MUTATIONS AFFECTING MOTONEURONAL PATHFINDING IN EMBRYONIC ZEBRAFISH. C.E. Beattie* and J.S. Eisen. Institute of Neuroscience, University of Oregon, Eugene OR 97403.

During zebrafish development, individually identified primary motoneurons innervate unique myotome regions. Normally the axons of these motoneurons leave the spinal cord, extend along a common pathway and then diverge along separate cell-specific pathways on the myotome. To identify the molecular mechanisms involved in these pathfinding events, we have undertaken a mutagenesis screen. Progeny of zebrafish containing germline mutations induced by exposure to N-ethyl-N-nitrosourea were screened with antibodies that recognize motoneuronal cell bodies and axons. Several mutations have been recovered that specifically affect the ability of these motoneurons to undergo correct pathfinding. One mutation, *stumpy*, affects a single identified primary motoneuron, CaP. In *stumpy* embryos, CaP extends an axon along the common pathway but fails to extend an axon on its cell-specific pathway. Genetic mosaic experiments reveal that this mutation disrupts a gene acting cell-autonomously in CaP. Another mutation, *topped*, also affects the ability of CaP to extend along its cell-specific pathway but acts at a different locus. In a third mutation, *split ends*, primary motor axons are disorganized and grow in inappropriate myotome regions. This collection of mutations will allow us to examine both cellular and molecular aspects of motoneuronal pathfinding. Supported by ACS PF-3982, NS23915 and NS01476.

EXPRESSION OF THE NEUROFILAMENT PROTEINS, PLASTICIN AND GEFILTIN, IN THE DEVELOPING ZEBRAFISH VISUAL PATHWAY. A.K. Canger, D. Leake, W.S. Asch, E. Glasgow, and N. Schechter*. Departs. of Biochemistry & Cell Biology and Psychiatry, State University of New York at Stony Brook, N.Y. 11794

The expression of the neurofilament proteins, plasticin and gefiltin, is linked to the development and growth of goldfish retinal ganglion cell (RGC) axons. In the adult retina, histological and biochemical results show that plasticin is expressed in young RGCs at the retinal margin, whereas gefiltin is constituitively expressed in all RGCs. After optic nerve injury and during regeneration, all RGCs show dramatic increases in the expression of plasticin mRNA, followed by an increase in gefiltin mRNA. Thus, plasticin and gefiltin expression are correlated with successive stages of RGC axonal growth.

The zebrafish embryo is best suited for determining the relationship between visual pathway development and the structure and function of these proteins. We isolated cDNA and genomic clones for zebrafish plasticin and gefiltin. Their predicted amino acid sequences show that they are highly homologous to the goldfish proteins. RNAse protection assays show that plasticin mRNA is expressed throughout the period of retinal development. Immunohistochemically, plasticin is localized to presumptive neurons as early as 14 hpf and labels selective subsets of PNS and CNS neurons at 22, 24, and 42 hpf. Furthermore, the antibody strikingly labels the zebrafish optic nerve and tract at 42 hpf. This early expression of plasticin is consistent with the hypothesis that this neurofilament protein supports early stages of axonogenesis in which a highly plastic cytoskeleton is required for the changing morphology of the developing axon. AXON GUIDANCE OF CEREBELLAR AND HIPPOCAMPAL NEURONS IN CULTURE BY STEP-GRADIENT FORMED OF SUBSTRATE-BOUND NEURITE-OUTGROWTH DOMAIN OF LAMININ. M. Matsuzawa[1]* and P. Liesi[2] 1. Team of Exotic Nanomaterials, FRP, RIKEN, Saitama, 351-01 Japan 2. Lab of Molecular and Cellular Biology, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852 USA

We investigated the effect of step-gradients formed of substrate-bound neurite-outgrowth domain of laminin on the morphological development and neurite outgrowth of both cerebellar and hippocampal neurons in culture. Patterns of parallel lines (step-gradients), having a variety of line widths and line spaces, were formed on glass substrates using a synthetic peptide derived from a neurite outgrowth domain of laminin via a photo-masking technique and silane chemistry. Cerebellar and hippocampal neurons were dissected from embryonic rats and grown on the substrates at low density in chemically defined media. During the early stage in culture (< 1 day), both cerebellar and hippocampal neurons extended neuritic processes along the patterned lines. After 24- hours in culture, the patterned hippocampal neurons started to extend multiple processes, where as the cerebellar neurons maintained a bipolar neuronal morphology. Interestingly, the hippocampal neurons extended their processes, especially longer processes, in a manner by reflecting the surface patterns. The majority of cerebellar neurons also followed the patterned lines although a small number of cells grew off the lines. Our results directly show that growing neurites, putatively axonal processes, possess an ability of detecting step-gradients formed by a neurite-outgrowth domain of the B2 chain of laminin, implying a role of such molecule in axon guidance.

INVESTIGATING THE MECHANISM FOR CONTACT GUIDANCE OF CNS GROWTH CONES. Ann M. Rajnicek* and C.D. McCaig. Department of Biomedical Sciences, University of Aberdeen, Aberdeen, Scotland, AB9 1AS.

Guidance of growth cones by substratum contours may influence pattern formation of the nervous system. Amphibian and mammalian CNS neurites respond orthogonally to identical arrays of parallel grooves and ridges: *Xenopus* spinal neurites grow parallel and rat hippocampal neurites grow at right angles to them (Rajnicek *et al.*, 1995. *Soc. Neurosci Abstr.* 21(1): 796). The cellular mechanism for sensing surface contours and translating them into directional growth are not understood. We have investigated the mechanism for contact guidance of CNS neurites.

Neurites were grown on quartz slides etched with a pattern of parallel, evenly spaced grooves and ridges. Neurite orientation was determined by measuring the angle (relative to the grooves) of a line connecting the neurite initiation site on the soma to the growth cone. Angles between 0 and 30° were categorized as "parallel" and angles between 60 and 90° were "perpendicular". Every neurite was assessed on *Xenopus* neurons but only the longest neurite on hippocampal neurons.

The influence on orientation of inhibitors of intracellular signalling pathways was assessed for neurons growing on grooves 130 nm deep x 1 um wide. These included the voltage-gated calcium channel blocker flunarizine (5uM), the G protein inhibitor pertussis toxin (500 and 800 ng/ml), the B oligomer of pertussis toxin (660 ng/ml) and cholera toxin (100 and 500 ng/ml), which stimulates adenylate cyclase activity. None of these drugs altered the perpendicular orientation of hippocampal neurites. Perpendicular orientation was also not affected by cytochalasin B (25 and 50 ng/ml), which eliminates filopodia.

COMPUTER SIMULATION OF ENVIRONMENTAL EFFECTS ON NEURITE OUTGROWTH. R.J. Podhajsky*. Division of Neurosurgery, University of North Carolina at Chapel Hill, NC 27599.

The local neural environment presented to an elongating neurite has been mathematically modeled to obtain simulations and visualizations that suggest possible mechanistic interactions that account for the permissive regeneration of the PNS and the abortive regeneration in the CNS. The model includes the interrelated activities of diffusible chemoattractants and chemorepellents as well as cell membrane bound repulsive and attractive cues. The model was governed by a reaction-diffusion algorithm used previously to simulate the biological activities of Wallerian degeneration, fibrin matrix development, glial cell activity, elongating neurites and vascularization in the process of peripheral nerve regeneration following crush and transection injuries (*J. Neurosci. Methods*, 60:79-88, 1995). In this present model, a two-dimensional labyrinth was defined with obstacles representing glial cells with either adhesive or repulsive boundaries. Chemoattractants and chemorepellents were then diffused into the labyrinth and represented basins of attraction and domes of repulsion, respectively, for outgrowing neurites. An algorithm to find optimal pathways in complex labyrinths (Steinbock et al. *Science*, 267:868-871, 1995) was used to simulate neurite outgrowth. The resultant simulations suggest the importance of glial orientation in relation to the source of chemotropic agents and neurites, and implicate the extracellular matrix as a major role player in the formation of a glial scar. INFLUENCING NEURONAL GROWTH WITH MULTIBIOMOLECULE PATTERNED SUBSTRATES J.M. Corey* (1), M.S. Chen (2), A.L. Brunette (2), D.W. Branch (3), J.A. Weyhenmeyer (1), B.C. Wheeler (1), and G.J. Brewer (4). 1. Neuroscience Program, 2. Department of Biology, 3. Department of Biophysics, University of Illinois at Urbana-Champaign, IL 61801 and 4. Dept. of Medical Microbiology and Immunology, Southern Illinois University School of Medicine, Springfield, IL, 62702.

Our laboratories have been developing techniques to localize the somata and neurites of developing hippocampal neurons to a pattern of circular nodes connected by narrow lines (Corey et al., *IEEE Trans. Biomed. Engr.*, in press.). This has been implemented in the past by producing cytophilic nodes and lines of aminosilanes or polylysine on a glass or phenylsilane background using laser and photoresist techniques. In order to increase the utility of patterned substrates, we have adapted a microstamping technique whereby the sequential deposition of proteins and polyaminoacids is spatially controlled. Polydimethylsiloxane stamps were fabricated essentially according to the method of Whitesides and colleagues (Singhvi et al., *Science*, 264: 696-8). A titanium pattern was produced on the glass substrate for alignment purposes. Extracellular matrix proteins or polylysine were adsorbed to the stamps and transferred to the substrates by contact printing. A mask aligner was used to sequentially stamp patterns of proteins. Hippocampal neurons from 18-day rat embryos were grown at 200 cells/mm^2 in serum-free Neurobasal/B27 medium. B104 cells, generously provided by Dr. David Schubert of the Salk Institute, were grown in DMEM with serum and differentiated with dibutyrylcyclic AMP in the absence of serum. Using the technique described above, we have controlled the localization of cell bodies and neurites of embryonic rat hippocampal neurons and differentiated B104 neuroblasts on substrates having at least two of a variety of extracellular matrix components and polylysine. Supported in part by PHS Training Grant 2P32HDO7333 and NSF Grant IBN 9320158.

FILOPODIAL AND LAMELLAR BEHAVIOR DURING GROWTH CONE-NERVE FIBER INTERACTIONS. E. D. Pollack* and G. Gallo. Dept. of Biological Sci., University of Illinois at Chicago, Chicago, IL 60607.

Interactions between growth cones and nerve fibers are believed to have a role in the establishment of neuronal projections during development. The response of growth cones of spinal cord explant neuritic outgrowth to spinal nerve fibers of the same explant of larval Rana pipiens was investigated in order to characterize the type of lamellar and filopodial behaviors exhibited. A variety of growth cone responses to contact were observed. The interactions of 21 growth cones with nerve fibers were followed for a period of one hour following initial contact. In 13 of these, growth cones lost lamelliform morphology, although the initial filopodial contact was maintained as growth cone collapse occurred. Loss of growth cone lamellar morphology in 39% of interactions occurred by a breaking up of the initially fan shaped lamella (lamellar break up), resulting in multiple smaller lamellae which eventually collapsed. During this process, individual filopodia were noted to give rise to small, transient, lamellae along their shaft (filopodial spreading). In 31% of interactions resulting in the loss of growth cone lamellae, filopodia were observed to pull on the contacted nerve fiber. Lamellae aligned themselves with the contacted nerve fiber (lamellar alignment) in 31% of interactions resulting in growth cone collapse. During the remaining 8 interactions, growth cones exhibited either no change in lamellar area or a temporary loss of less than 50% of the initial lamellar expanse during the interaction. Neither filopodial spreading nor pulling was observed during such interactions. However, in 75% of these interactions lamellar alignment occurred. Although in 63% of interactions not resulting in growth cone collapse fan-shaped lamellae did undergo periods of temporary lamellar break up, no loss of lamellar area resulted from this. All growth cones not undergoing loss of lamellar structures underwent growth during the interaction, while growth was halted in all interactions resulting in the loss of growth cone morphology. Our observations suggest that prolonged adhesive filopodial contacts with nerve fibers are associated with guidance cues resulting in growth cone collapse. SUBSTRATE PREFERENCE OF OLFACTORY RECEPTOR CELL NEURITES *in vitro*. K. W. Kafitz* and C. A. Greer, Sect. of Neurosurgery and Neurobiology, Yale Univ., Sch. Med., New Haven, CT 06510.

Prior studies have shown a differential expression of the extracellular matrix molecule (ECM) laminin (LN) in the olfactory pathway during development (Kafitz & Greer, '95; Schwarting et al., '96). This suggested that LN may contribute to the outgrowth of axons from olfactory receptor cells (ORCs). These findings have led to the hypothesis that in addition to its role in ORC migration (Calof and Lander, '91) LN may also provide a favorable substrate for neurite extension from ORCs. To test this hypothesis we developed an *in vitro* assay in which the substrate preference of neurites extending from ORCs can be quantified. ORCs harvested from the olfactory epithelium (OE) and OE explants of E14 rat embryos were cultured for 48 hrs. on coverslips coated with either poly-L-lysine (PLL), or PLL with a complete overlay of LN (P-LN), or PLL overlaid with 5 mm zones of LN (P-ZLN). Analyses were conducted on cells immunoreactive to OMP (generously provided by Dr. F. Margolis) and NSE. Primary neurites extended from OMP-positive neurons were 52 % longer on P-LN and P-ZLN compared to PLL. Control experiments showed this was not influenced by the density of cells on LN vs. PLL. Of ORCs located in a 35 µm wide area surrounding a LN zone, 56.33 % extended a primary neurite onto LN. In contrast, only 6.61 % of all ORCs located in the corresponding area within a LN zone extended a neurite onto PLL. LN also supported the fasciculation of subsets of ORCs in the explant experiments. The extension of the secondary neurite was not influenced by LN. In summary, the data support the hypothesis that LN provides a favorable substrate for the extension of the primary neurite of differentiated ORCs. We are currently exploring the influence of further simultaneously offered substrates on neurite extension from ORCs and possible mechanisms that may underlie the effects described.

POLARIZED RADIAL GLIA DIFFERENTIALLY AFFECTS AXONAL VERSUS DENDRITIC OUTGROWTH. B. Schlosshauer* H. Bauch and H. Stier. *Naturwissenschaftliches und Medizinisches Institut an der Universität Tübingen (NMI), 72762 Reutlingen, FRG.*

During development retinal ganglion cells of the chicken establish cell polarity in a spatiotemporal fashion. After extending axons towards the inner retina surface, dendrites grow out in the opposite direction (outer retina).
In order to analyse the guiding mechanisms of neuritic outgrowth, novel culture systems were developed. Ganglion cells were purified by an enzymatically facilitated detachment procedure. Isolated ganglion cells were cultured on cryostat sections of embryonic retinae, exposing the cells to the microenvironment of different tissue layers (cryoculture). Outer retina layers hampered axonal outgrowth, but stimulated dendritic growth. In contrast, the inner retina layer supported axonal growth. To investigate different cell compartments of radial glia as potential guiding cue, glial endfeet located in the inner retina were isolated by a physical detachment procedure. Glial somata were purified by complement/antibody-mediated lysis of nonglial cells. When both fractions were used as substrata for ganglion cells, dendritic growth was preferentially initiated on glial somata, whereas axonal growth was observed on glial endfeet. Time lapse video recording revealed that purified membranes of glial somata induced a growth cone collapse of axons in contrast to membranes of glial endfeet.
The data indicate that in contrast to endfeet, somata of radial glial cells are permissive for dendrites but inhibitory for axons. Consequently, polarized radial glia is likely to affect the development of the neuronal cytoarchitecture by differential neuron-glia cell interactions. Funded by DFG.

COMMITMENT OF IMMORTALIZED OLFACTORY NEUROBLASTS TO APOPTOSIS OR DIFFERENTIATION BY DOPAMINE IN VITRO. V. Coronas(1)*, F. Féron(1), R. Hen(2), G. Sicard(1), F. Jourdan(1), E. Moyse(1). Lab. Neurosciences et Olfaction, Univ.Lyon1-CNRS, F-69622 Villeurbanne;(2) LGME, UPR6520 CNRS, Univ.Strasbourg1, F67404 Illkirch.

Odorant-receptive sensory neurons of adult Mammals spontaneously die and are renewed throughout life by proliferation of progenitor cells located in the olfactory epithelium. Neuronal differenciation of progenies involves axon elongation and synaptic connection to olfactory bulb neurons within the glomerular layer, neuropil of which is circumscribed by numerous dopaminergic interneurons (A16 cell group) and contain an high density of D2 receptors. Dopamine might therefore affect differentiating sensory neurons since D2- and D3-mediated effects on axon elongation, branching and connectivity have been reported on neuronal cell lines.

We assessed here the influence of dopamine on proliferation and differentiation of the 13.S.1.24 line of rat olfactory cells immortalized with a retroviral vector of the E1A oncogen. Transformed cells, maintained alive in DMEM containing 10% fetal calf serum, displayed undifferentiated, epithelioid morphology while proliferating. Addition of 20µM DA in the medium induced within 2-3 days both decrease of cell survival (50-75% of control) and differentiation of surviving cells into a bipolar phenotype; most of differentiated cells contained immunoreactive Olfactory Marker Protein;that is specifically expressed by mature olfactory neurons in vivo. DNA extracts of DA-treated cell cultures yielded electrophoretic ladders typical of apoptosis. DA-induced death and differentiation of 13.S.1.24 cells were both blocked by co-treatment with the D2-selective antagonist eticlopride at 10nM. Differentiation of 13.S.1.24 cells was not obtained by mere decrease of initial plating density.

These data demonstrate that DA triggers apoptosis or differentiation of immortalized olfactory cells via D2 receptors.

NEUROTRANSMITTERS PROTECT BRAIN NEURONS FROM CELL DEATH IN SERUM-DEPRIVED LOW DENSITY CULTURES. N.D. Stull* and L. Iacovitti Dept. of Neurobiology and Anatomy, MCP and Hahnemann University, Philadelphia, PA.

Neurotransmitters are thought to play a number of critical roles in development as morphological and biochemical differentiators of the nervous system. In this study, we sought to determine whether neurotransmitters also act as trophic agents, improving the survival of growth factor-deprived neurons. To do so, cultures of E13 striatum or cerebral cortex were established at low density (50,000 cells/20mm^2) and maintained on defined media (DM) in the presence or absence of added dopamine (DA), norepinephrine (NE), serotonin (5HT), GABA or Dopac (10-100µM). Unlike high density cultures where neurons survived indefinitely on DM, in low density cultures, almost all neurons were dead or dying by 3-4 days, presumably due to growth factor deprivation. Supplementation of low density cultures with 10µM DA, NE, 5HT or GABA (but not Dopac) rescued nearly all neurons from imminent cell death. This effect was mimicked by 40mM KCl. Since glia were absent from the culture, improved survival resulted from a direct effect on the neurons. Interestingly, only a brief exposure (24hrs) to neurotransmitter early in the culture period (day 1) was sufficient to postpone the onset of cell death from day 3 until day 6. We conclude that depolarization by neurotransmitters or KCl rescues brain neurons from the cell death that inevitably occurs in long term low density cultures grown in the absence of added growth factors. Although we do not yet know the underlying mechanisms, it is possible that neural activity, even transiently, signals an up-regulation in intrinsic growth factors resulting in improved survival. (Supported by NIH NS 32519).

CONDITIONING STRESS IN NEURONS: RELATIONSHIP TO PROTEIN SYNTHESIS, HSP 70 SYNTHESIS AND CELL SURVIVAL, R.N. Nishimura*, B.E. Dwyer[1], S.-T. Fu and D.G. Santos. Molecular Neurobiology Laboratory, VA/UCLA Medical Center, Sepulveda, CA 91343; Molecular Neurobiology Laboratory, VA Medical Center, White River Jct., VT 05009 and Dartmouth Medical School, Hanover, NH 03756[1].

Heat shock proteins and specifically HSP 70 are thought to protect cells from immediate injury and subsequent injury. Conditioning neurons with a mild heat stress was studied to test whether HSP 70 was necessary for protection of neurons from a second subsequent severe heat stress. Rat cortical neurons (E16) were subjected to a mild heat stress of 43°C for 15 minutes, 6 and 24 hours prior to a subsequent severe heat shock of 45° C for 20 minutes. The conditioning heat stress did not cause significant cell death at 24 hours. Results showed that HSP 70 was highly induced after the second heat shock but that this was likely the effect of the additive effects of both heat shocks. Protein synthesis as measured by methionine incorporation was not improved by the conditioning heat stress in neurons. HSP 32, heme oxygenase 1, was induced by a single mild heat shock but not additively by the two heat stresses. This was in contrast with HSP 70. Preliminary cell counts did not show neuroprotection by conditioning. Support of this project was provided by VHA Medical Research funds at the Veterans Health Administration Medical Center, Sepulveda, CA.

PROTECTIVE EFFECT OF PYRIDOXAL PHOSPHATE AGAINST GLUCOSE DEPRIVATION-INDUCED DAMAGE IN CULTURED HIPPOCAMPAL NEURONS. M.Y.Geng, H.Saito* and N.Nishiyama. Dept. of Chem. Pharmacol., Fac. of Pharmaceutic. Sci., The Univ. of Tokyo, Tokyo 113, Japan.

Pyridoxal phosphate (PLP) was shown to exert neurotrophic activity on cultured brain neurons in our previous data, which raised the possibility that PLP might also play a beneficial role in pathological neurodegeneration and brain repair following metabolic and/or excitotoxic insults. In the present study, we investigated the effects of PLP on primarily cultured hippocampal neurons subjected to glucose deprivation. The dissociated cells from embryonic rat were cultured in a defined medium and glucose deprivation performed at the 7th day. Drugs were administered 24 hours prior to 6-hour glucose deprivation. PLP (1 and 10 µM) dose-dependently inhibited LDH release induced by glucose deprivation. Aminooxyacetic acid (AOAA), a nonspecific inhibitor of PLP dependent enzymes, which reversed the effect of PLP, did not counteract the neuroprotection produced by DL-2-amino-5-phosphonovaleric acid (DL-APV). Furthermore, PLP provoked an overshoot of pyruvate production, followed by a notable recovery of intracellular ATP, which was blocked by AOAA.

Taken together, PLP exerted neuroprotective effect against glucose deprivation. The protective activity may be due to its coenzymatic role in participating the biosynthesis of energy-yielding products. Moreover, the antagonizing effect of AOAA against PLP, together with its non-blocking action on DL-APV might preferably implicate the non-involvement of NMDA-receptor complex in PLP-mediated neuroprotective action.

THE ANTICANCER DRUG CYTARABINE IS A TROPHIC FACTOR FOR MESENCEPHALIC DOPAMINERGIC NEURONS. P.P. Michel*, M. Ruberg and Y. Agid. INSERM U289, Hôpital de la Salpêtrière, 47, bd. de l'hôpital, 75013 Paris, France.

Nanomolar concentrations of cytarabine (ara-C), a structural analog of 2'-deoxycytidine, used in the chemotherapy of cancer, proved to be highly effective in preventing the apoptotic death of tyrosine hydroxylase (TH+) immunopositive mesencephalic dopaminergic neurons which occurs spontaneously in vitro. The treatment also produced a dramatic increase in the energy-dependent uptake of [3H]-dopamine, suggesting that rescued cells were fully functional and differentiated. Cytarabine was most effective when added just after plating but delayed exposure could still prevent the progression of the degenerative process efficiently. 2'-Deoxycytidine and dCTP but not cytosine antagonized the stimulatory effects of cytarabine when added in excess to the cultures. The effects of cytarabine were mimicked by ara-CTP and by the halogenated pyrimidine nucleoside, fluoro-deoxyuridine. Our results suggest that anticancer drugs, and in particular cytarabine, might possibly be of some help in the treatment of Parkinson's disease, a degenerative condition of aging characterized by a severe loss of dopaminergic neurons.

L-DOPA AND L-DEPRENYL PROTECT AGAINST L-BSO INDUCED CELL DEATH IN CULTURED MESENCEPHALIC NEURONS. E.T. Kokotos Leonardi*, B. Cheng, P.R. Radcliffe, C.W. Olanow, G. Cohen, and C. Mytilineou. Dept. of Neurobiolgy and Neurology, Mt. Sinai Sch. of Medicine, New York, NY 10029.

It has been previously shown that L-DOPA protects dopaminergic neurons against L-BSO (L-buthionine sulfoximine) toxicity (Mytilineou et al., 1993). Similarly, L-deprenyl, a MAO-B inhibitor, has neuroprotective actions in various animal and cell culture models, although the exact mechanism of protection remains unclear. Glutathione (GSH) depletion sensitizes cells to oxidative stress. In this study, we sought to investigate whether L-DOPA or L-deprenyl can prevent mesencephalic cell death induced by GSH depletion. Fetal rat mesecephalic cultures were exposed to 10 µM L-BSO, an inhibitor of GSH synthesis, for 48h in the presence of control vehicle, L-DOPA or L-deprenyl. The cell culture media were subsequently collected and stored at -70°C until assay for lactate dehydrogenase (LDH). L-BSO treatment reduced GSH levels by 50-60% in 24 hrs and by 48 hrs resulted in cell death with increased LDH release into the media (300-600% of control). Cultures exposed to L-DOPA at 50, 100 or 200 µM in addition to L-BSO had significantly reduced LDH released into the media when compared to cultures treated with L-BSO alone. Similarly, 50 µM deprenyl protected mesecephalic cells against L-BSO induced LDH release. Measurement of GSH levels indicated that L-DOPA and L-deprenyl did not prevent loss of GSH induced by L-BSO. This observation suggests that the protection afforded to mesencephalic cells by L-DOPA and L-deprenyl is independent of GSH. Cells exposed to both cycloheximide and L-BSO also showed a significant decrease in LDH release compared to L-BSO alone, suggesting a role for protein synthesis in L-BSO induced cell death. Supported by NIH NS-23017 and the Lowenstein Foundation.

STABLE EXPRESSION OF CALBINDIN-D_{28K} IN C6 GLIOMA CELLS PROTECTS AGAINST CALCIUM IONOPHORE AND AMYLOID β-PEPTIDE CYTOTOXICITY: EVIDENCE FOR PROTECTION AGAINST APOPTOTIC CELL DEATH BY CALBINDIN. R. Wernyj, M. P. Mattson and S. Christakos*, UMDNJ-New Jersey Medical School and Graduate School of Biomedical Sciences, Newark, NJ 07103 and Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY 40536.

The calcium binding protein, calbindin-D_{28k} is normally present in neurons. Recently we reported that brain injury and tumor necrosis factors (TNFs) induce calbindin-D_{28k} in astrocytes. TNF-treated calbindin expressing astrocytes were resistant to acidosis and calcium ionophore toxicity, suggesting that calbindin may have a cytoprotective role in astrocytes in the injured brain (Mattson et al., J. Neurosci. Res. 42: 257, 1995). In order to obtain direct evidence for a role of calbindin, using the eukaryotic expression vector pREP4, rat calbindin-D_{28k} was stably expressed in C6 glioma cells. Cytotoxicity in response to calcium inophore or amyloid β-peptide (which accumulates in the brain in Alzheimer's disease and has been reported to be neurotoxic) was measured by MTT reduction in vector transfected cells and in two calbindin transfected clones. Stably expressed calbindin resulted in increased cell survival in the presence of calcium ionophore (1-10μM) or amyloid β-peptide (10-100 μM). In addition, the calcium ionophore or amyloid β-peptide mediated rise in intracellular calcium in vector transfected cells was attenuated 3-4 fold in calbindin expressing cells. Apoptotic cell death was detected by the TUNEL and Hoechst methods in vector transfected C6 glioma cells treated with calcium ionophore but not in similarly treated calbindin transfected clones. Our results support the involvement of calcium fluxes in apoptosis and suggest that calbindin-D_{28k}, by buffering calcium, can suppress death in apoptosis susceptible cells in the central nervous system.

EFFECTS OF INTERLEUKIN-1 AND INTERLEUKIN-6 ON CEREBRAL CORTICAL CULTURE RESPONSE TO NITROPRUSSIDE TOXICITY. M. Dorheim*, P. Moore, R. Auerbach, and P. Grammas. University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190, University of Wisconsin, Madison, WI 53706.

Inflammatory mediators, such as interleukin-1 (IL-1), interleukin-6 (IL-6), and nitric oxide, have been implicated in the pathogenesis of neurodegeneration within the central nervous system. The following study investigated the effects of IL-1 and IL-6 on the neuronal susceptibility to injury by sodium nitroprusside (SNP). SNP, a nitric oxide releasing compound, has been shown to cause neurotoxicity. Primary neuronal cultures were established from fetal rat brain cortices. These cultures were treated with IL-1β (10 U/ml) or IL-6 (10 U/ml), supernatant collected and assayed for lactate dehydrogenase (LDH), an enzyme released during lethal cellular injury. Acute treatment of cultures with IL-1 or IL-6 had no effect on neuronal survival. Addition of SNP (100 μM) evoked a 40% increase in LDH release that was not affected by concurrent treatment with either IL-1 or IL-6. Pretreatment of neuronal cultures with IL-1 significantly ($p < 0.05$) reduced toxicity to SNP. In contrast, pretreatment with IL-6 had no effect on toxic SNP challenge. These data suggest that inflammatory mediators work through separate mechanisms which may have both beneficial and deleterious effects on neurons. (Supported by NIH NS30457 and the Alzheimer's Association.)

APOPTOSIS-INHIBITORY FACTORS (AIF-20 AND AIF-22) AND GENES INVOLVED IN DENSITY-DEPENDENT SURVIVAL OF NEURONS IN SERUM-FREE CORTICAL CULTURES. [1]N. Fukushima* and [2]H. Ueda. [1]Dept. of Pharmacol., Yokohama City Univ. Sch. Med., Yokohama 236 and [2]Dept. Pharmacol., Sch. Pharma. Sci., Nagasaki Univ. Nagasaki 852, Japan.

Cortical neurons survive in a density-dependent manner under serum-free conditions. We have shown that the density-dependent survival is at least in part attributed to AIF-20 and AIF-22 in the conditioned medium (CM) from high-density cultures, and that AIFs exert the survival actions through activation of protein kinase C (PKC), but not of tyrosine kinase (TK), within 1 hr after seeding. Here, signal transduction of AIF-20 and AIF-22 and the survival mechanisms of AIFs were studied. The survival effects of both factors were completely inhibited by calphostin C (PKC inhibitor), but partially by herbimycin (TK inhibitor) when each drug was applied during 0 - 1 hr of culture. This finding is consistent with that for CM, suggesting that both factors inhibit apoptosis through activation of PKC, rather than of TK. The inhibition of apoptosis by AIFs or high-density was partially blocked by actinomycin D and cycloheximide. We attempted to clone genes specifically expressed and related in neuronal survival in high-density cultures. RNAs were extracted from cells in low- (1×10^5 cells/cm^2) or high-density (5×10^5 cells/cm^2) cultures 3 hr after seeding, and subjected to differential display methods. We selected 40 subclones specific for high-density cultures. Among them, 5 subclones were confirmed to be specific for high-density cultures on Northern blot analyses. Using these subclones as probes, we obtained 9 independent clones from cDNA library of high-density cultures. The expression of some genes was maintained in high-density cultures during 0 - 6 hr of culture, while decreased in low-density ones.

NEURONAL DEATH V

CELL CYCLE SIGNALS IN APOPTOTIC NEURONAL DEATH. E. J. Morris*†, D. S. Park‡, L. A. Greene‡, and H. M. Geller†. †Dept. of Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ, 08854. ‡Dept. of Pathology and Center for Neurobiology and Behavior, Columbia Univ. New York, NY, 10032.

Apoptosis of dividing cells normally involves a signal transduction cascade that interacts with the signals that control cell cycle. The extent to which these signals are utilized in terminally differentiated neurons is not known. It has been previously demonstrated that the cyclin dependent kinase (CDK) inhibitors flavopiridol and olomoucine as well as the G1/S blockers mimosine, deferoxamine, and ciclopirox promoted the survival of neuronal PC12 cells and primary sympathetic neurons deprived of trophic support. We now report that flavopiridol and olomoucine also delay the apoptotic death of sympathetic neurons, cortical neurons, and PC12 cells induced by the topoisomerase-I inhibitor camptothecin. Significantly, the concentrations of CDK inhibitors that promote the survival of camptothecin-treated neuronal PC12 cells correlate with their ability to inhibit cellular proliferation. Moreover, the IC50 for inhibition of cell death by flavopiridol was correlated with its ability to inhibit CDK activity. The G1/S blockers mimosine and deferoxamine also delayed the camptothecin-induced death of neuronal and naive PC12 cells whereas the S-phase blocker, aphidicolin had no effect on survival. This suggests that DNA damage by camptothecin, like withdrawal of trophic support, may trigger inappropriate cell cycle signals leading to apoptosis. Drugs that would lead to arrest at the G1/S checkpoint of the cell cycle are effective in promoting survival of challenged neurons and PC12 cells. The exact pathway of apoptotic death, however is not identical between the two death stimuli, since the ICE-family protease inhibitor zVAD-fmk is able to promote the survival of sympathetic neurons deprived of nerve growth factor, it had no effect on camptothecin-induced death. Supported by the NIH, March of Dimes, ALS Foundation and Aaron Diamond Foundation.

INVOLVEMENT OF CYCLIN D1 IN NEURONAL DEATH. R. J. Crowder* and R. S. Freeman. Department of Pharmacology and Physiology, University of Rochester School of Medicine, Rochester, NY 14642.

Neurons from the rat supeior cervical ganglion (SCG) undergo apoptotic cell death when deprived of nerve growth factor (NGF). Apoptosis in this model is blocked by inhibitors of RNA or protein synthesis. The expression of the cyclin D1 gene is upregulated after NGF withdrawal suggesting that ongoing synthesis of this protein may be necessary for neuronal death. The cyclin D1 protein, an important regulator of the G_1/S phase transition in proliferating cells, functions by modulating the activity of certain cyclin-dependent protein kinases (CDKs). Immunoprecipitation studies of cyclin D1 protein from ^{35}S-labeled neurons reveal that the synthesis of cyclin D1 that occurs in the absence of NGF is equal to or slightly greater than its synthesis in the presence of NGF, despite a large decrease in total protein synthesis after NGF withdrawal. To determine the significance of cyclin D1 for neuronal death, we have constructed plasmid DNAs (for microinjection experiments) and recombinant adenoviruses (for infection of neurons) that express a cyclin D1 cDNA or an antisense cyclin D1 cDNA. These constructs have been used to successfully overexpress cyclin D1 in the neurons. Preliminary experiments do not indicate that cyclin D1 overexpression is overtly toxic to neurons maintained in the presence of NGF. Studies have been initiated to analyze the long-term survival of neurons overexpressing cyclin D1 and the kinetics of their death after NGF withdrawal. Other vectors that we have constructed express mutant cyclin D1 proteins, the $p16^{INK4}$ protein (an inhibitor of cyclin D1-dependent kinases), and a dominant negative mutant of CDK4. Experiments are underway to test the effects of these vectors on neurons in the presence or absence of NGF. Supported by grants from the NIH (NS34400) and the Amyotrophic Lateral Sclerosis Association (to R.S.F.) and NIH predoctoral training grant GM08427 (to R.J.C.).

INHIBITION OF CYCLIN-DEPENDENT KINASES PROMOTES SURVIVAL OF POSTMITOTIC NEURONS BUT INDUCES APOPTOSIS IN DIVIDING NEURONAL CELLS, M. A. Markus, A. Winkler and G. D. Borasio*. Department of Neurology, University of Munich, D-81366 München, Germany.

Cyclin-dependent kinases and their regulatory partners, the cyclins, regulate the eukaryotic cell cycle. We examined the effects of cyclin-dependent kinase inhibitors (CDKIs) on the in vitro survival of chick embryonic neurons at different stages of development. Sensory, sympathetic and ciliary neurons, when prepared at their respective time-point of naturally occurring programmed cell death, could be rescued from apoptosis by CDKIs alone in a dose-dependent fashion, without promotion of neurite outgrowth. Conversely, premitotic sympathetic precursors, as well as postmitotic, but NGF-independent sympathetic neurons, undergo apoptosis when treated with CDKIs in the same range of concentration. These results suggest that certain cyclin-dependent kinases required for cell division in neuronal precursors become an essential component of the apoptotic machinery by the time neurons reach their phase of naturally occurring programmed cell death.

APOPTOSIS AFTER TERMINAL MITOSIS IN THE DEVELOPING RETINA S.K. Rehen[1,2], C.B.L. Campos[1] and R. Linden[1]* [1]Instituto de Biofísica-UFRJ and [2]Depto de Anatomia-UFRJ, Rio de Janeiro, Brasil.

In the retina of newborn rats, protein synthesis is required for apoptosis of axotomized ganglion cells. In contrast, other retinal cell types located in the mitotically active neuroblastic layer (NBL) undergo apoptosis after protein synthesis blockade (Rehen et al, *Development*, 1996, in press). We investigated whether cells in the NBL that undergo apoptosis following protein synthesis inhibition are proliferating or postmitotic cells. A technique to detect apoptosis *in situ* was combined with immunocytochemistry for BrdU, a nucleotide analog. Retinal explants from 5-day-old rats were incubated with BrdU for a period during which all cycling cells should have passed through the S phase of the cell cycle. Then, the medium was washed out and the explants were incubated with a protein synthesis inhibitor to induce apoptosis. BrdU-labeled cells died following blockade of protein synthesis. However, most of the cells that underwent apoptosis in this condition had not incorporated BrdU. Remarkably, these postmitotic cells were restricted to the least differentiated portion of the retina, bordering the emerging outer plexiform layer, indicating that they were recent postmitotic cells. These data suggest that both during the cell cycle and at an early stage of differentiation, retinal cells require proteins to block a latent program of apoptosis. After this period apoptosis switches to a mechanism dependent on the synthesis of proteins. The stage of maturation thus determines the mechanism of apoptosis.

APOPTOSIS OF ROD PHOTORECEPTORS IN VITRO: REQUIREMENT FOR PROTEIN SYNTHESIS IS DEPENDENT ON CULTURE CONDITIONS. J. Cheng, A. Moore, R. Alatorre, R.A. Cuthbertson and I.J. Kljavin*. Genentech Inc., South San Francisco, CA 94080.

A number of pathological conditions involve apoptotic cell death of photoreceptor cells. However, the cellular factors and the mechanisms that regulate photoreceptor cell death are largely unknown.

Retinal cells derived from 1 week old rats were cultured in serum free media for 1 to 3 days on poly-D-lysine or Müller cell monolayers. After one day in culture, rods free from contact with Müller glia displayed apoptotic features such as membrane blebbing, cytoplasmic shrinkage, retraction of neurites and DNA cleavage at the single cell level. DNA laddering detected by gel electrophoresis confirmed that the retinal cells were dying via apoptosis. In contrast, rods plated onto the Müller cell monolayers showed greater survival compared to poly-D-lysine cultures and the rods did not display apoptotic features. The protein synthesis inhibitors cycloheximide and anisomycin significantly reduced apoptosis of rods. However, if dissociated retinal cells were cultured in media containing the broad spectrum protein kinase inhibitor, staurosporine, or in media deficient in the essential amino acid L-glutamine, apoptotic cell death could not be reduced with the addition of the protein synthesis inhibitors.

These findings suggest that cultured rat retinal neurons die via apoptosis and that Müller cells provide signals which can promote survival. Furthermore, rod photoreceptors are capable of undergoing apoptosis even in the presence of protein synthesis inhibition suggesting that this cell type may constitutively express pro-apoptotic proteins.

CHANGES IN THE PLASMA MEMBRANE PRECEDES DNA BREAKDOWN AND CHROMATIN CONDENSATION IN TROPHIC-DEPRIVED INDUCED NEURONAL DEATH *IN VITRO*. C. Peña, J. Zhu, J. Brusés, and G. Pilar*. Dept. of Physiology and Neurobiology, University of Connecticut, Storrs, CT., 06268.

In the chick ciliary ganglion (CG) half of the neurons die during the naturally occurring cell death period. These dying cells undergo cytoplasmic changes (cellular swelling and organelle compromise), before any change in the nucleus of the cell can be detected (chromatin condensation). However, if the peripheral target tissue is removed before the period of innervation, the cell death sequence of events is reversed and nuclear changes are observed prior to cytoplasmic changes. These observations suggest two different neuronal death pathways. To better characterize this sequence of events, stage 34 CG neurons were cultured in the presence or absence of trophic support (CIPE, an aqueous extract from the CG target muscles in the eye). CG neurons cultured in the presence of CIPE survive for at least a week, however if CIPE is not added at the time of plating, the neurons die within 24 h. Neurons showed plasma membrane breakdown as early as 9 hours after trophic support deprivation, as visualized by the impermeant cellular stain acridine orange. This event is prior to the time cells become committed to die (>12 h after trophic factor deprivation). On the other hand, nuclear changes such as DNA breaks and chromatin condensation assessed by the TUNEL technique and by the cell-permeant DNA stain Hoechst 33342, only appeared after 13 h of trophic factor deprivation. These observations suggest that during the cell death process, the first changes occur at the plasma membrane level, which can still be reversed by the addition of trophic support. If trophic deprivation continues, the membrane changes may signal subsequent nuclear changes which lead to DNA damage and irreversibly commit the neuron to death. Supported by NIH GRANT NS 10338.

CROSSLINKING OF SPECIFIC PLASMA MEMBRANE RECEPTORS ON HIPPOCAMPAL NEURONS INDUCES PROGRAMMED CELL DEATH IN CULTURED NEURONS. D.H. Cribbs, and C.W. Cotman. Irvine Research Unit in Brain Aging, University of California, Irvine, CA 92717.

Programmed cell death has been implicated in the loss of neurons that occurs in many neurodegenerative diseases. This has led to an increased interest in the types of stimuli that can initiate neurons to undergo programmed cell death. Previously we have shown that crosslinking of membrane receptors with the lectin concanavalin A can trigger programmed cell death in neurons. Concanavalin A, however, binds to many surface glycoproteins and therefore it is important to determine whether certain specific receptors can initiate the program. Many cells are contact-dependent and receive survival signals from clustering receptors either from binding to other cells or the extracellular matrix. The loss of contact typically leads to initiation of programmed cell death. We found that surface immobilized anti-NCAM monoclonal antibodies provide an excellent substrate for adhesion and neurite outgrowth for cortical neurons. However, neurons treated directly with two different anti-NCAM monoclonal antibodies show significant cell death after 24 h and exhibit the morphological and biochemical characteristics of apoptosis, including membrane blebbing, condensation of nuclear chromatin and internucleosomal DNA fragmentation. In addition, these NCAM antibodies produced a rapid and prolonged increase in the immediate early gene c-jun which precedes the onset of other markers for apoptosis in neurons. The mechanism underlying this NCAM induced cell death is under investigation. Supported by NIA grant AG 13007.

SEGMENT-SPECIFIC, STEROID MEDIATED PROGRAMMED CELL DEATH OF IDENTIFIED MOTONEURONS IN CELL CULTURE. K.L. Hoffman* and J.C. Weeks. Institute of Neuroscience, University of Oregon, Eugene, OR 97403-1254.

During metamorphosis of the hawkmoth, *Manduca sexta*, a class of steroid hormones, the ecdysteroids, regulates the programmed cell death (PCD) of motoneurons. At the larval-pupal transformation, a stereotyped subset of motoneurons, designated APRs, dies in response to the prepupal peak of ecdysteroids. APRs die in a segment-specific pattern: APRs in abdominal segments 5 and 6 [APR(5)s and APR(6)s] die while APR(3)s and APR(4)s survive. Experiments done *in vivo* and in culture are consistent with ecdysteroids acting directly on the APRs.

We are investigating PCD of APR(6)s in culture. We cultured APR(6)s and APR(4)s in hormone-free medium immediately after pupal ecdysis [PE, which occurs after the prepupal peak but ~24 h before the APR(6)s die *in vivo*]. During the first 24 h in culture, nearly half the APR(6)s, but not APR(4)s, underwent PCD marked by cell shrinkage, loss of mitochondrial activity, and condensation of DNA. APR(6)s cultured 24 h prior to PE, however, were as viable as APR(4)s, even after 7 d in culture. These results suggest that during the 24 h prior to PE, some of the APR(6)s became irreversibly condemned to PCD. When APR(6)s were cultured at PE in medium containing a low concentration of ecdysteroids, the percent of APR(6)s that died during the 7 d culture period nearly doubled, showing that some APR(6)s required additional exposure to ecdysteroids to undergo PCD in culture. We plan to utilize this culture system to identify molecular mechanisms underlying of PCD of APR(6)s.

NITRIC OXIDE INDUCED PROGRAMMED CELL DEATH: A RAPID, MOLECULAR PROCESS OF NEURODEGENERATION. L. Kue, M. TenBroeke, N. Ge*, K. Maiese, Dept. of Neurology, Center for Molecular Medicine, Wayne State University School of Medicine, Detroit, MI, 48201

Neuronal degeneration is dependent, in part, upon the modulation of nitric oxide (NO) production (Maiese, et al. *J Neurosci* 13: 3034-3040, 1993). Programmed cell death (PCD) appears to be an important link in the signal transduction pathways that ultimately lead to neuronal death. To explore the molecular pathways that may mediate neuronal death, we examined (1) whether NO toxicity invoked the cellular processes of PCD, and (2) whether NO induced neurodegeneration was dependent upon the induction of PCD. Evidence of PCD, such as neuronal nuclear condensation and DNA fragmentation, was examined by hematoxylin and eosin stain, terminal-deoxynucleotide transferase-mediated dUTP-digoxigenin nick end-labeling, and transmission electron microscopy. Analysis of protein synthesis utilized an [S^{35}]-methionine incorporation assay. The NO generators sodium nitroprusside (300μM) and 3-morpholino-sydnonimine (300μM) were used to induce NO toxicity in primary hippocampal neurons. Within the initial hour following NO exposure, the percentage of neurons consistent with apoptosis increased from 20±5% (0 minutes) to 49±5% (60 minutes) (n=10, p<0.001). Over a 24 hour period, 74±6% of the neurons exhibited evidence of PCD. In addition, inhibition of protein synthesis at the level of mRNA production or at the level of protein translation during NO exposure increased neuronal survival from 18±5% (NO treatment only) to 43±4% (mRNA inhibition) and to 65±5% (translation inhibition) (n=10, p<0.001). Protein synthesis was decreased by approximately 70% with actinomycin-D (0.01ng/ml) and by approximately 50% with cycloheximide (1.0ng/ml). Thus, NO induced neuronal degeneration results in the early and significant, progressive induction of PCD, a process that is reversible at the molecular level. Further characterization of role of PCD may provide greater insight into the cellular mediators of neurodegeneration.

ENHANCEMENT OF DELAYED RECTIFIER CURRENT IN CORTICAL NEURONS UNDERGOING APOPTOSIS. S.P. Yu*, B.J. Gwag, S.L. Sensi, Z.S. Farhangrazi, L.M.T. Canzoniero, Ying, H.S., Dugan, L.L. and D.W. Choi, Center for the Study of Nervous System Injury and Dept. of Neurology, Washington Univ. School of Medicine, St. Louis, MO 63110.

Cortical neurons exposed to staurosporine or serum deprivation undergo apoptosis over about 24 hrs. Because K^+ channels participate in cell cycle regulation, we examined possible roles of K^+ channels during these forms of neuronal apoptosis using whole-cell patch clamp and fura-2 Ca^{2+} imaging.

A tetraethylammonium (TEA)-sensitive delayed rectifier current (I_K) increased after 3 hrs exposure to 0.1 μM staurosporine, reaching 70% enhancement after 10 hrs. Staurosporine shifted the I_K current -voltage relationship modestly to the left and increased the maximum conductance. Neurons in near-pure neuronal cultures exposed to serum deprivation also exhibited a marked increase in I_K, although the current-voltage relationship was unchanged. In contrast, the transient outward K^+ current (I_A), sensitive to 4-aminopyridine (4-AP), was suppressed after 9 hrs exposure to staurosporine.

TEA (1-5 mM) in the bathing medium, sufficient to attenuate I_K, reduced both staurosporine- and serum deprivation-induced neuronal apoptotic death; 5 mM 4-AP did not show such protection. While the possibility that TEA protection was due to proexcitant effects leading to increased [Ca^{2+}], cannot be excluded, the observation that 10 μM gadolinium (sufficient to prevent TEA induced [Ca^{2+}], responses in normal cells) did not eliminate TEA neuroprotection, argues against this. These results raise the possibility that persistent up-modulation of delayed rectifier channels participates importantly in at least certain forms of central neuronal apoptosis, and that pharmacological attenuation of I_K may be an effective strategy for interfering with neuronal apoptosis.

Iron chelators induce the transcription factor, hypoxia inducible factor-1 (HIF-1), and glycolytic enzymes in embryonic cortical cultures. **RR Ratan*, K O'Donovan, G Semenza, and JM Baraban. Johns Hopkins Univ.** Iron chelators have been shown to inhibit oxidative stress-induced damage and death in a number of paradigms, but the mechanism of protection remains unclear. We have found that iron chelators abrogate oxidative stress-induced apoptosis in primary neuronal cultures. Oxidative stress was induced by cystine deprivation and glutathione depletion. Toxicity was assessed by standard neurotoxiciologic methods, including the percentage of lactate dehydrogenase (LDH) released into the media. In performing LDH assays, we noted that iron chelators induced cell associated LDH activity by up to 300% above control without increasing the cell number above control levels. Aldolase, another glycolytic enzyme was also induced. Induction of both enzymes could be abrogated by cycloheximide and was correlated with induction of the transcription factor, hypoxia inducible factor-1 (HIF-1) as measured by gel-shift assays. HIF-1 has been shown to induce the message of glycolytic enzymes in non-neuronal cells. These results suggest that iron chelators induce glycolytic enzymes through the transcription factor, HIF-1 in primary neuronal cultures and suggest novel pathways by which iron chelators may abrogate cell death. ***Current address: Beth Israel Hospital, Harvard Medical School.** **Supported by NIH,Passano Foundation**

GANGLIOSIDE GM1 REDUCES CORTICAL NEURONAL APOPTOSIS. B.R. Ryu*[1], B.J. Gwag[1], E. Costa[2], D.W. Choi[3], 1Dept of Pharmacology, Ajou University, School of Medicine, Suwon, Korea; 2The Psychiatric Institute, University of Illinois at Chicago, Chicago, IL60612; 3Center for the Study of Nervous System Injury and Dept. of Neurology, Washington University, School of Medicine. St. Louis, MO 63110.

Neuroprotective effects of gangliosides have been documented against several types of insults. In the present study, we examined the ability of gangliosides to reduce neuronal apoptosis. Near-pure murine cortical neurons in cell culture undergo apoptosis when deprived of serum. This apoptosis is characterized by cell body shrinkage, nuclear chromatin condensation, and sensitivity to cycloheximide as well as certain neurotrophins. Inclusion of 10-100μM ganglioside GM1 in the bathing medium(kindly supplied by Fidia)strongly attenuated this serum deprivation -induced neuronal apoptosis. A protective effect was also seen with addition of GD1a, GT1b, GQ1b, but not with aGM1, suggesting a requirement for the sialic acid moiety. In contrast, 10-100μM GM1 had little protective effect against the excitotoxic necrosis induced by exposure of the same neurons to NMDA, AMPA, or kainate. LIGA 20, a semisynthetic ganglioside, lacked neuroprotective effects against serum deprivation-induced apoptosis, but did reduce the excitotoxic neuronal death induced by exposed to NMDA.

Supported by NIH NINDS grant NS 30337(DWC).

TARGETED PHOTOLYTIC APOPTOSIS IN PC-12 CELLS IS DEPENDENT ON INTRINSIC ENDONUCLEASE ACTIVITY V. Sheen,* A. Jaramillo, B.R. Leavitt and J.D. Macklis. Department of Neurology and Program in Neuroscience, Harvard Medical School, and Division of Neuroscience, MRRC, Children's Hospital, Boston, MA 02115.

Apoptosis is implicated in sculpting of neuronal number, differentiation, and connectivity during development, and it is hypothesized to underlie refinement in the adult CNS; e.g. seasonal neuronal replacement in the avian telencephalon. Embryonic neurons and multipotent precursors transplanted into regions of adult mouse cortex undergoing photolytically induced, synchronous, apoptotic degeneration of pyramidal neurons can respond to reexpressed developmental signal molecules, selectively migrate into these regions, differentiate into pyramidal neurons, accept afferent synapses, and re-form specific distant projections. The signal molecules include spatially and temporally specific upregulation of neurotrophins and the TrkB receptor, uniquely during ongoing apoptosis and directed differentiation. BDNF mRNA expression is specifically increased in local interneurons adjacent to degenerating pyramidal neurons. This cell death occurs by apoptosis following production of the reactive oxygen species singlet oxygen and lysosomal protease release: disruption of cytosolic proteins and cytoskeletal components, loss of calcium homeostasis by activation of L-type calcium channels and via increased membrane porosity, nuclear chromatin condensation, internucleosomal DNA fragmentation, cellular condensation, formation of apoptotic bodies, and phagocytic removal. These findings suggest that the induction of upregulated molecules is a specific effect of targeted apoptosis that may result from intercellular signaling between degenerating pyramidal neurons and surrounding interneurons. In the present study we use the pheochromocytoma cell line PC-12 as an *in vitro* model to further characterize this form of apoptosis, and to allow future study of potential intercellular signaling during neuronal death. We labeled PC-12 cells with or without NGF differentiation using photoactive nanospheres, pretreated with 0 to 300 uM of the endonuclease inhibitor aurintricarboxylic acid (ATA) or 0 to 1,000 ng/ml of the protein synthesis inhibitor cycloheximide (CHX), induced targeted cell death by exposure to 674 nm light, and assayed cell survival. We found that 100 uM or more ATA fully prevented the normally ~ 90% cell death (50 uM half-maximal), but CHX did not prevent apoptosis in undifferentiated PC-12 cells. These results that this cell death can be attenuated in a dose-dependent manner by ATA and not CHX in undifferentiated PC-12 cells resembles the findings with PC-12 cells and neurotrophin withdrawal. Analysis of NGF-differentiated PC-12 cells is ongoing. Such parallels may allow insight into intercellular signaling by apoptotic neurons. 6R-TETRAHYDROBIOPTERIN ENHANCES PC12 CELL DEATH FOLLOWING WITHDRAWAL OF TROPHIC SUPPORT. P.Z. Anastasiadis*[1,3], L. Bezin[1], B. Imerman[1], M.D. Flam[1], D.M. Kuhn[2], and R.A. Levine[1,2,3]. [1]W.T. Gossett Neurology Labs, Henry Ford Hosp.; [2]Cellular & Clinical Neurobiol. Prgm, Psychiatry; and [3]VA Med. Center, Detroit, MI.

6R-tetrahydrobiopterin (BH_4) is an essential cofactor in catecholamine (CA), serotonin, and nitric oxide (NO) synthesis. A growth-related role for BH_4 has also been suggested in murine erythroleukemia cells, while in PC12 cells BH_4 mediates the mitogenic effects of nerve growth factor (NGF) and epidermal growth factor. Under conditions restrictive for growth, PC12 cells can be rescued from apoptotic cell death by NGF. We have investigated the effects of BH_4 under the same conditions and whether BH_4 mediates the trophic effects of NGF. Following withdrawal of trophic support, sepiapterin (converted intracellularly to BH_4) increased PC12 cell death, as measured by the accumulation of extracellular lactate dehydrogenase (LDH) activity or ds-DNA. Cell counts and total LDH activity suggested that sepiapterin increases cell death through an enhancement of cell proliferation under conditions restrictive for growth. Sepiapterin also enhanced DNA fragmentation as compared to withdrawal of trophic support alone. This effect was reversed by NGF, but the NGF trophic effect was not blocked by inhibitors of intracellular BH_4 synthesis. In contrast, inhibition of BH_4 synthesis enhanced PC12 survival and potentiated the NGF-protective effect (LDH assay). The effect of sepiapterin was dose-dependent and specific to elevating BH_4 levels. This BH_4 effect was not mediated by NO or CA metabolism or by BH_4 auto-oxidation (generation of superoxide ions or hydrogen peroxide). Current studies are focusing on the characterization of the sepiapterin toxic effect (apoptosis vs necrosis) and the involvement of proto-oncogenes.

RETINA TROPHICALLY SUPPORTS OLIGODENDROCYTES FROM THE OPTIC NERVE *IN VITRO*, M. E. Stokely*, and S. J. Moorman. Dept. Anatomy & Cell Biology, Univ. North Texas Health Science Ctr., Ft. Worth, TX 76107.

It has been proposed that the mortality rate (approx. 50%) of optic nerve oligodendrocytes during development is regulated by competition for a combination of available trophic factors. The retina is one possible source for those trophic factors. To test this, oligodendrocytes from P5 rat optic nerve were grown in poly-lysine coated dishes under three conditions: 1) unsupplemented DMEM/F12 media, n=15; 2) unsupplemented DMEM/F12 media containing retinal explants (plated 5 days earlier from P0 littermates), n=45; 3) F12 media supplemented with heat inactivated horse serum, conalbumin, vitamin C, glucose, and insulin, n=60. Dishes were observed at 1, 3, and 5 days.

Oligodendrocytes appeared unhealthy and survived less than 5 days in unsupplemented DMEM/F12 media. In either supplemented F12 media or DMEM/F12 with retinal explants, oligodendrocytes appeared healthy, survived, differentiated and grew. These results suggest the retina is a possible source of trophic factors for oligodendrocytes in the optic nerve.

Supported by the UNT Health Science Center at Fort Worth.

K^+ CHANNEL EXPRESSION AND CELL PROLIFERATION ARE REGULATED BY MEMBRANE DEPOLARIZATION IN OLIGODENDROCYTE PROGENITOR CELLS. P. Knutson, J.M. Zhou, V. Gallo* & C.J. McBain. Lab. of Cellular & Molecular Neurophysiology, NICHD, NIH, Bethesda MD, 20892.

We have previously demonstrated that glutamate receptor (GluR) agonists inhibit oligodendrocyte progenitor (O-2A) proliferation and lineage progression by a blockade of delayed rectifier K^+ channels. Proliferation of rat cortical O-2A progenitor cells, cultured in the absence or presence of PDGF and/or bFGF for 24 hr, was also reversibly inhibited (30-60% inhibition) by 25-45 mM $[K^+]_o$ in the culture medium, as measured by $[^3H]$-thymidine incorporation. K^+-induced depolarization inhibited (20-50% inhibition) lineage progression from the O-2A to the pro-oligodendroblast stage, as detected by the % of $O4^+$ cells. To determine the effects of culturing O-2A progenitors in elevated K^+ conditions, whole cell patch clamp recordings were compared from cells cultured for 48 hrs either in 2.5 or 45mM $[K^+]_o$. In low $[K^+]_o$ conditions, test pulses to depolarized potentials activated delayed-rectifier outward currents (Vhold = -40mV). Two distinct delayed rectifiers were resolved with half activations of -25.3mV and 16mV (n=25). In 54% of cells a transient current was also evident when test pulses were delivered from a holding potential of -110mV. Test pulses to hyperpolarized potentials (-70 to -110mV) revealed the presence of an inward rectifier current of low density 13.5 $\pm$ 2.9 pA/pF (V_{rest} = -120mV), which was blocked by both $[Cs^+]_o$ and $[Ba^{2+}]_o$. In high $[K^+]_o$ cultures recorded in low $[K^+]_o$ conditions, there was a selective upregulation of the inward rectifier current (41.3 $\pm$ 16.6 pA/pF), with little evidence for change in the delayed rectifier current components. The cell resting membrane potential was also more negative in high $[K^+]_o$ cultures (-80.4 mV versus -46.6 mV in control), consistent with an upregulation of the inward rectifier current. These data suggest that signals affecting O-2A cell proliferation are capable of inducing potassium channel plasticity. This work was supported by the NIH.

INDUCTION OF THE APC TUMOR SUPPRESSOR PROTEIN IN DEVELOPING OLIGODENDROCYTES AS THEY EXIT THE CELL CYCLE. J.S. Fosnaugh* and J.M. Baraban. Johns Hopkins Univ. Sch. of Med., Dept. of Neuroscience, Baltimore, MD 21205.

In recent studies, we have demonstrated that the APC tumor suppressor gene, which has been linked to both familial and sporadic forms of colon cancer, is expressed at high levels in brain and appears to be selectively enriched in oligodendrocytes (Bhat, et al., GLIA, in press). As overexpression of APC in fibroblasts blocks cell cycle progression at the G_1 to S phase transition (Baeg et al., EMBO J. 14:5618-5625, 1995), we examined the possibility that this tumor suppressor gene may participate in the transition that oligodendrocytes undergo from proliferating progenitors to mature "post-mitotic" cells.

In this study, we assessed whether the appearance of intense APC staining displayed by oligodendrocytes *in vivo* occurs prior to, during, or after progenitors exit from the cell cycle. Employing a combination of anatomical mapping and BrdU labeling, we have found that APC immunostaining is not displayed by oligodendrocyte progenitor cells that are actively dividing. Instead, APC expression first appears during the interval between 1 and 3 days after BrdU incorporation, when commitment to exit the cell cycle occurs. Taken together, the ability of APC to induce cell cycle arrest *in vitro* and its appearance in developing oligodendrocytes as they exit the cell cycle *in vivo* suggest that the APC protein acts to limit proliferation in this lineage.

EFFECTS OF INFLAMMATORY CYTOKINES ON OLIGODENDROCYTE PRECURSOR MIGRATION ON ASTROCYTES

J. Fok-Seang, R.J.Keynes*, J.W. Fawcett. Depts. Of Anatomy and Physiology, Cambridge University, Cambridge CB2 3EG, England.

In Multiple Sclerosis demyelinated axons are largely surrounded by astrocytic processes, and we and others have shown that oligodendrocyte precursors migrate very poorly on postnatal astrocytes. It is likely, therefore that oligodendrocyte precursors are prevented from gaining access to demyelinated axons by the surrounding astrocytosis. Many lesions in MS and other conditions do remyelinate, and there appears to be a correlation between the presence of active inflammatory processes and remyelination. We have therefore investigated the effects of inflammatory cytokines on the migration of oligodendrocyte precursors on astrocytes.

CG4 oligodendrocyte precursor cells were stained with DiI, and allowed to attach to small shards of coverslip. These were placed on monolayers of astrocytes from postnatal brain or astrocyte cell lines, which had been treated for 24 hours with cytokines. CG4 cells were allowed to migrate for 3 days in the presence of cytokines. Migration was increased by FGF and Il-1 individually, but much more by both together. TGFβ1 blocked this effect, and interferon γ both blocked the effect and decreased baseline migration rates. TNFα, PDGF, EGF, IGF were without effect. None of the cytokines had equivalent effects on migration on laminin. Of several astrocyte cell lines, only one, 27A1, responded to FGF and Il-1 with greatly increased CG4 migration rates, suggesting that this response may be due to one astrocytic subtype. We conclude that inflammation will result in the release of some cytokines that will aid oligodendrocyte migration and remyelination, others that will inhibit it.

DEMYELINATION OF THE DORSAL COLUMNS BY PHOTOABLATION OF OLIGODENDROCYTES IN TRANSGENIC MICE J.L. Vanderluit*, J. Bourque, A. Peterson[1] and W. Tetzlaff Depts. of Zoology and Surgery, U.B.C., Vancouver, B.C., V6T 1Z4 and [1]McGill University, Montreal, Quebec, H3A 1A1.

Myelin and some of its associated membrane proteins have been shown to inhibit axonal regeneration in the central nervous system (CNS) of higher vertebrates. We are using focal demyelination of the spinal cord to examine the ability of axotomized spinal cord axons to regenerate in a myelin-free zone. Demyelination is produced using a photoablation technique which specifically targets the destruction of oligodendrocytes in transgenic mice which express β-galactosidase from the myelin basic protein (MBP) promotor. Following a laminectomy at T9-10, focal demyelination within the dorsal columns is produced by application of a fluorescein-linked β-gal substrate (fluorescein di-β-galactopyranoside, FDG) and fluorescent illumination. Myelin disruption is evident within 3 days yet, demyelination of axons is not complete until 7-10 days following photoablation. Utilizing an adjustable mercury lamp source allowed optimization of the photoablation technique by decreasing exposure time and increasing the light intensity which minimized the damage caused by light exposure alone. In addition, altering light intensity enhances light penetration through the full depth of the dorsal columns. Successful remyelination of the demyelinated area is undertaken by oligodendrocytes and Schwann cells invading from the periphery. Currently, we are examining the ability of dorsal column axons to sprout and regenerate through this myelin-free zone following a dorsal hemisection injury of the spinal cord.

IMMUNOCYTOCHEMICAL CHARACTERIZATION OF OLIGODENDROCYTE DEVELOPMENT IN HUMAN CEREBRAL WHITE MATTER. **S.A. Back, J.J. Volpe, and H.C. Kinney*. Depts. of Neurology & Pathology, Children's Hospital, Harvard Medical School, Boston, MA 02146**

Test of the hypothesis that cerebral white matter (WM) injury in the premature infant is characterized by death of oligodendrocyte (OL) precursors has been hampered by lack of a suitable means to visualize these cells in postmortem human brain. We used the 04 and 01 antisera to visualize OLs in 8 cases (21 gestational weeks to 12 months postnatal). Tissue from the parietal lobe at the level of the trigone was drop-fixed in 4% paraformaldehyde for 2-8 weeks. Antisera were visualized by peroxidase-antiperoxidase or immunofluorescent techniques. Staining localized to the cell surface and processes of apparent OL somata which were most heavily concentrated in the WM. The distribution of staining was unchanged with titers of 04 or 01 ranging from 1:50-1:500. Duration of fixation affected neither the magnitude nor distribution of staining. There was no overlap in the cellular elements visualized by double immunofluorescent labeling for 04 and anti-GFAP antisera (n=5).

The relative localization of 04 and 01 varied with developmental age. At 21-26 weeks, 04-staining predominated in WM in contrast to sparse staining for 01. 04-labeled somata appeared less differentiated than those labeled with 01. Cortical staining of OLs was visualized with 04 but rarely 01. At 33-35 weeks the distribution of 04 and 01 staining was similar in WM, but cortical staining remained largely 04. In general, the more differentiated cellular elements localized to deeper WM, where numerous processes in WM tracts were also visualized. The pattern of 04 and 01 WM labeling was similar at later ages from 40 weeks to 1 year. These data support differential expression of 04 and 01, with the 04+01- stage predominant between 21-26 weeks and the 04+01+ phenotype predominant by 33 weeks. These data provide critical baseline information for the study of cerebral WM injury in the premature infant. Dr. Stephen Pfeiffer generously provided the 04 and 01 antisera. RAT OLIGODENDROCYTE DEVELOPMENTAL STAGES GENERATED *IN VITRO* BY SELECTED COMBINATIONS OF GROWTH FACTORS. X.-D. Gan, S.A. Back*, P.A. Rosenberg and J.J. Volpe. Dept. of Neurology, Children's Hospital, Harvard Medical School, Boston, MA 02146.

Cerebral white matter injury in the premature infant is believed to arise from death of oligodendroglial (OL) precursors whose loss results in the impaired myelination which characterizes cerebral palsy. Here, we tested the effect of selected combinations of growth factors upon differentiation of OLs in culture with the ultimate aim of testing the relative vulnerability of these cells at different stages to death induced by cystine deprivation, a model of oxidative stress (Yonezawa et al., *J. Neurochem.*, in press).

OL precursors (O4+/O1-) were isolated using the immunopanning protocol of Gard et al. (Neuroprotocols 2:209-218), and were maintained in a chemically-defined medium supplemented every 72 h with selected growth factors. Three days after plating, cells cultured in 10 ng/ml of basic fibroblast growth factor (bFGF) and platelet derived growth factor AA (PDGF) were 91 ± 3% A2B5+ with only 21± 8% 04+ (n=3). By 8d after plating, cells in this medium were more differentiated with 83 ± 6% 04+ and only 23 ± 10% 01+ (n =5). A2B5 staining was present on 63 ± 17% of these cells. A more differentiated mixed population of cells was achieved after 8d in 10 ng/ml of PDGF, ciliary neurotrophic factor (CNTF), neurotrophin-3 (NT-3) plus 15 nM thyroid hormone (T3). These cells were 85 ± 4% 04+ and 62 ± 7% 01+ with 51± 10% retaining A2B5 staining (n=6). By contrast, a more differentiated population was achieved when cells were grown in medium containing only CNTF (10ng/ml), 5 μM forskolin plus 15 nM T3 with 91 ± 1% MBP+ (n=3) and only 12 ± 8% A2B5+. Thus, it is possible to generate immature and mature populations of OLs to characterize differences in their intrinsic susceptibility to oxidative stress and the molecular basis for these differences. Dr. Stephen Pfeiffer generously provided the 04 and 01 antisera. Supported by: a Grass Foundation Morison Fellowship, the Reynolds Rich Smith Foundation, NICHD P3018655 and NINDS NS01855-01.

A ROLE FOR INTEGRINS IN THE DIFFERENTIATION OF OLIGODENDROCYTES. PC Buttery, DAS Compston and C ffrench-Constant.* Wellcome/CRC Institute of Developmental Biology, Cambridge, U.K. and MRC Centre for Brain Repair, Cambridge, U.K.

Oligodendrocyte precursors migrate from their origin extensively throughout the CNS during the later stages of embryogenesis and early postnatal life. After a period of proliferation and migration the widely dispersed precursors differentiate into non-migratory, post-mitotic cells capable of myelinating axons. Previous work from our laboratory has demonstrated in rodents that such oligodendrocyte lineage cells when cultured in vitro express a limited repertoire of integrins and that this repertoire is modulated during maturation. Thus immature migratory cells express αvβ1, α6β1 and αvβ80kD, whilst the mature cells do not express αvβ1, but have upregulated αvβ5 (1).

Using similar in vitro methods we show here that in the presence of bFGF, a growth factor which is known to inhibit oligodendrocyte differentiation as assessed by standard markers, the cells maintain an immature pattern of integrin expression with αvβ5 remaining unexpressed. Further, following the withdrawal of bFGF in the presence of specific antibody blockade of αvβ5, the cells show a reduced ability to complete the normal maturation that follows growth factor withdrawal and show an increased degree of apoptosis. We suggest that an extracellular signal, mediated by the αvβ5 integrin, is necessary for oligodendrocyte precursors to complete successfully the normal maturational process.

EFFECTS OF CELL-CELL INTERACTIONS ON THE DEVELOPMENT OF OLIGODENDROGLIA AND NEURONS *in vitro*. C.A.Ingraham[1,2], L.J.Rising[1], T.L.Fletcher[1,2], P.A.Clamp[2], J.M.Morihisa[1]. Depts. of Psychiatry[1] and Pharmacology &Neuroscience[2], Albany Medical College, Albany, N.Y. 12208.

Interactions among neurons, oligodendroglia and astroglia are likely to play key regulatory roles influencing the development of neurons and oligodendroglia. This study was initiated to examine how these reciprocal interactions may affect the development of hippocampal pyramidal neurons, and the expression of stage-specific markers by developing oligodendroglia. Two primary cultures were prepared: (A) Cells were dissociated from E18 rat hippocampi (Goslin and Banker, 1991) and (B) O4+/O1- immunopanned cells were prepared from P4 rat cerebral cortices. Cells were then grown under four conditions: (1) Hippocampal cells were cultured on coverslips; (2) O4+/O1- cells were cultured on coverslips; (3) Hippocampal cells and O4+/O1- cells were co-cultured on the same coverslips; (4) Separate coverslips with hippocampal cells only and coverslips with O4+/O1- cells only were placed in a culture dish together. For all conditions, coverslips were inverted over type 1 astroglia, and maintained in Basal Defined Medium. Hippocampal pyramidal neurons cultured either with or without O4+/O1- cells were fixed 1 day after plating, and analyzed by phase microscopy to determine the proportion of cells at specific stages of development (Stages I-III). O4+/O1- immunopanned cells grown with or without hippocampal neurons were processed for fluorescence immunocyto-chemistry with either O4, O1 or MBP antibodies, and evaluated for their expression of these markers. Preliminary evidence suggests that soluble signals from oligodendroglia may accelerate the early development of hippocampal neurons *in vitro*. Supported by a Schaffer Faculty Fellowship.

PDGFα RECEPTORS AND mRNA IN OLIGODENDROCYTES OF THE DEVELOPING ANTERIOR MEDULLARY VELUM OF THE RAT. [1,2]M.F. Hornby, [1]A.M. Butt*, [1]M. Ibrahim & [2]M. Berry. Divisions of [1]Physiology and [2]Anatomy & Cell Biology, UMDS, London, UK.

Platelet-derived growth factor (PDGF) appears to be important in regulating oligodendrocyte development. *In vitro*, oligodendrocyte progenitors express PDGFα receptors (PDGFαR) initially, but these are then lost from developing oligodendrocytes with time. The aim of the present study was to investigate the role of PDGFαR in oligodendrocyte development *in vivo*, in the anterior medullary velum (AMV) of the rat. AMV were isolated intact and analyzed using immunocytochemistry, *in situ* hybridization and confocal microscopy. Double immunofluorescent labelling with Rip and PDGFαR showed co-localisation prior to myelination. These promyelinating oligodendrocytes expressed high levels of PDGFαR. PDGFαR labelling also appeared to be present on Rip negative cells, which were most likely oligodendrocytes. Double immuno-labelling with O4 and PDGFαR confirmed that a population of more immature oligodendrocytes were not labelled with Rip. PDGFαR labelling appeared to be down-regulated during development but receptors were observed in the somata and along axonal myelin sheaths of myelin-forming oligodendrocytes. *In situ* hybridization demonstrated that oligodendrocytes expressed mRNA for PDGFαR throughout development. These results support a role for PDGF in regulating oligodendrocyte development *in vivo* and suggest that PDGFαR may also be important in signalling between mature oligodendrocytes and the axons they myelinate.

CHARACTERIZATION OF A PUTATIVE TISSUE-SPECIFIC REGULATORY ELEMENT WITHIN INTRON 1 OF THE MOUSE PROTEOLIPID PROTEIN GENE. A. M. Watabe* and W. B. Macklin**. Mental Retardation Research Center, UCLA Medical Center, Los Angeles, CA 90024. **Dept. Neurosciences, The Cleveland Clinic Foundation, Cleveland, OH 44195.

The myelin proteolipid protein (PLP), one of the major CNS myelin proteins, has a highly restricted cellular and temporal expression pattern. Previously, we identified a putative tissue-specific suppressor element in intron 1 of the PLP gene by transient transfection analyses. This region suppressed both homologous and heterologous promoter activities in nonglial cells (COS-1), but had no significant effect on promoter activity in an oligodendrocyte cell line (N20.1). Further studies have been done to characterize this nonglial suppressor unit (NGS) in the PLP gene. DNase I footprinting of NGS identified a 27 bp region, FP1, that is bound by proteins both in COS-1 and N20.1 extracts, and a 10 bp region (FP2) that is bound only by proteins in N20.1 cells. However, binding to FP2 did not appear to be specific by gel shift assays. Transient transfection analyses with normal and mutated FP1 constructs suggested that FP1 might work as a general suppressor within NGS. Initial characterization of the FP1-binding protein complex from N20.1 cells was begun by DNA affinity chromatography and UV crosslinking analysis. The UV crosslinking study showed three specific bands around 38, 42, and 100 kD that bound to FP1, while DNA affinity chromatography demonstrated several bands at around 33, 38, 44, and 60 kD, which were eluted from an FP1-affinity column at different salt concentrations. Our data suggest that several proteins may be involved in a complex that binds NGS and that this unit may contribute to the regulation of the PLP gene expression in a tissue-specific manner. EFFECTS OF NEURAL IMPULSE ACTIVITY ON SCHWANN CELL ADHESION, PROLIFERATION, AND MYELINATION. B. Stevens, K. Itoh* and R.D. Fields. LDN, NICHD, NIH, Bethesda, MD 20892.

We have previously reported that the number of Schwann cells associated with mouse dorsal root ganglion (DRG) axons in culture is reduced after stimulation with patterns of neural impulses that lower neuronal expression of the cell adhesion molecule L1 (*Science*, 1995;**270**,1369-1372). The present study investigates the extent to which this reduction is due to reduced adhesion between Schwann cells and DRG axons or reduced Schwann cell proliferation, and tests whether these activity-dependent changes influence axon myelination. Incorporation of 5-bromo-2'-deoxy-uridine into Schwann cells undergoing mitosis was used to quantify Schwann cell proliferation, and morphological and immunocytochemical staining for MAG and Gal-C were used to monitor Schwann cell differentiation and myelination of stimulated and unstimulated axons in culture. Action potential stimulation that reduced L1 expression (0.1 Hz for 5 days) also reduced adhesion of purified Schwann cells to DRG neurites in an acute adhesion assay ($p < 0.001$). Preliminary results also suggest a decrease in proliferation of Schwann cells on axons stimulated at frequencies that lower expression of L1 ($p < 0.09$). Activity-dependent regulation of cell adhesion molecules may be important in controlling Schwann cell-axon association and myelination of peripheral axons during development and regeneration. EXPRESSION OF NITRIC OXIDE SYNTHASE (NOS) FOLLOWING HYPOGLOSSAL NERVE AVULSION. W. H. A. Yu*. Department of Cell Biol. & Anat. Sci., City University of New York Medical School, New York, NY 10031.

Following transection or crush of the rat cranial nerves, many axotomized motor neurons express NOS until axonal regeneration restores contact with targets, suggesting that postsynaptic targets likely inhibit NOS expression in neurons normally. However, there may be other NOS inhibitors since not all axotomized neurons expressed NOS; and in nerve ligation to prevent target reinnervation, the number of axotomized neurons being NOS positive was eventually reduced. Furthermore, BDNF and GDNF, neurotrophic agents known to block NOS induction in axotomized neurons, are synthesized in many cell types. The present study investigated the possibility of Schwann cells as NOS inhibitors. The right hypoglossal and vagus nerves of adult rats were transected, and the proximal hypoglossal nerve stump was avulsed to remove Schwann cells from interacting with axotomized neurons. At selected postoperative (PO) intervals, animals were perfused intracardially with 4% paraformaldehyde in PBS, and 30 um-thick coronal frozen sections were reacted for NADPH-diaphorase or stained for NOS immunocytochemically. At 2 wks PO, more than 90% of neurons in the avulsed hypoglossal nucleus (HN) were NOS positive, in contrast to the maximum of 60% in the HN attained at 2 wks following nerve transection shown previously. There was a 50 and 70% cell loss in the avulsed HN 4 and 6 wks PO, respectively, compared to about 6 and 13% loss in the HN at the same PO intervals following nerve transection. In the dorsal motor nucleus of the vagus nerve, the extent of NOS induction and cell loss were below those observed in the avulsed HN. These data are consistent with the view that Schwann cells in the proximal nerve stump play an important role in regulating NOS expression in neurons disconnected from their targets, and enhance the survival of axotomized neurons by dampening NOS expression thereby attenuating its neurodestructive effect.

PURIFICATION AND FUNCTIONAL ANALYSIS OF PRIMARY FETAL HUMAN SCHWANN CELLS. T. J. Lopez, M. F. Dauzvardis*, and G. H. De Vries. Dept. of Cell Biology, Neurobiology, and Anatomy, Loyola University Medical Center, Maywood, IL, 60153, USA, and Research Service, Hines VA Hospital, Hines, IL, 60141, USA.

We have developed methodologies useful for isolating large numbers of fetal human Schwann cells (FHSC) and obtaining highly pure cultures of FHSC *in vitro*. The FHSC originate from fetal peripheral nerve samples 18-20 weeks *in utero*. Our methods give a high cell yield of viable cells ($2.69\{\pm0.30\} \times 10^6$ living cells per 100 mg of tissue), and the number of contaminating fibroblasts is less than when SC are isolated and recovered from adult human nervous tissue. Fibroblasts were eliminated from FHSC cultures by cycling with AraC, and immunocytochemical staining was used to characterize primary FHSC. We find: *(a)* FHSC are bipolar, spindle-shaped, and align in fascicles similar to adult human SC; *(b)* fibroblasts can be eliminated from these primary FHSC cultures more readily than from adult human primary SC cultures, where they persist without addition of mitogens; *(c)* primary FHSC are immunoreactive with antibodies to S100, MBP, and P_0, and also are O1 and O4 positive; *(d)* these FHSC express the early glial cell markers GFAP and cKIT, as well as the low affinity nerve growth factor receptor, LNGFR, and do not express laminin; and *(e)* FHSC cultured *in vitro* can myelinate fetal human dorsal root ganglion neurites *in vitro*. These results indicate that FHSC can be obtained and cultured for months *in vitro*, morphologically resemble adult human SC but lack the mature SC immunocytochemical phenotype, however these FHSC are myelin-competent. This method of FHSC isolation and the *in vitro* system for assessing functional capacities of these primary FHSC provide valuable tools for understanding the development of normal human SC. PERIPHERAL MYELIN PROTEIN 22 BELONGS TO A GENE FAMILY V. Taylor, A.A. Welcher[1] and U. Suter*. *Institute of Cell Biology, ETH-Hönggerberg, CH-8093 Zürich, Switzerland.* [1]*Amgen Inc. Thousand Oaks CA 91320, USA.*

Peripheral myelin protein 22 (PMP22) is expressed in many tissues but mainly by Schwann cells as a component of compact myelin in the peripheral nervous system. Mutations affecting the *PMP22* gene are associated with hereditary motor and sensory neuropathies. Although these mutations lead mainly to abnormalities of myelin structure and function, PMP22 is thought to play an additional role in cell proliferation. We have defined the PMP22/EMP/MP20 gene family by characterizing the PMP22-related epithelial membrane proteins-1, -2 and -3 (EMP-1 to -3). The EMP cDNAs predict polypeptides with structural similarity and approximately 40% amino acid identity to PMP22. The EMPs are most prominent in non-neural tissues. However, EMP-1 and EMP-3 are expressed in the brain and EMP-1 protein is associated with PNS myelin in the adult. EMP-1 and PMP22 mRNA levels are inversely regulated in the degenerating rat sciatic nerve after injury and by forskolin in cultured Schwann cells.

These proteins are likely to serve similar functions possibly related to cell proliferation and differentiation and they may also be able to compensate for PMP22 mutations in non-nervous tissues.

A PROBE FOR PERISYNAPTIC SCHWANN CELLS AT FROG NEUROMUSCULAR JUNCTIONS.

T. R. Tyner*, S. H. Astrow, J. Morrow and C.-P. Ko, Dept. of Biological Sciences, University of Southern California, L.A., CA 90089-2520.

Perisynaptic Schwann cells (PSCs), the glia that cover nerve terminals at neuromuscular junctions (NMJs), have been proposed as guidance cues for nerve terminal growth during synaptic remodeling in frog muscle (Ko & Chen, *J. Neurosci.* 16:1780). However, the role(s) of PSCs in synaptic formation and reinnervation has been difficult to study due to a lack of suitable probes. Using *Torpedo* electric organ as an immunogen, we have generated a monoclonal antibody (SC-1) that recognizes a carbohydrate moiety associated with the surface of PSCs. Confocal microscopic examination of NMJs double-labeled with SC-1 and α-bungarotoxin reveals PSC "fingers" interdigitating with clusters of acetylcholine receptors (AChRs). SC-1 labeling disappears about two weeks after nerve section. In contrast, labeling is unchanged after muscle damage when the nerve is left intact. Thus, maintenance of the SC-1 epitope is innervation-dependent but muscle-independent. Indirect immunocytochemical staining with SC-1 can be performed in combination with vital staining of nerve terminals *in vivo* with separate visualization of the two probes. Such studies reveal PSC processes longer than nerve terminal branches at some adult NMJs. Repeated *in vivo* observations of these cases are being pursued to test the hypothesis that PSC processes lead nerve terminal sprouts. At NMJs in larval *Xenopus* (stages 28-35), clusters of AChRs are detected prior to SC-1 labeling, suggesting either that PSCs appear after synaptogenesis or that the SC-1 epitope is upregulated during development. On immunoblots from *Torpedo* electric organ and *Rana* nerve, SC-1 recognizes a major band of Mr. 200 kDa. The identity of this glycoprotein is currently being investigated through immunopurification and sequence analysis. [Supported by NIH 17954 to CPK & NSF IBN 9421238 to SHA.]

RETINAL DEVELOPMENT I

GENE EXPRESSION IN THE ADULT RAT RETINA MEDIATED BY DIFFERENT ADENOVIRUS VECTORS. T.N. Jelsma*, L.J. Aigner, A. Di Polo, G.M. Bray, A.J. Aguayo. Centre for Research in Neuroscience, Montreal General Hospital Research Institute and McGill University, Montréal, QC. H3G 1A4.

We have investigated the potential of adenovirus vectors for gene delivery to the retina of adult rats. Previous work in our laboratory with an adenovirus vector expressing ß-galactosidase under the control of the CMV promoter (*AdCMVβGal*, provided by Dr. R. Slack, MNI), demonstrated X-Gal staining in Müller glia at 5-7 days after injection, but expression in neurons was not observed. We have repeated these experiments with an adenovirus vector expressing ß-galactosidase under the control of the RSV promoter (*AdRSVβGal*, provided by Dr. U. Müller, UCSF). In addition to the expression in Müller cells with this vector, neurons in the ganglion cell and inner nuclear layers also showed reporter gene expression.

The differences in the cell type expression by the two adenovirus vectors may reflect differences in the activities of the RSV and CMV promoters in neurons of the retina. An alternative explanation is that expression of the CMV promoter may not be tolerated in retinal neurons, and infection of these neurons leads to cell death. These results suggest that some selectivity might be achieved by adenovirus vector-mediated gene delivery through the use of different viral promoters.

BIPOLARS SEPARATE; RETINAL GANGLION CELLS INTEGRATE: CONTRASTING GROWTH PROGRAMS IN CHANGED RETINAL CELL DENSITY CONDITIONS. B.D. Rubin, J.C. Crowley, M. Xiong, and B.L. Finlay*, Developmental Neuroscience Group, Cornell Univ., Ithaca, NY 14853.

The structure of the vertebrate retina reflects two contrasting functional requirements: preservation of precise spatial information, principally mediated through its vertical connections, and spatial integration, mediated through its horizontal connections. We have used two manipulations to alter cell density and convergence onto retinal ganglion cells (RGCs) to examine the developmental regulation of horizontal and vertical connections. Visual form deprivation induces eye growth in the chick, resulting in a decrease in RGC and bipolar cell density without changing their numbers. Partial optic nerve section decreases RGC number without changing bipolar cell number.

In conditions of experimentally induced low RGC density, or in the normal retinal periphery (relative to central retina), RGC arbors grow compensatorily, maintaining coverage of the retina. In the same conditions, bipolar inner plexiform arbor diameters increase by a smaller relative amount than RGC arbors. This limit on tangential growth may reflect a general limitation on arbor growth in bipolar cells. In the enlarged retina, bipolar cells have fewer strata, suggesting that arbor diameter increases at the expense of stratification. In all conditions, we find a negative correlation between a bipolar cell's number of strata and the total length of arbor in each stratum. RGCs respond to retinal expansion with dendritic growth that maintains arbor geometry and, in the goldfish, produces more synapses along their processes (Hitchcock, 1993). We observe that bipolar cells in enlarged retinas change their geometry, increasing their arbor density by adding new branches. In RGC depletion, RGC arbors increase in size and density while bipolar cells reduce their arbor area and increase arbor density.

The respective changes in branch geometry of RGCs and bipolar cells suggest the following inductive sequence: retinal stretch induces interstitial growth in RGC arbors which in turn induces sprouting of branches in bipolars. In the RGC depleted retina, increased local branching occurs at the expense of total arbor area. The different growth strategies of RGCs and bipolar cells act together to maintain both spatial resolution and integration in varying convergence conditions. (Supported by R01-NS 19245)

MONOCULAR ENUCLEATION PREVENTS RETINAL GANGLION CELL LOSS FOLLOWING NEONATAL VISUAL CORTEX DAMAGE IN CATS

Kurt R. Illig *, Von R. King and Peter D. Spear, Psychology Dept. and Center for Neuroscience, University of Wisconsin, Madison,WI 53706.

Damage to primary visual cortex (VC) in young cats leads to severe retrograde degeneration of the lateral geniculate nucleus and selective transneuronal retrograde degeneration of retinal ganglion cells (RGC) with medium-sized somata. Previous studies have shown that "programmed" RGC death associated with development in one eye can be prevented by removal of the other eye, suggesting a role for binocular competition in normal RGC death. The present study investigated whether eliminating binocular competition through monocular enucleation also attenuates the ganglion cell loss that accompanies an early VC lesion. Five one-week-old cats received a unilateral VC lesion (areas 17, 18, and part of 19), and three of these cats also received a monocular enucleation at the same time. Two normal control animals also were examined. RGC measurements were made from animals at five weeks of age from flat-mounted retinae. Sampling was restricted to a retinal area corresponding to the retinotopic representation included in the VC lesion. Results indicate a marked loss of medium-sized RGCs in the hemiretina projecting to the damaged hemisphere in cats that had received a VC lesion alone, but there was no such loss in animals that also had a monocular enucleation. No significant difference was found between hemiretinae in normal controls. These results suggest that the RGC loss seen after an early visual cortex lesion is influenced by binocular competition.

681.4

THE DEVELOPMENT OF RETINAL GANGLION CELL STRATIFICATION IN THE FERRET. Glendy Yeung, MacKenzie Hilfers, and Stefan R. Bodnarenko*. Dept. of Psychology, Smith College, Northampton, MA 01063.

A fundamental attribute of the vertebrate visual system is the segregation of ON and OFF pathways signaling increments and decrements of light. In the mature retina, dendrites of ON and OFF retinal ganglion cells (RGCs) stratify in different sublaminae of the inner plexiform layer (IPL), but early in development, the dendrites of these cells are multistratified, ramifying throughout the IPL. In the present study, we have examined the time course of ON and OFF RGC dendritic stratification in the developing ferret.

Postnatal ferrets were sacrificed at various ages from P0 to P40, retinas were fixed and optic nerves implanted with DiI. RGCs were examined in central and peripheral retinal regions in both flatmounts and cross-sections. The dendrites of labeled cells were identified as branching within one (unistratified) or more than one (multistratified) sublaminae of the IPL. Distinct classes of RGCs could be recognized by P10. At this age, beta RGCs are readily distinguished by their relatively short bushy dendrites branching in close proximity to the cell body. The stratification of beta RGC dendrites is already underway in both central and peripheral regions at P10. At this age, we estimate that over 80% of the cells are multistratified. During the next ten days, dendritic stratification proceeds concurrently in the central and peripheral regions so that by P20, about 60% of the cells are multistratified. By the end of the first postnatal month, around the time of eye-opening, approximately 35% of the cells remain multistratified. Dendritic stratification continues well past P40 when the incidence of multistratified cells is about 15%. The timing of ferret beta RGC dendritic stratification closely parallels the stratification process previously reported in cats. Supported by Smith College CFCD Grant

FORMATION OF ON AND OFF SUBLAMINAE WITHIN THE INNER PLEXIFORM LAYER OF RAT RETINA REVEALED BY RECOVERIN IMMUNOLABELLING. D. M. Kahn, C. Meissirel*, & L. M. Chalupa, Dept. Psych & Ctr. Neurosci., UC Davis, 95616.

In adult rat retina, a polyclonal antibody against recoverin stains two bands of processes within the inner plexiform layer (IPL), corresponding to ON and OFF cone bipolar cell terminals (Milam et al., 1993). In the present study we utilized this antibody (generously donated by Dr. A. M. Dizhoor) to examine the ontogeny of bipolar process stratification in the postnatal rat retina. At P5, the earliest age studied, the IPL was virtually devoid of recoverin labelling. By P12, immunoreactivity was clearly apparent within the IPL, and at this age there was a prominent band of labelled processes in the outer half of this layer, corresponding to the OFF sublamina. Furthermore, the intensity of label was greater in the central than peripheral retinal regions. Five days later, at P17, two distinct sublaminae could be visualized and these appeared largely indistinguishable from the pattern observed in the mature rat retina. These observations suggest that ON and OFF cone bipolar terminal processes become segregated during the first two postnatal weeks, and that the OFF sublaminae matures earlier than the ON.

THE METABOTROPIC GLUTAMATE AGONIST 2-AMINO-4-PHOSPHONOBUTYRIC ACID (APB) DOES NOT ACTIVATE CURRENTS IN POSTNATAL CAT RETINAL GANGLION CELLS. L.C. Liets & L.M. Chalupa*, Sect. of Neurobiology, Physiology & Behavior, University of California, Davis 95616.

Whereas in the mature retina APB selectively activates currents in rod bipolar and On-cone bipolar cells, recent molecular studies have suggested the possibility of a transient appearance of an APB-sensitive receptor in developing retinal ganglion cells (Duvoisin et al., 1995). In the present study the whole-cell and perforated variations of the patch-clamp method were employed to assess the responsivity of postnatal cat retinal ganglion cells to APB. We examined the developmental period (P8-P26) during which APB treatment has been shown in our laboratory to block the normal stratification of retinal ganglion cell dendrites into ON and OFF sublaminae of the IPL (Bodnarenko et al, 1995). In our initial studies, APB was purchased from RBI (Natick, Mass). Although application of this glutamate agonist elicited inward sustained currents, amino acid analysis revealed that the RBI product was contaminated by 8% glycine. In subsequent experiments applications of uncontaminated APB (Cal Biochem, La Jolla, CA) never yielded responses in postnatal retinal ganglion cells which displayed normal currents to other glutamate agonists. The findings do not support the notion of transient expression of APB receptors in retinal ganglion cells during the developmental period studied. (Supported by grants from NIH-NEI and NSF.)

BLOCKING CALCIUM-ACTIVATED POTASSIUM CHANNELS INDUCES BURSTING ACTIVITY IN DEVELOPING FERRET RETINAL GANGLION CELLS. G-Y Wang* & L.M. Chalupa. Sect. Neurobiology, Physiology & Behavior, University of California, Davis, CA95616.

Patch-clamp recordings were made from intact ferret retinas to assess the consequences of blocking two types of calcium-activated potassium channels (BK and SK) on spontaneous discharge patterns. At P30 or older, most retinal ganglion cells manifested sustained spontaneous firing patterns. Addition of apamin or charybdotoxin, (specific blockers of SK and BK, respectively) into the bath solution caused cells to change their firing to prolonged bursting pattern. This was observed in every cell tested, irrespective of morphological class identified by Lucifer-yellow filling. In contrast, at younger ages (P15), the spontaneous activity was characterized by bursting discharges. In these younger cells application of the calcium-activated potassium channel blockers had little or no effect. These findings imply that functional development of calcium-activated potassium channels may contribute to the shift from bursting to sustained spontaneous discharges pattern in ferret retinal ganglion cells. (Supported by NEI & NSF).

REORGANIZATION OF RECEPTIVE FIELD PROPERTIES AFTER TREATMENT OF THE DEVELOPING RETINA WITH APB. C. Gargini[1,2], L. M. Chalupa[3] and S. Bisti*[2,4] [1]Ist. Policattedra Discipline Biologiche, Università di Pisa,[2]Ist. di Neurofisiol. C.N.R., Pisa, Italy [3] Sect. Neurobiol. Physiol. & Behavior, UC Davis 95616 and [4]Dept. STBB, Univ. L'Aquila, Italy.

The gradual restriction of initially multistratified ganglion cell dendrites into ON and OFF sublaminae of the IPL can be arrested by treating the developing retina with APB, the metabotropic glutamate agonist (Bodnarenko & Chalupa, Nature 1992; Bodnarenko et al., J. Neurosci., 1995). To assess the possible functional consequences of such treatment, cats were administered a daily injection of APB from P3 until P30, with a 2 day respite on week-ends. When the animals were at least 3-months of age, extra-cellular recordings were made from the A and A1 laminae of the dLGN and receptive field properties were examined using computer-controlled stimulus presentations. In the dLGN layers innervated by the normal eye, all cells responded to small spots of light centered on the receptive field with either ON or OFF discharges . In marked contrast, about 40% of the cells in the layer innervated by the APB-treated eye responded to such stimuli with ON-OFF discharges. Such responses were elicited from all regions of the receptive field. This incidence of ON-OFF cells was nearly identical to the proportion of ganglion cells with multistratified dendrites in the APB treated retinas.

SODIUM VOLTAGE-GATED ACTIVITY REGULATES THE FORMATION OF GANGLION CELL MOSAICS IN THE DEVELOPING CAT RETINA. G. Jeyarasasingam*, C. J. Snider and L. M. Chalupa. Section of Neurobiology, Physiology & Behavior, UC Davis, CA 95616.

The adult cat retina is characterized by the regular distribution of ON and OFF ganglion cells (Wässle et al., 1981). Previous studies have shown that: (1) Retinal ganglion cell (RGC) loss during development contributes to the formation of mosaic distributions (Jeyarasasingam et al., 1995); (2) blocking sodium voltage-gated activity affects the pattern but not the magnitude of RGC loss (O'Leary et al., 1986). Here we have investigated whether intraocular tetrodotoxin (TTX) injections during the period of postnatal RGC death perturbs the formation of retinal mosaics. The regularity of retinal distributions was analyzed by comparing the incidence of opposite sign (ON/OFF) pairs in TTX injected and control animals. Computer simulations were used to demonstrate that the superimposition of two regular distributions results in a high incidence (~90%) of opposite sign pairs. Blocking retinal activity with increased TTX concentrations resulted in a decreased percentage of opposite sign pairs (Normal: ~90%; 4mM TTX: ~70%; 5mM TTX: ~60%). These observations suggest that sodium voltage-gated activity plays a role in the formation of RGC mosaic distributions. (Supported by NSF and NEI)

RETINAL GANGLION CELL DEPLETION INCREASES THE EXPRESSION OF GABA AND GAD IN THE GANGLION CELL LAYER. [1]Yamasaki, E.N.*; [1,2]Costa, B.L.S.A.; [1]Barbosa, V.D. and [1]Hokoç, J.N. Inst. Biofisica Carlos Chagas Filho, Univ. Federal Rio de Janeiro, RJ and Dept. Fisiologia e Farmacologia, Univ. Federal Pernambuco, PE, Brazil.

Destruction of visual target nuclei induces retrograde degeneration of retinal ganglion cells (RGCs) but fails to show clear morphological effects on other cell types (amacrine and bipolar cells) that now lack their normal intraretinal targets. Using immunohistochemistry in radial sections and whole-mounted retinas, we have investigated the effect of neonatal lesion of the optic tract and superior colliculus on the phenotypic expression of GABA and its synthetic enzyme, GAD, in the ganglion cell layer (GCL) of the rat retina. In radial sections of normal adult rats, immunoreactivity for GABA is present in orthotopic and displaced amacrine cells. In operated adult rats, many more cells are labeled in the GCL and quantitative analysis of the whole-mounted retinas revealed about 40% increase in the number of GABA immunoreactive cells. This finding probably reflects an increase in GABA synthesis since GAD-65 and GAD-67 immunoreactivity is also increased in retinas of operated animals. More cells are immunoreactive for the two GAD isoforms and GAD-65 is now also expressed in cells in the GCL, which was not observed in the normal adult animal. Other than its main action as an inhibitory neurotransmitter, GABA has been involved in several other roles during development including neuronal migration, proliferation, differentiation and survival. It is possible that increased GABA levels in operated rats could modulate inhibitory synaptic inputs onto surviving RGCs, have a protective effect on the survival of other cell types, or influence phenotypic differentiation of neurons at the time of lesion.

ORGANIZATION OF THE RETINA FOLLOWING EARLY CEREBRAL HEMISPHERECTOMY IN CAT. H. Theoret, M. Herbin*, D. Boire, M. Ptito. Departement de Psychologie and CRSN, Université de Montréal, Montréal, CAN.

Normal cats underwent the surgical removal of a whole cerebral hemisphere at post-natal ages of 25 and 26 days. After 68 months of survival, their retinae were removed, flat mounted and Nissl stained. Retinal ganglion cell (RGC) distribution and morphometry were studied using a computer-controlled image analysis system. The results obtained on the hemispherectomized cats (HC) were compared to normal cats (NC). The axial length of the eyeball was similar for both groups (ca 23,7 mm). The maximum density of RGC was observed in the *area centralis* of both groups and was not significantly different (HC= 7520; NC= 7692), neither was the total number of RGC (HC= 122 037; NC= 124 258). In each HC hemiretina the number of RGC was similar to that of the corresponding NC hemiretina. The RGC soma size distributions at different eccentricities revealed no significant differences between NC and HC. Moreover, the distribution of RGC in the central and peripheral regions of the HC retina is similar to that observed in the NC. It thus appears that the ablation of a whole hemisphere at post-natal ages of P25-P26 does not result in visible transneuronal retrograde degeneration of RGC. These results are comparable to previously reported data for visual cortex lesioned adult cats, where the relative proportions and absolute numbers of cells appear no different than those of normal animals (Kalil, 1984). This contrasts with a perinatal lesion (P1-P14) of areas 17-18-19 where the retinal periphery is affected.

EXPERSSION OF BETA-AMYLOID PRECURSOR PROTEIN IMMUNOREACTIVITY IN DEVELOPING RAT RETINA AFTER NEONATAL OPTIC TRACT LESION. S.T Chen[1], LJ Garey[2] and L.S. Jen[2*]. Department of Anatomy, National Cheng Kung University, Taiwan[1], Charing Cross and Westminster Medical School, London W6 8RF, U.K.[2]

In order to provide insight into the role of beta-amyloid precursor protein (ß-APP) and mechanisms involved in its metabolism in the developing central nervous system, the expression pattern of ß-APP in rat retinas at postnatal (P) day 0, 4, 7, 10, 14 and 30 was studied after neonatal optic tract lesion, using immunocytochemistry. In retinas contralateral to the lesion, immunoreactive cells were observed in the ganglion cell layer (GCL) at P0 and P4 but not from P7 onwards. The density of immunoreactive cells was considerably higher at P4 than at P0. The inner plexiform layer was immunoreactive at P7 and P10 but not in more mature retinas. At P14, however, immunoreactive cellular processes resembling endfeet of retinal Müller glial cells (RMGs) was observed. The inner part of the radial process of RMGs also became immunoreactive at later stages. While a similar pattern of immunostaining was observed in normal retinas and retinas ipsilateral to the optic tract lesion, immunoreactive cells were located only in the GCL at P0. These results suggest that: 1) axotomy results in upregulation or *de novo* synthesis of ß-APP in developing retinal ganglion cells (RGCs); 2) ß-APP has a role in synaptogenesis in the inner retina; 3) expression of ß-APP in developing RMGs is related to functional maturation of the retina and not affected by degeneration of RGCs. CHARACTERIZATION OF THE DYNAMICS OF RETINAL FIBERS DURING EARLY REGENERATION IN ADULT GOLDFISH *IN VIVO*. A.J. Dawson* and R.L. Meyer. Dev. Biol. Center, University of California, Irvine, Irvine, CA 92717

In many systems, the formation of orderly synaptic connections emerges from a less orderly projection. In goldfish, the regenerating retinotectal projection has been shown to initially form a grossly retinotopic map which becomes more refined with time. The initial changes in the projection are dramatic and proceed independently of impulse activity, perhaps in response to local signals. The dynamics of this early rearrangement are not well understood. To elucidate these changes, we labeled a small area of either dorsal or ventral retina 14 to 19 days after optic nerve crush with a small injection of DiI. Four to six days later, the tectum was exposed and labeled fibers in the dorsal tectum of the living fish were imaged with a cooled CCD camera. Images of the fibers were collected every hour for 5 to 8 hours to characterize the dynamic behavior of regenerating fibers. Fibers from ventral retina, which were consequently in their correct half of tectum, were found to be relatively stable. They either showed no change or grew or retracted by small amounts, usually less than 30µm. In contrast, regenerating fibers from dorsal retina which were in their incorrect half of tectum showed dramatic regressive changes. They retracted by larger amounts, up to 100µm, and showed little growth, while only a few fibers remained unchanged. It is also noteworthy that some retinotopically incorrect fibers persisted during the observation period indicating they did not immediately retract upon encountering inappropriate areas. These results together imply that fibers in non-retinotopic areas correct initial target errors primarily by retraction rather than by accelerated or directed growth toward their appropriate half of tectum.

WHOLE CELL AND SINGLE CHANNEL RECORDING FROM REGENERATING OPTIC AXONS OF ADULT GOLDFISH AND MICE IN VITRO. Brad J. Kolls* and R. L. Meyer. Dept. Dev. & Cell Biol. University of California, Irvine, CA 92717

Vertebrate axons have rarely been recorded from because of their small size. We have found, however, that optic axons from adult goldfish and mice that are regenerating in culture can be reliably recorded by patch clamp recording. When pieces of retina are placed in organotypic culture, optic axons will grow out from the explants onto the substrate. These fibers exhibit periodic varacosities along their shaft that can be patched with gigaohm seals. Single channel and whole cell currents can be observed.

Using this technique, we have begun to ask whether there might be differences in physiology, channels or receptor properties that might explain why severed optic axons can regenerate and restore function in adult goldfish but not in adult mice. An important first question is whether these fibers, which regenerate without myelin, can conduct action potentials. This is an issue for mammals since optic fibers are normally myelinated and demylination is associated with conduction failure. We found that both fish and mouse optic axons contain voltage sensitive sodium channels and are capable of generating action potentials. Further studies will determine if there is any difference between goldfish and mouse in their capacity to reliably propagate these action potentials. (Supported by PHS EY06746)

BLOCKING ELECTRICAL ACTIVITY ALTERS THE DYNAMICS OF REGENERATING RETINAL AXONS. F.A.Johnson* and R.L.Meyer Dev. Biol. Center, University of California, Irvine, Irvine CA 92717

The formation of correct connections is crucial to the proper functioning of the nervous system. In the retinotectal system in goldfish the initial projection is only roughly retinotopic and is progressively refined during regeneration in an activity-dependent manner. The dynamics of this process are not well understood. Previously we found that retraction played a major role, as axons in ectopic areas of the tectum frequently retracted by large amounts while retinotopic axons were fairly stable. To determine how the absence of activity affects the plasticity of retinal arbors, we observed axons in vivo in goldfish injected interocularly with TTX, an agent that blocks neural activity, throughout the period of activity-dependent refinement. Retinal arbors from a small area of retina were labeled by an injection of DiI 30 to 60 days following optic nerve crush. Four to six days later the tectum was exposed and images of labeled axons collected with a cooled CCD camera every hour for five to seven hours. In TTX-treated fish ectopic axons, i.e. branches in tectal areas with few or no other labeled branches, retracted by only small amounts- 10-30 um- in contrast to the large retractions (40-70 um) seen in ectopic areas of untreated goldfish. There was also no difference between ectopic axons and retinotopic axon branches: both showed changes about half the time, and the retractions of the retinotopic axons were also about 10-30 um. Thus both the elimination of ectopic axon branches and the stability of retinotopic ones was altered by the lack of activity. More importantly, the difference between the two is eliminated. Activity, therefore, is important in determining which axon branches will be eliminated.

DEVELOPMENT OF VISUAL CORTEX II

682.1

PLASTICITY FOLLOWING MONOCULAR DEPRIVATION IN FERRET PRIMARY VISUAL CORTEX. B. Chapman*[1], K.R. Zahs[2], S.L. Harris and M.P.Stryker. W.M. Keck Foundation Center for Integrative Neuroscience, Dept. of Physiology, UCSF, San Francisco, CA 94143-0444 Current addresses: 1. Center for Neuroscience, UCD, Davis, CA 95616. 2. Dept. of Physiology, Univ. of Minn., Minneapolis, MN 55455.

The ferret has become an increasingly common animal model for studies of development because it has a visual system very similar to that of the widely studied cat, but ferrets are born at a much more immature stage. There are, however, two prominent differences in the retinogeniculostriate pathway between ferrets and cats: ON- and OFF-center pathways of the ferret are more fully segregated in both LGN and cortex (Stryker and Zahs (1983) *J. Neurosci.* 3:1943; Zahs and Stryker (1988) *J. Neurophysiol.* 59:1410), and ferrets lack an ipsilateral Y-cell pathway (Baker and Stryker (1991) *Soc. Neurosci. Abstr.* 17:111).

In order to determine whether these differences in organization affect visual system development and plasticity, we have studied the effects of monocular lid suture on the ocular dominance of cells in the primary visual cortex of 2 adult and 24 juvenile ferrets. Monocular deprivation onset ranged from postnatal day 19 through 116; duration was 1 week in 18 ferrets and ranged from 2 to 19 weeks in the remaining animals.

Ferret visual cortex did show significant plasticity in response to monocular deprivation during a critical period early in life. The magnitude of the ocular dominance shift seen in the ferret at the height of the critical period is similar to that seen in the cat. Animals that experienced deprivation during the third postnatal week, when cortical cells are known already to respond to visual stimulation (Chapman and Stryker (1993) *J. Neurosci.* 13:5251) showed no ocular dominance shift, indicating that the critical period has a distinct onset.

EFFECTS OF UNEQUAL BINOCULAR INPUT ON THE ORGANIZATION OF OCULAR DOMINANCE COLUMNS (ODCS) IN DEVELOPING RHESUS MONKEYS. D.V. Bradley*, M. Tigges and R.G. Boothe. Div. of Vis. Sci., Yerkes Research Center, Depts. of Ophthalmol., Psychol., Anat. & Cell Biol., Emory Univ., Atlanta, GA 30322.

Previous studies have shown that an aphakic eye is at a disadvantage in its ability to retain cortical territory, unless the fellow phakic eye is occluded ("patched") continuously, which puts that eye at risk. Here we present the results for 3 groups of monkeys that were reared with unequal binocular input designed to enhance the outcome for each eye. Eight neonatal monkeys had the natural lens surgically removed, followed by optical correction of the aphakic eye to either a far point (AFP) or to a near point (ANP) with extended-wear contact lenses. To force usage of the aphakic eye, while preserving good vision in the fellow eye, the fellow eye was either focussed to a near point (NP), undercorrected (UC), or occluded (POAT) for part of the daytime. To label ODCs unequivocally by their reduced cytochrome oxidase reactivity, in 6 monkeys one eye was enucleated 2 wks prior to perfusion of the brain. Multiple effects of decorrelated input included strabismus, amblyopia, and an alteration in the amount of cortical territory for the aphakic eyes compared to the fellow eyes. While ODC widths of monkeys reared with AFP-NP and ANP-UC showed a reduction for the aphakic eye compared to the fellow eye, the aphakic eye (ANP) retained a normal amount of territory when paired with (POAT). We will discuss these results in terms of their implications for clinical treatment of aphakic amblyopia, as well as the modifications to ODC organization as a result of decorrelated retinal input. Supported by NIH grants RR00165, EY09737, and EY05975.

682.3

PROLONGING VISUAL CORTICAL PLASTICITY BY DARK-REARING CHANGES IMMEDIATE EARLY GENE EXPRESSION IN CAT VISUAL CORTEX. I.V. Kaplan*, Y. Guo and G.D. Mower. Department of Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, KY 40292.

An important issue in evaluating immediate early gene (IEG) inductions in the nervous system is whether they are involved in the plastic response of the neurons or simply reflect changes in neural activity. Plasticity in cat visual cortex can be maintained by dark-rearing. The aim of our study was to determine whether the inductions of *egr-1* and *c-fos* differ between normal and dark-reared cat visual cortex. Normal and dark-reared cats at 5, 10 and 20 weeks of age were used in these experiments. Normal cats at 4, 9, and 19 weeks of age were placed in total darkness for 1 week. Both normal and dark-reared animals were exposed to the visual environment for 1 hour immediately prior to sacrifice to induce the expression of IEGs. A combination of northern/slot blot analysis and immunohistochemistry was used to analyze changes in gene transcription and protein translation respectively. Brief visual experience resulted in a dramatic induction of mRNA and protein for both IEGs in both normal and dark-reared 5 weeks old animals. In 10 week old visual cortex, *egr-1* and *c-fos* remained induced though at lower levels in both rearing conditions. However, at 20 weeks of age, while the magnitude of both mRNA and protein inductions were further reduced in normal cats they remained high in dark-reared visual cortex.

Previous reports by our group indicated that the time course of IEG expression in cat visual cortex mirrors the one for visual cortical plasticity and that the inductions of these IEGs are higher in young (high plasticity) vs adult (low plasticity) cat visual cortex. The fact that delaying the decline of visual cortical plasticity by dark-rearing also delays the decline in the magnitude of IEG inductions further supports the hypothesis that the IEGs are involved in the development and plasticity of cat visual cortex.

A CORRELATION-BASED MODEL EXPLAINS THE MONOCULAR DEPRIVATION EFFECTS ON ORIENTATION AND OCULARITY MAPS AND ORIENTATION MAP RECOVERY AFTER REVERSE DEPRIVATION. E. Erwin* and K.D. Miller, W.M. Keck Center for Integrative Neuroscience and Dept. of Physiology, UCSF, San Francisco CA 94143.

Last year we presented a model of correlation-based competition between ON- and OFF-center inputs from left and right-eye LGN layers onto cortical cells. We showed how this model can lead to simultaneous development of simple cell receptive fields (RFs) organized in orientation (OR) and ocular dominance (OD) columns, with common preferred ORs on binocular cells and continuity of preferred OR across OD boundaries. We defined the patterns of LGN activity correlations necessary to achieve these results, assuming correlations were unchanging during development. We now consider changes in LGN correlations, due to onset of vision and to experimental modifications, *e.g.* monocular deprivation (MD). We assume that the two eyes' LGN activities are strongly correlated prior to eye-opening, giving correlated development of OR in the two eyes, and that inter-eye correlations subsequently become weak relative to within-eye, yielding OD columns. We model MD by assuming that lid suture causes low-level, broadly correlated activity, while retinal application of TTX eliminates activity. Either form of MD causes a shift in OD away from the deprived eye, which maintains influences particularly in patches that occur primarily near OR map singularities. Eyelid suture both reduces OR selectivity and increases ON/OFF segregation in the deprived eye, more so than TTX. Reverse deprivation restores an OR map in the newly open eye which is nearly identical to the map recorded through the originally open eye. These results are consistent with recent experimental data, with no requirement for an "innate" OR map produced by mechanisms separate from the activity-dependent process believed to occur after eye-opening. However, significant between-eye correlations in early LGN activities are required; these could be induced by the perigeniculate, corticogeniculate feedback, or LGN interneurons.

OCULAR DOMINANCE COLUMNS, ORIENTATION MAPS AND HORIZONTAL CONNECTIONS IN THE VISUAL CORTEX OF STROBE-REARED CATS. Siegrid Löwel*, Kerstin E. Schmidt and Wolf Singer. Max-Planck-Institut für Himforschung, D-60528 Frankfurt, FRG.

Ocular dominance (OD) columns develop out of an initially overlapping projection by a progressive segregation of the geniculocortical afferents serving the two eyes. Afferents conveying correlated activity group together while those conveying decorrelated activity segregate. To test whether synchronization of binocular responses prevents OD segregation we raised kittens in a stroboscopically illuminated environment. Since strobe-rearing prevents retinal motion signals we additionally tested the influence of coherent motion on the development of visual cortical maps and the specificity and layout of intrinsic horizontal connections in area 17. Five kittens were strobe-reared from birth (8 Hz; 24h/day) until 11 weeks of age. All kittens developed a divergent squint angle. In 2 kittens, [^{3}H]proline was injected into the right eye. In 3 kittens, the functional architecture of area 17 was visualized using optical imaging of intrinsic signals. Red and green beads were injected into identified monocular iso-orientation (OR) domains labelled additionally with 2-DG. The topographic relationship between labelled neurons and OR-columns was investigated in cortical flat-mount sections. Well segregated OD-columns were visible. Their mean spacing was in the range of 1000-1400µm. In area 17, cortical regions with similar orientation preferences were patchy and arranged around singularities. Horizontal connections were also patchy and in register with the 2-DG labelled same eye/same orientation domains. The presence of well-segregated OD-domains in strobe-reared cats indicates that segregation was already supported by the mismatch of responses to stationary contour borders independent of the global temporal patterning of retinal input. Furthermore,. growing up in an environment devoid of visual motion does not seem to interfere with the development of orderly orientation preference maps nor with the columnar specificity of horizontal intrinsic connections. *Supported by the MPG*

INHIBITION OF TISSUE PLASMINOGEN ACTIVATOR (tPA) IMPAIRS OCULAR DOMINANCE PLASTICITY INDUCED BY REVERSE OCCLUSION

Claudius B. Griesinger* and Christian M. Müller, Max-Planck-Institut for Developmental Biology, Spemannstr. 35/1, 72076 Tübingen, Germany

We previously demonstrated that chronical intracortical infusion of the serine-protease inhibitor leupeptin into kitten visual cortex blocks ocular dominance (OD) plasticity during reverse occlusion (RO). This deprivation paradigm predominantly induces progressive plasticity, e.g. collateral outgrowth and synaptogenesis of thalamocortical afferents. In contrast, leupeptin did not affect the consequences of short-term monocular deprivation (MD), which induces synapse elimination and branch retraction. Thus, leupeptin appears to selectively interfere with proteolytic activity necessary for the functional reactivation of thalamocortical arbors representing the reopened eye. This hypothesis is supported by the critical involvement of the plasminogen-activator/plasmin (PA/Pn) system in neurite outgrowth *in vitro (Pittman et al., J.Neurochem. 64:566, 1995)* and the effective blockade of plasmin by leupeptin. As tPA is the major PA in brain, we now chronically infused the specific tPA inhibitor tPA-Stop (1mM in pump reservoir) into the kitten visual cortex while performing RO for one week following an initial two week period of MD. Thereafter, OD, orientation selectivity, response strength and spontaneous activity of visual cortical units were electrophysiologically determined. While the latter features were unaltered in infused hemispheres, the OD shift towards the reopened eye was significantly retarded in tPA-Stop infused cortex (reversal index 40,9% versus 94% in controls). Thus, tPA does indeed participate in progressive OD plasticity. Its action can be due to the activation of the zymogen plasminogen to the active protease plasmin, which seems to be essential for sprouting. Alternatively, tPA may be implicated in the enhancement of synaptic efficacy.

DEVELOPMENTAL PLASTICITY OF MODULES IN MACAQUE V1 T. Yoshioka*, M. Tigges & S. H. C. Hendry. Krieger Inst., Johns Hopkins Univ., Baltimore, MD 21218 and Yerkes Primate Ctr., Emory Univ., Atlanta, GA 30322

Monocular deprivation in neonatal macaques alters the pattern of geniculocortical connections, so that in primary visual cortex (V1) columns dominated by the normal eye expand and those dominated by the deprived eye shrink. In examining rhesus monkeys raised from birth to P 8 months with an opaque contact lens in one eye we looked for evidence of a reorganization within V1 by using immunocytochemical staining for the neurofilament (NF) triplet proteins. Neuronal elements immunostained for these proteins included axons as well as pyramidal cell somata and dendrites. For each protein the pattern in layers IVB and IVC consisted of a series of thin, intensely immunostained stripes separated by wider, pale bands. Such a pattern contrasts with homogeneously intense staining for cytochrome oxidase (CO) in the deprived monkeys and with a pattern of alternating wide, intensely NF-immunostained bands and narrow pale bands in normally reared monkeys. In layers II-III of deprived monkeys, every other row of CO-rich puffs is marked by very intense immunostaining for the high molecular weight NF protein (NF-H), producing stripes that overlie similar stripes in layer IVC. The alternating rows of pale CO-stained puffs are characterized by poor immunostaining for each NF protein, particularly for the low molecular weight protein (NF-L), the pattern for which consists of a moderately intense matrix interrupted by the thin pale stripes (rows of CO-pale puffs). These patterns in layers II-III contrast with those of normally reared monkeys, in which intense immunostaining occurs in all puffs (NF-H) or moderately intense immunostaining occurs around them (NF-L and -M). Given the role of NF proteins in establishing and maintaining the neuronal cytoskeleton, we interpret these data to suggest that in both normal-eye and deprived-eye columns the over-all pattern of neuronal organization and the morphology of individual neurons in V1 may be altered by monocular deprivation. Supported by EY06432 (SH) and EY0937 (MT).

AXONAL AND DENDRITIC CIRCUITS OF V1 OCULAR DOMINANCE COLUMNS IN NORMAL AND STRABISMIC MACAQUE. L. Tychsen* K. Hanaway and A. Burkhalter Depts. of Anatomy and Neurobiology, and Ophthalmology, Washington Univ. Sch. of Medicine, St. Louis, MO 63110.

Monkeys who developed esotropic strabismus in the first weeks of life were studied to determine if they had alterations of V1 circuits that would explain deficits in binocular fusion and directional asymmetries of motion responsiveness. Behavioral testing documented that two strabismic monkeys had the motion VEP and pursuit asymmetries of human infantile strabismus. A double-labeling experiment was then carried out using the neuronal tracer BDA and the ODC label cytochrome oxidase. The axons and dendrites of individual neurons, the ODCs within which they resided, and the neighboring ODCs to which they connected were analyzed in tangential sections through layers 2-6. Axonal projections from injected neurons were distributed as ellipses with short/long axis ratios ~0.50. The long axis in both normal and strabismic macaque tended to orient orthogonal (± 30°)to rows of ODCs. The strabismic monkeys showed, in addition, a paucity of binocular connections between neighboring right and left eye ODCs. Dendritic patterns were less elliptical (short/long axis ratios ~0.75) but also tended to orient orthogonal to ODC rows, especially in the strabismic monkeys. The tendency for dendrites to stay within a single ODC, or to be otherwise directionally-biased, was not strong outside layer 4C. Our results show deficits in binocular connections between ODCs in strabismic V1, but otherwise no striking alteration in the elliptical distribution of axons and dendrites. The elliptical shapes do not change with visual field eccentricity, and do not conform to known rules of cortical magnification or retinotopic anisotropy.

PRONOUNCED INTRINSIC VARIABILITY OF OCULAR DOMINANCE COLUMN PERIODICITY IN NORMAL MACAQUE MONKEYS D.R. Hocking*, J.C. Horton, Dept. of Ophthalmology, UCSF, San Francisco, CA 94143-0730.

Mosaics of OD columns were examined in 6 normal adult *Macaca fascicularis* by CO staining after monocular enucleation. The range in periodicity is exemplified by the flatmounts shown below from 2 different animals. We measured 1.34 mm/column pair in the top specimen & 0.79 mm/column pair in the bottom specimen, along the V1/V2 border. This innate variability should be taken into account in analyzing the effects of manipulations (e.g., strabismus), which are reported to alter the periodicity of OD columns. (NEI supported)

BRAIN-DERIVED NEUROTROPHIC FACTOR DISRUPTS EFFECTS OF MONOCULAR DEPRIVATION IN KITTEN VISUAL CORTEX. Y. Hata*, N. Katsuyama, M. Fukuda, M. Ohshima, T. Tsumoto and H. Hatanaka. Dept. Neurophysiol., Osaka Univ. Med. Sch. and Div. Protein Biosynth., Inst. Protein Res., Osaka Univ., Suita, 565 Japan.

Neurons in the primary visual cortex are arranged in a columnar organization according to their receptive field properties such as orientation selectivity and ocular dominance. After monocular visual deprivation during the critical period of early life, an anatomical expansion of cortical territory serving nondeprived eye takes place concomitantly with a compensatory shrinkage of territory serving deprived eye. Recently a member of neurotrophic factors, Brain-derived neurotrophic factor (BDNF), has been suggested to play a role in ocular dominance column development. To test the possibility that BDNF plays a role also in the visual cortical plasticity, we analyzed its effects on rearrangements of geniculate afferents following monocular deprivation. BDNF was infused continuously using osmotic minipumps into the visual cortex of 5 week-old kittens. The kittens were deprived of vision monocularly by eyelid suture and injected with [^{3}H]-Proline into one eye to label the cortical territory occupied by geniculate afferents serving the injected eye. The surgical operations were done under anesthesia with sevoflurane (3.0-3.5 %) mixed with N2O/O2 (2:1). After two weeks of monocular deprivation, labeling representing the deprived eye territory was continuous rather than patchy in the area near the cannula infusing BDNF, whereas it shrunk in the area far from the cannula showing the effect of monocular deprivation. The continuous labeling near the cannula was observed also in animals whose nondeprived eye had been labeled. The nondeprived eye territory expanded in the area far from the cannula as expected. Considering that geniculate afferents from each eye had already segregated to form ocular dominance columns in kittens at the age when the BDNF application started, these results indicate that exogenously applied BDNF induced desegregation of geniculate afferents. DELAYED ONSET OF NGF EFFECTS ON OCULAR DOMINANCE PLASTICITY IN MICE M. Fagiolini and M.P. Stryker*. Keck Center for Integrative Neuroscience, Dept. of Physiology, Univ. of California, San Francisco, CA 94143-0444

Occluding vision through one eye (MD) during a critical period in early life induces a loss of responsiveness of visual cortical neurons to the deprived eye. NGF administration prevents the effects of long-term deprivation in rats, and it has been proposed as a candidate mediator of experience-dependent cortical plasticity in rodents. Since a brief period of MD at the peak of the critical period has the same maximal effects on cortical binocularity as long-term MD, we investigated whether NGF was able to prevent the rapid effects of short-term MD in mice.

Starting at P28, we monocularly deprived mice for 4 or 7 days. Concurrently, we injected 1 µl of NGF (1.25 µg/µl) or control solution in the lateral ventricles every other day. At P32-35 single unit recordings from the binocular portion of the primary visual cortex contralateral to the deprived eye were performed blind to treatment. For each animal, we evaluated binocular responses using the Contralateral Bias Index (CBI). In 4-day-MD mice, NGF did not prevent a shift in ocular domince in favor of the open eye (NGF-treated: CBI=0.55, 5 animals, 121 cells; control: CBI=0.54, 3 animals, 81 cells); while NGF did attenuate the effects of deprivation in 7-day-MD (NGF-treated: CBI=0.66, 3 animals, 73 cells; control: CBI=0.52, 3 animals, 78 cells).

Multiple intraventricular injections of NGF are required to produce a maximal and long-lasting activation of TrkA receptors in both septum/basal forebrain and neostriatum (Kromer & Kaplan, *Soc. Neurosci. Abstr. 1995*). To test a hypothesis that activation of the NGF signal transduction pathway before the onset of deprivation would be necessary to prevent the rapid effects of MD, we injected NGF in the lateral ventricles for two days before MD and every other day during 4-day-MD. We found that such NGF pretreatment blocked the rapid effects of MD (NGF: CBI=0.71, 6 animals, 137 cells; control: CBI=0.47, 4 animals, 100 cells) and left visual cortical responses like those in normal mice (Gordon & Stryker, *in press, J. Neurosci., 1996*). Our results suggest that exogenous NGF can prevent the physiological effects of short-term MD in mice and that the delayed onset of its action is likely to be due to the time necessary to maximal activate its signal transduction pathway. BRAIN DERIVED NEUROTROPHIC FACTOR (BDNF) MODULATES SYNAPTIC PLASTICITY IN RAT VISUAL CORTEX M.F. Bear* and K.M. Huber Dept. Neuroscience, HHMI, Brown University, Providence, RI 02912.

"Winner-takes-all" competition among converging sources of synaptic input can account for segregation of lateral geniculate nucleus (LGN) axons into ocular dominance (OD) columns and can explain why these patterns of innervation are disrupted by monocular deprivation (MD). It has been suggested an underlying mechanism may be competition for a limited supply of neurotrophins (NTs) provided by postsynaptic target neurons. Consistent with this model, supplying exogenous brain-derived neurotrophic factor (BDNF) can prevent segregation of OD columns in kitten visual cortex (Cabelli et al., Science 267: 1662, 1995), and supplying NT-4/5 to ferret visual cortex can prevent the shrinkage of LGN cells (and presumably axon arbors) that accompanies MD (Riddle et al., Nature 378: 189, 1995). An alternative model is that active synapses are retained or eliminated depending on how much postsynaptic NMDA receptor activity they evoke. According to this idea, low levels of NMDA receptor activation cause long-term depression (LTD) followed by synapse elimination, whereas higher levels of NMDA receptor activation cause "Hebbian" long-term potentiation (LTP; Bear et al., Science 237: 42, 1987). Consistent with this model, application of an NMDA receptor antagonist to visual cortex can prevent LGN cell shrinkage as a result of MD (Bear and Colman, PNAS 87: 9246, 1990). We reasoned that the NT findings could be reconciled with the NMDA model if NTs reduced LTD in the visual system. To test this hypothesis, we examined the effects of BDNF treatment on the induction of LTD in rat (P21-P28) visual cortex slices. Field EPSPs (fEPSPs) in layer II/III were elicited by stimulation of layer IV. LTD of fEPSP amplitudes (86 ± 2% of baseline values; n = 18) was induced by low frequency stimulation (900 pulses at 1 Hz; LFS). LFS in slices treated for 2-5 hours with BDNF (50 ng/ml) resulted in significantly less LTD (93 ± 2%; n = 13, p = 0.01). Based on this result, we propose that BDNF's action when perfused into developing visual cortex may be to reduce NMDA-receptor-dependent synaptic weakening which normally occurs during formation of OD columns. Support: HHMI.

FACILITATION OF SYNAPTIC PLASTICITY BY ACh AND NE IN RAT VISUAL CORTEX A. Kirkwood*, J. Kirkwood, F. Perez and M. F. Bear. Depto. Biol Fac. Ciencias, Univ. Chile. and Dept. of Neurosci., Brown Univ., Providence, RI 02912.

In hippocampus and neocortex an NMDA-receptor-dependent, homosynaptic form of long-term depression (LTD) can be induced by prolonged low frequency stimulation (LFS; 900 pulses at 1 Hz). We have found that in rat visual cortical slices, cholinergic and adrenergic activation markedly facilitates the induction of LTD

Our initial observations were made while investigating the effects of neuromodulators on the layer III field responses to paired-pulse stimulation applied in layer IV. Stimulation was given every 15 s; the interstimulus interval varied on each trial as follows (in ms): 20, 40, 80, 160, 320, 640, 1280, 2560, 20, 40, and so on. After 10 min. of baseline, carbachol (CCh, 50 µM) or norepinephrine (NE, 40 µM, in 80 µM ascorbate) was briefly applied (≤ 10 min). This resulted in a substantial and sustained depression in the response to the first pulses that far outlasted the drug application (67 ± 4 % of baseline 30 min after CCh application (n = 17) and 55 ± 2 % (n = 4) after NE application.) The lasting effect of CCh was dependent on the pattern of synaptic activity. Little depression was obtained if the drug was applied in the absence of stimulation (94.5 ± 4 %, n = 6) or during single pulse stimulation (95 ± 5 %, n = 6). The stimulation dependence of the LTD was confirmed in two-pathway experiments conducted on the same slices (stimulated pathway: 82 ± 4 %; unstimulated pathway: 94 ± 4 %; n = 3). These results indicate that in the presence of CCh as few as 80 stimulus pulses in the appropriate pattern can yield as much or more LTD as 900 pulses of LFS under normal conditions. To investigate if the CCh-dependent LTD employs the same mechanisms as LFS-induced LTD, we investigated its dependence on NMDA receptor activation. The NMDA-receptor antagonist APV (50 µM) reversibly blocked the induction of the CCh-dependent LTD (97.8 ± 3 % in the presence of APV; 76.5 ± 6 % following washout). The results suggest that neuromodulators dramatically facilitate NMDA-receptor dependent homosynaptic LTD in visual cortex. We are currently investigating the ACh and NE receptor subtypes involved. EXPOSURE TO LIGHT REVERSES MODIFICATION OF SYNAPTIC PLASTICITY INDUCED BY LIGHT-DEPRIVATION IN THE DEVELOPING VISUAL CORTEX. M.G. Rioult* and M.F. Bear. HHMI and Brown Univ., Dept. Neuroscience, Providence, RI 02912.

Rearing animals in the dark alters synaptic plasticity in visual cortex. Low-frequency stimulation (LFS; 1 Hz) of layer IV produces significantly less LTD of layer II-III synaptic responses in light-deprived animals than in controls, while medium-frequency stimulation (MFS, 20 Hz) produces significantly more LTP in light-deprived animals than in controls (Kirkwood and Bear, Soc. Neurosci. Abs., 1995). This shift in the frequency-response function in light-deprived animals is consistent with the idea of a variable LTD-LTP "modification threshold" that is determined by the history of cortical activation (Bienenstock et al., J. Neurosci., 1982). In the present study, we have asked whether the effects of dark-rearing can be reversed by subsequent light exposure and, if so, over what time-course. Coronal slices from visual cortex were prepared from 4-6 week-old Sprague-Dawley rats reared (1) under standard lighting conditions, (2) in complete darkness, or (3) in complete darkness followed by exposure to 1-4 days of light. Extracellular field potentials evoked by stimulation in layer IV were recorded in layer III. LTD was induced with 1 Hz (900 pulses). LTP was induced with either theta burst stimulation (TBS) or with MFS (120 stimuli total). We confirmed that LTD in slices from light-deprived animals is significantly less than in controls (72.4 ± 6.8 %; n = 5; P < 0.02). Remarkably, however, after only 2 days of light exposure the magnitude of LTD in light-deprived visual cortex returned nearly to control levels. The response 30 min after LFS was 77.0 ± 3.6 % of baseline in cortex exposed to light for 2 days (n = 11), which is significantly greater than in light-deprived cortex (P < 0.02). Preliminary data from experiments still in progress indicate that 2 days of light exposure are also sufficient to reduce the magnitude of LTP evoked by MFS compared to that in dark-reared animals. This shift in the frequency-response function is consistent with the idea that the modification threshold "slides" back as average cortical activity increases. Supported by HHMI.

INTRACORTICAL INTERACTIONS REGULATE OCULAR DOMINANCE COLUMN SEGREGATION T.K. Hensch* and M.P. Stryker. Keck Center for Integrative Neuroscience, Univ. of California, San Francisco, CA 94143-0444

During development, geniculocortical afferents serving the two eyes segregate into discrete ocular dominance columns (ODC) through an activity-dependent competition. In models of this Hebbian self-organizing process, intracortical interactions determine the final width of ocular dominance domains up to a possible limit set by arbor diameters (Miller & Stryker, 1990). We examined directly the role of cortical circuitry in ODC formation by locally modulating $GABA_A$-mediated postsynaptic inhibition during development.

Prior to the onset of ODC segregation (P14-17, LeVay et al, 1975), cannulae connected to osmotic minipumps delivering either a benzodiazepine agonist (diazepam), inverse agonist (DMCM), or vehicle solution were implanted into one hemisphere of kitten primary visual cortex (Area 17). After four weeks of normal visual experience, single-unit recordings were made and the animal perfused. The pattern of ODCs was made visible in sections of flattened visual cortex by ^{3}H-proline injections into one eye and subsequent autoradiography.

Diazepam enhanced $GABA_A$-mediated currents in cortical slices but did not severely affect visual responses *in vivo*, which remained vigorous and well-tuned for stimulus orientation. Surrounding and anterior to the diazepam infusion site (n=6), ODC spacing was found to be wider than in distant areas behind the cannula or in the opposite control hemisphere. The benzodiazepine inverse agonist DMCM did not produce the same effects (n=3). These results are consistent with a role for postsynaptic intracortical circuitry in shaping the final columnar layout of presynaptic afferent arbors in primary visual cortex. *Supported by EY02874 & HHMI.*

Ocular Dominance and Orientation Selectivity in Networks of BCM neurons Trained in a Natural Environment

Harel Shouval*, Nathan Intrator and Leon N Cooper.

Department of Physics and Neuroscience and Institute for Brain and Neural Systems, Brown University, Providence RI 02912.

Networks of BCM neurons were trained in a Binocular Visual Environment Composed of Natural Images. The images were pre-processed with a retinal like center surround filter. The inputs through the two eyes were assumed to be partially misaligned. A lateral interaction pattern with short range excitatory connections and long range inhibitory connections was assumed.

The networks developed Ocular Dominance bands and the cells became tuned to all different orientations. Changes in orientation tuning from cell to cell were usually gradual but sometimes abrupt. The detailed of the mapping changed with different choices of parameters.

The coding exhibited by this network is sparse since most cells respond with a high level of activity only to a small fraction of the patterns and have close to zero response to most of the patterns.

AUDITORY CORTEX WITH INDUCED VISUAL PROJECTIONS : HORIZONTAL CONNECTIVITY AND OPTICAL IMAGING OF FUNCTIONAL RESPONSES. J. Sharma*, A. Angelucci, S. C. Rao, B. R. Sheth and M. Sur, Department of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139

Early developmental manipulations cause retinal projections to innervate the auditory thalamus in ferrets, so that visual inputs drive cells in primary auditory cortex (A1). We have now examined the functional organization of visually responsive cells and the anatomical organization of horizontal connections in rewired A1. Optical imaging of intrinsic signals in A1 demonstrates large domains of visual activity whose strength correlates with the spatial frequency of oriented grating stimuli. The domains show a mild orientation bias, though all orientations are represented in individual domains. In contrast, we have shown previously that orientation selective cells in primary visual cortex (V1) of ferrets are organized in smaller, discrete iso-orientation domains. A focal injection of cholera toxin subunit B (CTB) in the middle of a rewired A1 domain shows retrogradely labeled, patchy cell clusters which spread anisotropically from the injection site, but are still confined to the same domain. In comparison, injections in an orientation domain in V1 label clusters of cells which are located in separate, often distant, iso-orientation domains.

These results indicate that visual activity significantly regulates the development of stuctural and functional modules within the cortex. Rewired A1 shows clustering of physiological responses and lateral projections, but in not as discrete a manner as normal V1.

DEVELOPMENT OF EXPERIMENTALLY INDUCED RETINAL PROJECTIONS TO THE FERRET AUDITORY THALAMUS: A QUANTITATIVE STUDY. A. Angelucci*, E. Bricolo and M. Sur, Department of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Extensive neonatal deafferentation of the ferret auditory thalamus induces retinal axons to innervate the medial geniculate nucleus (MGN). At adulthood, retino-MGN projections are clustered and eye-specific clusters are segregated. We have previously shown that both clustering and eye-specific segregation in the MGN arise as a refinement of initially diffuse and overlapped projections. Here we have analyzed the emergence of clustered retino-MGN projections quantitatively. Rewired ferrets ranging in age from postnatal day (P) 4 to adult received an injection of Cholera Toxin B (CTB) in one eye and WGA-HRP in the other eye. CTB staining in the MGN was quantified by digitizing the intensity of label, and normalized using retino-LGN staining as a reference. The extent of retinal projections to the MGN and the degree of clustering was estimated by thresholding the normalized images. Retino-MGN projections increase in extent by four fold from P4 to P22, but remain essentially unaltered afterwards. The volume of the MGN continues to increase after P22, so that there is approximately a two-fold decrease from P4 to adulthood in the proportion of the MGN innervated by retinal axons. The clustering of projections emerges progressively. Till P8, most of the retinal projection is diffuse, showing little or no clustering. By P22 the proportion of retinal projections within clusters increases by six fold. Over the same time period, projections from the two eyes progressively segregate into eye-specific regions within the MGN, with clear eye-specific zones evident by P22.

These results indicate that the development of novel retino-MGN projections involves a significant progressive remodeling of retinal axon arbors. In important respects, this remodeling resembles the formation of retinal axon termination patterns within the LGN, including the progressive segregation of eye-specific layers and On/Off sublayers from initially diffuse and intermingled projections.

PARAMETRIC ANALYSIS OF THE INVASIVENESS AND REPLICATION OF GENETICALLY ALTERED STRAINS OF PSEUDORABIES VIRUS IN VISUAL AND AUTONOMIC CIRCUITRY. J.-S. Kim, R.Y. Moore, L.W. Enquist , J.P. Card* Department of Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA, and [1]Department of Molecular Biology, Princeton Univ., Princeton, NJ.

The ability of neurotropic alpha herpesviruses to replicate within synaptically linked neurons has made these pathogens valuable tools for transneuronal analysis. Recent studies suggest that unique gene products expressed by genetically engineered strains of virus may permit the use of multiple strains of virus in complex tracing paradigms. In the present study we have examined the invasiveness of two genetically engineered strains of the swine pathogen known as pseudorabies virus (PRV). The two strains are isogenic with the attenuated Bartha strain of PRV; in one strain a lacZ reporter gene was inserted into the gX locus (PRV-BaBlu; 4.75 x 10^8 pfu/ml) and the other strain (PRV-D; 2.5 x 10^8 pfu/ml) contains a PRV envelope glycoprotein gene that is absent in PRV-BaBlu. Injection of 2 µl of either strain into the vitreous body of the eye produced the restricted pattern of infection of visual circuitry previously documented with PRV-Bartha, but both strains exhibited altered rates of transport and virulence. Simultaneous or temporally separated sequential injection of 4 µl of each strain into the ventral wall of the stomach also produced a predictable course of retrograde transynaptic infection of autonomic circuitry. However, the sequence of injection of each strain proved to be an extremely important variable in determining the outcome of infection. Collectively the data demonstrate that: 1) the rate of viral replication and transport is strain dependent, 2) prior infection of neurons with one strain may interfere with subsequent uptake and/or replication of another strain, and 3) dual injection paradigms may increase the virulence of infection.

683.2

THE EFFECT OF VIRAL CONCENTRATION UPON INVASIVENESS, REPLICATION, AND TRANSYNAPTIC PASSAGE OF PSEUDORABIES VIRUS INJECTED INTO STRIATUM. J. Park, L.W. Enquist*, R.Y. Moore, J.P. Card, Department of Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA, and [1]Dept. of Molecular Biology, Princeton Univ., Princeton, NJ.

Pseudorabies virus (PRV), a neurotropic swine alpha herpesvirus, has been used extensively for transneuronal analysis of multisynaptic circuitry after peripheral injection. In the present analysis we have examined factors that influence the invasiveness, replication and transynaptic passage of attenuated PRV (PRV-Bartha) following intracerebral injection into rat striatum. Different volumes (20, 50, 100 nl of a 1.4 x 10^9 pfu/ml stock) or concentrations (a total of 1.4 x 10^5, 7 x 10^4, or 3.5 x 10^4 pfu in 100 nl) of PRV were injected into the center of the striatum at a constant rate of infusion (10 nl/min) and animals were sacrificed 50 hours later. Immunohistochemical localization of PRV in the CNS revealed dramatic differences in the extent of viral infection that were directly dependent upon the concentration of injected virus. The largest concentrations of virus produced replication and transynaptic passage of virions in at least three orders of synaptically-linked neurons, whereas lesser concentrations of PRV-Bartha produced increasingly restricted infection of the same circuitry within the same postinoculation interval. Collectively the data demonstrate that: 1) axon terminals are the primary portal of viral invasion following intracerebral injection in this circuitry, 2) the virus is transported exclusively in a retrograde transynaptic direction, 3) the affinity of virus for glia participates in the restriction of virion diffusion from the injection site, and 4) the concentration of virus exerts a profound influence upon the onset of detectable viral replication. These data also provide considerable insight into the multisynaptic organization of afferent circuitry that influences the functional activity of the striatum.

INFLUENZA A VIRUS INFECTION TO PRIMARY CULTURED CELLS FROM RAT FETAL BRAIN. M. Takahashi, T. Yamada*, T. Yamamoto and H. Okada, Choju Med. Inst., Fukushi-mura Hosp., 19-14 Aza Yamanaka, Noyori-cho, Toyohashi-shi, Aichi-ken 441, Japan.

We previously reported that a neurovirulent influenza A virus strain, A/WSN/33 has a strong affinity for the substantia nigra in mouse brain. However, direct intracerebral inoculation of this virus only causes the acute phase of infection. Further investigation of cellular responses to viral infection could clarify the mechanisms essential to chronic, persistent viral infection of the brain. Therefore, we established neuron-glia co-culture system derived from pregnant Wister rats on the eighteenth gestational day. Neurons from the hippocampus, neocortex, cerebellum and substantia nigra were plated over a confluent identical glial cell layer. Five to seven days after the plating, large numbers of virus particles were overlayed on the serum medium for 30 min and washed. Several samples were fixed with 4% PFA and maintained up to 72 h after the infection. Cell differentiation was successfully performed with the following antibodies: anti-MAP-2 for neurons, anti-GFAP for astrocytes, anti-OX-42 for microglia and anti-TH for dopaminergic neurons. Lectins of MAA and SNA were used to localize the distribution of carbohydrate moieties of glycoproteins serving as virus receptors. Virus antigens were visualized by the well characterized anti-WSN antibody. Twenty to thirty % of all nigral neurons were TH-positive and 40-50 % of TH-positive neurons were also positive to anti-WSN antibody. Virus antigens were strictly localized in the neuronal cell bodies and their neurites, and none were found in glial cells or vascular endothelial cells. Seventy to eighty % of MAP-2 positive cells were also positive to anti-WSN antibody. Both SNA and MAA were diffusely distributed mainly in neurons. There was no increase in MHC-I expression in virus antigen positive cells. Thus, we can conclude that the virus preferentially infects neurons, not only TH-positive neurons in the substantia nigra but those of other regions as well. Neurotropism cannot be determined simply by the distribution of virus receptor. Finally, no antigen presenting response mediated by MHC-I in neurons was noted.

683.4

COMPARISON OF A CONVENTIONAL TRACER TO PSEUDORABIES VIRUS IN TRACING AFFERENTS OF THE PREOPTIC AREA. R.K.Leak*, J.P.Card, R.Y.Moore Depts of Neuroscience and Psychiatry, Univ. of Pittsburgh, PA

The swine herpesvirus (pseudorabies virus, PRV) is widely used for tracing multisynaptic functional circuits in which the virus is injected into viscera or the eye (cf Card,'95, Loewy, '95, Ugolini,'95). There have been few studies, however, in which virus is injected into brain parenchyma. In preliminary studies, we find that viral injections remain constrained and that transport occurs in the retrograde direction (Enquist et al., '93, Leak et al.,'95). To further analyze the pattern of uptake, replication and transport of virus, we injected PRV-Bartha with a conventional tracer, cholera toxin (CT), into the medial preoptic area (POA) of the rat. Survival timepoints were chosen to restrict viral labeling to first order neurons, so that viral transport could readily be compared to CT. A point of particular importance is whether virus is taken up selectively by subpopulations of neurons. In accord with prior studies (Simerly and Swanson, '87), areas consistently retrogradely labeled by both tracers include the subiculum, bed nucleus of stria terminalis, dorsomedial hypothalamic, arcuate, supramammillary, and paraventricular thalamic (PVT) nuclei and central gray (PAG). The number of neurons labeled with CT is greater than PRV in all areas, particularly the subiculum, PVT and PAG, but this appears related to density of CT deposition. We conclude that PRV is an effective retrograde tracer and that, at least in the POA, it is taken up by all afferent terminals. The advantage of PRV over CT lies in its transynaptic route of passage and purely retrograde labeling. Supported by NS-16304.

SP DiO and SP DiI: TWO NOVEL LIPOPHILIC SULFOPHENYLCARBOCYANINE DYES AS FLUORESCENT MEMBRANE PROBES WITH IMPROVED SOLUBILITY, FIXABILITY AND FLUORESCENT QUANTUM YIELD. F. Mao*, W-Y. Leung, M. Poot, Y-Z. Zhang and R.P. Haugland. Molecular Probes, Inc., PO BOX 22010, Eugene, OR97402

Fluorescent lipophilic cyanine dyes such as DiO and DiI have been widely used to trace the initial cells in studies involving cell fusion, cell migration and cell transplantation. However, the low aqueous solubility and inability to retain the stain after fixation and permeabilization of the cells limit the use of these dyes. Therefore, we developed two novel lipophilic carbocyanine dyes, named SP DiO (3,3'-dioctadecyl-5,5'-di(4-sulfophenyl)oxacarbocyanine) and SP DiI (1,1'-dioctadecyl-6,6'-di(4-sulfophenyl)-3,3,3',3'-tetramethylindocarbocyanine), which contain two sulfophenyl groups that enhance the dyes' solubility and fluorescence quantum yield and their retention after cell fixation. The excitation and emission spectra of SP DiO ($\lambda_{abs}/\lambda_{em}$ = 497 nm/517 nm, methanol) and SP DiI ($\lambda_{abs}/\lambda_{em}$ = 557 nm/573 nm, methanol) are similar to those of the analogous DiO and DiI. The new dyes showed both improved solubility in regular cell culture media and were retained after a combined treatment with formaldehyde and acetone. Acetone treatment alone enhanced the fluorescence intensities of the cells stained with the new dyes, particularly with SP DiO. The new dyes are about five times more fluorescent than DiO or DiI in cell membranes and are sufficiently water soluble to stain cells in normal culture medium. We found no evidence for cell toxicity and labeled cells did not transfer dyes to unlabeled cells during a 5-day co-culture experiment. During subculture the fluorescence of cells stained with SP DiO or SP DiI decreased exponentially, reflecting the normal proliferation of labeled cells. Thus, SP DiO and SP DiI are useful fluorescent membrane probes for long-term cell tracing and for applications where cell fixation and permeabilization subsequent to cell staining are required. SUCROSE POST-FIXATION: TOO MUCH SUGAR COULD SHRINK YOUR BRAINS. S.W. Scheff*, T.R. Gibson, S.A. Baldwin. Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY 40536-0230.

It is a common practice to post-fix nervous tissue in a sucrose solution prior to sectioning with a freezing microtome. Sucrose helps to cryoprotect the tissue, resulting in brain sections which are easy to cut and without freezing artifacts. For many laboratories the concentration of a sucrose post-fixation medium is the result of tradition; passed down from professor to graduate student and perhaps modified by a technician in the sake of expediency. Often the amount of time tissue post-fixes in sucrose varies from brain to brain, usually a consequence of too many activities and a limited number of hours. Are there any detrimental consequences in having the tissue remain in a sucrose fixation too long?

Young adult mice were killed by 10% formalin perfusion through the left ventricle. The brain was removed and post-fixed initially in the perfusate for 6, 12 or 24 hours. Brain tissue was then post-fixed in a sucrose solution (15% or 30% w/v) for 24 or 48 hours. Frozen 50 µm thick sections were taken throughout the hippocampal formation. Sections were immediately mounted, dried and stained with cresyl violet. Tissue was analyzed for possible shrinkage and volumetric changes using an image analysis system.

The total time in sucrose post-fixation significantly altered the amount of tissue shrinkage. There was a significant decrease in brain size when post fixed in 30% sucrose as compared to 15%. There was no observable qualitative difference between the 15% and 30% post fixed material. These results caution neuroscientists in the use of sucrose concentration in tissue post-fixation. A FLUORIMETRIC PROBE FOR FREE ZINC IONS

A.R. Kay *, T.P. Stricker & D.J. Krupa Biological Sciences, Univ. of Iowa, Iowa City,IA 52242.

Zinc has a multiplicity of roles in the cellular economy, prominently acting as a structural element in some proteins or at the active site of enzymes. There is, however, ~10% of the Zn^{2+} in the brain that is not in strong association with organic molecules, that is found in synaptic vesicles of glutamatergic terminals and is released on stimulation. Although the existence of this pool of free Zn^{2+} has been known for some time, its precise role remains obscure.

Here we describe the characteristics of the Zn^{2+}-specific fluorescent probe, TFLZn (N-(6-methoxy-8-quinoyly)-p-carboxy-benzoylsulphon-amide, Texas Fluorescence Labs, Austin, TX) that we have previously shown to be able to disclose the synaptic release of Zn^{2+} in hippocampal slices. The dye exhibits little fluorescence in the absence of Zn^{2+} and rises sharply on the addition of Zn^{2+} (K_d ~ 20 µM, Ex_{max} = 360 nm, Em_{max}= 498 nm). Ca or Mg (1mM) gave no appreciable fluorescence above background levels, nor did the metals Cd(II), Co(II), Cu(II) or Fe(III) at concentrations of 100 µM. Indeed Cu and Fe quenched the fluorescence induced by Zn^{2+}.

To determine the properties of TFLZn in a cell-free system, liposomes were prepared with 50 µM Zn^{2+} inside and outside. To effectively remove Zn^{2+} from the outside 2 mM EDTA was added. Addition of TFLZn to the zinc containing liposomes led to an exponential rise in the fluorescence that resulted from the passive movement of TFLZn across the membrane. That the signal was arising from intra-liposomal Zn^{2+} was demonstrated by quenching of the signal by the membrane-permeant Zn^{2+} chelator diethyldithiocarbamate.

FLUORESCENT LABELING OF ELECTRODE TRACKS IN BRAIN TISSUE, D.M. Snodderly*, R.I. Land, and M. Gur [1]
Schepens Eye Research Inst, Boston MA 02114, USA and [1]Biomedical Engineering, Technion, Haifa 32000, Israel.

For relating response properties of neurons in alert animals to the functional architecture of the brain, localization of recording sites is necessary. We coat microelectrodes with nontoxic fluorescent dyes to label electrode tracks with long survival times. The electrode is prepared by sterilizing it in 70% ethanol in 0.1M Tris buffer, pH 7.0 followed by a rinse with the solvent used for the dye. Carbocyanine dyes from Molecular Probes are used in saturated solutions. DiI is dissolved in ethanol, and DiO in propylene oxide. Under 300x magnification, the electrode is laid horizontally with the tip supported by a rubber V notch. A drop of dye solution (100-200 µL) is placed behind the notch with a 30 gauge needle. As the solvent evaporates, the tip of the electrode is lifted carefully upward with a micromanipulator so that the dye crystallizes in a relatively uniform coat with an abrupt border about 50 µm behind the tip. This avoids contamination of the electrode tip, and marks the penetration to a known distance from its deepest point. A second dye can be placed further back on the shank to create a two-color electrode. The two dyes can be distinguished by their colors and by use of a bandpass filter at 502±42 nm to reduce the stronger DiI fluorescence. Both dyes label tracks all the way from the cortical surface to the base of the brain. DiI labels have lasted as long as 1 yr. Experience with DiO is more limited but promising.

RAT PREFRONTAL CORTEX PROJECTS DIFFERENTIALLY TO THE VENTRAL TEGMENTAL AREA, DORSAL RAPHE, AND LATERODORSAL TEGMENTAL NUCLEUS R.S. Revay*[1] and S.J. Grant[2]. [1]Dept. of Biological Sciences, University of Delaware, Newark, DE 19716 and [2]Neuroscience Branch, National Institute on Drug Abuse, Addiction Research Center, Baltimore, MD 21224

Biotinylated dextran amine (10,000 MW; Molecular Probes, Inc.) was used as a retrograde tracer and iontophoretically ejected into the ventral tegmental area (VTA), dorsal raphe (DR), or the laterodorsal tegmental nucleus (LDT). These injections resulted in an overlapping yet distinct pattern of retrogradely labeled neurons in the prefrontal cortex (PFC). Although there was considerable overlap in the distributions of retrogradely labeled neurons, there were statistically significant differences in their distribution between some regions and areas depending on which nucleus was injected. Thus, while some PFC areas project in a similar fashion to all three nuclei, other PFC areas provide a significantly greater innervation to one or two of the three nuclei. Injection of tracer into any of the three nuclei resulted in appreciable labeling of pyramidal neurons of the medial PFC (cingulate cortex area 3, infralimbic cortex, and medial orbital/ventral orbital cortex). In contrast, tracer injection into these nuclei produced different patterns of retrograde labeling in other areas of the PFC. Research funded by anonymous private sources.

BIOCYTIN AND BIOTINYLATED DEXTRAN AMINE (BDA): FALSE POSITIVE ANTEROGRADE LABELING BY COLLATERAL -COLLATERAL TRANSPORT. Sheng Chen* and Gary Aston-Jones. Dept. Psychiatry, Med Coll PA & Hahnemann Univ., Philadelphia, PA 19102.

Some tract-tracers (e.g., WGA-HRP) are reported to be transported retrogradely by axons and transferred to other axonal collaterals of the same cell. Such collateral labeling has been employed often in studies tracing central projections of dorsal root ganglion neurons. However, if such a process occurred after conventional CNS injections false anterograde labeling could occur. Recently, this has been proposed to occur with certain tracers popularly used in anterograde labeling experiments (e.g., biocytin and BDA), but no direct evidence exists for this after CNS injections. We addressed this issue using cerebellar parallel fibers as a model system. Biocytin (2% in saline, Sigma) or BDA (2% in saline, Molecular Probes) was iontophoretically injected (+4.0 µA, 5 sec. on / 5 sec. off, for 10 to 15 min.) into the cerebellar cortex of adult Sprague Dawley rats through a glass micropipette (tip diameter = 3-10 µm; BDA, n=4; biocytin, n=10). After a survival period of 14 hr to 3 days (biocytin) or 3 to 9 days (BDA), rats were perfused with paraformaldehyde. Frozen coronal brain sections were processed with the ABC method and reacted with DAB-nickel. Both biocytin and BDA yielded focal injection sites ranging from 50 to 150 µm in diameter, and Golgi-like labeling of granule cells and parallel fibers. In cases with biocytin or BDA injections in the molecular layer (BDA, n=2; biocytin, n=6), many retrogradely labeled granule cells were observed up to 2.5 mm away from the injection site. In these cases, labeled axons included a beam of parallel fibers as well as ascending axons from granule cells. Clear examples of "T" branching of granule cell axons forming parallel fibers in the molecular layer were seen as far as 1.2 mm away from molecular layer injection sites. In contrast, injections in the granule cell layer (BDA, n=2; biocytin, n=4) yielded ascending axons with "T" branching only immediately above the injection sites. These data show that biocytin and BDA can be taken up and retrogradely transported by a granule cell axon collateral and anterogradely label the other branch. This provides direct evidence that biocytin and BDA undergo collateral-collateral transport and may lead to false positive labeling in studies using these molecules as anterograde tract-tracers. ELECTROPHYSIOLOGY AND MORPHOLOGY OF NEURONS IN LAYER II/III OF RAT SOMATOSENSORY NEOCORTEX,

H. F. Li* and L. J. Cauller GR. 41 Cognition and Neuroscience Program, University of Texas at Dallas, Richardson, TX 75083-0688.

Neurons in superficial layers are regarded as principal integrative elements in neocortical circuits. In this study, we examined the electrophysiological and morphological properties of layer II/III neurons in somatosensory cortex *in vitro* by means of intracellular recordings and biocytin staining techniques. Our sample of 31 neurons from layer II/III showed a morphologically diverse group with a majority of pyramidal neurons, some with irregularly oriented horizontal dendrites, and a few sparsely-spiny nonpyramidal neurons (2 out of 31). Morphological features of layer II/III pyramidal neurons varied progressively with the depth of the soma in the layer. The electrophysiological properties of layer II/III neurons showed less diversity than layer V neurons. The average V_{rest} of layer II/III neurons was more hyperpolarized than -75 mV and the R_{in} ranged from 15- 40 MΩ. The I/V curve of typical pyramidal neurons displayed considerable inward rectification in both the depolarizing and hypolarizing directions. The steady-state input resistance increased with depolarization and decreased with hypolarization, concomitant with increase and decrease, respectively, in the membrane time constant. The firing properties of the neurons recorded including those morphologically identified as nonpyramidal neurons were similar to those of regular spiking neurons, but varied in firing adaptation and postspike depolarizing afterpotential (DAP). Irregularly shaped pyramidal and nonpyramidal cells had stronger firing adaptation and more distinctive DAPs than typical pyramidal cells. We suggest these superficial neurons may be regarded as an electrophysiologically homogeneous group.

This study was funded by a grant from the Whitehall Foundation.

A RELIABLE WHOLE-MOUNT NERVE, BONE, AND CARTILAGE STAINING PROTOCOL.

[1] E. Rosa-Molinar* and [2]B. Fritzsch. [1]Dept of Cell Biol. & Anat., Univ. Neb. Med. Ctr., Omaha, NE 68198, and [2]Dept Biomed Sci, Creighton Univ, Omaha, NE 68178.

A persistent problem in elucidating the anatomy of the peripheral nervous system has been the inability of staining both the myelinated and unmyelinated nerve fibers. To overcome this problem we used dextran biotin as a neural tract tracer for the following reasons: its low molecular weight, rapid diffusion throughout neurons, fixability, and its high affinity for avidin. To examine the full complement of the sensory- motor nerves as well as the bone and cartilage at different stages of a bony fish we combined whole-mount immunocytochemistry followed by enzyme clearing and bone and cartilage staining. Dextran biotin (Molecular Probes Inc. Eugene. OR) was applied to cut nerves in newborn, immature and adult *Gambusia a. affinis*. Following 2-24 hrs, fish were fixed, washed, partially digested with 1% pancreatin, treated with 1% Triton X-100, 2% BSA, 2% horse serum, 0.1 sodium azide, and, neurons were visualized using ABC complex and DAB. Biotin labeled all neurons in a Golgi-like manner. Topological relations of nerves, bone and cartilage were readily observed in the whole specimens. All nerve fibers at all stages were labeled. Using this method, we describe spatial and temporal changes of nerve fibers and neuron numbers with the corresponding changes of the osseous elements during the transposition of the anal fin appendicular support of this fish.

QUANTITATIVE CYTOCHEMISTRY OF CYTOCHROME OXIDASE AND CELLULAR MORPHOMETRY OF THE HUMAN INFERIOR COLLICULUS IN CONTROL AND ALZHEIMER'S PATIENTS.

F. Gonzalez-Lima*, J. Valla, S. Matos-Collazo. Institute for Neuroscience and Dept. of Psychology, University of Texas, Austin, Texas 78712.

Quantitative cytochemistry of cytochrome oxidase (C.O.; Cada & Gonzalez-Lima, 1995) was applied to human brains to measure C.O. activity in the 3 main divisions of the inferior colliculus (IC): central (ICC), dorsal (ICD), and external (ICE). Units of C.O. activity (μmol/min/g tissue wet weight) were quantified in cellular compartments (overall average, neuropil, perikaryon, nucleus, and dendrites) at the light microscope level. The ICC and ICD were found to show higher ($p<0.008$) overall average activities (mean=183.40±18.7 and 184.98±45.1 units, respectively) relative to the ICE (56.46±15.9 units). Comparison of cellular morphometry (soma and nucleus area, perimeter, and diameter) revealed that the ICC contained cells of significantly larger soma size than in both the ICD and ICE ($p<0.002$). Brains from patients with Alzheimer's disease (AD; mean age=78.3±2.9, postmortem time=6.5±1.3 hrs) were compared with matched non-neurological controls (mean age=79.6±3.1, postmortem time=6.9±1.6 hrs). The distribution of soma diameters in the ICC of controls showed a clear bimodality, enabling a distinction to be made between large (>12.1μm) and small (<12.1μm) soma sizes. Subsequent comparison revealed that the AD large cell subgroup showed a decrement in C.O. activity relative to the corresponding controls in overall average activity (-18%; $p<0.03$) and in peak activity of neuropil near the soma (-10%; $p<0.01$). These findings provide the first quantitative cytochemical data of C.O. activity in humans. Supported by NIH grant RO1 MH43353.

DESTRUCTION OF MIDBRAIN DOPAMINERGIC NEURONS USING IMMUNOTOXIN TO THE DOPAMINE TRANSPORTER,

R.G. Wiley*, J. Brown, A.I. Levey and D.A. Lappi. Lab of Expl Neurology, VAMC, Nashville, TN, 37212, Neurology Dept, Emory University, Atlanta, GA and Advanced Targeting Systems, San Diego, CA.

3 immunotoxins are useful for making selective neural lesions. Intraventricular (i.c.v.) injections of OX7-saporin, directed against Thy 1, destroy cerebellar Purkinje neurons. I.c.v. injections of 192-saporin selectively destroy the cholinergic basal forebrain and i.c.v. injections of antiDBH-saporin selectively destroy brainstem adrenergic and noradrenergic neurons. In the present study, we sought to determine if an immunotoxin directed at the dopamine transporter (DAT) could produce selective neural lesions. A monoclonal antibody to an extracellular domain of the DAT was disulfide coupled to the ribosome inactivating protein, saporin, using standard SPDP technique. Purified immunotoxin was stereotactically injected into adult, male Sprague-Dawley rats. Animals survived for 10-35 days. Brain sections were stained with cresyl violet and for demonstration of tyrosine hydroxylase and choline acetyltransferase using peroxidase immunohistochemistry. 11 rats received unilateral injections of 0.056-2.8 μg into the striatum; 13 rats received 1.4-35 μg unilaterally into the lateral ventricle. Intrastriatal injections produced dose-related destruction of the ipsilateral substantia nigra, pars compacta (SNpc) and ventral tegmental area (VTA) dopaminergic neurons. I.c.v. injections produced dose-related destruction of the same neurons. Cresyl violet stains confirmed loss of neurons from the SNpc and VTA; cholinergic neurons were preserved. These results indicate that antiDAT-saporin can destroy CNS dopaminergic neurons known to express the dopamine transporter. REGULATION OF MUSCARINIC RECEPTORS COUPLED TO PHOSPHOINOSITIDE HYDROLYSIS IN OLIGODENDROCYTE PROGENITORS.

E.Molina-Holgado*, A.Korchid, H.N.Liu and G.Almazan, Dept. Pharmacology & Therapeutics, McGill University, Montreal, QC, Canada

Oligodendrocytes, the myelin forming cells, express a variety of neurotransmitter receptors coupled to signal transduction systems. In the present report we investigated the homologous regulation of muscarinic acetylcholine receptors (mAChR) coupled to phosphoinositide (PI) hydrolysis in oligodendrocyte progenitors in culture. Exposure to the muscarinic agonist carbachol (CCh) caused a time dependent desensitization of the PI hydrolysis, sequestration and down-regulation of mAChRs. After 1 h pretreatment (1 mM CCh), [^{3}H]NMS binding to surface receptors decreased by 47 %, while total receptors density ([^{3}H]scopolamine binding) decreased by 30 %. Desensitization of PI hydrolysis was apparent after 5 min of agonist exposure and reached 54 % by 1 h. Inhibition of receptor sequestration by decreasing the temperature to 10°C during the prestimulation period or in the presence of hyperosmotic sucrose blocked desensitization and receptor sequestration. Recovery of surface mAChRs, after 1 h CCh, was slow and returned to control levels by 24 h of agonist removal. Neither protein kinase C (PKC) nor protein kinase A (PKA) were implicated in the CCh-induced receptor sequestration. Activation of PKC with the phorbol ester TPA (1 μM) resulted in the attenuation of CCh-mediated PI hydrolysis. In contrast, PKA activation by forskolin (50 μM) was ineffective. CCh-mediated desensitization was not affected by inhibiting PKC, but, PKC inhibition abolished the effect of TPA. It is suggested that CCh-induced desensitization is independent of PKC and PKA. Overall, the present results indicate that mAChRs coupled to PI hydrolysis are regulated by CCh exposure. (Supported by the MRC and MSS of Canada and MEC of Spain).

PHARMACOLOGICAL CHARACTERIZATION OF α-ADRENOCEPTORS IN OLIGODENDROCYTES.

A. Khorchid and G. Almazan*. Department of Pharmacology and Therapeutics, McGill University, Montreal, PQ H3G-1Y6.

We have previously shown that oligodendrocyte proginitors express functional α_{1A}-adrenoceptors. In this study we characterized α-adrenoceptors, coupled to phosphoinositide metabolism, during oligodendrocyte development. Inositol phosphate levels were measured in [^{3}H]myo-inositol-labelled oligodendrocyte cultures following stimulation with 10 μM norepinepherine in the presence of 3 μM propanolol, a β-adrenergic antagonist (NE+Prop). Our results show that NE+Prop stimulated [^{3}H]inositol phosphates ([^{3}H]IP) in both progenitors and differentiated oligodendrocytes (3-, 6-, 12- and 24-days). Interestingly, this stimulation in [^{3}H]IP formation increased as oligodendrocytes matured. To pharmacologically identify the α-adrenoceptor subtype in mature oligodendrocytes, 12-days differentiated cultures were pretreated with prazosin, an α_1-adrenoceptor antagonist, that significantly decreased the agonist-stimulated [^{3}H]IP formation. In addition, pretreatment with chloroethylclonidine, which selectively blocks α_{1B}-adrenoceptors, had no effect on the levels of agonist stimulated [^{3}H]IP formation. However, these levels decreased with increasing concentration of WB4101, an α_{1A}-adrenoceptors antagonist, (IC_{50} of 10 nM). These results suggest that similar to progenitors cells, mature oligodendrocytes respond to NE with an increase in [^{3}H]IP formation that is mediated by α_{1A}-adrenoceptors. (Supported by Medical Research Council Of Canada).

H^+ AND Na^+ CHANGES EVOKED BY GLUTAMATE, KAINATE, AND D-ASPARTATE IN RAT HIPPOCAMPAL ASTROCYTES C. R. Rose* and B. R. Ransom, Dept Neurology, Yale University, New Haven, CT 06510 and Dept Neurology, University of Washington, Seattle, WA 98195-6465

Transmitter-induced pH changes in glial cells may mediate a special form of glial-neuronal interaction. We studied mechanisms underlying changes in intracellular H^+ concentration ($[H^+]_i$), and the correlation between changes in $[H^+]_i$ and intracellular Na^+ concentration ($[Na^+]_i$), induced by glutamate (Glu) and related compounds, in cultured astrocytes using fluorescence imaging with BCECF or SBFI

Glu, kainate (KA), or D-aspartate (D-Asp) caused rapid and reversible increases in $[Na^+]_i$; Glu or D-Asp application produced parallel intracellular acidifications. KA, in contrast, evoked biphasic changes in $[H^+]_i$, alkaline followed by acid shifts, which were unaltered after Ca^{2+} removal and persisted in 0 Cl^--saline, but were greatly reduced in CO_2/HCO_3^- or Na^+-free saline, or during application of the stilbene DIDS (4,4'-diisothiocyanato-stilbene-2,2'-disulphonic acid). The non-NMDA receptor antagonist CNQX (6-cyano-7-nitroquinoxaline-2,3-dione) blocked KA-evoked changes in $[H^+]_i$ and $[Na^+]_i$, indicating that these changes were receptor/ionophore mediated. In contrast, CNQX increased the $[H^+]_i$- and decreased the $[Na^+]_i$-changes induced by Glu. D-Asp, which is transported but does not act at glutamate receptors, induced $[H^+]_i$ and $[Na^+]_i$ changes that were unaltered by CNQX. Our results indicate that intracellular acidifications evoked by Glu or D-Asp in hippocampal astrocytes are mainly caused by the acidifying influence of Glu/Asp-uptake into the astrocytes. KA-evoked biphasic $[H^+]_i$ changes, in contrast, are probably due to transmembrane ion movements mediated by inward, followed by outward, electrogenic Na^+/HCO_3^--cotransport, reflecting KA-induced biphasic membrane potential changes.

INCREASED K^+ RELEASES EXCITATORY AMINO ACIDS (EAAs) FROM CULTURED ASTROCYTES BY BOTH REVERSAL OF THE EAA TRANSPORTER AND HIGH K^+ INDUCED CELL SWELLING. Eric Rutledge* and Harold K. Kimelberg Department of Pharmacology and Neuroscience and Division of Neurosurgery, Albany Medical College, Albany, NY 12208.

Astrocytic swelling is observed in ischemia and is thought to be caused predominantly by increased extracellular $[K^+]$. Extracellular glutamate concentrations >100 μM have also been measured in ischemia by *in vivo* microdialysis and contribute to neuronal death. Low extracellular glutamate levels are achieved by the Na^+ and K^+ dependent EAA transporters found on the plasma membranes of both neurons and astrocytes. However, these transporters can reverse and release EAAs when $[K^+]_o$ and $[Na^+]_i$ are increased. Primary astrocyte cultures prepared from the cerebral cortices of 1 day old rat pups exposed to a 100 mM KCl solution for 20 min. show two distinct phases of $[^3H]$-D-aspartate release. We propose that the initial transient phase is reversal of the glutamate transporter and the second sustained phase is a high K^+ swelling induced release mechanism. In support of this a 10 min ouabain pretreatment only enhances the initial phase of release, presumably due to raised $[Na^+]_i$. This release begins at $[KCl]_o$ of ~ 10 mM. Pretreatment for 40 min with the glutamate uptake inhibitor, threo hydroxy β aspartic acid, only inhibits the first phase of release. An anion transport inhibitor L-644,711 which inhibits swelling induced release due to hypotonic media, inhibits the second peak with no effect on the initial phase of release. These results suggest that astrocytes exposed to [KCl] ≥ 10 mM, as seen in epilepsy and spreading depression, could potentially serve as a source of EAAs released mainly by reversal of transporter when $[Na^+]_i$ increases concurrently. When extracellular $[K^+]_o$ is > 50 mM, as occurs during prolonged ischemia, both release mechanisms can contribute. (supported by NS 35205)

FUNCTIONAL NMDA RECEPTORS IN GLIAL PRECURSOR CELLS: A CRITICAL ROLE IN REGULATING PSA-NCAM EXPRESSION AND CELL MIGRATION. C. Wang[1], W.-F. Pralong[2], M.-F. Schulz[1], G. Rougon[3], J.-M. Aubry[4], S. Pagliusi[5], A. Robert[6] and J. Z. Kiss[1]*. Department of Morphology[1], Division of Clinical Biochemistry[2], Department of Pharmacology[6] University of Geneva Medical School; Department of Psychiatry, IUPG[4]; Glaxo Institute for Molecular Biology[5], Geneva, Switzerland; Laboratoire de Génétique et Physiologie du Développement, CNRS 9943, Marseille, France[3]

The capacity for long distance migration of the oligodendrocyte precursor (O-2A) cell is essential for myelin formation. To study the molecular mechanisms that control this process, we used an in vitro migration assay that utilizes neurohypophyseal explants. We provide evidence that O-2A cells in these preparations express functional NMDA receptors, most likely as homomeric complexes of the NR1 subunit. We show that NMDA evokes an increase in cytosolic Ca^{2+} that can be blocked by the NMDA receptor antagonist AP-5 and by Mg^{2+}. Blocking the activity of these receptors dramatically diminished O-2A cell migration from explants. We also show that NMDA receptor activity is necessary for the expression by O-2A cells of the highly sialylated neural cell adhesion molecule (PSA-NCAM) that is required for their migration. Thus, glutamate or glutamate receptor ligands may regulate O-2A cell migration by affecting expression of PSA-NCAM. These studies demonstrate how interactions between ionotropic receptors, intracellular signalling and cell adhesion molecule expression influence cell surface properties, which in turn are critical determinants of cell migration.

ASTROCYTES CAUSE SLOW GLUTAMATE-DEPENDENT CURRENTS AND MODULATE THE FREQUENCY OF MINIATURE SYNAPTIC CURRENTS IN CULTURED HIPPOCAMPAL NEURONS. A. Araque*, R.T. Doyle and P.G. Haydon, Laboratory of cellular Signaling. Iowa State University, Ames IA 50011.

Elevations of internal calcium in astrocytes cause a delayed elevation of neuronal calcium level (Parpura et al., *Nature*, 1994, 369:744-747), which we have attributed to be due to the release of glutamate. The electrophysiological nature of this Astrocyte-to-Neuron signal is ill-defined. To characterize this response, whole-cell currents of rat hippocampal neurons co-cultured with astrocytes (8-15 days *in vitro*) were monitored.

A slow inward current (42%), an increase in the rate of the spontaneous synaptic currents (SSCs) (15%), or both (12%), were evoked in neurons by mechanical or extracellular electrical stimulation of adjacent (<200 μm) astrocytes (n = 128). Inward currents reached a maximum (53 ± 7 pA) between 1-5 s after stimulation, and declined slowly, lasting several tens of seconds. The increase of SSC rate showed a similar time course. Both responses were unaffected by 1 μM tetrodotoxin (n = 19).

Since transmitter can be released from both astrocytes and neurons, we determined the nature of the direct astrocyte to neuron signal using tetanus toxin (TeTX), which selectively blocks neuronal transmitter release by specifically cleaving neuronal synaptobrevin. TeTX (30 nM) blocked neuronal transmitter release but did not affect the astrocyte-induced slow inward current (n = 24). The slow inward current was sensitive to 20 μM CNQX (n = 30), its magnitude augmented by removal of Mg^{2+} and addition of 10 μM glycine (n = 15), and this increase was abolished by 50 μM D-AP5 (n = 14), indicating that both NMDA and non-NMDA glutamate receptors were involved. These results provide further support to the presence of a direct astrocyte-neuron signaling pathway in which glutamate is released from astrocytes.

A NOVEL OLIGODENDROCYTE PROTEIN WITH HIGH SIMILARITY AT ITS 5'-END TO A GLUTAMATE-BINDING SUBUNIT. S. Szuchet *, P.E. Polak, M. Losekamp and B. Sanyal. Department of Neurology, The University of Chicago, Chicago, IL. 60637, USA.

Oligodendrocyte (OLG)-substratum adhesion results in their acquisition of a myelinogenic phenotype. Our aim is to decipher the signaling events and identify the molecules that initiate and propagate the myelination phenotype. OLG-adhesion initiates the synthesis and vectorial transport to the plasma membrane of heparan sulfate proteoglycans (HSPGs). We have shown that these HSPGs assemble into a developmentally regulated matrix. To characterize these HSPGs and define their function, we have designed probes after conserved sequences from known HSPGs and used them to screen a cDNA library generated from adhered OLGs. One of these probes, designed after a conserved sequence of the cytoplasmic domain of syndecan, specifically hybridized to a 3,573 bp cDNA. The cDNA encompasses the 3'-end of the molecule including the polyadenylation signal; the initiation codon has yet to be identified. We have sequenced the full-length cDNA. This sequence still has a few frame shifts and has to be refined. The first 1,238 nucleotides, at the 5'-end of the clone, have stretches of cDNA with a 64%-89% similarity to the glutamate-binding subunit of the NMDA receptor. That the isolated cDNA represents a novel molecule, distinct from the glutamate-binding subunit, is evidenced by the absence of sequence similarity with entries in the database of the remaining 2,335 nucleotides. Efforts are directed toward refining the sequence, sequencing the opposite strand. assessing the functionality of the glutamate-binding domain and establishing the location and role of this protein. Supported by NIH grant # NS24575.

Norepinephrine Suppresses Astroglial NOS-2 Expression at the Level of Promoter Activation. L. Lyandvert[1]*, E. Galea[1], Q.-W. Xie[2], D.J. Reis[1] and D.L. Feinstein[1]. [1]Dept. of Neurol. & Neurosci.; [2]Dept. of Med.; Cornell Univ. Med. Coll. New York, NY 10021.

Expression of the gene of the inducible isoform of nitric oxide synthase (NOS-2; iNOS) in astrocytes can be stimulated by exposure to bacterial endotoxin (LPS) and/or a combination of cytokines, nominally including interleukin 1-β (Galea et al., 1992). Moreover, this induction can be dose-dependently inhibited by norepinephrine (NE) via activation of β-adrenergic receptors and elevation of intracellular cAMP (Feinstein et al., 1994). We sought to determine whether the mechanism(s) by which NE inhibits NOS-2 mRNA accumulation is by reducing the stability of NOS-2 mRNA and/or the activity of its promoter. Exposure of primary cultures of rat astrocytes or C6 glioma cells to LPS or cytokines resulted in accumulation of NOS-2 mRNA, measured by quantitative RT-PCR, with maximal expression at 4-6 hr. Co-culture with NE (100 μM) at maximally stimulating doses of inducers reduced accumulation up to 50% ($P<0.05$). NE, introduced after 4 hr of induction did not decrease NOS-2 mRNA levels suggesting that NE did not accelerate the rate of NOS-2 mRNA decay, nor did NE modify NFκB p65 subunit activation. The mouse macrophage NOS-2 promoter was attached to the bacterial chloramphenicol acetyl transferase (CAT) reporter gene and used to transfect C6 cells. Transfectants expressing a NOS-2 promoter construct extending to base -1588 showed LPS and cytokine-dependent CAT expression, which was reduced by NE or cAMP analogues. In contrast, transfectants having only a minimal NOS-2 promoter (extending to base -85) showed LPS and cytokine-induced activity, but were unaffected by NE. We conclude that NE blocks NOS-2 gene expression by reducing NOS-2 promoter activity, possibly by activation of a suppressive factor which binds upstream of the minimal promoter. Heat Shock Protein 70 (HSP70) Reduces Expression of Inducible Nitric Oxide Synthase By Preventing Activation of NFκB. D.L. Feinstein*, E. Galea, D.A. Aquino, G.C. Li, H. Xu, and D.J. Reis. Dept. of Neurol. & Neurosci., Cornell Univ. Med. Coll. New York, NY, 10021.

Inflammatory activation of astrocytes induces expression of a calcium-independent isoform of nitric oxide synthase (NOS-2, iNOS), whose product, NO, may contribute to neuronal damage in response to brain injury. At the same time injury initiates expression of a heat shock (HS) response with expression of HS proteins (HSPs), agents which may reduce cellular immune responses and are cytoprotective by mechanisms as yet not fully understood. We investigated whether a protective mechanism of HSP activation is inhibition of stimulated NOS-2 expression, possibly by interruption of the NFκB transcription factor. A HS response was initiated in primary cultures of rat astrocytes or C6 glioma cells by heating to 43°C for 40-60 minutes. Cells were then exposed to NOS-2 inducers, bacterial LPS and/or cytokines. HS reduced the stimulated: (a) accumulation of nitrites (by 40 ± 8%; P<0.05); (b) activity of cytosolic NOS-2; (c) accumulation of NOS-2 mRNA (measured by quantitative RT-PCR); (d) activation of a NOS-2 promoter attached to the bacterial chloramphenical acetyl transferase reporter gene. Inhibition of HSP expression by quercetin (an inhibitor of all HSP expression) or by transfection of C6 cells with antisense oligonucleotides to rat HSP70 partially reversed the HS effect on stimulated expression of NOS-2. The effects of HS on NOS-2 expression were replicated by transient and stable transfection of C6 cells with human HSP70. In cells exposed to HS or cells expressing transfected human HSP70, the nuclear translocation of the NFκB p65 subunit induced by LPS and required for NOS-2 induction, was reduced suggesting HSP70 interferes with NFκB activation. The results demonstrate that induction of NOS-2 in astrocytes can be inhibited by HS, the reponse is mediated, at least in part, by HSP70 and possibly mediated by down-regulation of NFκB expression. The ability of HSPs to reduce NOS-2 expression may be an unrecognized mechanism preventing pathological NOS-2 expression in brain. Supported by National Multiple Sclerosis Society and NIH-HL18947.

SIGNALING FROM PURINERGIC RECEPTORS TO MAP KINASE IN HUMAN FETAL ASTROCYTES. J.T. Neary*[1], M. McCarthy[2], and Y. Kang[3]. Research Service[1,2,3], VA Medical Center, and Depts. of Pathology[1], Neurology[2], and Biochemistry & Molecular Biology[1], University of Miami School of Medicine, Miami, FL 33125.

Mitogen-activated protein (MAP) kinases are key elements of signal transduction pathways involved in cell growth. In rat astrocytes, stimulation of ATP/P2 purinoceptors leads to activation of MAP kinases and to cellular proliferation. To determine if purinergic receptors on human astrocytes are similarly involved in cell growth, we have evaluated purinoceptor activation of MAP kinase and stimulation of DNA synthesis. Human fetal astrocytes were prepared from first trimester mesencephalon. Cultures were shifted to the quiescent phase by incubation in media containing 0.5% horse serum for 2-3 days prior to treatment with purinoceptor agonists or antagonists. Extracellular ATP (100 uM) stimulated MAP kinase activity approximately 2-fold. This effect was mediated by P2 purinoceptors because a P2 purinoceptor antagonist, suramin (30 uM), inhibited the ATP-evoked stimulation by 50% ($p < 0.01$), but a P1 purinoceptor antagonist, 8-(para-sulfonphenyl)-theophylline (10 uM), had no effect. In contrast to rat astrocytes, an adenosine/P1 purinoceptor agonist, 2-chloroadenosine (10 uM), stimulated MAP kinase activity. Extracellular ATP (100 uM) or 2-chloroadenosine (10 uM) increased DNA synthesis by 40-50%. These studies indicate both P2 and P1 purinoceptors are coupled to MAP kinase and suggest a role for these receptors in the proliferation of human fetal astrocytes. (Supported by Dept. of Veterans Affairs.)

SIGNAL TRANSDUCTION PATHWAYS COUPLED TO P2Y PURINOCEPTORS IN ASTROCYTES. Y. Kang, Q. Zhu*, E. Yu and J.T. Neary. Res. Service, VA Med. Ctr. and Depts. Pathol. and Biochem. & Molec. Biol., Univ. Miami Sch. Med., Miami, FL 33215.

$P2Y_1$ and P2U-like purinoceptors signal to the mitogen-activated protein kinase (MAPK) cascade in rat astrocytes by a protein kinase C (PKC)-dependent mechanism. These P2Y receptors are also coupled to phospholipase C_β (PLC) which leads to increases in inositol phosphates, calcium mobilization, and PKC activation. To determine if P2Y receptors signal to distinct pathways or if PLC, PKC, and MAPK are part of a common transduction pathway, we investigated the effect of PLC inhibition on MAPK activation in primary cultures of rat cerebral cortical astrocytes. The PLC inhibitor U-73122 did not significantly reduce ATP-evoked MAPK activation but did block inositol phosphate formation. If P2Y purinoceptor signaling to MAPK is independent of PLC, a calcium-independent form of PKC may be involved in the P2Y purinoceptor/MAPK pathway. In this case, an inhibitor of calcium-dependent PKCs, Gö 6976, should have little effect on the stimulation of MAPK by P2Y agonists. Indeed, we found that Gö 6976 only partially reduced (10-20%) ATP- and UTP-evoked MAPK activation. By contrast, an inhibitor of both calcium-dependent and -independent PKC isoforms, Ro 31-8220, reduced ATP- and UTP-evoked MAPK activation by 88%. These findings suggest that (a) subtypes of P2Y purinoceptors are coupled independently to PLC and MAPK pathways and (b) the MAPK pathway involves a calcium-independent isoform of PKC, perhaps PKC ϵ. PROCESS EXTENSION AND MITOGEN-ACTIVATED KINASE (MAPK) ACTIVATION IN OLIGODENDROCYTES. R.L. Stariha*, S. Kikuchi, Y.L. Siow, S.L. Pelech, S.U. Kim. Department of Medicine, University of British Columbia; Kinetek Biotechnology Corp., Vancouver, Canada.

The relationship between process extension and MAPK activation in oligodendrocytes (OLG) was investigated using immunocytochemistry, kinase assays, western blots, and an inhibitor of the MAPK pathway. OLG were obtained from adult bovine brain and exposed to phorbol myristate acetate (PMA) for 10 min. Significant process extension was observed 24 hrs later in the PMA-treated OLG but not in control OLG. Control and PMA-stimulated OLG were then subjected to immunocytochemistry using an anti-Erk antibody against p42 Erk2 and p44 Erk1 isoforms of MAPK. The results showed a translocation of MAPK activity from OLG cytoplasm to nuclei after PMA stimulation. Control and PMA-stimulated OLG also were purified by MonoQ fractionation and subjected to kinase assays using myelin basic protein as substrate and [gamma-P^{32}]ATP. The kinase assays indicated that in PMA-treated OLG, MAPK was activated 5-fold over control OLG. Parallel western blots indicated that MAPK is phosphorylated by PMA stimulation in OLG. To confirm that this MAPK activation contributes to OLG process extension, we blocked the MAPK pathway with a specific inhibitor. OLG which were exposed to the inhibitor for 15 min. before PMA stimulation did not show any process extension even 1 week later. We conclude that MAPK activation is a crucial component in OLG differentiation and maturation. (Supported by the MS Society of Canada.)

PROTEIN KINASE C-MEDIATED CA^{++} SIGNALLING IN OLIGODENDROCYTES. A.S.J. Yoo*, C. Krieger, and S.U. Kim. Division of Neurology, Department of Medicine, University of British Columbia, Vancouver, Canada.

Process extension in oligodendrocytes (OLG), an important step for myelination, is believed to be mediated by a protein kinase C (PKC) signal transduction cascade. In addition, calcium (Ca^{++}), an important second messenger in various biological processes, is known to have effects on morphological changes in various cell types, including neurite outgrowth. In view of the possible involvement of Ca^{++} in OLG process extension in conjunction with PKC activation, we investigated the effect of phorbol myristate acetate (PMA), a potent PKC activator, on the intracellular free Ca^{++} concentrations of OLG in culture. OLG-enriched cultures were prepared from adult bovine brains, and the changes in intracellular Ca^{++} concentration were measured by microspectrofluorimetry using fura-2. Addition of PMA caused an irreversible increase of intracellular Ca^{++} levels by approximately 2- to 3-fold in most OLG. This response was abolished when Ca^{++}-free media was used during PMA stimulation. These observations indicate that PMA increases the transmembrane influx of Ca^{++}, an effect which may be mediated by PKC. These results suggest that enhanced OLG process extension could be related to an increase in extracellularly-derived free calcium in OLG cytoplasm induced by PKC activation. The mechanism for this transmembrane Ca^{++} influx in OLG is currently under investigation. (Supported by the MS Society of Canada.)

IMPACT OF CYTOPLASMIC CALCIUM BUFFERING ON THE SPATIAL AND TEMPORAL CHARACTERISTICS OF INTERCELLULAR CALCIUM SIGNALS IN ASTROCYTES., Z. Wang[2], M. Tymianski[1], O.T. Jones[1], R.Sattler[1], G. Bernstein[1], M.C. Wallace*[1], and M. Nedergaard[2] .[1]University of Toronto, Ontario, CANADA M5T-2S8 and [2]New York Medical College, Valhalla, NY 10595.

The impact of calcium buffering on the initiation and propagation of mechanically-elicited intercellular Ca^{2+} waves was studied using astrocytes loaded with different exogenous, cell-membrane permeant Ca^{2+} chelators and a laser scanning confocal microscope. Loading of the different chelators into cells was quantified by enzyme-linked immunoassays using a novel antibody to BAPTA. These showed that different permeant chelators, when applied at the same concentrations, accumulate to the same degree inside the cells. Loading cultures with BAPTA, a high Ca^{2+} affinity chelator, almost completely blocked calcium wave occurrence. Chelators having lower Ca^{2+} affinities had lesser affects, manifest as an attenuation of both the radius of spread and propagation velocity of the Ca^{2+} wave. The chelators blocked wave propagation, not initiation, because large $[Ca^{2+}]i$ increases elicited in the mechanically stimulated cell were insufficient to trigger the wave. Wave attenuation was a function of cytoplasmic Ca^{2+} buffering capacity, because applying increasing concentrations of low Ca^{2+}-affinity buffers mimicked the effects of lesser quantities of high affinity chelators. The exogenous chelators' effects were independent of Ca^{2+} binding kinetics, of chelation of other ions such as Zn^{2+}, and of effects on gap junction function. Slowing of the wave could be completely accounted for by the slowing of Ca^{2+} ion diffusion within the cytoplasm of individual astrocytes. The data obtained suggest that the endogenous cytoplasmic Ca^{2+} buffering capacity of astrocytes is low, but that alterations in Ca^{2+} buffering may provide a potent mechanism by which the localized spread of astrocytic Ca^{2+} signals is controlled. Ca^{2+} SIGNALING INDUCED BY PDGF-BB IN NORMAL AND TRANSFORMED OLIGODENDROCYTES: CORRELATION WITH THE CELL CYCLE. Alessandro Fatatis* and R.J. Miller, Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago (IL) USA.

In the transformed oligodendrocyte cell line CEINGE cl3, PDGF-BB causes either an oscillatory or a non oscillatory Ca^{2+} response. The percentage of cells showing the oscillatory response is greatly increased by blocking the enzyme sphingosine-kinase (JBC 271, 295-301,1996). When CG-4 cells, either as O-2A precursors or as mature oligodendrocytes, were exposed to PDGF-BB the same pattern of Ca^{2+} signaling was observed. However, although exogenously perfused sphingosine and sphingosine-1-phosphate (SP-1-P) produced both oscillatory and non-oscillatory Ca^{2+} responses respectively, as observed in CEINGE cl3, block of sphingosine-kinase during PDGF-BB exposure did not increase the percentage of oscillatory cells. On the other hand, the addition of PDGF-BB to PC-12 cells transfected with the β form of PDGF receptor or to NIH 3T3 fibroblasts, always elicited a non oscillatory Ca^{2+} response. This response was not affected by sphingosine-kinase blockade and sphingosine and SP-1-P both elicited a non oscillatory Ca^{2+} response. These data suggest that (1) the oscillatory Ca^{2+} response to PDGF-BB is an intracellular signal peculiar to oligodendroglial cells; (2) CEINGE cl3 transformed oligodendrocytes possess a higher sensitivity to changes in intracellular sphingolipid concentration in comparison to normal oligodendroglia. When CEINGE cl3 were serum deprived for 48 hrs only 13% of the cells observed were dividing. Exposure to PDGF-BB induced a non oscillatory signal in 90% of the responding cells. Staining for BrdU performed on the same cells studied by Ca^{2+} imaging, showed that all the non proliferating cells responded to PDGF-BB in a non oscillatory fashion. This suggests that the differences in the kinetics of PDGF-BB induced Ca^{2+} signaling observed in oligodendroglia are correlated with the position in the cell cycle of responding cells. ENDOTHELIN INDUCES PHOSPHORYLATION OF PEA-15 IN ASTROCYTES THROUGH THE ACTIVATION OF CALCIUM-CALMODULIN KINASE II. Chneiweiss H.*, Kubes M., Estellés A., Rolli M., Cordier J. and Glowinski J. INSERM U114/ Collège de France, Paris, France.

Neurotransmitters, growth factors and cytokines have been shown to mediate neuron-astrocyte communication. To study the regulation of morphological plasticity in astrocytes, we analyzed specific intracellular target phosphoproteins of extracellular signals in primary cultured astrocytes, using 2-dimensional polyacrylamide gel electrophoresis. PEA-15 is a novel substrate of protein kinase C (PKC) enriched in astrocytes and colocalized with microtubules. Two types of PEA-15 cDNAs (1.6 and 2.4 kb) were isolated from a mouse astrocytic library, encoding a 130 amino acid protein that exhibits no sequence similarity with any other protein in the databases.
Endothelins are known to exert several effects on astrocytes, triggered by multiple second messengers pathways. ET1 (0,1 μM) induces a potent phosphorylation of PEA-15, indeed still observed in the presence of PKC inhibitors. Comparison of phosphorylation performed both in vitro and in vivo, followed by microsequencing, demonstrate that PEA-15 is also a substrate for calcium-calmodulin-dependent protein kinase II (CaMKII), at a seryl residue (Ser 116) distinct from the PKC site (Ser 104). Endothelins as well as agents inducing an increase in intracellular calcium mainly enhanced the CaMKII-dependent phosphorylation of PEA-15. In addition, analysis of the microtubule-associated fraction suggests that both PKC and CamKII phosphorylation of PEA-15 may be involved in regulating the binding of the protein to microtubules.

THROMBIN INCREASES SYNTHESIS OF PLASMINOGEN ACTIVATOR INHIBITORS TYPE-1 AND TYPE-2 IN HUMAN GLIOMA CELLS. W. Zhang*and T.D. Bjornsson. Division of Clinical Pharmacology, Thomas Jefferson University, Philadelphia, PA 19107.

Plasminogen activators and their inhibitors are thought to play an important role in tumor invasion and dissemination by modulating plasminogen activator activity. Plasminogen activator inhibitors type-1 and type-2 (PAI-1 and PAI-2) may prevent tumor invasion by inhibiting the activity of urokinase (u-PA). However, little is known about the regulation of these inhibitors in tumor cells. The purpose of the present investigation was to examine the effects of the serine protease thrombin on PAI-1 and PAI-2 expression in human malignant glioma SF-188 cells. Increasing thrombin concentrations (0.1-10.0 unit/ml) caused enhanced synthesis of PAI-1 and PAI-2 antigens by ELISA, and increased cellular PAI-1 and PAI-2 mRNA levels by Northern blot analysis. The thrombin receptor acting peptide (SFLLRN) also increased both antigen and mRNA levels. Although u-PA synthesis in SF-188 cells was slightly enhanced by thrombin, plasminogen activator activity measured by a chromogenic substrate method revealed marked (90%) reduction in plasminogen activator activity after thrombin. In conclusion, thrombin stimulates PAI-1 and PAI-2 synthesis in glioma cells through interaction with the thrombin receptor, and may thus contribute to decreased plasminogen activation and glioma cell invasion in CNS.

ANALYSIS OF THE HEAT SHOCK RESPONSE IN THE HYPERTHERMIC RABBIT BRAIN USING NUCLEAR RUN-ON TRANSCRIPTION ASSAYS FOR HSP70 AND HSP90 GENES. C.A. D'Souza*, S.J. Rush, and I.R. Brown. Department of Zoology, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada, M1C 1A4.

In response to various forms of stress, cells induce the synthesis of heat shock proteins (hsps) which are involved in repair and protective processes. Previous studies in our laboratory have examined the induction of heat shock genes in the hyperthermic rabbit brain using Northern blotting and in situ hybridization methods which measure steady state levels of mRNAs. In the present investigation, run-on transcription assays with isolated brain nuclei were utilized to measure the time course of transcriptional activation of hsp70 and hsp90α and β genes in regions of the rabbit brain following a fever-like increase in body temperature. The kinetics of the transcriptional activation of hsp70 and hsp90 genes paralleled the rise and fall in body temperature in that peak signals were attained at 1 to 1 ½ hrs with a return to basal levels by 5 hrs. The heat shock response is mediated by the conversion of pre-existing heat shock transcription factor (HSF) to a DNA-binding form which facilitates its interaction with heat shock elements (HSE) in the promoter regions of heat shock genes. Gel mobility shift assays with extracts from various brain regions demonstrated that the time course of activation of HSF to a DNA-binding form paralleled the kinetics of the run-on transcription assays. In addition, the time course of the stress-induced phosphorylation of HSF was examined by Western blotting.

CONSTITUTIVE EXPRESSION OF HEAT SHOCK PROTEINS HSP90, HSC70 AND HSP60 IN THE RAT BRAIN DURING POSTNATAL DEVELOPMENT. S.M. D'Souza*, S.J. Rush, and I.R. Brown. Department of Zoology, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada, M1C 1A4.

The mammalian hsp70 multigene family is comprised of constitutively expressed hsc70 and stress-inducible hsp70 members. Our previous studies have demonstrated a glial induction of stress-inducible hsp70 mRNA in the 1 hr hyperthermic brain (+2-3°C) whereas signal was not detected in several populations of large neurons which exhibit high levels of constitutive hsc70. In addition, these neurons show abundant levels of constitutive hsp90 whereas adjacent glial cells do not. Stress-induced hsps are thought to be involved in cellular repair and protective processes. At present, it is not known when the high constitutive levels of hsc70 and hsp90 protein are attained during neuronal differentiation or whether these levels protect fully differentiated neurons from mild stress. We have now investigated the expression of hsc70, hsp90 and also hsp60 during postnatal development of the rat brain using Western blotting and immunocytochemistry. All three heat shock proteins were observed early in postnatal neural development (postnatal day 1). While levels of hsc70 remained fairly constant over the course of postnatal development of the brain, levels of hsp90 decreased somewhat in the adult and levels of hsp60 increased. The immunocytochemical analysis detected neuronal expression of hsp90, hsc70 and hsp60 from postnatal day 1 through to the adult. The specific roles that these hsps play in the developing mammalian nervous system are yet to be determined. (Supported by MRC)

685.4

DIFFERENTIAL EXPRESSION OF HEAT SHOCK PROTEIN mRNAs IN RAT CELLS. F. Passarelli*, B. Angeletti#, E. Carmenini, E. Pascale^, R. Verna^, L. Calò and E. D'Ambrosio#. Dept. Neuroscience, University 'La Sapienza', Rome; #Inst. Experimental Medicine, CNR, Rome; ^Dept. Experimental Medicine, University of L'Aquila, Italy.

Several HSP70-like proteins have been found in rat cells, where together with the strictly inducible member (HSP70) at least three other proteins have been identified: one regulated by intracellular level of glucose (GRP78), one highly expressed in the testis (HST70) and the third related to physiological temperature (HSC73). It has been shown that hypertermia or other noxious stresses in rats induce massive synthesis of two HSP70 transcripts. Using reversed transcription-polymerase chain reaction (RT-PCR) strategy two mRNA species were amplified from heat shocked PC12 cells and sequenced. Both cDNAs revealed the same open reading frame encoding a single predicted 641 aminoacid polypeptide of about 70 kDa. The two 3' untranslated regions of the two mRNAs were completely different both in lenght and composition. We investigated then the mRNA expression of the two corresponding genes and the one of rat HSP70 family member in PC12 cells, Rat1 cells and lung fibroblasts. Northern blot analysis revealed that 2.55 and 3.05 kb transcripts related genes were differentially expressed in the rat cell lines, while the third member of the subfamily was not induced. Our results confirm the fine regulatory pattern of the rat HSP70 gene subfamily in which two genes with completely different 3' untranslated regions are strongly induced, leading to the production of a large amount of a single protein.

ANTISENSE OLIGODEOXYNUCLEOTIDES DIRECTED TO INDIVIDUAL CALMODULIN GENE TRANSCRIPTS INHIBIT THE PROLIFERATION OF PC12 CELLS. W.F.Hou, S.-P.Zhang, G.Davidkova, R.A.Nichols and B.Weiss*. Dept. Pharmacol., Med. Coll. PA & Hahnemann Univ., Philadelphia, PA 19129

All five transcripts from CaM genes I, II and III are present in PC12 cells, but they are differentially distributed, regulated, and expressed, the mRNAs from CaM genes I and II being the most abundant. We employed antisense oligodeoxynucleotides (AS ODN) to the individual calmodulin genes in order to selectively block the expression of the different genes and to investigate the role these genes play in the proliferation of PC12 cells. Three 20-mer AS ODN targeted to unique sequences of CaM genes I, II or II were used. Culturing PC12 cells in the presence of AS ODN to CaM genes I and II caused a significant decrease in the proliferation of PC12 cells, when compared with control, untreated cells and with the corresponding random ODN-treated cells. However, AS ODN to CaM gene III did not significantly decrease the proliferation of PC12 cells. The inhibition of proliferation could be reversed by washing out the AS ODN. The levels of CaM in the cells treated with ODN AS to CaM genes I or II were reduced to 52% or 63%, respectively, of the levels found in control cells. However, the levels of CaM were not significantly reduced in PC12 cells treated with CaM gene III AS ODN. None of the random ODN had any significant effect on the levels of CaM in PC12 cells. These results show that AS ODN directed to the dominant CaM transcripts found in PC12 cells reduce the levels of CaM in these cells and inhibit their rate of proliferation, demonstrating an important role for CaM in PC12 cell proliferation. Furthermore, our data suggest that the individual CaM AS ODN may selectively inhibit the proliferation of only those cell types containing the corresponding target CaM mRNAs. Supported by NIH grant NS30724.

THE LTP ASSOCIATED GENE (LAG) IS DIFFERENTIALLY EXPRESSED IN THE BRAINS OF MALE AND FEMALE RATS HOUSED IN AN ENRICHED ENVIRONMENT COMPARED TO ANIMALS HOUSED IN A STANDARD ENVIRONMENT. S.A. Brooks*, S. Peña de Ortiz†, M.C. Diamond, J.L. Martinez, Jr†. Department of Integrative Biology, University of California, Berkeley, Ca. 94720;†Division of Life Sciences, University of Texas, San Antonio, TX 78249.

We previously reported the isolation of a novel gene from the cerebral cortex of a 64 day old rat housed in an enriched environment (Brooks et al. *Soc. Neurosci. Abstr.*, Vol. 20 Part 2, P.1428,1994) which we subsequently named LAG. Enriched environment (EC) rats, when compared to standard environment (SC), show a number of anatomical and structural changes in the cerebral cortex including: increased dendritic branching, increased dendritic spine counts, increased glial cell counts, and increased hybridization of rat brain RNA to unique rat DNA sequences. LAG is a highly conserved, bi-directionally promoted, polycistronic gene containing a recombinase . Multi-tissue Northern blotting of rat mRNA reveals strong binding in spleen and lung, moderate binding in brain, heart and liver, weak binding in kidney and testis, and no binding in skeletal muscle. Semi-quantitative densitometry of *in situ* hybridizations probed with an oligonucleotide against the recombinase portion of LAG was performed. This analysis revealed that EC males had increase expression of the recombinase strand compared to SC males ($p < 0.001$) and compared to EC females ($p < 0.001$). This research was supported by a grant from the Whitehall Foundation, #W94-33, to M.C. Diamond and a grant from NSF, IBN-9696033, to J.L. Martinez, Jr.

LAG, A RECOMBINASE-ENCODING cDNA, IS EXPRESSED IN MOSSY FIBER LTP AND BEHAVIORAL TRAINING. S. Peña de Ortiz, B.E. Derrick, S.A. Brooks, C. Vallejos, E.J. Barea-Rodriguez, and , J.L. Martinez, Jr*. Div. of Life Sciences, University of Texas, San Antonio, TX 78249.

Subtraction cloning experiments resulted in the isolation of a cDNA, upregulated after induction of mossy fiber LTP, designated LAG for LTP-Associated Gene. Sequence analyses determined LAG to be a polycistronic cDNA encoding polypeptide sequences on both DNA strands which are highly homologous to several gene regulatory factors, including a recombinase. Reverse transcription-PCR experiments confirmed the expression of polyadenylated mRNAs for both LAG DNA strands suggesting that this gene might be regulated by a bidirectional promoter. LAG mRNA levels increase bilaterally in dentate gyrus and area CA3 of the hippocampus 3 hours after the establishment of mossy fiber LTP in anaesthetized rats. The opioid receptor antagonist naloxone blocked both the induction of LTP and the upregulation of LAG mRNA, demonstrating the specificity of its expression to LTP induction. We have classified LAG as a late-effector gene based on the fact that its mRNA levels begin to increase 3 hours after LTP induction and remain elevated for at least 8 hours. Since mossy fiber LTP is a model for learning and memory we studied the changes in LAG mRNA levels after two training sessions in the spatial version of the Morris water maze. *In situ* hybridization analyses detected opioid receptor-dependent increases in LAG mRNA levels in hippocampal formation 5 hours after initial exposure to the maze. We conclude that LAG is an important gene associated with changes in neuronal plasticity which occur during spatial learning. *This work was supported by NSF (J.L.M., grant IBN 9411-564) and a NSF postdoctoral fellowship (S.P.O.)*

EXPRESSION OF DNA MISMATCH REPAIR PROTEINS IN POSTMITOTIC, TERMINALLY DIFFERENTIATED NEURON-LIKE CELLS. M. Belloni, D. Uberti, C. Rizzini, L. Piccioni, S. Algeri*, P.F. Spano and M. Memo Div. Pharmacol., Dept. Biomed. Sci. & Biotechnol., Brescia University School of Medicine, 25123 Brescia, Italy.

DNA repair is an important molecular defense system against agents damaging the integrity of the genome. There are several DNA repair pathways, each one specialized in a certain kind of damage. GT mismatches are recognized in human cells by a heterodimer formed by two nuclear proteins, named hMSH2 and GTBP (F. Palombo et al., Science 1995). Interestingly, a role for DNA repair proteins in the pathogenesis of neurodegenerative disorders has been recently hypothized. Although there are evidences of the activity of DNA repair enzimes in the brain there are not information on the capability of neurons to express these proteins. We evaluated immunohistochemically the expression of GTBP and hMSH2 in postmitotic, terminally differentiated neuron-like cells. Human neuroblastoma cell lines SH-SY5Y cells and primary culture of cerebellar granule cells have been used in this study. SH-SY5Y are a homogeneous population of cells that, when differentiated by retinoic acid, have morphological, neurochemical and electrophysiological properties characteristic of sympathetic neurons. Immunostaining with polyclonal antibodies against GTBP and hMSH2 was found in both undifferentiated and differentiated SH-SY5Y cells. The signal in both cases was specifically localized in the nucleus. A comparison with undifferentiated cells revealed a lower intensity of the signal in the differentiated cells. Since SH-SY5Y cells are tumors in origins, we extended our study to primary colture of cerebellar granule cells from neonatal rats. Culturing these cells for at least 10 days results in morphologically differentiated neurons. Immunohistochemical analysis revealed a significant staining in the nuclei. The role of GTBP and hMSH2 in postmitotic neuron-like as well as their contribution in the neurodegenerative processes is under investigation.

MOLECULAR VARIANTS OF RAT BRAIN GLUTAMATE TRANSPORTER mRNAs AND PROTEINS. K.Choudhury* and R.S. Roginski. Department of Anesthesia, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ. 08901.

Sodium dependent glutamate transporters participate in terminating glutamatergic neurotransmission in brain. We reported the cloning of a transporter cDNA (GluT-1ß) from rat brain, which generated a glutamate transporter protein from a downstream translation initiation site (ß) in the same reading frame of GLT-1 cDNA. Rapid amplification of cDNA ends (RACE) detected multiple 5' and polyadenylated 3'ends of the transporter mRNA. Detection of multiple polyadenylated 3'ends suggests the presence of multiple mRNA species sharing the same reading frame as reported cDNA clones (GenEMBL # U15098 and X67857). Probes derived from newly cloned untranslated sequences (5' and 3' RACE) upstream and downstream of reported sequences detected an ~11kb abundant mRNA species in Northern blots of rat brain polyadenylated RNA, the same size as that detected by a coding region probe. Therefore, 5' and 3' ends of the reported cDNA clones do not represent 5' and 3' ends of the ~11kb mRNA species. 5'RACE and nuclease protection assays suggest that 5' end of at least one of the transporter mRNA is at base 1 of U15098 sequence. HEK293 cells transfected with longer and shorter cDNAs produced 70kDa and 48kDa glutamate transporter proteins, respectively, and conferred Na-dependent high affinity glutamate transport activity.

DIFFERENTIAL EXPRESSION OF MONOAMINE OXIDASE (MAO) A AND B IN CACO-2 CELLS.
K. Chen[1]*, W. Liao[1,2], W-C. Shen[2] and J. Shih[1]. Dept. Mol. Pharmacol & Toxicol.[1] and Dept. Pharm. Sci.[2], University of Southern California, School of Pharm., Los Angeles, CA 90033.

Caco-2 cells develop morphological characteristics and marker enzyme activities of normal enterocytes after reach confluence in culture. Our study shows that these cells exhibit low level of MAO A but a high level of MAO B activities. Further study shows that MAO B, but not MAO A, activity increased significantly 14 days after reached confluence. MAO B enzymatic activity and its mRNA level were determined at one day before, and 3, 7, 10, and 15 days after confluence. Northern analyses were performed using radioactive oligonucleotide probes A9 and B2 specific to MAO A and B, respectively. After hybridization with B2 probe, a transcript of 2.5 kb was observed as expected. No positive signal was observed using A9 probe. The level of mRNA at various time parallels with MAO B catalytic activity. These results suggest that MAO B, but not MAO A, is related to the differentiation of enterocytes. Furthermore, Caco-2 cells may be an excellent model system to study the regulation of MAO B gene. (Supported by NIMH grants R37 MH39085 (MERIT Award), K05 MH00796 (Research Scientist Award), R01 MH37020 and Welin Professorship).

DYNAMICS OF OLIGONUCLEOTIDE DISTRIBUTION IN NEURONS AND GLIA AFTER INTRAHIPPOCAMPAL INJECTION
K. Yufu, Y. Yaida, W. A. Pulsinelli* and T. S. Nowak, Jr. Dept. of Neurology, University of Tennessee, Memphis, TN 38163.

Antisense oligonucleotides (oligos) are now widely used in attempts to modify gene expression in brain. Knowledge of oligo distribution is essential to achieving predictable effects with such reagents. We have reported the use of radiolabeled sense probes to detect unlabeled oligo in rat brain by in situ hybridization. In the present studies we evaluated the use of fluorescein-labeled probes, detected with anti-fluorescein antibodies, to localize oligos with cellular resolution. Wistar rat hippocampi were injected with 2 nmol phosphorothioate (PS) oligo antisense with respect to the translation start site of Wistar hsp70 mRNA, administered in a volume of 2 µl during 20 min. After various intervals animals were killed by decapitation or perfusion-fixed with 4% paraformaldehyde, and fresh frozen or vibratome sections were prepared, respectively. Oligo was detected in all major neuron populations within 1 h after acute injection when frozen sections were evaluated, with an apparent nuclear localization. Vibratome sections of brains fixed at this early interval yielded a diffuse signal with no evidence of cellular concentration. Neuronal signal was progressively lost from frozen sections, and by 24-48 h there was little oligo detected by this method. Conversely, striking oligo accumulation was evident in astrocytes in fixed vibratome sections evaluated at 48 h, apparently in a vesicular compartment. These results confirm that PS oligos rapidly target neurons and later redistribute into glia. The basis of differential detection of these compartments in fresh vs. fixed tissue is under study.

Supported in part by USPHS Grant R01-NS32344.

LOCALIZATION OF IP3R-I, L7 AND MAP-2 mRNAS DURING THE POSTNATAL DEVELOPMENT OF THE CEREBELLAR PURKINJE CELLS IN THE RAT.
E.R. Torre* and O.Steward. Dept. of Neuroscience, University of Virginia. Charlottesville. VA22908.

In neurons, a subset of the mRNA population is transported, and probably translated within dendrites. In these studies, we evaluated whether mRNAs translated in different cellular compartments are differentially translocated into dendrites. The distribution of mRNAs translated in membrane bound polysomes (inositol 1,4,5 triphosphate receptor type I (IP3r-I); or cytosolic/ cytoskeletal bound polysomes (L7 and MAP-2) was evaluated in cerebellar Purkinje cells (PC) during their postnatal development. *In situ* hybridization using ^{35}S and digoxigenin-labeled riboprobes was performed on brain sections from 1, 4, 7, 10, 15, 20 and 90 day old rats. Before the emergence of dendrites (P1-P4) IP3r-I mRNA was concentrated in the cell body of nearly all PCs. In contrast, L7 mRNA was restricted to a small subpopulation of cells (P1), and it is not until P4 that this mRNA is present, although with variable intensity, in almost all PCs. During this period MAP2 mRNA was barely detectable. Dendritic growth begins at P4 and is mostly complete by P20. Between P4 and P7 it is possible to distinguish PCs at different stages of dendritic growth. L7 and IP3r-I mRNAs were present in dendrites during all developmental stages. The label filled the dendrites reaching the external granule cell layer or the pia in the mature animal. The levels of MAP2 mRNA seemed to increase concurrently with the beginning of dendritic growth (P4-8). However, the label was in proximal dendrites and did not seem to extend into distal dendrites even in mature animals. Thus, independently of their site of translation, these mRNAs are translocated into dendrites at the same time as processes develop. However, different signals may regulate the final localization of these mRNAs within dendrites. Supported by NS 12333 to OS.

TEMPORALLY-REGULATED GENE EXPRESSION IN EMBRYONIC RAT THORACIC SPINAL CORD REVEALED BY DIFFERENTIAL DISPLAY.
W.C. Perryman*, Y.F. McKee, C.A. Perry, J.A. Rada, and K.G. Ruit. Department of Anatomy and Cell Biology, University of North Dakota School of Medicine and Health Sciences, Grand Forks, ND 58202.

During the prenatal period, sympathetic preganglionic neurons (SPNs) become distinct in their location and morphology. Using the fluorescent tracer DiI in fixed tissues, we have described prenatal and early postnatal SPN process outgrowth in detail. Among our observations has been the apparent expression of axon collaterals by SPNs. These collaterals of parent SPN axons descend up to 5 segments within the spinal cord IML and lateral funiculus and are observed in close proximity to SPN somata and dendritic arborizations. Their expression is first observed on E15, they reach their maximum length (up to 2100µm) by E17, and by the day of birth (E21) the collaterals have been all but eliminated.

In an effort to further understand the temporal and spatial aspects of SPN development, especially the transient expression of axon collaterals, we sought to identify genes that are temporally expressed during prenatal development in the rat thoracic spinal cord. From E17 and E21 embryos taken by ceasarean section from timed-pregnant rats, thoracic spinal cords were dissected, isolated, and frozen in liquid nitrogen. Total RNA was then isolated, treated with RNAase-free DNAase and differential display RT-PCR was utilized to produce cDNAs using three one-base-anchored oligo-dT primers and eight upstream primers (Genehunter). PCR products from E17 and E21 were differentially displayed using a 6% sequencing gel. Reproducibility was verified by a second gel and 5 differentially displayed bands (four on E17 and one on E21) were chosen for further analysis. The reamplified cDNA probes are presently being cloned and verified by northern blot analysis prior to use for sequencing and *in situ* hybridization. Supported by NSF EPSCoR.

SINGLE-STEP COMPETITIVE RT-PCR FOR MEASUREMENT OF Na CHANNEL mRNA ABUNDANCE. F.N. Quandt*. Multiple Sclerosis Center and Dept. Molec. Biophys. and Physiol., Rush Univ. Chicago, IL 60612.

Changes in the expression of a neuronal protein can result from an alteration in the level of the species of mRNA coding for the protein. The abundance of mRNA is therefore often measured to test the mechanism of variations in expression. One technique developed recently to measure mRNA is the competitive reverse transcription (RT) polymerase chain reaction (PCR) assay. Traditionally, RT of the isolated RNA is first performed. The RT reaction is then followed by PCR of the cDNA in the presence of a known concentration of competitor. The competitor is a DNA template constructed to share the PCR primer recognition sequences, but differs in some other measurable characteristic, such as length. The ratio of cDNA to competitor obtained after PCR amplification is given by the same ratio before amplification, enabling quantification of the cDNA. I have found that the RT and competitive PCR procedures can be combined in a single step using *rTth* polymerase in the presence of Mn. Under this condition, the enzyme is known to exhibit both reverse transcriptase and DNA polymerase activity. All components for RT and competitive PCR can be added initially to a single tube, or additional PCR-specific components added after RT. To test for the presence of genomic DNA, Mg can be substituted for Mn to eliminate RT. Levels of mRNA for voltage-dependent Na and K channels in N1E-115 neuroblastoma cells have been measured with the single step assay, and are similar to levels measured by the traditional method. The assay can measure the appropriate difference in mRNA between dilutions of total RNA. Because a separate RT step is eliminated, the single step mRNA assay is fast and there is no cost of reverse transcriptase. Sensitivity is high, as mRNA levels from 5 ng total RNA are easily measured. Supported by the National Multiple Sclerosis Society.

A BASIC HELIX-LOOP-HELIX PROTEIN, KW8, IS EXPRESSED IN ADULT RAT BRAIN AND ACTIVATES GAL4 TRANSCRIPTION.
K. Maruyama, H. Kume, H. Kuzume, H. Asada, T. Tomita and K. Obata*. Laboratory of Neurochemistry, National Institute for Physiological Sciences, Myodaiji, Okazaki, Aichi 444, Japan.

Recently it was reported that LTP (long term potentiation) like potentiation of synaptic transmission was induced by the treatment of tetraethylammonium (TEA), a K^+ channel blocker (Aniksztejn, L. and Ben-Ari, Y. 1991, Nature 349, 67-69). We tried to screen new genes related to LTP by subtraction between the message of TEA-treated hippocampal slices and that of untreated whole brain from the rat. During this course of study, we cloned a novel basic helix-loop-helix (bHLH) protein, KW8. It was expressed specifically in neurons, and had the message size of 2.5 kb. The predicted amino-acid sequence revealed its bHLH domain was highly homologous with that of NeuroD, although another part did not show any homology with reported proteins by data base search. Generally, bHLH proteins bind DNA and regulate transcription. To study this, Two-Hybrid System was applied. When the carboxyl region of KW8 was subcloned to the GAL4 DNA binding domain vector (pGBT9, CLONTECH), it alone activated the reporter genes. Hence KW8 could activate transcription of a certain gene. The target gene of KW8 is still unknown. However, bHLH proteins seem to have an important role in cellular differentiation. Since KW8 was expressed in adult brain, it might work in neural plasticity.

UNUSUAL CNS LOCALIZATION OF A DNA-BINDING PROTEIN
J. G. Kim, R. C. Armstrong*, J. A. Berndt and L. D. Hudson. Lab. of Dev. Neurogenetics, NINDS, NIH and Dept. Anatomy & Cell Biology, USUHS, Bethesda, MD

In the process of cloning transcription factors from human fetal brain that recognize the myelin PLP gene, we isolated a DNA-binding protein (named MYT2 for MYelin Transcription factor 2) that has several unusual features. Localization of the DNA-binding domain of MYT2 to the carboxy terminus revealed a novel alpha-helical domain that specifically recognizes a motif including TTCCA in the PLP promoter region. The MYT2 transcript has an extremely long 5' untranslated region, over one kb, that contains an internal ribosome entry site. In the CNS, MYT2 protein is found in the cytoplasm of oligodendrocyte progenitor cells, soma and axons of diverse neuronal populations, and apical cytoplasm of ciliated ependymal cells. The latter localization is not surprising in light of the near identity of MYT2 to a recently cloned constituent of cerebral spinal fluid, cerebrin-50. DNA-binding proteins are rarely found in extracellular fluids, suggesting that MYT2 may have functions unrelated to transcriptional controls.

HIV-1 REPRESSOR TAR-BINDING PROTEIN (TBP)HOMOLOGUE IN THE NEONATAL BRAIN, A. Dobi*, M. Palkovits, A. Eitel, M. Mahan, F. Lim, M. Ring, C.G. Palkovits and D.v. Agoston , MCN, Lab. of Dev. Neurobiol., NICHD, NIH, Bethesda, MD ,20892

Viral DNA elements and intracellular factors of the host cell can engage in various forms of interactions that may result in altered cellular functions or changes in viral replication. The human immunodeficiency virus type 1 (HIV-1) requires several DNA elements including TAR DNA and numerous cellular factors to achieve transactivation by the Tat protein. In the HIV-1 infected cell, presence of viral DNA elements can perturb cellular functions through altered gene expression by "decoying" cellular factors /DNA binding proteins from their natural intracellular target DNA. Conversely, intracellular factors can alter HIV-1 replication by interfering with its transcriptional machinery. We have identified a novel intranuclear protein through its ability to bind to an AT-rich repressor element of the rat enkephalin gene. The protein shows structural similarity to the novel human TAR DNA binding protein 43 (hTDP-43) which is a strong repressor of HIV-1 replication by inhibiting the assembly of transcriptional complexes responding to Tat. The normal cellular function of hTDP-43, however, is unknown. Gel shift assays with HIV LTR between -18 and -28 showed that the rat protein (rTDP-43) is very abundant in early postnatal brain but undetectable in adult brain. In the postnatal brain, however, its abundance significantly varies among different brain regions. In contrast to its human homologue, rTDP-43 is undetectable in peripheral organs at any age. Identifying the cellular functions of these proteins could provide important clues about normal neurodevelopment and the pathomechanism of HIV-1-induced neuropathology in neonates.

PREFERENTIAL EXPRESSION OF KIN ZINC-FINGER PROTEIN IN NEURONS OF ADULT RATS. S.Araneda[1*], N. Mermet[1], J.S. Lin[1] and J. Angulo[2] .[1] Dép. Méd. Exp., Univ. C. Bernard, Lyon, F. [2]Lab. Génet. Radiosensib., CEA, Fontenay-aux-Roses, F.

The KIN17 gene has been identified in the CNS by using crossing immunoreaction and DNA recombining methodology, and is likely to encode the protein KIN, which is thought to be involved in the recombination-repair machinery. The mouse gene coding for KIN17 protein correspond to 1440 bp, displays a zinc finger motif and can bind to curved double-stranded DNA. In a previous study, we have demonstrated the presence of an high level of KIN in cell nuclei of the CNS using both immunocytochemistry with anti-RecA antibodies and in situ hybridization with KIN17 cDNA. It remained uncertain, however, if KIN is present in both neuronal and glial cells or is confined to neurons. The present study in adult rats was, therefore, carried out to identify its cell localization using immunocytochemistry of KIN protein, coupled with immunostaining of GFAP, a glial cell marker. Cryostat sections of paraformaldehyde-fixed brains were incubated with anti-RecA antibodies (gifted of Angulo), biotinylated IgG and ABC complex. Immunoreactivity was revealed by DAB-nickel. Sections were then submitted to GFAP immunocytochemistry using PAP/DAB. The results obtained confirmed our previous report on the existence of KIN in the cell nuclei of a great majority of neurons throughout the CNS, e.g. the cortex, hipocampus and hypothalamus. Moreover, in these areas, a large number of cells with typical glial morphology were found immunoreactive to GFAP. However, KIN protein was not detectable in these GFAP positive cells by the present technique, suggesting its trace amounts or absence in glial cells. These data suggest that the nuclear protein KIN is confined to neuronal cells. This preferential expression in neurons, which are unable to divide themselves, supports the role of KIN in the DNA recombination-repair mechanisms, essential for the maintenance of gene integrity. Supported by CNRS and INSERM.

CHARACTERIZATION OF C/EBP TRANSCRIPTION FACTORS EXPRESSED IN MAMMALIAN BRAIN. C.M. Alberini*, R. Ingrassia, M. Ungari[§], T. Gulotta°, G. Pollonini, F. Facchetti[§]. Chemistry and [§]Anatomy Pathology, Dipartimento Materno-Infantile e Tecnologie Biomediche, University of Brescia, and °CNR-ITBA, Brescia, Italy.

From invertebrates to primates, long-term synaptic plasticity requires a brief, initial phase of "consolidation" during which RNA and protein synthesis are essential. In the invertebrate Aplysia californica, during the consolidation phase, the induction of the immediate early gene ApC/EBP, a member of the C/EBP family of transcription factors, is essential. In fact, blocking ApC/EBP during consolidation selectively blocks the long-term response. Because the gene-induction phase is conserved throughout the evolution, we are interested in studying C/EBP transcription factors in the mammalian CNS. DNA binding activity, immunohistochemical analysis, western blots and hybridization tests showed that C/EBPs or C/EBP-like members are detectable in all, mouse, rat and human brain. C/EBP-binding activity resulted very abundant in mammalian CNS and it may include new members of the family. Western blot staining and immunohistochemical studies showed that murine and human CNSs are specifically recognized by an antiserum raised against ApC/EBP, suggesting that mammalian CNS expresses ApC/EBP-like factors. Moreover antibodies specific for known C/EBP members such as C/EBPß and CRP1 are also detected by western blot in both human and rodent's CNS. We will discuss the distribution and possible roles of C/EBP transcription factors in mammalian brain.

NEURONAL SPECIFIC EPITOPES ARE SHARED BETWEEN THE NICOTINIC ACETYLCHOLINE RECEPTOR, DISINTEGRINS AND SIGNAL TRANSDUCTION MOLECULES. B.A. Chase*, S. Slominski and K. Markopoulou. Dept of Biology, Univ. of Nebraska at Omaha, Omaha NE 68182-0040.

We have previously described a panel of monoclonal antibodies that cross-react with defined regions of the vertebrate muscle nAChR that also cross-react with specific subsets of the *Drosophila* CNS and PNS. To address the basis for this crossreactivity we have isolated cDNAs from a screen of an expression vector library with these antibodies. One of these antibodies, mAb 27.1A.16.42 that crossreacts with the neuropil identifies three distinct genes. These genes are expressed predominantly in the larval and adult CNS, but also in imaginal discs and developing oocytes. The patterns of expression are overlapping, but not identical and are consistent with the patterns of immunoreactivity of mAb 27.1A.16.42. Sequence analysis of these cDNAs (4-1, 8-1 and 10-1) reveals that they show no homology to nAChR subunits. cDNA 4-1 contains a putative open reading frame (ORF) that encodes a 421 amino acid polypeptide that is a member of the ADAM domain protein family. cDNA 8-1 contains a putative ORF that encodes a 660 amino acid polypeptide showing amino acid sequence similarity to glycerol-3-phosphate acyltransferases. cDNA 10-1 contains an ORF that encodes a polypeptide showing amino acid sequence similarity to E1-E2 ATPases. These findings indicate that epitopes in the vertebrate nAChR are shared in diverse neuronal proteins which are involved in cell-cell and/or cell-matrix interaction, membrane metabolism and signal transduction. That tertiary structural similarity is conserved among diverse neuronal proteins suggests that conserved tertiary structures serve as potentially functional modules in proteins involved in cellular interactions.

DISTRIBUTION OF MARCKS-RELATED PROTEIN (MRP) GENE EXPRESSION IN THE ADULT RAT BRAIN: COMPARISON WITH MARCKS. R. K. McNamara[1*] R. A. Schnizer[1] & R. H. Lenox[1,2,3]. Departments of Psychiatry[1], Pharmacology[2], and Neuroscience[3], University of Florida College of Medicine, Gainesville, FL, 32610-0256.

The *m*yristoylated *a*lanine-*r*ich *C*-*k*inase *s*ubstrate (MARCKS) and MRP (MacMARCKS/F52) belong to a small family of related proteins which are specific substrates for protein kinase C, bind to plasma membrane via N-terminus myristoylation, and bind calmodulin in a calcium- and phosphorylation-dependent manner. However, the MRP and MARCKS cDNAs have <50% base sequence homology and their genes possess distinct promotors which may confer differential expression. The present study examined the distribution of MRP and MARCKS mRNAs in the adult rat brain using *in situ* hybridization histochemistry. Serial brain sections were hybridized with radiolabeled antisense riboprobes corresponding to bases 354-1505 of the murine MARCKS cDNA (Seykora *et al.*, 1991) and bases 1-1200 of the murine MRP cDNA (Umekage & Kato, 1991). Specificity of both antisense riboprobes was verified by the absence of hybridization signal after incubation with sense oriented riboprobes. Moreover, labeled MRP antisense hybridization was prevented by excess unlabeled MRP antisense probe but unaffected by excess unlabeled MARCKS antisense probe, and labeled MARCKS antisense hybridization was prevented by excess unlabeled MARCKS antisense probe but unaffected by excess unlabeled MRP antisense probe, indicating that the two probes do not cross react. Both MRP and MARCKS hybridization were moderate-pronounced in the olfactory bulb, including the glomerular layer, piriform cortex (layer II), medial habenular n., hippocampal granule and CA1 pyramidal cells, entorhinal cortex (layer II), and low-absent in caudate-putamen, thalamic nn., and hippocampal CA3 pyramidal and hilar neurons. MRP hybridization was more pronounced in the anterior olfactory n. and lateral habenula relative to MARCKS whereas MARCKS hybridization was more pronounced in cerebellar cortex. Overall, these data indicate a high degree of similarity in the distribution of MRP and MARCKS gene expression in the adult rat brain. POTENTIATION OF SPONTANEOUS SYNAPTIC INPUTS IN RAT MOSSY CELLS: CHANGES IN FREQUENCY AND AMPLITUDE OF EPSPS. B.W. Strowbridge*. Dept. of Neurological Surgery, Univ. of Washington, Seattle, WA.

Hilar mossy cells are characterized by frequent, large-amplitude spontaneous EPSPs which can be dramatically potentiated by depolarization of a single postsynaptic cell. Analysis of membrane potential variance, an indicator of spontaneous EPSP activity, showed that depolarization resulted in a prolonged epoch of potentiated EPSPs (~2 minutes) with a characteristic time course.

Two methods were used in the current study to assess changes in EPSP amplitude and frequency during depolarization-induced epochs of potentiated EPSPs. In the first method, spontaneous EPSPs were visually identified using a computer display. This method generated estimates of the mean interval between EPSPs in the basal (non-potentiated) state of 65.0 ± 4.8 ms and 40.6 ± 2.6 ms (n=8) when potentiated. These results were then used in a stochastic model of summated EPSPs. This model predicted that an increase in mean EPSP amplitude of 90.3 ± 17 %, in addition to the 60% increase in EPSP frequency, was needed to account for the six-fold increase in variance measured during potentiated epochs. These estimates were confirmed in the second study in which EPSPs were identified by an automated computer program and direct measurements of EPSP frequency and amplitude were made. Amplitude histograms from potentiated epochs often showed two clear peaks: one at ~2 mV corresponding to the single peak observed in basal conditions, and another peak centered at ~7 mV. Analysis of the intervals between small- and large-amplitude EPSPs showed clear differences. The intervals between small (~2 mV) EPSPs in both basal and potentiated states were distributed randomly, as expected for a random process, while the large-amplitude EPSPs present in potentiated epochs showed a preferred interval of ~100 ms. These results suggest that depolarization of mossy cells recruits a new population of large-amplitude EPSPs.

Supported by NIH (NS33590) and the Epilepsy Foundation of America.

NITRIC OXIDE INTERACTS WITH FREE RADICALS TO EVOKE PURINE RELEASE FROM RAT HIPPOCAMPAL SLICES. R.M. Broad* and B.B. Fredholm.Division of Pharmacology, Karolinska Institutet, S171 77, Stockholm.

We have previously shown that nitric oxide donors evoke the release of adenosine, as well as other purines, from perfused rat hippocampal slices. In non-neural tissues, certain functional effects of NO were shown to be mediated via interactions with oxygen free radicals. In nerve, NO radicals have been shown to act by enhancing ADP-ribosylation in response to DNA damage. We postulated that such mechanisms may be responsible for NO-mediated adenosine release. Rat hippocampal slices were incubated with [^{3}H]adenine, perfused and sampled for release of [^{3}H]purines. As expected, perfusion with the NO donor S-nitrosyl-N-acetyl penicillamine (SNAP; 300 μM) enhanced the field-stimulated (10 Hz; 5 min) release of purines from hippocampal slices. This effect was completely eliminated in the added presence of the free radical scavengers superoxide dismutase (250 U/mL), catalase (1000 U/mL) or a combination of the two. These enzymes did not alter purine release in the absence of SNAP. The free radical generating system, xanthine (5 μM) and xanthine oxidase (25 mU/mL), enhanced purine release in the absence of SNAP. Benzamide (500 μM), a compound shown in biochemical assays to inhibit ADP-ribosylation, did not affect the enhancement of purines mediated by SNAP. These data indicate that oxygen free radicals alone can enhance the field-stimulated release of purines from rat hippocampal nerves, although not at levels present endogenously. In this model, the ability of NO to augment adenosine release appears to depend entirely on interactions with such endogenous concentrations of free radicals. This suggests an increased potency of nitroxy vs oxygen free radicals. Since benzamide did not influence SNAP-mediated release, it is likely that the nitroxy radicals do not function via DNA damage with subsequent ADP-ribosylation. These studies were supported by MRC Canada (RMB) and MFR Sweden (BBF).

EVIDENCE FOR A PRESYNAPTIC LOCUS OF EXPRESSION OF LTD INDUCED BY GROUP I mGluRs IN THE CA1 REGION OF THE IMMATURE RAT HIPPOCAMPUS. S.M.Fitzjohn[1], D.Lodge[2] and G.L.Collingridge*[1]. Dept. of Anatomy[1], University of Bristol, Bristol, U.K., BS8 1TD and Lilly Research Centre[2], Erl Wood Manor, Windlesham, U.K., GU20 6PH.

In the CA1 region of the immature rat hippocampus, long-term depression (LTD) of the field EPSP can be induced by the non-selective metabotropic glutamate receptor (mGluR) agonist (1S,3R)-1-aminocyclopentane-1,3-dicarboxylate and the group I specific agonist (RS)-3,5-dihydroxyphenylglycine (DHPG) (Overstreet *et al.* Neurosci. Ab. 616.11, 1995; Fitzjohn *et al*, Physiol. Soc. Proc., in press). Here we have investigated the locus of expression of this phenomenon.

Whole-cell patch-clamp recordings were made from CA1 pyramidal neurones of CA3-ectomised hippocampal slices prepared from 13-14 day old rats. Neurones were voltage-clamped at -80 mV. EPSCs were elicited by stimulation of the Schaffer collateral-commisural fibres every 15s. IPSCs were eliminated by addition of 50 μM picrotoxin to the perfusate and the use of a Cs^+-based intracellular solution.

In 8/10 neurones, 30 μM DHPG (20 min) resulted in LTD of the EPSC (mean depression = 36 ± 10 %; mean ± sem; 15 minutes of washout), without any change in holding current or input resistance, which lasted for the time that the neurone was held (maximum time 1 hour). In the remaining 2 neurones, 30 μM DHPG resulted in a transient depression that reversed fully within 10 minutes of washout. To determine the locus of expression of LTD we used 2 methods: paired-pulse facilitation (50 ms inter-stimulus interval) increased from 2.1± 0.2 (baseline) to 3.1 ± 0.4 following LTD induction (n=5; p<0.05); the coefficient of variation of EPSC amplitude increased from 0.22 ± 0.03 (baseline) to 0.31 ± 0.03 (15 minutes of washout; n=6; p<0.01).

The data obtained using both methods suggest that LTD induced by group I mGluR activation exhibits a presynaptic element.

This work was funded by the BBSRC.

DOPAMINE DEPRESSES EPSCs IN THE NUCLEUS ACCUMBENS VIA NMDA RECEPTOR-DEPENDENT RELEASE OF ADENOSINE. J. Harvey & M.G. Lacey* Dept. of Pharmacology, University of Birmingham, Birmingham, UK.

In the nucleus accumbens (NAcc), dopamine D_1 receptor (D_1R) activation results in depression of glutamate receptor-mediated EPSCs, via a presynaptic mechanism. However, D_1Rs are distributed exclusively on intrinsic neurones rather than nerve terminals. To resolve this discrepancy, we investigated whether D_1R activation causes release of a retrograde messenger which in turn inhibits glutamate release. Whole cell patch clamp recordings were made from NAcc neurones in 350 μm horizontal rat forebrain slices, maintained at 32 ^{0}C and perfused with standard medium. EPSCs were evoked by cortical stimulation in the presence of picrotoxin (50 μM). In the presence of the adenosine A_1 receptor antagonist, DPCPX (200 nM), which itself caused a rapid facilitation of EPSCs (94 ± 22%; n=17), the depression of EPSCs by dopamine (30 μM n=4) and the D_1R agonist, SKF 38393 (10 μM; n=3) was abolished. Thus the ability of dopamine to depress EPSCs in the NAcc is dependent on the activation of A_1 receptors In another 3 cells, the NMDA receptor antagonist, D/L-AP5 (100 μM), also reduced dopamine-induced depressions from 52 ± 2.6% to 8.0 ± 1.7%, indicating that NMDA receptor activation is required for dopamine-induced depressions. Furthermore, application of NMDA itself reduced EPSCs by 28 ± 8.3%, which was reduced to 5.3 ± 2.2% in the presence of DPCPX (n=3). To determine whether dopamine could directly modulate synaptically activated NMDA receptors, the NMDA component of synaptic transmission ($EPSC_N$) was pharmacologically isolated and cells were voltage clamped at -50 mV. In a similar manner to its action on EPSCs, dopamine (30 μM) depressed the $EPSC_N$ by 57 ± 7.1 % (n=3). However, in the presence of DPCPX, dopamine (30 μM) caused a reversible enhancement of the $EPSC_N$ (34 ± 7.5%; n=5). Together these data show that D_1R activation not only enhances NMDA currents, but also that activation of NMDA receptors and subsequent release of adenosine is critical for the dopamine-induced depression of glutamatergic synaptic transmission in the NAcc.

PROTEIN KINASE C ACTIVATION PARTIALLY COUNTERACTS THE PRESYNAPTIC INHIBITION OF EPSC. T. Miyazaki*, H. Kobayashi and T. Tosaka Dept. of Physiol., Tokyo Medical College, Tokyo 160, Japan

We had reported that noradrenaline (NA) presynaptically inhibited the excitatory postsynaptic currents (EPSCs) in sympathetic preganglionic neurons (SPNs) of neonatal rat spinal cord thin slices evoked by focal stimuli. The result obtained by quantal analysis was consistent with the previous result, since the mean amplitude and frequency of miniature EPSCs in solutions with 1 μM tetrodotoxin were not affected by NA (10 μM). While clonidine (5 μM) and oxymetazoline (5 μM) mimicked the inhibition by NA, phenylephrine (100 μM) exerted only a weak inhibition on EPSCs. Idazoxan (2 μM) increased the EPSC amplitude and abolished the NA inhibition. Relatively high concentration of yohimbine or prazosin (4-5 μM) was required to decrease the inhibition. The EPSC amplitude was significantly increased in the solutions with dibutyryl cyclic AMP (1 mM), forskolin (10 μM) or phorbol dibutyrate (PDBu, 500 nM). However, the NA inhibition was partially counteracted only in the solution with PDBu (65 % reduction in control and 38 % in PDBu, n=5). These results may suggest that the reduction of the protein kinase C activity rather than the cyclic AMP decrease after the α_{2A}-adrenoceptor activation is one of the possible signal transduction mechanisms contributing to the presynaptic inhibition by NA of EPSCs in SPNs.

INTERLEUKIN-1 REGULATION OF ^{3}H-NOREPINEPHRINE RELEASE FROM RAT HIPPOCAMPAL SLICES AND THE EFFECT OF BETA-ADRENERGIC RECEPTOR ACTIVATION. T.J. Nickola, T.A. Ignatowski, P.R. Knight, and R.N. Spengler*. Depts. Pathology and Anesthesiology, SUNY Buffalo, Buffalo, NY 14214.

Bi-directional communication between the nervous and immune systems may be accomplished by an interaction between the release of neurotransmitters and cytokines. Norepinephrine (NE) released from noradrenergic nerve terminals activates adrenergic autoreceptors, resulting in the regulation of subsequent NE release. Cytokines such as interleukin-1 (IL-1) are also among the endogenous mediators that may control NE release. Field stimulation and super-perfusion of rat hippocampal slices was utilized to study the functional interaction between pre-synaptic responsiveness to IL-1 and the activation of β-adrenergic autoreceptors. ^{3}H-NE release during field stimulation was potentiated by the β-adrenergic agonist isoproterenol, an effect which was competitively blocked by the β-adrenergic antagonist propranolol. While the potentiation of NE release elicited by activation of β-adrenergic receptors alone was modest, concomitant addition of IL-1 (30 ng/ml) greatly enhanced this effect. Conversely, IL-1 alone inhibited NE release, dependent upon the frequency of stimulation of the hippocampal slice, with a greater potency at increasing frequencies. Blockade of β-adrenergic receptors resulted in IL-1 enhancing, rather than inhibiting NE release. These results demonstrate that IL-1 modulates NE release in the brain, and that there is an interaction between this response and activation of β-adrenergic receptors. The dependence between pre-synaptic responsiveness to IL-1 and its interaction with the β-adrenergic receptors would be expected to have significant implications in the response of the CNS to immune/inflammatory states.

EFFECTS OF METABOLISM INHIBITION AND TISSUE INCUBATION PERIOD ON THE MODULATORY EFFECTS OF BRADYKININ ON NOREPINEPHRINE RELEASE IN MOUSE ATRIA

C. Chulak*, R. Couture and S. Foucart. Département de physiologie, Faculté de médecine, Univ. de Montréal, Montréal, Québec, Canada, H3C 3J7.

Effects of tissue incubation period and kininases I and II inhibition were examined on the modulation of norepinephrine (NE) release by bradykinin (BK) through B_1 and B_2 receptors. Mouse atria were incubated for 20 min with [^{3}H]-NE and then inserted into a suprafusion system where the radioactivity was washed out for 75 min. The experimental protocol consisted in a 60 min sampling period during which two electrical stimulations (2 ms pulses for 60 sec at 50 mA and 5 Hz) were given at 10 (S_1) and 45 min (S_2). The drugs were given 20 min before S_2 and their effects were assessed by the ratio S_2/S_1. The administration of BK (10 nM) did not change the stimulation-induced (S-I) release of NE after 75 min of washing. In contrast, pre-treatment with mergepta (1 μM), a kininase I inhibitor, enalaprilat (1 μM), a kininase II inhibitor, or increasing the washing period to 130 min significantly increased the S-I release of NE by BK. This facilitatory effect was abolished by a B_2 receptor antagonist, HOE 140 (100 nM). The B_1 agonist, des-Arg^9-BK (10 nM) did not affect the S-I release of NE after 75 min of washing but significantly inhibited it when co-administered with HOE 140. Following 130 min of washing, des-Arg^9-BK did not change the S-I release of NE either alone or in the presence of HOE 140. The results suggest that preventing BK degradation or increasing the period of tissue incubation favors the B_2 mediated facilitation of NE release and reduces the ability of des-Arg^9-BK to inhibit NE release. Thus, the temporal in vitro regulation of kinin receptors in mouse atrium sympathetic fibers may differ from other experimental models. Support by FCAR-FRSQ.

METABOTROPIC GLUTAMATE RECEPTORS MODULATE EXCITATORY TRANSMISSION IN THE RAT NUCLEUS ACCUMBENS

O. Manzoni, P. Mollard* and J. Bockaert
UPR 9023, Rue la Cardonille 34094 Montpellier Cedex 5 France

The effects of glutamate metabotropic receptors (mGluRs) on excitatory transmission in the nucleus accumbens (NAc) have been investigated using electrophysiological techniques in rat NAc slices. We found that the broad-spectrum agonist (1S,3R)-ACPD, the group 2 selective agonists L-CCGI and (S)-4C3HPG, as well as the group 3 specific agonist L-AP4 all reversibly inhibited evoked excitatory synaptic responses indicating the involvement of group 2 and 3 mGluRs. Group 2 and 3 mGluRs inhibited transmission via a presynaptic mechanism, as inhibition was accompanied with an increase of paired-pulse facilitation. Dose-response curves showed that the rank order of agonist potencies was: L-CCG1>L-AP4>(1S,SR)-ACPD with EC50 values of 0.8 ± 0.2 μM (n=4), 5.3 ± 2.8 μM (n=3) and 25 ± 7,7 μM (n=3), respectively. We found (R,S)-3,5-dihydroxy- -phenylglycine ((R,S)-DHPG) inefficacious to depress transmission arguing against an inhibitory presynaptic function for group 1 mGluRs at these synapses. However, current clamp recordings have shown that (R,S)-DHPG blocked postsynaptic Iahp whereas group 2/3 agonists were without effect. The inhibitory actions of mGluRs action were not affected by dopamine antagonists of both D1- and D2-subtypes. Our results represent the first direct demonstration of functional mGluRs in the rat NAc. Both group 2 and 3 mGluRs can presynaptically modulate excitatory synapses whereas postsynaptic group 1 mGluRs may regulate neuronal excitability.

INHIBITION BY 2,4-DITHIOBIURET OF STIMULUS-INDUCED ENHANCEMENT OF ACh RELEASE AT RAT NEUROMUSCULAR JUNCTIONS.

Y. F. Xu* and W. D. Atchison. Dept. Pharmacol. Toxicol., & Neurosci. Program., Mich. State Univ., E. Lansing, MI 48824

Neuromuscular weakness caused by 2,4 dithiobiuret (DTB) is associated with a decreased release of ACh from motor nerve terminals. Neurochemical studies in PC12 cells suggested that DTB disrupts the mobilization of ACh vesicles. To gain further insight into the mode of action of DTB, the effects of Ba^{2+}, Sr^{2+} and Ca^{2+} on frequency-dependent stimulus-induced enhancement of transmitter release were studied at end-plates of DTB-treated (1 mg/kg/day, 6 days, i.p.) and untreated *extensor digitorum longus* muscles of the rat. The magnitude of augmentation and potentiation of MEPP frequency and EPP amplitude in DTB-treated rats was decreased in Ca^{2+}-free, Ba^{2+} solution, while decay for these components in DTB-treated preparations was more rapid. The decay process for facilitation of MEPPs and EPPs of DTB-treated preparations was almost absent. Similar results occurred in Ca^{2+}-free, Sr^{2+} solution. The magnitude as well as the time constant of decay for augmentation and the second facilitation of MEPP frequency were significantly decreased and the first component of facilitation of MEPP frequency was absent in DTB-treated rats. In Ca^{2+}-containing solutions, enhancement of MEPP frequency cannot be evoked by repetitive stimulation at most endplates of DTB-treated rats. At 20% of the endplates from DTB-treated preparations, there was a pronounced decreased in the augmentation of MEPP frequency. Frequency augmentation-facilitation has been shown to be a reliable tool for determining frequency-dependent mobilization of ACh. Decreases in ACh release in DTB-treated muscles occurred for each rate of stimulation tested in Ba^{2+}-containing solutions. Thus frequency-dependent facilitation, augmentation and potentiation reflecting the multiple steps of transmitter mobilization and of Ca^{2+}-dependent and -independent ACh release are all impaired by DTB.

NICOTINIC PRE- AND POST-SYNAPTIC EFFECTS IN DORSAL RAPHE NUCLEUS.

X.Y. Li, D.G. Rainnie, R.W. McCarley and R.W. Greene*. Harvard Medical School & VAMC Brockton, Brockton MA.

Dorsal raphe is the major source of 5-HT in central nervous system (CNS) and the neurons in this nucleus project to a majority of brain areas. Acetylcholine and nicotine have significant effects on CNS function through the nicotinic receptor. Previous reports indicated that dorsal raphe nucleus contains nicotinic receptors and choline acetyl transferase, however, the electrophysiological effects of nicotine in dorsal raphe nucleus have not been evaluated. We employed whole cell patch-clamp technique to record the response of the serotonergic neurons to nicotine agonist, 1,1-dimethyl-4-phenylpiperazinium iodide (DMPP). For this purpose, dorsal raphe slices were obtained from 17 to 25-day hooded rats of either sex as previously reported. The neurons were held at -60 mV in either current- or voltage-clamp. 51 out of 84 neurons that were hyperpolarized by 5- 40 μM 5-HT also responded to 1 to 30 μM DMPP. In the absence of TTX, DMPP usually elicited 3-7 mV depolarization with reduced input resistance. In the presence of TTX or lower calcium (0.1μM and high magnesium (10 millimolar) or alpha 1 antagonist prazosin, DMPP elicited hyperpolarization varying from -63 to -70 mV. In the voltage clamp mode, the DMPP-induced outward current was blocked by 100 micromlar barium but not 1 mM cesium or lower calcium and high magnesium; each reversal potential for the DMPP-induced current was near potassium equilibrium potential at extracelluar potassium concentration ranging from 2 to 12.5 mM. In conclusion, nicotinic activation exerts an excitatory presynaptic effect through the enhancement of alpha 1 receptor function and in addition, can directly inhibit postsynaptic neurons through increase in the inward potassium rectifier conductance.

STIMULATORY EFFECT OF VX ON EXCITATORY SYNAPSES OF CULTURED HIPPOCAMPAL NEURONS.

E.S. Rocha*, M. Alkondon, K.L. Swanson and E.X. Albuquerque. Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

The organophosphate (OP) VX produces a large increase in transmitter release at neuromuscular junctions by a presynaptic mechanism not related to cholinesterase inhibition (*J. Pharmacol. Exp. Ther.* **87**:337, 1987). To evaluate the effect of this agent in the CNS, we used the patch-clamp technique to record from cultured hippocampal neurons, excitatory spontaneous miniature postsynaptic current (MPSCs) in the presence of 150 nM tetrodotoxin (TTX), and multiquantal postsynaptic currents (EPSCs) in the absence of TTX. The frequency of MPSCs was unaffected by a 5-min perfusion of the neurons with external solution containing the OP soman even at the high concentration of 2 μM, but it was increased 2-fold and 6-fold by subsequent application to the neurons of VX 10 nM and 100 nM, respectively. The increase in the frequency of MPSCs was observed 1-2 min after exposure of the neurons to 10 nM VX, and it was obtained in the presence of the muscarinic receptor antagonist atropine (1 μM). This stimulation was not reversed after 30 min of washout, and since the cholinesterase inhibitor soman or nicotinic agonists had no stimulatory effect, we concluded that this effect was not related to cholinesterase inhibition or modulation of nicotinic receptors. Removal of Ca^{2+} from the bath significantly reduced the effect of VX on frequency of MPSCs, indicating that extracellular Ca^{2+} is important for mediating the effect of VX. In the absence of TTX, the increase in the frequency of MPSCs was followed by an increase in the frequency of EPSCs, indicating that increases in the firing rate during VX exposure may be secondary to the increase in the spontaneous transmitter release. The high synaptic activity or burst-like spikes triggered by VX are important for the convulsive effect induced by acute intoxication with this OP. *(US Army Med. Res. Dev. Command Contr. DAMD17-95-C-5063).*

EFFECTS OF ALDICARB ON NEUROTRANSMITTER RELEASE AND NEURONAL EXCITABILITY.

S.R. Chebabo[2]*, O.V. Souza[1], M.F.M. Braga[1], Y. Aracava[1,2] and E.X. Albuquerque[1,2]. [1]Lab. Mol. Pharmacol., IBCCF; Dept. Pharmacol., UFRJ, Rio de Janeiro, RJ 21944, Brazil; Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201, USA.

Aldicarb (Ald) is a pesticide, whose primary action is cholinesterase (ChE) inhibition. Previously we demonstrated that Ald interacts with the muscle nicotinic receptor (*Soc. Neurosci. Abs.* **21**:432.1, 1995). In this study, we evaluated the effects of Ald on acetylcholine (ACh) release and neuronal excitability in the neuromuscular transmission of frog (*Leptodactyllus occelata)* and in rat hippocampal slices. In a concentration-dependent fashion, Ald (1-300 μM) increased the amplitude and prolonged the decay time constants of evoked and spontaneous end-plate potentials recorded intracellularly from sciatic-nerve sartorius muscle preparation. These effects could not be fully explained by the anti-ChE activity of Ald, because maximal ChE inhibition was achieved at 10 μM. In addition, 30 μM of Ald induced a 70% augmentation of evoked ACh release and at higher concentrations (100-300 μM) a 10% reduction was observed. To investigate whether these presynaptic effects of Ald (30-300 μM) could be attributed to changes in ion channel activity at the motor nerve terminal, perineural waveforms were recorded from frog cutaneous pectoris preparations. Ald (10-30 μM) induced repetitive nerve terminal action potentials and at 100-300 μM decreased the first negative deflection of the perineural waveform that is related to Na^+ activity. These effects could account for the changes in ACh release produced by Ald. In rat hippocampal slices Ald (1-30 μM) increased the amplitude of evoked excitatory post-synaptic potentials recorded extracellularly and induced spontaneous activity, however, at higher concentration (100-300 μM) a reduction in the amplitude was observed. In conclusion, our results indicate that Ald induces changes in transmitter release and neuronal excitability that can contribute to its toxicity in the peripheral and central nervous system. *(Support:* FINEP/ UMAB, FINEP and CNPq).

PARAOXON INCREASES TRANSMITTER RELEASE AT SYNAPSES OF EXCITATORY AND INHIBITORY AMINO ACID RECEPTORS. W.M. Cintra*[2], E.S. Rocha[1,2], K.L. Swanson[1], H.R. Santos[2], J. Goolsby[1], Y. Aracava[2], E.X. Albuquerque[1,2]. [1]Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201; [2]Lab. Mol. Pharmacol., IBCCF, UFRJ, Rio de Janeiro, 21944, Brazil.

Paraoxon (300 nM) increases the release of GABA from cultured hippocampal neurons by a local presynaptic mechanism (*Soc. Neurosci. Abs.* **21**:1093, 1995). The effects of paraoxon on hippocampal neurons were studied further using the whole-cell patch-clamp technique to examine synaptic function during acute exposure and using dye-injection techniques to examine morphology after subchronic exposure. Miniature postsynaptic currents (MPSCs) in the presence of tetrodotoxin (0.3 μM) and atropine (1 μM) were recorded for 5-10 min in the absence and then in the presence of paraoxon. Paraoxon (3 μM) stimulated reversibly the release of transmitters, increasing the frequency of GABA-mediated MPSCs to a maximum of 265% of the control frequency. Above 3 μM, the facilitatory effect of paraoxon was counteracted by a direct blockade of $GABA_A$ receptors. The frequency of glutamate-mediated MPSCs was also increased by application of paraoxon, but no inhibition of postsynaptic AMPA receptor-mediated MPSCs was observed. Since neither the cholinesterase inhibitor soman nor nicotinic agonists increased MPSC frequency, we suggest that paraoxon's stimulatory effect on transmitter release (in the presence of atropine) was unrelated to cholinesterase inhibition or to modulation of nicotinic or muscarinic receptors. Paraoxon (100-1000 μM) reversibly inhibited the activation of postsynaptic currents induced by applications to the neurons of 2- to 10-sec pulses of GABA, glycine, NMDA or nicotinic agonists. These inhibitory effects were voltage and concentration dependent, suggesting that the ion channels of these receptors were blocked in the open state. In contrast, paraoxon had no effect on kainate- and AMPA-activated currents. The facilitation of transmitter release and the inhibition of postsynaptic receptors by paraoxon may be relevant to the acute toxicity of this cholinesterase inhibitor. In morphology studies, subchronic exposure *in vivo* to paraoxon (75 μg/kg, s.c.) of postnatal rats (P8-P20), during the period of synaptogenesis of the developing hippocampus, resulted in 30-40% inhibition of brain cholinesterase. No differences were observed in the pattern of the dendritic branching or spine density on apical or basal dendrites of Lucifer Yellow-filled pyramidal neurons in the CA1 area. Thus, no alteration on the hippocampal spine apparatus was apparent, in contrast to studies showing that many cholinesterase inhibitors can affect pre- and postjunctional morphology (*Toxicol. Appl. Pharmacol.* **97**:98, 1989; *Synapse* **2**:139, 1988). On the other hand, presynaptic (noncholinergic) mechanisms are strongly implicated in acute toxicity of paraoxon. *(USPHS Grants NS25296, ES05730; U.S. Army Med. Res. & Devel. Command Contr.DAMD17-95C-5063; FINEP/CNPq-Brazil)*

686.14

ENHANCEMENT OF WHOLE-CELL SYNAPTIC CURRENTS BY LOW OSMOLARITY AND LOW $[NaCl]_o$ IN RAT HIPPOCAMPAL NEURONS. R. Huang, D.F. Bossut, D.V. Lewis* and G.G. Somjen. Dpts of Cell Biology, Neurobiology and Pediatrics, Duke Univ. Med. Center, Durham, NC 27710

The effect of hypotonia of extracellular fluid on synaptic transmission is controversial. We recorded whole-cell currents of pyramidal neurons in CA1 of hippocampal slices. Stimulation in st. radiatum evoked synaptic currents with holding potential set at varying voltages. Extracellular osmolarity (π_o) was lowered by deleting NaCl from the bathing fluid. Low π_o caused a concentration-dependent, reversible increase of excitatory postsynaptic currents (EPSCs) (to 190% of control at 230 mosm/l) and in many cases also of IPSCs. Isosmotic (fructose-substituted) low $[NaCl]_o$ solution caused a similar but more moderate (145%) increase of EPSCs. Low π_o caused a slowing of the decay of the capacitive charging current. Input resistance did not show consistent changes. Virtual input capacitance (time constant divided by input resistance) increased reversibly to 134% of control indicating cell swelling during low π_o (230 mosm/l), but did not change during isosmotic low $[NaCl]_o$ superfusion. The increase of EPSCs recorded in low π_o from the cell soma may in part be due to the swelling of dendrites. Additionally, presynaptic and/or postsynaptic calcium uptake (Chebabo et al., J.Physiol. 487: 685-697, 1995) probably facilitated synaptic transmission during both isosmotic and hypotonic lowering of $[NaCl]_o$.

EFFECTS OF NUCLEOTIDES ON EXOCYTOSIS AND ENDOCYTOSIS DURING SUSTAINED STIMULATION OF ADRENAL CHROMAFFIN CELLS J. K. Angleson, and W. J. Betz* Department of Physiology, University of Colorado Medical School, Denver, CO 80262.

Exocytosis and endocytosis were monitored simultaneously in isolated bovine adrenal chromaffin cells by combination of fluorescence microscopy of FM1-43 stained membrane and whole cell patch clamp recordings of membrane capacitance (Smith and Betz, Nature 380:531, 1996). When voltage clamped cells bathed in 4 μM FM1-43 were dialyzed with solution containing 2 mM Mg-ATP, 0.5 mM GTP and 50 μM free Ca^{2+} the cell capacitance and cell size gradually increased in parallel to approximately 130% of control before reaching a plateau while cell fluorescence increased at a constant rate throughout the recordings. This reflects the onset of endocytosis to a rate equal to that of exocytosis. Similar results were obtained when cells were stimulated by dialysis of 1 mM Ba^{2+} instead of Ca^{2+}. Cells dialyzed with 50 μM free Ca^{2+} and no added nucleotides initially displayed increases in cell capacitance, size, and fluorescence that all reached a plateau at the same time suggesting that exocytosis and endocytosis were absent after depletion of nucleotides. When cells were dialyzed with 50 μM free Ca^{2+}, 2 mM Mg-ATP and 0.5 mM GTPγS (instead of GTP) cell capacitance and fluorescence increased in parallel up to 130% of control while cell size did not significantly change. This suggests that GTP hydrolysis is required for either full collapse of secretory granules into the plasma membrane or that it is required for complete fission of endocytosed granules.

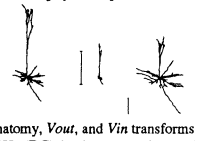
POSTSYNAPTIC MECHANISMS: NETWORK ACTIVITY AND MODELS

687.1

THE ELECTROTONIC WORKBENCH. N.T.Carnevale*[1,2], K.Y.Tsai[3], and M.L.Hines[1,4], Neuroengineering and Neuroscience Center[1] and Departments of Psychology[2] and Computer Science[4], Yale University, New Haven, CT, and Harvard Medical School[3], Boston, MA.

The *Electrotonic Workbench* is a new set of software tools for analyzing neuronal electrotonic architecture. Created using the simulation program NEURON [Hines 1989, 1993], these tools run on workstations and PCs under Xwindows or MS-Windows (3.1, NT, 95), and do not require the purchase of commercial software. They implement the *electrotonic transformation*, which we and our collaborators have used to study electrical signaling in neurons [Brown et al. 1992; Carnevale et al. 1995a, b; Tsai et al. 1994; Zador et al. 1995]. Computations and graphical renderings are all handled in an integrated fashion, so results are immediately available and there is no need to move intermediate data files between different programs. All operations are customizable, and the user can automate a series of analyses that iterate over a range of frequencies, biophysical parameters, and anatomical dimensions.

The *Electrotonic Workbench* is a practical and convenient way to examine the functional consequences of neuronal anatomy and biophysics. It computes the logarithm of voltage attenuation along each branch of the cell for signals propagating away from (*Vout*) and toward (*Vin*) a user-selected reference point. Graphical renderings of the transforms are generated in either the "*neuromorphic*" (shown here) [Carnevale et al. 1995a] or "*L vs. x*" [O'Boyle et al. *in press*] format. These *Vout and Vin transform pairs* provide a complete picture of the electrotonic architecture of the cell.



Anatomy, *Vout*, and *Vin* transforms at 0Hz (DC) (scale bars = 1 log unit)

BEYOND THE SPONTANEOUS ACTIVITY - THE APPLICATION OF STOCHASTIC MODEL IN NEOCORTICAL CELL. P. Maršálek and C. Koch*, Div. of Biol.,California Institute of Technology 139-74, Pasadena, CA 91125.

It has frequently been observed that the rise time of firing rates in cortical cells responding to visual stimuli remains equally sharp at different stages of processing. Furthermore, single units in several cortical regions of monkeys appear to fire as members of a so-called synfire chains, in which individual units show a strong time modulation of firing with very small temporal jitter (on the order of 1 *msec*). This raises the question how cortical cells respond to temporal jitter in their synaptic input.

We here use analytical tools (derivation of the first passage time to threshold for simplified model) and numerical tools (numerical solving cable equation with active elements in detailed model using NEURON). We analyze the precise relationship between the standard deviation in time of excitatory and inhibitory synaptic input (input jitter) and the variability in the spike output timing (output jitter) in leaky integrate-and-fire units as well as in a biophysical and anatomical detailed model of a layer 5 pyramidal cell. In all cases, we find a linear relatinoship between input and output jitter, with a slope of less than 0.35. That is, the output jitter will always be less than the input jitter. We conclude that in networks of such spiking cells, the temporal jitter in spiking times will converge to a small fixpoint. (Supported by the Natinal Institute for Mental Health through the center for "Cell & Molecular Signalling" and by a NIMH grant.)

MCELL: GENERALIZED MONTE CARLO COMPUTER SIMULATION OF SYNAPTIC TRANSMISSION AND CHEMICAL SIGNALING. T.M. Bartol Jr.*, J.R. Stiles, M.M. Salpeter, E.E. Salpeter, and T.J. Sejnowski.
Computational Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92037, and Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853-2702.

We have developed MCELL, a software tool for 3D Monte Carlo simulation of ligand diffusion and chemical signaling, focusing on neurotransmitter release and quantal current generation at a peripheral (Bartol et al., 1991, Biophys. J. 59:1290; Anglister et al., 1994, Neuron 12:783; Stiles et al., 1996, PNAS, in press) and central synapse (Bartol et al., 1993, Soc. Neurosci. Abst. 19:1515). MCELL's generality has been expanded to allow simulation of multiple ligand and receptor classes, along with complex 3D arrangements of diffusion boundaries representing multiple cell or organelle membranes. Simulations are designed using a Model Description Language to define ligands and other molecular constituents (e.g. receptors, enzymes, uptake sites), the arrangement of boundaries, the timing of ligand release, and additional parameters. Thus, many processes in addition to synaptic transmission can now be modeled. We plan to make MCELL available to other investigators, and will present here its overall design, capabilities, system requirements, and planned future features. Tutorial simulations designed to highlight MCELL's use will be presented: (1) Random walk model of ligand diffusion, with net flux(es) in 1, 2, or 3 dimensions. (2) Subcellular structures defined by diffusion boundaries. (3) Ligand diffusion and chemical reaction (e.g. receptor binding and activation, enzymatic hydrolysis) within structures, for single or multiple classes of ligand and receptor. (4) Neurotransmitter release from a synaptic vesicle with changing fusion pore dimensions. (5) Quantal and multi-quantal synaptic current generation. Supported by NIH K08NS01776 (JRS), NS09315 (MMS), and The Howard Hughes Medical Institute (TJS).

TRANSMITTER CONCENTRATION PROFILES IN THE SYNAPTIC CLEFT J. Kleinle, K. Vogt & J. Streit*
Physiologisches Institut, Buehlplatz 5, 3012 Bern, Switzerland

It has recently been observed that EPSCs from one synaptic terminal show a broad amplitude distribution [Bekkers et al., PNAS '90], [Liu & Tsien, Nature '95], [Vogt et al., Pflueg. Arch. '95]. Experiments with competitive antagonists and variance analysis of mEPSCs suggest a saturation of the involved receptors [Clements et al., Science,'92], [Tong & Jahr, Neuron '94], [Vogt '95]. As a possible explanation for these conflicting results we tested the hypothesis of a clustered substructure of the postsynaptic receptors opposite single boutons by using a diffusion model. The diffusion equation in three dimensions was solved using a source function for a continuous alpha-shaped release [Bruns &Jahn, Nature '95]. We found that the release function is critical in determining the time course of the transmitter concentration at the postsynaptic side. Accordance with transmitter concentration profiles as reported in [Clements '92] was only observed if the diffusion coefficient for glutamate is an order of magnitude lower than in aqueous solution. Under such conditions the transmitter is sharply concentrated opposite the site of release. From the transmitter concentration profiles at the postsynaptic side postsynaptic currents were modeled using AMPA receptor kinetics. Under conditions where the model currents best fitted the time course and the dose response curve of excitatory synaptic currents in spinal neurons, crosstalk between patches of receptors more distant than $300nm$ was shown to be minimal. From these findings we suggest that several independent functional units could exist within one synaptic terminal even in the absence of specific diffusion barriers.

687.5

A METHOD FOR DETERMINING THE TIME COURSE OF THE SYNAPTIC CONDUCTANCE UNDER CONDITIONS OF INADEQUATE SPACE CLAMP

Michael Häusser* & Arnd Roth. Laboratoire de Neurobiologie, Ecole Normale Supérieure, Paris, France; Abteilung Zellphysiologie, Max-Planck-Institut für medizinische Forschung, Heidelberg, Germany.

Many neurons have extensive dendritic trees, and therefore somatic "voltage clamp" of distal synapses is associated with substantial distortion of the synaptic currents. We introduce a novel method which allows for faithful extraction of the decay time course of the synaptic conductance independent of dendritic geometry and the electrotonic location of the synapse. The method is based on the experimental procedure of Pearce (Neuron 10: 189, 1993), consisting of a series of voltage jumps at various times during the synaptic conductance. The synaptic charge associated with each jump is determined, and the time course of the recovered charge is then fitted with one or more exponentials. The relative amplitude of multiple exponentials is best estimated by fitting the differentiated charge recovery.

The method was tested with simulations using simple "ball-and-stick" cable models as well as detailed compartmental models of pyramidal and Purkinje cells. The method was successful in all the tested geometries, even with high access resistances, leaky cells, and the most distal synapses: the decay time course of the synaptic conductance could be recovered to within a few percent. We have used the method to demonstrate that the climbing fibre and compound parallel fibre synaptic currents in Purkinje cells have a prominent slow component.

PERIRHINAL-AMYGDALA NEURAL NETWORK MODEL OF TEMPORAL ENCODING IN FEAR CONDITIONING. K. H. Tieu, B. Faulkner, and T. H. Brown*. Depts. of Psychology and Cellular and Molecular Physiology, Yale University, New Haven, CT 06250.

In fear conditioning, animals not only associate the conditioned stimulus (CS) and unconditioned stimulus (US), but also learn about the CS-US interval, which can be several seconds or longer. Explanations for encoding such long durations—such as endogenous clocks or huge numbers of reverberations around long polysynaptic circuits—suffer on empirical and/or theoretical grounds.

We have developed an hypothesis that offers an explanation based on observations (see Faulkner and Brown, *Neurosci. Abstr.*, 1996; Moyer and Brown, *Neurosci. Abstr.*, 1996) of the physiology and morphology of neurons in the rat perirhinal cortex (PR) and the lateral amygdala nucleus (LA). Here we begin to formalize the hypothesis in terms of a dynamic neural network model. The model's neurons, designed to capture key aspects of the observed input-output relationships, are of three general types: fast-firing, delayed- firing, and regular-firing. The latter vary widely in accommodation. The CS is represented by activity in PR layer I afferents, which make connections with specific cell types in layers I, II/III, and V. Projections to LA are from layers V and VI.

The CS generates a restricted activity window in LA at various delays from the CS onset—from several milliseconds to several seconds. The duration of the delays and activity windows depend on the particular cells in the pathway. We assume that a Hebbian synaptic modification can occur in LA when CS-generated input to a cell coincides with US-generated activity to the same neuron. After conditioning, the CS causes an enhanced response only in those LA neurons whose original activity was appropriately timed relative to the US. CS-produced activity in LA causes appropriately-timed output from the central nucleus of the amygdala, resulting in conditioned fear.

SYNAPTIC CURRENTS EVOKED IN LAYER V PERIRHINAL CORTEX. J. R. Moyer, Jr.* and T. H. Brown, Departments of Psychology and Cellular & Molecular Biology, Yale University, New Haven, CT 06520.

The perirhinal cortex (PR) and lateral nucleus of the amygdala seem importantly involved in aversive conditioning. We have been interested in understanding at a cellular level how information is processed within and between these brain regions. As part of this effort, we have been characterizing aspects of the cellular physiology and morphology (see Faulkner and Brown, *Neurosci. Abstr.*, 1996) that seem relevant to a theoretical understanding of circuit-level computations (see Tieu et al., *Neurosci. Abstr.*, 1996).

During aversive conditioning, some of the information concerning the conditioned stimulus presumably enters PR via afferents in layer I. We have therefore been studying synaptic transmission between layer I and other layers of PR. Here we examine synaptic transmission from layer I to layer V. Using horizontal rat brain slices, whole-cell recordings were made from PR layer V neurons under direct visual control using infrared, differential-interference-contrast, video microscopy. Synaptic responses were evoked by passing brief current pulses through a bipolar stimulating electrode positioned in layer I. Using minimal stimulation, we attempted to evoke unitary synaptic currents, which were then compared with spontaneous synaptic currents in the same cell. Spontaneous and evoked currents were examined at several holding potentials. The active and passive properties of the cells were also examined.

Results from 5 experiments revealed relatively small (usually 30 - 70 pA) evoked currents in layer V and even smaller spontaneous currents (commonly 5 - 30 pA). The synaptically-evoked currents often had latencies as long as 4 to 7 ms, with very little variability. All of these spontaneous and evoked currents are would be unobservable using conventional intracellular recording techniques.
Supported by grants from the Office of Naval Research (THB) and the National Institutes of Health (THB & JRM).

SPATIAL ORGANIZATION AND DIVERSITY OF NEURONS IN THE RAT PERIRHINAL — LATERAL AMYGDALA REGION. B. Faulkner*, and T. H. Brown. Depts. of Psychology and Cellular and Molecular Physiology, Yale University, New Haven, CT 06250.

Perirhinal cortex (PR) and lateral amygdala (LA) seem critically involved in aversive conditioning. To understand how information is processed and stored in this region, we need to elucidate neuronal structure-function relationships and local circuitry. Such data are being acquired using whole-cell recording techniques combined with video microscopy, which allows visual preselection of neurons. After recording, biocytin-filled cells and their axons are reconstructed using a camera lucida.

PR layer I contains sparsely-distributed fast-firing neurons, presumed to be inhibitory, with processes contained within the layer. Fast-firing cells occur throughout PR and LA. Regular-firing and delayed-firing neurons in layers II/III are relatively small pyramids whose apical dendrites extend to the edge of cortex. Their axons collateralize throughout PR, but are most extensive within II/III. Layer Va contains large pyramids, either regular-firing or burst-firing, whose dendrites extend through layer I and whose primary axon travels in the external capsule. In contrast, large pyramids in Vb often have bifurcating apicals that do not extend beyond V and primary axons that cross the external capsule and project across LA. Layer VI is replete with horizontally-elongate delayed-firing cells and regular-firing stellates. LA contains all of the physiological heterogeneity seen in PR as well as cells that exhibit extreme accommodation, being very resistant to spiking more than once or twice to a long current step.

The spatial organization and physiological diversity of PR-LA neurons have functional implications for the temporal associations formed by pairing a neutral conditioned stimulus (CS) with an aversive unconditioned stimulus (US) (see Tieu et al, *Neurosci. Abstr.*, 1996).

A ROLE FOR $GABA_B$-DEPENDENT MECHANISMS IN TEMPORAL PROCESSING: EXPERIMENTAL AND COMPUTATIONAL STUDIES. D. Buonomano*, P. Hickmott, M. Merzenich. Keck Center, UCSF, San Francisco, CA 94143.

The role of $GABA_B$-dependent mechanisms in information processing is not well understood. Two well described $GABA_B$-mediated processes are slow IPSPs and paired-pulse depression of fast IPSPs (PPD). Both of these mechanisms operate on the time-scale of a few hundred milliseconds and in general peak between 150 and 250 ms. We propose that one of the computational roles of $GABA_B$-mediated events is to process temporal information by altering the state of a network in a time- and history-dependent manner. Using intracellular recordings from hippocampal slices, we examined the responses of CA3 pyramidal neurons to paired-pulse stimulation of the dentate gyrus (DG). Paired pulses were delivered with interpulse intervals (IPIs) of 50, 100 and 200 ms. Depending on the cell, either depression or facilitation of the second EPSP ($EPSP_2$) was observed, although at 50 ms facilitation was more common, and at 200 ms depression was predominant. Application of the $GABA_B$ antagonist CGP-55845 (1 μM) produced a dramatic decrease in the amplitude of the slow IPSP, and narrowing of the EPSP width, reflecting the decrease in PPD of the fast IPSP. On average, CGP-55845 tended to equalize the amplitude of all EPSPs. In essence CGP-55845 erased information regarding the occurrence the first spike. To analyze the average data, we measured the difference in the maximal amplitude of $EPSP_2$ and $EPSP_1$ (ΔEPSP). CGP-55845 did not produce significant changes in the amplitude of first pulse or on ΔEPSP at 50 ms pulse. By contrast, CGP-55845 produced significant changes in ΔEPSP of the 100 and 200 ms IPI. In the control condition there were significant differences between the amplitude of ΔEPSP at the three different intervals, while in the presence of CGP-55845 the ΔEPSP function was flat over the three IPIs. Computer simulations of disynaptic circuits that incorporated slow IPSPs and PPD were then used to demonstrate that - depending on the balance of excitatory and inhibitory synaptic weights - interval-selective neurons can be generated and that $GABA_B$-dependent events are critical for this processes. The Pattern of Afferent Input to the Apical Dendrites of Layer V-VI Prefrontal Cortical Neurons Influences the Immediate and Prolonged Amplification of Synaptic Signals by High Threshold Ca^{2+} Spikes. J.K.Seamans*, N. Gorelova, & C.R. Yang. Dept. of Psychology, & Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1Z4, Canada.

Dendro-somatic signal-integration by layer V-VI cortical neurons can be problematic since the apical dendrites receive >10,000 synaptic inputs while unitary EPSPs generated in the apical dendrites are strongly attenuated enroute to the soma by the cell's passive membrane properties. Although active ionic potentials in the dendrites such as high threshold Ca^{2+} spike(s)(HTS) are thought to amplify EPSPs and aid in the transmission of signals from the dendrites to soma, it is unclear as to what factors determine which inputs are amplified. The present study suggests that the afferent input pattern may be one important factor. Layer V-VI prefrontal cortex (PFC) neurons were recorded from the soma using micropipettes containing QX-314 and Cs^+, or from the apical dendrites using patch pipettes containing QX-314. During brief repetitive single pulse synaptic stimulation (2-10Hz, 15-30s) of layers I-II, mimicking the input provided by regular spiking cortical neurons, suprathreshold responses (composite EPSP + regenerative HTS) recorded from both sites were transformed to small EPSPs. This synaptic depression (SD) outlasted the period of stimulation by ≈20s, was frequency-dependent, input specific and affected by alterations of $[Ca^{2+}]_o$, suggesting that it was due primarily to reductions in transmitter release. Long-term changes in release may have also occurred because greater SD was observed on subsequent repetitive stimulation trials despite full recovery of the suprathreshold response prior to each trial (2 min intertrial interval). By contrast, burst-patterned stimulation (1-10pulses/100Hz) resulted in summation of EPSPs and the generation of suprathreshold responses. Burst trains (4 pulse/100Hz burst, delivered at 1 Hz for 15 s) led to long-lasting synaptic potentiation which transformed small EPSPs into suprathreshold responses for up to 1hr. These results suggest that the firing pattern of the pre-synaptic neuron influences whether synaptic signals remain within local regions of the dendrites, or evoke dendritic HTS which aid in the active transmission of signals to the soma.

ANALYSIS OF INTERACTIONS BETWEEN MULTI-STATE RECEPTORS AND CONTINUOUS SIGNALS IN A MODEL OF SYNAPTIC TRANSMISSION. V. Uteshev and P. Pennefather*, Dept. of Physiology & Fac. of Pharmacy, Univ. of Toronto, Toronto, M5S 2S2.

We have developed a novel computational approach to drive n-state kinetic systems defining receptor sensitivity to a neurotransmitter signal, with a series of phases each having a specific intensity and duration chosen so that the train of steps approximates the expected time course of the intrasynaptic neurotransmitter signal produced by the quantal release from a single synaptic vesicle. This time course was predicted using published dimensions of glutamatergic synapses between CNS neurons and equations describing 2-D diffusion from an exponential source (expected for release through a fusion pore) in a plane sheet. The kinetic schemes were obtained from the literature on the responses of CNS neurons to step changes in glutamate concentration. We first determined the response to the quantal signal of single receptors at different displacements from the point of release. Then we considered the response of a postsynaptic receptor cluster (PRC) with specific shapes and densities. The analysis suggests that the morphology and receptor properties observed at CNS synapses are near optimal for synaptic function.

INTEGRATION OF SYNAPTIC POTENTIALS IN ELECTRICALLY COUPLED NEURONS. F. Fernández-de-Miguel*. Departamento de Neurociencias, Instituto de Fisiología Celular, UNAM. Apartado Postal 70-253, 04510, D.F., México

Integration of excitatory synaptic potentials has been studied in electrically coupled neurons. Retzius neurons in the leech *Haementeria officionalis* are coupled by a non-rectifying electrical synapse. In addition, excitatory synaptic potentials (EPSPs) appear synchronously in both neurons although with varying amplitudes. Eventual EPSP failures occurred in any of the neurons. If an EPSP failed in one neuron, the corresponding EPSP from the other neuron spread to the first, arriving to the soma attenuated in amplitude and time course. Local and propagated EPSPs summated to produce action potentials which initiated at the primary process. The influence of coupling resistance and cable properties in spreading of EPSPs from one neuron to the other was analyzed through the delay and the coupling ratio between somas. The spread of EPSPs upon failure in one neuron was compared to the spread of artificial excitatory potentials produced by current injection into the soma of one neuron. The coupling ratio for EPSPs was 0.5 ± 0.04 (S.E.), and the EPSP arrived to both somas at the same time. In contrast, artificial excitatory potentials had a coupling ratio of 0.31 ± 0.01 and arrived to the opposite soma after 16 msec. This data suggest that EPSPs are produced in the vicinity of gap junctions and that 85% of the decay of EPSPs from one neuron to the other is due to the coupling resistance while the remaining 15% is due to cable properties.

Characterisation of Ca^{2+} currents in heart interneurons and their contributions to graded and spike mediated inhibition in leech *Hirudo medicinalis*. **J. Lu, J. F. Dalton IV and R. L. Calabrese*. Biology Department, Emory University, 1510 Clifton Rd. Atlanta, GA 30322**

Each pair of reciprocally inhibitory heart interneurons (HN) in ganglia 3 and 4 from leech *Hirudo medicinalis* plays an essential role in forming the beat timing oscillator for heartbeat in the leech. Ca^{2+} currents are critical in determining this reciprocal synaptic inhibition. Using single electrode voltage clamp, we previously characterised a low-threshold Ca^{2+} current, activating around -60 mV and exhibiting a fast inactivation time constant (~60 msec at -37.5 mV) and a slower inactivation time constant. The fast component of the low threshold Ca^{2+} current shows Ca^{2+}-dependent inactivation. 5 mM Ba^{2+} solution (replacing equimolar Ca^{2+} in the bath) substantially increases the inactivation time constant (~150 msec at -37.5 mV). Further, the inactivation time constant of the Ca^{2+} current is also greatly increased by using 200 mM BAPTA in electrodes (~500 msec at -37.5 mV). In addition, we characterised another type of Ca^{2+} current (high threshold) by using 37.5 mM Ba^{2+} solution. Ca^{2+} channel blocking agents, such as calciludine (up to 1 μM), ω-conotoxin (up to 2 μM), nitrendipine (up to 40 μM), nifedipine (100 μM) and amiloride (1 mM) applied in the bath fail to block these high and low threshold Ba^{2+} currents. But the 1 mM Zn^{2+} eliminate both Ba^{2+} currents. Cd^{2+} (100 μM) and Ni^{2+} (200 μM) selectively block the high threshold Ba^{2+} current. Recordings of a pair of HN cells bathed in 0-Na^+ show that the grade synaptic transmission between the pair remains unaffected with presence of 100 μM Cd^{2+} in the bath. In normal saline, addition of 150 μM Cd^{2+} eliminates the spike-mediated synaptic inhibition and doesn't affect the graded synaptic inhibition between a pair of HN cells, which suggests that the high threshold, long lasting Ca^{2+} currents is responsible for the spike-mediated synaptic inhibition in reciprocally inhibitory HN cells. VOLTAGE CLAMP RECORDINGS OF CALCIUM CURRENT IN PRESYNAPTIC TERMINALS OF SPINAL NEURONS FROM *XENOPUS* Christopher Thaler, Anatoly Shcherbatko and Paul Brehm*
Department of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, NY 11794

We have turned to the study of synapses between *Xenopus* spinal neurons and skeletal muscle in order to examine the role of individual presynaptic calcium channel types in mediating transmitter release. Dissociated embryonic spinal neurons form functional synapses with *Xenopus* myotomal muscle and the terminals are amenable to whole-cell perforated patch recordings. Spatial control over presynaptic voltage was achieved by 1) block of K currents by intracellular Cs and extracellular TEA 2) Global inhibition of inward current by low calcium and TTX and 3) use of a puff-suck device to locally apply high calcium to the voltage-clamped region. Terminal calcium currents showed varying degrees of inactivation in response to 200 msec pulses, but no inactivation occurs during the brief presynaptic action potentials. Voltage-dependence of activation is variable and generally positive shifted with peak currents between +5mV and +15mV. Inhibition of terminal calcium current by 6μM ω-conotoxin GVIA and single channel properties indicate that this current is carried by N type channels as also seen in the neuronal somata. Soma recordings have revealed additional channel types suggesting differences in calcium channel distributions within the cell. Through simultaneous pre- and post-synaptic recordings we are investigating the relationship between calcium channel function and activation of postsynaptic ACh receptors at the neuromuscular junction.

THE PRESENCE OF BOTH ωAGATOXIN- AND ωCONOTOXIN-SENSITIVE CALCIUM CHANNEL SUBTYPES PRIOR TO SYNAPTOGENESIS IN HIPPOCAMPAL NEURONS. F. H. Bahls* and P. G. Haydon. Laboratory of Cellular Signaling, Department of Zoology and Genetics, Iowa State University, Ames, IA 50011.

Excitatory synaptic transmission in the adult hippocampus is dependent on 2 classes of calcium channels, class A (P/Q) and class B (N). However, early after synapse formation, class B channels are the predominate channel subtype coupled to transmitter release. In this study we asked whether differences in the contribution to transmitter release were reflected in the contribution of class A and class B calcium channel subtypes to the whole cell barium current in developing rat hippocampal neurons.

Rat E18 hippocampal neurons were isolated and plated on astroglia. Neurons were voltage clamped using patch pipettes in the whole cell mode at various ages after plating. The contribution of different calcium channel subtypes to the whole cell barium current was determined through the use of the selective calcium channel blockers, ωAgaIVA and ωCTXGVIA. Both were applied by pressure ejection over the cell. Recordings were made from neurons ranging in age from 2 to 16 days. At all ages examined, both ωAgaIVA and ωCTXGVIA produced a reduction in the amplitude of the whole cell barium current. No consistent differences between the action of ωAgaIVA and ωCTXGVIA were detected at any age suggesting that both calcium channel subtypes are inserted into the soma membrane early in development. Other regulatory mechanisms must exist to explain the differences in coupling to transmitter release. Supported by NS24233.

METABOTROPIC GLUTAMATE RECEPTORS MODULATE THE VOLTAGE-DEPENDENT CALCIUM CURRENT IDENTIFIED IN CATFISH HORIZONTAL CELLS. C. L. Pfeiffer-Linn* and A. C. Gafka. Department of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

We have studied the effects of metabotropic glutamate agonists on the sustained voltage-dependent calcium current found on catfish (*Ictalurus punctatus*) horizontal cells. Studies were done using the whole-cell patch clamp technique on acutely dissociated cone horizontal cells. Selected cells were voltage- or current-clamped in catfish saline containing pharmacological blockers of sodium and potassium channels, as well as NMDA and non-NMDA receptors. Other pharmacological agents were applied by perfusion. Under voltage-clamp conditions, calcium channel activity was elicited by depolarizing the membrane potential of selected cells to the calcium current's activation range. Under these conditions, perfusion of micromolar concentrations of L-glutamate, APB (L-AP4) or ACPD increased the amplitude of the sustained calcium current from control conditions. Furthermore, application of each metabotropic agonist shifted the current activation range toward a more hyperpolarized membrane potential. Under current-clamp conditions, action potentials were recorded from selected isolated horizontal cells. Application of the metabotropic glutamate agonists acted to increase action potential duration.

To determine if the effects of the metabotropic glutamate agonists were consistent with the involvement of a pertussis toxin sensitive G-protein, several experiments were conducted 1) after pertussis toxin was allowed to diffuse into the cell through the recording pipette, 2) with zero magnesium in the recording pipette, or 3) with GTP$_\gamma$S in the recording pipette. Results from these experiments support the hypothesis that metabotropic agonist actions are mediated through a pertussis toxin sensitive G-protein. Taken together, these results suggest that metabotropic glutamate receptors exist on catfish cone horizontal cells and may be involved in modulation of the sustained calcium current. Supported by NIH grant EY 11133-01.

ACTIVITY-DEPENDENT, SELECTIVE MODULATION OF A P-TYPE Ca^{2+} CHANNEL IN A CRAYFISH PHASIC MOTONEURON. S.J. Hong and G.A. Lnenicka*. Dept. of Biol. Sci., State Univ. of New York, Albany, NY 12222.

In a previous study, we demonstrated that increased impulse activity in a crayfish phasic motoneuron resulted in a long-term reduction in the voltage-dependent Ca^{2+} current density at the cell body. This reduction in Ca^{2+} current is Ca^{2+}-dependent and persists for days (Hong and Lnenicka, 1995. *J. Neurosci.* **15**:3539-3547). In order to determine which subtype of Ca^{2+} channel is modulated by Ca^{2+} influx, Ca^{2+} channel subtypes were characterized using specific Ca^{2+} channel antagonists and conventional two-electrode voltage-clamp techniques.

Based upon pharmacological and electrophysiological criteria, the cell body has at least two high-voltage-activated Ca^{2+} channel subtypes; an ω-agatoxin (AgTX) IVA-sensitive, P-type and a dihydropyridine, ω-conotoxin GVIA, and ω-AgTX IVA-resistant, non-P-type. To examine the effect of impulse activity upon these Ca^{2+} channel subtypes, the axon was electrically stimulated at 5 Hz for 45-60 min. Six to seven hours after stimulation, the amplitude of the P-type and non-P-type Ba^{2+} currents were determined by measuring the Ba^{2+} current before and after the addition of 600 nM ω-AgTX IVA. The stimulation produced a significant 43% reduction ($p<0.05$, $n=8$) in the density of the P-type Ba^{2+} current (control -25.1 ± 2.7; stimulated -14.4 ± 2.9 nA/nF), but no reduction in the density of the non-P-type Ba^{2+} current (control -57.1 ± 4.1; stimulated -56 ± 6.3 nA/nF). Thus, an increase in neuronal impulse activity selectively produced a long-term reduction in the P-type Ba^{2+} current.

CALCIUM CHANNEL KINETICS CHANGES REVEAL LOCALIZED OPIOIDS AND ATP SECRETION IN BOVINE CHROMAFFIN CELLS. V. Carabelli, A. Albillos[§], A.G. Garcia[§] and E. Carbone*. Dept. of Neuroscience, Univ. of Turin, Italy, [(§)]Dept. of Pharmacology, Univ. of Madrid, Spain.

Besides catecholamines, chromaffin cells release opiates, nucleotides and peptides. Their membrane possess voltage-dependent Ca channels (L-, N-, P- and Q-type) as well as purinergic and opioids autoreceptors. The secreted material (opioids and ATP) is shown to delay the Ca channel activation kinetics by causing Ca current depression. This autocrine loop is mediated by G proteins, involves non-L-type channels, opioids and purinergic autoreceptors and is readily reverted by strong depolarizations (facilitation). In order to address the question of whether the autocrine modulation of Ca channels is controlled by local secretion or is due to material released from surrounding cells, we measured the non-L-type channel activation kinetics in cell-attached patches of bovine chromaffin cells in three different conditions. The recording pipette contained either the control solution (100 mM Ba, 5 μM nifedipine), the same solution plus saturating doses of ATP, δ- and μ-opioid agonists or, the control solution plus opioids and purinergic receptor antagonists. We found that 70% of the control patches (n=28) and 80% of the patches containing the agonists (n=9) exhibited non-L-type ensemble currents with markedly delayed activation kinetics (τ 18-20 ms at +30 mV) (Fig. 1), which could be accelerated by step depolarizations (Carabelli et al., 1996. *Biophys. J.* **70**:2144). In contrast, 70% of the patches containing the antagonists (n=19) showed Ca channel activities with rapid activation (τ < 2 ms at +30mV) and fast inactivation kinetics (Fig. 1). Our data suggest that the vesicle content directly released in the recording pipette down-modulates Ca channel kinetics through their fast coupling to activated autoreceptors and that the secretory system in chromaffin cells is highly localized in membrane micro areas.

N- AND P- TYPE CALCIUM CHANNELS REGULATE STRIATAL ACETYLCHOLINE RELEASE IN THE RAT BRAIN
J. Robert Bostwick*, Gunilla Ericsson, and Anita Westlind-Danielsson.
Astra Arcus USA. Rochester, NY 14623 and Astra Arcus AB, Södertälje, Sweden

In vitro acetylcholine (Ach) release from striatal slices is evoked by depolarization with elevated potassium (K^+) in a concentration dependent manner. Release evoked with 15 mM K^+ is partially inhibited by either the N-type voltage-operated calcium channel (VOCC) blocker ω-conotoxin GVIA or by the P-type VOCC blocker ω-agatoxin IV A (Aga IV A) but not by the Q-type blocker ω-conotoxin MVIIC. Total inhibition is achieved when saturating concentrations of GVIA and Aga IV A are combined. These results indicate that, under these conditions, Ach release in the striatum is regulated by N- and P- but not by Q-type VOCCs. Both N- and P-type channels appear to coexist on the same population of nerve terminals because the sum of the maximal percent inhibition achieved with individual blockade by either toxin exceeds 100%. Selective inhibition of VOCC subtypes results in disproportionate reduction of neurotransmitter release evoked by low levels of depolarization because the effect is related to a power function of calcium concentration in the presynaptic terminal. At higher levels of depolarization (65 mM K^+), the magnitude of response begins to saturate and the ability of either toxin alone to inhibit release is dramatically reduced. However, the combination effect is synergistic. For Ach release evoked with 65 mM K^+, potent and near complete inhibition by GVIA and Aga IV A is revealed when the concentration-effect for one toxin is measured in the presence of a saturating concentration of the other. These results indicate that the concerted action of N- and P-type VOCCs is not required to achieve maximal neurotransmitter release evoked by strong depolarization. Under such conditions, the operation of either VOCC subtype alone appears to be sufficient for elevating the intraterminal calcium concentration to a level high enough to nearly saturate the triggering mechanism.

FUNCTIONAL DIVERSITY OF P-TYPE AND R-TYPE CALCIUM CHANNELS IN RAT CEREBELLAR NEURONS.
D. Pietrobon*, A. Tottene, and A. Moretti. Dept. of Biomedical Sciences, University of Padova, 35121 Padova, Italy.

By combining single channel and whole-cell patch-clamp recordings we have shown that most of the non-L Ca^{2+} current of rat cerebellar granule cells is due to Ca^{2+} influx through three different non-N-type Ca^{2+} channels, that we have called G1, G2 and G3. Being blocked irreversibly by both ω-conotoxin-MVIIC and low doses of ω-agatoxin-IVA (saturation at 30-50 nM), according to pharmacological criteria, G1 channels must be classified as P-type channels, even though they are slowly inactivating during depolarizing pulses and are completely inactivated at voltages where steady-state inactivation of P-type channels in Purkinje cells is negligible. Neither G2 nor G3 were blocked irreversibly by ω-conotoxin-MVIIC, and therefore both are R-type Ca^{2+} channels. Most of the biophysical properties of G2 and G3 are intermediate between those of LVA and HVA Ca^{2+} channels, with LVA properties prevailing in G2 (e.g. voltage range for steady-state inactivation, $V_{1/2}$=-90 mV) and HVA properties prevailing in G3. The R-type whole-cell current was inhibited by Ni^{2+} with a biphasic dose-response curve (IC_{50}s: 4 and 153 μM), suggesting a differential sensitivity of G2 and G3 to Ni^{2+} block. Our results uncover a previously unrecognised functional diversity of both native P-type and R-type Ca^{2+} channels in CNS neurons.

THE HUMAN GONADOTROPIN-RELEASING HORMONE RECEPTOR INHIBITS M-TYPE K^+ AND N-TYPE CA^{2+} CURRENTS IN A NEURONAL EXPRESSION SYSTEM. Deborah L. Lewis* and Stephen R. Ikeda, Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA 30912

Whole-cell patch clamp recordings were made from rat superior cervical ganglion neurons injected with *in vitro* transcribed cRNA coding for the human gonadotropin-releasing hormone (GnRH or LHRH) receptor (Chi et al., Mole. Cell. Endo. 91:R1, 1993). The human GnRH receptor inhibited the M-type K^+ current. M current inhibition decreased from 95.2±4.5% (n=5) to 9.9±1.3% (n=5) with 2 mM GDPβS in the pipette indicating that the effect was G protein-dependent. Pertussis toxin had no effect on M current inhibition. Ca^{2+} currents were recorded with 0.1 mM BAPTA in the pipette. GnRH inhibited the Ca^{2+} current by 42.9±5.2% (n=6) in a voltage-independent manner. Pertussis toxin had no effect, but inclusion of 11 mM EGTA in the patch pipette abolished the inhibition of the Ca^{2+} current by GnRH. Macropatch experiments indicated that a diffusible second messenger was responsible for Ca^{2+} current inhibition. The tyrosine kinase inhibitor genistein had no effect on this pathway.

The effect of GnRH on the M-type K^+ current is similar to the effect of LHRH in bullfrog sympathetic neurons (Brown & Adams. Nature 283:673, 1980) but unlike the Ca^{2+} current inhibition which is voltage-dependent and occurs with 9 mM EGTA in the patch pipette (Elmslie et al. Neuron 5:75, 1990; Boland & Bean. J. Neurosci. 13:516, 1993). By contrast, Ca^{2+} current inhibition mediated by the human GnRH receptor is voltage-independent and mediated by a diffusible messenger. RECONSTITUTED MUSCARINIC INHIBITION AND PREPULSE FACILITATION OF RECOMBINANT A-CLASS CALCIUM CHANNELS IN HEK 293 CELLS.

Parag G. Patil*, Terry P. Snutch, and David T. Yue.
Dept. of Biomedical Engineering, Johns Hopkins University, Baltimore, MD 21205

Voltage-activated calcium channels transduce action potentials into presynaptic calcium entry, triggering neurotransmitter release from a wide variety of nerve terminals. Because calcium entry through even a single open channel may initiate release, selective modulation of neuronal calcium channels constitutes a potent mechanism for spatial and temporal control of synaptic transmission. G-protein-coupled receptor inhibition of both N-type and P/Q-type calcium channels reduces presynaptic calcium entry, sharply attenuating neurotransmitter release. Detailed study of this important mechanism of synaptic control has been hampered, however, by the heterogeneous mixture of ion channel and receptor subtypes in native neuronal preparations. Co-expression of recombinant M2-muscarinic receptors and P/Q-type calcium channels (α1A+β1b+α2) in human embryonic kidney cells allowed G-protein inhibition to be studied in homogeneous populations of receptors and channels. As shown in the accompanying exemplar records, 50 μM carbachol, an M2 agonist, potently inhibited A-class currents. Inhibition (+) is characterized by a sharp reduction in Ba^{2+} current entry, with little apparent change in whole-cell activation kinetics. Furthermore, a strong (100 mV) depolarizing prepulse failed to substantially reverse M2-mediated G-protein inhibition (*). These features contrast with results for N-type (B-class) calcium channels in the same recombinant system, where slowed activation kinetics and prepulse facilitation effects are more pronounced. (NSF PFF)

CA^{2+}-DEPENDENT CA^{2+} CHANNEL INACTIVATION IN PEPTIDERGIC NERVE TERMINALS DURING PHYSIOLOGICAL BURSTS. J.L. Branchaw* and M.B. Jackson. Physiology Dept., University of Wisconsin Medical School, Madison,WI 53706.

Inactivation of Ca^{2+} channels limits depolarization-induced increases in $[Ca^{2+}]_i$. Because exocytosis is triggered by Ca^{2+}, inactivation of Ca^{2+} channels may limit secretion. Inactivation will have greater effects in cells that secrete in response to bursts of action potentials, because a single action potential is rarely long enough to produce significant amounts of inactivation. Neurohypophysial nerve terminals secrete the neuropeptides oxytocin and vasopressin in response to bursts of action potentials. The inactivation properties of Ca^{2+} channels in these nerve terminals were investigated in slices using whole-terminal patch clamp techniques to measure Ca^{2+} current, and the Ca^{2+}-sensitive fluorescent dye fura-2 to measure $[Ca^{2+}]_i$. Ca^{2+} channel inactivation was both voltage- and Ca^{2+}-dependent. Ca^{2+} strongly inhibited recovery from inactivation at negative potentials, but had weaker effects on inactivation at positive potentials. Inactivation during physiological bursts (14 Hz and 20 Hz) was frequency dependent, with increasing inactivation at higher frequencies. Addition of 10 mM BAPTA to the patch pipette eliminated the frequency dependence of Ca^{2+} current inactivation, suggesting a role for Ca^{2+} in the dependence on frequency. Fatigue of neuropeptide secretion has previously been shown to increase with increasing stimulation frequency. Thus, our studies imply that Ca^{2+} channel inactivation can play a role in the use-dependent fatigue of release from peptidergic terminals.

REGULATION OF L-TYPE CALCIUM CHANNELS IN PITUITARY GH_4C_1 CELLS BY MEMBRANE DEPOLARIZATION. Ravikumar Peri, Satpal Singh and David J. Triggle*. Dept. of Biochemical Pharmacology, State University of New York at Buffalo, Amherst NY 14260.

The neurosecretory anterior pituitary GH_4C_1 cells exhibit the high voltage activated dihydropyridine (DHP) sensitive L-type, and the low voltage activated T-type calcium currents. The activity of L-type calcium channels is tightly coupled to secretion of prolactin and other hormones in these cells. Depolarization (50mM K^+) reduces the DHP ([^{3}H] PN 200-110) binding site density and $^{45}Ca^{++}$ uptake in these cells (Liu et.al. Mol. Pharmacol. 45, 1198-1206, 1994). The present study correlates the loss of DHP binding sites to the loss of L-type calcium channel current.

Depolarization of GH_4C_1 cells (50mM K^+) rapidly reduced the barium currents through L-type calcium channels by approximately 70% and shifted the voltage dependence of activation by 10mV to more depolarized potentials. This down-regulation was reversible and the currents recovered to control levels on repolarization. Down-regulation of calcium channel currents occurred only in the presence of extracellular calcium. Buffering intracellular calcium ions with BAPTA-AM did not prevent the down-regulation indicating that it may not be due to excessive intracellular accumulation of calcium. Prevention of endocytic internalization of the channels by pretreating cells with concanavalin-A did not prevent the down-regulation. Prevention of intracellular acidification using chloroquine did not prevent the down-regulation. Membrane depolarization by veratridine in the presence of extracellular calcium also exhibited a down-regulation of calcium channel currents. However the voltage dependence of activation was not affected.

Regulation of calcium channel currents on depolarization with elevated extracellular potassium may involve the dissociation of the β-subunit from the channel complex. Studies are in progress to further characterize the second messenger pathway(s) involved in the down-regulation.

Endothelin-1 (ET-1) inhibits voltage-sensitive Ca^{2+} channels (VSCCs) in cultured rat cerebellar granule neurones. B. Held, N.L. Smeeton, H.A. Pearson*, Dept. of Pharmacology, University of Leeds, LS2 9JT, UK

Endothelin-1, a potent vasoconstrictor peptide, has been shown to increase intracellular free Ca^{2+} concentration in vascular smooth muscle cells, mediated in part by a prolongation of VSCC openings[1]. The presence of ET receptors in the CNS suggests a role for ETs as neurotransmitters. We therefore studied the action of 400nM ET-1 on voltage-dependent Ca^{2+} channels in cerebellar granule cells using the whole-cell, perforated-patch and cell-attached configurations of the patch-clamp technique. In the whole-cell configuration, ET-1 (400nM) had no effect on Ca^{2+} channel currents (I_{Ba}). When amphotericin-B perforated recordings were made, I_{Ba} was significantly reduced by 28±6.4% from -237±31pA to -170±26pA ($p<0.05$, n=3). In cell-attached patches, current through L-type Ca^{2+} channels in response to a 400ms depolarisation was calculated as the integral of the ensemble average current. ET-1 caused inhibition in this current of 90.7±5.1% from -0.087±.028pAs to -0.007±0.004pAs (n=3). Voltage ramps between -100mV and +100mV indicated that this inhibition was not due to a shift in activation voltage of the channel (n=4). Channel amplitude and mean open time were not significantly reduced by ET-1 (n=3), however the mean closed time was increased from 16.9±11.1ms to 67.9±56.1ms and the frequency of channel opening was reduced from 0.078±0.04 to 0.034±0.02openings/ms ($p<0.05$, n=3). 20ms prepulses to +100mV were applied to overcome any direct, voltage-dependent inhibition by G-proteins but had no effect in cell-attached patch recordings. We conclude that ET-1 inhibits VSCCs in cerebellar granule cells via a cytosolic second messenger pathway and that a direct, voltage-dependent inhibition by G-proteins is not involved.

EFFECTS OF ω-AGA IVA AND ω-CONOTOXIN MVIIC ON CALCIUM CURRENTS OF NEURONS ISOLATED FROM THE VENTROBASAL NUCLEUS OF THE RAT THALAMUS. P. J. Kammermeier* and S. W. Jones. Department of Neurosciences and Department of Physiology & Biophysics, Case Western Reserve University, Cleveland, OH 44106.

Ventrobasal (VB) thalamic relay neurons possess both low voltage-activated and high voltage-activated (HVA) calcium channels. We found previously (*Biophys. J.* **68**:A209, 1994) that the HVA channels of acutely isolated VB neurons were only partially blocked by the dihydropyridine antagonist nimodipine (33 ± 1% at 5 μM, mean ± SEM, n=12) or by ω-conotoxin GVIA (25 ± 5% at 1 μM, n=3), in whole-cell recordings. We report here that nearly all of the remaining HVA current is blocked by 3-5 μM ω-conotoxin MVIIC (90 ± 4%, n=4, with 2 mM Ba^{2+}_o). The current resistant to nimodipine and ω-conotoxin GVIA is weakly sensitive to ω-Aga IVA (26 ± 7% at 100 nM, 54 ± 4% at 1 μM, n=5, with 25 mM Ba^{2+}_o). The total HVA current is blocked only 7 ± 2% by 100 nM Aga IVA (n=5), compared to 91 ± 2% block in cerebellar Purkinje neurons (n=3). We conclude that there are three main HVA currents in VB neurons: ~25% N-current, ~33% L-current, and ~40% that resembles the 'Q-current' of cerebellar granule neurons (Randall and Tsien, *J. Neurosci.* **15**:2995-3012, 1995). There is little or no 'P-current.'

LOW-AFFINITY BINDING SITES FOR 1,4-DIHYDROPYRIDINES IN SKELETAL MUSCLE CALCIUM CHANNELS REVEALED BY CHANGES IN INTRINSIC PROTEIN FLUORESCENCE. D. J. Bao and S. M. J. Dunn*. Division of Neuroscience, University of Alberta, Edmonton, Alberta, Canada T6G 2H7.

The binding of 1,4-dihydropyridine calcium channel ligands to low affinity binding sites in skeletal muscle transverse tubule membranes has been measured by changes in protein intrinsic fluorescence. Binding results in a decrease in protein fluorescence at 325 nm when excited at 290 nm. All dihydropyridines examined, including the agonist (-)-Bay K8644, and the antagonists, nicardipine, nitrendipine, felodipine and amlodipine, induce this fluorescence quench with measured dissociation constants in the range of 3-21 μM. In the case of the fluorescent derivatives, felodipine and amlodipine, binding can also be monitored by changes in their fluorescence when excited directly or via energy transfer from membrane protein. These sites are of too low an affinity to measure in equilibrium radiolabelled ligand binding studies, but the fluorescence changes also occur in the purified and reconstituted high affinity dihydropyridine receptor. These results suggest that the high and low affinity sites are associated with the same calcium channel protein.

ANOMALOUS NEUROTRANSMITTER RELEASE INHIBITION PROFILES OF ω-CONOTOXIN MVIIA AND ω-CONOTOXIN MVIIC. R. A. Keith*, M. J. Hyde, T. J. Mangano, P. A.DeFeo and B. A. Donzanti. Dept. of Pharmacology, Zeneca Pharmaceuticals Group., Wilmington, DE 19850-5437.

ω-Conotoxin MVIIA (MVIIA) and ω-conotoxin MVIIC (MVIIC) were evaluated in several pharmacological assays that are reflective of actions at neuronal voltage-sensitive calcium channels (VSCC). MVIIA (IC_{50}=3 nM) and MVIIC (IC_{50}=70 nM) inhibited ^{125}I-ω-conotoxin GVIA binding to neuronal membranes. MVIIC caused a monophasic inhibition of rat synaptosomal $^{45}Ca^{2+}$ influx (IC_{50}=100 nM), whereas MVIIA was inactive at 1000 nM. MVIIC caused a monophasic and near-complete inhibition of [^{3}H]-norepinephrine release from rat brain slices (IC_{50} =300 nM), whereas MVIIA caused a potent (IC_{50}=7 nM), yet incomplete (max~50%) inhibition. MVIIC caused a monophasic and near-complete inhibition of [^{3}H]-D-aspartate release from rat brain slices (IC_{50}=800 nM), whereas MVIIA was inactive at 3000 nM. MVIIC caused a potent (IC_{50}= 7 nM) yet incomplete (max~75%) inhibition of hippocampal glutamate release in awake rats using microdialysis. MVIIA caused a near-complete, but relatively weak (IC_{50}=1000 nM) inhibition of hippocampal glutamate release *in vivo*. Our studies suggest: 1) There is an anomalous loss of *in vivo* potency of MVIIA, which could cause one to underestimate the importance of N-type VSCC *in vivo*; 2) MVIIC caused a monophasic inhibition of [^{3}H]-norepinephrine release, which contrasts with a previously described biphasic inhibition; and 3) MVIIC, although an inhibitor of N-type VSCC, is incapable of inhibiting a component of N-type VSCC mediated glutamate release *in vivo*; thus, we propose a primary interaction of MVIIC with Q-type VSCC *in vivo*. (funded by Zeneca Pharmaceuticals)

N-TYPE CA-CHANNEL ACTIVATION BY ACTION POTENTIALS: SEQUENTIAL INHIBITION AND AUGMENTATION BY GABA. P. Christophersen, E.Ø. Nielsen*, and S.P. Olesen NeuroSearch A/S, DK 2600 Glostrup, Denmark.

Using cultured embryonic chick DRG cells we characterized the effects of GABA on voltage dependent Ca-channels activated by action potentials (AP's) or by AP-like command voltages. Single AP's exhibited a Ca^{2+}-dependent "shoulder" in the repolarizing phase. The N-channel blocker ω-CmTx MVIIA (0.5 μM), irreversibly narrowed the AP by ≈ 50 %. GABA (50 μM) caused an immediate narrowing too, but the shoulder reappeared upon prolonged exposure (min). The current activated by AP-like command voltages was blocked > 90 % by ω-CmTx MVIIA, whereas GABA blocked ≈ 60 - 70 %. In the presence of GABA the current amplitude increased gradually towards the control level (see Figure). Wash-out resulted in a large overshoot (100-200 %), which decayed towards control levels within 5-20 minutes. Analysis of steady-state activation curves showed that the block was due to a right-hand shift and a decrease in steepness of voltage dependence, whereas the augmentation was due to a leftward shift. The biphasic response to GABA was mimicked by GTP-γ-S and exogeneously applied baclofen, indicating that both components were secondary to GABA-B receptor stimulation. The augmentation may involve protein kinase C, since current transients were stimulated by PMA.

THE NEUROPROTECTIVE COMPOUND ELIPRODIL (SL 82.0715) BLOCKS N-, P- BUT NOT L-TYPE Ca^{2+} CHANNELS IN RAT CULTURED CEREBELLAR GRANULE CELLS. P. Avenet*, B. Biton, H. Depoortere and B. Scatton. Department of CNS Research, Synthélabo Recherche, 31 Ave. P. Vaillant-Couturier, 92220 Bagneux, France.

The neuroprotective compound eliprodil has been shown to block NR1A/NR2B NMDA-receptors as well as L, N- and P-type Ca^{2+} channels. By using the whole cell patch-clamp technique we examined the Ca^{2+} channel antagonist properties of this compound in cultured cerebellar granule cells which are known to express L, N, P, Q and R-type Ca^{2+} channels (Randall and Tsien, 1995; J. Neurosci. 15: 2995). Eliprodil reversibly antagonized 50 % of the voltage-dependent Ba^{2+} current at the saturating concentration of 30 μM. 3 μM of ω-Conotoxin-GVIA (ω-Ctx) and 0.5 μM ω-Agatoxin-IVA (ω-Aga-IV) blocked 27.8 and 43.3 % of the current, respectively. When eliprodil (30 μM) was added to ω-Ctx or ω-Aga-IV the level of maximal inhibition was identical to that obtained with eliprodil alone confirming a full block by eliprodil of N-, P- and Q-type Ca^{2+} channels. The L-type channel antagonist nimodipine (10 μM) blocked 23.6 % of the current. In contrast to the toxins, this blockade was fully additive to that of eliprodil, indicating that the nimodipine-sensitive component of the current was eliprodil-insensitive. In the presence of eliprodil and nimodipine a residual Cd^{2+} sensitive current (30 %) which could be of R-type remained unblocked. We conclude that in cerebellar granule neurons two Ca^{2+} channels types are insensitive to eliprodil. One of these types is nimodipine-sensitive and may represent a neuronal L-type channel distinct from that (eliprodil-sensitive) present in cortical neurons.

IN VIVO ANALYSIS OF VOLTAGE-DEPENDENT Ca^{2+}-CURRENTS CONTRIBUTING TO RESPIRATORY BURSTING O.Pierrefiche, A. Haji and D.W. Richter* II. Inst. Physiol., Univ. Göttingen, Humboldtallee 23, 37073 Göttingen, FRG

Current- and voltage-clamp measurements with fine-tipped electrodes were combined with extra- and intracellular phoresis of channel blockers to identify and study the functional significance of voltage-dependent Ca^{2+} currents in expiratory neurons of anesthetized, paralyzed and vagotomized cats.

After extracellular phoresis of TTX and TEA, depolarizing voltage commands starting from a holding potential of -60 mV induced transient (Ca_{LVA}) and persistent (Ca_{HVA}) Ca-currents. Ca_{HVA} was greatly reduced or blocked by extracellular Cd^{2+}. Ca_{LVA} was less sensitive to extracellular Cd^{2+}. The amplitude of both currents increased with depolarization and reached a maximum at -10 mV. A transient Ca_{LVA} was also elicited at the end of voltage commands hyperpolarizing the neurons beyond -70 mV. This "rebound" Ca-current was fully deinactivated at -120 mV, completely inactivated at -60 mV and abolished by Cd^{2+}. Intracellular injection of the L-type Ca^{2+} channel blocker D600 or extracellular Cd^{2+}, reduced action potential discharge. Neuronal input resistance was increased and excitatory synaptic inward currents decreased.

We conclude that in respiratory neurons Ca_{LVA} currents can be activated at the end of inhibitory synaptic periods and thus contribute to onset of phase activities. Ca_{HVA} currents contribute to sustained burst discharges, but consequent rise of intracellular Ca2+ triggers repolarizing K^+-conductances shaping the burst pattern.

BLOCKADE OF TRANSMITTER RELEASE AT FROG AND CRAYFISH NEUROMUSCULAR JUNCTIONS BY PHONEUTRIA SPIDER TOXIN PF-3.

[1,2]L.R.P. Troncone, [1]J.Georgiou, [1]S.-Y. Hua, [2]I. Lebrun, [2]F. Magnoli, and [1]M.P.Charlton*. [1]*Dept. Physiology, Univ. Toronto, Toronto, Canada, M5S 1A8 and* [2]*Butantan Institute, São Paulo, Brazil.*

Peptide channel blockers found in venoms of many predators have become useful pharmacological tools and potential therapeutic agents. The venom of the Brazilian spider *Phoneutria nigriventer* contains a fraction, PF-3 (8,360 MW), which blocks Ca^{2+} channels.

At frog NMJs (normal $[Ca^{2+}]_o$), PF-3 did not affect spontaneous release but reversibly reduced evoked transmitter release by 75 and 95% at 12 and 24 nM. Stimulation at 50 Hz partially relieved the blockade. Imaging of nerve terminal Ca^{2+} showed that PF-3 blocked influx. Raising $[K^+]_o$ from 2 to 8 mM, increased spontaneous release frequency 8-fold, but this could be blocked by PF-3. At crayfish NMJs, 0.3 μM PF-3 blocked transmitter release without affecting presynaptic action potentials. Upon removal of the toxin, transmitter release recovered. Similar to its effects at mammalian NMJs (Souccar et al., 1995; Br. J. Pharm. *116*, 2817), PF-3 may block P-type channels at crayfish NMJs.

We conclude that PF-3 blocks neurotransmission in frog and crayfish by binding to Ca^{2+} channels which may include N- and P- type. Its high affinity and reversible blockade is unlike many other Ca^{2+} channel blockers, and may prove to be useful in both research and clinical settings.

MODULATION OF THE DIHYDROPYRIDINE-SENSITIVE CALCIUM CHANNELS IN *DROSOPHILA* MUSCLES.

A.Bhattacharya,* G.G. Gu & S. Singh. Department of Biochemical Pharmacology, School of Pharmacy, SUNY Buffalo, Amherst, NY 14260.

Calcium channels, like all ion channels, are modulated by second messenger pathways. Larval muscles of *Drosophila melanogaster* show a dihydropyridine (DHP)-sensitive and an amiloride-sensitive calcium channel current (Gielow et al., *J. Neuroscience*, 15[9]:6085-6093, 1995). We are interested in studying the role of various second messenger systems in modulating the DHP-sensitive calcium channel. Single-gene-mutations that disrupt the activity of specific signal transducers provide a way to study their importance in channel modulation. We are examining the effect of such mutations on the calcium channel current recorded by two-electrode voltage clamping with barium as charge carrier. Barium current was significantly reduced by the *norpA* mutation which disrupts phospholipase C (PLC) activity. This effect was rescued by protein kinase C (PKC) activation in the mutant and mimicked by PKC inhibition in the wild type. These results indicate that the DHP-sensitive calcium channel may be modulated by the PLC/PKC pathway. Barium currents significantly increased as result of the *dunce* mutation, which affects phosphodiesterase activity leading to increased cyclic AMP (cAMP) levels, whereas the current was significantly reduced in the *rutabaga* mutant where cAMP levels are low due to disruption of the calcium/calmodulin-sensitive adenylate cyclase activity. These data indicate modulation of the DHP-sensitive calcium-channel by the cAMP signal transduction cascade. At present we are studying the nature of this modulation in more depth.

N-TYPE VOLTAGE-DEPENDENT CALCIUM CHANNELS SELECTIVELY TARGETED BY NOVEL INSECT NEUROPEPTIDE.

L.M. Harding[1] R.H. Scott[2*], H. Hietter[3], B. Luu[3], I. Bermudez[1]. [1]Oxford Brookes University, U.K., [2]Aberdeen University, U.K., [3]CNRS, Strasbourg, France.

PMP-D2 has been shown to block high voltage-activated Ca^{2+} currents (HVA ICa^{2+}) in cultured rat DRG neurones (Harding *et al.*, 1995, J. Sig. Trans & Recep. Res 15: 355-364). Here we present data showing the effects of the peptide on cerebrocortical synaptosomes and DRG neurones showing that PMP-D2 displays selectivity towards N-type channels.

PMP-D2 is a 35 amino acid peptide isolated from the brain of the locust *Locusta migratoria* (Nakakura *et al.*,1992, Euro. J. Biochem. 204: 147-153). This peptide is dissimilar in its amino acid structure to any established Ca^{2+} channel ligand but it bares many tertiary structural similarities to ω-conotoxin GVIA. In rat cerebrocortical synaptosomes PMP-D2 (10μM) inhibited 20mM K^+ stimulated $^{45}Ca^{2+}$ influx by 25%. With more strongly depolarising saline (50mM K^+) PMP-D2 has no significant effect on $^{45}Ca^{2+}$ influx which is mediated predominantly by P/Q channels. ω-conotoxin GVIA (1μM) only blocks a significant proportion of $^{45}Ca^{2+}$ influx into synaptosomes depolarised with 20mM K^+ and the effects of PMP-D2 and ω-conotoxin GVIA together are not additive.

This data is corroborated by electrophysiological pharmacological studies of the effects of PMP-D2 on HVA ICa^{2+} in primary cultures of neonatal rat DRG neurones. In this preparation PMP-D2 partially blocks the ω-conotoxin GVIA sensitive current but has no effect on the Bay K 8644 potentiated L-type current or T-type currents thus showing a degree of selectivity for the N-type channel.

In both cerebrocortical nerve terminals and DRG soma PMP-D2 appears not to completely abolish all the ω-conotoxin GVIA sensitive $^{45}Ca^{2+}$ influx or Ca^{2+} current; this presents speculation that more than one type of N-type channel may be expressed in these sites.

EFFECTS OF Ca^{2+} CHANNEL BLOCKERS ON MURINE NEUROMUSCULAR TRANSMISSION AND ON CURRENTS IN LAMBERT-EATON SERUM TREATED MOUSE MOTONEURONS.

S.M.Ho*, K.D.García, M.Mynlieff & K.G.Beam. Dept. Anat. and Neurobiol. Colo.St.Univ. Ft. Collins CO 80525

Patients with Lambert-Eaton myasthenic syndrome (LES) exhibit decreased neuromuscular transmitter release, thought to result from antibodies that target presynaptic calcium channels. Here, we pharmacologically analyzed the motoneuronal calcium channels affected by LES serum and those involved in controlling neuromuscular transmission. The residual HVA current in LES-serum treated motoneurons was unaffected by 5 μM ω-CTx MVIIC but reduced >95% by 10 μM nimodipine. In contrast, the HVA current recorded from control motoneurons was reduced 56±7% by 5 μM MVIIC but decreased by <10% by 10 μM nimodipine. Therefore, LES serum appears to eliminate MVIIC-sensitive while mostly sparing L-type (nimodipine-sensitive) channels. To investigate the pharmacology of presynaptic calcium channels involved in neuromuscular transmission, compound muscle action potentials (CMAPs) in response to sciatic nerve stimulation were recorded from gastrocnemius muscles. A 10 min application of 1 and 10 μM Aga IVA caused an essentially irreversible reduction of the CMAP by 60% and 81%, respectively. HVA calcium current was reduced by 37% with 1 μM Aga IVA and reduced 60% by 10 μM Aga IVA, but was not affected by prolonged exposure to 100 nM Aga IVA. About 1/3 of the HVA current was irreversibly blocked by application of 10 μM ω-CgTx GVIA. 10 μM ω-GVIA caused about a 50% decrease in the CMAP, which was readily reversed by washing. These results indicate that neither N-type nor classical P-type channels are involved in controlling neuromuscular transmission, whereas P/Q-type channels play a prominent role. Furthermore, decrease of current through a P/Q related channel may, in part, be responsible for the development of disease in LES patients.

689.11

MUSCARINIC MODULATION OF Ca^{2+} CHANNEL CURRENTS IN PYRAMIDAL CELLS FROM RAT SENSORIMOTOR CORTEX

Stewart,† A.E., and Foehring R.C.*, Dept. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38613

We studied the muscarine receptor-mediated modulation of Ca^{2+} channel currents in pyramidal cells (cultured or acutely isolated) from sensorimotor cortex using whole cell patch clamp recordings. We found that muscarine reduces Ca^{2+} channel currents in a reversible and dose-dependent manner (IC_{50} = 1.3 μM) and the modulation was prevented by the addition of the muscarinic receptor antagonist atropine. Dialysis of GTPγS rendered the muscarinic modulation irreversible. Preincubation with pertussis toxin eliminated the modulation indicating the possibility that this modulation is mediated through G proteins of the Gi/Go subclass. The muscarinic modulation is rapid with an τ_{onset} of 1.1 seconds and was voltage dependent in 90% of the cells examined. Specific Ca^{2+} channel antagonists were used to determine which channel type is modulated by muscarine. The N-type Ca^{2+} channel antagonist ω-conotoxin GVIA blocks an average of 47 ± 33% (N=12) of the muscarinic modulation. The P-type Ca^{2+} channel antagonist ω-agatoxin (25nM) on average blocks 54 ± 34% (N=12) of the muscarinic modulation. The combination of the two toxins blocks 57 ± 36% (N=7) of the muscarinic modulation for all cells tested. In 3 of the 7 cells examined, however, the combination blocks from 75-100% of the modulation. This data suggests that muscarine acts via muscarinic receptors and PTX-sensitive G proteins to modulate N- and P-type channels. The rapid onset kinetics and partial voltage dependence of muscarine's activation suggest that this is a membrane-delimited response. Supported by NINDS grant NS33579 (R.C.F) & an APA MF in Neuroscience (A.E.S.). ω-Agatoxin was a gift from Pfizer Res. Inc.

689.12

P- AND Q-TYPE CALCIUM (Ca^{2+}) CURRENTS ARE INVOLVED IN THE GENERATION OF AFTERHYPERPOLARIZATIONs (AHPs) IN RAT SENSORIMOTOR CORTICAL PYRAMIDAL NEURONS.

J. C. Pineda*, R. S. Waters and R. C. Foehring. Dept. of Anatomy & Neurobiology, Univ. of Tenn., Memphis, TN 38163.

We previously reported that (1) the slow AHP (sAHP) and most of the medium AHP (mAHP) following multiple action potentials are Ca^{2+}-dependent, (2) N-type currents, which are blocked by ω-Conotoxin GVIA (ω-Cgtx GVIA: 1-5 μM), contributed to approximately 40 % of the slow AHP (no effect on mAHP), and (3) L-type currents did not participate in either AHP in pyramidal neurons (Foehring and Waters: Soc. Neurosci. Abstr. 25: 341, 1995). These findings suggest that other Ca^{2+}-current types participate in the generation of these AHPs.

We used sharp electrode recordings from layer II-III neurons in rat sensorimotor cortex in an *in vitro* slice preparation and specific Ca^{2+} blockers to determine which subtype(s) of Ca^{2+} currents are involved in the generation of AHPs in pyramidal neurons of rat sensorimotor cortex. We found that: (1) ω-Agatoxin IVA (ω-Agtx, 25 nM), which at this concentration blocks specifically P-type channels, reduced the sAHP by 53% and the mAHP by about 40%. (2) Applied together, ω-Cgtx GVIA (1 μM) and ω-Agtx (25 nM) blocked 70 % of the sAHP. (3) ω-Cgtx MVIIC (MVIIC: 1 μM), which blocks N-, P- and Q-type currents, blocked the sAHP remaining after ω-Cgtx GVIA (1 μM) and ω-Agtx, without further effect on the mAHP. No effect was found for any of these blockers on the fast AHP or on the action potential.

These data suggest that N-, P-, and Q-type currents are coupled to the sAHP, P-type currents are coupled to the mAHP, and L-type currents are not coupled to either AHP. Supported by NINDS grant NS33579 (R.C.F.) and NSF grant IBN-9400318 (R.S.W.), ω-Agtx was a gift from Pfizer Res.Inc.

VOLATILE ANESTHETICS DECREASE CA^{2+} TRANSIENTS IN CEREBELLAR GRANULE CELLS MEDIATED BY NON-L-, NON-N-TYPE CA CHANNELS
N. Miao, J. J. Pancrazio, C. Lynch III*, Department of Anesthesiology, Box 238 University of Virginia Health Sciences Center, Charlottesville, VA 22908

The primary effect of volatile anesthetics has been attributed to depression of synaptic transmission in the nervous system, in part mediated by inhibition of voltage-gated Ca channels (VGCC). Therefore the effects of halothane and isoflurane on VGCC influx in cultured rat cerebellar granule cells were examined.

Cerebellar granule cells were isolated from 6-7-day old rat pups, cultured on glass cover slips in growth medium with 25 mM K^+, and used at days 5-10 days of culture. After 20 min incubation in 3 μM fura-2 AM, cover slips were placed in a spectrofluorometer cuvette at 37°C. In control, ~0.8 or ~1.6 MAC (minimum alveolar conc) anesthetic studies, Ca^{2+} influx was initiated by depolarization with 50 mM KCl. $[Ca^{2+}]_i$ was estimated by a calibrated ratiometric method. Effects were recorded in the absence and in the presence of complete L-type VGCC with 1 μM nicardipine (NIC) and complete N-type Ca channel blockade with 0.1 μM ω-conotoxin GVIA (ω-CgTx). Whole cell patch clamp studies at 22°C were also performed on identical cells.

Changes (mean±SEM) in $[Ca^{2+}]_i$ are expressed as percent of same day control

	NIC & ω-Ctx	+ isoflurane		+ halothane	
$[Ca^{2+}]_i$	alone	1.3%	2.5%	0.75%	1.5%
peak	53 ±3	32 ±5 *	10 ±1 *	18 ±1 *	6 ±1 *
plateau	48 ±3	38 ±5	21 ±4 *	26 ±3 *	12 ±1 *

* P<0.05 versus NIC & ω-Ctx alone. Patch clamp studies demonstrated a somewhat more modest reduction of the inward Ca^{2+} current remaining after blockade of N- and L-type channels; 2.5% isoflurane decreased currents to ~60% of control.

Depression of both N- and L-type Ca^{2+} currents (to 30-70% of control) by relevant clinical concentrations of volatile anesthetics has been reported previously. However, depression of P/Q- and R- type currents is less well defined. These results suggest that at clinical anesthetic levels and physiological temperatures, isoflurane and halothane cause significant inhibition of non-L-, non-N-type VGCC-mediated influx.

Supported by NIH Grant R01-GM31144 to CL.

PHARMACOLOGICAL DISSECTION OF VOLTAGE-GATED CALCIUM CURRENTS IN EMBRYONIC RAT SPINAL MOTONEURONS.
F.Viana*, L. Van Den Bosch #, L. Missiaen, G. Droogmans, W. Robberecht # and B. Nilius. KULeuven, Lab. of Physiology and Neurobiology (#), Leuven, B-3000, Belgium.

In view of the importance of Ca^{2+} in neuronal cell death, we characterized the different Ca^{2+} channels in spinal motoneurons (SM) using the whole-cell configuration of the patch-clamp technique. Embryonic (E14) rat SM were isolated and cultured according to the methods of Camu and Henderson (*J. Neurosc. Meth, 44: 1992*). From -90 mV, depolarizations to -30 mV revealed a small (<40 pA) inward current that inactivated rapidly and almost completely within 100 ms. This current was preferentially blocked by amiloride (1 mM) or nickel (50 μM), characteristic for T-type Ca^{2+} channels. From the same potential, steps to 0 mV activated a larger (~ 300 pA) and more sustained (5 mM Ba^{2+}) inward current.

Nifedipine (NIF) (10 μM) blocked only a small (<10 %) fraction of peak high-voltage activated (HVA) current. In contrast, the dihydropyridine Ca^{2+} channel agonist Bay K 8644 nearly doubled the peak HVA current and caused a slowing of the inward tail, suggesting the presence of L-type channels. A larger fraction (~30%) of the HVA current was blocked slowly and irreversibly by application of 100 nM ω-agatoxin IVA (AGA), suggesting the presence of P-type channels. Application of the N-type channel blocker ω-conotoxin GVIA (CgTX) (2 μM) caused a rapid reduction of a similar fraction of calcium current. Sequential application of NIF, AGA and CgTX still left a residual component of HVA current that could be blocked by 200 μM Cd^{2+}. Current experiments address how the different Ca^{2+} channels contribute to the Ca^{2+} signal detected in the soma and neurites. These results show that cultured embryonic motoneurons develop Ca^{2+}channel phenotypes very similar to those detected in postnatal motoneurons recorded in slices.

PHENOTYPIC AND FUNCTIONAL ANALYSIS OF VOLTAGE-DEPENDENT CALCIUM CHANNEL SUBUNITS IN CEREBELLAR PURKINJE NEURONES IN VITRO.
S. E. Gillard, W. Smith, R. Beattie and D. Lodge*, Lilly Research Centre, Windlesham, Surrey. GU20 6PH, United Kingdom.

Voltage-dependent calcium channels (VDCC) are heteromeric complexes containing a pore-forming α_1 subunit in conjunction with $\alpha_2\delta$ and β subunits. The α_1 subunit, which codes for the P-type VDCC predominant in cerebellar Purkinje cells, is undetermined, although α_{1A} is the prime candidate.

Purkinje cell enriched cultures obtained from E16 rats were used to study the α_1 and β subunit composition of native Purkinje cells. Subunit specific antibodies were used in immunocytochemical studies to follow the VDCC subunit expression in developing Purkinje cells. Pharmacological analysis of their calcium currents was performed by whole-cell patch-clamp and calcium imaging experiments.

α_{1A} and β_3 expression is prominent on the day of culture. Expression of α_{1B}, α_{1E} and β_2 is relatively weak at this stage but increases during the first days of culture. β_4 expression is initially very weak but increases significantly between days in vitro (DIV) 8-10. β_{1b} expression is not detected at any stage. α_{1B}, β_2 and β_3 are well expressed in Purkinje cell dendrites. The calcium current is slowly inactivating and is reduced by ω-Agatoxin IVA (50nM). This sensitivity increases from 40% at DIV 9 to >60% at DIV 13.

Since multiple VDCC subunits are expressed in these neurones, antisense knockdown experiments in conjunction with functional analysis are being used to elucidate which genes encode for the P-type calcium channel.

ACTION POTENTIAL GENERATION BY MULTIPLE CALCIUM CHANNELS IN IMMATURE CEREBELLAR GRANULE CELLS *IN SITU*
E. D'Angelo, G. DeFilippi, P. Rossi, V. Taglietti. Istituto di Fisiologia Generale, Universita` di Pavia, I-27100, Pavia, Italy.*

The neurons expess multiple Ca^{2+} channel types playing differential roles in regulating neurosecretion and excitability. We have investigated membrane excitability in immature granule cells (n=53) by using current-clamp whole-cell patch-clamp recording techniques in acute cerebellar slices obtained from 4-15 day-old rats. The granule cells generated Ca^{2+} action potentials upon positive current injection. Ca^{2+} action potentials comprised a spike activating at -50/-60 mV (i.t.s.), and a spike activating at >-30 mV (h.t.s.). I.t.s. showed voltage-inactivation and was poorly affected by K^+ currents. H.t.s. showed poor voltage inactivation and was strongly limited by the repolarizing action of K^+ currents. Different i.t.s. Ca^{2+} channel components were blocked by 10 μM nifedipine (L-type), 5 μM ω–CTX GVIA (N-type), or 3-300 nM ω–Aga IVA (P-type), and a resistant component was reversibly reduced by 5 μM ω–CTX MVIIC (putative R-type, R_{its}). The R_{its}- had faster decay (τ<30 ms) and lower voltage inactivation (apparent $V_{1/2}$=-72 mV) than L-, P-, and N-channel currents. The L-, P-, and N-channel currents (i) boosted R_{its}-channel activation, (ii) generated Ca^{2+} plateaus, and (iii) concurred to h.t.s. generation. The major h.t.s. component was resistant to all the antagonists used (putative R-type, R_{hts}). These results indicate that channels of L-, P-, N-, and R-type are expressed in the somato-dendritic compartment of immature granule cells and concur to generate Ca^{2+}-dependent excitable responses.

ALTERED COUPLING OF Ca^{2+} CHANNELS TO ADRENOCEPTORS INVOKES ECTOPIC ACTIVITY IN DAMAGED SENSORY NERVES.
F.A. Abdulla & P.A. Smith*. Dept. of Pharmacology, University of Alberta, Edmonton, T6G 2H7, Canada.

Adrenergic mechanisms contribute to chronic pain syndromes that follow peripheral nerve injury. We sought to elucidate the mechanism(s) of noradrenaline (NA)-induced activity in axotomized rat DRG cells. 2-7 weeks after axotomy, DRG cells were dissociated and A-, H- and C-cells examined by whole-cell recording. The excitability of control neurones was unchanged by NA (10-100μM) whereas it was slightly increased in A-cells and markedly inceased in H- and C-cells from axotomized rats. Effects of NA were especially strong in cells from axotomized rats that exhibited autotomy. NA (10μM) potentiated I_{Ca} in control C- and H-cells whereas it inhibited I_{Ca} in axotomized cells. The effects of NA on I_{Ca} were greatest in cells from rats that exhibited autotomy. In control cells, the NA-induced potentiation of I_{Ca} was occluded by 2μM nifedipine, blocked by 1μM propranolol and mimicked by 10μM isoprenaline. By contrast, the effects of NA on repetitive discharge and I_{Ca} in cells from axotomized rats were blocked by 1μM yohimbine and were mimicked by 10μM clonidine and by 10μM U.K.14,304. The effects of NA in cells from axotomized rats were insensitive to prazosin and propranolol (up to 10 μM) and were not mimicked by isoprenaline. Suppression of I_{Ca} was occluded by 1μM ω-conotoxin GVIA. NA therefore affects β-adrenoceptors to increase L-type I_{Ca} in control neurones and acts on α_2-adrenoceptors to suppress N-type I_{Ca} and to increase excitability (by affecting Ca^{2+}-sensitive K^+-conductance) in axotomized neurones. This change in coupling between Ca^{2+}-channels and adrenoceptors may underlie the ectopic activity in injured sensory nerves that may contribute to chronic pain. This is supported by the observation that NA is more effective in animals that exhibit autotomy and in C-cells that normally transmit nociceptive information.

ISOLATION OF CALCIUM CHANNEL INACTIVATION FROM PROTON CURRENT ACTIVATION IN *LYMNAEA STAGNALIS*.
S.Gera and L.Byerly*, Dept. of Biol., USC, L.A., CA 90089

In molluscan neurons, the measurement of Ca^{2+} channel inactivation during a depolarizing pulse is complicated by the activation of overlapping outward H^+ currents, which cannot be blocked pharmacologically. We have devised two protocols for measuring Ca^{2+} channel inactivation that are insensitive to H^+ currents and to rundown. The first uses a three-pulse protocol that is a variant of the double pulse protocol used by Tillotson (PNAS 76:1497, 1979), while the second uses tail currents measured at potentials close to the reversal potential of H^+ currents. The two methods yield measurements of inactivation that agree closely in magnitude and voltage dependenee. The measurements diverge at higher voltages, possibly due to the slowing of deactivation kinetics of Ca^{2+} channels by a process independent of the inactivation process. Using 5mM EGTA in the internal solution, the maximum inactivation observed in the cells ranges from 35% to 60% and appears to be independent of Ca^{2+} influx, even though the inactivation-voltage curves have a pronounced U-shaped region. These methods of measuring Ca^{2+} channel inactivation are being used to determine whether conditions leading to an increase in internal Ca^{2+} can augment Ca^{2+} channel inactivation and to investigate the roles that phosphorylation and cytoskeleton may play in inactivation.

CALCIUM HOMEOSTASIS IN BASAL FOREBRAIN NEURONS DURING AGING. D. Murchison* and W.H. Griffith. Dept. Med. Pharmacol. and Toxicol., Texas A&M Univ. Health Science Center, College Station, TX 77843-1114.

Alterations in calcium homeostasis may underlie some age-related changes and pathologies of the nervous system. This investigation examines calcium homeostasis and the response to calcium loads from voltage-gated currents with age. Standard whole-cell and perforated patch voltage clamp techniques were combined with fura-2 fluorimetry in acutely dissociated medial septum/nucleus of the diagonal band neurons from young (1-4 month) and aged (24-27 month) male Fisher 344 rats. There were no age-related differences in resting internal calcium concentrations ($[Ca^{2+}]_i$) in cells loaded with fura-2 AM (n=77 young, 44 aged) or the pentapotassium salt. In the latter, the resting $[Ca^{2+}]_i$ was 63.1 $\pm$ 11.5 nM in young (n=20) and 38.5 $\pm$ 17.2 nM in aged (n=10). Ca^{2+} transients were imposed by activation of HVA Ca^{2+} currents with -60 to 0 mV steps (25 to 400 ms duration). Peak $[Ca^{2+}]_i$ changes ($\Delta[Ca^{2+}]_i$) were measured and normalized to cell size by dividing total membrane charge by capacitance to yield charge density (Q_n=pC/pF). In whole-cell recordings of 78 voltage steps from 20 young cells and 42 steps from 10 aged, there were significant ($p<.01$) differences in $\Delta[Ca^{2+}]_i/Q_n$ (young: 43.08 $\pm$ 2.72 nM/[pC/pF]; aged: 30.02 $\pm$ 2.25 nM /[pC/pF]). Decay time constants (τ) of the transients were not different. These data suggest that a mechanism to rapidly limit $\Delta[Ca^{2+}]_i$ may be present in aged cells in order to reduce potential cytotoxicity. (Suppported by NIH grant AG07805).

RNA EXPRESSION LEVELS OF MEMBRANE PROTEINS INVOLVED IN Ca INFLUX ARE REGULATED BY CORTICOSTEROID RECEPTOR STIMULATION: A SINGLE-CELL STUDY. T. R. Werkman*†, S. M. Nair#, J. H. Eberwine#‡ and M. Joëls†. †Dept. Exp. Zoology, Univ. of Amsterdam, Kruislaan 320, 1098 SM Amsterdam, The Netherlands and Depts. #Pharmacology and ‡Psychiatry, Univ. Pennsylvania, Philadelphia, PA 19104.

Corticosteroid hormones acting at mineralocorticoid (MR) and glucocorticoid (GR) receptors modulate the excitability of CA1 hippocampal neurons. In this respect membrane channel proteins involved in the regulation of Ca influx are important targets for steroid receptor activation. The single-cell antisense RNA amplification technique was used to estimate the relative RNA expression levels for Ca channel subunits and AMPA and NMDA receptors in acutely dissociated rat CA1 hippocampal neurons. Over a period of 4 weeks adrenalectomized (ADX) Wistar rats received in their drinking water 1) a low corticosterone (CT) concentration (20 µg/ml; occupying mainly MR), or 2) a high CT concentration (0.3 mg/ml; occupying both MR and GR) or 3) no steroid (both MR and GR not occupied). SHAM operated control animals were only vehicle treated. It was found that under conditions with mainly MR occupation, expression levels of P/Q- and L-type Ca channels were decreased, expression levels of the AMPA receptor GLUR-2 versus the GLUR-1 subunit were increased and that the ratio of the NMDA receptor subunit NR2A to NR2B was also increased as compared with untreated ADX animals and ADX animals treated with high CT. This indicates that with predominant MR occupation Ca influx through voltage- and ligand-gated channels is limited and can therefore be neuroprotective. From whole-cell voltage clamp experiments performed concurrently, indications were obtained that in addition to the chronic effects of steroid treatment, Ca influx through voltage-gated Ca channels is also modulated by steroid receptor activation on a shorter time scale.

CALCIUM CHANNELS: PHYSIOLOGY, PHARMACOLOGY, AND MODULATION VI

690.1

TOXIN-RESISTANT CALCIUM CURRENTS IN MOUSE SENSORY NEURONS.
J. Valmier , C. Hilaire, S. Diochot, G. Desmadryl, C.J. Dechesne*, S. Richard, INSERM U.249, 34033 Montpellier, France

The whole-cell patch clamp technique was used to characterize toxin-insensitive calcium currents expressed in acutely dissociated embryonic (day 13) dorsal root ganglion neurons. In the presence of 3 µM GVIA, 3 µM nitrendipine and either 500 nM Aga IVA or 500 nM MVIIC that inhibited, respectively, N-, L- and P/Q-type currents, all neurons expressed a residual current, which we referred to as R-type. This current had (i) an inactivating and a sustained components, (ii) a threshold of activation and a voltage-dependent availability for activation (steady-state inactivation) at voltages comprised between that of the low voltage activated T-type calcium current and that of the high voltage activated currents, (iii) the same permeability for barium and calcium as charge carriers. R-type was insensitive to concentration of drugs inhibiting T-, N-, L- and P/Q-type currents but was highly sensitive to both cadmium and nickel. The dose-inhibition curve for these two inorganic blockers suggested the possible presence of two distinct binding sites for each of these divalent cations. Comparison of the R-type current with the current expressed following injection of different α1E subunits in oocytes, suggests that R-type channels in sensory neurons may be closely related to α1E calcium channels.

ω-AGA-AND ω-CONOTOXIN RESISTANT CALCIUM ENTRY STIMULATED BY 50mM POTASSIUM OR 10µM VERATRIDINE IN RAT CORTICAL SYNAPTOSOMES. C.Carter*, D.Fage and A.Deffois. Synthèlabo Recherche, CNS research Department, 10 rue des Carrières, BP 248, 92504 Rueil-Malmaison, France.

KCl (50mM, 10min) stimulated calcium entry in rat cortical synaptosomes, measured in a microplate fluorescence reader using FLUO-3, was insensitive to the P-type antagonist ω-agatoxin (300nM) , the N/Q antagonists ω-conotoxins -GVIIA (300µM) , -MVIIC (1µM) , -SVIB (3µM) or the L-type antagonists nifedipine (300µM) or calciseptine (1µM). ω-conotoxin -MVIIA antagonised the response (IC_{50}, 10.4µM). Nickel was a potent antagonist (IC_{50} µM) Ni^{++} (34), Co^{++} (77), Cd^{+} (110) and the response was blocked by BAY K 8644 (IC_{50}, 41.2µM) . T-type channel antagonists (IC_{50} µM) penfluridol (3.4), fluspirilene (3.5), flunarizine (4), pimozide (32), blocked the response which was also sensitive to (IC_{50} µM) lubeluzole (3.3µM), SB 201823A (4.6), and emopamil (28.5). At lower potassium concentrations others have noted P-type channel activation in synaptosomes but this may not to be the case at higher prolonged depolarisation levels. Toxin resistance may reflect reverse use dependence related to prolonged depolarisation or the activation of different calcium channels (T or R). Calcium entry was also stimulated to a similar extent by 10µM veratridine. The veratridine response had a similar pharmacology in terms of toxin resistance and sensitivity to T-type calcium channel antagonists or to lubeluzole, SB 201823A and emopamil suggesting activation of a similar type of calcium channel. The effects of veratridine (but not of potassium) on synaptosomal Ca^{++}_{int} were blocked by (IC_{50}, µM) tetrodotoxin (0.02), cinnarizine (1.5), lifarizine (4), riluzole (5), phenytoin, (70) and lamotrigine (200). The model can thus be useful to define both sodium and calcium channel antagonist activity.

690.3

EFFECTS OF THE CALCIUM CHANNEL BLOCKERS ω-AGATOXIN IVA, ω-CONOTOXIN GVIA, AND ω-CONOTOXIN MVIIC ON CHEMICALLY-INDUCED HYPERACTIVITY IN MICE. H. Ogura* Y. Furuya T. Niidome and Y. Nishizawa. Tsukuba Research Lab. Eisai Co., Ltd. Tsukuba, Ibaraki 300-26, JAPAN.

Voltage-sensitive calcium channels are widely distributed in mammalian nervous systems and calcium entry through the channels in presynaptic nerve terminals is a crucial part of neurotransmitter release. In this study, three types of calcium antagonists, ω-agatoxin IVA (P-type), ω-conotoxin GVIA (N-type) and ω-conotoxin MVIIC (O/P/Q-type), were studied to determine if they inhibit chemically-induced hyperactivity. Male ddY mice were treated intracerebroventriclarly with one of the blockers at a dose of 1 to 3 pmol/head, and then challenged 30 min later with methylphenidate, methamphetamine, phencyclidine or apomorphine. ω-Agatoxin IVA blocked methylphenidate-induced hyperactivity, while it had either weak or no effects on activation elicited by methamphetamine or phencyclidine. ω-Conotoxin GVIA antagonized methylphenidate-, methamphetamine- and phencyclidine-induced hyperactivity in a dose-dependent manner. ω-Conotoxin MVIIC was only effective at counteracting a change induced by methylphenidate. None of the blockers showed any effect on spontaneous motor activity or apomorphine-induced hyperactivity at the doses used, suggesting that the inhibitory effects of the calcium channel blockers on stimulators are unlikely to be due to nonspecific behavioral depression. Taken together, the antagonism of calcium channels, in particular N-type, is one effective way to relieve the activated dopaminergic system.

690.4

VOLTAGE-ACTIVATED CALCIUM CHANNEL CURRENTS OF RAT DORSAL ROOT GANGLION CELLS ARE REDUCED BY TRIMETHYL LEAD D. Büsselberg*, E. Gawrisch and R. Leonhardt. Physiology, University Düsseldorf and Dep. of Physiology, University Essen, Germany.

Lead is known to generate neurotoxic defects at very low concentrations. Trimethyl lead (TML) is a widely used organic lead compound. Many functions of the nervous system - including learning and memory - depend on the exact regulation of the intracellular calcium concentration. Therefore, the intracellular calcium concentration is closely regulated. Calcium enters the cell via membrane channels which are opened by ligands or by depolarisation. As we have shown in a variety of preparations, some of the actions of various metal cations result from their effects on voltage-gated calcium channels.

Using the conventional whole-cell patch-clamp recording technique with cultured neurones of rat dorsal root ganglions (DRG), we analysed the effects of TML on voltage-activated calcium channel currents.

TML reduces low- and high-voltage-activated calcium channel currents in a dose-dependent manner, with a threshold concentration below 0.5 µM and a total reduction of the current (≥ 80% of control) at concentrations above 50 µM. Half of the current is abolished at a TML concentration of ~3.5 µM. The action is irreversible and not voltage dependent. After application of TML the current decreases with each activation of the channel until a steady state is reached after 5 to 10 min, when the channel was activated every 10 sec. The channel had to be in the open state for TML to act.

TML is a potent compound for reducing voltage activated calcium channel currents. These effects of TML must be taken into account in explaining the neurotoxic effects of this organic metal compound.

690.5

DIFFERENTIAL pH_i SENSITIVITY AMONG HVA Ca^{2+} CURRENTS IN RAT HIPPOCAMPAL CA1 NEURONS. G.C. Tombaugh* and G.G. Somjen, Dept. of Cell Biology, Duke Univ. Med. Ctr., Durham, NC 27710.

The effects of intracellular pH on HVA calcium currents were examined in acutely dissociated rat hippocampal CA1 neurons (21-23°C) using the whole-cell patch clamp technique. Intracellular alkalosis was induced by exposure to NH_4Cl. During voltage ramps, increases in current amplitude occurred in the presence of NH_4Cl, reversed completely during washout, were sensitive to the level of internal pH buffering, but were unchanged when internal BAPTA was used in place of EGTA. During 200ms voltage pulses (Vh=-100mV) internal alkalosis caused a proportionally larger increase in the steady-state current compared to the peak. Neither Cd^{2+}-resistent outward currents nor HVA Ca^{2+} current decay was affected by NH_4Cl. At a depolarized holding potential (Vh=-50mV), a slowly-inactivating nifedipine-sensitive current could be evoked that increased by ~50% in the presence of NH_4Cl. In most cells, this current represented a large fraction of the total current shortly after break-in, but exhibited a more rapid rate of rundown than the remaining, rapidly inactivating (N-type?) current. The enhancement of ramp-evoked currents by internal alkalosis was time-dependent in that it increased when cells were exposed to a second NH_4Cl wash. In the presence of nifedipine (5μM), NH_4Cl triggered a much larger increase in ramp-evoked HVA currents (100%) when compared to control cells examined shortly (5-7min) after break-in (30%). These results indicate that different HVA Ca channels in mammalian neurons exhibit distinct pHi sensitivities, a feature that may provide a source of target specificity during uniform, transient shifts in intracellular pH.

690.6

ACTION OF RUTHENIUM RED ON CLASS A AND CLASS C VOLTAGE-GATED CALCIUM CHANNELS. L. Siconolfi, S.M. Cibulsky & W.A. Sather.* Dept. of Pharmacology and Neuroscience Prog., Univ. of Colorado Health Sciences Center, Denver, CO 80209.

Neurons generally possess multiple types of voltage-gated calcium channels, with each type specialized for particular tasks. To study the role of various calcium channel types in neuronal function, it is desirable to isolate single channel species during electrophysiological recording. While this is straighforward for many varieties of calcium channels, in some cases cost or antagonist availability are limiting. It has recently been reported that ruthenium red, in addition to its many other actions, can block non-L-channel mediated, Ca^{2+}-dependent neurotransmitter release from synaptosomes and synaptic transmission at the rat neuromuscular junction (Hamilton & Lundy, JPET 273: 940-7). We have studied the action of this inexpensive and readily available compound upon class A (P/Q-type) and class C (L-type) calcium channels heterologously expressed in *Xenopus* oocytes. Ruthenium red preferentially blocks class A channels, with an IC_{50} of approximately 50 nM. The IC_{50} for block of class C channels is ~70 μM. Recovery from block was extremely slow and never complete over the life time of our experiments (~20 min). Block of either channel by ruthenium red (charge = +6) showed only weak voltage dependence. (Supported by the Neuroscience Program and NIH grant NS 35245).

EXPOSURE OF NORMAL PRIMARY SENSORY NEURONS TO SERUM FROM DIABETIC RATS WITH NEUROPATHY CAUSES AN INCREASE IN CALCIUM CURRENTS AND A DECREASE IN TONIC INHIBITORY G-PROTEIN ACTIVITY. H. Ristic, K.E. Hall, A.A.F. Sima, J. Wiley*. Dept. of Internal Medicine. University of Michigan, Ann Arbor, MI.

Many reports have linked neuronal cell injury and death with excessively high cytosolic Ca^{2+} concentrations. Recent studies have demonstrated that 1) Ca^{2+} influx is enhanced in non-neuronal cell lines with exposure to serum from humans with type I diabetes (Science, 1993) and 2) Ca^{2+} entry through voltage-activated Ca^{2+} channels is enhanced in neurons from diabetic rats with neuropathy (J. Physiol, 1995). We examined whether 24 hr exposure to sera from diabetic BB/W rats with demonstrable neuropathy (nerve conduction velocity of 43.8 ± 0.6 m/s compared to age-matched control rats of 59.1 ± 0.7 m/s, $p<0.0001$) enhanced Ca^{2+} currents in dorsal root ganglion cells (DRGs) from normal SD rats (3-8 wk old). Mean whole-cell voltage-dependent Ca^{2+} currents were recorded from single DRG neurons. DRGs incubated with diabetic sera demonstrated an increased Ca^{2+} current density (140.2 ± 13.9 pA/pF, n=19) vs neurons incubated with control sera (73.0 ± 9.2 pA/pF, n=24; $p<0.01$). To explore the role of G-proteins in this effect a two-step facilitation protocol was used to modulate G-protein activity. The current elicited with a test-pulse depolarization to +10 mV from -80 mV is enhanced when preceded by a strong depolarizing pre-pulse to +90 mV from -80 mV. Facilitation of the Ca^{2+} current is due to inactivation of inhibitory G-proteins. Treatment with GDP-ß-S (prevents activation of G-proteins), blocked facilitation; whereas GTP-γ- S (promotes activation of G-proteins) increased facilitation. Neurons incubated in diabetic sera facilitated 20.5 ± 3.7% vs neurons incubated in control sera (28.4 ± 2.7%, $p<0.01$). This data suggests that neurons exposed to diabetic sera demonstrate decreased tonic regulation of the inhibitory G-protein-Ca^{2+} channel complex. The resulting enhanced Ca^{2+} current may be involved in diabetes-induced neuropathy. (NIH DK 45820 JW)

690.8

RILUZOLE, A NEUROPROTECTIVE DRUG, BLOCKS CALCIUM CHANNELS IN RAT DORSAL ROOT GANGLION NEURONS. C-S Huang*, K. Nagata, J.Z. Yeh and T. Narahashi. Dept. of Mol. Pharmacol. and Biol. Chem., Northwestern Univ. Med. Sch., Chicago, IL 60611

The effect of riluzole, a neuroprotective drug, on the high voltage-gated calcium channels of rat dorsal root ganglion neurons was studied using the whole-cell patch clamp technique. Riluzole inhibited the calcium channels in a dose- and time-dependent manner. The onset and offset of riluzole effect took more than 3 min. Following washout, a rebound of calcium currents was observed in 20 % of the cells tested. The EC50s for riluzole in inhibiting the transient and sustained high voltage-gated calcium currents were 42.6 and 39.5 μM, respectively. Riluzole shortened the time to peak of current without affecting voltage dependence of activation. It accelerated the fast deactivation kinetics without affecting the slow deactivation kinetics. It also accelerated fast and slow inactivation kinetics, and shifted the steady-state inactivation curve in the hyperpolarizing direction. Omega-conotoxin but not nimodipine abolished riluzole inhibition of the currents, indicating that riluzole selectively affects the N-type calcium currents. Riluzole inhibition of the N-type calcium currents may result in the reduction of calcium influx to presynaptic terminals thereby decreasing release of excitatory neurotransmitters. Riluzole may reduce the cellular damage by preventing excess activations of NMDA receptors, a condition known to cause neuronal death. Supported by NIH grant NS14144 and by Mitsui Pharmaceutical Co.

PROPERTIES OF HIPPOCAMPAL CA1 NEURONS IN GLUCOCORTICOID RECEPTOR KNOCKOUT MICE. W.Hesen [1], H.Karst[1,2], T.Cole[3], W.Schmid[3], E.R. de Kloet[2], G. Schütz[3] and M. Joëls*[1] Dept. Exp. Zoology, University of Amsterdam, [2] Leiden-Amsterdam Center for Drug Research, The Netherlands, and [3] German Cancer Research Center, Heidelberg, Germany.

Previous research showed that excitability of neurons in the CA1 hippocampal area is affected by selective occupation of mineralo- or glucocorticoid receptors (MRs and GRs respectively). However, with the pharmacological approach used in these studies selectivity of the receptor activation is never fully achieved. To examine electrical properties of CA1 hippocampal neurons under conditions that GRs are completely absent, we now used mice with a genetic defect in the GR obtained by homologous recombination. It appeared that in the heterozygous group of mice (with a reduced amount of GRs in CA1 neurons and chronically elevated plasma corticosterone levels) responses to the monoamine serotonin and the muscarinic analogue carbachol were significantly increased when compared to the wild type control group. The amplitude of voltage gated Ca-currents was also increased. This is reminiscent of the effects observed earlier in rats with GR occupation in addition to MR activation. We tentatively conclude that the electrical properties of CA1 neurons in heterozygous GR knockouts are governed by the relatively large degree of GR occupation, due to high corticosterone levels and fewer GRs, rather than by the absolute amount of functional GRs. In a limited amount of mice homozygous for the mutated GR we observed that responses to serotonin and carbachol were moderate, whereas voltage gated Ca-currents were large. These transmitter responses and Ca-current characteristics were comparable to those observed in tissue from adrenalectomized wild type and heterozygous GR knockouts, indicating that activation of MRs in complete absence of functional GRs does not evoke appreciable changes compared to the situation when no MRs are activated.

690.10

MODULATION OF HUMAN α_{1A}-CONTAINING CALCIUM CHANNELS BY RAT GROUP I AND II METABOTROPIC GLUTAMATE RECEPTORS IN HEK 293 CELLS. K.C. Tang*+, B.A. McCool+, G. Gerdeman+, P. Brust#, K. Stauderman#, M.A. Harpold# and D.M. Lovinger+. Dept. Mol. Physiol. & Biophys., Vanderbilt Univ. Med. School, Nashville, TN 37232+; SIBIA Inc., La Jolla, CA 92037#

Metabotropic glutamate receptors (mGluRs) inhibit N- and non-N-type voltage-gated calcium channels in rat cortical neurons and N-type channels in recombinant expression systems. To determine if mGluRs can inhibit recombinant α_{1A}-containing (P/Q-type) calcium channels expressed in HEK 293 cells, we have transiently expressed rat group I & II mGluRs (rmGluR1a, 2, 3 & 5a) in HEK 293 cells engineered to stably express the human α_{1A-2}, α_{2b}, and β_{1b} calcium channel subunit coding sequences (A68-9 cell line). Calcium currents were then examined using the whole-cell patch-clamp recording technique. Evidence for calcium channel inhibition by all four rmGluR subtypes was observed. Application of glutamate (0.1-300μM) produced inhibition of calcium current peak amplitude in 62% and 57% of the cells expressing rmGluR2 and rmGluR3 cDNA respectively whereas glutamate had no effect on untransfected cells (6 of 6 cells). Maximal percent inhibition in cells expressing rmGluR2 and rmGluR3 at 0 mV averaged 46.36±7.63 (mean±SEM) and 29.50±3.38 (mean±SEM) respectively. Inhibition by glutamate was concentration-dependent in cells transfected with rmGluR2 (EC_{50} ~ 1.12μM) and rmGluR3 (EC_{50} ~ 0.9μM). Modulation by all rmGluR subtypes was characterized by kinetic slowing and was relieved by a depolarizing pre-pulse. These findings indicate that both group I and group II rmGluRs are capable of functionally coupling to the α_{1A}-containing (P/Q-type) calcium channel in a recombinant system and that inhibition of the function of this channel type shares many characteristics with inhibition of α_{1B}-containing (N-type) calcium channels. DIFFERENTIAL CONTROL OF L-TYPE Ca^{2+} CHANNELS BY DOPAMINE D_2 RECEPTOR ISOFORMS. SJ Morris*, DE Howard, SE Hudson, DM Beatty and BM Chronwall♦ Mol Biology and Biochem & ♦Cell Biology and Biophysics, UMKC, Kansas City, MO 64110-2499

Dopamine D_2 receptors have two isoforms differing by 29 amino acids in the G-protein α-subunit binding domain in the third intracellular loop. This generates the hypothesis that the two isoforms may have different interactions with Gα subunits. Melanotropes of the rat pituitary intermediate lobe produce and secrete POMC-derived peptides. Secretion-related activities are tonically inhibited through D_2 receptors. Anterior lobe corticotropes are similar to melantropes: they produce and release POMC peptides; but they lack D_2 receptors.

To create a melanotrope-like cell line in which differential effects of D_2 receptor isoforms could be tested, we transfected corticotrope-derived AtT20 cells with either the long (D_{2L}) or the short (D_{2S}) receptor isoform. Both receptors functionally couple to acute inhibition of L-type Ca^{2+} channels (LTCC). Antisense knockouts show that this is signaled through $G\alpha_o$. Chronic (4 day) treatment of both cell lines with D_2 agonist quinperol results in inhibition of LTCC activity, which persists after the drug has been withdrawn. This is signaled through $G\alpha_{i2}$ for D_{2L} and through $G\alpha_{i3}$ for D_{2S}. Both isoforms also show some chronic inhibition linked to $G\alpha_o$. The possibility that acute inhibition is *via* a membrane delimited process and chronic inhibition involves down regulation of LTCC α-subunit genes will be discussed.

COINCIDENT SIGNALING: SYNERGISTIC EFFECTS OF DOPAMINE D_2 AND $GABA_B$ RECEPTORS ON HIGH VOLTAGE ACTIVATED CALCIUM CHANNEL ACTIVITY IN PITUITARY INTERMEDIATE LOBE MELANOTROPES. DM Beatty, S Martin, SJ Morris, BM Chronwall*. School of Biological Sciences, UMKC, Kansas City, MO 64110-2499

Melanotrope biosynthesis and secretion are tonically inhibited by dopamine D_2 and $GABA_B$ receptor stimulation. The D_2 and $GABA_B$ receptors show evidence of "coincident signaling"--synergistic, enhanced effects resulting from their simultaneous stimulation.

Synergistic effects of D_2 and $GABA_B$ receptors on acute blockade of high voltage activated Ca^{2+} channel (HVA-CC) activity was studied in cultured melanotropes by fluorescence video microscopy image analysis. K^+ depolarization produced an increase in intracellular Ca^{2+} concentration due to activation of HVA-CC (Chronwall *et al.* 1994; Beatty *et al.* 1996, in press). Acute incubation with dopamine or baclofen, a $GABA_B$ receptor agonist, reduced K^+ depolarization-induced Ca^{2+} influx. Responses were dose dependent, with dopamine being more effective than baclofen. In the presence of both dopamine and baclofen, there was a significantly greater inhibition in Ca^{2+} influx following depolarization. This reduction in Ca^{2+} influx *via* HVA-CC was also dose-dependent and demonstrated a greater inhibition than the additive effect of either drug alone.

Thus, coincident signaling by D_2 and $GABA_B$ receptors results in synergistic depression of HVA-CC activity; other secretion related activities of melanotropes could be regulated by receptor interaction.

NEUROPEPTIDE Y (NPY) MODULATION OF CALCIUM CHANNEL CURRENTS IN ISOLATED RAT VENTROMEDIAL HYPOTHALAMIC NEURONS. S.P. Aiken, G. Yasay and J.M.H. ffrench-Mullen*, Dept. of Bioscience, Zeneca Pharmaceuticals, Wilmington, DE 19850-5437.

Neuropeptide Y (NPY) is a 36 amino acid peptide involved in the central control of food ingestion. NPY injection into the third ventricle or the hypothalamic ventromedial (VMN) or paraventricular (PVN) nuclei strongly stimulates food ingestion in satiated or fasted rats; the latter are implicated as the satiety and hunger centers, respectively. NPY has also been shown to inhibit voltage-dependent Ca^{2+} channels in both mammalian peripheral and central nervous systems.

We examined the effect of NPY on voltage-gated Ca^{2+} channel currents in freshly dissociated rat VMN and PVN neurons and also in spinal dorsal horn neurons using the whole-cell patch clamp technique, with 10mM Ba^{2+} as the charge carrier. Currents were evoked in all preparations by 200 ms depolarizing steps from -80 to -10 mV. Steady-state inhibition of the peak high threshold Ca^{2+} current in the VMN by NPY increased in a concentration-dependent (1pM to 1μM; n=23) manner with a K_D of 193 pM and *nH*=0.5. NPY inhibited a fraction of the Ca^{2+} channel current with a maximal inhibition of 47±3% of the total current at 50nM; plateau inhibition was 50nM to 1μM. NPY had no effect on the activation of the Ca^{2+} channel current (n=12). In the presence of 10μm ω-conotoxin GVIA, NPY continued to inhibit the Ca^{2+} channel current, suggesting that the N-type Ca^{2+} current was not affected. Intracellular dialysis with GTP-β-S (500μM; n=14) significantly (P<0.008) diminished the 100nM and 1μM NPY-induced inhibition.

In the PVN, NPY also inhibited a fraction of the peak high threshold Ca^{2+} channel current in a concentration-dependent (100 pM - 1 μM) manner, with a K_D of 6.5nM and *nH*=0.7 (n=7); maximal inhibition was 38±5% of the total current at 100 nM. In contrast to VMN and PVN, 1μM NPY had no effect (5±1.5% inhibition; n=8) on the Ca^{2+} channel currents in isolated spinal dorsal horn neurons.

690.14

THE ARACHIDONIC ACID SIGNALING PATHWAY MEDIATES MUSCARINIC INHIBITION OF L-TYPE CALCIUM CURRENTS IN SYMPATHETIC NEURONS. Liwang Liu and Ann R. Ritttenhouse*. Dept. of Physiology, University of Massachusetts Medical Center, Worcester, MA 01655.

In rat sympathetic neurons two major signaling pathways exist by which neurotransmitters inhibit Ca currents. A membrane-delimited pathway that is voltage-dependent selectively inhibits N-type current. The second pathway involves an undefined diffusible second messenger that inhibits both N- and L-type currents (see Hille, 1994. *TINS*, 17: 531). We have been examining whether the arachidonic acid (AA) signaling pathway mediates the diffusible second messenger inhibition of L-type current. Ca currents were recorded from neonatal rat SCG neurons using standard whole cell patch clamp techniques. 20 mM Ba was used as the charge carrier and a low concentration of BAPTA (0.1 mM) was used as the internal chelator. 10 μM Oxotremorine M (Oxo-M) inhibited peak current 44±4% and dihydropyridine-enhanced tail currents 43±6 % (n=5). When the phospholipase A2 inhibitor 7,7-dimethyl-eicosadienoic acid (DME, 100 μM) was included in the bath, the inhibition of the slow tail current was significantly reduced (n=5), indicating that PLA2 activity is necessary for M1 inhibition of L-type current. DME had no effects of its own on peak or tail currents (n=4), nor on the inhibitory actions of direct application of AA. Bath application of 5 μM AA mimicked the biophysical characteristics of the inhibition of both N and L-type currents by Oxo-M. There was 1) no change in the activation (n=5) or 2) inactivation (n=10) kinetics and 3) the magnitude of the inhibition did not change with test potential. Bath application of 30 μM ETYA, an analog of AA that blocks the metabolism of AA, had no inhibitory effects of its own, however, it was unable to prevent inhibition of whole cell currents by 5 μM AA (n=4). These data are consistent with a model where AA, itself, can mediate at least a component of M1 inhibition of L-type current.

ATRIAL NATRIURETIC PEPTIDE INHIBITS Ca^{2+} INFLUX THROUGH VOLTAGE-DEPENDENT CALCIUM CHANNELS IN RAT HYPOTHALAMUS. V.A. Alvarez Maubecin[1], R. Pisnoy[1], O.D. Uchitel[1], S. Starkstein* B. Fernandez[2] and M. Vatta[2]. [1] Inst. de Biologia Celular y Neurociencias, Facultad de Medicina; [2] Cátedra de Fisiol. y Fisiopatol. (PROSIVAO-CONICET). Facultad de Farmacia y Bioquímica, Universidad de Buenos Aires and * FLENI.

Extracardiac synthesis and binding sites of Atrial Natriuretic Peptide (ANP) have been reported in some regions of the CNS involved in the regulation of blood arterial pressure, such as hypothalamus. ANP has been shown to enhance noradrenaline (NA) uptake, inhibit its synthesis and reduce evoked NA release in hypothalamic nuclei and median eminence. Many evidences suggest that ANP inhibition of NA release is through modulation of Ca^{2+} influx.

We studied the effects of ANP on $^{45}Ca^{2+}$ uptake by synaptosomes prepared from rat hypothalamus. In this preparation, the K^+-evoked Ca^{2+} uptake was strongly sensitive to ω-Aga IVA (100 nM inhibited 80 ± 4 %). ANP exerts a dose-dependent inhibition of the K^+-induced Ca^{2+} uptake (IC_{50} = 2.5 nM, maximal effect ~86% at 1 μM). No significant effect was observed on the basal Ca^{2+} uptake. On the other hand, CNP, another peptide from the natriuretic family that also inhibits K^+-evoked NA release in hypothalamus, did not show any effect on either basal or stimulated Ca^{2+} uptake. Since many of the ANP biological effects are associated with an increase in cGMP concentration, we tested the effect of a guanylate cyclase inhibitor on this preparation. Methylene Blue (MB) (100 μM) had no effect per se on the Ca^{2+} uptake in either basal or stimulated conditions. When ANP (10 nM) and MB were added together, the inhibitory effect of ANP (95 ± 10 %) was reduced to 30 ± 3 %.

We conclude that ANP inhibits the ω-Aga IVA-sensitive Ca^{2+} uptake. This effect may be mediated by a cGMP dependent pathway and it could account for the observed reduction of NA release by ANP in rat hypothalamus.

MODULATION OF CALCIUM CURRENTS BY NEUROTRANSMITTERS IN ACUTELY DISSOCIATED INTRACARDIAC NEURONS FROM ADULT RATS. R.D. Wurster* and S.W. Jeong Depts. of Physiology and Neurological Surgery, Loyola Stritch School of Medicine, Maywood IL 60153.

Voltage-activated calcium channels(VACC) are major target for the modulation of synaptic transmission by a variety of neurotransmitters because the influx of calcium ions into neuronal cells is an important signal for neurotransmitter release. Recently, intracardiac neurons have been found functionally to express multiple subtypes of calcium channels. In the present study we screened the neurotransmitters/ neuromodulators which are found in intracardiac ganglia to see if they modulate calcium currents. Using the whole-cell patch clamp technique, VACC currents were measured in the absence and presence of a number of candidates($n \geq 6$) as follows(in μM): oxotremorine, a muscarinic agonist(10); norepinephrine(NE)(1); neuropeptide Y(NPY)(1); substance P(1); calcitonin gene-related peptide(CGRP)(0.1); vasoactive intestinal peptide(VIP)(1); somatostatin(1); serotonin(5-HT)(1); met-enkephalin(EK)(1); bradykinin(BK)(1); angiotensin II(1); atrial natriuretic peptide(ANP)(0.1); SNAP, a nitric oxide donor(500); and adenosine(n=6). Among these candidates, oxotremorine, NE, NPY and EK inhibited 78.1 ± 4.9, 25.4 ± 4.2, 20.6 ± 2.4 and 44.7 ± 4.4 %(mean ± SEM) of the peak currents, respectively. Interestingly, substance P and CGRP had no effect on calcium currents although some afferent nerve fibers are known to terminate near intracardiac neurons. ANP had also no effect but tended to enhance the total current in a high concentration such as 5 μM. The inhibitory effects of neurotransmitters seem to be mediated by G-proteins because a prepulse to +100 mV relieved the inhibition of calcium currents. The pretreatment of PTX(200 ng/ml) for 24 hr prevented the inhibition of calcium currents by neurotransmitters. In conclusion, the calcium currents in rat intracardiac neurons are modulated by muscarinic, adrenergic and some peptidergic receptor activations. Supported by NIH grant 27595.

Ca^{2+} CHANNELS IN RAT SUPRAOPTIC NEURONS ARE MODULATED BY μ-, BUT NOT δ- OR κ-OPIOID RECEPTORS. B.L. Soldo* and H.C. Moises. Department of Physiology, University of Michigan, Ann Arbor, MI 48109.

Opiates are known to inhibit the secretion of vasopressin (VP) and oxytocin (OT) via their interactions with opioid receptors located on the cell bodies and nerve terminals of hypothalamic supraoptic nucleus neurons (SON). Activation of opioid receptors has been shown to inhibit Ca^{2+} influx through voltage-sensitive Ca^{2+} channels in several classes of neurons, and this could provide the mechanism whereby opiates depress Ca^{2+}-dependent neurosecretion. In this study, whole cell Ca^{2+} currents were recorded from SON neurons acutely isolated from adult rats to characterize the coupling between the different kinds of opioid receptors and specific Ca^{2+} channel types. Bath application of the μ-opioid agonist DAGO (1 μM) reversibly suppressed high threshold Ca^{2+} currents by 16 ± 2% (n=24, R_{max} =20% at 3 μM), whereas currents were unaffected by κ-opioid (U69,593, n=16) or δ-opioid agonists (DPDPE, n=6). By contrast, recordings from the terminal endings of these neurons revealed that κ-opioid receptors selectively reduce Ca^{2+} currents and depolarization-evoked secretory responses (Rusin et al, 1996). SON neurons that were sensitive to DAGO stained positive for either VP or OT; yet, Ca^{2+} currents were not significantly modified by either of these peptides (n=5 and n=3, 100-300 nM). The DAGO-sensitive component was not modified by administration of nicardipine or nifedipine (10 μM), but was significantly reduced following blockade of N-type Ca^{2+} channels by ω-CgTx-GVIA (1 μM, n=3) or of P/Q-type Ca^{2+} channels by ω-Aga-IVA (100 nM, n=3). These data suggest that postsynaptic μ-opioid receptors are negatively coupled to N- and P/Q-type Ca^{2+} channels in VP- and OT-containing SON neurons and emphasize the likelihood that Ca^{2+} channels expressed in the cell body and nerve terminal differ in both function and regulation. PHARMACOLOGICAL IDENTIFICATION OF CALCIUM CURRENTS IN ACUTELY DISSOCIATED INTRACARDIAC NEURONS FROM ADULT RATS. S.W. Jeong* and R.D. Wurster. Depts. of Physiology and Neurological Surgery, Loyola Stritch School of Medicine, Maywood IL 60153.

Voltage-activated calcium channel currents were investigated using the whole-cell patch clamp technique in acutely dissociated intracardiac neurons from adult rats. Multiple subtypes of high-voltage activated calcium(HVAC) currents were identified using different drugs and toxins. A L-type calcium channel activator FPL 64176(2 μM)(n=9) increased current amplitude, prolonged tail current decay and slowed activation and inactivation kinetics. A dihydropyridine antagonist, nifedipine(10 μM)(n=17) blocked a small portion of the total current. The major component(N-type) of calcium currents was blocked by 1 μM ω-conotoxin GVIA(ω-CgTX GVIA)(n=23). The remaining currents(P/Q-types) after blockade of L- and N-type currents, were slowly blocked by 5 μM ω-conotoxin MVIIC(ω-CgTX MVIIC)(n=8). The currents(R-type) resistant to nifedipine and all used toxins, were further blocked by 100 μM $NiCl_2$(n=4). To distinguish P type from Q type, both ω-agatoxin IVA(ω-Aga IVA) and ω-CgTX MVIIC were applied. Low concentrations of ω-Aga IVA(30 and 100 nM) were not able to block the calcium currents after over 3 min(n=4 and 7, respectively). However, a high concentration of ω-Aga IVA(1 μM) slowly blocked a portion of calcium currents(n=4) and ω-CgTX MVIIC(5 μM) was not able to block further the currents after the application of ω-Aga IVA(1 μM)(n=3). Taken together, these results suggest that Q-type, not P-type, is expressed in the intracardiac neurons. The inactivation rates(s^{-1}) for N-, Q- and R-type currents were 24.4 ± 1.9, 15.3 ± 1.7 and 38.8 ± 4.8(mean ± SEM, n=6), respectively. L-type currents showed a slow activation and non-inactivation during a 100 ms test command. In conclusion, the intracardiac neurons from adult rats functionally express four different subtypes of HVAC channels: L-, N-, Q- and R-types which contribute approximately 10, 64, 19 and 7 % of the total calcium current, respectively. Supported by NIH grant 27595.

POTASSIUM CHANNELS: EXPRESSION

691.1

THE DIVERSITY OF POTASSIUM CHANNELS MAY CONTRIBUTE TO BRAIN AREA SPECIFIC DIFFERENCES IN SEIZURE SUSCEPTIBILITY. M. Madeja*, U. Mußhoff and E.-J. Speckmann. Institut für Physiologie, Robert-Koch-Str. 27a, D-48149 Münster, Germany

The family of voltage-operated potassium channels contains a variety of members which have on the one hand different properties and on the other hand different distributions in brain. These differences might contribute to the distinct seizure susceptibility of several brain areas. In order to shed some light on this question, we have investigated the effect of the epileptogenic drug pentylenetetrazol (PTZ) on eight potassium channel types (slow and fast inactivating cloned neuronal potassium channels of the rat; expression in oocytes of Xenopus laevis; investigation with the two-electrode voltage-clamp-technique).

The investigations revealed that the potassium channels had a different sensitivity to PTZ. For example, at a potential of 0 mV there were strong current reductions for the $K_v1.1$, $K_v1.4$ and $K_v2.1$ channel, moderate for the $K_v1.3$ and $K_v1.6$ channel and small reductions for the $K_v1.2$, $K_v1.5$ and $K_v3.4$ channel. Correlating the PTZ-sensitivity of the channels with their frequency of appearance (in-situ hybridization data from literature) showed that the hippocampus, a region with a high seizure susceptibility, predominantly contains the channels with the strong sensitivity to PTZ (regression coefficient for PTZ-sensitivity of the channels vs. their frequency of appearance: positive, 0.33), whereas in the cerebellum, a region of low seizure susceptibility, the amount of channels with a low sensitivity is much more pronounced (respective regression coefficient: negative, -0.43).

Although the relevance of the above shown results has to be further elucidated, the data lead to the speculation that the different distributions and properties of potassium channels play a role in the development of different seizure susceptibility of the brain areas.

NEUROTROPHINS AND DEPOLARIZATION REGULATE Kv3.1 mRNA IN RAT BRAIN DURING DEVELOPMENT. S-Q. J. Liu* and L.K. Kaczmarek. Dept. of Pharmacology, Yale University School of Medicine, New Haven, CT 06520-8066.

Expression of the Kv3.1 potassium channel gene in rat brain has been shown to increase during development (Perney et al., J. Neurophys. 1992, 68:756). To investigate the developmental regulation of the Kv3.1 gene, we examined the ability of neurotrophins and membrane depolarization to modulate Kv3.1 mRNA levels in brain slices taken at post natal days 3, 8 and 15. Brain slices of cerebellum (CB) and inferior colliculus (IC) were incubated in ACSF containing BDNF, bFGF or 50 mM KCl for 6 hours and mRNA levels were measured using a RNase protection assay. Treatment with BDNF induced a 2-fold increase in Kv3.1 mRNA in P3 CB, but did not affect the expression at other times. Conversely, bFGF treatment caused an increase in the Kv3.1 message in the P8 CB, not at P3 or P15. Thus these neurotrophins may differentially upregulate the expression of Kv3.1 mRNA in CB. 50mM KCl treatment did not change the Kv3.1 mRNA levels in the developing CB. Interestingly, the combined treatment of P8 CB with bFGF and 50 mM KCl selectively increased the expression of the Kv3.1b transcript, in contrast to bFGF treatment alone which upregulated both the Kv3.1a and b mRNAs. These results indicate that neuronal activity may modulate the bFGF-induced regulation of Kv3.1 expression in CB. A different pattern of response was found in the IC. While the neurotrophins did not affect the levels of Kv3.1 expression, incubation in 50 mM KCl induced a 2-fold increase in the Kv3.1 mRNA in the IC at P3 and P8, but not P15. Depolarization may thus play a role in the modulation of Kv3.1 expression in the early postnatal development of the IC. (Supported by NIH).

691.3

AN ATP-DEPENDENT INWARDLY RECTIFYING K^+ CHANNEL (K_{AB}-2) IS ESSENTIAL FOR GENERATION OF ENDOCOCHLEAR POTENTIAL OF INNER EAR. H. Hibino[1,2], Y. Horio[1], A. Inanobe[3], K. Doi[2]*, M. Ito[3], T. Kubo[2], and Y. Kurachi[1,3]. [1]Dept. of Pharmacology II, and [2]Dept. of Otolaryngology, Fac. of Med., Osaka Univ., Suita, Osaka 565 and [3]Dept. of Cell Biology and Signaling, Yamagata Univ., Fac. of Med., Yamagata, Japan.

The endolymph of the inner ear has a highly positive potential of ~+80 mV, which is called the endocochlear potential (EP). High EP is essential for auditory function of the inner ear, however, the mechanism responsible for generation of the EP is still unknown. We have identified that an ATP-dependent inwardly rectifying K^+ channel, K_{AB}-2, ($K_{ir}4.1$) plays a pivotal role in generation of high EP. Perfusion of Ba^{2+}, a non-specific blocker of inwardly rectifying K^+ channels, in vertebral artery of a guinea pig caused marked depression of the EP, while neither 4-aminopyridine nor tetraethylammonium did not affect the EP. By using the reverse transcription-polymerase chain reaction (RT-PCR) and *in situ* hybridization histochemistry, we have identified the expression of mRNA of K_{AB}-2 channel in stria vascularis of rat cochlea. In the immunohistochemistry using a specific anti-K_{AB}-2 antibody, the K_{AB}-2 immunoreactivity was detected only at the invaginated basolateral membrane of marginal cells. Furthermore, K_{AB}-2 immunoreactivity was first detected in the basolateral membrane of marginal cells of 8 day-old rat and increased gradually to the saturated level at 14 day. This time-course is parallel with the elevation of the EP. These results strongly suggest that K_{AB}-2 channel play an essential role in generation of the positive EP. (supported by the grants from the Ministry of Education, Culture and Science of Japan.)

691.4

EXPRESSION OF K+ CHANNEL PROTEINS IN THE MEDIAL NUCLEUS OF THE TRAPEZOID BODY. J. Strout[1], A. Chow[2], W. Thornhill[3], M. Ellisman,[1] and B. Rudy[2]*. 1. Natl. Ctr. for Microscopy and Imaging Research, Univ. California San Diego, La Jolla, CA 92093-0608; 2. Department of Physiology and Neuroscience, New York University Medical Center, New York, N.Y. 10016; 3. Department of Physiology and Biophysics, Mount Sinai School of Medicine, New York, NY 10029.

Very few presynaptic terminals are large enough to allow electrophysiological recording. Among these is an axosomatic terminal in the Medial Nucleus of the Trapezoid Body (MNTB). Principal cells in the MNTB are innervated by large presynaptic terminals, the calyces of Held, that are projections from cells in the contralateral ventral cochlear nucleus (VCN) and surround the soma of the postsynaptic cells. Large K+ currents have been reported in both presynaptic and postsynaptic membranes, and attempts are being made to identify the underlying channels. To contribute to this effort, double labelling with markers for specific neuronal compartments and confocal immunofluorescence were used to help determine the subcellular localization of several K+ channel subunits in the rat MNTB. The studies include proteins of the Kv family, subunits of voltage-gated K+ channels, such as Kv3.1b, as well as members of the inward rectifying family, such as GIRK1. Kv3.1b, a member of the Kv3 or Shaw-related subfamily of Kv proteins, which produces in heterologous expression systems high voltage-activating K+ channels, is expressed mainly in the postsynaptic membrane as well as in the axons of the postsynaptic cell in the adult rat. There is little staining of the dendrites of the MNTB neurons. This pattern is consistent with the somatoaxonal distribution of Kv3.1b proteins in other neuronal populations in the CNS. However, although neurons in the VCN have Kv3.1b mRNA transcripts and proteins, there is little staining of the calix of Held. GIRK1 proteins, components of G-protein activated K+ channels, are also present in both the VCN and the MNTB. The pattern of staining with antibodies against GIRK1 is consistent with presynaptic staining in MNTB neurons. This research was supported by NIH Grants RR04050, NS14178, and NS26739 (MH), NS30989 (BR), NS29633 (WT), and an NSF Graduate Fellowship (JS).

691.5

TEMPORAL EXPRESSION AND LOCALIZATION OF A MURINE *SHAKER*-LIKE K^+ CHANNEL (mKv1.1) DURING EMBRYONIC DEVELOPMENT. Janice Hallows and Bruce L Tempel* VM Bloedel Hearing Research Center, Dept. of Otolaryngology, Box 357923, University of Washington, Seattle, WA 98195-7923

Various voltage-gated K^+ currents have been described in mammalian embryos, but little is known regarding the molecular identity of the channels responsible for these currents. We have performed RNAse protection assays (RPA) to demonstrate that mKv1.1, a *Shaker*-like K^+ channel, is expressed embryonically, with 2 periods of relatively high expression (embryonic day (E)9.5 and E14.5), separated by a period of relatively low message levels. This modulation of mKv1.1 expression is confirmed by *in situ* hybridization experiments. At E9.5, robust signal is detected throughout the forming neural tube. At E10.5, coinciding with the low point of message assayed by RPA, only moderate expression is detected in the thalamus, hypothalamus, tectum of the mesencephalon, and isthmus. At E14.5, mRNA is widely distributed in the embryonic nervous system, and is particularly prevalent in sensory structures. Regions of high expression include the cerebral cortex, hippocampus, pineal, trigeminal ganglia, dorsal root ganglia, and spinal cord. Moderate levels are found in the superior colliculus, inferior colliculus, pituitary, and epithelium of the tongue. These results are being extended by using antibodies specific to mKv1.1 to examine the cellular and subcellular location of mKv1.1 protein in the mouse embryo. Supported by NIH grants NS27206 (BLT) and GM07750 (JH).

691.6

XENOPUS KV3.3 POTASSIUM CHANNEL TRANSCRIPTS ARE DEVELOPMENTALLY UPREGULATED IN THE EMBRYONIC SPINAL CORD. D. Gurantz* and N.C. Spitzer. Department of Biology and Center for Molecular Genetics, UCSD, La Jolla CA 92093.

The developmental increase in density of delayed rectifier potassium current (I_{KV}) and inactivating A current (I_{KA}) in embryonic *Xenopus* spinal neurons shortens the action potential duration and thereby limits the calcium influx governing neuronal differentiation. Development of I_{KV} is dependent on RNA synthesis. Moreover mRNAs of Kv1.1 and Kv2.2 are upregulated during development of the current in subpopulations of neurons, indicating that the Kv1 and Kv2 gene subfamilies may contribute to I_{KV}. To determine whether other gene subfamilies contribute to developmental increases in potassium current, we have cloned a Kv3 gene and followed its embryonic expression. Using RT-PCR with degenerate primers to conserved sequences in the pore region and in S6, a 102 bp DNA fragment was generated for screening of a *Xenopus* tadpole brain cDNA library. The resulting 1.8 kb partial clone extends from 130 aa 5' to S1 to the poly A tail and has 74% aa sequence identity to the rat Kv3.3a gene. This homologous rat gene encodes a slowly inactivating potassium current. Using an RNA probe derived from this clone, the presence of transcripts in the spinal cord region was examined by whole mount *in situ* hybridization at three stages: neural plate (E15), neural tube (E22-23) and tailbud (E32-34). These stages encompass the period during which both I_{KV} and I_{KA} develop. Expression is first detected at stages 22-23 and appears only in the anterior spinal cord. By stages 32-34, the gene is expressed throughout the spinal cord in an anterior-to-posterior gradient. Examination of expression of the gene in cultured spinal neurons by single cell RT-PCR shows that 50% of the neurons express the gene at one day in culture (equivalent to stages 32-34). At this age I_{KV} is fully developed in all neurons and I_{KA} is expressed in 50% of neurons. The contribution of the gene to endogenous potassium currents will be further investigated. Supported by NS07220 (DG) and NS25916 (NCS).

ADENOVIRUS-MEDIATED EXPRESSION OF NEURONAL POTASSIUM CHANNELS IN PRIMARY AND SECONDARY CELL CULTURES. M. U. Ehrengruber*, M. C. Jasek, Y. Xu, S. J. Stary, C. A. Doupnik, J. Garvey, H. A. Lester and N. Davidson. Div. Biol. 156-29, Caltech, Pasadena, CA 91125.

Heteromeric G protein-activated inwardly rectifying K^+ channels (GIRKs) are important in modulating cellular excitability. GIRK1 was originally cloned from rat atrium where it forms a heteromultimer with GIRK4. The family members GIRK1, GIRK2, GIRK3, and GIRK4 are expressed in the brain. To study the role of GIRKs in neuronal synaptic transmission, we plan to use recombinant adenovirus for *in vitro* and *in vivo* ectopic overexpression of GIRKs. We have inserted GIRK1 and GIRK2 cDNA under the control of a CMV promoter into adenovirus. An adenoviral vector with a *Shaker* K^+ channel cDNA was also constructed. We infected primary cultures of rat atria and ventricle cells, and secondary cultures of pancreatic βTC3, HEK 293, CHO, and Hela cells with these adenoviral recombinants. *Shaker* peak currents of several nA were recorded in all cell types 1-2 d after infection. To test the GIRK1 recombinant we cotransfected CHO cells with plasmids carrying cDNA for GIRK4 and m2 acetylcholine (ACh) receptor, and infected them with GIRK1. ACh-activated GIRK currents of up to 1 nA (at -120 mV and 25 mM $[K^+]_o$) were found, proving that our GIRK1 adenovirus is useful for ectopic overexpression. The GIRK2 adenovirus, however, induced no GIRK currents in combination with GIRK1, and no GIRK2 protein was detected by immunoblots. By contrast, total RNA from infected cells expressed GIRK2 currents in *Xenopus* oocytes. Significant GIRK currents were detected in cells cotransfected with GIRK1 and GIRK4, but not with GIRK1 and GIRK2, nor with GIRK2 and GIRK4. Thus an unknown mechanism interferes with expression of our GIRK2 adenoviral construct in mammalian cells. We are now constructing an adenovirus carrying GIRK4 cDNA to allow ectopic expression of GIRK currents by coinfection with GIRK1 and GIRK4.

EXPERIMENTAL LOCALIZATION OF K^+ CHANNEL α- and β- SUBUNIT POLYPEPTIDES IN THE RAT HIPPOCAMPUS. M.M. Monaghan*, J.S. Trimmer†, and K.J. Rhodes. CNS Disorders, Wyeth-Ayerst Res., Princeton, NJ 08543 and †Dept. Biochem. and Cell Biol., SUNY, Stony Brook, NY 11794.

In the present study we examined the association of the Kv1.1, Kv1.2, Kv1.4, Kvβ1, Kvβ2, and Kv2.1 voltage-gated K+ channel subunits with intrinsic and afferent connections of the rat hippocampus. Unilateral intrahippocampal or entorhinal lesions were made using ibotenic acid (10 μg/μl; 0.1-0.4 μl/injection). Unilateral fornix transections were made using a Scouten wire knife. After a seven day survival, animals were perfused, and the brains were sectioned and processed to visualize K^+ channel subunits and acetylcholinesterase (AChE) using standard immunohistochemical and histochemical techniques.

Lesions of entorhinal cortex eliminated the prominent band of Kv1.1, Kv1.2, Kv1.4 and Kvβ2 immunoreactivity (IR) in the middle third of the molecular layer of the dentate gyrus (DG), indicating that in the DG these subunits are associated with entorhinal afferents. Lesions of the DG eliminated Kv1.1, Kv1.4 and Kvβ1 IR in stratum lucidum of CA3, indicating that these three subunits are associated with the mossy fiber pathway. Lesions of CA3 reduced the density of Kv1.1 IR in stratum radiatum, indicating that Kv1.1 is associated with Schaffer collaterals. Moreover, lesions of CA3 and CA1 eliminated Kvβ2 and Kv2.1 IR within the lesion site, indicating that these subunits are localized on the somata and dendrites of hippocampal neurons. Fornix lesions reduced the density of AChE reaction product, but did not have a dramatic effect on the distribution of any of the K+ channel subunits. Taken together, these findings indicate that the heterogeneity of K^+ channel complexes associated with afferent and intrinsic hippocampal projections may contribute to the distinct electrophysiological properties of these pathways.

DEVELOPMENTAL DISTRIBUTION OF A MOUSE POTASSIUM CHANNEL β-SUBUNIT mRNA. D.M. Butler[1], J.K. Ono[1,2], T. Chang[1], R.E. McCaman[1] and M.E. Barish[1]*. [1]*Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010, and* [2]*Department of Biological Science, California State University, Fullerton, CA 92634.*

Accessory β-subunits associated with the channel-forming α-subunits of multimeric potassium channels influence both the kinetics of these channels and their targeting/insertion into the plasmalemma. To better understand the role of potassium channel β-subunits in the differentiation of excitability, we have cloned the mouse homologue of a rat potassium channel β-subunit (Ono et al., in preparation) and localized β_1 mRNA. In situ hybridization of digoxigenin-labeled cRNA probes to frozen sections of mouse brain, taken from animals between stages embryonic day 16 and adult, was carried out on fixed brain (4% paraformaldehyde via cardiac perfusion) with 2 pmol/ml β_1 probe for 36 hours at 50°C. In adult mice β_1 mRNA is localized to CA1, CA3, and dentate gyrus of the hippocampus, caudate putamen, cerebellar Purkinje cells, cerebral cortex, and colliculus; this pattern is established by P23. Prior to this time, β_1 mRNA is detected at E16 in the subplate, and by P1 in hippocampus. Within the hippocampus, the mature distribution (CA1 > CA3) is not noted until P23. A more complete chronology is presented in the table. The appearance of β_1-subunit mRNA in hippocampus during the first three weeks of postnatal development could be related to the maturation of potassium currents that occurs during this same period. This work was funded by NIH R01 NS23857 to MEB, NSF IBN-9408133 to JKO, and funds from the Beckman Research Endowment to REMC.

CREATION OF A DOMINANT NEGATIVE MUTANT Kv2.2 SUBUNIT. J.T. Brittan*, and A.B. Ribera. Department of Physiology C-240, University of Colorado Health Sciences Center, Denver, CO 80262.

Sensory, motor and interneurons of the developing amphibian spinal cord regulate the development of electrical excitability in a synchronous manner. Maturation of the delayed rectifier potassium current is crucial in effecting the developmental changes that result in action potentials of shorter duration.

In contrast to the homogeneous electrical behaviour of the spinal neurons, their potassium channel gene expression is heterogeneous. Both Kv1.1 and Kv2.2 transcripts localize to the developing *Xenopus* neural tube. In addition, overexpression of a dominant negative mutant Kv1.1 subunit results in complete suppression of the delayed rectifier potassium current in only ~20% of spinal neurons (Ribera, 1996), suggesting that other non-Kv1 subunits contribute to the functional channel population *in vivo*.

In order to determine whether members of the Kv2 subfamily encode functional endogenous potassium channels, a dominant negative mutant Kv2.2 subunit has been created for the purpose of overexpression in the developing *Xenopus* embryo. Initial mutagenic attempts focused on changing a single tryptophan residue within the pore to a phenylalanine as the analogous mutation in Kv1.1 resulted in a dominant negative subunit. When expressed in the oocyte, however, mutant Kv2.2 channel homomultimers still conducted ionic current. The next approach involved mutation of the tryptophan residue to a cysteine. This resulted in a subunit that, although nonfunctional, was not dominant negative. Two amino acid substitutions within the Kv2.2 pore were ultimately required to create a mutant with the desired properties. Analysis of the current amplitudes obtained on coexpression of different ratios of wildtype : double mutant RNA in the oocyte suggest that two mutant subunits suffice to make the resulting heteromer nonfunctional. A pharmacological assay is being used to provide an independent test of the potency of the mutant subunit.

DIFFERENTIAL EFFECTS OF ACUTE AND CHRONIC ELECTROCONVULSIVE SHOCK ON THE GENE EXPRESSION OF VOLTAGE-ACTIVATED POTASSIUM CHANNEL SUBUNITS IN THE RAT BRAIN Q. Pei, P.W.J. Burnett, D.G. Grahame-Smith, T. Sharp and T.S.C. Zetterström. Oxford University SmithKline Beecham Centre for Applied Neuropsychobiology, University Department of Clinical Pharmacology, Oxford, OX2 6HE. (Spon: BRA)

The effect of acute and chronic electroconvulsive shock (ECS) on the abundance of mRNAs encoding voltage-dependent potassium channel subunits in the rat brain was determined by in situ hybridization histochemistry with ^{35}S-labelled oligonucleotides at 6h, 24h and 3 weeks following the last shock. The mRNA levels of two voltage-dependent potassium channel subunits, Kv1.2 and Kv4.2, were altered by ECS compared to sham-ECS controls but in different manners. In acute ECS experiments, Kv1.2 and Kv4.2 mRNA abundance in dentate gyrus was reduced by 50%, 6h following the shock and returned to control levels 24 h later. In chronic ECS-treated rats, Kv1.2 mRNA abundance showed similar changes to those in acute ECS: it was reduced 6h after the last shock and recovered 24 h after. Kv4.2 mRNA abundance, however, showed adaptive changes: 6h after the last shock there were no changes in its abundance while 24 h after the last shock there was a significant increase by 47% in the dentate gyrus. The changes in Kv1.2 and Kv4.2 mRNA abundance following ECS observed in dentate gyrus were not detected in CA1 and CA3 of hippocampus or cortex. Two other potassium channel subunits, Kv1.1 and Kv1.4, were not affected by either acute or chronic ECS.

ABSENCE OF I_{KA} IN CULTURED PRIMARY RAT HIPPOCAMPAL NEURONS FOLLOWING INFECTION WITH A REPLICATION DEFECTIVE HERPES SIMPLEX VIRUS VECTOR ENCODING A GENE FOR AN ANTIMORPH K^+ CHANNEL SUBUNIT. D.R. Beers[1*], E.D. Di Pasquale[2], and J.L. Noebels[1,2]. [1]Dept. of Neurology and [2]Div. of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

Deletion of viral ribonucleotide reductase (RR$^-$) renders herpes simplex virus type 1 (HSV-1) incapable of replicating in post-mitotic neurons. Membrane conductances were recorded from neurons following the expression of an engineered dominant-negative *Aplysia* K^+ channel subunit (gift from P. Pfaffinger) inserted within an RR$^-$ HSV-1 vector. This *Shaker*-type K^+ channel subunit has a T to A point mutation changing a valine (GTT) to an aspartic acid (GAT) in the putative pore region of the channel. Cultured rat hippocampal neurons were infected with the vector at a multiplicity of infection equal to 1 and studied under voltage clamp mode 2 days post infection. The parent virus (PV), identical to the vector except with *lacZ* replacing the K^+ channel subunit, was used as a control. All recordings were performed in a solution containing TTX, TEA, and Co^{2+}. Following infection, I_{KA} was absent in 13/17 neurons with only TEA-insensitive delayed rectifier currents remaining. No significant differences in cell capacitance, input resistance, and mean resting potential were noted between neurons infected with the HSV-1 encoded K^+ channel subunit and those infected with the PV. Although the PV did not alter half activation or half inactivation when compared to uninfected neurons, there was a significant modification in the rate of I_{KA} inactivation. When combined into tetramers with itself or native *Shaker*-type subunits, the expression of this construct should result in the elimination of only *Shaker*-type K^+ currents. However, the data suggest that it may also eliminate other I_{KA} currents. *Supported by the National Multiple Sclerosis Society and the Phillippe Foundation.*

HIGH-CONDUCTANCE CALCIUM-ACTIVATED POTASSIUM CHANNELS IN RAT BRAIN: PHARMACOLOGICAL PROFILE, QUANTIFICATION OF EXPRESSION, SUBUNIT COMPOSITION AND FUNCTIONAL IMPLICATIONS. Robert O.A. Koch[1], Alexandra Koschak[1], Siegmund G. Wanner[1], Gregory J. Kaczorowski[2], Reilinde Wittka[3], Maria L. Garcia[2] & Hans-Günther Knaus[1*§] [1]Institut. Biochem. Pharmakologie, Innsbruck, Austria; [2]Dept Membrane Biochemistry & Biophysics, MERCK Res. Lab. Rahway, NJ, 07065, USA.; [3]Troponwerke GmbH, Cologne, Germany

In rat brain, high-conductance Ca^{2+}-activated K^+ (*Slo*) channels are targeted to axons and nerve terminals (Knaus HG et al., (1996) *J.Neurosci.* **16**, 955-963) but the absolute levels of regional expression, subunit composition, and function are not yet fully established. To investigate these subjects, we introduce an iberiotoxin analogue ([^{125}I]IbTX-D19Y/Y36F) which selectively binds to neuronal *Slo* channels with high affinity (K_d 21 pM). Quantitative autoradiography reveals the highest levels of *Slo* channel expression in the outer neocortical layers, hippocampal perforant path projections, and the interpeduncular nucleus. This distribution pattern is confirmed in immunocytochemical experiments using a *Slo*-selective antibody. Covalent labeling experiments by [^{125}I]IbTX-D19Y/Y36F in conjunction with deglycosylation and immunoprecipitation studies demonstrate the existence of a novel, heavily glycosylated neuronal *Slo* channel ß-subunit with an apparent molecular weight of 25 kDa. In neocortical pyramidal neurons, block of *Slo* channels by IbTX results in broadening of action potentials through retardation of the bottom two thirds of the repolarization phase. These findings imply that neuronal *Slo* channels show a restricted distribution in brain, display a different subunit composition than their smooth muscle congeners, and serve an important role in neuronal repolarization. §supported by FWF grants S6611-MED and P11187-MED and by APART.

AGGREGATES OF POTASSIUM CHANNELS IN EMBRYONIC XENOPUS MUSCLE CELLS, M. Fry and F. Moody-Corbett*. Division of Basic Medical Science, Faculty of Medicine, Memorial University, St. John's, NF A1B 3V6.

Not all membrane proteins are evenly distributed in the membrane; often proteins are aggregated into patches of high density. This is particularly apparent in excitable cells. For example, in skeletal muscle both the receptors to the neurotransmitter acetylcholine (ACh) and the sodium channels involved in the action potential are aggregated in a high density at the site of nerve-muscle contact. The purpose of the present study was to determine if potassium channels, like ACh receptor channels, are present in high density patches in the membrane of embryonic muscle cells. *Xenopus* muscle and nerve cells were isolated from one day old embryos and grown in culture. Macroscopic currents were recorded from tight seal-macropatches on nerve-contacted and non-contaced muscle cells. Electrodes, which varied in resistance from 1MΩ to 5MΩ, were filled with extracellular recording solution (140mM NaCl, 5mM KCl, 1.2mM Mg Cl_2, 1.0mM $CaCl_2$, 10mM HEPES, pH 7.4). It was found that much of the surface area passed very little current in response to a sequence of hyperpolarizing or depolarizing pulses. However, macropatches were found in which there were large inward or outward potassium currents. These results suggest that these macropatches have a higher density of potassium channels than other areas of the membrane and like ACh receptors and sodium channels, potassium channels aggregate into regions of high density. MICROHETEROGENEITY IN HETEROMULTIMERIC ASSEMBLIES FORMED BY *Shaker* (Kv1) AND *Shaw* (Kv3) SUBFAMILIES OF VOLTAGE-GATED K^+ CHANNELS. M. Shahidullah*, N. Hoshi, S. Yokoyama, and H. Higashida. Dept. of Biophysics, Neuroinformation Res. Inst., Kanazawa Univ. Sch. of Med., Kanazawa 920, Japan

It has been proposed that tetrameric assemblies of voltage-gated K^+ channels can be formed not only by homomeric, but also by heteromeric subunits within subfamilies, which could give rise to the diversity of K^+ channels. Also, it has been shown that Drosophila channels belonging to these different subfamilies do not form heteromultimeric K^+ channels. We have isolated two cDNAs encoding voltage-gated K^+ channels from NG108-15 cells: NGK1 (Kv1.2) and NGK2 (Kv3.1a). In oocytes injected with both NGK1- and NGK2-specific mRNAs, a whole-cell outward current which cannot be explained as a simple sum of NGK1 and NGK2 voltage-dependent K^+ current is recorded, suggesting that channels subfamilies, may form heteromultimers. To obtain more direct evidence for this hypothesis, we attempted to record single K^+ channels in the inside-out configuration of the patch voltage-clamp method, in oocytes injected with both mRNAs. A new class of channels of 18 pS conductance was observed, and was designated as NGK1,2 channels. According to their properties of activation voltages and open life times, four types of NGK1,2 channels with microheterogeneity were detected. The results suggest that voltage-dependent NGK1 and NGK2 channels, from different subfamilies, assemble to form heteromultimeric K^+ channels at a single channel level.

IDENTIFICATION OF VOLTAGE-GATED K^+ CHANNELS CONTAINING Kv3 SUBUNITS IN NEURONS FROM THE GLOBUS PALLIDUS. R. Hernández-Pineda, A. Hernández-Cruz, H. Moreno* A. Chow and B. Rudy. Instituto de Fisiología Celular, UNAM, CU, México city 04510, D.F. México, and Dept. of Physiology and Neurosciences, NYU Medical Center NY, NY,10016 USA.

A combined immunohistochemical and electrophysiological approach was used to identify native K^+ channels containing subunits of the Kv3 subfamily of K^+ channel proteins in neurons from the rat globus pallidus (GP). Previous studies have shown that in GP neurons, Kv3.1b and Kv3.2 proteins have a somatic membrane localization and are abundantly expressed. Whole-cell patch-clamp recordings of K^+ currents were obtained from acutely dissociated GP neurons. The currents were recorded in the presence of TTX to block Na^+ currents. Extracellular Cd^{2+}, and internal BAPTA were also used to prevent the activation of Ca^{2+}-dependent conductances. From a holding potential (HP) of -80 mV, all GP cells showed low voltage-activating "A" type K^+ currents as well as a delayed-rectifier type component. A HP of -40 mV removed the A-type component, remaining only the delayed rectifier current. Current components likely to result from the expression of Kv3 subunits were identified by their high sensitivity to external TEA (1mM). In many neurons, the TEA-sensitive component of the current observed when the HP was -40 mV had a voltage dependence and kinetics strongly resembling those of the K^+ currents observed in CHO cells transfected with Kv3.1 or Kv3.2 cDNAs. In these cells the currents do not inactivate significantly when the HP is changed from -80 to -40 mV, and were nearly completely blocked by 1 mM TEA. In some GP neurons the TEA-sensitive component also included a high voltage-activating, fast-inactivating K^+ current that resembles currents expressed by Kv3.4 proteins in heterologous expression systems. Single-cell RT-PCR will be used to explore whether these neurons express Kv3.4 transcripts. Supported by grants from CONACyT México (400-346-5-2366PN) and NIH (NS-30989) USA.

PRENATAL EXPRESSION OF THE BRAIN INWARDLY RECTIFYING K^+ CHANNEL (BIRK1) IN THE RAT CEREBRAL CORTEX. V Kowtha[1]* W Ma[2] L Zhang[3] and JR Clay[2]. [1]Naval Research Lab, Code 6900, Washington, DC 29375, [2]Lab of Neurophysiology, NINDS, NIH, and [3]Biological Psychiatry Branch, NIMH, NIH, Bethesda, MD 20892.

Two brain-specific inwardly rectifying K^+ channels (BIRK1 & BIRK2) have recently been cloned (Bredt, et al., *PNAS*, 92:6753, 1995; Cohen, et al., *Soc. Neurosci. Abstr.* 21:1324, 1995). BIRK1 mRNA is found in all brain regions of the adult rat with highest levels in the brainstem (Bredt, et al., *ibid*). We have extended the BIRK1 work to the embryonic rat brain with *in situ* hybridization and immunocytochemistry. These results were obtained from coronal sections through the cerebral cortex of embryonic (E) rats at days 13,14,15,17, and 20. Both the *in situ* signal for BIRK1 and immunoreactivity were first detected in the ventricular zone (VZ) of the cortex at E15. BIRK1 signals increased steadily in the VZ and appeared in the cortical plate at E17. At E20 significant levels of BIRK1 signals were seen in the VZ, subventricular zone and cortical plate. The early appearance of BIRK1 mRNA and immunoreactivity in both the germinal matrix and the matured cortical zone suggests an involvement of BIKR1 in cell proliferation, migration, and differentiation of the cortex.

REGULATION OF VOLTAGE-GATED POTASSIUM CHANNELS IS DIFFERENT IN ASTROCYTE CULTURES DERIVED FROM SPINAL CORD AS COMPARED TO CORTEX. S.D. Collins*, X. Zhang, D.M.D. Landis and A.S. Chang Dept. Neurology, Case Western Reserve University and Rammelkamp Center., Metrohealth Medical Center, Cleveland, Ohio 44106

We investigated the expression of inwardly and outwardly rectifying K channel families, including the presumed "glial specific" inward rectifier, Kab-2, in cultures of astrocytes derived from P0 rat spinal cord or cortex using an RT- PCR approach.

Astrocyte cultures were prepared with methods designed to eliminate macrophages, oligodendrocytes and astrocyte precursor cells; 95% of the cells in confluent cultures expressed glial fibrillary acidic protein immunoreactivity. We amplified mRNA under conditions which provided linear yields of target sequences. Amplification of cyclophilin provided the basis for semi-quantitative comparisons of mRNA expression. Amplimers were designed for the Kv and Kir families as well as the glial specific inward rectifier, Kab-2.

Since cAMP and bFGF have been shown to regulate some K channels in cardiac and pituitary cells, mRNA levels were measured following treatment with those agents. We found bFGF to decrease expression of Kv,Kir and Kab-2 mRNA in cortical but not spinal cord derived astrocytes. The stable analogue cpt-cAMP decreased spinal cord but not cortical Kv, Kir and Kab-2 expression. We are extending these findings by Southern blot analysis and nucleotide sequencing to structurally identify individual channels regulated under these conditions.

Funded by a Department of Obstetrics and Gynecolgy, MetroHealth Medical Center grant-in-aid to S.D.C.

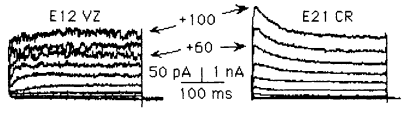
K CHANNEL EMBRYOGENESIS IN RAT TELENCEPHALON, AN IN SITU WHOLE-CELL VOLTAGE-CLAMP STUDY. J-M Mienville*, JR Clay and JL Barker, Lab of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

We studied K currents (I_K) in the embryonic (E) telencephalon with *in situ* patch-clamp techniques. I_Ks were found at E12 and increased in density with highest densities observed in E21 Cajal-Retzius (CR) cells. Fast inactivating I_Ks (I_A) developped in a similar manner, with CR cells having the highest peak / steady-state current ratio. Curiously, steady-state inactivation of I_A occurred at very negative voltages (V½ ~ -100 mV). Ventricular zone (VZ) cells displayed a combination of slowly activating I_Ks (I_{DR}) and noisy, sustained I_Ks sensitive to $[Ca_i]$ (I_{BK}). An important issue of this study is to determine whether I_Ks fullfill targeted functions at specific stages of nervous system development.



691.20

NERVE AXON EXCITABILITY RE-EXAMINED. JR Clay*, Lab of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

Surprisingly, sustained depolarizing current elicits only a single spike from squid giant axons, regardless of pulse amplitude. In contrast, the Hodgkin and Huxley model (HH) predicts a steady train of AP's over a broad range of suprathreshold pulse amplitudes. The primary reason for this discrepancy concerns I_K. 90% activation of I_K in HH occurs at +60 mV (threshold is -60 mV). No native or wild type I_K has an activation curve this broad. The reason for this discrepancy is that the I_K IV relation is non-linear - consistent with the GHK equation (Clay, 1991, *J. Physiol.*,444: 499), rather than the linear dependence upon $(V-E_K)$ found by HH. Normalization of I_K records by GHK gives an activation curve with 90% activation at -10 mV, and a steep rising phase at ~ -50 mV, which acts as an impedance shunt during sustained depolarization, thereby shortcircuiting I_{Na} as the membrane potential approaches threshold a 2nd time during a sustained current pulse. The position of the I_K activation curve on the voltage axis determines the response type of the axon: tonic firing in response to a sustained stimulus for a relatively positive midpoint of I_K ($V_{1/2}$); or rapid accomodation in the case of squid axons, which have a relatively negative $V_{1/2}$.

ACETYLCHOLINE RECEPTORS: MUSCARINIC—STRUCTURE/FUNCTION II

692.1

EFFECT OF L-NAME ON FUNCTIONALLY CHARACTERIZED MUSCARINIC RECEPTORS IN ANESTHETIZED CATS. Michael C. Koss*. Department of Pharmacology, University of Oklahoma College of Medicine, Oklalahoma City, OK 73190.

This study was undertaken to determine if the nitric oxide (NO) synthase inhibitor, L-NAME, is a competitive antagonist of muscarinic receptors *in vivo* (Buxton et al., Cir. Res. 72: 1993). Cats were anesthetized with pentobarbital (36 mg/kg, i.p.). Five peripheral muscarinic responses were characterized based on their sensitivity to i.v. atropine (1-100 μg/kg), pirenzepine (1-100 μg/kg) and gallamine (30-3000 μg/kg) as follows: 1) muscarinic ganglionic transmission to the nictitating membrane (M_1), 2) vagal bradycardia in spinalized cats (M_2), 3) neurally evoked sudomotor (EDR) responses (M_3; non-endothelial), 4) pupillary diameter (M_3; non-endothelial) and 5) methacholine depression of arterial blood pressure (M_3; endothelial). Following receptor characterization, we determined if a high dose of L-NAME (50 mg/kg, i.v.) would alter activation of these systems. L-NAME was devoid of effect on responses elicited by stimulation of M_1, M_2, and M_3 (non-endothelial) receptors. In contrast, L-NAME significantly reduced the depressor responses to i.v. methacholine (M_3; endothelial). These results support the conclusion that L-NAME does not block muscarinic receptors *in vivo*.

Supported by NIH grant EY09344.

CROSSTALK AMONG SEVERAL TRANSDUCTION PATHWAYS OF THE m1 MUSCARINIC RECEPTOR (m1AChR) ENHANCES β-AMYLOID PRECURSOR PROTEIN (APP) SECRETION. A. Fisher*, R. Haring, Z. Pittel, D. Marciano, N. Eshhar, # Y. Kloog and E. Heldman Israel Inst. Biol. Res., Ness-Ziona, # & Tel Aviv Univ, Israel.

AF102B (a selective m1 agonist) and carbachol induce APP secretion in PC12 cells expressing the m1AChR. This effect is enhanced by NGF (Haring et al, BBRC 213:15, 1995) or bFGF. Since growth factors and muscarinic agonists activate different receptors, the enhancement of the m1AChR-induced APP secretion by growth factors has to occur intracellularly. To this end, the protein kinase inhibitor K252a potentiated the muscarinic-induced APP secretion, inhibited the augmentation induced by NGF, but had no effect on the increment induced by bFGF. Moreover, K252a potentiated tyrosine phosphorylation of several proteins > 50kDa and enhanced m1AChR-mediated tyrosine phosphorylation. Genistein, an inhibitor of tyrosine phosphorylation, effectively inhibited m1AChR-induced APP secretion. In addition, FTS, an inhibitor of *ras* activation, also inhibited m1AChR-induced APP secretion, but this inhibition was reversed by K252a. Thus both *ras* activation and tyrosine phosphorylation participate in transduction pathways that mediate m1AChR-induced APP secretion. GF109203X, a specific inhibitor of PKC, inhibited partially the muscarinic-induced APP secretion but fully inhibited APP secretion induced by PMA. On the other hand, K252a, an inhibitor of PMA-induced APP secretion, still potentiated m1AChR-induced APP secretion. All these results indicate that: i) several transduction pathways mediate APP secretion via the activation of m1AChR; ii) tyrosine phosphorylation lies downstream from the *ras* activation and PKC; iii) the transduction pathways converge, and when activated in parallel, the signal is intensified at the convergence point; iv) transduction pathways of the growth factors also converge with the m1AChR-transduction pathways, resulting in an intensification of the muscarinic-induced APP secretion in presence of growth factors. These data add further support to the potential of m1 agonists, (*e.g.* AF10B) in the treatment of Alzheimer's disease.

Supported in part by Snow Brand, Japan.

692.3

IN VIVO BINDING OF ^{3}H-SCOPOLAMINE TO MUSCARINIC RECEPTORS IN RAT BRAIN, R.A. Duffy, R.D. Smith, M.E. Grzelak* and R.D. McQuade. Schering-Plough Research Institute, 2015 Galloping Hill Road, Kenilworth, N.J. 07033.

In vivo binding was utilized to study muscarinic receptor occupancy in rat brain. Rats were dosed s.c. with 10 μCi ^{3}H-scopolamine in the presence or absence of muscarinic antagonists. One hr. later, rats were sacrificed and bound radioactivity was determined in heart and brain. Time course studies demonstrated that the binding of ^{3}H-scopolamine was significantly different in heart versus brain. Binding in heart peaked within 5 min. of dosing and had disappeared within 2 hrs., while binding to brain peaked 2 hrs. after dosing and persisted for up to 24 hrs. Binding at these later time points was still sensitive to inhibition by unlabeled scopolamine given 30 min before sacrifice. These findings suggest that scopolamine has a lower affinity for heart (m2) receptors and that binding to brain receptors (m1, m4) is of high affinity and long duration.

Competition studies in vivo indicated that the relative potencies of muscarinic antagonists to inhibit ^{3}H-scopolamine binding in rat brain is correlated with the abilities of these compounds to produce deficits in a passive avoidance response (PAR) test. Scopolamine was significantly more potent than atropine while methylscopolamine was more potent than methylatropine. These data suggest that muscarinic receptor occupancy is related to the behavioral effects of these compounds in a learning and memory paradigm.

CHOLINERGIC RECEPTOR AGONISTS POTENTIATE CRH STIMULATION OF ADENYLYL CYCLASE ACTIVITY IN RAT FRONTAL CORTEX. P. Onali* and M.C. Olianas. Dept. of Neurosciences, Univ. of Cagliari, Cagliari, Italy.

Anatomical data indicate that acetylcholine (ACh) and corticotropin-releasing hormone (CRH) are colocalized in neurons that project to frontal cortex and there is evidence that both neurotransmitters are affected in cortical diseases, such as Alzheimer's disease. In this study we report that cholinergic receptor agonists and CRH interact in the control of adenylyl cyclase activity in membranes of rat frontal cortex. ACh increased the CRH-stimulated enzyme activity by ~ 40 %, without changing the potency of the peptide. ACh (1 mM) maximally increased basal cyclic AMP production by ~ 20 %. In the presence of CRH (500 nM) , the net ACh stimulation was enhanced by twofold. The effect of ACh was mimicked by other cholinergic receptor agonists, such as carbachol, oxotremorine M and methacholine. A number of muscarinic receptor antagonists counteracted the ACh potentiation of the response to CRH, with the M1 receptor antagonists pirenzepine and telenzepine displaying high affinity. As CRH possesses cognitive-enhancing effects, the muscarinic potentiation of cortical CRH receptor activity may play a role in the cholinergic regulation of learning and memory.

MUSCARINIC RECEPTOR-IMMUNOREACTIVE CELLS IN THE CHICK RETINA. K. C. Calaza and P. F. Gardino*. Lab. Neurobiologia da Retina, Instituto de Biofisica Carlos Chagas Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, 21949-900.

In the chick retina the presence of muscarinic acetylcholine receptors (mAChR) was previously demonstrated by autoradiography of specific binding sites with ^{3}H-quinuclidinyl-benzilate (Sugiyama et al., PNAS, *74*:5524, 1977). In this work we identify the specific cell populations expressing mAChRs using immunohystochemical techniques in the chick retina. In radial sections, immunoreactive cell bodies were present in different rows in the innermost third of the inner nuclear layer (INL). Labeled cells in the ganglion cell layer were observed and in some we visualized a process extending towards the optic fiber layer. At the optic disc, a dense net of thick fibers exhibit mAChR immunoreactivity. These fibers are intermingled with the optic nerve and invade the retina reaching the INL. In the inner plexiform layer two more intensely labeled bands were observed at *sublaminae* 2 and 4. In the outer plexiform layer (OPL) an intense and continuous band was visualized. Radial mAChR immunoreactive processes were observed spanning from the outer to the inner limitant membranes of the retina. Based on our results we conclude that mAChR immunoreactive neurons are amacrine and ganglion cells. In addition, mAChRs are expressed in Müller cells. The bands found at *sublaminae* 2 and 4 are coincident with the pattern of choline-acetyltransferase immunoreactivity. The immunoreactivity found in the OPL could be provided by Müller processes. In contrast with the expression of nicotinic acetylcholine receptors, which are present only in neuronal cell types, the mAChR immunoreactive cells comprise neurons and glia.

DEVELOPMENT OF ANTISERA AGAINST PEPTIDES OF THE RAT M5 MUSCARINIC ACETYLCHOLINE RECEPTOR. C.-F. Liao*[1,2], Y.-F. Wang[1,2], Y.-J.Chou[2], C.-C. Lin[1], J.-L. Wu[1], W.-H. Tsai[3]. [1]Inst. Zool., and [3]Inst. Biomedical Sciences, Academia Sinica, Taipei, Taiwan 115, ROC; [2]Inst. Physiology, National Yang-Ming University, Taiwan 112, ROC.

This study was aimed to develop antibodies against peptides of the rat m5 muscarinic acetylcholine receptor (mAChR) and use these antibodies to localize the m5 mAChR in the rat brain. The N- and C-terminal peptides of the m5 mAChR were synthesized on Fmoc MAP resins. The multiple antigen peptides (MAP), designed as m5N-MAP and m5C-MAP, were injected into chicken to produce antisera. The cells expressing transfected m5 mAChR and chimeric m5/ß$_2$ receptor were stained positively or negatively with anti-m5N or anti-m5C as expected. A few primary cultured cells prepared from the hippocampus and mesencephalon of the embryonic rat brain also were stained positively by the anti-m5 antisera. Western blotting of membrane proteins prepared from the cultured cells and several rat brain regions by the anti-m5 antibodies revealed that the apparent molecular weight of m5 mAChR is 58-60 kDa. EXPRESSION OF MUSCARINIC RECEPTOR mRNAs IN HUMAN BRAIN MICROVASCULAR FRACTIONS, CULTURED VASCULAR CELLS AND ASTROCYTES. A. Elhusseiny, Z. Cohen, A. Olivier, W.Yong, D. Stanimirović[1] and E. Hamel*. Montreal Neurological Institute, McGill University, Montréal, QC, and [1]National Research Council of Canada, Canada.

Muscarinic acetylcholine receptors (mAChRs) have been identified pharmacologically in human brain microvessels (MVs) and capillaries (CAPs). They correlated with the pharmacological profile of the cloned human m1, m3, and/or m5 receptor subtypes (Naunyn-Schmiedeberg's Arch Pharmacol 352:179;1995). We investigated the expression of mAChRs (m1-m5) mRNAs by reverse transcriptase-polymerase chain reaction (RT-PCR) and gel electrophoresis in MVs and CAPs isolated from post-mortem tissues, subcloned microvessel endothelial (HBEC) and primary smooth muscle (HBSM) cell cultures harvested from temporal lobe biopsies and in astrocytes cultured from human fetal brain (HFBA). The presence of functional mAChRs was assessed in the cells by their coupling to second messengers. ACh (1mM) or carbachol (1-5 mM) induced IP_3 (30-114%) in HBSM and HFBA, whereas betanechol (0.2-1mM) moderately increased cAMP (20-99%) in all cell types. In MVs and CAPs, PCR products were detected for the m2, m3 and less so, m1 and m5 receptor subtypes. In cells, messages for the m1, m2, m3 and m5 subtypes were found in HBSM and HFBA. In contrast, the HBEC strongly expressed the m2 and m5, less so the m1, and not the m3 receptor subtypes. The m4 receptor subtype was expressed exclusively in HFBA. The presence of various mAChRs, including the m1, in HBSM is compatible with a role for mAChRs in cerebral vasoconstriction. The lack of message for m3 receptors in HBEC, however, does not support its involvement in the endothelium-dependent cerebral vasodilation. Putatively, the m5 receptor subtype which couples to nitric oxide (NO) production (JPET 286:552;1994) could mediate this effect. The expression of all subtypes of mAChRs in astrocytes further underlines their putative role in the neurogenic control of brain microvessels by intrinsic cholinergic neurons. STREPTOZOTOCIN, AN INDUCER OF NAD$^+$ DECREASE, ATTENUATES M-POTASSIUM CURRENT INHIBITION BY ATP, BRADYKININ, ANGIOTENSIN II, ENDOTHELIN 1 AND ACETYLCHOLINE IN NG108-15 CELLS. H. Higashida*, A. Egorova, N. Hoshi, M. Hashii, R. Knijnik, Z.-G. Zhong, S. Yokoyama and M. Noda. Kanazawa Univ. Sch. of Med., Kanazawa 920, Japan.

The voltage-dependent potassium M-current leads to up-modulation of the membrane excitability of neuronal cells, when inhibited by muscarinic agonists. The M-current inhibition is elicited by a number of different transmitters, including bradykinin, ATP, UTP, angiotensin II, endothelin 1, substance P and LHRH. However, the signal transduction pathway from these receptors to M channels is not yet clear. Recently, we have shown that the muscarinic acetylcholine receptor (mAChR)-M channel coupling is partially blocked in streptozotocin-treated NG108-15 hybrid cells in which the cellular NAD$^+$ concentration is reduced, and that the M-current is slowly decreased by intracellular injection of cyclic ADP ribose (cADPR), a product of NAD$^+$ formed by ADP ribosyl cyclase. Therefore, we have proposed that NAD$^+$ or NAD$^+$ metabolites may be involved in the signal pathway from mAChRs to M channels (J. Physiol., *482*, 317, 1995). Here we present data showing that the M-current inhibition induced by 100 μM ATP, 10 nM bradykinin, 100 nM angiotensin II, 100 nM endothelin 1 and 10 μM ACh is blocked to the same extent in streptozotocin-treated NG108-15 cells. The results suggest that signal transduction from these 5 different receptors to M channels shares a common pathway which is susceptible to a streptozotocin-induced decrease in cellular NAD$^+$ content.

DEVELOPMENTAL CHANGES IN NICOTINIC ACETYLCHOLINE RECEPTOR α4 AND β2 SUBUNIT mRNAs AND (-)-[^{3}H]NICOTINE BINDING SITES IN RAT BRAIN X. Zhang*, C. Liu, H. Miao, Z-H. Gong and A. Nordberg Department of Clinical Neuroscience and Family Medicine, Division of Nicotine Research, Karolinska Institute, Huddinge University Hospital, B84, S-141 86, Huddinge, Sweden

The predominant nicotinic acetylcholine receptor (nAChR) subtype in rat brain binds nicotine with high affinity and is composed of α4 and β2 subunits. In this study, we investigated the changes in α4 and β2 mRNA levels and the number of α4β2 receptor subtype in six brain regions of male and female Sprague-Dawley rat during postnatal development. The α4 and β2 mRNA levels were simultaneously quantitated by ribonuclease protection assay and the number of the receptor subtype was measured by (-)-[^{3}H]nicotine (5nM) binding. Our data reveal that α4 mRNA level was high during the first 1-3 weeks of life in the hippocampus, striatum, cerebellum and brain stem, and decreasing thereafter, to a minimum at adulthood (12 weeks after birth). While in the cortex and thalamus, the α4 mRNA level remained stable during postnatal development. The β2 mRNA level also remained stable during postnatal development in most of the brain regions studied, except in the striatum where a high mRNA level was observed during the first two weeks of life. The number of high affinity (-)-[^{3}H]nicotine binding sites was high during the first three weeks of life in the cortex, hippocampus, thalamus, brain stem and cerebellum, then decreasing to adult level. In the striatum, the number of the binding sites was low at birth, then increasing gradually to adult level at 8 week after birth. These data suggest differential expressions of nAChR α4 and β2 subunit mRNAs, aswell as the number of α4β2 receptor subtype in different regions of rat brain during postnatal development.

MUSCARINIC RECEPTOR MEDIATED RESPONSES OF GUINEA PIG DORSAL RAPHE NEURONES *IN VITRO*

R.M. Craven*[1], D.G. Grahame-Smith[1,2] & N.R. Newberry[2]
University Department of Clinical Pharmacology[1] & Oxford University - SmithKline Beecham Centre for Applied Neuropsychobiology[2], Radcliffe Infirmary, Woodstock Road, Oxford, OX2 6HE, UK

Muscarinic cholinergic receptors are present in the dorsal raphe nucleus (DRN) which has been implicated in sleep regulation and pain modulation (Baghdoyan *et al.*, *Neuroreport* **5**, 1631; Wang & Nakai, *Brain Res. Bull.* **34**, 575); however, the direct effects of cholinergic receptor activation have not been determined. We have examined the effects of the cholinergic receptor agonist carbachol (10 μM) on neurones of the guinea pig DRN *in vitro* using intracellular recording techniques. In 25 of 54 'classical' presumed 5-HT containing neurones (wide action potentials, hyperpolarized by 5-HT) carbachol induced a prolonged depolarization. This effect of carbachol was mimicked by muscarine (10 μM), persisted in the presence of tetrodotoxin (TTX, 1 μM) and was abolished by the muscarinic receptor antagonist atropine (1 μM). The remaining 29 classical neurones gave little or no detectable response to carbachol. Two sets of 'nonclassical' neurones (narrow action potentials, faster firing) could be distinguished by their responses to carbachol: 14 gave a predominantly hyperpolarizing response, whereas 10 gave a depolarization. These carbachol induced effects were resistant to TTX (1 μM) and abolished by atropine (1 μM). A diversity of muscarinic receptor mediated responses has also been observed in the nucleus raphe magnus *in vitro* (Pan & Williams, *J. Neurosci.* **14**, 1332).
R.M.C. is a Wellcome Trust Prize Student.

ALLOSTERIC INTERACTIONS OF UH-AH 37 AT CHIMERIC MUSCARINIC CHOLINERGIC RECEPTORS. J. Ellis*, A. Gnagey, and M. Seidenberg. Department of Psychiatry, Penn State College of Medicine, Hershey PA 17033-0850.

All five subtypes of muscarinic receptors are sensitive to allosteric regulation by a variety of polymers, peptides, and small molecules. Gallamine is the prototypical muscarinic allosteric ligand and, like all muscarinic allosteric agents studied to date, it has a marked preference for the m2 subtype. Through the use of chimeric receptors composed of short stretches of m2-sequence substituted into an m5 background, we have previously reported that gallamine's subtype-specificity appears to reside in a span of the receptor that includes the third outer loop. UH-AH 37 is of particular interest because it exhibits higher affinity for m5 than for m2 receptors (under equilibrium conditions) and yet its subtype-specificity appears to derive from the same segment of the receptor that affects gallamine (*Wess et al., Mol. Pharmacol.* ***41:369***).

In the present study, we have found that UH-AH 37 does exert subtype-specific allosteric effects at muscarinic receptors. It markedly slows the rate of dissociation of labeled N-methylscopolamine from m2 receptors with an apparent affinity of about 3 μM, while its allosteric effects at m5 receptors are weaker and of lower affinity. We found that the chimeric receptor implicated in the previous studies of gallamine and UH-AH 37 (above) did *not* rescue the m2 allosteric characteristics. However, another chimeric receptor was quite effective, implicating region(s) near the amino- and/or carboxyl-terminal(s) of the receptor. The discrepancy between the epitopes implicated in equilibrium and dissociation studies suggests that UH-AH 37 interacts with muscarinic receptors both competitively and allosterically. *[Supported by PHS R01 AG05214]*

Neuronal Cell-specific Expression of the Rat m4 Muscarinic Acetylcholine Receptor Gene is Regulated by a Silencer Element.
M. Mieda, T. Haga, H. Nakata*[1], and D. W. Saffen, Institute for Brain Research, University of Tokyo, Tokyo 113, [1]Dept.of Pharmacology, National Defense Medical College, Saitama 359, Japan.

We have characterized the structure of the rat m4 mAChR gene and identified its promoter region as a first step toward understanding the mechanisms of subtype- and tissue-specific expression of muscarinic acetylcholine receptors (mAChRs).

Two 5'-noncoding exons are located approximately 5 kb upstream from the m4 receptor coding exon, from which two alternatively spliced variants of m4 mRNA are generated in the neuronal cell line PC12D. The promoter region is GC-rich, contains no TATA-box, but has several consensus binding sites for Sp1 and AP-2 transcription factors. Transient transfection assays showed that the 1073 bp segment immediately upstream from the transcription initiation site is a neuronal cell-specific promoter. Deletion of 638 bp from the 5' side of this segment allowed the remaining 435 bp sequences to function as a promoter in both neuronal and non-neuronal cell lines, indicating that the deleted region contains a silencer element or elements. This 638 bp fragment contains a putative neuron-restrictive silencer element/repressor element 1 (NRSE/RE1), which is known to regulate the expression of several neuron-specific genes. Deletion of a 92 bp fragment in the m4 mAChR promoter containing this element abolished the specificity of the expression. Furthermore, fusion of this element directly to the 435 bp segment resulted in neuronal-specific expression. Gel-shift assays showed the existence of NRSE/RE1 binding activity in non-neuronal cell lines that is absent from neuronal cell lines that express m4 mAChR. These data suggest that the NRSE/RE1 regulates the neuron-specific expression of the m4 mAChR gene. (Supported by grants from the Ministry of Education, Science, and Culture of Japan)

CHARACTERIZATION OF MUSCARINIC RECEPTOR MEDIATED STIMULATION OF MITOGEN-ACTIVATED PROTEIN KINASE. D. R. Wotta*, E. V. Wattenberg‡ and E. E. El-Fakahany. Division of Neuroscience Research in Psychiatry, Medical School, ‡Division of Environmental and Occupational Health, School of Public Health, University of Minnesota, Minneapolis, MN 55455.

Five subtypes of muscarinic acetylcholine receptors have been cloned, sequenced and characterized pharmacologically. Past studies with muscarinic receptors have grouped the 5 receptor subtypes into two groups in terms of their preferred signal transduction pathways. M1, M3 and M5 muscarinic receptors couple to the G protein alpha subtype, Gq, and regulate IP_3 production. On the other hand, M2 and M4 muscarinic receptors normally couple to the inhibitory G protein subtype, G_i, that inhibits adenylyl cyclase. Interestingly, however, our data show that agonist-induced stimulation of the mitogen-activated protein kinase (MAP kinase) can be seen in Chinese hamster ovary (CHO) cells transfected with each of the five receptor subtypes. Time courses show that activation of each of the M1 through M5 receptors by the muscarinic agonist, carbachol, maximally stimulates MAP kinase activity between 5 and 10 minutes. Dose response curves suggest similar potencies for activation of MAP kinase by carbachol at each of the muscarinic receptor subtypes. Muscarinic receptor activation of MAP kinase by carbachol was blocked by the antagonist atropine. Pharmacological selectivity of MAP kinase activation by each of the muscarinic agonists, acetylcholine, methacholine, arecoline, muscarine, oxotrmorine M, oxotremorine, pilocarpine as well as the M1 selective agonist McN-A-343 was also studied. (This study was funded by NIH NS25743 and the U.S. Army Research Office).

CONTROL OF MUSCARINIC ACETYLCHOLINE RECEPTOR GENE EXPRESSION.

Noel J. Buckley* Avtar Roopra, Stefania Pepitoni, Mohini Mistry and Ian C. Wood, Wellcome laboratory for Molecular Pharmacology, University College London, London WC1E 6BT, UK.

G-protein coupled receptors are encoded by a diverse gene family, accounting for up to 1% of the mammalian genome. The muscarinic acetylcholine receptors are members of this gene superfamily and the five subtypes of muscarinic receptor have unique expression profiles within the nervous system. Cellular responses are dependent on the receptors expressed on the cell surface and it is therefore important that each neuron acquires the correct complement of cell surface receptors. In order to ascertain how the correct spatio-temporal expression of these receptor genes is brought about, we are studying the gene regulation of the muscarinic receptors. The m4 gene is expressed mainly in the telencephalic regions of the CNS, autonomic ganglia and also in rabbit lung. The m4 gene contains a 460 bp non-coding exon separated from a coding exon by a 4.8kb intron. Several strategies have been utilised to examine the role of regions of the m4 promoter responsible for controlling gene expression both *in vitro* and *in vivo* with the aim to thus identify those transcription factors important in defining m4 gene expression. The core promoter of the m4 gene is constitutively active in neuronal and non-neuronal cell lines and expression is suppressed in both non-neuronal and non-expressing neuronal cells by an RE1/NRSE silencer element. Transgenic animal experiments are aimed at establishing the role played by this and other elements in regulating gene expression *in vivo*.

This work is supported by the Wellcome Trust.

COOPERATIVE PROPERTIES OF CARDIAC MUSCARINIC RECEPTORS. N. Pyo and J. W. Wells*. Dept. of Pharmacology and Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada M5S 2S2.

N-Methylscopolamine (NMS) and quinuclidinylbenzilate (QNB) were examined for binding at equilibrium in two preparations from porcine atria: sarcolemmal membranes, and solubilized purified M_2 receptors largely devoid of G-protein. The apparent capacity for [^{3}H]NMS was about 75% of that for [^{3}H]QNB in both preparations, and the discrepancy cannot be attributed to distinct and independent sites. At concentrations of [^{3}H]QNB that achieved 95% occupancy, specific binding was inhibited fully at relatively low concentrations of unlabelled NMS; that is, unlabelled NMS inhibited [^{3}H]QNB at sites that were not labelled at similar concentrations of [^{3}H]NMS. Similarly, the inhibitory potency of unlabelled QNB on the binding of [^{3}H]NMS was inconsistent with the affinity of [^{3}H]QNB measured directly. The retention of non-competitive effects after purification suggests that such behavior is intrinsic to the receptor. All of the data can be rationalized in terms of cooperative interactions within a tetravalent receptor, presumably a tetramer. In that context, sites labelled by [^{3}H]QNB but not by [^{3}H]NMS result from negative cooperativity between successive equivalents of the latter; the inhibition of [^{3}H]QNB by NMS derives in part from negative cooperativity between the two ligands. In sarcolemmal membranes in which 80% of the sites labelled by [^{3}H]NMS were blocked by propylbenzilylcholine mustard, the ratio of apparent capacities for [^{3}H]NMS and [^{3}H]QNB decreased from 0.76 to 0.57. The effects of alkylation are consistent with the notion that the mustard reduces the number of functional, interacting sites within an oligomeric array. Supported by the Heart and Stroke Foundation of Ontario and by NSERC.

REGULATION OF MUSCARINIC RECEPTOR-MEDIATED STIMULATION OF NO SYNTHESIS BY NO DONORS. E.E. El-Fakahany*, J.A. Johanning, A.E. Cuadra, M.J. Chell and A.M. Parsons, Division of Neuroscience Research in Psychiatry, Univ. of Minnesota Medical School, Minneapolis, MN 55455.

Nitric Oxide (NO), a highly reactive signaling molecule, is synthesized in neurons predominantly by activation of neuronal nitric oxide synthase (nNOS). The synthesis of NO is tightly regulated, possibly by autofeedback mechanisms effected by NO itself. This study investigated whether NO donors attenuate activation of nNOS or dampen the levels of components of the cellular pathways that may contribute to nNOS activation (i.e. inositol phosphate formation and intracellular calcium concentration) in intact cells. Chinese hamster ovary (CHO) cells that co-express M_1 muscarinic receptors and nNOS were grown in DMEM with 10% bovine calf serum until confleuncy (4-5 days). Intact cells were stimulated with the muscarinic receptor agonist carbachol (100 μM) or the calcium ionophore ionomycin (3 μM) in the presence or absence of the NO donors SNP, SNAP or SIN-1. The activity of nNOS was determined by measuring conversion of [^{3}H]L-arginine to [^{3}H]L-citrulline. The formation of inositol phosphates was determined in CHO cells that expressed M_1 receptors, but not nNOS, by prelabeling cells with [^{3}H]inositol and measuring recovery of [^{3}H]inositol phosphates. Both carbachol and ionomycin significantly stimulated nNOS activity. All three NO donors concentration-dependently attenuated both the carbachol- and ionomycin-induced activation of nNOS. In addition, the NO donor, SNP, inhibited carbachol-induced inositol phosphate formation in a concentration-dependent manner. Together, these results suggest that NO regulates its own synthesis by attenuating nNOS activity and dampening the formation of inositol phosphates. (This study was funded by NIH NS25743 and the U.S. Army Research Office.)

ISOLATED CHANGES IN NOREPINEPHRINE ACTIVITY ALTER HIPPOCAMPAL CHOLINERGIC MUSCARINIC RECEPTORS.

M.R. Roberson*, K. Kolasa, D.S. Parsons, L.E.Harrell. Alzheimer's Disease Center, Departments of Psychology and Neurology, VA & University of Alabama Medical Centers, Birmingham, Alabama 35294.

Our laboratory has previously investigated how increased concentrations of norepinephrine (NE), in the setting of cholinergic deficiency, affect behavior and brain biochemistry. Recently we have begun to examine how isolated changes in NE activity may alter cholinergic systems. Male Sprague-Dawley rats were treated (IP) with either phentolamine (n = 5: 20 mg/kg) or vehicle (n = 5) for 5-6 weeks, followed by assessment of the cholinergic muscarinic receptors (mAChRs) in dorsal and ventral hippocampus with [3H]-QNB (non-selective mAChR antagonist) binding. The number (Bmax) of mAChRs were found to be significantly ($p<.04$; both regions) decreased by phentolamine when compared to vehicle treatment in both dorsal and ventral hippocampus. Affinity (Kd) was unaffected by phentolamine treatment. We next assessed mAChR QNB binding in the setting of unilateral locus ceruleus (LC) lesions (n = 4), and found that LC lesions induced a significant decrease in affinity of mAChRs in ventral hippocampus when compared to control ($p<.0001$). Receptor number was unaffected in both regions.

A pharmacologic reduction in NE decreased total mAChR number, while NE activity reduced via LC lesions altered mAChR affinity. Although these results are preliminary, they indicate that isolated changes in NE activity cause alterations in hippocampal mAChRs.

INFLUENCE OF ACUTE AND CHRONIC ETHANOL EXPOSURE ON ARACHIDONIC ACID RELEASE MEDIATED BY MUSCARINIC ACETYLCHOLINE RECEPTORS EXPRESSED IN CHO CELLS. S. Stair, C.L. Williams, S. Phelps, H.L. Puhl, L.G. May, and R.S. Aronstam*, Guthrie Research Institute, Sayre, PA 18840.

Ethanol disrupts signal transduction mediated by a variety of G protein-coupled receptors. We examined the effects of ethanol on arachidonic acid release induced by muscarinic acetylcholine receptor (mAChR) activation. Chinese hamster ovary (CHO) cells transfected with different mAChR subtypes (m1–m5) were incubated with ^{3}H-arachidonic acid (^{3}H-AA) for 18 hours, washed, and exposed to the mAChR agonist carbamylcholine for 15 minutes. The amount of ^{3}H-AA released by the cells was determined by liquid scintillation counting. Carbamylcholine induced ^{3}H-AA release from CHO cells expressing m1, m3, or m5, but not m2 or m4, mAChR. For example, carbamylcholine increased ^{3}H-AA from CHO cells expressing m1 receptors by 650% with an EC50 of ≈ 1 μM. Maximal responses were obtained with 10 μM carbamylcholine; higher concentrations produced smaller responses. Exposure of m1-, m3- or m5- expressing cells to ethanol for 5 minutes before stimulation by carbamylcholine reduced ^{3}H-AA release by 40–65%, with an ethanol IC50 of 30–50 μM. Ethanol did not affect basal ^{3}H-AA release measured in the absence of carbamylcholine. Dose response curves indicate that ethanol acts as a non-competitive inhibitor of mAChR-induced ^{3}H-AA release. Exposure of CHO cells to 38 μM ethanol for 48 hours increased ^{3}H-AA release induced by carbamylcholine without affecting basal ^{3}H-AA release. These results indicate that ethanol acutely inhibits mAChR signal transduction in a non-competitive manner, but chronically may enhance mAChR signal transduction. The biochemical basis for these different effects of ethanol are currently being investigated. (Supported by PHS grant CA-52471 and Department of the Army Grant DAMD17-94-J-4011).

ALTERATIONS IN mAChR EXPRESSION IN RAT DENTATE GYRUS FOLLOWING COMMISSURAL/ASSOCIATIONAL PATHWAY LESIONS S.T. Rouse* and A.I. Levey. Dept. of Neurology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

The role of mAChR subtypes in cholinergic transmission in the hippocampus is poorly understood. Recent immuno-localization studies have revealed highly laminated patterns of m1-m4 protein expression in the hippocampus, suggesting possible presynaptic localizations. To test the hypothesis that some mAChR subtypes expressed in the inner third of the molecular layer (ML) are localized on terminals of the commissural/associational (C/A) pathway neurons, we performed a series of physical and chemical lesions to cause specific degeneration of commissural and/or associational pathways in rat brain.

In all lesions, m1 expression in the molecular layer (ML) was unchanged, indicating that m1 immunoreactivity (IR) in the ML is not due to presynaptic expression in the C/A pathway. An m2 immunoreactive band in between the inner and middle thirds of the ML was eliminated only by lesions of the associational pathway, consistent with m2 expression in hilar interneurons. m3 IR in the outer third of the ML was not altered by any of the C/A lesions. However, m3 IR in the inner third of the ML was decreased by lesions of both pathways simultaneously. Likewise, m4 IR in the inner third of the ML was dramatically decreased by lesions of the commissural and associational pathways alone, and nearly eliminated by lesions of both pathways simultaneously. However, m4 IR in the middle third of the ML was largely unchanged by any of the C/A lesions. These results suggest that both m3 and m4 receptors are presynaptic receptors on C/A pathways. Supported by RO1 NS30454 (A.I.L.) and NIMH NRSA MH11186-02 (S.T.R.).

CARBACHOL-DRIVEN γ-BAND POPULATION OSCILLATIONS IN MOUSE HIPPOCAMPAL SLICES.

T. Ono[1*], Y. Fueta[2], Y. Murai[1], T.Mita[3] and K. Ohno[4]

Depts. of [1]Neurology & [4]Biophysics, Sch. of Med., [2]Dept. of Med. & Envir. Tech., Sch. of Health Sci., UOEH and [3]Dept. of Biol., Kyushu Women's Univ., Kitakyushu 807, Japan.

We found carbachol (CCh)-driven γ-band (~40Hz) population oscillations in mouse hippocampal CA3. While the oscillations were most obvious and reproducible in genetically seizure-susceptible El mice, we also observed these oscillations in ddY (a mother strain of El) and BALB/c mice, suggesting that the CCh-driven γ-band oscillations are common phenomena in mouse hippocampi.

The characteristic oscillations were reproduced by a muscarinic receptor agonist bethanechol (30μM) and completely blocked by the antagonist atropine (0.5μM); nicotine had no effect up to 100μM.

In addition, an important role of the GABAergic system in the oscillatory mechanisms was illuminated by the following observations. (a) Bicuculline (1μM), a $GABA_A$ receptor antagonist, completely inhibited the oscillation induced by CCh. (b) Pentobarbital (15μM), which enhances the $GABA_A$ receptor function, lowered the oscillation frequency (e.g., from 34Hz to 26Hz).

We conclude that the CCh-driven γ-band oscillations are generated in response to the activation of muscarinic acetylcholine receptors, and that the $GABA_A$ receptor-Cl^-channel complex is indispensable for the oscillations to occur, the oscillation frequency being controlled by the opening time of the Cl^- channel.

ARACHIDONIC ACID METABOLISM IN BRAIN LIPIDS: USE OF A SPECIFIC PHOSPHOLIPASE A_2 INHIBITOR, MANOALIDE, IN AWAKE RAT WITH OR WITHOUT CHOLINERGIC STIMULATION.

E. Grange, M.C. Chang, O. Rabin, J. Bell and S.I. Rapoport*. Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892,

Phospholipid metabolism is involved in signal transduction in neural tissue. Data suggest cholinergic muscarinic receptor activation stimulates the incorporation of arachidonate (AA) into brain phospholipids which could be mediated by activation of phospholipase A_2 (PLA_2). To examine this, awake rats were treated with a PLA_2 inhibitor, manoalide (10 mg/kg) followed by an i.v. infusion of [1-^{14}C]AA. Some animals received a muscarinic agonist, arecoline. The rats were killed, brains were removed and extracted for lipid analysis. Manoalide inhibited PLA_2 activity but not phospholipase C activity measured on whole brain homogenate. Arecoline increased incorporation of [1-^{14}C]AA into brain phospholipids by 70% and diluted the brain [1-^{14}C]arachidonoyl-CoA compartment by stimulating release of unlabeled AA from phospholipid by 40%. In the arecoline-stimulated group, manoalide reduced by 73% [1-^{14}C]AA incorporation into phospholipids and prevented dilution of the arachidonoyl-CoA pool. In unstimulated rats, manoalide administration decreased [1-^{14}C]AA incorporation into phospholipids by 23% and concomitantly increased [1-^{14}C]AA incorporation into triacylglycerol by 200%. Thus, the muscarinic receptor-coupled PLA_2 activity can be blocked, *in vivo*, by an irreversible and specific inhibitor of the enzyme. Manoalide decreases the cerebral incorporation of [1-^{14}C]AA into phospholipid classes by partial inhibition of PLA_2 activity and shunting the [1-^{14}C]AA into neutral lipids. Results support PLA_2 activation by the muscarinic agonist-arecoline.

CARBACHOL-INDUCED INOSITOL PHOSPHATE FORMATION IN RAT STRIATAL SLICES IS MEDIATED BY MORE THAN ONE MUSCARINIC RECEPTOR SUBTYPE.

D.I. Limón[1], M. Segura[2], D.E. García-Díaz[3*] and J.-A. Arias-Montaño[1]. [1]Depto. de Neurociencias, CINVESTAV-IPN, [2]UPIBI-IPN and [3]Fac. de Medicina, UNAM. México, D.F., México.

Cholinergic innervation to the striatum is mainly provided by intrinsic interneurones, namely large aspiny neurones. Acetylcholine binds to muscarinic receptors (M_1, M_3, M_5) coupled to phospholipase C activation and formation of IP_3 and diacylglicerol (E.C. Hulme *et al.* Ann. Rev. Pharmacol. Toxicol. 30: 633). In this work we set out to determine which muscarinic receptor subtypes participate in carbachol-induced inositol phosphate accumulation in rat striatum.

In homogenates of striatum the density of muscarinic receptors, as estimated from saturation binding curves with [^{3}H]-*N*-methyl-scopolamine was 110 ± 3 fmol.mg prot.$^{-1}$. In vibratome-cut slices and in the presence of 10 mM LiCl, carbachol stimulated the accumulation of total [^{3}H]-inositol phosphates with an EC_{50} of 11 ± 2 μM (n_H 1.1 ± 0.1) and maximum effect of 410 ± 43% of basal accumulation. The effect of carbachol was inhibited in a concentration-dependent manner by pirenzepine. The inhibition curve best fit to a two-site model with pK_i values of 8.3 (accounting for 66% of the response) and 6.7 for the high and low affinity sites respectively. These values are in good agreement with those reported for M_1- and M_3-subtypes indicating that al least two subtypes are involved in the functional response.

MUSCARINIC RECEPTOR SUBTYPES IN THE HUMAN RETINA AND IRIS +CILIARY BODY.

J.B. Williams*, A. Kuo, W.J. Thompson, M.F. Sugrue and P. Mallorga. Merck Research Labs, West Point, PA.

The nature of muscarinic receptor subtypes present in the human retina and iris+ciliary body (ICB) was investigated using immunoprecipitation and radioligand binding techniques. Muscarinic receptor subtype-specific antisera raised in rabbits against the i3 loop of the five human muscarinic receptor subtypes were obtained from A. Levey, Emory Univ., Atlanta. Human retinas and ICBs dissected and frozen between 10-20 hours after death were obtained from the Medical Eye Bank of Western Pennsylvania, Pittsburgh, PA. Membranes were prepared and solubilized with Tris buffer containing 1% digitonin, 0.1% cholic acid and protease inhibitors. Solubilized muscarinic receptors were labelled with ^{3}H-NMS at 4°C, incubated with the five separate antisera and immunoprecipitated with goat anti-rabbit IgG. Immunoprecipitates were resuspended in 1% SDS, and radioactivity was counted. Corrections for nonspecific trapping and binding were made.

The m2 subtype represented 53% of the solubilized receptors in the retina followed by m3 (39%), m1 (5%) and m4 (1%). In the ICB m3 was the predominant subtype (56%) followed by m2 (27%). Displacement of ^{3}H-NMS binding from retinal membranes by L-764,974 (5-methyl-1,3-dihydro-1-{-1-[1-(5-pyrimidinecarbonyl)-piperidin-4-yl]piperidin-4-yl}-2H-benzimidazol-2-one), a muscarinic receptor antagonist with low affinity for the m3 subtype (Ki values for m1, m2, m3, m4 and m5 cloned human muscarinic receptor subtypes expressed in CHO cells were 3, 6, 1915, 3 and 42 nM, respectively), confirmed the presence of the two major populations of muscarinic receptor subtypes in the retina. Other known antagonists like atropine, pirenzepine and 4-DAMP were unable to clearly distinguish between the m2 and the m3 subtypes in this tissue.

In conclusion the m2 subtype was found to be predominant in the human retina. In contrast the m3 subtype was found to be the most abundant in the human ICB.

CARBACHOL STIMULATES INOSITOL PHOSPHATE FORMATION IN RAT THALAMUS SLICES THROUGH MUSCARINIC M_3-RECEPTOR ACTIVATION.

L.E. Soria, T. de la Vega, A. Nuñez and J.-A. Arias-Montaño*. Depto. de Fisiología, Biofísica y Neurociencias, CINVESTAV-IPN. Apdo. postal 14-740, 07000 México, D.F., México.

Noradrenaline, histamine and acetylcholine (ACh) modulate the firing pattern of thalamic relay neurones through the activation of α_1-, H_1- and muscarinic receptors respectively (D.A. McCormick, Prog. Neurobiol. 39: 337). ACh binds to muscarinic receptors (M_1, M_3, M_5) coupled, likewise α_1- and H_1-receptors, to phospholipase C activation and formation of IP_3 and diacylglicerol (E.C. Hulme *et al.* Ann. Rev. Pharmacol. Toxicol. 30: 633). Therefore we set out to establish whether the cholinergic agonist carbachol stimulates inositol phosphate accumulation in rat thalamus slices and the muscarinic-receptor subtype involved.

In cross-chopped slices and in the presence of 10 mM LiCl, carbachol stimulated the accumulation of total [^{3}H]-inositol phosphates with an EC_{50} of 44 ± 6 μM (n_H 1.1 ± 0.1) and maximum effect of 199 ± 6% of basal accumulation. The effect of carbachol was inhibited with high potency (pK_i 9.1) by 4-diphenylacetoxy-N-methylpiperidine methiodide (4-DAMP) and concentration-response curves were shifted to the right in a parallel fashion by pirenzepine (0.1, 0.3 and 1 μM). A Schild plot of the data was linear (slope 0.95 ± 0.04) and yielded a log K_D for pirenzepine of -6.8 ± 0.1. Taken together these results suggest that carbachol-induced inositol phosphate accumulation in rat thalamus is mediated by muscarinic M_3-receptors.

NMDA-R1 ANTISENSE ATTENUATES MORPHINE TOLERANCE. C.E. Inturrisi, N. Shimoyama, M. Shimoyama, K. Foley* and K. Elliott. Dept. of Pharmacology, Cornell U. Medical College and Pain Research Program, Dept. of Neurology, MSKCC, NY, NY 10021.

Previous studies have demonstrated that NMDA receptor antagonists can attenuate or reverse tolerance to morphine's (MOR) analgesic effects (Tiseo and Inturrisi, 1993, Elliott et al., 1994). In support of this hypothesis, we evaluated the ability of an 18 mer phosphodiester (ODN) antisense (AS) targeted to nucleotides 4-21 of rat NMDAR1 (Wahlestedt et al., 1993) to attenuate MOR tolerance produced by the intrathecal (IT) injection (tid) of escalating doses of MOR for three days. Rats prepared with a chronic lumbar IT catheter received AS or a 4 base mismatch (MM) IT, bid at 30 nmol/dose for 8 days. After 5 days of ODN pretreatment , MOR ED50 values (tail-flick) were determined using cumulative dose response (CDR). Then 3 days of concurrent treatment with MOR or saline and ODN. On day 10 the MOR CDRs were repeated. On day 6 neither AS nor MM ODN treatment altered the MOR ED50 value. On day 10 the MOR ED50 in MOR and saline treated rats had increased 30 fold. AS but not MM significantly attenuated the development of MOR tolerance (ED50 increased only 5 fold). These results demonstrate that in vivo administration of NMDAR1 AS reduces MOR tolerance and provides additional support for the critical role of NMDA receptors in MOR tolerance. Supported in part by NIDA grants DA01457, DA00198, DA00255 and the VZV Foundation.

CHRONIC ETHANOL TREATMENT PRODUCED UPREGULATION OF NMDA RECEPTOR POLYPEPTIDE SUBUNITS IN MOUSE CORTICAL NEURONS IN CULTURE P. Follesa* and M.K. Ticku. Department of Pharmacology, The University of Texas Health Science Center, San Antonio, Texas 78284-7764

Our previous work has shown that chronic ethanol treatment specifically upregulated the N-methyl-D-aspartate receptor (NMDAR) subunit *in vivo* and *in vitro* (Follesa and Ticku, Mol. Br. Res. 29:99, 1995; Hu et al., Mol. Br. Res. 36:211, 1996). The aim of this study was to determine whether the chronic ethanol-mediated upregulation of the NMDAR was associated with an augmentation of the NMDAR polypeptide subunits. The results showed that chronic ethanol treatment produced an increase in the R1 and R2B polypeptide subunits. The R2A subunit was not expressed in the cortical neurons in culture (7 days) despite the mRNA encoding the R2A subunit was present suggesting a pivotal role for the R2A subunit in the NMDA induced neurotoxicity (Follesa and Ticku, J. Biol. Chem. in press). The NMDAR antagonist CPP also increased the R1 and R2B polypeptide subunits. A similar increase was still present when ethanol and CPP were used in combination. These results are in contrast with our previous finding where the ethanol-mediated increase of the R2B mRNA subunit was completely blocked by CPP. In addition binding studies using [^{3}H]MK-801 confirmed that concomitant exposure of ethanol and CPP upregulated the NMDAR. Taken together, these observations suggest a non-complementary mechanism of regulation for mRNA and polypeptide synthesis. Our results demonstrate for the first time that chronic ethanol treatment increased the NMDA receptor polypeptide subunit synthesis and that it was associated with an increase in [^{3}H]MK-801 binding sites. Supported by NIH-NIAAA grant #AA10552.

693.3

CHRONIC ETHANOL-INDUCED REGULATION OF N-METHYL-D-ASPARTATE RECEPTOR SUBTYPES OCCUR AT MULTIPLE LEVELS M. Kumari and M.K. Ticku*. Department of Pharmacology, The University of Texas Health Science Center, San Antonio, Texas 78284-7764

Chronic ethanol treatment specifically augments the synthesis of NMDA R1 and R2B polypeptide subunits in murine fetal cortical neurons *in vitro* (Follesa and Ticku JBC: In Press). Previous *in vivo* and *in vitro* results from our laboratory have shown that chronic ethanol exposure increased the NMDA R2B subunit mRNA levels by ~ 40% with respect to the control values, without altering the NMDA R1 subunit mRNA levels (Follesa and Ticku, Mol. Brain Res. 29:99, 1995; Hu et al., Mol. Brain Res. 36:211, 1996). Taken together, these observations suggest a differential regulation of NMDA receptor subunits in cortical cells after chronic ethanol treatment. To further understand the mechanism(s) involved in differential regulation of NMDA R1 and R2B receptor subunits, we have determined the cytoplasmic stability and the rate of transcription of these two mRNAs in murine fetal cortical neurons after chronic ethanol exposure. Cytoplasmic stabilities of the two mRNAs were detected by inhibiting transcription with actinomycin-D while transcription rates were measured by nuclear run-on assays. No decay of the NMDA R1 mRNA was detected up to 24 hours but a decline in NMDA R2B mRNA was seen reaching ~ 50% at 24 hours. A concomitant rise in rate of NMDA R2B transcription was observed while no difference was noted for NMDA R1 subunit mRNA. These observations suggest that regulation of NMDA R1 and R2B receptor subtypes occurs at multiple levels.

THE SELECTIVITY OF RO 25-6981 FOR NMDA RECEPTOR SUBTYPES EXPRESSED IN XENOPUS OOCYTES. G. Trube, P. Ehrhard, P. Malherbe and G. Huber *. Pharma Division, Preclinical Research, F. Hoffmann - La Roche Ltd., CH-4070 Basle, Switzerland.

Ro 25-6981 inhibited ^{3}H-MK801 binding to rat brain membranes in a markedly biphasic manner. Therefore, we investigated its selectivity for recombinant NMDA receptor subtypes. cRNA mixtures coding for three different subunit combinations of the rat NMDA receptor (NR1C + NR2A, NR1C + NR2B and NR1F + NR2B) were expressed in Xenopus oocytes. The sensitivities of the receptors for agonists and for the allosteric antagonists Ro 25-6981, CP-101,606, ifenprodil and eliprodil were studied in voltage-clamp experiments.

The EC_{50}s for L-glutamate, L-aspartate and glycine were lowest for the NR1C + NR2B subunit combination (1.3, 12 and 0.22 µM, respectively), and highest for NR1C + NR2A (4 µM, 70 µM, 2.6 µM).

The most potent and selective antagonist for NR2B-containing receptors was Ro 25-6981 (NR1C + NR2B, IC_{50} 0.009 µM versus NR1C + NR2A, 60 µM). The IC_{50}s of CP-101,606, ifenprodil and eliprodil were 0.06, 0.25 and 0.7µM, respectively, on NR1C + NR2B and 100, 40 and 50 µM, respectively, on NR1C + NR2A. The polyamine spermidine (2 mM), which potentiated the responses of NR1C + NR2B to aspartate and glycine about 4-fold, did not change the inhibitory effect Ro 25-6981. The additional N-terminal exon in the NR1F subunit, which abolished spermidine-dependent potentiation, increased the IC_{50} of Ro 25-6981 only slightly (to 0.017 µM) indicating that the compound does not block the NMDA receptor by binding to the polyamine binding site.

The results show that Ro 25-6981 is a selective high-affinity antagonist of NMDA receptors containing the NR2B subunit.

693.5

THE NEUROPROTECTIVE ACTIVITY OF RO 25-6981, A NMDA RECEPTOR NR2B SUBTYPE SELECTIVE BLOCKER. G. Fischer, A. Bourson, J.A. Kemp*, H.P. Lorez. Pharmaceutical Division, Preclinical Research, F. Hoffmann - La Roche Ltd., CH-4070 Basel, Switzerland.

The neuroprotective potential of Ro 25-6981, a selective blocker of NMDA receptors containing NR2B subunits (see Trube et al. and Mutel et al., this meeting), was evaluated *in vitro* and *in vivo*. For *in vitro* toxicity, cortical neurons from 16 days old rat embryos were cultured in 24 well plates for 12 days on astrocyte feederlayers in DMEM with 10 % HS and LDH release was used to quantify cell death. Ro 25-6981 produced a concentration-dependent neuroprotection against glutamate toxicity (permanent exposure to 100 µM in BME for 16 h) as well as combined oxygen and glucose deprivation (60 min in a modified ACSF with 16 h of recovery in BME) with IC 50 values of 0.3 ± 0.05 and 0.2 ± 0.08 µM, respectively. *In vivo* it showed a dose-dependent protection against sound-induced seizures in DBA/2J mice (21 days old, 110 db for 60 s) with an ED 50 of 12 mg/kg i.p. (95 % conf. range 8.3 - 18.6) following 30 min pretreatment with no motor impairment up to 100 mg/kg. In a rat (Fischer 344) permanent middle cerebral artery occlusion model, Ro 25-6981 produced dose-dependent protection with a maximal reduction of cortical infarct volume by 37 ± 5 % (1.9 mg/kg bolus i.v. 5 min post occlusion followed by 4.4 mg/kg/h infusion for 6 h) with no cardiovascular side-effects and no motor impairment. These data indicate that Ro 25-6981 is neuroprotective at doses without cardiovascular or CNS side-effects and has potential for the treatment of ischemic brain injury.

693.6

IFENPRODIL AND Ro 25-6981 ARE ACTIVITY-DEPENDENT ANTAGONISTS OF NMDA NR2B SUBUNIT CONTAINING RECEPTORS. J.A. Kemp, G. Trube and J.N.C. Kew* Pharma Division, Preclinical CNS Research, F. Hoffmann-La Roche Ltd., 4070 Basel, Switzerland.

The subtype selective non-competitive NMDA receptor antagonist, ifenprodil, is neuroprotective in *in vivo* models of cerebral ischaemia but lacks many of the undesirable side effects associated with NMDA antagonists. Using whole-cell voltage-clamp recordings from rat cultured cortical neurons in the presence of saturating concentrations of glycine, we have found that ifenprodil antagonises NMDA receptors in an activity-dependent manner, whilst increasing the receptor affinity for glutamate site agonists. Ifenprodil inhibition curves against both 10 and 100 µM NMDA evoked currents yielded IC_{50}s of 0.88 and 0.17 µM, respectively. Thus, the apparent affinity of ifenprodil for NMDA receptors is increased in an NMDA concentration-dependent manner. Currents evoked by 0.3 or 1 µM NMDA were potentiated to approximately 200% of control levels in the presence of 3µM ifenprodil. Thus, with increasing concentrations of NMDA the effect of ifenprodil changes from one of potentiation to one of increasing inhibition. These results are predicted by a reaction scheme derived from models of NMDA receptor activation and desensitisation in which ifenprodil exhibits a 35- and 50- fold higher affinity for the agonist-bound activated and desensitised states of the NMDA receptor, respectively, relative to the resting, agonist-unbound states, whilst the affinity for glutamate site agonists is increased 7-fold by ifenprodil binding. Ro 25-6981, a more potent and selective NMDA receptor subtype antagonist, inhibited 100µM NMDA evoked currents with an IC_{50} of 56nM and shares both the mechanism of action *in vitro* and the lack of side effects *in vivo* exhibited by ifenprodil. In addition to the subtype selectivity of these compounds, this novel mechanism of antagonism presumably contributes to their attractive *in vivo* profile.

693.7

IN VITRO BINDING CHARACTERISTICS OF THE SELECTIVE NMDA RECEPTOR 2B SUBTYPE ANTAGONIST [3H]Ro 25-6981 IN RAT BRAIN

V. Mutel, D. Buchy, A. Klingelschmidt, J. Messer and J.G. Richards*, Pharmaceuticals Division, Preclinical CNS Research, F.Hoffmann-La Roche Ltd, CH-4070 Basel, Switzerland.

Ro 25-6981 [R-(R*,S*)]-α-(4-Hydroxyphenyl)-ß-methyl-4-(phenyl-methyl)-1-piperidinepropanol] is a potent NR2B-selective NMDA antagonist which is devoid of cardiovascular and behavioural side effects in rats at maximal neuroprotective doses. In rat whole brain homogenates, [3H]Ro 25-6981 bound with a high affinity and capacity (KD=2±0.4nM; Bmax= 1.3±0.05pmoles/mg protein); non-specific binding was ~10% of total binding. In competition binding experiments, the rank order of affinities (Ki) of reference compounds was: CP-101,606 (9nM), ifenprodil (10nM), haloperidol (270nM), eliprodil (340nM). Dizocilpine was inactive and the sigma site ligands, BMY 14802 and DTG only displaced a moderate fraction of the binding at 100μM (25-30%). Interestingly, spermine and Mg2+ were both found to inhibit [3H]Ro 25-6981 binding competitively (Ki: 4 and 800μM, respectively). Quantitative receptor radioautography and image analysis revealed a high density of high-affinity specific binding to rat cerebral cortex (layers 2,3,5), hippocampus (CA1>>CA4>CA3), dentate gyrus, striatum and a lower density in thalamus, whereas binding to midbrain, cerebellum and brainstem was negligible. From saturation studies, KD and Bmax profiles demonstrated the unique regional binding characteristics of [3H]Ro 25-6981. Radioautographic data on monkey and human brain will also be reported. We conclude that Ro 25-6981 is a high-affinity NMDA receptor ligand with a unique pharmacology and restricted brain distribution. These features probably reflect its selectivity for NR2B subunit-containing receptors as shown electrophysiologically in oocytes.

693.8

IFENPRODIL SENSITIVITY OF RECOMBINANT AND NATIVE NMDA RECEPTORS.

K.R. Tovar* and G.L. Westbrook, Vollum Institute, Oregon Health Sciences University, Portland, OR 97201.

To investigate the molecular phenotype of synaptic NMDA receptors in cultured hippocampal neurons, we characterized the sensitivity of native and recombinant NMDA receptors to the atypical NMDA receptor antagonist ifenprodil. Whole-cell recordings were made at -60 mV from hippocampal neurons on glial microislands or transfected HEK293 cells. Extracellular solutions contained (in mM) 0.01 glycine and 1.3 Ca. For neurons, 0.005 CNQX; 0.1 picrotoxin and 0.002 strychnine were added. Agonist and antagonist solutions contained 0.2 Ca; no added Mg and either 1 NMDA alone or with 0.003 ifenprodil. In HEK293 cells co-transfected with the NMDA receptor subunits NR1a and NR2A, ifenprodil had no significant effect on the whole-cell NMDA-evoked current amplitude (102.5±6.3% of control, SEM, n = 9). In contrast, ifenprodil greatly reduced the current amplitude in cells transfected with NR1a and NR2B (30.1±6.3% of control, n = 5), confirming its NR2B specificity (Williams, Mol Pharmacol, 1993). Neither the steady-state inhibition nor the macroscopic on- and off-rates of ifenprodil were voltage-dependent, indicating that at this concentration, ifenprodil is not an open-channel blocker. Additionally, recovery from inhibition was not dependent on open NMDA channels.

In hippocampal neurons, before synaptic activity developed (1-2 days in culture), ifenprodil reduced whole-cell NMDA currents (23.0±3.1% of control, n=9) to a similar extent as recombinant NR1a/2B receptors. The kinetics of ifenprodil inhibition in these neurons was the same as NR1a/2B receptors. The macroscopic on- and off-rates were 1.06±0.08 and 63.2±4.6 sec in neurons compared to 0.92±0.08 and 73.9±8.3 sec in HEK293 cells. However, in neurons in which we detected synaptic activity (7-10 days in culture), the extent of ifenprodil block of whole-cell as well as evoked NMDA EPSCs was much more variable, ranging from 50-90% of control (n=4). These results suggest that NR2B-containing receptors may predominate at nascent synapses. Whether the NR2B subunit is critical for synapse formation remains to be determined. *This work was supported by MH11204 (KRT) and MH46613 (GLW).*

REDOX MODULATORY SITE(S) OF RECOMBINANT NMDA RECEPTORS: SUBUNIT COMPOSITION AND CONFORMATION.

Yun-Beom Choi*, H.-S. Vincent Chen, Nikolaus J. Sucher, and Stuart A. Lipton. Dept. of Neurology, Children's Hospital & Prog. in Neurosci., Harvard Med. Sch., Boston, MA 02115.

Redox modulatory site(s) of the NMDA receptor (NMDAR) can be operationally defined by the effect of the sulfhydryl reducing agent DTT, which enhances, and the oxidizing agent DTNB, which decreases NMDA responses. Nitric oxide-related species, such as S-nitrosocysteine (SNOC), also decrease NMDA responses by acting at redox site(s). In recombinant NMDARs, redox modulation is observed in heteromeric receptors but virtually not in homomeric NMDAR1 receptors. Yet, two cysteines of NMDAR1 are required for at least the persistent form of redox modulation (Sullivan et al., *Neuron* 1994). Redox modulation of NMDAR1/NMDAR2A receptors shows an additional reversible component which was localized to the N-terminal 370 amino acids of NMDAR2A by chimeric studies (Köhr et al., *Neuron* 1994). To investigate which, if any, cysteines may form the reversible redox site, we mutated all 3 cysteines in this region to alanines and co-expressed the mutants with NMDR1 in *Xenopus* oocytes. The reversible component of DTT (3 mM) potentiation of NMDA-evoked currents was not abolished in heteromeric NMDAR1/NMDAR2A$_{C87,231,320A}$ receptors (305 ± 18%, n = 6 vs. NMDAR1/NMDAR2A wild-type 324 ± 27%, n = 9; Ba^{2+}-Ringer). SNOC (500-1000 μM) decreased the NMDA-evoked currents ~30% in NMDAR1/NMDAR2A but not in NMDAR1/NMDAR2B receptors. These results suggest that the subunit composition of NMDARs effects the conformation of the subunits and the properties of the redox modulatory site(s). Funded by P01 HD29587 & R01 EY05477.

NATIVE AND RECOMBINANT NMDA RECEPTORS ARE CLEAVED BY THE SERINE PROTEASE THROMBIN.

M. A. Butler* and S. F. Traynelis, Department of Pharmacology, Emory University, Atlanta, GA 30322.

Both NMDA receptor activation and thrombin extrusion are associated with brain damage in several pathological situations, including stroke, head trauma and Alzheimer's Disease. Excessive activation of the NMDA receptor is a major contributor to ischemia-induced neuronal death, and concentrations of thrombin can reach elevated levels if the blood brain barrier is compromised. mRNA for thrombin precursor is also widely expressed in the developing and adult brain, suggesting that thrombin is normally present in the CNS. We have discovered a direct interaction of thrombin with the NMDA receptor: thrombin cleavage of the NR1 subunit in transfected cells and brain homogenates. HEK293 cells were transfected with the NR1 subunit, and subsequently exposed to variable concentrations of thrombin for one hour. Protein immunoblot analysis of purified membranes with an antibody specific for the NR1 subunit showed that thrombin cleavage produced a decrease in molecular weight of 11.9 ± 4.0 kD from the wild type receptor (n=12), probably near the C- terminal. Heteromeric receptors were also sensitive to thrombin proteolysis (NR1 + NR2A, NR2B, NR2C, n=7). NMDA receptors in homogenates of adult rat brain hippocampal and cortical tissue were sensitive to proteolysis by 5 μM thrombin (approximately blood levels), while receptors from cerebellar and brainstem tissue were cleaved by 20 μM thrombin (n=3). By contrast, the NR2B subunit was insensitive to proteolysis by thrombin (n=2).

In summary, NMDA receptors are substrates for thrombin cleavage, and their sensitivity to proteolysis may have important functional or pathological implications.

DENDRITIC LOCALIZATION AND REGULATION OF NMDAR1 mRNA IN HIPPOCAMPAL NEURONS.

D. L. Benson*, A. H. Gazzaley, Y.-L. Hu, J. H. Morrison, G. W. Huntley. *Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, New York 10029.*

NMDAR1 (NR1) is an obligatory subunit for all NMDA receptors, and its mRNA is expressed in all neuronal somata in rat hippocampus. Using in situ hybridization, we found low levels of NR1 mRNA in the molecular layers of both dentate gyrus and CA fields, strongly suggesting that NR1 mRNA is one of a restricted population of mRNAs that is transported into dendrites. We confirmed the dendritic localization of NR1 mRNA by examining its distribution in dissociated, cultured hippocampal neurons: hybridization for NR1 mRNA was highest in cell somata, but extended into dendrites where it decreased over a proximal-distal gradient. Astrocytes did not contain detectable levels of the mRNA. In order to assess potential differential regulation of somatic and dendritic NR1 mRNA, we examined the distribution of NR1 mRNA in the dentate gyrus following unilateral entorhinal cortex (EC) lesions by transection of the angular bundle. Five days postlesion, we observed an increase in the level of NR1 mRNA through the *entire extent* of the dentate gyrus molecular layer on the side ipsilateral to the lesion, which decreased, but was still evident at 9 days postlesion. Although the time course of mRNA changes correlates closely with immunocytochemically detectable changes in NR1 protein (Gazzaley et al, adjacent abstract), changes in the protein are confined to the *outer 2/3* of the dentate gyrus molecular layer in conformity to the restricted termination of EC afferents. These data indicate that perturbations of afferent input can regulate cellular NR1 mRNA and protein levels with a similar time-course, but with a spatially unique pattern along dendrites. The more wide-spread increase of NR1 mRNA in comparison to the more restricted increase in NR1 immunoreactivity suggests that mechanisms involving posttranscriptional control or differential protein targeting may also play a role in compensatory changes in the final localization of NMDA receptors induced by deafferentation. *Supported by NSF grant IBN-9419900 (D.L.B.), the Sinsheimer Foundation (G.W.H.), and NIH grant AG06647 (J.H.M.).*

LAMINA-SPECIFIC REGULATION OF NMDAR1 IMMUNOREACTIVITY IN DENTATE GYRUS FOLLOWING ENTORHINAL CORTEX LESIONS.

A. H. Gazzaley*, D. L. Benson, G. W. Huntley, J. H. Morrison. *Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, New York 10029.*

Certain forms of memory are linked to NMDA receptor-mediated inputs from the entorhinal cortex (EC) to the outer molecular layer (OML) of the dentate gyrus. Furthermore, NMDAR1 (NR1) immunoreactivity is decreased in the OML relative to the inner molecular layer (IML) of the dentate gyrus in aged monkeys (Gazzaley et al, 1996, PNAS: 93). To explore potential mechanisms for compensatory changes in NMDA receptor localization and concentration following compromise of the EC input, we examined NMDAR1 immunoreactivity in the dentate gyrus of rats following unilateral EC lesions by transection of the angular bundle. Using a NR1-specific antibody and quantitative confocal laser scanning microscopy, we determined the ratio of immunofluorescence intensity within the dendrites of the OML of the dentate gyrus relative to the IML (OML/IML) at 2, 5, and 9 days postlesion (PL). On the side ipsilateral to the lesion, there was no detectable change at 2 days PL, but at 5 and 9 days PL, there was a *50% increase* in the OML/IML ratio of dendritic NR1 immunofluorescence intensity in comparison with non-lesioned and sham-lesioned control animals. By contrast, the side contralateral to the lesion showed no statistically significant differences in OML/IML at any of the PL time points when compared to control animals. Taken together with the changes observed in NR1 mRNA (Benson et al, adjacent abstract), these data suggest dynamic regulation of NR1 subunits in response to deafferentation and/or reactive synaptogenesis. *Supported by NIH grant AG06647 (J.H.M.), the Sinsheimer Foundation (G.W.H.), and NSF grant IBN-9419900 (D.L.B.).*

Regulation of GluRζ1 and GluRε1-3 protein levels by competitive and non-competitive NMDA receptor antagonists in cultured mouse cerebellar neurons. M. Didier*, M. Xu, S.A. Berman, S. Bursztajn. Lab. for Molecular Neuroscience, McLean Hospital and *Dept of Psychiatry, Harvard Med. Sch. Belmont and Boston, MA, USA.

The regulation of NMDA receptor expression and activity by antagonists has been previously reported in vivo as well as in vitro. Although, the NMDA receptor has a heteromeric structure, the effect of NMDA antagonists on the individual subunits remains unclear. We investigated the potential modulation of NMDA receptor subunits by competitive (CPP) and non-competitive (MK801, 7Cl-kynurenate) antagonists in cerebellar granule cells which express GluRζ1 and GluRε1,2 and 3. In 8 day-old cerebellar culture, treatments with 100 μM CPP, 10 μM MK801 or 100 μM 7Cl-kynurenate upregulated all the GluRε proteins whereas the total GluRζ1 level remained unaffected. GluRε1 displayed a 4-5 fold increase whereas GluRε2 and 3 levels were upregulated by 2.5-3.5 times. A maximal upregulation for all of GluRε proteins was observed after 48 hr of NMDA receptor blockade. Spontaneous synaptic activity of granule cells in primary culture is mainly mediated by endogenous excitatory amino acids. We investigated whether blockade of this neuronal activity by TTX may also affect NMDA subunit levels. However, one week of culture treatment with 1 μM TTX failed to modulate GluRε1-3 protein amounts whereas MK801 exposure upregulated these NMDA subunits. This observation suggests that antagonist-induced NMDA receptor upregulation is not predominantly due to a reduction of the spontaneous glutamatergic activity in cerebellar culture. Further experiments are in progress to investigate this hypothesis. This work was supported by NIH and AFAR grants.

DEVELOPMENTAL CHANGES IN NMDA RECEPTOR CHANNELS IN CEREBELLAR GRANULE CELLS. N. Suzuki, D. Feldmeyer, K. Onodera, S. G. Cull-Candy, K. Sakimura, M. Mishina, and T. Takahashi*. Department of Neurophysiology, Institute for Brain Research, Faculty of Medicine, University of Tokyo, Tokyo 113, Japan.

NMDA receptor subunits, ε1-4, are differentially expressed with respect to developmental periods. However, their functional roles are not known. We have compared an ε1 subunit knockout mouse with the wild-type to characterize the effect of ε subunit expression on NMDA receptor-mediated single channel currents and synaptic currents of granule cells in cerebellar slices. Single-channel and western blot analyses indicated that the ε2 subunit disappeared gradually during the first postnatal month in both wild-type and mutant mice. Concomitantly, the voltage-dependent Mg^{2+} block of NMDA receptor-mediated excitatory postsynaptic currents (NMDA-EPSCs) was decreased. Comparison of wild-type and mutant NMDA-EPSCs at P21-24 revealed that the decay time constant of NMDA-EPSCs in mutant was slower than that in wild-type mice. These results suggest that the late expression of ε3 subunit contributes to a developmental reduction in the voltage-dependent block of the NMDA-EPSCs by Mg^{2+} and that the receptors containing the ε1 subunit govern the kinetics of the NMDA-EPSCs.

PLATELET-DERIVED GROWTH FACTOR (PDGF) INDUCES A LONG-TERM INHIBITION OF NMDA RECEPTOR FUNCTION. C.F.Valenzuela*, Z.Xiong, J.F.MacDonald, J.L.Weiner, C.J.Frazier, T.V.Dunwiddie, A.Kazlauskas, P.J.Whiting, and R.A.Harris. Pharmacology Dept. and Neurosci. Prog., U. of Colorado HSC and VAMC, Denver, Colorado, 80262; Physiology Dept., U. of Toronto, Canada M5S 1A8; and MSD Research Labs., Harlow, Essex, U.K.

Platelet-derived growth factor (PDGF) is a multifunctional protein that plays important roles in the mammalian central nervous system (CNS). PDGF and PDGF receptors (PDGFRs) are expressed in practically all regions of the CNS and they are important for the development, survival, growth and differentiation of both neuronal and glial cells. We found that brief activation of PDGFRs produced a long-lasting reduction of N-methyl-D-aspartate (NMDA)-dependent excitatory postsynaptic currents in CA1 pyramidal neurons in rat hippocampal slices. Activation of endogenous PDGFRs in cultured hippocampal neurons also resulted in inhibition of NMDA-R function. The mechanism of this inhibition involved a decrease in NMDA-R single-channel open probability. Non-NMDA receptor function was not reduced by PDGF in hippocampal neurons in slices or in culture. Experiments with mutant PDGFRs and the Ca^{2+} chelator EGTA in Xenopus oocytes showed that this inhibition depends on a phospholipase C-γ-induced elevation of intracellular Ca^{2+} levels. The PDGF-induced inhibition of NMDA-Rs is produced by a mechanism different than the phenomenon of Ca^{2+}-dependent NMDA-R rundown because the effect of PDGF was blocked by the phosphatase inhibitor, calyculin A, and was not altered by the microtubule polymerizing agent, phalloidin. Elevations in PDGF levels are associated with neurological trauma or disease. Therefore, we propose that PDGF can produce neuroprotective effects by inhibiting NMDA-R-dependent excitotoxicity.

THE CARBOXYL - TERMINAL REGION OF THE ε2 SUBUNIT IS INVOLVED IN MODULATION OF ζ1/ε2 NMDA RECEPTORS BY PROTEIN TYROSINE KINASES. Guey-Ying Liao*, David A. Wagner and John P. Leonard. Dept. of Biological Sciences, University of Illinois at Chicago, Chicago, IL 60607.

Modulation of NMDA receptors plays an important role in synaptogenesis, synaptic plasticity and excitotoxicity. Genes for five different NMDA receptor subunits from mouse have been identified. Assembly of the common ζ1 subunit with different ε (ε1, ε2, ε3 or ε4) subunits gives rise to ζ1/ε heteromeric channels with distinct properties. Protein tyrosine kinase (PTK) modulation of individual ζ1/ε receptors has been characterized in our laboratory by activation of endogenous oocyte insulin and insulin-like growth factor I receptors using bath applied insulin. Insulin potentiated NMDA currents from ζ1/ε1, ζ1/ε2, and ζ1/ε4 receptors by 50 - 150%. Insulin had no effect on ζ1/ε3 receptors. To identify the structural domain involved in the PTK-mediated modulation of NMDA receptors, two chimeras, ε2C3 and ε3C2, were constructed between the ε2 and ε3 subunits by exchanging the carboxyl-terminals. The response of ζ1/ε3C2 receptors in *X*enopus oocytes, like ζ1/ε2 but not like ζ1/ε3 receptors, was potentiated approximately 2 fold by PTKs. Injection of an exogenous PTK, $pp60^{c\text{-}src}$, showed the same subunit selectivity for NMDA current potentiation as insulin. Vehicle control only influenced the basal current by about 10% on every tested heteromeric channel. The response of ζ1/ε2C3 is also under investigation. These results suggest that the carboxyl-terminal of the ε2 subunit is involved in the modulation of ζ1/ε2 receptor by PTKs. Supported by NIH R01-NS31962.

MODULATION OF NMDA CHANNEL GATING BY TYROSINE PHOSPHORYLATION IS THROUGH ENDOGENOUS SRC KINASE IN SPINAL CORD DORSAL HORN NEURONS. X.-M. Yu* and M.W. Salter. Div. of Neurosci. Hosp. for Sick Children and Dept. Physiol. Univ. Toronto. Toronto, M5G 1X8, Canada.

Our previous studies have indicated that the gating of NMDA channels is regulated by endogenous protein tyrosine kinase/phosphatases (PTK/PTPs) which may be closely linked to the channels. The **aim** of this study was to identify which endogenous PTKs are involved in regulating NMDA channel activity. NMDA single-channel currents were recorded in the inside-out patch configuration from cultured spinal cord dorsal horn neurons. NMDA channel activity was evoked by including NMDA (10μM) and glycine (3μM) in the extracellular solution present in patch pipettes. The cytoplasmic face of the cell membrane was perfused with solution containing (in mM): CsCl (140), HEPES (10), $CaCl_2$ (1), BAPTA (10), $MgCl_2$ (2), K-ATP (4). Application of a peptide, EPQ(pY)EEIPI, known to activate kinases of the *src* family to the cytoplasmic face of the cell membrane increased the overall open probability (P_o), mean open time, and duration of bursts and clusters by 156±37%, 51±17%, 66±14% and 104±36% (mean±SEM; n=7, $p<0.05$), respectively. In contrast, a non-phosphorylated peptide, EPQYEEIPI, did not have such effects (n=5). Application of anti-cst1, an antibody which blocks kinase activity of the *src* family, decreased the P_o, mean open time, and duration of bursts and clusters by 53±9%, 35±9%, 39±10% and 49±10% (n=6, $p<0.05$). Rabbit IgG did not produce such effects (n=4). Further, we found that anti-src1, an antibody which blocks the function of Src selectively, reduced the P_o, mean open time, and duration of bursts and clusters by 69±7%, 22±2%, 27±5% and 37±7% (n=6, $p<0.05$). Also, pre-administration of anti-src1 prevented the effects of the peptide activator (n=5). No significant change in single channel conductance was found in any of the experiments reported. These results suggest that the gating of NMDA channels may be regulated by Src kinase, possibly associated with the channels. SRC KINASE IS ASSOCIATED WITH NMDA RECEPTOR COMPLEXES IN THE RAT SPINAL CORD. R. Askalan*, X.-M. Yu, and M. W. Salter. Division of Neuroscience, The Hospital for Sick Children, 555 University Av., Toronto, Ontario, M5G 1X8, and Department of Physiology, University of Toronto, Toronto, Ontario, M5S 1A8, Canada.

Protein phosphorylation is a well characterized mechanism for modulating ion channel function. Electrophysiological studies in our lab have shown that NMDA channel activity is potentiated by endogenous protein tyrosine kinase (PTK) (Wang and Salter, *Nature* **369**:233, 1994) and reduced by endogenous protein tyrosine phosphatase (Wang *et al, Natl. Proc. Acad. Sci.* **93**:1721, 1996). Native NMDA receptors are heteromeric complexes formed by the NMDAR1 subunit and NMDAR2A-D subunits. To determine whether a tyrosine kinase is physically associated with NMDA receptor complexes, we have used immunoprecipitation/Western blot analysis with specific antibodies that recognize NMDA subunits and tyrosine kinases. Plasma membranes were prepared from fetal rat (E17-E19) spinal cord. Under non-denaturing conditions of membrane solubilization, NMDAR1-specific antibody not only immunoprecipitated NMDAR1 subunit but also NMDAR2A/2B and the PTK $pp60^{src}$. The potassium channel subunit Kv3.1 was not immunoprecipitated with NMDAR1 indicating that co-immunoprecipitation of Src kinase was not a result of antibody crossreactivity. Conversely, monoclonal Src antibody immunoprecipitated NMDAR1 subunit. Co-immunoprecipitation of $pp60^{src}$ or of NMDAR1 was abolished by denaturation of membrane proteins. In order to determine whether NMDA receptors were associated with the Src kinase in intact neurons, we used immunocytochemical staining of cultured dorsal horn neurons with anti NMDAR1 or anti NMDAR2 and anti Src kinase. Using confocal microscopy, we observed that NMDA subunits and Src kinase are co-localized on the cell body and dendrites of these neurons. These studies show direct evidence that NMDA receptors and Src kinase are present in the same complex. (Supported by the Medical Research Council of Canada).

CHIMAERIC NMDA RECEPTORS EXPRESSED IN *XENOPUS* OOCYTES DEMONSTRATE THAT PKC-POTENTIATION IS ONLY PARTIALLY DEPENDENT ON THE C-TERMINAL REGION OF THE ε2 AND ε3 SUBUNITS. (D.A. Wagner* and J.P. Leonard, University of Illinois at Chicago, Dept. of Bio. Sci., 60607)

Previous work using chimaeras, in which the C-terminal portion of the NMDA ε2 and ε3 subunits were exchanged, showed that channels consisting of wild type ζ1 subunits and chimaeric ε3C2 subunits (ε3 N-terminal and transmembrane regions with the ε2 C-terminal tail) were potentiated by Protein Kinase C (PKC) activators to the same extent as ζ1/ε2 receptors. On the other hand, chimaeric ζ1/ε2C3 receptors, like ζ1/ε3 receptors, were not potentiated by PKC activation (Mori et al, 1993). This suggested that susceptibility to PKC-potentiation was completely determined by residues in the C-terminal tail. Further study of these constructs (re-created in our lab) has revealed that this is only partially true. Heteromeric ζ1/ε2C3 NMDA receptors experience a small but significant potentiation (≈120% of control) following PKC activation which was not previously noted. Furthermore, the ζ1/ε3C2 receptors support robust PKC-potentiation (≈250% of control) but are potentiated *less than* wild type ζ1/ε2 receptors (≈470% of control). We have also noted that current rundown, which is normally seen in ζ1/ε2, but not ζ1/ε3, receptors, associates with the C-terminal tail. After 12 minutes of recording ζ1/ε3C2, currents run down to ≈75% of their initial value while ζ1/ε2C3 currents only run down to ≈90% of their initial value. These data show that the C-terminal tails of the ε2 and ε3 subunits do not completely control PKC-potentiation as previously thought and that they also contain residues that are involved in current rundown. Supported by NIH R01-NS31962.

EXCHANGE OF SERINES IN THE ***C1*** SPLICE CASSETTE INCREASES PKC POTENTIATION OF NMDA RECEPTORS. L. Zhang*, X. Zheng, M.V.L. Bennett and R.S. Zukin *Dept. Neurosci., Albert Einstein Coll. Med. Bronx* ***NY 10461.***

Protein kinase C (PKC) potentiates neuronal NMDA receptors in hippocampus and spinal cord and recombinant NMDA receptors expressed in *Xenopus* oocytes. Alternative splicing of the NR1 subunit alters the degree of PKC potentiation. NR1 subunits that contain the C1 splice cassette exhibit reduced potentiation by TPA, a PKC activator. The C1 cassette plays an important role in NMDA receptor phosphorylation and receptor distribution (Tingley et al., *Nature,* **364**, 70-73, 1993; Ehlers et al., *Science*, **269**, 1734-1737, 1995). PKC phosphorylation occurs at four serine residues, Ser 871, Ser 872, Ser878, and Ser879. To elucidate the role of ***C1*** serines in regulating PKC potentiation of NMDA receptors, we exchanged the four serine residues by site-directed mutagenesis. Exchange of alanines for serines in the $NR1_{011}$ splice variant increased PKC potentiation of NMDA responses to the level observed in C1 lacking receptors. These findings, together with our previous finding that alternative splicing regulates PKC potentiation of recombinant NMDA receptors, provides insight into the molecular mechanisms underlying PKC potentiation of NMDA responses.

MOLECULAR ANALYSIS OF THE HUMAN NPFF (FMRFAMIDE) GENE. J F Burke*, S J Perry, D Cronk+, G M P Lawrence+ and S Wilson+. Biochemistry Laboratory, Biological Sciences, University of Sussex, Brighton. BN1 9QG, UK and +Smith Kline Beecham Pharmaceuticals, New Frontier Science Park, Third Avenue, Harlow, Essex, CN19 5AW, UK.

Neuropeptide FF (NPFF, a FMRF amide related peptide) has been previously isolated from bovine CNS. In rats it has been shown to potentiate the anti-nociceptive effects of morphine as well as increasing blood pressure and heart rate. In order to ascertain the presence of NPFF in humans, a molecular cloning strategy was used. This resulted in the identification of an expressed cDNA and a genomic clone. This revealed an open reading frame of 113 amino acids containing two potential NPFF related peptides, SQAFLFQPQRF amide and AGEGLNSQFLSLAAPQRF amide. The gene contains two introns within the neuropeptide precursor protein encoding sequence, one intron is located within the DNA that encodes the first deduced peptide. Unexpectedly the human NPFF is extended at the N-terminus by three amino acids in comparison to the bovine peptide. The second, larger, peptide (18 amino acids) also encodes an RF amide and differs from the bovine sequence at only two positions. Each can be accounted for by single nucleotide changes.

The isolation of this sequence will allow us to determine the pattern of expression and the location of the gene within the human genome.

Acknowledgement: we thank Human Genome Sciences for the gift of a cDNA.

MASS SPECTROMETRIC PROFILING AND SEQUENCING FROM TWO ELECTROTONICALLY COUPLED GIANT NEURONS OF *LYMNAEA* REVEALS COMPLEX DIFFERENTIAL EXPRESSION AND PROCESSING OF PEPTIDES C.R. Jiménez[1], K.W. Li[1], K. Dreisewerd[1], B. Bateman[2], S. Spijker[1], A.B. Smit[1], J. van Minnen*, C. Janse[1], K.S. Kits[1], W.P.M. Geraerts[1]. [1]Research Institute Neurosciences Vrije Universiteit, Faculty of Biology, De Boelelaan 1087, 1081 HV Amsterdam, The Netherlands; [2]Fisons Instrument, Manchester, England.

We used a combined strategy employing matrix-assisted laser desorption ionization mass spectrometry (MS) for peptide profiling, tandem MS for structural analysis of small unidentified co-transmitters directly from the single neuron, and conventional peptide chemical techniques for characterization of larger co-transmitters, to get an insight into peptide expression and processing in neurons VD1 en RPD2 of the mollusc *Lymnaea*. Subsequently, we examined the cardioexcitatory effects of the various peptides and their modifications on the isolated auricle and investigated the underlying ionic basis of these actions using whole cell voltage clamp analysis of dissociated heart muscle cells. Mass profiling of single VD1 and RPD2 revealed the exact processing of the previously identified prohormones that arise from alternative splicing and a number of unidentified peaks, not predicted by the cDNA precursors. We determined the primary structures of two unidentified molecules at masses 1041 Da and 1123 Da, only present in VD1, directly from one neuron by tandem MS. The fragment ions yielded two related nonapeptides that belong tot the family of small cardioactive peptides (SCPs). Through amino acid sequence analysis and mapping of purified peptides, we identified the other unknown molecules, present in both VD1 and RPD2, as post-translationally modified forms of previously identified α2 and β peptides, and also a novel co-expressed peptide derived from an unrelated prohormone could be structurally identified. Direct MS profiling of target auricle tissue indicated the presence of all VD1/RPD2 peptides. Application of α peptides and SCPs to the isolate auricle showed distinctly different cardioexcitatory effects. Preliminary electrophysiological data suggest that α peptides strongly increase the inward calcium current in isolated heart muscle cells and that the modified α2 peptides are more potent than the unmodified α2.

PEPTIDYL GLYCINE α-AMIDATING ENZYME OF THE MOLLUSC *LYMNAEA STAGNALIS*: A BIFUNCTIONAL ENZYME WITH MULTIPLE COPIES OF A CATALYTIC DOMAIN. S. Spijker, A.B. Smit*, #B.A. Eipper, #R.E. Mains and W.P.M. Geraerts, Dep. of Experimental Zoology, Graduate School Neurosciences Amsterdam, Institute of Neurosciences Vrije Universiteit, De Boelelaan 1087, 1081 HV Amsterdam, The Netherlands, and #Dep. of Neuroscience, The Johns Hopkins University School of Medicine, 725 North Wolfe Street, Baltimore, MD 21205.

Neuroendocrine cells produce biologically active peptides by various post-translational processing events such as specific cleavages of precursor proteins and α-amidation. In vertebrates α-amidation is carried out by a bi-functional enzyme (called peptidylglycine α-amidating monooxygenase - PAM), of which the catalytic core consists of a monooxygenase (PHM) domain and a lyase (PAL) domain. Recently, we have cloned a *Lymnaea* PAM cDNA (LPAM) encoding a protein that is organized differently from vertebrate PAM, *i.e.*, it contains four copies of the PHM domain, a single PAL domain, in addition to a signal peptide, an exon A domain, a transmembrane domain (TMD) and cytoplasmic tail. Unlike the rat PAM gene, the LPAM gene gives rise to a single transcript of ~6.7 kB, consistent with the cloned cDNA. The four *Lymnaea* PHM (LPHM) domains and the single *Lymnaea* PAL (LPAL) domain display a 36-40% amino acid sequence identity with the respective rat sequences. The sequence identity among the LPHM domains is 71-76%. Paired basic amino acid cleavage sites are absent between the LPHM domains, and between the LPAL domain and the TMD. The exon A domain contains basic cleavage sites, which implies that the LPHM domains can be solubilized, whereas the LPAL domain may remain an integral membrane protein. The α-amidating activity of each of the catalytic domains was studied after heterologous expression in hEK-293 cells. To date, LPAL, LPHM-2 and -4 show catalytic activity. The LPHMs have a pH, copper and ascorbate dependence similar to rat PHM. The Km of LPHM-4 is in the same range of rat PHM whereas the Km of LPHM-2 is 10-fold higher. This may suggest a substrate-specificity for each of the LPHM domains. Both LPHM proteins are *N*- glycosylated, and LPHM-2 contains *O*-linked sugars. The cellular expression pattern of the genes encoding previously identified prohormones, prohormone convertases and PAM are being examined using *in situ* hybridization. Comparison of the *Lymnaea* PAM domains with its vertebrate counterparts provides a useful tool in future mutagenesis studies that delineate the structure-function relation of this class of enzymes.

IN SITU HYBRIDIZATION HISTOCHEMICAL ANALYSIS OF PYROGLUTAMYL PEPTIDASE II MRNA DISTRIBUTION IN THE RAT BRAIN. R.M. Uribe, P. Jasso, C. Morales, P. de Gortari, J.L. Charli and P. Joseph-Bravo*. Instituto de Biotecnologia, UNAM, Cuernavaca, Mor., Mexico.

Pyroglutamyl peptidase II (PPII; EC 3.4.19.6) is an ectoenzyme that cleaves the pyroglu-his bond of TRH with narrow substrate specificity. It is mainly present on brain neurons, presumably on postsynaptic membranes. To find whether PPII distribution correlates with markers of TRH synapses, we have analyzed by in situ hybridization histochemistry the macroscopic distribution of PPII mRNA in the rat brain. A pair of 50-mer specific oligonucleotides labeled with ^{35}S was used. Northern blot analysis revealed that oligonucleotides hybridized to the set of brain mRNAs detected by the cDNA. The two 50-mers gave an identical pattern of hybridization. Labeling was displaced with a 10-fold excess cold oligonucleotide and increased in adenohypophysis from animals treated with triiodothyronine according to Northern blot analyses. Highest labeling was found in various cortical regions (piriform, cingulate, rhinal...), habenula, the CA layers of the hippocampus... Lower levels were detected in superior coliculus, septal nuclei, mammillary nuclei, anterior hypothalamic nucleus... PPII mRNA was not observed in dentate gyrus, various thalamic nuclei including the nucleus reticularis... These findings were consistent with a Northern blot analysis of the mRNA distribution. There was a good correlation between PPII and TRH receptor mRNA distributions, except for dentate gyrus. Our data agree with the involvement of PPII in TRH inactivation in brain. Partially supported by grants from DGAPA-UNAM (IN206094) and from CONACYT (0776-N9110).

PITUITARY ADENYLATE CYCLASE ACTIVATING PEPTIDE IS INVOLVED IN INFLAMMATION.

Y-Z. Zhang*, L. Overgaard, L. M. Bjursten, H. Mulder, N. Danielsen, F. Sundler. Dept. Exp. Res., Dept. Hand Surg., Malmö Univ. Hosp., Univ. Lund, Malmö; Dept. Physiol. and Neurosci., Univ. Lund, Lund, Sweden.

Sensory neuropeptides have been implicated in neurogenic inflammation and nociception in arthritis. Adjuvant monoarthrits has been shown to increase primary afferent activity and alter expression of neuropeptide in dorsal root ganglia (DRG). The occurrence of pituitary adenylate cyclase activating peptide (PACAP) in rat DRG, spinal cord and some peripheral tissues is well documented. PACAP in lumbar DRG is upregulated following sciatic nerve transection. Intrathecal PACAP suppresses the C-fibre evoked flexion reflex and the formalin-induced pain-related behavior. PACAP is released from the rat spinal cord by capsaicin. In the present study, we investigated the role of PACAP in inflammation. The DRG L3-L5 of Lewis rats with or without general arthritis (avridine induced arthritis) were dissected and processed for immunocytochemistry and in situ hybridization. The numbers of PACAP mRNA labelled neurons and PACAP immunoreactive neurons in inflamed DRG were significantly increased by 69% and 43% respectively, indicating that expression of PACAP was enhanced and expanded to include more neurons in the general arthritis. Together with the depressive effect of PACAP on the formalin-induced reponse, this finding suggests that PACAP plays a role in inflammation and in the transmission of inflammation evoked nociceptive information in the rat spinal cord.

PORCINE AND RAT GALANIN LABEL THE GALANIN RECEPTOR WITH DIFFERENT PHARMACOLOGICAL PROPERTIES IN RAT BRAIN AND RINm5F CELLS. D. C. Deecher* and F. J. López. Peptide Pharmacology, Women's Health Research Institute, Wyeth-Ayerst Research, Radnor, PA 19087.

Galanin (GAL) is a biologically active peptide that participates in a variety of physiological functions. The action of GAL is mediated via interaction with G-protein coupled receptors, which results in decreases in intracellular cAMP and activation of other signal transduction systems. In the past, pharmacological characterization of GAL receptors (GALR) demonstrated the presence of different receptor subtypes in various locations (pituitary *vs.* brain). In the majority of the studies, however, [^{125}I] porcine GAL (pGAL) has been used to label GALR in different species. Therefore, the question arises as to whether receptors identified by a heterologous tracer represent physiologically relevant GALR in the species of interest. The purpose of this study was to evaluate whether [^{125}I]pGAL identifies GALR with the same pharmacological fingerprints in rat brain and RINm5F (rat insulinoma) cells as [^{125}I](rat) GAL (rGAL) using radioligand binding assays. Scatchard analysis revealed differences in affinities and receptor number dependent on radioligand used. In the RINm5F cells [^{125}I]pGAL labeled approximately 60% more receptors than [^{125}I]rGAL but the affinity was 2-fold lower. Exposure of GALR membranes to increasing concentrations of GppNHp, a non-hydrolyzable GTP analog, showed that receptors labeled by [^{125}I]rGAL are more sensitive to GppNHp-induced uncoupling of G-proteins than those labeled by [^{125}I]pGAL. Moreover, competition studies using GAL from different species (GAL[1-16], human , porcine or rat) and GAL chimeric peptides (M35, M40, C7 or galantide) showed different rank order potencies when competed in parallel experiments for either radioligand. In conclusion, the choice of radioligand is an important consideration when characterizing GALR, since the use of a heterologous ligand may demonstrate a misleading receptor characterization. Therefore, these data strongly suggest that homologous radioligand be used when characterizing GALR in a particular species.

DEPOLARIZATION OF SYMPATHETIC NEURONS ELICITS DISTINCT MODULATION OF NPY, SUBSTANCE P, VIP AND GALANIN CONTENT, SECRETION AND mRNA. K. M. Braas*, S. A. Harakall and V. May. Dept. of Anat. and Neurobiol., Univ. of Vermont Coll. of Med., Burlington, VT 05405.

Neurons of the superior cervical ganglion (SCG) can alter neurotransmitter and neuropeptide expression in response to external signals; both the neurochemical profile and levels of transmitter/peptide production may vary. Depolarization is one mechanism shown to modulate expression of certain transmitters and peptides. To identify peptide specific modulation, primary cultured rat SCG neurons were depolarized with 40 mM potassium for four 24 h periods, and neuronal peptide content, secretion and mRNA were examined. Depolarization increased the rate of sympathetic neuron neuropeptide Y (NPY) secretion over 15-fold without altering cellular NPY levels significantly. In contrast, both neuronal content and rate of secretion of substance P (SP), vasoactive intestinal peptide (VIP) and galanin (GAL) were elevated; however, the magnitude of the increases was peptide specific. Neuronal SP content increased less than 3-fold with chronic depolarization, whereas GAL and VIP levels increased about 50- and 125-fold, respectively. Stimulated release of SP, VIP and GAL also demonstrated peptide specific differences. While cellular levels of SP increased modestly, the rate of SP release increased over 15-fold. The rates of VIP and GAL release mirrored the changes in peptide content. The elevated levels of peptide content and secretion were reflected in augmented peptide precursor mRNA levels. Depolarization elicited higher levels of both pro-GAL and pro-VIP mRNA; moreover, specific forms of protachykinin mRNA were increased. We are currently examining whether depolarization modulates the number of neurons expressing these peptides and/or the amount of peptide per neuron. Our studies suggest that different neuropeptides exhibit distinct mechanisms in response to depolarization. Supported by HD27468 and NS01636 (VM) and AHA94015540 (KMB).

RESP18 is Co-localized with Neurohormones in Neurons of the Paraventricular (PVN), Supraoptic (SON) and Arcuate (ARC) Nuclei and Brainstem. D.N.Darlington*, M.R.Schiller[1], R.E.Mains[1] and B.A. Eipper[1]. Depts Surgery and Physiology, Univ. Maryland Sch. of Med, Baltimore, MD 21201 and [1]Dept Neuroscience, The Johns Hopkins Univ. Sch. of Med, Baltimore, MD 21205

Regulated Endocrine-Specific Protein of 18kDa (RESP18) was isolated from a neurointermediate pituitary cDNA library and is regulated by dopamine, thyroid hormone and glucocorticoids. In the AtT-20 corticotrope tumor cell line, RESP18 is localized in the endoplasmic recticulum and is rapidly degraded when exiting this compartment. Using full length ^{35}S-labeled riboprobes and antiserum against recombinant RESP18, we found RESP18 mRNA and protein in the PVN, SON and ARC and in the brainstem. RESP18 mRNA was co-localized in neurons immunostaining for AVP, CRH, OXY, POMC and somatostatin. In contrast to these peptides, RESP18 immunostaining visualized cell bodies with little staining in processes. Differential centrifugation of extracts from PVN, SON and ARC followed by Western blots identified 18kDa RESP18 in microsomal fractions. These data suggest that RESP18 is localized in the early secretory pathway of peptide secreting neurons. Supported by GM46540, DA 05540 and DA00266

INDUCTION OF A NOVEL PITUITARY ADENYLATE CYCLASE ACTIVATING POLYPEPTIDE (PACAP) PRECURSOR MESSENGER RNA IN RAT SUPERIOR CERVICAL GANGLION NEURONS. C. A. Brandenburg*, V. May and K. M. Braas. Department of Anatomy and Neurobiology, University of Vermont College of Medicine, Burlington, Vermont 05405.

Neurons of the rat superior cervical ganglion (SCG) synthesize and secrete both PACAP38 and PACAP27 (Neurosci Abstr 21:1598). Chronic depolarization of primary cultured SCG neurons with 40 mM potassium elevated PACAP content and secretion 15- to 20-fold. Northern blot analysis identified low levels of a 2.2 kb PACAP mRNA in cultured neurons, similar in size to the predominant transcript reported for other nervous tissues. Depolarization elicited both an increase in 2.2 kb mRNA levels and an induction of a smaller variant (0.9 kb) of pro-PACAP mRNA. A smaller form of pro-PACAP mRNA previously identified in rat testis is characterized by truncated 5'- and 3'-untranslated regions and addition of a unique 126 bp sequence to the 5'-end. Using primers specific for the neuronal transcript, reverse transcription polymerase chain reaction (RT-PCR) of RNA from SCG neurons yielded the expected amplified product; similarly, testis exhibited the expected product using primers specific for the testicular transcript. However, although depolarized neurons expressed a 0.9 kb transcript, RT-PCR using primer pairs specific for the testicular PACAP message failed to produce amplified material of the anticipated size. Current studies are examining whether the smaller neuronal mRNA species results from a shortening of the 2.2 kb transcript following usage of an alternative polyadenylation site. Ultimately, changing the length of the 3'-untranslated region could have significant implications for the overall stability of the message. Depolarizing conditions thus appear to initiate a cascade of cellular events in sympathetic neurons that include alterations in PACAP transcription and/or mRNA stability as well as peptide biosynthesis and secretion. Supported by HD27468 and NS01636 (VM) and VHA9506248S (KMB).

CELLULAR LOCALIZATION OF THE PRO-HORMONE CONVERTASES IN THE HYPOTHALAMIC PARAVENTRICULAR AND SUPRAOPTIC NUCLEI: SELECTIVE REGULATION OF PC1 IN CRH PARVOCELLULAR NEURONS MEDIATED BY GLUCOCORTICOIDS. W. Dong, B. Seidel, M. Marcinkiewicz, M. Chrétien*, N.G. Seidah and R. Day. Clinical Research Institute of Montreal, Montreal, Quebec, Canada, H2W 1R7

Pro-hormone convertases (PCs) activate pro-peptides via cleavage at specific single or pairs of basic residues. The hypothalamic paraventricular nucleus (PVN) and supraoptic nucleus (SON) are sites of biosynthesis of several neuroendocrine hormone precursors, including pro-vasopressin (AVP), pro-oxytocin (OT) and pro-corticotrophin-releasing hormone (CRH), all of which require post-translational processing to yield active products. We examined the co-localization of each PC with AVP, OT and CRH in the PVN and SON. PC1 and PC5 mRNAs were localized in SON and magnocellular PVN, PC2 was distributed in magnocellular and parvocellular subdivisions. By Western analysis, the expected forms of PC1, PC2 and PC7 were demonstrated. The protein distributions of PCs matched the mRNA distributions. The SON and PVN express higher furin mRNA levels than other hypothalamic areas. PC7 mRNA was expressed in these regions with the similar pattern of furin. PACE4 mRNA levels were low. PC1 mRNA was co-localized with AVP and OT mRNA, but very low levels in CRH neurons. PC2 mRNA was in all AVP, OT and CRH cells. PC5 mRNA was in OT cells. The effects of adrenalectomy (ADX) on PC mRNA levels were also studied. In the parvocellular PVN, PC1 mRNA levels were upregulated in CRH/AVP expressing neurons. We also observed that PC1 and PC2 cleaved proOT to yield mature OT. These results established the anatomical organization of each enzyme and pro-neuropeptide substrates in the PVN and SON and suggest potential roles for each PC under resting and stimulated conditions. THE C-FOS GENE IS NOT NECESSARY FOR INDUCTION OF STRIATAL NEUROTENSIN GENE EXPRESSION BY HALOPERIDOL.
L. P. Shearman* and D. R. Weaver. Laboratory of Developmental Chronobiology, Pediatrics, Mass. General Hospital, Boston, MA 02114.

Treatment of rodents with the D2-dopamine receptor antagonist, haloperidol, increases neurotensin/neuromedin N (NT) gene expression in the dorsolateral striatum (DLSt) and nucleus accumbens. Disruption of FOS expression with antisense oligonucleotides reduces haloperidol's effect on NT gene expression (Mol Cell Neurosci 5:336,1994; Neurosci 67:325,1995). To directly test the hypothesis that c-fos gene expression is necessary for induction of NT expression, we examined the effects of haloperidol in c-fos "knockout" mice (Cell 71:577,1992) and their wildtype (WT) littermates. Mice were genotyped by PCR, injected with saline or haloperidol (1 or 4 mg/kg) and killed 4-5 hrs later. In situ hybridization was used to assess NT gene expression. Mice receiving saline had low levels of NT mRNA in the DLSt. Haloperidol treatment caused a large increase in NT mRNA in both c-fos knockout and WT mice; the magnitude of response was equivalent in the two genotypes. Levels of dynorphin, enkephalin, tachykinin and CCK mRNAs were similar in c-fos deficient and WT mice.

During development, other genes may adapt to compensate for a gene disrupted by knockout technology. Therefore, we studied the ontogeny of haloperidol-induced NT gene expression in the DLSt to determine whether deficiency of c-fos might prevent a response to haloperidol at earlier ages. A robust effect of haloperidol treatment on NT mRNA was first observed at PD 15 in c-fos knockout and WT mice. Thus, the c-fos gene is not essential for haloperidol to induce NT mRNA in the DLSt. It is possible that other immediate-early genes may functionally substitute for c-fos, or other molecular pathways may exist, leading to induction of NT gene expression. *Supported by HD29470.*

EFFECTS OF ACUTE CLOZAPINE OR HALOPERIDOL TREATMENT ON NEUROTENSIN/NEUROMEDIN N AND NEUROTENSIN RECEPTOR mRNA EXPRESSION IN DISTINCT REGIONS OF THE RAT BRAIN. E.Binder*, P.Kinkead, M.J. Owens, C.B. Nemeroff, Lab. of Neuropsychopharmacology ,Dept. of Psychiatry and Behavioral Sciences, Emory Univ. Sch. Med., Atlanta, GA 30322

Neurotensin is an endogenous neuropeptide hypothesized to be involved both in the pathophysiology of schizophrenia and in the mechanism of action of antipsychotic drugs. Classical and atypical antipsychotics have been shown to differentially increase neurotensin/neuromedin N (NT/N) mRNA and neurotensin receptor (NTR) mRNA expression in discrete neurons associated with the nigrostriatal or mesolimbic brain dopamine systems. Atypical antipsychotics such as clozapine have been shown to increase NT/N mRNA expression only in the nucleus accumbens (NA), whereas classical antipsychotics such as haloperidol increase NT/N mRNA expression in the NA and the caudate nucleus. In order to further differentiate between the effects of classical and atypical antipsychotics on the neurotensin system, male rats received a single s.c. injection of either 10.0 mg/kg clozapine or 2.0 mg/kg haloperidol and were killed either 3 or 7 hours later, respectively. RNase protection assays demonstrated an increase in NT/N mRNA expression after acute haloperidol in the NA and caudate while acute clozapine increased expression only in the NA and the ventral tegmental area. Neither acute clozapine nor haloperidol altered NTR mRNA expression. Thus, acute clozapine increases NT/N mRNA expression exclusively in the mesolimbic system whereas haloperidol increases NT/N expression in the mesolimbic as well as nigrostriatal system. Acute treatment with these two antipsychotic drugs did not effect NTR mRNA expression. Studies with chronic antipsychotic drug administration are underway.

SEIZURES INCREASE TRH ENHANCING PEPTIDE, PS4, LEVELS IN SPECIFIC LIMBIC FOREBRAIN REGIONS. A.E. Pekary*, R.L. Lloyd, A. Sattin. Endocrinology Research Laboratory and Psychiatry Service, West Los Angeles VA and UCLA, Los Angeles, CA 90073.

We have previously reported that electroconvulsive seizures (ECS) increase the level of TRH (pGlu-His-Pro-NH_2) and TRH-Gly (pGlu-His-Pro-Gly), a TRH precursor peptide, in specific anterior limbic regions of the male rat and that these changes correlate significantly with the reduction in the immobility time during the Porsolt forced swim test, an established bioassay for antidepressant effects (Ann NY Acad Sci 739:135,1994). We have developed a sensitive and specific radioimmunoassay for the PS4 peptide [prepro-TRH(160-169)], which increases TRH-induced thyrotropin (TSH) secretion from rat anterior pituitaries but lacks intrinsic TSH-releasing activity. ECS increases PS4 levels in parallel with TRH and TRH-Gly in the hippocampus, pyrform (olfactory) cortex, and amygdala ($p < 0.01$), but not the striatum or anterior cortex. Tissue levels of PS4 in μg/g wet weight (mean ±SD) were

	Hippocampus	Pyriform ctx.	Amygdala	Striatum	Anterior ctx.
Sham (25)	0.15±0.10	0.21±0.11	0.22±0.16	0.19±0.09	0.11±0.07
ECS (21)	0.70±0.73*	0.36±0.28*	0.60±0.73*	0.23±0.55	0.11±0.10

*$p < 0.01$, 2-tailed, nonpaired t test.

We conclude that ECS accelerates the processing, in the limbic system, of prepro-TRH into a variety of bioactive products including TRH, TRH-Gly and PS4 and that PS4 may function in the brain as an enhancer of the putative antidepressant activity of TRH.

Neuropeptide Y Biosynthesis and Metabolism in the Hippocampal Mossy Fiber System J. B. McCarthy* and J. D. White Trophix Pharmaceuticals Inc., South Plainfield, NJ 07080

Neuropeptide Y biosynthesis and metabolism was investigated in the hippocampal mossy fiber system. Male Sprague Dawley rats were subjected to a single behavioral seizure with pentylenetetrazole (57mg/kg). Newly synthesized NPY was radiolabeled with ^{35}S-methionine delivered to the dentate gyrus with osmotic mini pumps via an indwelling cannula. *In vivo* radiolabeling was performed on control animals and on animals at a post seizure time point coincident with maximal NPY-LI content as determined by RIA. Following labeling CA3 subfields were collected, acid extracted, and subjected to sequential reverse phase, HILIC, and cation-exchange purification. Resulting isolation of NPY peptide indicates only a portion of the NPY-LI following seizure is the mature form of NPY. HPLC/RIA analysis performed on control and post PTZ treated animals indicate that the majority of the NPY-LI following seizure is an alternative molecular form of NPY. Combined results of further purification and MALDI-mass spectrophotometry suggest the alternate NPY-LI species is an oxidized from of mature NPY. A mossy fiber enriched hippocampal synaptosomal preparation was used for analysis of peptide release. These studies indicate a differential mechanism of release for the oxidized and non-oxidized forms of NPY. Mature NPY displays characteristic depolarization stimulated, calcium dependent release, whereas the majority of the putative oxidized form is released upon membrane depolarization displaying little additional calcium dependency. Synaptic peptidase mediated degradation was investigated with exogenous application of NPY to the synaptosome preparation. Subsequent HPLC/RIA analysis revealed metabolites of NPY which, upon partial micro-sequencing analysis, proved to be N-terminal fragments of NPY. These data support a role for NPY in hippocampal physiology. The implications for hippocampal pathophysiology will be discussed. NIMH-MH42074

OPIOID RECPTORS IV

695.1

MECHANISM OF MORS196L ACTIVATION BY ANTAGONISTS. P.A. Claude*, H.H. Loh and P.-Y. Law. Department of Pharmacology, University of Minnesota, Minneapolis, Minnesota 55455.

We have reported a single point mutation in the fourth transmembrane region of opioid receptors, corresponding to S196L in the μ-opioid receptor, which allows classical opioid antagonists to activate the receptor like opioid agonists. Preliminary data obtained from Chinese hamster ovary cells stably expressing MORS196L suggest that opioid antagonists (naloxone and naltrexone) are able to inhibit forskolin stimulated adenylyl cyclase activity with potencies similar to their potencies to reverse agonist induced inhibition of adenylyl cyclase activity at MOR wildtype receptors stably expressed in CHO cells. It is possible that the mutation of the hydrogen bonding serine residue to the non-hydrogen bonding leucine residue disrupts hydrogen bonding between the transmembrane regions and allows the more sterically hindered antagonists to activate the opioid receptor. To determine if hydrogen bonding is involved in the activation of MORS196L by antagonists, serine 196 was mutated to alanine (non-hydrogen bonding), threonine (hydrogen-bonding hydroxyl group in the same position as the serine) and glutamine (hydrogen bonding group in different position than serine). The amino acid substitutions (S196A, S196T and S196Q) were created by site-directed mutagenesis and stably expressed in CHO cells. They were assayed with antagonists for their ability to inhibit forskolin stimulated adenylyl cyclase activity. Additionally, they were co-expressed in *Xenopus* oocytes with the GIRK1 channel to characterize antagonist activation of the G-protein coupled inwardly rectifying potassium channel. 695.2

NALOXONE ACTIVATION OF μ OPIATE RECEPTORS MUTATED AT AN ACTIVE SITE HISTIDINE RESIDUE C.E. Spivak*, C.K. Surratt, C.L. Beglan & G.R. Uhl. Molecular Neurobiology, NIDA IRP, NIH, Baltimore, MD 21224.

The μ receptor TM 6 His-297 residue is critical for both agonist and antagonist recognition; ligand affinities were best maintained with glutamine (H297Q) or asparagine (H297N) substitutions at this position (Surratt *et al., Abstr. Neurosci.***21**:1605, 1995). His-297 was selective alkylated using diethylpyrocarbonate (DEPC); pretreatment of the wildtype receptor with DAMGO, morphine or naloxone significantly protected the receptor from alkylation, indicating that His-297 is in the vicinity of the ligand binding sites. Molecular modeling suggested that this residue could participate in bridging interactions with other residues in the relatively hydrophilic interior cavity. Disruption of such interactions could alter the position of TM 6 and the geometry of the connected third intracellular loop, and therefore alter receptor-G protein contacts and intrinsic activity. The H297Q and H297N mutant receptors were thus compared to the wildtype receptor in their ability to mediate opening of an inwardly-rectifying K^+ channel coexpressed in oocytes. EC_{50} values for the agonists DAMGO and PL017 were indistinguishable for the wildtype and two mutant receptors, while increased EC_{50} values for morphine and normorphine were observed for H297Q, and especially for H297N (≥ 3-fold). As expected for competitive antagonists, naloxone and nalorphine shifted all normorphine concentration-response curves to the right without depressing the asymptotic maximum current. Most intriguing was the finding that naloxone, naltrexone, nalorphine and diprenorphine elicited K^+ channel activity via the H297N and H297Q receptors but not the wildtype receptor; this effect was not observed for the μ-selective peptide antagonist CTOP. Each alkaloid "antagonist" served only as a partial agonist at the mutant receptors. Identification of μ receptor ligand requirements for signal transduction will further the rational development of clinically useful drugs in combatting physical dependence.

CYSTEINE RESIDUES IN TRANSMEMBRANE DOMAINS OF MU OPIATE RECEPTOR ARE INVOLVED IN RECEPTOR BINDING H. B. Deng and J.B.Wang* Department of Pharmaceutical Sciences, School of Pharmacy, University of Maryland at Baltimore, Baltimore, MD 21201

The effects of polar, sulfhydryl specific reagents (MTS) on mu receptor binding of [^{3}H]DAMGO, has been assessed using a established CHO cell line stably expressing human mu opiate receptor (hμCHO). Three MTS reagents (MTSEA, MTSET and MTSES) displayed inhibitory effects on the receptor binding to 1 nM [^{3}H]DAMGO, with maximal inhibition at more than 90% of specific [^{3}H]DAMGO binding and IC_{50} values of 0.57 mM, 3.76 mM and 0.54 mM respectively. The inhibition of mu receptor specific binding was caused by lost of substantial amount of receptor binding sites as Bmax reduced to 49% of control of hμCHO, as well as decrease in binding affinity. To pin point the MTS-sensitive cysteine(s), we mutated eight cysteines in transmembrane regions of the receptor to serine, one by one. The binding affinity (Kd) of each mutants was similar to that of wild type. Four mutated receptors displayed significantly less sensitivity to MTSEA treatment compared with wild type receptor. Among them, C161S, C192S and C237S are the most less sensitive mutants, 0.1 mM MTSEA inhibited agonist binding of C161S, C192S and C237S by only 15%. By contrast, same concentration of MTSEA inhibited specific agonist binding by > 60% in wild type mu receptor. These data suggest that cysteines located at different receptor domains have played differential roles in the receptor binding, cysteines in TM3 (C161), TM4 (C192S), TM5 (C237) and TM7 (C332S) might be crucial residues as either having direct contact with agonist or being exposed in the binding site crevice. Supported by School of Pharmacy, UMAB.

ISOLATION OF OVINE OPIOID RECEPTOR cDNA CLONES: SEQUENCE ANALYSIS AND ANATOMICAL CHARACTERIZATION. R.C. Thompson*, Reproductive Sciences Program, University of Michigan, Ann Arbor, MI 48109.

Opioid modulation of GnRH secretion has been suggested to play a key role in the central regulation of the reproductive axis. The anatomical site of action of endogenous opioid peptides influencing GnRH secretion and which pharmacological class of opioid receptor mediates these effects remains to be fully elucidated. A model system which offers the unique opportunity to measure GnRH secretion in the portal vasculature in the awake, non-anesthetized animal is the sheep. This model system has been used to evaluate the effects of opioid antagonists upon GnRH secretion which demonstrate naloxone regulation of GnRH pulse amplitude (Goodman, et al., 1995). To more fully characterize the anatomical links between opioids and GnRH secretion, we sought to identify opioid receptor clones in the sheep prior to in situ hybridization analysis of the distribution of opioid receptor expressing neurons in this species. Utilizing reverse transcriptase polymerase chain reaction (RT-PCR) with oligonucleotide primers designed from the rat opioid receptor cDNA sequences and striatal cDNA, we isolated several amplified products which were of the expected molecular weight. These PCR fragments were subcloned in plasmid vectors (Novagen) and completely sequenced (USB). DNA sequence analysis of these PCR fragments suggests that both mu (μ) and delta (δ) cDNA fragments were obtained. The ovine mu DNA sequence is 81 % homologous to the rat mu receptor and 75 % homologous to the rat delta opioid receptor cDNA. The ovine delta DNA sequence is 89 % homologous to the rat delta opioid receptor cDNA and 68 % homologous to the rat mu opioid receptor cDNA. Preliminary in situ hybridization analysis suggest that these respective opioid receptor cDNA fragments hybridize to anatomical regions of the ovine CNS consistent with their pharmacological labels. Complete sequence analysis and in situ hybridization results will be presented. This work is supported by set up funds provided by RSP, University of Michigan.

695.5

IDENTIFICATION OF A NOVEL SPLICE VARIANT OF THE MOUSE MU OPIOID RECEPTOR. Y.-L. Du, J. Degen, Y.-X. Pan, G.W. Pasternak and C.E. Inturrisi* Depts. of Pharmacology, Neurology and Neuroscience, Cornell U. Med. College, N.Y., N.Y. 10021.

The pharmacological effects of morphine and several clinically used opioids are mediated primarily at the mu opioid receptor. Although this receptor appears to exist as subtypes (mu_1 and mu_2), only a single cDNA for the rat, human and mouse (MOR) has been identified. Using RNase protection of CD-1 and CXBK mouse brain RNA with a riboprobe that is complementary to the sequences that span the junction between exons 1 and 2 of the MOR, three protected bands were observed. In addition to a 400 base band indicative of the MOR, we found a 260 base band, consistent with protection of the exon 1 sequence and a 155 base band, consistent with protection of exon 2 sequences. RT-PCR with exon 1 and exon 4 derived primers and Southern blotting identified a 1200 bp band (derived from MOR) and a 270 bp band. Cloning and sequence analysis demonstrated that the 270 bp band has 100% homology with the corresponding sequences of exons 1 and 4 of MOR. This mRNA (designated as Mu 1,4) appears to be a new mu splice variant, which does not contain the sequences of exons 2 and 3 of the MOR. Mu 1,4 is found in nearly equal proportions to the MOR in mouse brain RNA and is 2.5 times more abundant in CD-1 mouse brain RNA compared to the CXBK strain. Supported by NIDA Grants DA01457, DA00198, DA07242, DA00220, DA07274, NS07384 and the Aaron Diamond Foundation.

695.6

THE ENANTIOMERS OF RTI-4614-4 DIFFER IN EFFICACY, POTENCY AND INTRINSIC ACTIVITY AS MEASURED BY STIMULATION OF [35S]GTP-gamma-S BINDING BY CLONED MU OPIOID RECEPTORS. H. Xu*1, Y.F. Lu1, J.S. Partilla1, G.A. Brine2, F.I. Carroll2, P.A. Stark2, F. Porreca3, J. Lai3, K.C. Rice4 and R.B. Rothman1. 1CPS, DIR, NIDA and 4LMC, DIR, NIDDK, NIH, Baltimore and Bethesda, MD. 2Chemistry and Life Sciences, Research Triangle Institute, Research Triangle Park, NC 27709. 3Department of Pharmacology, College of Medicine, University of Arizona, Tucson, AZ 85724.

Recent studies have revealed that the opioid agonist-mediated stimulation of [35S]GTP-gamma-S binding provides a "functional" measure of agonist occupation of μ-opioid receptors. The "super-potent" methylfentanyl congener RTI-4614-4, (+)-cis-N-[1-(2-hydroxy-2-phenylethyl)-3-methyl-4-piperidyl]-N-phenylpropanamide is a mixture of four stereoisomers [(2S,3R,4S)-1a, (2R,3R,4S)-1b, (2R,3S,4R)-1c and (2S,3S,4R)-1d]. Isomer 1a is the most potent compound in vivo and in the MVD preparation, yet has the lowest binding affinity of the four enantiomers using cloned mu receptors and mu/kappa chimeras (Lu et al., this meeting). We hypothesized that 1a has greater intrinsic activity than the other enantiomers. We therefore measured agonist-mediated stimulation of [35S]GTP-gamma-S binding in HN9.10 cell membranes stably transfected with rat mu opioid receptors and determined potency (ED50), efficacy (maximal stimulation) and intrinsic activity (effect as a function of receptor occupation). In the presence of 100 μM GDP: 1) the order of potency was etorphine=1c > RTI-4614-4 >1a >1b > DAMGO > morphine, 2) the maximal stimulations were 1a (71%), 1b (153%) > 1c=DAMGO=etorphine> morphine (99%) > 1d=IOXY (0 %). The ED50 of 1a (12 nM) was much lower than its Ki value (374 nM). The receptor occupancies producing a 50% maximal response were: 1a (0.51%), 1b (49.37%) and 1c (46.95%). These data demonstrate that the four enantiomers of RTI-4614-4 differ in potency, efficacy and intrinsic activity. The hypothesis that this results from binding to different domains of the mu opioid receptor will be tested by site-directed mutagenesis.

D147 OF THE RAT μ OPIOID RECEPTOR FORMS ION-PAIRING WITH SOME, BUT NOT ALL, LIGANDS. C. Chen, J. Yin, J. K. de Riel[1], R. L. DesJarlais[2], L. F. Raveglia[3], J. Zhu and L.-Y. Liu-Chen*. Dept. of Pharmacology and [1]Fels Institute, Temple Univ. Sch. of Med., Philadelphia, PA; [2]SmithKline Beecham Pharmaceuticals, King of Prussia, PA; [3]SmithKline Beecham S.P.A., Milan, Italy.

Cloning of μ, δ and κ opioid receptors allows molecular characterization of ligand-receptor interactions. The tyramine moiety of morphinans and enkephalin analogs is essential for high affinity binding to receptors. We recently reported that K233 in the rat μ receptor formed a covalent bond with ß-FNA. This linkage provides an anchoring point for molecular modeling of interaction between morphinans and the μ receptor. Based on our model, N17 of morphinans was hypothesized to interact with D147 of TMH 3 of the μ receptor. In this study, we generated D147A, D147N and D147E mutants of the μ receptor and examined effects of these mutations on binding of peptide and non-peptide ligands. D147A and D147E bound [^{3}H]diprenorphine with similar K_d values as the wildtype, whereas D147N showed a 14-fold increase in K_d. K_i values of nonpeptide ligands naloxone, naltrexone, ß-FNA, morphine and sufentanil in inhibiting [^{3}H]diprenorphine binding to D147A or D147N were increased 10-300 fold over those of the wildtype, whereas their K_i values for D147E were similar to those of the wildtype (<5-fold increase). Reduction in binding affinities of peptide ligands (PL017, DAMGO and CTAP) by these mutations were more pronounced. K_i values of PL017 binding to all three mutants were increased over 100-fold; those of both DAMGO and CTAP were increased by >500-, >4000- and >4000-fold for D147E, D147A and D147N, respectively, over the wildtype. Thus, there is an ion-pairing interaction between D147 and nitrogen of the tyramine moiety of most opioid ligands examined. This interaction appears to be stronger for DAMGO and CTAP than for naloxone, naltrexone, ß-FNA, morphine and sufentanil. In contrast, diprenorphine and PL017 may not have ion-pairing interactions with D147.
(Supported by NIH grants DA04745 and T32 DA07237).

695.8

EVIDENCE THAT THE ENANTIOMERS OF RTI-4614-4 BIND TO DIFFERENT DOMAINS OF THE MU OPIOID RECEPTOR AND CHIMERIC MU/KAPPA RECEPTORS. Y.F. Lu1*, H. Xu1, J.S. Partilla1, G.A. Brine2, P.A. Stark2, F.I. Carroll2, K.C. Rice3, C.M. Bertha3, H. Kayakiri3, W. Sadee4, C. Chen5, L.Y. Liu-Chen5 and R.B. Rothman1. 1CPS, DIR, NIDA and 3LMC, DIR, NIDDK, NIH, Baltimore and Bethesda, MD. 2Research Triangle Institute, Research Triangle Park, NC 27709. 4UCSF, San Fransisco CA 94143.5Department of Pharmacology and Physiology, Temple University School of Medicine, Philadelphia, PA 19140.

To determine if mu opioid receptor agonists bind to different binding domains, we assessed the interaction of the 3-methylfentanyl congeners RTI-4614-4 and its four enantiomers with the cloned mu opioid receptor stably expressed in HEK-293 cells and μ/κ chimera receptors. Receptors were labeled with the peptide agonists [3H]DAMGO and [3H]DADL, the opiate agonists [3H]etorphine ([3H]ET) and [125I]IOXY-AGO and the opiate antagonist [125I]IOXY. Most test agents had considerably higher K_i values with [3H]etorphine ([3H]ET) than with [3H]DAMGO. The "ET/DAMGO" shift was greatest for DAMGO (68-fold) and least for isomer C (6.0-fold). The enantioselectivity of the "ET/DAMGO" shift of isomers a, b, c, d was different than the enantioselectivity of their Ki values measured with [3H]DAMGO. Chimera III(aa κ1-141/μ151-398) bound [^{125}I]IOXY with high affinity. When the region from the N terminal to the start of the TMH3 of the μ receptor was substituted by that of the κ receptor (chimera III), affinities for most test agents were substantially decreased as compared with those of the μ receptor. The K_i(chimera III)/K_i(RMOR) shift was greatest for isomer b (590-fold) and 72-fold for isomer c. These and other data suggest that 1) peptide and alkaloid ligands bind to different domains of the mu receptor, 2) the region from N terminal to the start of the TMH3 of the mu opioid receptor is important for μ agonist selectivity and 3) enantiomers of RTI-4614-4 bind to different domains of the mu receptor.

INVESTIGATION OF THE BINDING POCKET IN THE KAPPA OPIOID RECEPTOR BY A COMBINATION OF ALANINE SUBSTITUTIONS AND STERIC HINDRANCE MUTAGENESES.
Kenneth Thirstrup, Siv A. Hjorth and Thue W. Schwartz*. Laboratory for Molecular Pharmacology, Rigshospitalet 6321, DK-2100, Copenhagen, Denmark.

Background: Only a limited amount of information is yet available concerning the binding of both peptide and non-peptide compounds to the opioid receptors. Binding epitopes have so far mainly been localized by the use of chimeras between the different opioid receptor subtypes, and only a few amino acids have been pointed out to be direct interaction points for their ligands. **Methods:** Based on the Rhodopsin structure, and molecular models refined by the construction of artificial metal-ion sites, 17 sites which were facing the hydrophilic ligand binding crevice at the top of transmembrane domain III, V, VI and VII were systematically substituted by 25 amino acids. A few amino acid pointing into the center of the presumed binding pocket were also substituted to cause steric hindrance. **Results:** Surprisingly, only a few substitutions affected the affinities of a series of different agonists and antagonists. The most important agonist interaction point was found to be the aspartate in TM-III corresponding to the classical amine interaction point. Alanine substitution of this amino acid resulted in a more than 100-fold reduction in affinities for the kappa opioid agonists while antagonists binding affinities were almost unaffected. **Conclusion:** As mutation of only a few amino acids within the transmembrane domains appear to affect both peptide and non-peptide compounds it is suggested that the extracellular loops may be important for the binding of both types of compounds.

THERMODYNAMICS OF BINDING TO THE DELTA OPIOID RECEPTOR. P.A. Maguire* and G.H. Loew. Molecular Research Institute, Palo Alto, CA 94304.

Competitive binding studies, using recombinant mouse δ-receptors (BioSignal, Inc.), were carried out at 0°C, 12°C, 25°C and 37°C with [^{3}H]naltrindole and with four competing ligands: the peptide agonist, DPDPE, the peptide antagonist, TIPP(ψ), the nonpeptide agonist, SNC80 and the nonpeptide antagonist, naltrindole. The goal of the study was to determine the relative contribution of entropy ($\Delta S°$) and enthalpy ($\Delta H°$) to the total free energies of binding ($\Delta G°$) at the δ receptor and the extent to which ligand behavior differed in this respect. The temperature dependence of the binding affinities clearly indicated that for all ligands, the entropy contribution ($T\Delta S$) was the major component of the free energy, accounting for >80% of the value of $\Delta G°$ obtained. Thus, entropic effects, such as ligand and receptor desolvation and changes in degrees of freedom of the ligand/receptor system play a key role in binding affinities regardless of the ligand activity (agonist/antagonists) or chemical nature (peptide/nonpeptide). Although the entropic term dominates for all ligands, differences in the sign of the enthalpy term could distinguish agonists from antagonists. Antagonist binding was to be endothermic, with a positive $\Delta H°$ value, while agonist binding was exothermic with a negative value of $\Delta H°$. Thus, for antagonists, the entropic contribution overcomes an unfavorable interaction between the ligand and receptor. Although the physiological significance of this difference is not clear, it is possible that the more favorable interaction with the receptor found for agonists contributes to their ability to alter receptor properties leading to receptor activation.

FUNCTIONAL EFFECTS OF THE IRREVERSIBLE SITE-DIRECTED ACYLATING AGENT BIT ON MU AND DELTA OPIOID RECEPTOR MEDIATED INCREASES IN [35S]-GTP-γ-S BINDING.
Q. Ni1*, H. Xu1, J.S. Partilla1, K.C. Rice2, D. Matecka2, S. Calderon2, F. Porreca3, J. Lai3, and R.B. Rothman1. 1CPS, DIR, NIDA and 2LMC, DIR, NIDDK, NIH, Baltimore and Bethesda, MD. 3Department of Pharmacology, College of Medicine, University of Arizona, Tucson, AZ 85724.

The site-directed irreversible ligand BIT has been used in vitro to produce brain membranes depleted of μ opioid receptors. There is little information available on the functional effects of BIT. We utilized the [35S]-GTP-γ-S binding paradigm to probe the effect of BIT on opioid mu and delta receptors. Preparation of control and BIT-treated rat brain membranes, the [3H]DAMGO (for mu receptors) and [3H]SNC80 (for delta receptors) binding assays and the [35S]-GTP-γ-S assay used published methods. BIT had no effect on [3H]SNC80 binding but reduced [3H]DAMGO binding by over 90% using standard assay conditions and by 50% using the GTP-γ-S binding buffer. The mu-selective antagonist CTAP (10 μM) completely inhibited DAMGO-stimulated [35S]-GTP-γ-S binding and but had no effect on SNC80-stimulated [35S]-GTP-γ-S binding. BIT did not significantly alter the ED50 values of DAMGO or SNC80, but decreased the maximum effect of DAMGO by 20%. BIT had no effect on the IC50 of CTAP for inhibiting 10 μM DAMGO. The IC50 values for inhibition of 10 μM DAMGO (about 130 nM) or 10 μM SNC80 (about 15 nM) were not affected by BIT. Treating membranes with chlornaltrexamine reduced both [3H]DAMGO binding and DAMGO-stimulated [35S]-GTP-γ-S binding by over 90%. Viewed collectively, these data demonstrate the utility of the [35S]-GTP-γ-S binding assay to probe the functional effects of irreversible ligands. Experiments with cloned mu receptors will be reported at the meeting.

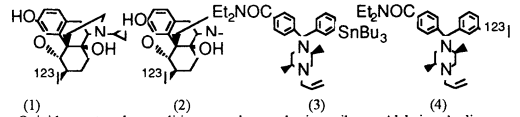
POTENTIAL SELECTIVE RADIOLIGAND FOR SPECT IMAGING OF δ SUBTYPE OPIOID RECEPTORS.
K.S. Lee, H. K. Kayakiri, , D.W. Jones, M.B. Knable*, J. G. Gorey, R.C. Coppola, A. Heinz, K.C. Rice, and D.R. Weinberger. CBDB, NIMH, Washington, D.C. and Lab Medicinal Chemistry and lab of Neuroscience, NIDDKD, NIH, Bethesda, MD.



(1) (2) (3) (4)

Opioid receptor abnormalities may play a role in epilepsy, Alzheimer's disease, and dementia. We previously reported that (1) showed high selectivity and affinity for μ and κ opioid subtypes and that (2), a naltrexone derivative, showed high selectivity and affinity for the μ opioid subtype. We have also showed that both radioligands readily penetrated into the brain and accumulated in regions known to be rich in these opioid subtypes by SPECT imaging of primates. We now report a new radioiodinated ligand (4) with a potent and selective affinity for δ subtype of opioid receptors as demonstrated by binding assays with rat Frotz-Frotz membranes.

The radioligand (4) is prepared by adding 100 μl of 0.32% peracetic acid to a reaction mixture containing of 50 μl of precursor (3) (1mg/ml of ethanol), 50 μl 1N HCl, 200 μl of ethanol, and 5mCi -10 mCi of no carrier-added [I-123]NaI in a sealed vial. The reaction proceeds for 5 minutes at room temperature, then 20 mg of sodium bisulfite in 1 ml of water is added to quench the reaction. The addition of 25-30 mg of sodium bicarbonate in 1 ml of water makes the reaction mixture basic. Radiochemical yield and purity was determined by thin layer chromatography (TLC). 3-5 μl of the reaction mixture was applied to a silica gel TLC plate which was developed in a solvent of chloroform:ethanol:ammonium hydroxide (9:1:0.2). The radiochemical yield was more than 70% with a purity of more than 95%.

695.13

IDENTIFICATION OF MOLECULAR DETERMINANTS INVOLVED IN LIGAND SELECTIVITY FOR HUMAN δ-OPIOID RECEPTOR.
P. Walker*, M. Valiquette, H.K. Vu, S.Y. Yue, E. Roberts, C. Wahlestedt and M.-C. Pepin. Astra Pain Research Unit, Montreal, Qc, H4P 2R2.

The aim of this investigation was to identify residues in the human δ-opioid receptor responsible for the selectivity of δ-selective ligands. Initially, we constructed a chimeric receptor (δ/μ291-300) in which 10 amino acids in the 3rd extracellular loop of the δ receptor were replaced by the corresponding residues from the μ receptor. This chimera retained the ability to bind non-selective opioid ligands but completely lost ability to bind δ-selective ligands. These results suggested that the region of the 3rd extracellular loop of the δ receptor is crucial for the type selectivity. To further characterize this region we used two different approaches. The first approach consists of an alanine scan of 20 amino acids located in or proximal to the 3rd extracellular loop. Among all the point mutations, only mutations of W-284, V-296 or V-297 significantly decreased the binding of δ-selective ligands. Triple point mutation dramatically decreased the affinities of the receptor for the δ-selective ligands compared to the single point mutations. The second approach was based on a "restoration of function" strategy. Using δ/μ291-300 as a template, we generated a library of 16834 mutants in which μ residues of the 3rd loop were randomly reverted to their δ counterparts. After screening of 2000 clones using a receptor binding assay, we identified 9 revertants having recovered the ability to bind δ-selective ligands. Sequencing of these 9 revertants revealed that R-291, L-300 and an hydrophobic region (295 to 300) of the 3rd extracellular loop, are important determinants of the δ selectivity in the δ-opioid receptor. These results suggest that the hydrophobic character of the 3rd extracellular loop seems essential to its recognition by δ-selective ligands and that specific residues may be critical for their binding.

695.14

POTENCY, SELECTIVITY, AND AGONISM OF OPIOID LIGANDS AT CLONED HUMAN DELTA RECEPTORS.
K. Payza*, S. St-Onge, M. LaBarre, C. Godbout, and C. Wahlestedt. Astra Pain Research Unit, 275 bis., Boul. Armand-Frappier, Bldg. 3000, Laval, Quebec H7V 4A7, Canada.

To assess the δ affinity and selectivity of opioid ligands in competitive binding experiments, we used membranes of 293S cells expressing human δ, μ, and κ-opioid receptors in conjunction with the iodinated radioligands: [^{125}I]-[D-Ala^2]-Deltorphin II (K_d = 3.3 nM for δ), [^{125}I]-FK33824 (K_d = 4.7 nM for μ), and [^{125}I]-D-Pro^{10}-Dynorphin A[1-11] (K_d = 0.17 nM for κ). Naltrindole, DPDPE, Deltorphin I, Deltorphin II, Biphalin, and SNC-80 had δ IC_{50} values in the nM range. SNC-86 was the most potent ligand (0.23 nM), but SNC-80 was the most selective (265-fold) for δ vs. μ receptors. We also assessed agonism of the ligands at human δ-receptors by measuring ligand-induced GTP[γ]^{35}S binding to G-proteins in 293S-hDOR membranes. In this assay SNC-80 (3 μM) was used to define 100% E_{max}. As in the receptor binding assay, SNC-86 was the most potent agonist, with an EC_{50} of 0.12 nM (SNC-80 = 6 nM). We observed a range of E_{max} values, indicating:

1. Full agonism (SNC-80, SNC-86, Morphine, M-6-ß-D-glucuronide),
2. Partial agonism (Deltorphin I, Deltorphin II, Biphalin, DPDPE, DAMGO, Dermorphin, and to a low degree Nalbuphine and Dezocine),
3. Antagonism (Naloxone, Naltrindole), and
4. Inverse agonism (ICI-174,864, which decreased basal GTP[γ]^{35}S binding).

There was good correlation for agonists between the δ receptor binding and GTP assays, indicating that these assays can be used to determine affinity, selectivity, and relative efficacy of novel ligands at human δ-opioid receptors.

HIGH AFFINITY ANTAGONISTS FOR OPIOID RECEPTORS: 14-OH-DIHYDROMORPHINONE DERIVATIVES WITH BULKY N-SUBSTITUENTS. A. Borsodi*[1], G. Tóth[1], S. Hosztafi[2], A.Z. Rónai[3] and S. Benyhe[1] Inst. [1]Biochemistry, Biol. Res. Ctr. Hung. Acad. Sci., H-6701 Szeged, P.O.Box 521, [2]ALKALOIDA Chemical Works Ltd., Tiszavasvári, [3]Dept. Pharmacol. Semmelweis Univ. Med. Sch., Budapest, Hungary

A series of N-substituted *noroxymorphone* derivatives were synthesized, and their potencies were assessed in opioid receptor binding experiments in rat brain membranes and in mouse *vas deferens* (MVD) bioassay. In receptor binding experiments performed with [^{3}H]naloxone in the absence or presence of 100 mM Na^+ ion, N-substituted *noroxymorphone* compounds exhibited either pure agonist or strong antagonist properties depending upon the substituent used. Sodium index values varied between 0.4-1.2 in cases of the propyl-, propargyl-, allyl- and cyclopropylmethyl substituents (antagonists). N-propyl- and N-propargyl-*noroxymorphone* proved to be equipotent, pure opioid antagonists against *normorphine* in the MVD bioassay. Their antagonist potencies were approximately 3 and 15 times weaker than those of naloxone and naltrexone in this system. Tritiation of N-propyl-, and N-propargyl-*noroxymorphone* resulted in specific radioactivities of 126 and 21 Ci/mmol, respectively. Equilibrium binding of the labeled compounds to rat brain membrane fraction was reversible, saturable, stereospecific and of high affinity. Binding sites of the newly synthesized radioligands were characterized by various type-selective opiate alkaloids and opioid peptides. The affinites of the investigated compounds were between 0.2-4000 nM and showed $\mu > \delta > \kappa$ rank order of potencies. It is concluded that both tritiated compounds are good tools in examining opioid binding sites of the central nervous system. Supported by OTKA-T 017750, 017687 and ETT 1-27/94 (Hungary); COPERNICUS CIPA CT 94022 (European Commission).

PHARMACOLOGICAL CHARACTERIZATION OF [^{3}H]GLYCYL-L-GLUTAMINE [ß-ENDORPHIN(30-31)] BINDING SITES IN BOVINE FOREBRAIN. D.C. Pendergrass[1], C.B. Unal[2] and W.R. Millington*[1]: Division of Molecular Biology and Biochemistry, University of Missouri-Kansas City[1], Kansas City, MO 64108 and Department of Pharmacology, Uludag University[2], Bursa, Turkey.

Glycyl-L-glutamine (Gly-Gln) is a biologically active dipeptide synthesized during the post-translational processing of ß-endorphin(1-31). The receptor mechanism for Gly-Gln's central actions is wholly unknown, however. Here we report that [^{3}H]Gly-Gln binds in a saturable and stereospecific manner to membrane preparations of bovine forebrain. Scatchard analysis revealed that [^{3}H]Gly-Gln binds to a single, low affinity site with a K_d of 44 ± 33 nM and B_{max} of 1.51 ± 0.34 pmol/mg protein. [^{3}H]Gly-Gln binding was linear with respect to protein and was abolished by protease digestion and heat denaturation. [^{3}H]Gly-Gln did not appear to label a glycine binding site because glycine exhibited low affinity for [^{3}H]Gly-Gln binding (K_i = 109 µM) and ligands selective for the strychnine-insensitive glycine binding site were ineffective at 100 µM; conversely, Gly-Gln displayed low affinity for [^{3}H]glycine binding (K_i = 19 µM). The opioid receptor antagonist, naloxone (100 µM), also failed to displace [^{3}H]Gly-Gln binding and Gly-Gln did not displace [^{3}H]naloxone at concentrations up to 10 mM. [^{3}H]Gly-Gln binding was displaced by structurally related dipeptides with a rank order potency of Gly-Gln >> Gly-Asn = Gln-Gly > Gly-Glu > Gly-Gly with K_i values in the 0.1 - 10 µM range. Gly-D-Gln was ineffective, however, confirming that [^{3}H]Gly-Gln binding was stereospecific. These data indicate that [^{3}H]Gly-Gln binds stereospecifically to a low affinity site unrelated to glycine, glutamate or opioid receptors. (Supported by USAMRDC DAMD17-90-Z-0022).

CATECHOLAMINE RECEPTORS: PHARMACOLOGY

696.1

IN VITRO AND *IN VIVO* PHARMACOLOGY OF RS-100975, A NOVEL ALPHA$_{1A/1L}$-ADRENOCEPTOR ANTAGONIST FOR BENIGN PROSTATIC HYPERPLASIA. D.R. Blue, Jr., A.P.D.W Ford, F. Padilla, D.J. Morgans, Q.-M. Zhu, M.S. Kava, J.R. Jasper*, D. Bonhaus & D.E. Clarke. Institute of Pharmacology, Roche Bioscience, Palo Alto, CA 94304.

The preclinical pharmacology of the novel $\alpha_{1A/1L}$-adrenoceptor (AR) antagonist, RS-100975, is as follows. Affinity estimates (pA_2±SEM) for RS-100975 in tissues contracted with norepinephrine: rabbit bladder neck (α_{1L}; 8.9±0.1), rat aorta (α_{1D}; 6.8±0.1), human lower urinary tract tissue (α_{1L}; 8.8±0.1) and human renal artery ($\alpha_{1?}$; 6.8±0.3). Functional affinity estimates at α_{1L}- ARs were comparable to those obtained by binding to the cloned bovine α_{1A}-AR (pK_i=9.0). In conscious rat blood pressure models, RS-100975 was 100 and 206-times less potent than prazosin at producing a 15mmHg fall in blood pressure (rats pretreated with β_1-AR and AT_1-receptor antagonists) and evoking postural hypotensive responses (2 min, 60° head-up tilt), respectively. In anesthetized male mongrel dogs and female micropigs, RS-100975 (0.03-300µg/kg, iv) was 76 and 218-times more potent, respectively, at inhibiting hypogastric nerve stimulation (20-50V, 10Hz, 10sec) and/or phenylephrine (6-20µg/kg, iv)-induced increases in intraurethral pressure (balloon catheter) over phenylephrine-induced increases in diastolic blood pressure. "Uroselectivity" and prolonged activity were also observed in this model following intraduodenal administration of RS-100975 (30-300µg/kg) to dogs. Lastly, unlike prazosin, terazosin and tamsulosin, prostate-selective doses of RS-100975 (30-300µg/kg, po) did not evoke postural hypotension upon head-up tilts (2 min, 80°) in male mongrel dogs instrumented with telemetry devices in a carotid artery. These results clearly demonstrate the "uroselectivity" of RS-100975 and underline its potential for the treatment of urinary outlet obstruction associated with benign prostatic hyperplasia without producing cardiovascular side effects.

696.2

DOPAMINE D_1-LIKE RECEPTOR-MEDIATED SIGNALING IN EEDQ-TREATED RATS. A. S. Undie* and A. B. Cseresnyes. Neuropharmacology Lab., Medical Biotechnology Center, Univ. of Maryland at Baltimore School of Pharmacy, Baltimore, MD 21201.

Systemic administration of the irreversible monoamine receptor antagonist, N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) consistently inactivates only a fraction of dopamine D_1-like receptors in the rat brain. To determine the coupling mechanisms of striatal EEDQ-insensitive D_1-like receptors, rats were pretreated with ip injections of up to 10 mg/kg EEDQ, followed by measurements of dopamine agonist-stimulated cyclic AMP formation in striatal membranes and phosphoinositide metabolism in striatal slices. Consistent with previous observations, EEDQ-treated animals showed behavioral and receptor changes indicative of D_1-like receptor inactivation. Parallel deficits in dopamine-stimulated cyclic AMP accumulation were observed in the EEDQ-treated animals, whereas SKF38393-induced accumulations of inositol phosphate and CDP-diacylglycerol were unchanged by EEDQ treatment. These data suggest that the phosphoinositide-coupled dopamine receptor is insensitive to EEDQ-induced inactivation, and that this receptor system may mediate a specific subset of dopaminergic behaviors.

696.3

DIFFERENTIAL EFFECTS OF ADRENOCEPTOR BLOCKADE ON CORTICAL IMMEDIATE EARLY GENE mRNAS FOLLOWING CEREBRAL INFARCTION. P.-J. Shen*, A.-M. Arabia and A. L. Gundlach, Univ of Melbourne, Clin. Pharmacol. & Therap. Unit, Austin & Repatriation Med. Ctr., Heidelberg, Vic. 3084, Australia.

Noradrenaline is an important neurotransmitter in the CNS involved in cerebral plasticity and functional recovery after brain injury. Brain damage has been shown to increase immediate early gene (IEG) expression and increase levels of regulatory proteins, enzymes and receptors in the homolateral cortical hemisphere in the rat. To examine the role of different adrenoceptors in these effects, we studied the effect of prazosin (5 mg/kg), an α_1-adrenoceptor antagonist, 2-methoxyidazoxan (5 mg/kg), an α_2-adrenoceptor antagonist, and propranolol (10 mg/kg), a β-adrenoceptor antagonist, on IEG (c-*fos* and c-*jun*) expression after a minimal cortical lesion. Unilateral cortical lesions were performed in anaesthesized Sprague-Dawley rats (n = 3 per group) by removing a piece of parietal bone and making needle cuts ~1 mm into the underlying cortex across the hole (~3 mm). Drugs were injected intraperitoneally, 30 min prior to surgery. Lesioned and sham-operated animals were killed after 1 h and processed identically. Levels of IEG mRNA, detected by *situ* hybridization of [^{35}S]-oligonucleotides, were low in cortex of sham-operated rats. Parietal cortex lesion increased c-*fos* (557 ± 40%, P < 0.01) and c-*jun* (63 ± 6%, P < 0.01) expression in ipsilateral cortex *cf* contralateral side. Propranolol potentiated lesion-induced c-*fos* (36 ± 2%, P < 0.05) and c-*jun* (58 ± 9%, P < 0.01) expression. 2-Methoxyidazoxan had similar effects. Prazosin reduced the lesion-induced c-*fos* (55 ± 2%, P < 0.01) and c-*jun* (57 ± 4%, P < 0.05) mRNA levels relative to untreated values. No differences were observed in levels of c-*fos* and c-*jun* mRNA in contralateral cortex of all groups. Effects of α- and β-agonists are currently being examined. These results suggest that noradrenaline, acting via different adrenoceptors, has differential effects on increased IEG expression after injury, with α_2- and β-adrenoceptors mediating a net inhibitory, and α_1-adrenoceptors an excitatory, influence. These adrenergic actions may be functionally important in cortical injury, contributing to the adaptive and 'recovery' responses of brain neurones. *Supported by the NH&MRC of Australia.*

INVERSE AGONIST ACTIVITY OF D1 ANTAGONISTS: EFFECT ON INCREASED BASAL ADENYLYL CYCLASE ACTIVITY. S.E. Côté*[1], P.J. Bédard[2], and P. Falardeau [1]. [1]Centre de Recherche du CHUL and School of Pharmacy, Université Laval, Ste-Foy (Québec), Canada, G1V 4G2, [2]Neurobiology Res. Center, Enfant-Jésus Hospital, Québec, Canada G1J 1Z4.

In Parkinson's disease, D1 receptor stimulation leads to a rapid and extensive therapeutic tolerance of the motor effects. Interestingly, our previous results showed that this phenomenon is due to a desensitization of D1 receptors and is different depending on the agonist used. These results revealed the importance of the agonist itself in the specific molecular mechanisms of desensitization (Soc. Neurosc. Abstr, Vol 21:1118, 1995). The present experiments were done using a mouse fibroblast Ltk- cells expressing 350 fmole/mg protein of the human dopamine D1 receptor. In this system, treatment with either of the D1 agonists A81686 or SKF-82958, induced a significant increase of basal adenylyl cyclase activity. In the present work, we showed that specific D1 dopamine antagonists such as R(+)SCH 23390, (+)butaclamol and cis-(Z)-flupenthixol can reestablish adenylyl cyclase level under basal level in a dose-reponse fashion. Our results suggest that these antagonists have inverse agonist activity on D1 receptors. Such antagonists might be useful to reverse agonist induced-desensitization.

Supported by Medical Research Council and Parkinson Foundation of Canada.

696.5

FUNCTIONAL SELECTIVITY: DIHYDREXIDINE, A D_2 AGONIST, ACTS AS AN ANTAGONIST AT DOPAMINE RELEASE-MODULATING D_2 RECEPTORS. J.D. Kilts*, C.P. Lawler, D.E. Nichols[1], K.L. O'Malley[2], R.D. Todd[2], and R.B. Mailman. Univ. of North Carolina, Chapel Hill, NC 27599, [1]Purdue Univ., W. Lafayette, IN 47907, and [2]Washington Univ., St. Louis, MO 63110.

The full D_1 agonist dihydrexidine (DHX), while ten-fold D_1 selective, also has high affinity for the D_2 receptor ($K_{0.5}$ = 50 nM in rat striatum). In brain, DHX has an unusual functional profile: despite binding with similar affinity to both pre- and postsynaptic D_2 receptors, DHX has agonist properties at D_2-mediated postsynaptic functions (e.g., inhibition of adenylate cyclase activity), yet not at D_2-mediated presynaptic functions (e.g., inhibition of either nigral cell firing or dopamine release). The present study investigated the effects of DHX and some of its analogs on the K^+-stimulated release of preloaded [^{3}H]dopamine in MN9D cells stably transfected with the D_{2L} receptor. MN9D cells are a clonal mesencephalon-derived line that can synthesize and release dopamine, yet contain no endogenous dopamine receptors. In this line, DHX and several of its analogs ($\leq$ 100 μM) were unable to inhibit K^+-stimulated [^{3}H]dopamine release, whereas the D_2 agonists quinpirole and R(-)NPA inhibited the stimulated release by 70% and 60%, respectively, at 10 μM. Although having no actions alone, DHX and two of its D_2-selective analogs (N-n-propyl-DHX and 4-Me-N-n-propyl-DHX) reversed the inhibition by either quinpirole or R(-)NPA, thus showing D_2 antagonist properties. Previously we have shown that DHX and its analogs act as full agonists for D_{2L}-mediated inhibition of cAMP accumulation in the MN9D cells. Thus, in this molecular expression system, a drug may bind to the same isoform of a receptor (in this case the D_{2L}), yet affect different functions in diametrically opposite ways. These data confirm and extend our earlier studies in the intact nervous system, and lead to the present hypothesis: "functionally selective" drugs induce conformational changes in a given receptor isoform that can differentially activate only a subset of the available G proteins. 696.6

FUNCTIONAL ASSESSMENT OF THE EFFECTS OF PROLYL-LEUCYL-GLYCINAMIDE ANALOGS ON D_2 DOPAMINE RECEPTOR STIMULATION OF G-PROTEINS, W. J. Costain[1], K. P. Berin[1], R. L. Johnson[2], R. K. Mishra[1]*. [1] Dept. Biomed. Sci., McMaster Univ., Hamilton, ON, Canada, L8N 3Z5. [2] Dept. Medicinal Chem., Univ. of Minnesota, Minneapolis, MN, USA, 55455-0343

The predominant theory of schizophrenia is based on the concept of dopaminergic neuronal hyperactivity within the limbic system. This is supported by the observation that neuroleptics act as antagonists at dopamine (DA) receptors. Further, neuroleptic potency correlates well with D_2 DA-receptor binding affinity. Several studies have indicated a modulatory role for prolyl-leucyl-glycinamide (PLG) and its analogs on DA-receptor function, including: ❶ PLG maintains D_2 DA-receptors in a high affinity state, ❷ PLG potentiates DA stimulated inhibition of adenylyl cylcase activity and ❸ PLG potentiates apomorphine stimulated rotational behaviour in hemi-parkinsonian rats. We report here, for the first time, direct functional evidence of a modulatory role for PLG in D_2 DA-receptor G-protein coupling. Specifically, the D_2 receptor agonist N-propylnorapomorphine (NPA) was shown to increase [^{35}S]-GTPγS binding in a dose dependent manner. Furthermore, NPA stimulation of [^{35}S]-GTPγS binding was inhibited in the presence of haloperidol, indicating that the effect was specific to D_2 DA-receptors. PLG and its analogs were found to modulate NPA stimulated increases in [^{35}S]-GTPγS binding in bovine striatum. The observations presented here demonstrate that PLG, and its more active analogs, modulate D_2 DA receptor function at the G-protein site in addition to other sites.

696.7

COUPLING OF D_{2L} AND D_3 RECEPTORS TO G-PROTEIN ACTIVATED INWARD RECTIFIER POTASSIUM CHANNELS IN MAMMALIAN CELLS. E. V. Kuzhikandathil* and G. S. Oxford. Department of Physiology, University of North Carolina, Chapel Hill, NC 27599

The inhibition of neurotransmitter secretion by autoreceptors is thought to be mediated through hyperpolarization induced by G-protein activated inward rectifier potassium channels (GIRKs). The dopaminergic system provides a useful model for studying the mechanism of autoinhibition since both the D_2 and the D_3 receptors have been shown to function as autoreceptors in various parts of the brain. In this study we examined the coupling of the human D_{2L} and D_3 receptor to members of the GIRK protein family. Chinese hamster ovary cell lines (CHO) stably transfected with plasmids expressing either the human D_{2L} or D_3 receptors were transiently-transfected with plasmids expressing the human GIRK2 and the Green fluorescent protein (GFP). The expression of GFP allowed positive identification of individual transfected cells, which were then subjected to electrophysiological characterization. Application of 100 nM Quinpirole elicited inward currents in high potassium solution, only in CHO cells expressing the dopamine receptors (D_{2L} or D_3) and GIRK2. These results suggest that both the D_{2L} and D_3 receptors can couple to human GIRK2 in CHO cells. Similar results were obtained when the human D_3 receptor was stably transfected and expressed in the AtT20 mouse pituitary cell line which have been previously shown to express endogenous GIRKs. The results from this study suggests that the dopamine receptors D_{2L} and D_3 can functionally couple to GIRKs in mammalian cells and also identifies GIRKs as endogenous effectors of D3 receptors. CHARACTERIZATION OF AN AMINO TERMINAL TAGGED DOPAMINE D4 RECEPTOR. J. Oldenhof*, J.N. Oak, M. Knapp, O. Schoots, Y. Li and H.H.M. Van Tol. Clarke Inst. of Psychiatry, Toronto. Ont. Canada M5T 1R8.

Conventional expression of the dopamine D4 receptor in cultured cell lines typically results in relatively low expression of the receptor. To increase expression we modified the amino terminal end of the receptor and the 5' and 3' untranslated sequences. Stable and transient expression of these modified receptors were checked for their pharmacological and functional characteristics.

The following modified dopamine D4.4 constructs cloned into RSV were made: D4.4 (RSV D4.4); D4.4 preceded by an amino-terminal cleavable signal sequence and a flag tag sequence (RSV SSF D4.4); D4.4 preceded by a signal sequence, a flag tag and the SV40 intron (RSV SSF D4.4 SV40); and D4.4 preceded by a signal sequence, a flag tag and 5' and 3' untranslated globin sequences (RSV SSF D4.4 GLOBIN). The constructs were transiently expressed in HEK293 cells. Cells expressing the RSV SSF D4.4 or the RSV SSF D4.4 SV40 constructs showed 5 fold and 10 fold higher expression respectively compared to control D4.4 RSV. Addition of the globin sequence (RSV SSF D4.4 GLOBIN) did not alter the expression of the receptor significantly compared to RSV SSF D4.4.

The RSV SSF D4.4 construct was stably expressed in CHO cells. Two cell lines were selected (SSF D4.4 #1 and SSF D4.4 #10) which showed high expression and typical spiperone binding. Functional characterization showed that the SSF D4.4 #10 cell line showed proper functional inhibition of forskolin stimulated cAMP levels. Pre-incubation with dopamine showed desensitization of the receptor. Further we were able to immunoprecipitate the D4.4 from the membrane using an antibody directed against the flag tag sequence.

Addition of an amino terminal sequence allows for the up-regulation of the D4 receptor while maintaining pharmacological and functional properties of the receptor. Supported by the Canadian Medical Research Council (MRC PG11121).

OPPOSING ROLES FOR D_1 AND D_2 RECEPTORS IN THE REGULATION OF TUBEROINFUNDIBULAR DOPAMINE NEURONS IN MALE RATS J.D. Johnson, R.A. Durham, K.E. Moore* and K.J. Lookingland, Dept. Pharm.& Toxicol., Michigan State University, E. Lansing, MI 48824

Selective activation of D_2 receptors with quinelorane stimulates tuberoinfundibular dopaminergic (TIDA) neurons via inhibition of tonically active inhibitory afferent neurons. Selective activation of D_1 receptors has no effect *per se*, but prevents the stimulatory effects of prolactin, neurotensin and reserpine on TIDA neurons (Berry and Gudelsky, 1990, J. Pharm.Exp.Ther. 254:677). The ability of D_1 receptor agonists to reverse reserpine-induced activation of TIDA neurons suggests a direct action of these agonists on tyrosine hydroxylase (TH) activity. To test this, the effects of the D_1 receptor agonist SKF38393 were determined on two indices of TIDA neuronal activity in quinelorane-treated male rats; 1) concentrations of 3,4-dihydroxyphenylacetic acid (DOPAC) in the median eminence (ME)(a TH-dependent index), and 2) expression of FOS protein in TH-immunoreactive (IR) neurons in the dorsomedial (DM) and ventrolateral (VL) arcuate nucleus (ARC)(a TH-independent index). Quinelorane increased DOPAC in the ME and the number of TH-IR neurons containing FOS-IR in the DM-ARC, but not the VL-ARC. SKF38393 had no effect *per se*, but blocked the stimulatory effects of quinelorane on DOPAC in the ME and FOS protein expression in TH neurons in the DM-ARC. These results support the hypothesis that D_1 receptor agonists modulate the activity of TIDA neurons via D_1 receptors rather than non-specific interactions with TH, and suggest that D_1 and D_2 receptors exert opposing roles in the regulation of TIDA neurons. (Supported by NIH Grant MH 42802)

DIFFERENTIAL RESPONSES IN THE RAT AFTER CHRONIC ADMINISTRATION OF D_1 DOPAMINE AGONISTS HAVING DIFFERENT INTRINSIC ACTIVITY M.A. Mayleben*, C.D. Striplin, C.P. Lawler, S. Kongsamut[1], D.E. Nichols[2] and R.B. Mailman. Neuroscience Center, Univ. of North Carolina, Chapel Hill, NC 27599, [1]Hoechst Marion Roussel Inc., Somerville, NJ, and [2]Dept. Med. Chem., Purdue Univ., W. Lafayette, IN. 47907

While most pharmacotherapy for Parkinson's disease has focused on D_2 dopamine receptor agonists, we recently demonstrated that dihydrexidine (DHX), the first high affinity full D_1 agonist, has marked antiparkinsonian activity in the MPTP-treated monkey. While another full D_1 agonist, A77636, also is effective acutely, the partial D_1 agonist SKF38393 has modest effects either in MPTP-treated primates, or in humans with Parkinson's disease. These data make it important to understand the effects of chronic administration of full vs. partial D_1 agonists. Using osmotic minipumps, we administered vehicle or D_1 agonists (DHX, SKF38393, A77636) having different intrinsic activities and receptor selectivities to rats for 14 days. At 14 days, all drug-treated rats displayed enhanced grooming compared to vehicle-treated rats. In the striatum (STR), the B_{max} of D_1 receptors was decreased by A77636, increased by SKF38393, and unaffected by DHX. Conversely, none of the treatments affected D_1 receptors in the nucleus accumbens. Stimulation of adenylyl cyclase by dopamine was decreased by A77636, but was not affected by the other two drugs. We explain these results as follows: 1) the receptor down-regulation caused by the selective full D_1 agonist A77636 is as expected by a full agonist; 2) the receptor up-regulation caused by the partial agonist SKF38393 is due to the fact that this compound is also a partial antagonist; and 3) DHX, although a full D_1 agonist, also has D_2 agonist properties that offset the D_1 down-regulating effects. These data demonstrate for the first time the interaction of D_1 and D_2 receptors in accommodating the long term receptor occupancies of various combinations. D5 DOPAMINE RECEPTOR MEDIATES INHIBITION OF TRH-INDUCED IP3 PRODUCTION. B.H. White*, K. Kimura and A. Sidhu. Lab. Neurochem., Georgetown Univ. Med. Ctr., Washington, DC 20007

The exact function of the D5 dopamine (DA) receptor subtype remains to be elucidated. D5 receptor activation stimulates cAMP accumulation in a number of cell systems. We have some evidence to indicate that D5 couples to a G-protein other than Gs, and so could quite possibly be involved in signaling pathways other than regulation of adenylyl cyclase. To more fully describe the interactions of the D5 receptor with cellular effectors, we have used GH_4 C_1 cells transfected with cDNA for the human D5 receptor. D1 agonists have been demonstrated to stimulate phosphoinositide hydrolysis in brain slices, but in contrast, we did not detect any stimulation of IP3 production, but rather an inhibitory effect. TRH (100 nM) stimulated IP_3 production approximately five-fold in $D_5GH_4C_1$ cells. Dopamine (DA) inhibited this stimulation by 61%, with an IC_{50} of 600 nM. The D1 agonist R-SKF 38393 only partially mimicked this effect, causing a maximum of 21% inhibition. SCH23390, a D1 antagonist, blocked the inhibition caused by R-SKF 38393. The D2 agonist PPHT did not inhibit IP3 production. Neither cAMP analogues nor forskolin lowered IP3 formation in response to TRH. The DA-mediated suppression of IP3 levels was not sensitive to pertussis toxin, but cholera toxin blocked both TRH stimulation and DA decrease of the amount of IP3.

Research support is provided by NIH grant NS 29685.

DOSE-DEPENDANT EFFECTS OF DOPAMINE ANTAGONISTS ON LOCOMOTOR ACTIVITY IN THE LOBULES 9 AND 10 OF THE CEREBELLUM: A ROLE FOR THE D3 RECEPTORS. S Barik, R de Beaurepaire*. Lab. Pharmacologie, INSERM U.320, 14032 Caen, France.

The dopamine D3 receptor has been cloned in 1990, and its functional role remains elusive, mainly because all the D3 receptor ligands also have a high affinity for the D2 receptors, which makes it difficult to differenciate the proper role of the D2 and D3 receptors. However, dopamine D2 and D3 receptors are expressed in anatomically distinct areas in the brain. The lobules 9 and 10 of the cerebellum contain high densities of dopamine D3 receptors and are devoid of D2 receptors. The functional role of this cerebellar dopamine D3 receptor system is unknown. We microinjected high (20 µg in 0.2 µl) and low (2, 20, 200 ng in 0.2 µl) doses of 3 dopamine antagonists (amisulpride, nafadotride and haloperidol), and of a dopamine agonist (apomorphine), in the lobules 9 and 10 of the cerebellum, and in the nucleus accumbens of the rat. Amisulpride and nafadotride, but not haloperidol, have a high affinity for the dopamine D3 receptors. The results show that low doses of amisulpride and nafadotride dose-dependantly activate locomotor activity in the lobules 9 and 10 of the cerebellum and in the nucleus accumbens, while high doses decrease locomotor activity. Low doses of haloperidol or apomorphine had no effects, and high doses of these componds decreased locomotor activity (the decrease of activity with apomorphine is explained by a strong effect on presynaptic receptors). The effects were of the same kind in the cerebellum and nucleus accumbens, however the effects were stronger in the nucleus accumbens. These results provide the first demonstration of a functional role for the dopamine D3 receptor system in the cerebellum, and show that this system is involved in locomotion. These results also give physiological support for the dose-dependant clinical effects of amisulpride (an antipsychotic drug marketed in European countries).

FOCAL DENDRITIC D1 RECEPTOR STIMULATION DIFFERENTIALLY MODULATES LAYERS I-II & V-VI GLUTAMATE INPUTS TO DEEP LAYER PREFRONTAL CORTICAL (PFC) PYRAMIDAL NEURONS *IN VITRO*. C.R. Yang*, J.K.Seamans, and N. Gorelova. Dept. of Psychology, Univ. of British Columbia, Vancouver, B.C. V6T 1Z4, Canada.

Several voltage-dependent currents are modulated by the dopamine (DA) D1 receptor in deep layer PFC pyramidal neurons. This DA modulation may differentially alter the effects of synaptic afferents to the apical (layers I-II) and proximal dendritic (layers V-VI) regions, as proposed by our recent neuronal model (Yang & Seamans, J. Neurosci. 16: p1922). This possibility was examined using somatic intracellular or apical dendritic whole-cell patch-clamp recordings of layers V-VI PFC pyramidal neurons.

Focal pressure ejection of the D1 agonist SKF81297 (20psi,0.05-1sec puffs, 0.3mM, 0.1% Fast Green) confined only to the apical dendrites (layers I-II) in intrasomatically recorded PFC neurons *reduced*: 1) the firing of action potentials atop the NMDA EPSPs (10µM bicuculline+10µM DNQX) evoked by layers I-II stimulation (0.05Hz), 2) the synaptically evoked high threshold dendritic Ca^{2+} spikes ($HTS_i[Cs^+ + QX\text{-}314]_i$). which normally amplify synaptic signals Furthermore, during direct apical dendritic patch recordings ($[QX\text{-}314]_i$) from biocytin-stained deep layer PFC neurons, SKF81297 suppressed the late components more than the initial peak amplitude of the regenerative multiphasic dendritic Ca^{2+} plateau potential, suggesting that D1 receptor activation spatially restricts the dendritic sites that generate Ca^{2+} potentials.

Intrasomatic recordings from deep layer pyramidal neurons with the apical dendrites and axon collaterals removed (layers I-III cut) showed that EPSPs evoked by layer V-VI stimulation were *enhanced* by SKF81297 (1-5µM bath-applied) to the point where action potentials were fired. This EPSP enhancement in the soma-proximal dendritic region may involve D1 receptor modulation of the subthreshold slowly inactivating Na^+ and K^+ currents. These results suggest that mesocortical DA localizes the effects of synaptic inputs within subregions of the apical dendrites, while the soma receives a more "focused" effects from such inputs. Conversely, DA provides an overall enhancement of synaptic signals arriving in the proximal dendrites. (Funded by B.C.H.R.F & M.R.C. of Canada)

DOPAMINE ACTS VIA A D_1 RECEPTOR TO ELICIT A MEMBRANE HYPERPOLARIZATION IN SYMPATHETIC PREGANGLIONIC NEURONES.
Simon J. Gladwell and John H. Coote. Department of Physiology, University of Birmingham, Birmingham B15 2TT UK SPON: Brain Research Association

Intracellular recordings were made from sympathetic preganglionic neurones (SPN) in the lateral horn of thin transverse spinal cord slices of neonatal rats. We have previously shown that dopamine (DA) when added to the superfusate (10^{-4}M 30 secs) causes either a slow depolarization a slow hyperpolarization or a biphasic effect consisting of a slow depolarization followed by a slow hyperpolarization or vice-versa. Experiments performed in low Ca^{2+} Krebs confirmed that the direct action of DA on the membrane of these SPN is a slow hyperpolarizing one. The D_1 receptor agonists SKF 38393 (10^{-4}M) and SKF 81297-C (10^{-4}M-10^{-5}M) were used after prior characterization of the DA response. Irrespective of the response to DA, the D_1 agonists SKF 38393 (n=10) and SKF 81297-C (n=3) always evoked a slow hyperpolarization. The SKF 38393 evoked slow hyperpolarization was still evident following synaptic blockade by low Ca^{2+} (0.25mM, n=2) Krebs. This hyperpolarization evoked by SKF 38393 remained after superfusion of the broad spectrum DA antagonist Haloperidol (10^{-5}M, n=2) onto the slice for 15 mins. Addition of the D_2 agonist Quinpirole to the superfusate (10^{-4}M-10^{-5}M 30secs, n=13) caused either a slow depolarization (n=4) or no effect (n=9). These data indicate that selective activation of the D_1 receptor on the membrane of SPN causes a slow hyperpolarization which is not blocked by Haloperidol.

DIFFERENTIAL EFFECTS OF QUINPIROLE ON STRIATAL NEURONS IN INTACT AND DOPAMINE-DEPLETED FREELY MOVING RATS. K.C. Hooper*, A.S. Fender, M.D. Pacyga, A.K. Mosemiller, and G.V. Rebec. Program in Neural Science and Dept. Psychology, Indiana University, Bloomington, IN 47405.

The striatum, the principal input nucleus of the basal ganglia, is richly populated with D1 and D2 dopamine receptors, which may be segregated on neurons that project to the substantia nigra pars reticulata and to the globus pallidus, respectively. Using the freely moving preparation, we have previously shown that systemic administration of quinpirole (LY-171555), a D2 agonist, routinely decreases the activity of striatal neurons (Hooper et al., Soc. Neurosci. Abstr. 18:995, 1992). We extended this work in the present study by testing quinpirole (1.0 mg/kg, sc) in the striatum of rats pretreated unilaterally with 6-hydroxydopamine, a catecholamine neurotoxin. In contrast to its effects in intact rats, quinpirole often failed to inhibit striatal activity in the dopamine-depleted striatum and in some cases produced marked increases in firing rate. The pattern and intensity of individual behaviors also was altered. Collectively, our results indicate that striatal D2 receptors function in a qualitatively different manner in intact and dopamine-depleted animals.

ALPHA$_2$ ADRENERGIC RECEPTOR MODULATION OF CALCIUM CHANNELS IN LOCUS CERULEUS NEURONS. P. P. Lakhlani*, D. M. Lovinger# and L. E. Limbird, Departments of Pharmacology and #Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN 37232.

The alpha$_2$-adrenergic receptor (α_2AR), a member of the G-protein-coupled receptor superfamily, regulates physiological responses such as sedation and anesthesia, via modulation of a variety of effector systems including inhibition of voltage-activated calcium (Ca^{++}) channels. However, α_2AR coupling to different types of Ca^{++} channels in central neurons and the molecular mechanisms responsible for the coupling have remained largely unexplored. We have utilized mouse locus ceruleus neurons as a model system to examine α_2AR modulation of voltage-activated Ca^{++} channels in the CNS. Locus ceruleus neurons were acutely dissociated by enzymatic treatment; Ca^{++} current was elicited by depolarizing pulses from -80mV holding potential using the whole-cell patch clamp technique. The α_2AR agonist UK 14,304 attenuated Ca^{++} current in a voltage- and concentration-dependent manner (maximal inhibition-25±3%, EC_{50}-0.3µM, n=4-9). Suppression of the Ca^{++} current by 1µM UK 14,304 remained unaltered in the presence of the L-type Ca^{++} channel blocker nifedipine (5µM) (23±2% vs. 18±3%, n=6), although nifedipine alone produced a small but significant attenuation of the Ca^{++} current (12±2%, n=5). In contrast, 1µM UK 14,304-mediated inhibition of the Ca^{++} current was completely abolished in the presence of the N-type Ca^{++} channel blocker ω-conotoxin-GVIA (1µM) (17±2% vs. -2±0.4%, n=4). Also, ω-conotoxin-GVIA alone significantly attenuated the Ca^{++} current (37±4% inhibition, n=4). Together these results suggest that the α_2AR attenuates voltage-activated Ca^{++} current in locus ceruleus neurons primarily via inhibition of N-type Ca^{++} channels. Mechanisms linking α_2AR to voltage-activated Ca^{++} channels currently are under investigation. (supported by NS30470 and HL25182).

NOREPINEPHRINE (NE) DECREASES POSTSYNAPTIC POTENTIALS (PSP) IN THE DEEP PIRIFORM CORTEX (PC) VIA THE α_2 RECEPTOR. A.J.Rechs* and D.W.Gietzen, Dept Anat, Physio, Cell Bio, Sch Vet Med & Food Intake Laboratory, UC Davis, Davis, CA 95616.

We have observed that NE decreases the amplitude of the PSP recorded in layer III of the PC (Soc Neurosci 21:1186, 1995). To learn which receptor subtypes mediate this effect of NE, coronal slices (400 μm) from male adult albino rats were used. Stimulating and recording electrodes were placed 1 mm apart in layer III of the PC slice. A constant current necessary to elicit a half-maximal PSP was applied for 100 μsec. A stable baseline was recorded for at least 1 h prior to each experimental treatment; drugs were washed out to assure restoration of baseline. NE (31 μM for 30 min) caused a 46.7$\pm$6.7% decrease in the amplitude of the PSP. In one study, 3 different NE agonists (31μM) were used. The α_1 agonist methoxamine had no effect on the PSP, while the α_2 agonist guanabenz caused a 24% decrease in PSP amplitude, mimicking the response to NE. The ß agonist isoproterenol increased the amplitude of the PSP to 122% of baseline, and nearly doubled the duration of the PSP. In three separate studies, four NE antagonists (60μM for 2.5 h) were used. After 1 h of antagonist application, NE was added (31μM for 30 min). Both α_2 antagonists, rauwolscine and yohimbine, blocked the effect of NE, while neither corynanthine (α_1) nor propranolol (ß) had any effect on the inhibitory response to NE. Thus the NE-induced decrease in the PSPs in layer III of the rat PC seems to be mediated through α_2 adrenergic receptors, and not α_1 or ß receptors. Yet, a reciprocal effect of NE at the ß receptor may also exist.

RESULTS OF SOLUBILIZATION EXPERIMENTS FOR D_{1A} DOPAMINE RECEPTORS HETEROLOGOUSLY EXPRESSED IN SF-9 INSECT CELLS. C. J. DuRand*, M. M. Teeter, S. Grünewald, H. Reiländer. Department of Molecular Membrane Biology, Max Planck Institute for Biophysics, Frankfurt/Main, Germany, D-60528

The human D_{1A} dopamine receptor has been expressed and characterized in Baculovirus-infected insect cells. We have used this expression system for the production of quantities of the protein for initial solubilization experiments. From raw membrane preparations, we have explored a variety of detergents, salt concentrations, and other conditions. Our results will be compared with existing literature on solubilization of D_{1A} receptors in other expression systems as well as the natural source. Solubilization of D_{1A} dopamine receptors is a step toward structure determination and subsequent drug design.

CATECHOLAMINE RECEPTORS: ANTI-PSYCHOTIC/NERVOUS SYSTEM DISORDERS

697.1

CP-293,019: A D4 DOPAMINE ANTAGONIST WITH AN *IN VITRO* AND *IN VIVO* PROFILE SUGGESTIVE OF AN ATYPICAL ANTIPSYCHOTIC. S.H. Zorn*, C.G. Johnson, E.R. Jackson, P. Seymour, M. Majchrzak, R. Mansbach, E., Winston, J.R. de Wet, A. Dunaiskis, T.A. Chappie, & M.A. Sanner. Pfizer Inc., Central Research Div., Groton, CT 06340.

The D4 dopamine receptor, with its limbic distribution in brain, and preference for the atypical antipsychotic clozapine (CLOZ), may be an important target for atypical AD's. The present study describes CP-293,019, a new antagonist with selectivity for human dopamine D_4 receptors (hD4). [3H]-CP-293,019 exhibits high affinity and saturable binding to COS cell membranes expressing the hD4 receptor (Kd = 0.56 $\pm$ 0.027 nM). CP-293,019 inhibits [3H]-spiperone binding to the hD4 and hD2 receptors with a Ki = 3.9 $\pm$ 0.4 nM and a Ki > 10 µM, respectively. The binding of CP-293,019 to hD4 receptors expressed in COS cell membranes is not sensitive to guanine nucleotides. CP-293,019 antagonizes quinpirole's inhibition of forskolin-stimulated cAMP accumulation in CHO cells expressing the hD4 receptor (Ki = 2.6 $\pm$ 0.2 nM), but has little effect in cells expressing the hD2 receptor (Ki > 10µM). *In vivo*, CP-293,019, like the atypical AD CLOZ, inhibits apomorphine (APO)-induced hyperactivity (CP-293,019 ID50= 12.2 mg/kg, CLOZ ID50 = 6.0 mg/kg, p.o.) and APO induced disruption of prepulse inhibition (ID50 between 5-10 mg/kg, s.c.). Activity in these behavioral assays is thought to predict clinical antipsychotic activity. Unlike conventional neuroleptics, like haloperidol, CP-293,019 (at doses up to 56 mg/kg, p.o.) does not produce catalepsy, blockade of APO-induced stereotypy, or a temporal shift in the APO hyperactivity response in rats, effects thought to reflect *in vivo* D2 receptor antagonism and EPS liability. In addition, unlike many antipsychotics, CP-293,019 did not produce sedation or prolactin elevation at doses up to 32 mg/kg, po. Taken together, the data indicates that CP-293,019 is a highly selective hD4 receptor antagonist with a preclinical profile of activity that predicts efficacy in psychosis without producing extrapyramidal, prolactin, or sedative side effects. (Commercial funding)

697.2

CP-293,019: A D4-SELECTIVE DOPAMINE ANTAGONIST PRODUCES CLOZAPINE-LIKE EFFECTS ON C-FOS mRNA AND DOPAMINE LEVELS IN RAT BRAIN. J.P. Holland*, D.G. Costello, J.R. de Wet, H. Rollema, M.A. Sanner, S.H. Zorn, and T.F. Seeger. Pfizer Inc., Central Research Div., Groton, CT 06340.

The atypical antipsychotic, clozapine (CLOZ) is differentiated from haloperidol (HAL) by site-specific effects on the expression of c-fos and on dopamine (DA) release in rat brain. The atypical clinical profile of CLOZ may result from its higher affinity for D4 vs. D2 DA receptors. CP-293,019 (CP), a highly D4-selective DA antagonist with potential utility as an antipsychotic, was compared to CLOZ and HAL. cfos mRNA was detected by *in situ* hybridization (c-fos riboprobe) on brain slices at the level of prefrontal cortex (PFC) and dorsolateral striatum (DLS)/nucleus accumbens shell (NA-s) from rats pretreated s.c. 45 min before sacrifice with CP, CLOZ, or HAL. HAL (1 mg/kg) induced c-fos mRNA in DLS and NA-s, but not in PFC, while CLOZ (20 mg/kg) elevated c-fos mRNA levels only in the NA-s. CP (17.8-56 mg/kg) had no effect on DLS, increased c-fos mRNA slightly in the NA-s, and caused a marked increase in PFC and cingulate cortex. In microdialysis studies, CP produced region-selective effects on DA release that resembled those seen with CLOZ. Thus, 32 mg/kg CP, increased DA release 2-3 fold in PFC, like 3.2 mg/kg CLOZ, but had no effect on DLS. In contrast, 0.3 mg/kg HAL had a pronounced effect in DLS. In summary, a D4 DA-selective antagonist, CP-293,019, produced a clozapine-like profile in subcortical DA areas, and increased c-fos mRNA and DA release in limbic cortical structures which are thought to be involved in the pathophysiology of schizophrenia. (Funded by Pfizer Inc.)

697.3

NOVEL THIAZOLE DERIVATIVES, HUMAN DOPAMINE D_4 RECEPTOR ANTAGONISTS: RECEPTOR-BINDING AND NEUROPHARMACOLOGICAL PROFILES. **S. Okuyama[1]*, S. Chaki[1], R. Yoshikawa[1], S. Ogawa[1], N. Kawashima[1], Y. Imagawa[1], Y. Suzuki[1], Y. Ikeda[2], K. Tomisawa[1]. 1st Lab. and Molecular Biology Lab., Medicinal Research Laboratories, Taisho Pharmaceutical Co., Ltd., Ohmiya, Saitama 330, Japan**

Novel thiazole derivatives (compounds **I** and **II**) have a high affinity for the human D_4 receptor, with IC50 values of 5.23 and 6.75 nM, respectively. The dopamine D_2/D_4 ratio of **I**, **II** and clozapine (CZP) was 104, 359 and 3.7, respectively. **I** and **II** had also a high affinity for the serotonin $_{2A}$ receptor and alpha$_1$ adrenoceptor, but had a negligible affinity for 51 other-related receptors. Animal models of antipsychotic activity (e.g. blockade of methamphetamine (MAP)-induced hyperlocomotion in mice; dopamine D_4-related behavior) and extrapyramidal symptoms (e.g. blockade of MAP-induced stereotyped behavior in mice; dopamine D_2 related behavior) were also examined. MAP-induced hyperlocomotion was blocked by **I** (ED50=0.5mg/kg, i.p.), **II** (ED50=0.21mg/kg, i.p.), CZP, haloperidol (HPL) and chlorpromazine (CPZ). HAL and CPZ also blocked the MAP-induced stereotyped behavior, whereas, **I**, **II** and CZP had little effect on this behavior. Thus, **I**, **II** and CZP have selective effects on MAP-induced hyperlocomotion vs. MAP-induced stereotyped behavior in mice. **I**, **II** and CZP failed to induce catalepsy in rats. Phencyclidine-induced cognitive dysfunction in rats (Eur. J. Pharmacol., 263, 9-15, 1994) was overcome by **I**, **II** and CZP, but HAL was without effect. **I**, **II**, CZP and HAL reverse the inhibitory effects of MAP on substantia nigra (A9) and ventral tegmental area (A10) dopamine neurons. **I**, **II** and CZP were more potent in reversing effects of MAP on A10 than A9 dopamine neurons, and **I** and **II** were more potent than CZP. HAL had selective effects on A9 vs. A10. These findings indicate that **I** and **II** will be effective antipsychotic agents, and extrapyramidal side effects in humans are not likely to occur.

DISCRIMINATIVE STIMULUS PROPERTIES OF (+)-7-OH-DPAT AND (+)-PD 128,907: INVOLVEMENT OF DOPAMINE D_3/D_2 AND SEROTONIN (5-HT)$_{1A}$ RECEPTORS. J.-L. Peglion*, R. Schreiber, S. Monneyron and M.J. Millan, I.D.R.S., 125 Chemin de Ronde, 78290 Croissy, France.

Drug-discrimination models are of use in the exploration of the roles of novel receptors. Here, we examined the preferential dopamine D_3 receptor ligands, (+)-7-OH-DPAT (7-hydroxy-2-(di-n-propylamino)-tetralin) (7OH) and (+)-PD 128,907 ((+)-(4aR, 10bR)-3,4,4a,10b-tetrahydro-4-propyl-2H, 5H-[1] benzopyrano-[4,3-b]-1,4-oxazin-9-one)) (PD). Rats were trained (Fixed Ratio$_{10}$) alternately with vehicle or 7OH (0.16 mg/kg, i.p.) and vehicle or PD (0.16 mg/kg, i.p.) 30 min pre-testing until > 90 % recognition was obtained. For generalisation, drugs were given at -30 min and, for antagonist studies, drugs were given at -60 min.

	← Generalisation →					← Antagonism →		
	7OH	PD	QUIN	8-OH	FLES	HAL	S 14297	WAY
7OH	0.07	0.02	0.001	0.08	3.4	0.02	2.5	> 0.31
	(90)	(100)	(100)	(80)	(60)	(67)	(50)	(40)
PD	0.01	0.12	0.001	0.08	3.8	> 0.04	> 2.5	0.03
	(100)	(100)	(100)	(100)	(80)	(40)	(20)	(100)

Doses (mg/kg, base, s.c.) are Effective Dose$_{50}$s (% maximal effect). Data are Means.

7OH, PD and a further D_3 agonist, quinerolane (QUIN), generalised. However, the D_2/D_3 antagonist, haloperidol (HAL), and the D_3 antagonist, S 14297 ((+)-[7-(N,N-dipropylamino)-5,6,7,8-tetrahydro-naphto[2,3-b]2,3-dihydrofurane]), only partially blocked. Further, the 5-HT$_{1A}$ agonists, 8-OH-DPAT (8-OH) and flesinoxan (FLES) generalised, and the selective 5-HT$_{1A}$ antagonist, WAY 100,635 (N-{2-[4-(2-methoxyphenyl)-1-piperazinyl] ethyl}-N-(2-pyridinyl)cyclo-hexanecarboxamide) (WAY), blocked 7OH (partially) and PD (fully). Thus, D_3/D_2 *and* 5-HT$_{1A}$ receptors are involved in the stimulus properties of 7OH and PD.

OPPOSITE EFFECTS OF DOPAMINE D1 AND D2-LIKE RECEPTOR ACTIVATION ON GLUTAMATE NMDA RECEPTOR-MEDIATED RESPONSES IN THE PREFRONTAL CORTEX. P. Zheng, B.S. Bunney* and W.-X. Shi. Depts of Psychiatry and Pharmacology, Yale Univ Sch of Med, New Haven, CT 06510

In schizophrenia, D2 receptor-mediated synaptic transmission has been suggested to be overactive, whereas glutamate transmission mediated by NMDA receptors may be hypoactive. To investigate if the proposed changes in the two transmitter systems may be related, we examined whether activation of DA receptors alters the response of individual neurons to NMDA in the prefrontal cortex (PFC), an area suggested to play a key role in the pathogenesis of schizophrenia. *Pyramidal cells in Layers V and VI of the rat medial PFC were* visually identified in slices under an upright microscope. DA and NMDA-induced responses were recorded in whole cell mode under voltage-clamp. As reported, D1 and D2 agonists by themselves had no effect on the resting membrane current or conductance (Shi and Bunney, *Soc. Neurosci. Abstr.* **20**:1354,1994; Liang, Bunney and Shi, *Soc. Neurosci. Abstr.* **21**:1140, 1995). However, when they were co-administered with NMDA, the response of the cell to NMDA was significantly changed. In most cells tested (12/16), the D2 agonist quinpirole dose-dependently decreased NMDA-induced inward current, whereas the D1 agonist SKF38393 enhanced this current (13/19). These effects were selectively blocked by the D2 antagonist sulpiride and the D1 antagonist SCH23390, respectively. These results suggest that DA, in addition to the previously suggested presynaptic modulation, interacts with glutamate postsynaptically. The finding that D2 receptor activation reduces NMDA receptor function is consistent with the hypothesis that schizophrenia is due to a hypoactivity of glutamate on NMDA receptors and this hypoactivity could be caused by either an overactivity of DA on D2 receptors or other non-DA related changes. In either case, antipsychotic drugs, by blocking D2 receptors, should indirectly enhance NMDA receptor-mediated function, thereby ameliorating psychotic symptoms. Our data also suggest that stimulating, rather than blocking, D1 receptors may be clinically beneficial to schizophrenia.

ANTIPSYCHOTIC DRUG INTERACTIONS WITH DOPAMINE IN C6 GLIOMA CELLS SELECTIVELY AND STABLY EXPRESSING D2A DOPAMINE RECEPTORS. M. Avalos*, C. Mak, P.K. Randall, and R. E. Wilcox, College of Pharmacy, University of Texas, Austin, TX 78712.

Dopamine (DA) interactions with the prototype typical antipsychotic, haloperidol, the prototype atypical antipsychotic, clozapine, the novel antipsychotic, OPC-14597, and the strong agonist, N-propyl-norapomorphine (NPA), were determined in C6 glioma cells selectively and stably expressing D2A DA receptors at a density of ≈200 fmoles/mg protein (Machida *et al.*, Mol. Pharmacol., 41, 652-659, 1992). Dose response curves were run on each drug independently and in combination with DA to determine inhibition of forskolin-stimulated cAMP accumulation in intact cells. Schild analysis yielded affinity values as follows: haloperidol (0.0017 uM), clozapine (2.6 uM), OPC-14597 (0.0040 uM), and NPA (0.62 uM). Partial agonist -full agonist interaction analysis (Avalos *et al.*, Neuropharmacology, submitted) yielded actual relative intrinsic efficacy values for the compounds (Er; compared to that of the reference agonist, DA). Haloperidol, clozapine, and OPC-14597 interactions with DA were consistent with competitive antagonism, and Er values of 0. NPA interactions with DA were consistent with high-efficacy partial agonism and an Er of 0.93. Partial agonists are currently under investigation as drug therapy for schizophrenia. The present partial agonist - full agonist interaction analysis of second messenger functions in intact cells may allow categorization of potential antipsychotics based on their efficacy at recombinant receptors. PROGRESSIVELY GREATER BLOCKADE OF D2 DOPAMINE RECEPTORS MAY INTERFERE WITH c-*fos* INDUCTION IN RAT PREFRONTAL CORTEX BY CLOZAPINE. Z.H.Meng*, L.M.Needham, K.M.Merchant. CNS Diseases Res., Pharmacia & Upjohn, Inc., Kalamazoo, MI 49001.

Acute administration of the atypical antipsychotic drug, clozapine, but not the typical antipsychotic, haloperidol, enhances c-*fos* expression in the medial prefrontal cortex. In contrast, haloperidol, but not clozapine, induces c-*fos* in the dorsolateral striatum (DLSt). We hypothesized that the differential regional effects of clozapine versus haloperidol may be due, in part, to the differences in their affinity for the D2 dopamine receptor (K_i ≈ 150 and 3 nM, respectively) which leads to relatively low *in vivo* occupancy of D2 receptors by clozapine. The present dose-response study was carried out to test this hypothesis. Clozapine (i.p.) dose-dependently induced c-*fos* mRNA expression in the infralimbic, prelimbic and dorsoanterior cingulate cortex (IL, PL and daCg) at doses of 1 to 20 mg/kg. However, a further increase in dose to 60 mg/kg led to significantly lower c-*fos* induction than that seen at 20 mg/kg. Additionally, in the DLSt and nucleus accumbens shell (NA-s), a significant increase in c-*fos* mRNA level was observed only at 60 mg/kg of clozapine. These data suggest that the smaller c-*fos* mRNA induction in the IL/PL cortex by 60 mg/kg of clozapine may be due to greater *in vivo* blockade of D2 receptors at this dose. Further indirect support of this possibility was seen in the effects of clozapine on NGFI-A induction in subcortical regions. Unlike c-*fos*, induction of NGFI-A mRNA in the DLSt and NA-s is greater after haloperidol than clozapine suggesting a positive correlation with D2 receptor blockade. Clozapine-induced NGFI-A expression in the DLSt and NA-s also showed positive dose-response relationship through the whole range of doses used (1 to 60 mg/kg).

U-101387G, A SELECTIVE ANTAGONIST OF DOPAMINE D_4 RECEPTORS, ALTERS MESOCORTICOLIMBIC DOPAMINE RELEASE WITHOUT ALTERING NERVE IMPULSE RATE. M.F.Piercey, W.E.Hoffmann, D.K.Hyslop*, M.Camacho-Ochoa, A.Saleem, P.A.Broderick [1]. Pharmacia & Upjohn Inc, Kalamazoo, MI 49001, and [1]City University of NY Medical School, New York, NY 10031.

Because of its low abundance and interactions with antipsychotic drugs, particularly clozapine, the dopamine (DA) D_4 receptor has been enigmatic. We have used microelectrode recordings of nerve cell firing rates and *in vivo* voltammetry recordings of DA release to evaluate functional effects of U-101387G (U10), a highly selective D_4 antagonist, in chloral hydrate anesthetized rats. In the nigrostriatal system, U10 did not alter firing rates or antagonize DA agonist effects on DA neurons in substantia nigra pars compacta or on their target neurons in caudate nucleus or substantia nigra pars reticulata. However, U10 did produce a statistically significant, albeit slight, increase in DA release in caudate nucleus. Also, U10 did not affect firing rates of mesocorticolimbic DA neurons in ventral tegmental area or their responses to DA agonists. Similarly, U10 did not affect firing rates of nucleus accumbens or infralimbic prefrontal cortical neurons or the responses of accumbens neurons to quinpirole. However, U10 did produce a marked, statistically significant increase in DA release in infralimbic regions of the medial prefrontal cortex and a decrease in DA release in the nucleus accumbens. It is not clear whether the effects on DA release are mediated indirectly via postsynaptic receptors or via nerve terminal D_4 receptors. Nonetheless, the increase in cortical DA release coupled to a decrease in accumbens release could be useful for treating negative and positive schizophrenic symptoms, respectively.

S 18126, A NOVEL, POTENT AND SELECTIVE ANTAGONIST AT HUMAN (h) RECOMBINANT DOPAMINE (DA) hD_4 RECEPTORS. M.J. Millan*, A. Newman-Tancredi, V. Audinot, M. Brocco, A. Gobert, J.-M. Rivet and J.-L. Peglion, I.D.R.S., 125 Chemin de Ronde, 78290 Croissy, France.

The cloning of dopamine D_4 receptors has attracted much interest and, here, we describe a novel ligand, S 18126 (structure to be disclosed), selective for hD_4 receptors. *In vitro* studies were on cloned hD_2, hD_3 and hD_4 receptors transfected into CHO cells. Radioligands were [^{125}I]-iodosulpride (0.1 nM for hD_2 and 0.2 nM for hD_3) and [^{3}H]-spiperone (0.1 nM) for hD4. As a measure of efficacy, we tested stimulation of [^{35}S]GTPγS binding. In rats, we tested blockade of locomotion induced by amphetamine (1.25 mg/kg, s.c.) (AMPH) as well as induction of catalepsy (CAT) and prolactin (PRL) secretion. In mice, we tested blockade of apomorphine (0.63 mg/kg, i.p.) (APO)-induced climbing. Doses (base) are means in mg/kg, s.c.

	← pK_i →			pK_b	ID_{50}	ID_{50}	ED_{50}	ED_{50}
	hD_4	hD_2	hD_3	GTPγS/hD_4	APO	AMPH	CAT	PRL
S 18126	8.8	6.1	5.6	8.9	3.9	5.9	> 160	> 40
Clozapine	7.6	7.1	6.6	7.3	2.2	8.8	> 40	> 40
Haloperidol	8.7	9.4	8.5	8.9	0.01	0.04	0.1	0.2

Affinities are pK_is. For inhibition of DA (0.1 μM)-stimulated [^{35}S]-GTPγS binding, values are pK_bs. ID = Inhibitory Dose and ED = Effective Dose.

S 18126 was a potent ligand at hD_4 sites and blocked stimulation of GTPγS binding by DA. Its affinity at D_1 and other (> 20) receptors was low (≥ 1 μM). S 18126 showed modest antipsychotic activity and, in freely-moving rats, S 18126 (40.0) increased (201 % vs basal = 100 %) DA release in frontal cortex, but not accumbens (103 %) or striatum (104 %) It did not elicit extrapyramidal effects. S 18126 should be a useful tool and its potential clinical utility is under exploration.

STRUCTURE BINDING STUDIES OF SELECTED ISOCHROMAN PHENYLPIPERAZINES: SELECTIVE D_4-DOPAMINE RECEPTOR ANTAGONISTS WITH POSSIBLE UTILITY IN THE TREATMENT OF SCHIZOPHRENIA. M.W. Smith+, R.E. TenBrink+, C.L. Bergh+, D.M. Dinh+, R.M. Huff+, R.A. Lahti+, C.F. Lawson+, S.K. Schlachter+, and R.B. McCall*+. +Upjohn Laboratories, Pharmacia & Upjohn, Kalamazoo, MI 49001. ++Maryland Psychiatric Res. Cntr., Univ. of Maryland, Baltimore, MD 21228

An emerging hypothesis concerning the treatment of schizophrenia states that the antipsychotic affects of existing therapies are exerted primarily through blockade of D_4-dopamine receptors in limbic brain regions, while the adverse motor effects of neuroleptic agents represent interactions with striatal D_2-dopamine sites. A test of this hypothesis would be to evaluate the therapeutic effectiveness and side-effect profile of a highly selective D_4-dopamine antagonist. The present report provides *in vitro* receptor binding data for a series of important mono-aminergic receptors, including D_2- and D_4-dopamine, of a series of substituted isochroman phenylpiperazine compounds discovered at Pharmacia & Upjohn. The analog selected for clinical testing, U-101387, S(-)-4-[4-[2-(chroman-1-yl)ethyl]piperazin-1-yl]benzenesulfonamide), is shown to be a potent antagonist for the human D_4-dopamine receptor with at least 600-fold binding selectivity over D_2-dopamine and other monoaminergic receptors.

HETEROLOGOUS SENSITIZATION OF ADENYLATE CYCLASE BY D4 DOPAMINE RECEPTORS M. N. Vu,[1] V. J. Watts,[1] V. Jovanovic,[2] H. H. M. Van Tol,[2] and K. A. Neve[1]* Oregon Health Sciences University and VA Medical Center, Portland OR, 97201[1] Laboratory for Molecular Neurobiology, Clarke Institute of Psychiatry, Toronto, Ontario, Canada[2]

Previous studies have shown that pretreatment with D2 dopamine (DA) receptor agonists results in the sensitization of agonist-stimulated cAMP accumulation in both HEK293 and C6 glioma cells expressing D2 DA receptors. The present study was designed to examine and compare the ability of D4.2, D4.4 and D4.7 receptor allelic variants as well as the D3 DA receptor to sensitize forskolin-stimulated cAMP accumulation in HEK293 cells. Two hour pretreatment with DA resulted in a sensitization of forskolin-stimulated adenylate cyclase activity in cells expressing all 3 D4 DA receptor variants. Similar to their ability to inhibit cAMP accumulation acutely, all D4 receptor variants appeared to sensitize cAMP accumulation to comparable levels. The sensitization by D4 DA receptor variants was manifest as a greater than 60% increase in the stimulation of cAMP accumulation in DA-treated cells compared to vehicle-treated cells. D4 receptor-mediated sensitization was blocked by the D4 antagonist, clozapine and prevented by overnight pretreatment with pertussis toxin, implying a role for Gi/Go proteins. In contrast, pretreatment with DA did not alter forskolin-stimulated cAMP accumulation in cells expressing D3 DA receptors. The potency for D4-mediated sensitization was only slightly lower than that required for acute inhibition of forskolin-stimulated cAMP accumulation, whereas the potency for D2 DA receptor-mediated sensitization is nearly 2 orders of magnitude lower than its IC50 for inhibition of cAMP accumulation. These studies show that D4 DA receptors sensitize forskolin-stimulated cAMP accumulation in HEK293 cells transfected with D4.2, D4.4 and D4.7 DA receptors and suggest that the polymorphic repeat sequence does not influence the heterologous sensitization mediated by D4 DA receptor variants. Supported by MH45372 and the VA Merit Review Program.

Inhibition of Rat Prefrontal Cortex Neurons by U-101387G. ME Clement* and RB McCall. Pharmacia & Upjohn Kalamazoo, MI.

The prefrontal cortex (PFC) and the mediodorsal thalamic nucleus are reciprocally connected through an excitatory amino acid pathway. Cortical excitatory responses can be elicited from stimulation of the mediodorsal thalamic nucleus. The PFC also receives a convergent inhibitory dopaminergic input from the ventral mesencephalic tegmentum. Excitatory amino acids have been shown to modulate release of dopamine in PFC. For instance, local infusion D,L-α-amino-3-hydroxy-5-methyl-4- isoxalone propionic acid (AMPA) and kainate, but not *N*-methyl-D-aspartic acid (NMDA), facilitates dopamine release in the PFC. The NMDA antagonist ketamine has been shown to increase dopamine levels in the PFC. We have examined the effects of the D4 antagonist U-101387G on spontaneously active PFC neurons identified by orthodromic activation from the mediodorsal thalamic nucleus in ketamine/pentobarbital anesthetized rats. We found a subpopulation of short latency neurons (onset latency = 3-8 ms) which exhibited transient (~5 minutes) inhibition by low doses (<1 mg/kg) of U-101387G. Higher doses up to 10 mg/kg of U-101387G were without effect. Inhibition was often, but not always, preceded by a brief marked exciation. Long latency (onset latency = 12-20 ms) neurons showed no response to U-101387G. U-101387G sensitive neurons were unaffected by intravenous ketamine (15 mg/kg) but were inhibited by pentobarbital (10 mg/kg) or chloral hydrate (40 mg/kg). These data indicate that the selective D4 receptor antagonist U-101387G inhibits a subpopulation of PFC neurons and that these neurons are sensitive to either the type or level of anesthesia. A role in regulating dopamine release is under investigation.

697.13

EFFECTS OF A SELECTIVE D4 DOPAMINE ANTAGONIST ON AMPHETAMINE-INDUCED c-*fos* AND NGFI-A mRNA EXPRESSION. B.Garimella*, A.Jazayeri, L.M.Needham, C.M.Spangler, K.Essani and K.M.Merchant, Dept. of Biological Sciences, Western Michigan University, and CNS Diseases Res., Pharmacia & Upjohn, Inc., Kalamazoo, MI 49007.

Within the D2 family of dopamine receptors, D4 receptors may play a role in the unique therapeutic efficacy of the atypical antipsychotic drug, clozapine. The present study investigated the effects of a D4-selective antagonist, U-101387G, on amphetamine induced expression of immediate early genes, c-*fos* and NGFI-A using *in situ* hybridization. Rats were treated with vehicle, amphetamine (2 mg/kg, sc), U-101387G (10 mg/kg, ip), or amphetamine plus U-101387G, and sacrificed 1 h later. Amphetamine enhanced c-*fos* mRNA levels in the infralimbic/prelimbic cortex (IL/PL), dorsal anterior cingulate cortex (daCg), cingulate cortex (Cg), parietal cortex, nucleus accumbens shell (NA-s), and the dorsomedial striatum (DMSt). Concomitant blockade of the D4 receptor with U-101387G further enhanced amphetamine-induced c-*fos* mRNAlevels in the IL/PL and daCg. However, in the DMSt, NA-s, Cg and parietal cortex, U-101387G attenuated amphetamine-induced c-*fos* mRNA expression. In contrast to c-fos, NGFI-A mRNA levels were not increased in the IL/PL and daCg by either amphetamine or U-101387G. However, their combined administration significantly induced NGFI-A mRNA in the medial prefrontal cortex. DMSt was the only region that showed significant NGFI-A mRNA induction by amphetamine. However, unlike c-*fos* expression, amphetamine-induced NGFI-A response was not modulated by U-101387G. The data demonstrate selective effects of the D4 antagonist, U-101387G, on cellular effects of amphetamine. (Supported in part by Stanley Research Foundation).

697.14

DOPAMINE D4-SELECTIVE ANTAGONIST, U-101387G, BLOCKS AMPHETAMINE-SENSITIZATION IN RATS: BEHAVIORAL AND BIOCHEMICAL CHANGES. D.L.Feldpausch*, L.M.Needham, Z-H.Meng, M.P.Stone, K.A.Svensson and K.M.Merchant. CNS Diseases Research, Pharmacia & Upjohn, Inc., Kalamazoo, MI 49001

Sensitization to psychostimulants is thought to involve biochemical changes similar to those underlying psychotic diseases such as schizophrenia. This study compared the effects of a dopamine D4-selective antagonist and an investigational antipsychotic drug, U-101387G, with haloperidol and clozapine in the development of behavioral sensitization to d-amphetamine (AMP). Context-independent behavioral sensitization was observed in rats primed with AMP in their home cages (2 mg/kg/d x 5 d, SC) prior to a challenge of AMP (2 mg/kg) given 7 days after the last priming dose. Co-administration of U-101387G (0.1 or 10 mg/kg IP), haloperidol (0.1 mg/kg IP) or clozapine (4 mg/kg IP) with AMP during priming blocked the development of behavioral sensitization. Cellular mechanisms underlying AMP sensitization were investigated by examining alterations in the expression of the immediate early gene, c-*fos*, and the neuropeptide, neurotensin. In AMP-primed rats, the acute AMP challenge produced a significantly smaller induction of c-*fos* mRNA in the medial prefrontal cortex and neurotensin mRNA in the nucleus accumbens-shell than in saline-primed rats. Interestingly, blockade of D4 receptors by U-101387G (10 mg/kg IP) during AMP priming restored both c-*fos* and neurotensin mRNA response to the AMP challenge to levels seen in saline-primed rats. These data indicate a role of D4 receptors in cellular alterations leading to behavioral sensitization produced by repeated AMP administration.

PSYCHOSTIMULANTS DEPRESS INHIBITORY SYNAPTIC TRANSMISSION IN THE NUCLEUS ACCUMBENS *VIA* A D1-LIKE DOPAMINE RECEPTOR. S.M. Nicola* and R.C. Malenka. Neuroscience Graduate Program and Departments of Psychiatry and Physiology, University of California, San Francisco, CA, 94143, USA.

Dopamine modulates cortico-accumbens excitatory synaptic transmission (Nicola et al., J Neurosci 16:1591) by acting on a D1-like dopamine receptor. We now show that inhibitory synaptic transmission is also modulated by dopamine and psychostimulants. Using whole-cell recording in a rat nucleus accumbens slice preparation, IPSPs were elicited by a stimulating electrode placed in the dorsal nucleus accumbens. Slices were perfused with DNQX (10 μM) and d,l-APV (75 μM) to ensure that responses were monosynaptic. Picrotoxin-sensitive IPSPs were depressed by amphetamine (10 μM) to 81% of baseline (n=6) and by dopamine (75 μM) to 68% of baseline (n=19). The D1 antagonist SCH23390 completely inhibited the effect of 75 μM dopamine (98% of baseline, n=7) while the D2 antagonist sulpiride (20 μM) did not significantly reduce the effect of 60 μM dopamine (83% of baseline in sulpiride *vs* 79% of baseline in controls, n=8). These results suggest that the dopamine receptor responsible for the depression of IPSPs may be pharmacologically similar to the receptor involved in inhibition of excitatory synaptic transmission. (Supported by NIMH and NIDA.)

697.16

DOPAMINE RELEASE IS INCREASED IN THE ACCUMBAL SHELL IN AMPHETAMINE-SENSITIZED RATS: BLOCKADE BY THE D4-SELECTIVE ANTAGONIST, U-101387G. K.M. Merchant* and B.K.Yamamoto[1]. CNS Diseases Research, Pharmacia & Upjohn, Inc., Kalamazoo, MI 49001 and [1]Dept. of Psychiatry, Case Western Reserve University, Cleveland, OH.

Priming with d-amphetamine (AMP, 2 mg/kg/d x 5 d s.c.) followed by a 7-day withdrawal produced a significantly greater locomotor response to an acute AMP challenge (2 mg/kg s.c.) in rats. The behavioral sensitization was accompanied by a decrease in the AMP challenge-induced c-*fos* expression in the prefrontal cortex and neurotensin mRNA in the accumbal shell. A role of dopamine D4 receptors in these phenomena was evident in: (a) blockade of the behavioral sensitization and (b) restoration of the c-*fos* and neurotensin induction by AMP in rats that received the D4 selective antagonist, U-101387G (10 mg/kg i.p.) with AMP during priming (see Feldpausch *et al.*, this meeting). Here we examined the release of dopamine and glutamate in the nucleus accumbens by *in vivo* microdialysis in freely moving rats to see if it correlated with the behavioral and cellular alterations accompanying the sensitization. Supporting the behavioral sensitization, acute AMP produced greater dopamine release in the AMP-primed rats than vehicle-primed rats, and this effect was completely blocked in rats that received U-101387G with AMP during priming. The enhanced dopamine release after AMP priming and its blockade by U-101387G given during priming were seen only in the shell and not the core of the nucleus accumbens. In contrast, AMP priming had no effect on accumbal glutamate release produced by an acute AMP challenge. These data indicate further a role of the mesolimbic dopamine system, and particularly of D4 receptors in the development of AMP sensitization.

697.17

EFFECTS OF THE SELECTIVE DOPAMINE D4 ANTAGONIST U-101387G ON LOCOMOTOR ACTIVITY AND BRAIN MONOAMINE NEUROCHEMISTRY IN THE RAT. M.P.Stone, N.Waters[1], J.B.Green, J.E.Myers, R.A.Lewis, M.G. Cimini and K.A.Svensson*, CNS Diseases Research, Pharmacia & Upjohn, Inc., Kalamazoo, MI and [1]University of Goteborg, Sweden.

U-101387G has been evaluated in behavioral and neurochemical assays in rats. U-101387G (at doses up to 100 µmol/kg) failed to affect locomotor activity in actively exploring or habituated rats. The typical and atypical antipsychotic compounds haloperidol (1 µmol/kg s.c.) and clozapine (200 µmol/kg s.c.), respectively, produced strong hypomotility. In antagonism studies in normal or reserpinized rats, U-101387G failed to block the hyperactivity induced by either amphetamine (1.5 µmol/kg) or apomorphine (0.25 µmol/kg s.c.). In contrast, both clozapine and haloperidol completely blocked the dopamine agonist-induced hyperactivity. Treatment with U-101387G did not significantly affect post-mortem levels of norepinephrine, dopamine, DOPAC, HVA, serotonin or 5-HIAA in various brain regions including the striatum, various parts of the limbic brain region, and the prefrontal cortex. For a comparison, clozapine and, especially haloperidol, increased dopamine turnover in both limbic and striatal brain areas. In a separate brain microdialysis study in freely moving rats, U-101387G did not change dialysate levels of dopamine DOPAC, HVA and 5-HIAA in the nucleus accumbens or the striatum. On the other hand, clozapine increased dopamine turnover in both brain regions. It is concluded that the clear-cut behavioral effects observed with clozapine and haloperidol are not ascribed to their interaction with central dopamine D4 receptors. Our neurochemical data also suggest that the rat D4 receptor does not likely serve an important autoregulatory function.

697.18

ANTAGONISM OF LIMBIC AND CORTICAL EFFECTS OF AMPHETAMINE ON GLUCOSE UTILIZATION BY U-101387G, A DOPAMINE D_4 RECEPTOR-SELECTIVE ANTAGONIST. E.L.Walker, N.F.Nichols*, P.J.K.D. Schreur, E.Knedgen[1], S.Mummaneni[2] and M.F.Piercey*, Pharmacia & Upjohn, Inc., Kalamazoo, MI, 49001, [1]Western Michigan University, and [2]Kalamazoo College, Kalamazoo, MI 49007.

Because of its low abundance and interactions with antipsychotic drugs, particularly clozapine, the dopamine (DA) D_4 receptor has been enigmatic. Sokoloff's 2-deoxyglucose (2-DG) autoradiography procedure was used to evaluate the effects of U-101387G (U10), a dopamine (DA) D_4 receptor-selective antagonist, and amphetamine (AMP) on local cerebral glucose utilization (LCGU) in rats. Alone, U10 (1 and 10 mg/kg i.v.) had no effects on regional brain energy metabolism. As expected, AMP (1 mg/kg i.v.) significantly increased brain energy metabolism in basal ganglia, mesolimbic regions and cerebral cortex. In rat locomotor activity (LMA) assays, U10 alone (from 0.3-30 mg/kg s.c.) likewise had no effect on open field activity of rats habituated to the test cage, though AMP in this protocol causes marked stimulation. In 2-DG antagonism studies, U10 (1 mg/kg) was able to antagonize the stimulant effects of AMP in only the mammillary body. In contrast, AMP stimulation of the AV and VL thalamus were enhanced by U10, 1 mg/kg. Given in a higher dose of 10 mg/kg i.v., U10 significantly antagonized AMP in mammillary body and some cortical regions, although a non-significant trend toward antagonism was demonstrated throughout the brain. U10 failed to produce catalepsy or antagonize AMP-stimulated locomotor activity. The results suggest that U10 has discrete effects on DA brain function with the potential for producing antipsychotic activity without extrapyramidal side effects.

ANALYSIS OF DOPAMINE RECEPTOR EXPRESSION IN THE HUMAN BRAIN BY RIBONUCLEASE PROTECTION ASSAY (RPA).
J. N. Bresnick[1], N. Stefanis[2], R. Kerwin[2], G. Seabrook* and G. McAllister[1]. [1]Merck Sharp & Dohme Research Laboratories, Terlings Park, Harlow, Essex CM20 2QR, England, [2]Institute of Psychiatry, De Crespigny Park, Denmark Hill, London SE5 8AF, England.

The dopamine hypothesis of schizophrenia suggests that changes in dopamine receptor transmission underlie the neuropathology of the disease. In this study, we compare the regional distribution and relative levels of expression of dopamine receptor subtypes in both normal and schizophrenic post-mortem brain tissue.

Initially, we have made antisense riboprobes to the dopamine D3 and D4 receptor genes and used these to determine a distribution of receptor mRNAs in normal post-mortem brain and non-brain tissue. A probe to the constitutively expressed glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene was included as an internal standard. To date, these experiments suggest that D4 receptor mRNA is expressed in most brain regions examined, including both motor and limbic areas and at roughly equivalent levels. However, the highest level of D4 receptor mRNA was detected in retina. In contrast, the expression of D3 receptor mRNA appears more restricted than D4, with the highest levels being detected in caudate. We shall repeat these analyses using schizophrenic brain tissue and compare these with the normal distributions.

So far, these findings argue against a predominantly limbic distribution of these receptors in human brain and might prove a useful tool in understanding the antipsychotic properties of dopamine receptor antagonists.

THE NOVEL ANTIPSYCHOTIC (OPC-14597) FUNCTIONALLY DISCRIMINATES BETWEEN PRE- AND POST-SYNAPTIC D_2 DOPAMINE RECEPTORS: C. Prioleau*, J.D. Kilts, M.A. Bunin, K.L. O'Malley[1], R.D. Todd[1], C.P. Lawler, and R.B. Mailman. Dept. of Pharmacol. & Neuroscience Ctr., Univ. of North Carolina, Chapel Hill NC 27599 and [1]Washington Univ., St. Louis, MO 63110.

OPC-14597 is a novel antipsychotic drug candidate that appears to have antipsychotic efficacy without inducing the extrapyramidal side effects (EPS) seen with typical neuroleptics. This lack of EPS is surprising because OPC-14597 has high affinity for D_{2L} and D_{2S} dopamine receptors, yet blockade of D_2 receptors is the mechanism generally believed responsible for EPS. Early data had suggested that OPC-14597 exerted differential effects at presynaptic vs. postsynaptic D_2-like receptors, a phenomenon we term "functional selectivity". The present studies were designed to explore further the functional activity of OPC-14597. First, we studied the effects of this compound on K^+-stimulated release of [^{3}H]dopamine in D_{2L} transfected MN9D cells. OPC-14597 partially attenuated the inhibition of [^{3}H]DA release produced by quinpirole, and produced modest inhibition of release when administered alone. Next, the effects of OPC-14597 on electrically-stimulated dopamine overflow were measured in rat striatal slices using cyclic voltammetry. In this paradigm, the prototypical antipsychotic drug haloperidol reliably blocked the inhibitory actions of the full agonist quinpirole on dopamine efflux. In contrast, OPC-14597 caused slight inhibition of release when administered alone, and failed to antagonize markedly the effects of quinpirole. Taken together, these data are consistent with a partial agonist profile of OPC-14597 at the presynaptic D_2 receptor coupled to inhibition of DA release. These agonist actions contrast sharply with the clear antagonist actions of OPC-14597 at functions associated with D_2 postsynaptic receptors (e.g., inhibition of apomorphine-stimulated activity). Further experiments aimed at elucidating the mechanism(s) underlying the differential actions of OPC-14597 will be important for understanding its interesting clinical profile. SEROTONIN RECEPTORS: $5HT_2$—ANATOMY AND BEHAVIOR

698.1

IMMUNOCYTOCHEMICAL LOCALIZATION OF 5HT2 RECEPTORS: PRODUCTION, PURIFICATION, AND IMMUNOCYTOCHEMICAL USE OF AN ANTI- PEPTIDE ANTIBODY A. Diaz, A Oliver, J. Hassler, and M.S. Brownfield*. Dept of Comp Biosci, Univ of Wisconsin, Madison, WI 53706.

Serotonin (5HT) stimulates secretion of oxytocin (OT) and vasopressin (VP) by a 5HT2 receptor mechanism. Sites where this could occur are unclear, due in part by the lack of an adequately detailed map of the distribution of brain 5HT2 receptors, particularly in the hypothalamus. The purpose of these studies was to generate a sensitive and specific antibody allowing us to produce a high resolution map of rat brain 5HT2 receptors.

We targeted the antibody to the N-terminal domain of the receptor by raising antisera to a peptide selected from this region. A peptide corresponding to the N-terminal 22-41 sequence was synthesized and conjugated to cyclic poly-lysine (a MAP antigen) or to bovine thyroglobulin with glutaraldehyde. Rabbits were inoculated with a series of MAP-peptide injections, and following a rest period, with a series of the peptide-TG antigen. Antibody titers were followed by an enzyme linked assay (ELISA) directed against bovine serum albumin-glutaraldehyde- peptide conjugate, and by avidin-biotin immunocytochemistry (ICC) with nickel intensification. Antisera was purified by affinity chromatography with a peptide-gel matrix using two elution systems. Affinity purified antibodies were dialyzed and concentrated by ultrafiltration. Antibodies were characterized by immunoblot analysis and by ICC immunoabsorption studies.

A single band was detected by immunoblot analysis and preabsorption with the peptide blocked staining. Immunoreactivity was seen in paraventricular (PVN) and supraoptic (SON) magnocellular cells having a distribution similar to that of OT cells. Other reactive cells were seen in the parvocellular PVN and the ventromedial nucleus (VMN). Fibers were also observed in these cites and in the dorsomedial nucleus (DMN). Labeled extrahypothalamic sites included the medial and basolateral amygdala, basal ganglia, hippocampus, and in different densities across all layers of the cerebral cortex.

698.2

LOCALIZATION OF 5-HT_{2A} RECEPTOR IN RAT CEREBRAL CORTEX BY IMMUNOHISTOCHEMISTRY. S. Hamada*[1], K. Senzaki[1], K. Tabuchi[1], H. Yamamoto[3], T. Yamamoto[4], S. Yoshikawa[2], H. Okano[2] and N. Okado[1] [1]Dept. of Anat. and [2]Mol. Neurobiol., Inst. of Basic Med. Sci., Univ. of Tsukuba, Ibaraki 305; [3]Dept. of Psychopharmacol., Tokyo Inst. of Psychiatry, Tokyo 156; [4]Lab. of Mol. Recognition, Grad. Sch. Integ. Sci., Yokohama City Univ., Yokohama 236, Japan.

Three kinds of polyclonal antibodies that recognize rat/mouse 5-HT2A receptor were raised in chicken against synthetic peptides corresponding to two N-terminus peptides (5HT2A-N1 [14-33AA], -N2 [58-75AA]) and in rabbit against mouse 5HT2A C-terminus (407-471AA)-GST fusion protein (5HT2A-C). Chicken anti-peptide antibodies were extracted from eggs of immunized hens and affinity purified using the synthetic peptide antigen. Among several fixation procedures tested, perfusion with Zamboni's and PLP fixatives yielded the best immunostaining. The distribution of immunopositive structures by 5HT2A-N1, -N2 and -C antibodies was virtually the same. The highest levels of immunoreactivity were observed in the olfactory bulb and frontal cortex of the adult rat brain. In the neocortex , pyramidal neurons in layer V were most heavily labeled. The number and intensity of labeled cells were higher in frontal cortex compared to the caudal regions. Granular cells in layer II of piriform cortex were also densely labeled. In the hippocampus, pyramidal cells in CA1 and CA3 regions were moderately labeled. Our results were in agreement with previous receptor autoradiographic studies (Blue, ME. et al., 1988, Brain Res. 453: 315-328) and the localization of mRNA using in situ hybridization technique (Mengod, G. et al., 1990, Brain Res. 524:139-143) *Supported by Grant-in-Aid for Scientific Research on Priority Area from the Ministry of Education, Science and Culture, Japan.*

CELLULAR MAPPING OF 5-HT2A RECEPTOR PROTEIN IN ADULT RAT CNS. V. Cornea-Hébert* [1], M. Riad [1], F. Zerari [1], S. Garcia [1], L. Descarries [1], C. Wu [2] and S. Singh [2]. [1] Département de pathologie et CRSN, Université de Montréal, Montréal, Québec, Canada H3C 3J7, and [2] PharMingen, San Diego, CA 92121, USA.

Adult rat brain and spinal cord sections were processed for light and electron microscope immunocytochemistry (diaminobenzidine and colloidal gold labeling), using a monoclonal antibody against the N-terminal domain of the 5-HT2A receptor (Wu et al, *Soc Neurosci Abstr*, 21:1226, 1995). Somatodendritic immunoreactivity was observed in all regions previously reported by in situ hybridization to contain 5-HT2A mRNA (Wright et al, *J Comp Neurol*, 351:357-373, 1995). In neocortex, the immunostaining of pyramidal neurons in layer V was particularly intense and extended to the distal branches of their apical dendrites. In hippocampus, the dendrites of pyramidal neurons were more intensely stained than their somata. In neostriatum, some of the large interneurons were immunopositive. In the diencephalon and the brain stem, many nuclei displayed selective labeling. These included the mesencephalic nucleus of the Vth nerve and the motor nuclei of cranial nerves. Motoneurons were also immunostained at all spinal cord levels. Lastly, intense immunoreactivity was detected in myelinated tracts known to originate from the cell bodies displaying immunoreactivity (e.g. internal capsule and mesencephalic tract of trigeminal nerve). These data suggest that the 5-HT2A receptor i) is primarily somatodendritic; ii) reaches out into the distal dendrites, and iii) is transported by the axons of the neurons which express it. FACILITATION OF GABAERGIC NEUROTRANSMISSION BY 5-HT$_2$ RECEPTOR ACTIVATION IN HIPPOCAMPUS CA1 REGION. R. Shen* and R. Andrade. Dept. Psychiatry and Behavioral Neurosci., Wayne State University School of Medicine, Detroit, MI 48201.

5-HT$_2$ receptors are present in the hippocampus, but their physiological role in this region is not well understood. In cortical neurons, activation of 5-HT$_2$ receptors leads to an increase in GABAergic neurotransmission. Similar actions of 5-HT$_2$ receptors may exist in the hippocampus. We investigated this possibility by examining spontaneous inhibitory postsynaptic currents (IPSC's) in CA1 pyramidal neurons using whole cell recordings in hippocampal slices. Spontaneous IPSC's were recorded as inward currents at negative holding potentials (-70 to -90 mV) with a high chloride intracellular solution and could be abolished by GABA$_A$ receptor antagonist bicuculline. Bath application of 5-HT (30 μM) increased the frequency and amplitude of the spontaneous IPSC's in the presence of 5-HT$_1$, 5-HT$_3$, and 5-HT$_4$ receptor antagonists. This effect was mimicked by a selective 5-HT$_2$ receptor agonist DOI (30 μM) and blocked by ketanserin (1μM). Because TTX (1 μM) was able to eliminate DOI-induced increases in frequency and amplitude of spontaneous IPSC's, it is most likely that 5-HT$_2$ receptor activation facilitates GABAergic neurotransmission by increasing the neuronal firing of presynaptic GABAergic interneurons innervating CA1 pyramidal neurons. Therefore, 5-HT$_2$ receptors appear to regulate GABAergic neurotransmission in the hippocampus CA1 region. [Supported by AA09829 and MH43985]

DIFFERENTIAL EXPRESSION OF 5HT2A AND 5HT2C SEROTONIN RECEPTOR SUBTYPE MRNAs BY HIPPOCAMPAL INTERNEURONS. G. A. Mathews[1]*, M.V. Sofroniew[2], & M. Rattray[1]. [1]UMDS Biochem. & Mol. Biol., Guy's Hospital, London SE1 9RT, U.K. & [2]MRC Cambridge Centre for Brain Repair, Robinson Way, Cambridge CB2 2PY, U.K.

Little is known about the serotonin (5HT) receptor subtypes expressed by hippocampal interneurons, which are targets for the ascending serotonergic pathways originating in the raphé nuclei. We combined radioactive and non-radioactive *in situ* hybridization (ISH) to ask whether the expression of 5HT2a and 5HT2c receptor mRNA correlates with the non-overlapping expression of mRNAs for cholecystokinin (CCK) and somatostatin (SST) in glutamate decarboxylase-67 (GAD-67) mRNA-containing interneurons.

Sections of dorsal hippocampus from adult male rats were processed for combined ISH using ^{35}S-labelled and fluorescein-labelled riboprobes. Sequential alkaline phosphatase staining and liquid emulsion autoradiography were used to detect hybridizations of fluorescein-labelled and ^{35}S-labelled riboprobes, respectively. Across 3-4 sections per side from each of 5 animals, we calculated the mean (± s.e.m) percentage of interneurons positive for glutamate decarboxylase (GAD-67) mRNA, SST mRNA, or CCK mRNA, **and** for a receptor mRNA. GAD-67/5HT2a co-expression was more frequent than was GAD-67/5HT2c co-expression (39 ± 5% vs. 9 ± 1%). SST/5HT2c co-expression was not observed, whereas CCK/5HT2c co-expression was more common (48 ± 5%). Finally, SST/5HT2a co-expression was more frequent (47 ± 5%) than was CCK/5HT2a co-expression (27 ± 4%).

These results show that inhibitory interneurones in the hippocampus have further complexity on the basis of 5HT receptor mRNA expression. Serotonin afferents may therefore exert differential effects on hippocampal interneurons, depending on their 5HT receptor subtype expression.

AUTORADIOGRAPHIC CHARACTERIZATION OF (±)[^{125}I]DOI BINDING TO 5-HT$_{2A}$ AND 5-HT$_{2C}$ RECEPTORS IN THE RABBIT BRAIN. G.L. Salt, V.J. Aloyo and J.A. Harvey*. Div. of Behavioral Neurobiology, Dept. of Pharmacology, The Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA 19129.

Conditions for autoradiographic visualization of (±)-([^{125}I]DOI-labeled 5-HT$_{2A}$ and 5-HT$_{2C}$ receptors in the rabbit brain were optimized and binding to slide-mounted sections was characterized with respect to pharmacology and anatomical distribution. [^{125}I]DOI binding to 5-HT$_{2A}$ receptors was defined by subtracting binding in the presence of 100 nM spiperone from total binding. Binding to 5-HT$_{2C}$ receptors was determined by subtracting binding in the presence of 1 μM methysergide from that in the presence of 100 nM spiperone. DOI binding was saturable and of high affinity. The binding to 5-HT$_{2A}$ receptors was confirmed using the 5-HT$_{2A}$ selective ligand ketanserin. The binding to 5-HT$_{2C}$ receptors was indirectly confirmed using the 5-HT$_{2A/2C}$ ligand methysergide. 5-HT$_{2A}$ and 5-HT$_{2C}$ binding was observed in a variety of brain structures. In particular, high density 5-HT$_{2A}$ binding was noted in the cerebral cortex (laminae I-IV), caudate and putamen with moderate binding in the hippocampus and hypothalamic nuclei. 5-HT$_{2C}$ binding was seen in cortex (lamina I), choroid plexus and claustrum. The pharmacological profile and anatomical distribution of [^{125}I]DOI binding in the rabbit brain as seen in this study was consistent with that of 5-HT$_{2A}$ and 5-HT$_{2C}$ receptors reported in other mammals. Supported by NIMH MERIT award MH16841.

KINETIC ANALYSES OF [C-11]MDL 100907 *IN VIVO*: A SELECTIVE SEROTONIN 5-HT2A RADIOTRACER FOR POSITRON EMISSION TOMOGRAPHY (PET). JC Price*, B Lopresti, CA Mathis, N Simpson, D Holt, K Mahmood, Y Huang, GS Smith, M Mintun. PET Facility Department of Radiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213

[C-11]MDL 100907 ([C-11]MDL) is a promising radiotracer for the *in vivo* imaging of the serotonin system with PET. [C-11]MDL has a more selective pharmacologic profile as a 5-HT2A antagonist than [F-18]altanserin or [F-18]setoperone and is more suitable for multiple single day studies. [C-11]MDL PET studies in monkeys demonstrated localization that followed the known distribution of 5-HT2A receptors and was blocked by ketanserin (Mathis CA et al., *J Label Compd Radiopharm* 316-318, 1995; Lundkvist C et al., *Life Sciences* 187-192, 1996).

Baboons were studied (>1000 Ci/mmole, 30-40 mCi) after bolus (n=7) and bolus+constant infusion (BI) (n=2) administration of [C-11]MDL. Data were acquired for 90 min (CTI 951R/31 PET scanner). Plasma data were corrected for metabolites using arterial samples. Distribution volumes (DV) were estimated by 3-compartment models for cerebellum (Cer) and constrained 4-compartment models (bolus) and tissue:plasma ratios (BI) for the frontal (Frt) and temporal (Tem) cortices and striatum (Str).

The DV estimates were variable with means that followed 5-HT2A rank order (Frt: 57±22; Tem: 56±17; Str: 33±11; Cer: 24±8.0). Normalization of the individual DV values by the Cer DV reduced the variability while maintaining rank order (Frt: 2.4±0.4; Tem: 2.2±0.3; Str: 1.4±0.2). The preliminary BI studies yielded DVs that were ~20% lower than the model DVs (for the baboon) and corresponded to variable concentration plateaus.

These results demonstrate significant non-specific binding (Cer DVs), as has been observed for other serotonin radiotracers, that may be elucidated through further analysis of [C-11]MDL metabolites and refinement of the BI protocol. (Supported by NIH grant NS 22899)

698.8

SEROTONIN$_{2/C}$ RECEPTORS FACILITATE DEFENSIVE RAGE BEHAVIOR IN THE CAT. M.B. Shaikh*, J. Perez, N. De Lanerolle, and A. Siegel. Lab. of Limbic Syst. & Behav., Depts. of Neurosciences & Psychiatry, NJ Medical School, UMDNJ, Newark, NJ 07103, and Dept. of Neurosurgery, Yale University School of Medicine, New Haven, CT.

The midbrain periaqueductal gray (PAG) is known to receive serotoninergic inputs from the raphe system and medial hypothalamic fibers essential for the integration of defensive rage behavior (DR) in the cat. Recently, we have demonstrated that microinjections of a selective agonist for the 5-HT$_{1A}$ receptors into the PAG suppressed DR elicited from the medial hypothalamus (MH). The present study describes the role of 5-HT$_{2/1C}$ receptors within the PAG upon this form of aggressive behavior. Stimulating electrodes were implanted into DR sites within the MH and cannula electrodes were implanted into DR sites within the PAG for microinfusion of a selective agonist for the 5-HT$_{2/iC}$ receptor (DOI-HCL, in doses of 1.5-0.1 nmol). Drug infusion resulted in a significant decrease in response latencies in a dose and time dependent manner ($p<.001$). Anatomical/immuncytochemical data demonstrated the presence of large quantities of serotoninergic fibers within the region of the dorsal PAG from which DR is typically elicited. Collectively, these results demonstrate that 5-HT$_{1A}$ and 5-HT$_{2/1C}$ receptors differentially modulate aggressive behavior in the cat.
[Supported by NIH grant NS 07941-26].

698.9

THE ROLE OF 5-$HT_{2A/2C}$ AND 5-HT_3 RECEPTORS IN THE DISCRIMINATIVE STIMULUS PROPERTIES OF MIANSERIN.

J. H. Porter*, S. A. Varvel and H. E. Covington III. Psychology Dept., Va. Commonwealth University, Richmond, VA 23184.

Two groups of rats were trained to discriminate the tetracyclic antidepressant mianserin from saline in a two-lever drug discrimination procedure. The training dose was 4.0 mg/kg (i.p.) for one group and 1.0 mg/kg for the other. In the 4.0 group 10 of 10 rats acquired the discrimination (mean = 35.6 sessions) and generalization testing revealed an ED_{50} of 0.48 mg/kg (95% C.I. = 0.34 to 0.68 mg/kg). In the 1.0 group 7 of 10 rats acquired the discrimination (mean = 60.4 sessions) with an ED_{50} of 0.15 mg/kg (95% C.I. = 0.08 to 0.28 mg/kg) during generalization testing. Time course testing with the 4.0 group revealed full generalization at 30, 60, and 120 min pre-session injection times, and partial generalization at 15, 240 and 480 min pre-session injection times (30 min was the training pre-session injection time).

The selective serotonin 5-$HT_{2A/2C}$ antagonist ritanserin produced complete substitution for mianserin in all rats at one or more of the doses tested (0.5 to 16.0 mg/kg). Results with the selective 5-HT_3 antagonist MDL 72222 were less consistent. Some rats did not generalize to MDL 72222 at any of the tested doses (1.0 to 8.0 mg/kg); whereas, other rats generalized to MDL 72222 at one or more of the doses (i.e., partial generalization). These results demonstrate that antagonism of 5-$HT_{2A/2C}$ receptors is sufficient to produce mianserin-appropriate responding and suggest that these receptors may mediate the discriminate stimulus properties of mianserin. Additional research is being conducted to determine the role of other 5-HT receptors and other neurotransmitters such as norepinephrine, histamine, and acetylcholine.

698.10

5HT_{2C} receptor densities in the spinal cord of normal and spinal transected rats.

V. Adipudi[1], S. Croul[2], J. Moul[1], V. Aloyo[3], K. J. Simansky[3], W. P. Battisti[1]* and M. Murray[1]. [1]Department of Neurobiology & Anatomy, [2]Pathology and [3]Pharmacology. Medical College of Pennsylvania & Hahnemann University, Philadelphia, PA 19129.

Fetal neural tissue transplanted into the site of spinal cord transection in newborn rats allows regeneration of the denervated axons, some of which may also form synapses with host neurons. Serotonergic agents such as quipazine (a non selective agent) and DOI (5$HT_{2A/2C}$ agonist) modify locomotor function in animals receiving transplants as adults and neonates (Soc Neurosci Abs 329.10, 1995). However the specific serotonergic receptors mediating this effect are still not clear. In order to answer this question we performed quantitative receptor autoradiography for 5HT_2 receptors in the spinal cord of normal, spinal transected and spinal transected rats receiving transplants as neonates. The problem of high nonspecific binding of ^{125}I-DOI to myelin in the white matter (Soc Neurosci Abs 796.16, 1995) was eliminated by using ^{3}H-mesulergine as the ligand. One group of rats underwent mid thoracic transection at T8-T9 on postnatal day 1 or 2 (n=6). A second group of transected rats received a transplant of embryonic day 14 spinal cord tissue into the lesion site (n=6). A separate group of normal litter mates were maintained as unoperated controls. The spinal cords of the rats from all three groups were harvested at 2, 4 and 8 weeks postnatally and processed for receptor autoradiography. Preliminary studies with ^{3}H-mesulergine suggest a developmental decrease in levels of 5HT_{2C} receptor densities in the ventral horn of the spinal cord of normals. Further studies are in progress to see if this trend is altered by transection and tranplantation. Supported by grants from NS 24707 from NIH, SCRF #.300 from PVA and ASRI

MODULATION OF FRONTAL CORTEX 5-HT_2 SEROTONIN RECEPTORS IN OVARIECTOMIZED RATS: A MODEL OF CNS CHANGE OCCURING AT MENOPAUSE.

Michel Cyr*, Roger Bossé and Thérèse Di Paolo. Centre de recherche en endocrinologie moléculaire du CHUQ and École de pharmacie, Université Laval, Québec, Qué., Canada, G1V 4G2.

We have investigated the effect of ovariectomy on serotonin (5-HT) receptors in female rats as a model of decreased gonadal function as occuring in menopause. The effect of short-term (ST-OVX, 2 weeks) and long-term ovariectomy (LT-OVX, 3 months) on frontal cortex 5-HT_2 receptors and its possible correction with an 17β-estradiol (E_2) treatment (10 µg, b.i.d., 2 weeks) were studied in comparison to intact rats at random stages of the estrous cycle (CTRL). Two breeds of rats were studied, Sprague-Dawley (SD) and Fisher (F). To estimate 5-HT_2 receptor density and affinity, saturation binding assays were performed using [^{3}H]-ketanserin on tissue homogenate of frontal cortex of Fisher rats. To evaluate 5-HT_2 receptor density and 5-HT_{2A} receptor expression, quantitative autoradiography using [^{3}H]-ketanserin and in situ hybridization of frontal cortex brain slices was performed in the two breeds of rats. Our results show a time dependent decrease of the 5-HT_2 receptor density and 5-HT_{2A} mRNA levels, with no change of affinity, suggesting a genomic mecanism for the 5-HT_{2A} receptor changes. Indeed, we have observed for the two breeds of rats a decrease of 5-HT_2 receptor density in ST-OVX (SD:16%) and in LT-OVX (SD:31%, F:20%) with a parallel decrease in levels of 5-HT_{2A} mRNA in ST-OVX (SD:11%) and LT-OVX (SD:16%, F:13%). The E_2 treatment reversed partially in Fisher and completely in Sprague-Dawley rats the decreased receptor levels caused by ovariectomy. Furthermore, changes of expression of 5-HT_2 receptors were completely reversed by E_2 in LT-OVX for the two breeds of rats. The receptor changes observed in the ST-OVX animals were similar but less extensive. These results suggest that gonadal hormone withdrawal affect 5-HT_2 receptors wich may predispose to mood and movement disorders associated with menopause and that an estrogen treatment is able to reverse this change. Supported by the MRC of Canada.

698.12

CORTICAL 5HT_{2A} RECEPTOR UPREGULATION BY AN ANTISENSE OLIGODEOXYNUCLEOTIDE.

J.M. Scalzitti*, K.A. Truett, S.A. Kratowicz, and J.G. Hensler. University of Texas Health Science Center, San Antonio, TX 78284.

We have previously shown that an antisense oligodeoxynucleotide (AS oligo) directed against the translation initiation site of the 5HT_{2A} receptor mRNA (-11 to +7) significantly decreased both 5HT_{2A} receptor density and second messenger function in A1A1 variant cells (Scalzitti et al., 1995; Soc. Neurosci. Abst. 21: 1123). We have now determined the effect of intracerebroventricular (i.c.v.) infusion of AS oligo on cortical 5HT_{2A} receptors. Stainless steel guide cannulae (ALZET brain infusion kits, Alza Corporation, Palo Alto, CA) were stereotaxically implanted into the lateral ventricle of male Sprague-Dawley rats. AS or control oligo (250 µg/day) or vehicle (saline) was administered for one, two, four or eight days at a rate of approximately 1 µl/hour by osmotic pump implanted subcutaneously. Animals were sacrificed shortly after infusions were completed. The effect of i.c.v. oligo infusions on cortical 5HT_{2A} receptors was determined by the binding of [^{3}H]-ketanserin (0.5 - 9 nM) in the presence of 100 nM prazosin and 100 nM pyrilamine. Nonspecific binding was defined by 10 µM methysergide. One and two day infusions with AS or mismatch oligo did not alter the binding of [^{3}H]-ketanserin in cortical homogenates from vehicle controls. However, four day infusions of AS oligo significantly increased (25%, $p \leq 0.01$) cortical 5HT_{2A} receptor density compared to control oligo or vehicle. Eight day infusions of AS oligo resulted in a 50% ($p \leq 0.05$) increase in the density of cortical 5HT_{2A} receptors as compared to control oligos or vehicle. These data suggest that the presence of AS oligo produced a compensatory response by perturbing 5HT_{2A} receptor regulation at the level of translation. Currently, we are investigating this compensatory response by examining the mRNA levels by Rnase protection assays of AS and control oligo or vehicle treated animals after two and eight day infusions. USPHS grant MH52369 and research funds from NARSAD.

SEROTONIN RECEPTORS: $5HT_2$ I

699.1

A SINGLE MUTATION OF THE HUMAN 5-HT_{2A} RECEPTOR DETERMINES LIGAND POSITIONING IN THE BINDING POCKET AND MARKEDLY INCREASES THE INTRINSIC ACTIVITIES OF SOME PARTIAL AGONISTS.

B.J Ebersole*, N. Almaula, D. Zhang, S.C.Sealfon, and H. Weinstein. Departments of Anesthesiology, Pharmacology, Neurology , Physiology and Biophysics, and Fishberg Center in Neurobiology, Mount Sinai School of Medicine, New York, NY.

A Ser->Ala mutation in helix 3 of the 5-HT_{2A} receptor reveals a molecular mechanism underlying partial agonism of indole-based ligands. We found from computational simulations and mutation studies that $Ser^{3.36(159)}$ reinforces the interaction of the protonated amine of 5-HT with $Asp^{3.32(155)}$, but the partial agonists N,N-dimethyl 5-HT and LSD cannot interact with this site due to steric clashes with the substituents of the amine nitrogen. In the absence of this second interaction in helix 3, the positioning of 5-HT and indole-based partial agonists becomes similar. In order to test the hypothesis that this difference in positioning contributes to differences in agonism of these ligands, their relative intrinisc activities (i.a.) for stimulation of phosphatidylinositol turnover was evaluated with the wild-type (WT) receptor and with a $Ser^{3.36(159)}$->Ala receptor stably expressed in HEK293 cells. For the WT receptor, N,N-dimethyl 5-HT and LSD had i.a. of 0.23 and 0.1, respectively, relative to 5-HT. For the mutant, however, their i.a. relative to 5-HT increased to 1.0. Partial agonists such as 4-HT (i.a.=0.5) and tryptamine (i.a.= 0.56) would, like 5-HT, interact with $Ser^{3.36}$ in the WT receptor. These ligands remained partial agonists at the mutant receptor (i.a. of 0.5 and 0.45, respectively). These results suggest that the mutation differentially affects the position of the ligand in the receptor complex for substituted and unsubstituted agonists and thereby alters the ligand-induced conformational changes involved in receptor activation. Thus, the extent of agonist activity appears to depend on the positioning of the ligand in the binding pocket. Supported by NIH grants RO1 DA09088, RO1 DA 09083, T32 DA07135 and KO5 DA00060.

LARGE SCALE PRODUCTION, SOLUBILIZATION AND PARTIAL PURIFICATION OF 5-HT2A RECEPTORS FROM INSECT CELLS.

E. G. Hyde*, S. Choudhary, M. Dennis† and B. L. Roth. Departments of Biochemistry and Psychiatry, Case Western Reserve University Medical School, Cleveland, OH 44106 and † BioSignal, Inc., Montreal, Canada.

At present, the precise means by which drugs bind to and regulate G-protein coupled receptors are unknown. Most prior investigations have focussed on a combination of molecular modeling and mutagenesis approaches using rhodopsin and bacteriorhodopsin molecules as templates. We have used 5-HT2A receptors as a model system for determining how drugs of diverse structure bind to and activate a single receptor. We now report our initial results aimed at obtaining large quantities of 5-HT2A receptors for biophysical and structural studies. We initially constructed a his6-tagged 5-HT2A receptor which was then subcloned into a baculovirus vector and used to infect SF-9 and SF-21 insect cells. Time-course studies revealed that SF-21 cells expressed approximately 5-fold higher levels of 5-HT2A receptors as compared with SF-9 cells. A variety of detergents were tested to obtain optimal solubilization of the 5-HT2A receptor including: Chaps, n-octylglucoside, β-D-maltoside, sucrose monolaurate, digitonin and sodium cholate. The combination of Chaps, glycerol, NaCl and cholesterol hemisuccinate was found to be optimal. Studies are currently ongoing utilizing a variety of affinity chromatography techniques (amoxapine affinity, Ni-affinity, hydrophobic affinity) to obtain optimal purification with suitable yields.

ALCOHOLS AND ANESTHETICS INHIBIT THE FUNCTION OF 5-HYDROXYTRYPTAMINE2 A RECEPTORS EXPRESSED IN XENOPUS OOCYTES.

K. Minami, M. Minami, N. Yanagihara*, R.A. Harris. Department of Pharmacology, University of Colorado Health Sciences Center, Denver, CO, 80262, *Department of Pharmacology, University of Occupational and Environmental Health, Kitakyushu, Japan, 807.

The study of the effects of alcohols and anesthetics on G-protein coupled receptors has been the focus of recent attention. 5-Hydroxytryptamine$_2$ A receptors (5HT2A) receptors are coupled to Gq and regulate sleep and alterness in the CNS. We studied the effects of alcohols and anesthetics on 5HT2A receptors expressed in Xenopus Oocytes. Ethanol inhibited 5HT responses in a concentration-dependent manner; i.e. 10nM 5HT responses were decreased to 83% of control by 50mM ethanol and to 43% of control by 200mM ethanol. Although all short chain alcohols (ethanol to hexanol) inhibited 5HT responses, long-chain alcohols had little effect at anesthetic concentrations. The volatile anesthetics, halothane and F3 (1-chloro-1,2,2-trifluorocyclobutane) inhibited 5HT responses at 1 MAC concentrations; however, intravenous anesthetics, propofol, ketamine, pentobarbital and etomidate did not affect the 5HT responses. The non-anesthetic compound, F6 (1,2-dichlorohexaflurocyclobutane) inhibited on the 5HT responses; F6 inhibited the 5HT response to 68 % of control at 1 MAC concentration. These results indicate that (1) G-protein coupled 5HT2A receptor are inhibited by short chain alcohols and volatile anesthetics and (2) the non-anesthetic compound may have inhibitory effects on 5HT2A receptor function. CHARACTERISTICS OF DESENSITIZATION OF 5-HT_{2A} AND 5-HT_{2C} RECEPTOR SYSTEMS. B.D. Stout[1]*, K.A. Berg[1], S. Maayani[2], W.P. Clarke[1]. Dept. of Pharmacology[1], Univ. of Texas Health Science Center, San Antonio, TX 78284, Dept. of Anesthesiology[2], Mount Sinai Med. Cntr., CUNY, NY, NY 10029.

Previous work has shown differences in signal transduction between 5-HT_{2A} and 5-HT_{2C} receptor systems. In this study we have investigated differences in desensitization characteristics associated with these two receptor systems. Phospholipase C-(PLC) mediated phosphoinositde (PI) hydrolysis was measured in CHO cells stably expressing human 5-HT_{2A} (≈200 fmol/mg) or 5-HT_{2C} (≈200 fmol/mg) receptors. Receptor alkylation experiments indicated the absence of receptor reserve for either receptor system. Cells were labeled for 24 hrs with 1 μCi/ml [^{3}H]-*myo*inositol and pretreated with 5-HT for 0 to 60 min (desensitization period) followed by measurement of accumulation of [^{3}H]-inositol phosphates in the presence of LiCl and a maximal 5-HT concentration for 10 min. Pretreatment with 5-HT at maximal concentrations (full occupancy; 10 μM for 5-HT_{2C} or 100 μM for 5-HT_{2A}) resulted in a maximal loss of response at approximately 10 min . The magnitude of desensitization was greater for the 5-HT_{2C} than for the 5-HT_{2A} receptor system (70% ± 1% vs 47% ± 5%; n= 5-8). Although the magnitude of desensitization remained constant for up to 1 hr for the 5-HT_{2C} receptor system, interestingly, an apparent resensitization of the 5-HT_{2A} (25% ± 4%; n=7) receptor system occurred after pretreatment for 30 min. Following 10 min pretreatment, both receptor systems recovered partially (to 70-80% of control) within 15 min of agonist washout. However with prolonged pretreatment (60 min), recovery of both systems was attenuated. When cells were pretreated with 5-HT to produce 50% occupancy (0.03 μM for 5-HT_{2C} or 0.3 μM for 5-HT_{2A}), the rate and magnitude of desensitization was markedly reduced for the 5-HT_{2C}, but not the 5-HT_{2A}, receptor system. These results further illustrate differences in the signal transduction systems associated with 5-HT_{2A} and 5-HT_{2C} receptors. (Supported by USPHS grants DA 09094 and MH 48125).

699.5

RELATIVE DRUG EFFICACY OF 5-HT_{2A} RECEPTOR AGONISTS IS SIGNAL TRANSDUCTION PATHWAY DEPENDENT. K.A. Berg[1]*, E.D. Loh[1], J.D. Cropper[1], S. Maayani[2] and W. P. Clarke[1]. Department of Pharmacology[1], University of Texas Health Science Center, San Antonio, TX 78284 and Department. of Anesthesiology[2], Mount Sinai Medical Center., CUNY, New York, NY 10029.

The manner by which a G-protein coupled receptor couples to multiple effectors has important pharmacological consequences with respect to agonist efficacy. Previously we have found that agonist efficacy at human 5-HT_{2C} receptors expressed in CHO cells was dependent upon whether activation of phospholipase C (PLC) or phospholipase A_2 (PLA_2) was measured (Berg, *et al.*, Soc Neurosci. Abstr., **21**:1365 1995). Similar to the 5-HT_{2C} receptor, the human 5-HT_{2A} receptor transfected stably in CHO cells appears to couple independently to both PLC and PLA_2. Incubation of cells with 5-HT in the presence of 20 mM LiCL (10 min, 37°C) increased [^{3}H]-inositol phosphate (IP) accumulation 259% ± 17% above basal with an EC_{50} of 482 nM (pEC_{50} = 6.32 ± 0.15; mean ± SE, n =7-12) and increased [^{14}C]-arachidonic acid (AA) release 75 ±11 % above basal with an EC_{50} of 423 nM (pEC_{50} 6.37 ± 0.12; mean ± SE, n = 5-10). IP measurements were made, simultaneously, from the same intact cell preparation as AA release measurements. Because results of alkylation studies indicated a lack of receptor reserve for 5-HT on either pathway, relative efficacy was evaluated using intrinsic activity (i.a.) measures of agonists (20 x EC_{50} or Ki values). The rank order of agonist efficacy (mean i.a., n=5-7) for PLC activation was 5-HT (1) > 5-methoxytryptamine (0.88) ≥ αMethyl 5-HT (0.83) > tryptamine (0.60) > quipazine (0.44) > DOI (0.34) = bufotenine (0.33) > LSD (0.13) and for AA release was αMethyl 5-HT (1.54) = tryptamine (1.54) ≥ 5-methoxytryptamine (1.31) > bufotenine (1.02) = 5-HT (1) > DOI (0.66) ≥ LSD (0.55) ≥ quipazine (0.40). These data indicate that 5-HT_{2A} receptor agonists have different relative efficacies depending upon the effector pathway measured. Further, these data suggest that agonist-dependent changes in 5-HT_{2A} receptor conformation promotes differential G protein coupling in CHO cells. (Supported by USPHS grants DA 09094 and MH 48125.)

THE RAT 5HT2A AND 5HT2C RECEPTORS STABLY EXPRESSED IN NIH-3T3 CELLS COUPLE TO MULTIPLE SECOND MESSENGER SYSTEMS. M. Jurzak*, D. Van de Wiel, G. Van Hecke, D. Van Oekelen and J. E. Leysen. Janssen Research Foundation, Department of Biochemical Pharmacology, 2340 Beerse, Belgium

Functional studies on serotonin- 5HT2 type receptors revealed coupling to multiple second messengers. However, those studies were performed in different laboratories using various cell lines and tissues. This might have confounded intrinsic receptor-related factors and relative potencies in second messenger coupling. Therefore, we studied the cloned rat $5HT_{2A}$ and $5HT_{2C}$ receptors expressed in NIH-3T3 cells (gift from D. Julius). Since serum-borne serotonin might cause receptor desensitization the cells were cultured under conditions of low or not detectable serotonin. Antagonist-radioligand binding showed Bmax values of about 4-5 pmol/mg protein for both receptor subtypes, with a K_D of 0.3 nM for [^{3}H]mesulergine binding to the $5HT_{2C}$ receptor and a K_D of 0.07 nM for [^{125}I]5-iodo-R91150 binding to the $5HT_{2A}$ receptor. In binding competition experiments the pharmacology of the cloned receptors matched that of tissue receptor preparations. We studied functional responses of the transfected cells to 5HT on inositol phosphate (IP) formation, rise in intracellular [Ca^{++}] ($[Ca^{++}]_i$) and release of [^{3}H]arachidonic acid (AA). In IP formation studies 5HT showed EC_{50}-values of 143 nM and 8.4 nM for the $5HT_{2A}$- and $5HT_{2C}$ receptors, respectively. Comparable values were found in measurements of $[Ca^{++}]_i$ in fura2 loaded cells. The Ca^{++} signals were derived from intracellular stores and could be blocked by specific antagonists. Out of the ligands tested, methysergide was a full antagonist on the $5HT_{2C}$- and a partial agonist on the $5HT_{2A}$ receptor. In addition, a concentration and time dependent coupling of both receptors to phospholipase 2A could be demonstrated by the release of AA.

FLUOXETINE-INDUCED INCREASE IN G-PROTEIN COUPLING OF HYPOTHALAMIC 5-$HT_{2A/2C}$ RECEPTORS: TIME COURSE OF ADAPTIVE CHANGES L. D. Van de Kar*, Q. Li, T. M. Cabrera, W. Pinto, and G. Battaglia, Dept. Pharmacol. Sch. Med., Loyola Univ. Chicago, Maywood, IL. 60153.

Fluoxetine and other antidepressants produce a delayed onset (14-21 days) clinical improvement. Previously we reported (*J. Pharmacol. Exp. Ther.* 266:836-844, 1993) that fluoxetine injections for 21 days potentiate hormone responses to the 5-$HT_{2A/2C}$ agonist DOI, and increase the B_{max}, but not Kd of ^{125}I-DOI binding in the hypothalamus. The present study investigated the **time-course** of fluoxetine-induced increases in ^{125}I-DOI and ^{3}H-ketanserin binding in the hypothalamus. Rats received daily injections of fluoxetine (10 mg/kg, ip) for 0, 3, 7, 14 or 22 days. ^{125}I-DOI binding was used to determine the density of G-protein coupled (high affinity state) 5-$HT_{2A/2C}$ receptors, while ^{3}H-ketanserin labeled the total density of 5-$HT_{2A/2C}$ receptors. ^{125}I-DOI binding in the hypothalamus was significantly increased after 7 and 14 daily injections of fluoxetine (49-50%). However, no changes in ^{3}H-ketanserin binding were observed with any fluoxetine treatment regimen. These results demonstrate that repeated injections of fluoxetine produce a delayed-onset increase in the density of the high affinity state of 5-$HT_{2A/2C}$ receptors in the hypothalamus. Because there was no change in the total density of 5-$HT_{2A/2C}$ receptors, the increased density (and percent) of high affinity state 5-$HT_{2A/2C}$ receptors is likely due to an increase in the coupling of the 5-HT $_{2A/2C}$ receptors to their G-proteins. No comparable changes were observed in the cortex, suggesting that the effects are region-specific. (Supported by USPHS NS34153).

INVOLVEMENT OF PKC AND INTRACELLULAR CALCIUM IN THE REGULATION OF 5-HT_{2A} RECEPTOR mRNA LEVELS IN P11 CELLS. **K.L. Wohlpart[1] and P.B. Molinoff[2]*. [1]Dept. of Pharmacology, Univ. of Pennsylvania School of Medicine, Phila., PA 19104 and [2]Bristol-Myers Squibb, Wallingford, CT 06492.**

P11 cells express 5-HT_{2A} receptors coupled to the hydrolysis of phosphatidylinositol (PI). PI hydrolysis results in the generation of IP3 and diacylglycerol which stimulate a rise in levels of intracellular Ca^{+2} and activation of protein kinase C (PKC), respectively. We have previously shown that exposure of P11 cells to 10 μM serotonin (5-HT) results in a transient increase in the amount of 5-HT_{2A} receptor mRNA. The involvement of PKC and intracellular Ca^{+2} in the regulation of 5-HT_{2A} receptor mRNA was examined. Activation of PKC with 100 nM phorbol 12-myristate 13-acetate (PMA) stimulated a transient increase in levels of 5-HT_{2A} receptor mRNA. The maximum increase occurred following exposure times between 1 and 1.5 hours and levels of mRNA returned to basal levels within 6 hours. The change in levels of receptor message following exposure of cells to PMA followed a time course similar to that seen on exposure to 5-HT. Exposure of cells to PMA for 24 hours resulted in downregulation of PKC activity and blocked the increase in receptor message seen following a 90 minute incubation with 5-HT but did not affect the ability of serotonin to stimulate an increase in the level of inositol phosphates. The effects of increased levels of intracellular Ca^{+2} on the regulation of 5-HT_{2A} receptor mRNA were investigated using the calcium ionophore, ionomycin. Exposure of cells to ionomycin (2.5 μM) for 90 minutes resulted in a greater than two-fold increase in the level of 5-HT_{2A} receptor mRNA. Downregulation of the activity of PKC following a 24 hour exposure to PMA had no effect on the ability of ionomycin to stimulate an increase in levels of 5-HT_{2A} receptor RNA. These data suggest that 5-HT_{2A} receptor mediated regulation of receptor mRNA levels involves a mechanism that is dependent upon the activation of PKC (downstream of the generation of inositol phosphates) in addition to a distinct mechanism that involves a change in intracellular calcium.

MECHANISM OF AGONIST-INDUCED 5-HT_{2A} RECEPTOR UP-REGULATION IN CEREBELLAR GRANULE CELLS. E. Chalecka-Franaszek*, P. Saunders, H. Chen and D.-M. Chuang. Section on Molecular Neurobiology, Biological Psychiatry Branch, NIMH, NIH, Bethesda, MD 20892.

We have reported that 5-HT and DOI induce an increase in the density of 5-HT_{2A} receptor binding sites in rat cerebellar granule cells (CGC) by a calmodulin-dependent mechanism. The present study was undertaken to further characterize this agonist-induced up-regulation process. We confirmed the increase in 5-HT_{2A} receptor protein after DOI treatment by Western blotting using a monoclonal antibody specific for 5-HT_{2A} receptors. Immunocytochemical studies using the same antibody revealed that 5-HT_{2A} receptors are located on both neurites and cell bodies of CGC. DOI treatment did not change the level of Gq/11 protein α-subunit but unexpectedly appeared to enhance the Gs α-subunit level. Electrophoretic mobility shift assay showed that DOI increased AP-1 and CREB binding to their consensus sequences. Curcumin, a putative inhibitor of c-jun activation, failed to influence DOI-induced up-regulation of 5-HT_{2A} receptor binding. Levels of c-fos mRNA were transiently increased following DOI stimulation. Our results are compatible with the view that DOI induces c-fos expression via CREB activation, through a calmodulin-dependent process. The induced c-fos then increases AP-1 transcriptional factor binding to the 5-HT_{2A} receptor promoter, resulting in an enhancement of its transcription.

CONSTITUTIVELY ACTIVE MUTANT $5HT_{2A}$ SEROTONIN RECEPTORS: INVERSE AGONIST ACTIVITY OF CLASSICAL $5HT_{2A}$ ANTAGONISTS. C.Casey *,K.Herrick-Davis, and M.Teitler. Dept.of Pharmacology, Albany Medical College, Albany, NY 12208.

Recently, several G-protein coupled receptors(GPCR) have been shown to have constitutive activity and may play a role in several pathophysiological states. The $5HT_{2A}$ receptor is involved in many peripheral functions as well as in the CNS where it is the site of action of hallucinogens and is a purported site of action of atypical anti-psychotics and anti-depressants. Due to the wide ranging effects of the $5HT_{2A}$ receptor, we wanted to determine if the $5HT_{2A}$ receptor could be made constitutively active. We hypothesized that due to the structural homology of the GPCR family, that the $5HT_{2A}$ receptor if mutated in amino acid position #322 would be made constitutively active. We then wanted to study the binding and intracellular responses of these mutants by several anti-psychotics as the $5HT_{2A}$ is a purported site of action of clozapine and other atypicals. Amino acid #322 in the $5HT_{2A}$ receptor was mutated from cysteine to lysine,glutamine, and arginine. The mutant $5HT_{2A}$ receptors were then transiently transfected into COS-7 cells and radioligand binding studies showed that they all displayed higher affinity for serotonin than the native $5HT_{2A}$ receptor. The mutant lys, glu, and arg had Ki values of 33, 60, 34nM as compared to 200nM of the native $5HT_{2A}$ receptor. In PI assays these mutant receptors all had a greater basal activity than the native receptor. The lysine mutant was ~four fold more active than the native $5HT_{2A}$ receptor. Clozapine caused a 50% decrease in basal activity of the mutant lysine $5HT_{2A}$ receptor. Data using other atypical anti-psychotics will be presented as well as other properties of these constitutively active $5HT_{2A}$ such as the binding and stimulation of partial agonist and agonists.

[^{3}H]MDL 100,907: A NOVEL SELECTIVE 5-HT_{2A} RECEPTOR LIGAND. M.P. Johnson*, B.W. Siegel and A.A. Carr. Hoechst Marion Roussel, Inc., CNS Research, Cincinnati, OH, 45215.

MDL 100,907 has a high degree of selectivity for the 5-HT_{2A} receptor. Using standard radioligands, MDL 100,907 has been shown to lack significant affinity for the 5-HT_{2B}, 5-HT_{1F}, 5-HT_{1D}, 5-HT_3, 5-HT_4, 5-HT_{5A}, 5-HT_{5B}, 5-HT_6, 5-HT_7, $D_{1\text{-}5}$, muscarinic, GABA, glycine and benzodiazepine receptors and shows a greater than 100-fold selectivity over the 5-HT_{2C} and α_1 receptors. The present study describes the binding characteristics of [^{3}H]MDL 100,907 in rat cortical homogenates. [^{3}H]MDL 100,907 reached equilibrium at 37°C after 15 min. Saturation experiments indicated binding to a single site: K_D 0.56 ± 0.05 nM; Hill slope 1.15 ± 0.15; B_{max} 512 ± 14 fmol/mg protein. In parallel experiments with [^{3}H]ketanserin, a similar Hill slope and B_{max} were noted but a two-fold higher K_D was found. In competition binding studies using 0.5 nM [^{3}H]MDL 100,907, 19 standard ligands to various receptors including the 5-HT_{2C}, D_2, α_1, and σ receptors resulted in estimated K_i values consistent with [^{3}H]MDL 100,907 selectively binding to the 5-HT_{2A} receptor. A comparison of the K_i values for 17 standard 5-HT_{2A} receptor agonists and antagonists displacing [^{3}H]MDL 100,907 versus [^{3}H]ketanserin resulted in a highly significant linear correlation (r^2 = 0.96, $p < 0.001$). Taken together these results suggest that [^{3}H]MDL 100,907 is labeling only the 5-HT_{2A} receptor with a sub-nanomolar affinity.

DOI PRODUCES A BIPHASIC REGULATION OF NITRITE LEVELS IN CORTICAL SLICES PREPARED FROM RAT BRAIN. Keith J. Miller*#, Greg Hotsenpiller@ and Beth J. Hoffman@. #Dept. Pharm. Sci., Nova SE Univ.; N. Miami Beach, FL 33162;@Lab of Cell Biol., NIMH; Bethesda, MD.

Activation of $5HT_2$ receptors can result in the activation of protein kinase C (PKC) and/or the elevation of intracellular calcium levels. Both of these second messenger systems have been shown to modulate the activity of constitutive nitric oxide synthases (cNOS). Experiments were performed to determine if $5HT_2$ receptor activation in cortical slices from rat brain could modulate nitrite levels, as a measure of NOS activity. At concentrations ranging from 10^{-10}M to 10^{-7}M, DOI produced a dose dependent decrease in nitrite levels in the cortical slices. The maximal decrease was 48%. At DOI levels above 10^{-7}M a dose dependent increase in nitrite levels was observed, with a maximal increase of 59%. The dose response curve of low DOI levels was shifted to the right by 10nM mianserin but not by 10nM spiperone, suggesting the involvement of $5HT_{2c}$ receptors. 0.1μM chelerythrine (a PKC inhibitor) inhibited the decrease in nitrite levels produced by 10^{-8}M DOI by 50%, but did not inhibit the increase produced by 10^{-5}M DOI. The increase in nitrite levels produced by 10μM DOI was prevented by 100μM L-NAME. These results demonstrate that cNOS activity can be modulated by $5HT_2$ receptor activation. The data suggest that activation of the serotonergic system can modify the biological procceses governed by NO in the brain.

$5HT_{2A}$ RECEPTOR ACTIVATION DECREASES NITRITE PRODUCTION IN LIPOPOLYSACCHARIDE STIMULATED C6-GLIOMA CELLS. C.L. Horton, A. Malave' and K.J. Miller. Dept. of Pharmaceutical Sci., Nova Southeastern Univ., Col. of Pharm., N. Miami Beach, FL 33162.

C6-glioma cells endogenously express both $5HT_{2A}$ receptors and inducible nitric oxide synthase (iNOS). iNOS can be induced to synthesize nitric oxide (NO) in response to a challange with lipopolysaccharide (LPS). Experiments were conducted to determine whether $5HT_{2A}$ receptor activation could modify the production of NO in response to LPS. C6-glioma cells were incubated with $5HT_2$ receptor selective compounds and LPS for 24 hours. Samples were collected and monitored for nitrite levels using the Greiss reagent. 1μM (±)-2,5-dimethoxy-4-iodoamphetamine (DOI) decreased LPS-induced nitrite levels by 22%. 1μM DOI alone had no effect on basal nitrite levels. Dose response analysis of DOI revealed an IC_{50} of 71nM. Interestingly, the addition of 10μM spiperone to LPS with or without DOI resulted in a potentiation of LPS-induced nitrite levels. The addition of 0.1μM chelerythrine, a PKC inhibitor, prevented the DOI-mediated decrease in LPS-induced nitrite levels. These results demonstrate that iNOS activity can be modified by $5HT_{2A}$ receptor compounds via PKC. The data indicates a possible link between the serotonergic system and immune function in the brain.

DOES CHRONIC ADMINISTRATION OF PAROXETINE OR THE 5-HT_{2B} RECEPTOR AGONIST, BW 723C86, AFFECT RAT 5-HT_{2B} RECEPTOR FUNCTION? G.A. Kennett, J. Ranson, F. Bright, T.P. Blackburn,* Dept of Psychiatry Research, SmithKline Beecham Pharmaceuticals, New Frontiers Science Park, Third Avenue, Harlow, Essex, CM19 5AW, U.K.

The effects of chronic treatment with the 5-HT reuptake inhibitor, paroxetine, or the 5-HT_{2B} receptor agonist, BW 723C86 (BW, Kennett et al. 1996, Br. J. Pharmacol. 117, 1443) on three models of 5-HT_{2B} receptor function, 5-HT mediated contractions of the rat stomach fundus (Baxter et al., 1994, Br. J. Pharmacol., 112, 323) and BW-induced anxiolysis (Kennett et al., 1996,) and hyperphagia (Ainsworth et al. 1996, Br. J. Pharmacol., 117, 178P), were studied.

Male Sprague-Dawley rats (250 g) were given paroxetine (10 mg/kg p.o.), BW (1 or 3 mg/kg i.p.) or vehicle, b.i.d. x 14 days and singly housed on day 11. On day 15, groups of paroxetine treated rats were given saline or BW 3 mg/kg s.c. in treatment and weight matched pairs and tested in a rat social interaction (SI) test 20 min later (see Kennett et al., 1996 for conditions). Others were food deprived 1 h pre-test at 13.00 h and given saline or BW 30 mg/kg s.c. 30 min before restoring food and monitoring intake over 4 h. Stomach fundi were removed from saline or BW treated rats on day 15, set up as previously (Baxter et al., 1994) and contractile responses to 5-HT (10^{-5}-10^{-10} M) examined.

24 h withdrawal from chronic paroxetine had no effect alone in the SI test and did not reduce the anxiolytic-like response to BW. Chronic paroxetine did not affect BW-induced hyperphagia over 4 h either, although alone, it modestly increased basal feeding. Finally, chronic BW had no effect on rat stomach fundus responses to 5-HT. Thus, in contrast to the 5-HT_{2C} and perhaps the 5-HT_{2A} receptors (Kennett et al., 1994, Neuropharmacol., 33, 1581), the 5-HT_{2B} receptor seems resistant to desensitisation on prolonged stimulation.

EXPRESSION AND FUNCTION OF THE RAT 5-HT$_{2B}$ RECEPTOR. M.S. Duxon; G.A. Kennett[1]; S. Lightowler[1]; T.P. Blackburn[1] and K.C.F. Fone, (SPON: Brain Research Association), Dept. of Physiology and Pharmacology, University of Nottingham, U.K. [1]SmithKline Beecham Pharmaceuticals, New Frontiers Science Park, Harlow, Essex. U.K.

As few ligands discriminate between the 5-hydroxytryptamine$_2$ (5-HT$_2$) receptor subtypes, functions currently ascribed to 5-HT$_{2A}$ or 5-HT$_{2C}$ receptors may in fact be mediated by the more recently characterised 5-HT$_{2B}$ receptor [Foquet et al., (1992) Embo J., 11, 3481].

A sheep polyclonal antibody was raised against the N-terminus of the rat 5-HT$_{2B}$ receptor, conjugated to bovine serum albumin (BSA) and purified using size-exclusion chromatography. Antibody was used for immunocytochemistry on paraformaldehyde-fixed coronal rat brain slices (100μm) or Western blot analysis of plasma membranes from male Hooded Lister rats and the human SH-SY5Y neuroblastoma cell line. Immunocytochemistry revealed intense 5-HT$_{2B}$-like immunoreactivity upon cell bodies in the medial amygdala, and also in the lateral septum, cerebellar Purkinje cells and hypothalamus. Western blot analysis revealed two intense bands of 70 and 52 KDa, which were blocked by BSA and the N-terminal 5-HT$_{2B}$ receptor peptide respectively.

A functional role of the 5-HT$_{2B}$ expressing neurones in the medial amygdala was investigated by central bilateral injection (500nl) of the selective 5-HT$_{2B}$ receptor agonist, BW 723C86 (0.31-3.1 nmol) (Kennett et al., 1996 Br. J. Pharmacol., 117,1443) into the medial amygdala immediately prior to monitoring in the social interaction test with a similarly treated animal.

BW 723C86 produced an anxiolytic effect in the social interaction test in which an increase in total interaction time was evident without concurrent locomotor effects as previously reported on systemic injection (see Kennett et al., 1996). These results suggest that the 5-HT$_{2B}$ receptor protein is expressed in the rat brain and mediates anxiolytic-like behaviour in the social interaction test.

TETRAHYDRO-ß-CARBOLINES AS SELECTIVE ANTAGONISTS FOR THE SEROTONIN$_{2B}$ (5-HT$_{2B}$) RECEPTOR. D.L. Nelson*, D.B. Wainscott, V.L. Lucaites, J.J. Droste, J.S. Nissen, and J.E. Audia, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

In a search for compounds having selectivity for the 5-HT$_{2B}$ receptor a series of compounds based on rauwolscine, i.e., 1-benzyl substituted 1,2,3,4-tetrahydro-β–carbolines (THBC's), was examined at the cloned human forms of the 5-HT$_2$ family of receptors. Initial studies examined affinities against agonist radioligand labeled sites, using [^{125}I]DOI to label 5-HT$_{2A}$ and 5-HT$_{2C}$ receptors and [^{3}H]5-HT to label 5-HT$_{2B}$ receptors. Rauwolscine itself showed good affinity for the 5-HT$_{2B}$ receptor (see table), very good selectivity for 5-HT$_{2B}$ relative to 5-HT$_{2C}$ (>100-fold), and moderate selectivity for 5-HT$_{2B}$ compared to 5-HT$_{2A}$ (18-fold). The THBC's showed a range of affinities and selectivities across the 5-HT$_2$ family of receptors. However, certain examples showed a > 10-fold increase in affinity for the 5-HT$_{2B}$ relative to rauwolscine while retaining selectivity for the 5-HT$_{2B}$ receptor compared to 5-HT$_{2A}$ and 5-HT$_{2C}$. Examples included 1-(2-chloro-3,4-dimethoxybenzyl)-6-methyl-THBC (THBC-1) and 1-(2-bromo-3,4-dimethoxybenzyl)-6-methyl-THBC (THBC-2).

	Ki Value (nM) vs. Agonist Radioligands		
Compound	5-HT$_{2A}$	5-HT$_{2B}$	5-HT$_{2C}$
Rauwolscine	252 ± 8	14 ± 1	1690 ± 309
THBC-1	10.9 ± 2	0.52 ± 0.1	23.4 ± 1
THBC-2	13.8 ± 2	0.50 ± 0.12	18.9 ± 2

Examination of these compounds at the cloned 5-HT$_{2B}$ receptors revealed antagonism of 5-HT-induced IP$_3$ production with no agonist activity. Thus, these compounds represent high-affinity selective antagonists at the 5-HT$_{2B}$ receptor and should be valuable aids in its characterization.

(Funded by Eli Lilly and Company)

ROLE OF THE CONSERVED ASP100 IN THE SEROTONIN (5HT)2C RECEPTOR. Y.G. Ni*, M.M. Panicker[1], R. Miledi, Laboratory of Cellular and Molecular Neurobiology, Department of Psychobiology, University of California, Irvine, CA 92717 (USA). [1]Present address: National Center for Biological Sciences TIFR Center, IISc Campus, Bangalore (India).

5HT2c receptors are widely expressed in the mammalian brain and spinal cord, can couple to different second messenger pathways and appear to mediate many of the effects of 5HT, including locomotion, pain and anxiety. To study the structure-function relation of this receptor, we have constructed a number of mutant 5HT2c receptors. One of these is a mutant, D100N, in which the Asp100 residue in the second transmembrane domain was replaced by an asparagine residue. When expressed in *Xenopus* oocytes, the mutant receptor mediated much smaller membrane current responses to 5HT than the wild type receptor. Accordingly, when this mutant receptor was transiently expressed in HeLa cells, it displayed impaired binding to [^{3}H]5HT. The mutant D100N 5HT2c receptor showed reduced binding of both 5HT and dopamine, with the K_d for 5HT and the K_i for dopamine changing from 4.3 to 245 nM and 16 to 462 μM, respectively. Interestingly, the mutant D100N receptor retained the ability to bind several ergoline compounds, such as LSD, mesulergine and methysergide.

CONSTITUTIVELY ACTIVE 5HT2C SEROTONIN RECEPTOR CREATED BY SITE-DIRECTED MUTAGENESIS.

K.Herrick-Davis[1] and M. Teitler*[2], Pharmacology and Neuroscience Department, Albany Medical College, Albany, NY 12208.

Mutant 5HT2C receptors were created in an attempt to mimic the active (ligand bound) conformation of the receptor. Structural alteration of receptor conformation was achieved by changing Ser(S) AA#312 to Phe(F) or Lys(K). Compared to native receptors, F and K mutants displayed 3 and 30 fold increases, respectively, in 5HT binding affinity and EC_{50} for stimulation of PI hydrolysis. Both mutants were constitutively active. F and K mutations resulted in 2 and 5 fold increases, respectively, in basal levels of IP accumulation versus native 5HT2C receptors. Mianserin displayed inverse agonist activity by decreasing basal K mutant IP production. Basal levels of IPs stimulated by K mutant receptors represented 50% of total IP production stimulated by native receptors in the presence of 10uM 5HT. In contrast to native receptors, 3H-5HT and 3H-mesulergine labeled the same number of K mutant receptors and guanyl nucleotides had no effect on 3H-5HT binding. These results indicate that S→K mutation produces an agonist high affinity state of the receptor that couples to G proteins in the absence of agonist and partially mimics the active conformation of native receptor in the presence of agonist.

AGONIST-MEDIATED PHOSPHORYLATION OF 5-HT$_{2C}$ RECEPTORS IN A FIBROBLAST CELL LINE

E. Sanders-Bush and J. R. Backstrom* Department of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN 37232.

We developed a method to examine phosphorylation of 5-HT$_{2C}$ receptors non-radioactively on immunoblots. Treatment of cells stably expressing 5-HT$_{2C}$ receptors with serotonin results in increased incorporation of [^{32}P] (Westphal et al., 1995). When cells were grown in the presence of serum with tunicamycin to prevent *N*-linked glycosylation, receptors migrated in SDS-polyacrylamide gels with masses of 40 and 41 kDa (Backstrom et al., 1995). In the absence of serum, only the 40 kDa protein was detected. Stimulation of cells with the agonists 5-HT, DOI, DOB, or m-CPP resulted in the appearance of 41 kDa receptors on immunoblots. Only the 40 kDa form was detected after treatment with the antagonists mianserin, Br-LSD, or methysergide. Pretreatment of cells with mianserin before serotonin prevented formation of the 41 kDa protein. Treatment of cell extracts with alkaline phosphatase eliminated the 41 kDa form of the 5-HT$_{2C}$ receptor but did not affect the 40 kDa receptor. Similar results were attained in experiments with glycosylated receptors. Maximal phosphorylation was attained by 10 min. of agonist treatment and dephosphorylation was completed by 1 h after agonist removal. Pre-incubation of cells with the inhibitors H-7, staurosporine, W-7, KN-62, or KN-93 before treatment with serotonin did not prevent the appearance of 41 kDa receptors. Additionally, treatment of cells with the phorbol ester PMA did not generate significant amounts of the 41 kDa receptor. Thus, early phosphorylation of 5-HT$_{2C}$ receptors in this system may be independent of protein kinase C and Ca^{2+}-calmodulin pathways. SEROTONIN RECEPTOR-MEDIATED PHOSPHOLIPASE C ACTIVITY IN RAT BRAIN MEMBRANES: DIFFERENTIAL EFFECTS OF MCPP

W.A. Wolf* Hines VA Medical Center, Hines, IL 60141 and Dept. of Pharmacol., Loyola Univ. Chicago Sch. of Med., Maywood, IL 60153

5-Hydroxytryptamine (5-HT)$_{2A}$ and 5-HT$_{2C}$ receptors share similar pharmacological properties and mediate phosphoinositide breakdown via G-protein coupled activation of phospholipase C (PLC). In general, brain slices or transfected cell lines have been used to study 5-HT$_{2A/2C}$ signal transduction. To allow similar transduction studies to be carried out in previously frozen brain tissue, an assay was developed for 5-HT$_{2A}$ and 5-HT$_{2C}$ coupled PLC activity in membrane preparations. Using this assay the actions of m-chlorophenylpiperazine (mCPP) at 5-HT$_{2A}$ and 5-HT$_{2C}$ receptors, an issue generating considerable debate, was determined. PLC activity was assayed in washed membranes by a modification of the method of Wallace and Claro (JPET 255:1296-1300, 1990). Exogenously added ^{3}H-phosphatidylinositol was used as substrate. Following extraction, the ^{3}H-inositol phosphate produced provided an index of PLC activity. An EC_{50} for Ca^{+2} and GTPγS of approximately 0.3 μM and 0.2 μM, respectively, was observed. In frontal cortex, the EC_{50} for 5-HT stimulation of PLC was approximately 300 nM. Spiperone (300 nM) antagonized the action of 5-HT. mCPP had no effect on PLC activity in frontal cortex and antagonized the actions of 5-HT. By comparison, mCPP stimulated PLC activity in caudate (EC_{50} of approximately 200 nM). 5-HT also stimulated PLC activity in caudate, but to a greater extent than mCPP. Spiperone (300 nM) antagonized the action of higher concentrations (10 μM) of 5-HT but did not affect the stimulation produced by mCPP or lower concentrations of 5-HT. These data, together with radioligand binding data to be presented, suggest that 5-HT$_{2A}$ and 5-HT$_{2C}$ linked PLC activity can be assayed in various brain regions and that mCPP acts as an agonist at 5-HT$_{2C}$ sites and an antagonist at 5-HT$_{2A}$ sites.

DISTRIBUTION OF 5-HT$_3$ RECEPTOR-IMMUNOREACTIVE NEURONS IN THE BRAIN AND SPINAL CORD.

M. Morales*, E. Battenberg and F. E. Bloom. The Scripps Research Institute, Neuropharmacology. 10666 N. Torrey Pines Rd., La Jolla CA 92037.

The cellular distribution of the type 3 serotonin receptor (5-HT3R) in the rat brain was established immunocytochemically, using a polyclonal antibody raised against a synthetic peptide from the deduced amino-acid sequence of the cloned 5-HT$_3$R. The 5-HT$_3$R immunoreactive neurons were found in the forebrain, brainstem and spinal cord with widely distinct patterns of intensity across the brain. Within the forebrain, intensely immunoreactive cells were found in all layers of the neocortex, anterior olfactory cortex, hippocampal formation and amygdala. Immunopositive cells were observed in the subiculum, all the sub-fields of the hippocampus, stratum oriens, stratum pyramidale, stratum radiatum and stratum lacunosum-moleculare of the CA1 and CA3 subfields. Labeled interneurons were also detected in the dentate gyrus. A few strongly immunoreactive neurons were consistently observed in the caudate putamen, and moderately or weakly labeled neurons were occasionally found in the nucleus accumbens. Intensely labeled neurons were found in the brainstem, including the sensory and motor nuclei and nuclei of the reticular formation. Labeled neurons were observed in the dorsal and ventral horn of the spinal cord, and motoneurons of the ventral horn were among the cells with the strongest label in the central nervous system. These results reveal that 5-HT$_3$R immunoreactive neurons are extensively distributed in the rat brain and spinal cord, and suggest a broad participation of the 5-HT$_3$R in the central nervous system neurotransmission. CELLULAR LOCALISATION OF SEROTONIN$_3$ RECEPTOR EXPRESSION IN NORMAL AND EPILEPTIC HUMAN HIPPOCAMPUS

N.M.Barnes*[1], P.C.Barber[2] and R.M.C.Parker[1]
[1]Pharmacology, [2]Pathology, The Medical School, University of Birmingham, Birmingham B15 2TT UK.

The localisation of serotonin$_3$ receptor (5-HT$_3$R) expression in 'normal' and epileptic human hippocampus was assessed using receptor autoradiography and *in situ* hybridisation histochemistry with antisense [^{35}S]-riboprobes generated from 5-HT$_3$R-As cDNA (Belelli *et al*, Mol. Pharmacol. 486, 1054-62, 1995).

In 'normal' hippocampus, 5-HT$_3$R mRNA expression was detected in a subpopulation of large neurones within the dentate hilus area and a few cells in the dentate gyrus (molecular and granule cell layer). This pattern of expression persisted in the 'epileptic' hippocampus (and was not detectable using the sense probe under identical conditions). 5-HT$_3$R binding was also seen in scattered large hilar neurones and in a band associated with the granular layer. Cell numbers in the epileptic dentate gyrus displayed comparable [^{3}H]-(S)-zacopride binding levels to 'normals', except binding increased in the dentate molecular layer to cover its full width.

This study demonstrates a discrete subpopulation of 5-HT$_3$R-expressing neurones within the human hippocampus which may be important in the neuropathology of hippocampal sclerosis of temporal lobe epilepsy.

We thank Drs A.G. Hope, J.A. Peters and Prof. J.J. Lambert for the gift of human 5-HT$_3$-As cDNA. Supported by the MRC.

IMMUNOLOGICAL CHARACTERIZATION OF 5-HYDROXYTRYPTAMINE$_3$ RECEPTOR TRANSMEMBRANE TOPOLOGY. A. D. Spier, H. T. McMahon* and S. C. R. Lummis. Neurobiology Division, MRC Laboratory of Molecular Biology, Hills Rd, Cambridge, CB2 2QH, UK and Department of Zoology, University of Cambridge, Cambridge, UK.

The 5-HT$_3$ receptor is a member of the ligand-gated ion channel superfamily and has 27% sequence identity to the nicotinic acetylcholine receptor. These receptors are predicted to share a similar structure with N- and C- terminals extracellular and four transmembrane domains (TM1-4). Presented here is the first experimental evidence that the N-terminal of the 5-HT$_3$ receptor is extracellular, thus confirming theoretical models.

Cells were transiently transfected with plasmid encoding 5-HT$_3$ receptor DNA and expressed receptors were visualized by immunofluorescence. An antiserum used to label the N terminal was generated against peptide ^{23}GSRRATQARDTT^{36}Q, and to label the predicted intracellular loop between TM3-4, an antiserum was generated against a fusion protein corresponding to ^{301}T-^{429}V. Cells were permeabilised with Triton X-100 for the labelling of intracellular protein moieties.

A strong immunofluorescence signal in transfected permeabilised cells was found using both anti-N terminal and anti-intracellular loop antisera. This staining was localised mainly in the nuclear and plasma membranes, Golgi, endoplasmic reticulum and intracellular vesicles. In the absence of detergent the intracellular loop antiserum did not label cells, whereas the anti-N terminal antiserum labelled a distinctive ring around transfected cells (n>50 cells observed). Patches of intense fluorescence, due to clustering of receptors, were observed in the plasma membrane.

The localisation of the N-terminal peptide on the outer side of the plasma membrane demonstrates that this region of the receptor is extracellular. This conclusion supports the ligand-binding role of the N-terminal domain of the 5-HT$_3$ receptor.

Supported by the MRC and Royal Society.

ZINC EXERTS DIFFERENTIAL EFFECTS UPON NATIVE AND RECOMBINANT 5-HT$_3$ RECEPTORS. C.H.Gill*, D.Belelli, A.G.Hope, J.A.Peters and J.J.Lambert. Neurosciences Institute, Department of Pharmacology & Clinical Pharmacology, Ninewells Hospital & Medical School, University of Dundee, Dundee, DD1 9SY, Scotland, U.K.

It has previously been demonstrated that Zn^{2+} inhibits the 5-HT-evoked current recorded from the murine clonal cell line NCB 20 in a concentration- and voltage-dependent manner (Lovinger, 1991). In agreement with this report we have observed that the 5-HT-activated whole-cell currents, recorded from rabbit, guinea-pig and mouse nodose ganglion neurones and guinea-pig coeliac ganglion neurones are also inhibited by Zn^{2+} in a concentration-dependent manner (IC_{50} values = 62, 15, 200 and 31 μM, respectively). The differing potencies of Zn^{2+}, inhibiting the function of these receptors, may reflect inter-species variation in the properties of the 5-HT$_3$ receptor.

A subunit encoding the 5-HT$_3$ receptor has recently been cloned (5-HT$_3$R-A). Both the "long" and "short" splice variants of the murine 5-HT$_3$R-A subunit form functional receptors when expressed as homo-oligomers. Contrasting with the action of Zn^{2+} at native 5-HT$_3$ receptors, described above, the 5-HT-evoked current, recorded from either splice variant, expressed in *Xenopus laevis* oocytes, is modulated in a biphasic manner by Zn^{2+}. Low concentrations (1-10 μM) enhance the 5-HT-evoked current and higher concentrations (60-300 μM) inhibit the response. A similar biphasic effect is observed when the long splice variant is expressed in HEK 293 cells. However, Zn^{2+} does not enhance the function of all recombinant 5-HT$_3$ receptors. The 5-HT-activated current recorded from the human homologue of the 5-HT$_3$R-A, expressed in either *Xenopus leavis* oocytes or HEK 293 cells, is inhibited in a concentration-dependent manner by Zn^{2+}.

NICOTINIC RECEPTOR LIGANDS ANTAGONIZE 5-HT$_3$ RECEPTORS EXPRESSED IN *XENOPUS* OOCYTES. T.K. Machu, J. Strahlendorf*, and W. R. Kem. Depts.*of Pharmacology and Physiology, TX Tech Univ. HSC, Lubbock, TX 79430, and Dept. of Pharmacology and Therapeutics, Univ. of FL Coll. Med., Gainesville, FL 32610-0267.

The 5-Hydroxytryptamine$_3$ (5-HT$_3$) receptor, which belongs to the ligand-gated ion channel superfamily , displays considerable homology with nicotinic receptor subunits. Some nicotinic drugs, including d-tubocurarine, inhibit 5-HT$_3$ receptor function. Certain derivatives of the marine toxin, anabaseine, have been recently shown to be partial agonists at α7 homo-oligomeric receptors. When co-applied with acetylcholine (Ach), these anabaseine compounds also inhibited subsequent Ach-mediated currents of both α4β2 and α7 receptors expressed in oocytes, suggesting a non-competitive form of inhibition. One of these derivatives, 3-(2,4-dimethoxybenzylidine)-anabaseine (also called GTS-21), has memory enhancing and neuroprotective effects, and is in clinical trials for Alzheimer's disease. Given the significant homology (40%) between the 5-HT$_3$ and α7 nicotinic receptor subunits and the implication that 5-HT$_3$ receptors are involved in memory formation, we investigated the effects of anabaseine, GTS-21, and mecamylamine on 5-HT$_3$ receptor function. In oocytes expressing 5-HT$_3$ receptors cloned from the NCB-20 cell line, GTS-21 inhibited 0.5 μM 5-HT mediated currents with an IC_{50} of 25 μM and a Hill coefficient of 1.5. The inhibition was apparently competitive, since the inhibition produced by 25 μM GTS-21 was reduced to only 9% in the presence of 10 μM 5-HT. Anabaseine, at 50 and 100 μM, decreased 0.5 μM 5-HT induced currents by ~18 and 24%, respectively. Neither GTS-21 nor anabaseine displayed any agonist activity at the 5-HT$_3$ receptor. The ganglionic blocker, mecamylamine, partially inhibited the 5-HT current. Finally, none of the three compounds, when coapplied with 5-HT, exhibited any inhibition of subsequent applications of 5-HT. Thus, anabaseine compounds have markedly different actions on α7 and 5-HT$_3$ receptors, and the role, if any, of 5-HT$_3$ receptors in mediating memory enhancing or neuroprotective actions of GTS-21 remains to be determined. (Partially supported by Taiho Pharmaceutical, Co., Ltd.)

PHORBOL ESTER MODULATION OF SEROTONIN 5-HT$_3$ RECEPTOR FUNCTION. S. J. Coultrap and T. K. Machu*. Department of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

Phorbol 12-myristate 13-acetate (PMA), a compound known to stimulate protein kinase C (PKC) activity, has been shown to modify the activity of many ligand-gated ion channels (LGIC). Specific serine/threonine residues have been identified as PKC dependent phosphorylation sites for several LGIC subunits. Mutation of these residues to alanine reduces or eliminates the phorbol ester effect. We aim to show that 5-HT$_3$ receptor function is modified by application of PMA and to determine if this effect is mediated by PKC.

Complementary RNA transcribed from NCB-20 cell-line cDNA was injected into *Xenopus* oocytes. The two-electrode voltage clamp technique was used to record serotonin (0.25-10μM) induced currents with or without PMA (10-25 nM) pre-incubation. The presence of PMA caused an increase in efficacy and potency of serotonin at the 5-HT$_3$ receptor. PMA (10 nM) potentiated serotonin (0.5μM) induced currents by 93 ± 11 %. This potentiation was partially (44 ± 18%) reversed by injection of PKCI, a PKC pseudosubstrate peptide. The inactive phorbol ester phorbol, 12-mono-myristate (PMM), had no effect. Mutation of four serine residues in putative PKC consensus sequences to non-phosphorylatable alanine residues was without effect on PMA potentiation of 5-HT$_3$ receptor mediated currents. Three remaining serine/threonine residues in putative PKC consensus sequences are being mutated to alanine in order to determine if they are phosphorylation sites.

PMA enhancement of serotonin induced currents in oocytes expressing the 5-HT$_3$ receptor may be all or in part mediated by PKC dependent phosphorylation. Supported by NIH grant AA10561 (TKM).

RECOMBINANT 5-HT3 RECEPTOR ACTIVATION AND DESENSITIZATION.
Stephen F. Traynelis* and David D. Mott. Department of Pharmacology, Emory University, Atlanta GA 30322.

Desensitization is an important but poorly understood property of all ligand-gated ion channels. The desensitization of native 5-HT3-type serotonin receptors is complex, being dependent on the concentration of extracellular Ca^{2+}/Mg^{2+}, the transmembrane voltage, and the activating agonist. We have studied both the activation and desensitization of recombinant rat and mouse 5-HT3A receptors by different agonists. 5-HT3 receptor-mediated current responses recorded from transfected HEK293 cells under voltage clamp activate slowly in comparison to other ligand-gated cation-selective channels. The 10-90% risetime in response to rapid application (exchange time <0.5 ms, measured using kainate receptors) of supra- maximal (100μM) serotonin (5-HT) was 13.7 ms (n=8 cells); dopamine activation appeared much slower (>50ms; n=6). Like activation, desensitization also was agonist-dependent. 5-HT and *m*-chlorophenylbiguanide (mCPBG) responses desensitized by more than 89-96% with a dual exponential time course, in contrast to dopamine (300 μM), which produced only modest and slow desensitization. The fast component of 5-HT-induced desensitization (τ=0.2 ms; n=8) was voltage- and Ca^{2+}/Mg^{2+}-dependent (n=12), consistent with the idea that Ca^{2+} may act in the permeation pathway or at a site that senses the transmembrane electric field. Recovery from desensitization was voltage-independent for 5-HT, occurring with a time constant of 12 s (n=8). Recovery from desensitization in response to mCPBG was 10-fold slower (120 s; n=6).

These data suggest that the desensitization properties of native receptors are reproduced by homomeric 5-HT3A receptors, and that the 5-HT3 receptor activation profile in vivo will be highly dependent on the activating agonist (5-HT or dopamine). *Supported by the Markey Center for Neurological Studies.*

700.8

CONVERSION OF THE ION SELECTIVITY OF THE 5-HT_3 RECEPTOR FROM CATIONIC TO ANIONIC: A CONSERVED FEATURE OF THE LIGAND GATED ION CHANNEL SUPERFAMILY?
M. J. Gunthorpe, E. J. Fletcher* & S. C. R. Lummis. Neurobiology Division, MRC Laboratory of Molecular Biology, Cambridge, CB2 2QH and Dept. Zoology, Cambridge University, UK.

The 5-HT_3 receptor is a ligand-gated ion channel. Each of the subunits which constitute the receptor possesses four transmembrane domains (M1 - M4) with M2 lining the wall of the channel. Galzi *et al.* (1992) identified channel regions that on mutation converted the ion selectivity of the α7nACh receptor from cationic to anionic. We have generated equivalent mutations in the 5-HT_3 receptor and assessed changes in ion selectivity using electrophysiological techniques.

                ____________
WT      DSG ERVSFKITLLLGYSVFLIIVSDTLP
Mutant  ---PA----------T----------
```

Receptor proteins were stably expressed in HEK293 cells. Reversal potentials (E_{rev}) for the WT and mutant receptors were determined in normal extracellular (EC), 50%NaCl-Mannitol (0.5NaCl) and 15%NaCl-85%Isethionate (Na-Ise) solutions.

The reversal potential for WT was similar in both EC and Na-Ise solutions (E_{rev} was -4.75 ± 1.61 mV and -5.98 ± 1.33 mV, repectively, n=5) but shifted to a more negative potential in 0.5NaCl (E_{rev} = -22.40 ± 2.03 mV, n=5) indicating a cation-selective receptor. For the mutant receptor the reversal potential in EC solution (4.09 ± 1.81 mV) shifted to more positive values in both 0.5NaCl and Na-Ise solutions (E_{rev} 18.49 ± 0.94 mV and 28.01 ± 2.88 mV, respectively, n=5) indicating a predominantly chloride-permeable receptor.

The results indicate the changes in amino acids are sufficient to switch the ion selectivity of the 5-HT_3 receptor. Thus the α7nACh and 5-HT_3 receptors appear to share common determinants of ion selectivity, and this may be a conserved feature of the ligand-gated ion channel superfamily.

INHIBITION BY PENTOBARBITAL OF 5-HT_3 RECEPTOR-MEDIATED CURRENTS USING A RAPID SOLUTION EXCHANGE SYSTEM ON EXCISED PATCHES OF N1E-115 CELLS.
M.Barann, H.Bönisch, M.Göthert, B.W.Urban*. Departments of Anesthesiology and Pharmacology, University of Bonn, D-53105 Bonn, Germany.

A fast perfusion system (J.P.Dilger and R.S.Brett, Biophys. J. 57: 723-731, 1990) with an exchange rate <1 ms was used to study 5-HT_3 receptor-mediated currents in outside-out patches of cultured mouse neuroblastoma cells of the clone N1E-115. 5-HT induced fast inward currents in a concentration-dependent manner (ED_{50}= 3.7 μM; applied potential= -100 mV). The 5-HT_3 receptor antagonist ondansetron (0.3 nM) reversibly inhibited the 5-HT (30 μM) signal by 50%. The 5-HT-induced (30 μM) current was characterized by inward rectification, an onset of $\tau \leq$ 50 ms and desensitization ($\tau \leq$ 200 ms). Onset and desensitization were slower at lower 5-HT concentrations. Fully desensitized patches recovered after a washout period of 45 s. Pentobarbital inhibited 5-HT-induced (30 μM) peak currents in a concentration-dependent manner (IC_{50}= 0.4 mM). The full inhibitory effect was reached within 200 ms when 5-HT and pentobarbital were applied simultaneously. The additional application of pentobarbital during preincubation for up to 5 min did not enhance the inhibitory effect. In contrast, pentobarbital applied during the preincubation period only did not affect the 5-HT response. These results suggest a fast, open-channel related mechanism of the inhibitory action of pentobarbital at the 5-HT_3 receptor. Supported by the Department of Anesthesiology, University of Bonn, 53105 Bonn, Germany and a grant of the DFG.

NOVEL 5HT RECEPTORS: $5HT_6$, $5HT_7$, AND OTHERS

DEVELOPMENT OF REPORTER CELL LINES FOR G PROTEIN-COUPLED RECEPTORS THAT MODULATE ADENYLATE CYCLASE.
N. J. Stam*, C. Van de Hurk, J. van Heijst, W. Olijve and H. Theunissen. N.V. Organon, Dept. Biotechnology & Biochemistry. Scientific Development Group, P.O. Box 20, 5340 BH Oss, The Netherlands.

A large number of G protein-coupled receptors (GPCRs) modulate adenylate cyclase activity upon receptor activation. To identify compounds that bind to receptors which are linked to the cAMP signal transduction pathway, we have developed a transcription-based screening assay. We have generated a series of cAMP-inducible reporter gene (firefly luciferase) constructs. These constructs vary with respect to the promoter (VIP, TK, and oxytocin), and origin and number of cAMP-responsive elements (CREs).
When expressed in CHO and L^{tk-} cells, the different reporter constructs varied considerably with respect to both basal and forskolin-induced cAMP levels. Furthermore, addition of the phosphodiesterase inhibitor IBMX to the reporter cell lines strongly increased basal promoter activity whereas no effect was found on forskolin- and ligand-induced cAMP levels. Addition of agonist and antagonists to reporter cell lines that were cotransfected with Gs-coupled 5-HT receptors modulated luciferase expression in a dose-dependent manner. The currently described reporter assay is well suited for high-throughput screening of large numbers of ligands acting on Gs and Gi coupled receptors.

IDENTIFICATION OF AMINO ACID RESIDUES CONTRIBUTING TO THE LIGAND BINDING SITE OF THE 5-HT_6 RECEPTOR.
F. G. Boess, A. J. Sleight and F. J. Monsma Jr.*. Pharma Division, Preclinical Research, F. Hoffmann-La Roche Ltd., 4002-Basel, Switzerland.

We have examined the ligand-binding site of the 5-HT_6 receptor using site-directed mutagenesis. Interactions with residues in two characteristic positions of transmembrane region V are important for ligand binding in several adrenergic, dopamine, histamine and 5-HT receptors. In the 5-HT_6 receptor, one of these residues is a Thr (T196), while in most other mammalian 5-HT receptors (except human 5-HT_{2A}), the corresponding residue is Ala. After transient expression in HEK293 cells, we determined the effects of the mutation Thr196->Ala (T196A) on [^{3}H]-LSD binding and adenylyl cyclase stimulation. This mutation produced a receptor with a tenfold reduced affinity for [^{3}H]-LSD (T196A: 32nM; wildtype: 3nM) and a sixfold reduction for 5-HT (T196A: 990nM; wildtype: 170nM). The potency of both LSD and 5-HT for stimulation of adenylyl cyclase was also reduced by 18 and 7fold, respectively. The affinity of other N1-unsubstituted ergolines (ergotamine, lisuride) was reduced 10-30 fold, while the affinity of N1-methylated ergolines (metergoline, methysergide, mesulergine) and other ligands such as methiothepine, clozapine, ritanserin, amitriptyline and mianserin changed very little. This indicates that in wildtype 5-HT_6 receptor, Thr196 interacts with the N1 of N1-unsubstituted ergolines and tryptamines, probably forming a hydrogen bond. This hypothesis is consistent with observations made for species variants of the 5-HT_{2A} receptor, that possess an Ala (rat) or a Ser (human) residue in the corresponding position (1). Identification of this specific interaction will help to create a model of the 5-HT_6 receptor ligand binding site.

GLUCOCORTICOIDS REGULATE $5HT_6$ AND $5HT_7$ RECEPTOR GENE EXPRESSION IN THE RAT HIPPOCAMPUS. J.L.W.Yau*, J.Noble, J. Widdowson and J.R.Seckl, Dept. Medicine, Western General Hospital, Edinburgh EH4 2XU.

Both abnormal serotonin (5HT) neurotransmission and excess glucocorticoids have been implicated in affective disorders. $5HT_6$ and $5HT_7$ receptors may be key because of their high affinity for psychotropic agents/ antidepressants and distribution in limbic regions of the brain. Previous studies have shown the selective regulation of $5HT_{1A}$ and $5HT_{2C}$ receptor gene expression in the hippocampus by adrenal steroids. In the present study, we examined the effects of pharmacological adrenalectomy on hippocampal $5HT_6$ and $5HT_7$ receptor mRNA expression. Endogenous glucocorticoid synthesis was blocked by injection of metyrapone and aminoglutethimide (M + A; both 200mg/kg, sc) to rats over 2 days. Another group received corticosterone (2.5mg/kg,sc) in addition to M + A. Control animals received vehicle injections. M + A reduced plasma corticosterone levels from 9.6 ± 1.8 μg/dL (vehicle group) to 0.2 ± 0.1 μg/dL while corticosterone replacement maintained levels to 8.0 ± 2.6 μg/dL. $5HT_6$ receptor mRNA was evenly expressed in all hippocampal subregions while $5HT_7$ receptor mRNA showed the highest expression in CA2 and CA3. Chemical adrenalectomy significantly increased $5HT_6$ receptor mRNA expression in CA1 (31% rise, $p<0.05$) and $5HT_7$ receptor mRNA expression in CA3 (39% rise, $p<0.01$) but expression in other subregions was unaltered. Exogenous corticosterone reversed these changes in $5HT_6$ and $5HT_7$ receptor mRNA expression. These data indicate that adrenal steroids regulate both $5HT_6$ and $5HT_7$ receptor mRNA expression in selective hippocampal subregions. This may provide a basis for the therapeutic actions of adrenal steroid synthesis inhibitors in resistant depression. (Supported by the Wellcome Trust)

701.4

IMMUNOCYTOCHEMICAL VISUALIZATION OF 5-HT_6 RECEPTORS IN THE RAT BRAIN. M.C. Miquel[1], K. Lefèvre[1], Y. Sari[1], M.J. Brisorgueil[1], A. Calas*[1], C. Gérard[2], M. Hamon[2] and D. Vergé[1]. [1]CNRS URA 1488, Univ. Paris VI, Paris. [2] INSERM U288, CHU Pitié-Salpêtrière, Paris, France.

5-HT_6 receptors (5-HT_6-R) have been visualized in the rat brain with specific antibodies directed against a synthetic octadecapeptide corresponding to a selective portion (L^{398}-V^{415}) of the C-terminal domain of the rat receptor.

Rats were perfused intracardially with 4% paraformaldehyde. Brains were cryoprotected with 30% sucrose for 48h, and frozen. Cryostat sections were incubated with rabbit anti-peptide polyclonal antibodies against 5-HT_6-R and processed for the ABC staining method, using DAB to reveal peroxidase activity. Sections were then processed for light or electron microscopy.

5-HT_6-R immunoreactivity (5-HT_6-R-ir) appeared diffuse within the neuropile, with no clearcut labeling of cell bodies. The highest densities of immunolabeling were found in the striatum and the hippocampus. In the latter area, the pyramidal and the granular cell layers were devoid of immunolabeling, whereas the layers corresponding to dendritic fields were stained. A dense immunolabeling was also found in the islands of Calleja and the olfactory tubercle. In both areas as well as in the striatum, numerous short fiber-like immunoreactive processes were found. Lower levels of immunostaining were found in the cerebral cortex and the substantia nigra. In the cerebellum, 5-HT_6-R-ir was concentrated in the molecular layer.

At the electron microscope level, immunoreactivity in the hippocampus and the striatum was confined to dendritic processes. These results suggest that 5-HT_6-R are located on distal dendrites of pyramidal and granular cells in the hippocampus, and of medium spiny neurons in the striatum. Further studies are under way to explore whether 5-HT_6-R are also addressed exclusively to dendritic fields in other brain regions. (Work supported by CNRS and INSERM).

PHARMACOLOGICAL CHARACTERIZATION OF THE RAT 5-HT_7 RECEPTOR EXPRESSED IN CHO-CELLS. L. Unelius, S. Rosqvist and Å. Malmberg*. Department of Molecular Pharmacology, Preclinical R&D, Astra Arcus AB, S-151 85 Södertälje, Sweden.

The 5-HT_7 receptor is a member of the large family of serotonin receptors. It couples positively to adenylyl cyclase and is distributed mainly in limbic areas of the brain. The 5-HT_7 receptor has been suggested to participate in the control of mammalian circadian rhythm, as well as in several neuropsychiatric disorders. In the present study the *in vitro* receptor binding characteristics of [^{3}H]5-HT to cloned rat 5-HT_7 receptors expressed in CHO-cells were investigated. The effect of various ions, guanine nucleotides and incubation conditions were studied. We found that Tris/HCl buffer (50mM) with addition of $MgCl_2$ (4mM) and EDTA were the most favourable incubation conditions. In these high affinity conditions [^{3}H]5-HT labeled a single class of binding sites (B_{max} = 700 fmol/mg protein and K_d = 0.4 nM). Neither the GTP analogue Gpp(NH)p nor Na^+ ions had any significant effect on the [^{3}H]5-HT binding. This finding was in contrast to the effect of GTP on 5-HT competition of [^{3}H]spiperone binding observed in these cells by Ruat *et al.*, 1993. In addition, an increase in cAMP levels has been shown after agonist stimulation in these cells. Different incubation conditions were tested, in order to elucidate the mechanism behind this lack of GTP effect. The effect of treatment of cells with bacterial toxins will also be studied. In competition studies using [^{3}H]5-HT as a radioligand the following rank order of potency was obtained: 5-carboxamidotryptamine > methiothepin > pimozide = risperidone = tiospirone > 5-HT > lisuride > mesulergine > clozapine > 8-OH-DPAT > ritanserin > thioridazine > buspirone. Several atypical and typical antipsychotic agents, as well as 5-HT_{1A} and 5-HT_{2C} ligands had high affinities for the 5-HT_7 receptor. Thus, the 5-HT_7 receptor seems to be a target for many drugs used in treatment of various neuropsychiatric disorders.

AN EVALUATION OF THE 5-HT_7 RECEPTOR MEDIATED SIGNAL TRANSDUCTION PATHWAY IN A TRANSFECTED CELL LINE BY USING THE CYTOSENSOR MICROPHYSIOMETER. H. Eriksson* and K. Evrin. Dept. of Mol. Pharmacol., Preclinical R&D, Astra Arcus, S-151 85 Södertälje, Sweden.

Microphysiometry has been proposed to be a general alternative to other conventional assays of receptor activation in vitro. The method monitors the rate of extracellular acidification. There are several reported examples from all categories of receptors, i. e. G-protein coupled, tyrosine kinase activating and ion-channel containing receptors. We evaluated the microphysiometer assay for a known Gs-coupled receptor in a cultured CHO cell line heterologously expressing rat 5-HT_7 receptors. The effects of several putative 5-HT_7 agonists and antagonists were compared in a cAMP assay and a microphysiometer assay. The EC_{50}/K_B values as well as the efficacy were estimated and found to correlate well between the two methods. The potencies estimated with the microphysiometer were, however, better than with the cAMP assay. The mechanistic background for the signal in the microphysiometer was then further analysed. The response to an agonist (5-CT) was almost completely abolished (>85%) by pretreating the cells with cholera toxin. Pertussis toxin treatment, in contrast, did not have any influence on the agonist efficacy or potency. Thus, the effect seems to be mediated by a Gs protein. The response was mimicked by 8-Br-cAMP and abolished by a protein kinase A inhibitor (H-89). In addition, the agonist effect in the microphysiometer assay was reduced dose dependently with an inhibitor (5-(N-methyl-N-isobutyl)-amiloride; MIA) to the Na^+/H^+ antiporter, without influencing the EC_{50} of 5-CT. The inhibition was almost complete at 30 μM MIA. It has previously been reported that a phosphorylation by protein kinase A of Na^+/H^+ antiporters is activating. Thus, the rate of extracellular acidification as measured during 5-HT_7 receptor activation in the microphysiometer seems to be through a Na^+/H^+ antiporter as a downstream event of Gs coupled activation of adenylyl cyclase in CHO cells.

701.7

EXPRESSION OF 5-HT1Dβ, 5-HT1F, 5-HT2B, 5-HT2C and 5-HT7 RECEPTOR mRNAS IN HUMAN INTRAPARENCHYMAL MICROVESSELS AND RELATED CELLS IN CULTURES. **Z. Cohen* and E. Hamel, Montreal Neurological Institute, McGill University, Montréal, QC, Canada.**

Serotonin (5-HT) nerve terminals are closely associated with intraparenchymal blood vessels in the cerebral cortex. In addition, endogenously released 5-HT can modulate a variety of vascular functions such as local cerebral blood flow and blood brain barrier (BBB) permeability. Previously, we reported the expression of mRNAs for 5-HT1Dα but not 5-HT2A receptors in human cerebral microvascular tissues (*Soc Neurosci Abst* 21:#727.10). In the present study, we investigated the expression of additional 5-HT receptor subtypes, namely 5-HT1Dβ, 5-HT1F, 5-HT2B, 5-HT2C and 5-HT7 receptors, in microvessels and capillaries isolated from human cerebral cortex obtained post-mortem and, more specifically, cell cultures of human brain endothelial (HBEC) and smooth muscle (HBSM) cells harvested from temporal lobe biopsies and fetal brain astrocytes (HFBA). Total RNA was isolated from the tissues, reverse transcribed, submitted to polymerase chain reaction (PCR) using receptor specific oligonucleotide primers. The PCR products were size fractionated on an agarose gel and digested for restriction mapping analysis. Expression of mRNAs for the 5-HT1Dβ receptor was predominantly found in HBSM but also in HFBA. In contrast, 5-HT1F receptor message was exclusively detected in HFBA although at very low intensities. Messages for the 5-HT2B and 5-HT7 receptors was distributed ubiquitously whereas 5-HT2C receptor mRNA was not detected in any of the tissues, despite positive 5-HT2C PCR products in human choroid plexus and cerebral cortex. The present data suggest that the 5-HT1Dβ receptor may be the mediator of the intracerebral vasoconstriction, as is the case in human pial vessels (*Mol Pharmacol* 44:242; 1993). However, activation of 5-HT2B and 5-HT7 receptors might possibly be involved in vasodilatation and/or changes in BBB permeability. The exact physiological roles of these receptors still awaits further investigation. Cell cultures were generously provided by Drs D. Stanimirović and W.V. Yong. This study was supported by MRC of Canada (E.H.) and an FCAR studentship (Z.C.).

701.8

FOUR SPLICE VARIANTS OF THE 5-HT_7 RECEPTOR IN HUMAN AND RAT Doris Heidmann , Mark Metcalf, Ruth Kohen, Mark Hamblin* Depts. Psychiatry and Behavorial Science, Univeristy of Washington and VA Puget Sound Health Care System, GRECC, Seattle, WA 98108.

The 5-HT_7 receptor is widely distributed throughout the CNS as well as some peripheral tissues and is thought to be involved in a variety of behavorial and physiological functions. The 5-HT_7 receptor was cloned by several groups, but Lovenberg et al. found a deduced amino acid sequence 13 AA shorter at the C-terminus than that reported by others. This divergence starts at a site corresponding to an intron suggesting the occurence of alternative splicing. Using RT-PCR we have now confirmed the presence of two splice variants and have found two additional forms. In keeping with IUPHAR recommendations we propose naming these 5-$HT_{7(a)}$, $_{(b)}$, $_{(c)}$, and $_{(d)}$, respectively. Using quantitative RT-PCR we found the ratio of the mRNA levels for the splice variants 5-$HT_{7(a)}$ and 5-$HT_{7(b)}$ to vary in different rat brain areas between 9:1 (cortex) and 4:1 (cerebellum). The mRNA of the 5-$HT_{7(c)}$ receptor includes an additional exon cassette of 98 bp inserted at the same splice site and was expressed throughout the rat brain but at a lower level than 5-$HT_{7(a)}$ or 5-$HT_{7(b)}$. Binding studies in transiently transfected Cos-7 cells as well as comparison of the cAMP stimulation using a CRE-coupled luciferase luminescensce system revealed only minor differences in EC50 values for 5-HT. Similiar to 5-$HT_{7(c)}$ the mRNA of the 5-$HT_{7(d)}$ variant is created by insertion of an extra exon. There is no sequence homology between the 5-$HT_{7(c)}$ and 5-$HT_{7(d)}$ retained exons. Formation of 5-$HT_{7(d)}$ is not detectable by the used RT-PCR in rat brain. The different C-terminal ends of the 5-HT_7 receptor in human and rat created by the use of alternative splice donor sites (5-$HT_{7(a)}$ or $_{(b)}$) or use of different exons (5-$HT_{7(c)}$ and $_{(d)}$) suggest further functional diversity within the Gs-coupled serotonin receptors.

CHARACTERISATION OF STRUCTURE-FUNCTION RELATIONSHIPS OF DROSOPHILA 5-HT RECEPTORS AND THE MOUSE 5-HT7 RECEPTOR. K. TH. Nip, L.A. Obosi, L.A.King, I. Bermudez, J.A Benson*[1], School of Biological and Molecular Sciences, Oxford Brookes University, Oxford, OX3 OBP, UK. [1]Institute of Pharmacology, University of Zurich, Switzerland.

Studies on the vertebrate β—adrenergic receptor have shown that the third intracellular loop of these receptors may be essential for their interaction with the stimulatory G-proteins ($G_{\alpha s}$). The *Drosophila* 5-HT_{Dro1} and the 5-HT_7 mouse receptors have been shown to interact with ($G_{\alpha s}$). A number of amino acid substitutions were made in the C-terminus of the third intracellular loop of the 5-HT_{Dro1} *Drosophila* and 5-HT_7 mouse receptors, using site directed mutagenesis. These were expressed in Sf900 II insect cells. Saturation and competition binding analysis has revealed little difference between the wild type (WT) and mutant receptors ability to bind either agonists or antagonists. The ability of the mutant and WT receptors to maximally stimulate cAMP was analysed and it was found that the mutants do not significantly affect maximal stimulation of cAMP in the presence of 5-HT. Additional point and deletion mutations are being carried out on the third intracellular loop of the 5-HT_{Dro1} of the 5-HT_7 mouse receptors to define the regions of the receptor that interact with ($G_{\alpha s}$). This work is supported by the U.K Biotechnology and Biological Sciences Research Council.

5-HT_7 RECEPTORS EXPRESSED BY ASTROCYTES *IN VITRO* INCREASE cAMP LEVELS AND STIMULATE S-100β SYNTHESIS AND RELEASE. W.D. Hirst, G.W. Price[1], M. Rattray and G.P. Wilkin. SPON: Brain Research Association. Biochemistry Department, Imperial College, London SW7 2AZ, [1]SmithKline Beecham, Harlow, Essex CM19 5AW.

In the present study we have investigated whether astrocytes *in vitro* express 5-HT receptors positively coupled to adenylyl cyclase. Stimulatory cAMP responses have been reported for 5-HT_4, 5-HT_6 and 5-HT_7 receptors. Intracellular cAMP accumulation was measured in primary astrocyte cultures derived from neonatal rat thalamic/hypothalamic area in response to a variety of serotonergic agonists and antagonists. 5-HT and 5-CT stimulated cAMP levels to 572% ± 63 and 588% ± 75 of basal levels respectively (n=8). The rank order of agonist EC_{50} values was 5-CT > 5-HT = 5-MT > 8-OH-DPAT. Methiothepin, clozapine, mesulergine and ritanserin were antagonists. The pharmacological profile observed most closely resembles that of the 5-HT_7 receptor. RT-PCR demonstrated that the cultured astrocytes expressed 5-HT_7 receptor mRNA. However, 5-HT_6 receptor primers also amplified cDNA. The identity of the amplified products was confirmed by cloning and sequencing. S-100β is a neurotrophic factor which is synthesised and released by astrocytes, the S-100 gene is subject to cAMP dependent transcriptional control. Intracellular and extracellular levels of S-100β protein were measured by ELISA in astrocytes cultures which were exposed to 5-HT, 5-CT and 8-OH-DPAT, these agonists increased extracellular S-100β levels to 1242% ± 82, 946% ± 37 and 1114% ± 218 of basal levels respectively (n=3). However, intracellular levels of the protein were not significantly affected. These data show that astrocytes *in vitro* express a functional 5-HT receptor positively coupled to adenylyl cyclase, and a functional consequence of its activation is the production of a neurotrophic factor.

A NEW 5-HT RECEPTOR SUBTYPE WITH HIGH AFFINITY FOR 5-CARBOXAMIDOTRYPTAMINE ?

C. del Arco*, M.E.Castro, T. Romón, M.J. Castillo and A. Pazos. Dpto. Physiol. & Pharmacol., Univ. Cantabria, 39011 Santander, Spain

5-HT exerts its actions by stimulating a wide family of receptor subtypes. We here report that high-affinity ^{3}H-5HT binding to homogenates of cortical guinea-pig tissues could include an additional 5-HT receptor subtype. The maximal density of remaining binding sites of ^{3}H-5HT in guinea-pig cortex in the presence of 100 nM mesulergine (M), and 100 nM 5-carboxamidotryptamine (5-CT), to inhibit binding to 5-HT_{1A}, 5-HT_{2C}, 5-HT_{1D} and 5-HT_7 sites, resulted significantly lower (33%) than that of remaining binding sites of ^{3}H-5HT in the presence of 100 nM 8-hydroxy-dipropylaminotetralin (P), M and ergotamine (E) (wich should occupy, in principle, the same 5-HT subtypes). Furthemore, competition studies with 5-CT, performed in the presence of P+M+E to facilitate the examination of this new site, revealed a biphasic pattern, with a high affinity site (pK=9,9) accounting for about 50% of the amount of binding sites and a low affinity site (pK=5,6) corresponding to the population of 5-HT_{1E} and 5-HT_{1F} receptors. Saturation studies with ^{3}H-5CT in presence of P+M+E still revealed the existence of a high affinity site. Competition binding studies with different pharmacological substances revealed that this receptor subtype presents high affinity for 5-HT, intermediate for 5-Me-OT, and low for all other 5-HT drugs tested, including sumatriptan, WAY-100635, methiotepin and ketanserin, among others. Similar results have been obtained in membranes from human cortical tissue when using both radioligands. In conclusion, our data suggest the existence of a new subtype of 5-HT receptor that should display high affinity for 5-CT, and 5-HT, intermediate for 5-Me-OT and low affinity for several selective 5-HT_{1A}, 5-HT_{1D}, 5-HT_2 and 5-HT_7 receptor compounds (supported by DGICYT SAF95-0362)

701.12

MOLECULAR CLONING OF A PUTATIVE SEROTONERGIC RECEPTOR FROM THE KIDNEY AND BRAIN OF *APLYSIA*. L. DesGroseillers*, A. Angers and C. Bouchard. Département de Biochimie, Université de Montréal, Montréal, Québec, Canada, H3T 3J7.

Serotonin is a neurotransmitter that modulates numerous behavioral functions (e.g. feeding, locomotion, circadian rhythm) and plays an important role in memory, learning and synaptic plasticity by interacting with different 5-HT receptor subtypes coupled to various second-messenger systems. In mammals, cloning has revealed the existence of no less than 14 different 5-HT receptors, some of which present different isoforms. Using degenerated oligonucleotide primers corresponding to the highly conserved sequences of transmembrane domains six and seven, we amplified a 150 bp fragment in *Aplysia* CNS and kidney cDNA libraries. Sequence analysis of this PCR product reveals strong homology to the mammalian 5-HT-1D subtype serotonin receptor. We were also able to detect a 2.6 kb transcript using this PCR product as a probe in northern blot experiments. We then screened a kidney cDNA library as well as a genomic library in order to isolate the full-length serotonin receptor gene. Our gene represents the third isolated subtype of serotonin receptors in *Aplysia* and may be valuable to pursue the study of the molecular components of behavior in this animal. (Suported by the Medical Research Council of Canada).

THE PHARMACOLOGICAL CHARACTERIZATION OF THE MOLECULARLY CLONED HUMAN DOPAMINE TRANSPORTER EXPRESSED BY HEK CELLS.

M. Yamada*, M. Tatsumi, K. Groshan, Mi. Yamada and E. Richelson, Mayo Foundation and Mayo Clinic Jacksonville, Jacksonville, FL 32224

Some psychotropic drugs, including antidepressants and neuroleptics, may exert some of their therapeutic effects and side effects by blocking the dopamine transporter in brain. Especially, so-called dopamine reuptake inhibitors enhance dopaminergic transmission in the central nervous system through an increase in dopamine concentration in the synaptic cleft as the result of reuptake inhibition. The affinities of these drugs for the dopamine transporter are predictive of the likelihood of their causing these clinical effects. Recently, a cDNA encoding the human dopamine transporter was isolated and sequenced by the other group. This protein showed characteristic features of the dopamine transporter. In this study, we directionally ligated the receptor cDNA into the expression vector and transfected it into HEK cells by the calcium phosphate method. The receptor protein expressed on HEK cell membranes specifically bound [^{3}H]GBR12935. The expression of the dopamine transporter in stably transfected HEK cells allowed the pharmacological characterization of several different classes of drugs. With the information obtained in these experiments, we can investigate further the structure-activity relationships among psychotropic drugs at the human dopamine transporter. (This work is supported by Mayo Foundation for Medical Education and Research and USPHS grant MH27692 from NIMH.)

KINETIC CHARACTERIZATION OF DOPAMINE EFFLUX VIA THE DOPAMINE TRANSPORTER. Sue L. Povlock*, Mark S. Sonders and Susan G. Amara. Howard Hughes Medical Institute & Vollum Institute, Oregon Health Sciences University, Portland, Oregon 97201.

The dopamine transporter (DAT), like other plasma membrane transporters, has been shown to mediate bidirectional flux of substrates. Amphetamines, tyramine and other agents which promote Ca^{2+}-independent DA efflux (i.e. "releasers") have been shown by electrophysiological criteria to be substrates of human DAT expressed in *Xenopus* oocytes. These data suggest two potential mechanisms for DA efflux via DAT. There may be a stoichiometric exchange of releaser for DA, or alternatively, DA efflux may take place in the context of net cellular accumulation of DAT substrates. The precise relationship between DA efflux and releaser influx has yet to be elucidated.

To investigate this issue, we have undertaken a study of the kinetics of simultaneous influx and efflux with hDAT-expressing oocytes. Preliminary studies of pre-loaded oocytes have shown that both the velocity and extent of [^{3}H]DA efflux are increased when they are incubated in 20 μM DA or 2 μM S(+)amphetamine. In contrast, the velocity of efflux is diminished by 20 μM cocaine. Voltage clamp and double-labeling studies will be used to measure the kinetics of flux through DAT and should provide insight into the mechanism underlying DA efflux.

702.3

DOPAMINE OR NOREPINEPHRINE PRETREATMENTS CAN PRIME DOPAMINE TRANSPORT IN EXPRESSING CELLS. Ning-Sheng Cai#, Qing-Rong Liu*#, Jun-Min Wu#, Randal Revay#, & George Uhl#+. #Mol. Neurobiol. Br., NIDA, IRP, NIH; +Depts. Neurol. & Neurosci., JHUSM, Balto., MD 21224

If the dopamine transporter (DAT) adapted to the presence of dopamine, temporal and spatial distributions of this important transmitter could be significantly altered. DAT-expressing cells lines lacking dopamine receptors were preincubated with dopamine and other substances, washed, and the effects of the preincubation on subsequent dopamine uptake examined. Short pretreatments with dopamine or norepinephrine yielded up to 4-fold enhancement of the uptake of 10 nM [^{3}H]-dopamine tested after washing. Pretreatment effects were temperature, time, and concentration-dependent. They were saturable, not dependent on either sodium or chloride, displayed structure-activity relationships different from those for dopamine transport, were robust when the human transporter was expressed in several cell lines and present at lower levels in cell lines expressing the rat transporter. Pretreatment effects persisted during washes as long as 30 min at 37°C, and longer at 4°C. Uptake of dopamine was enhanced, but accumulation of several other substrates was unaffected. Pretreatment effects were noted following pretreatment with dopamine or norepinephrine, but not with other substrates or metabolites tested. Preincubation could interact with currently uncharacterized sequestering and/or degrading mechanisms in the expressing cell test systems. Alternatively, pretreatment could alter transporters, perhaps by placing them into states more readily able to translocate dopamine.

702.4

CHARACTERIZATION OF RECOMBINANT CATECHOLAMINE TRANSPORTER FUNCTION USING ROTATING DISK VOLTAMMETRY. AJ Eshleman*, CE Earles, KA Neve, A Janowsky and JO Schenk. Dept. Physiology & Pharmacology and Psychiatry, OHSU & VAMC, Portland, OR and Dept. Chemistry, WSU, Pullman, WA.

The ability of HEK 293 cells stably expressing the human dopamine transporter (HEK-hDAT) to transport dopamine (DA) and to be blocked by transport inhibitors was characterized using rotating disk voltammetry, which measures transporter function on a millisecond time scale. The density of transporters in these cells is 11 pmol/mg protein or ~600,000 transporters/cell. The K_m and V_{max} of transport were calculated to be 1.6 μM and 4.0 pmol/sec/million cells or approximately 4 molecules of DA/transporter/sec. No transport was measured in untransfected HEK cells. HEK-hDAT cells ($2x10^7$) cleared 1μM DA in 60 seconds to background levels and uptake was completely inhibited by 100 μM cocaine. Drugs which are substrates for the transporter released preloaded DA from the cells: the maximal release of DA by S(+)methamphetamine and S(+)amphetamine was 37% and 35% with EC_{50} values of 1.4 and 1.2 μM, respectively. Cocaine inhibited methamphetamine-induced DA release with a maximal inhibition of 80% at 100 μM and an IC_{50} value of 6 μM. In addition, the rate of uptake of norepinephrine (500 nM) by HEK cells expressing the norepinephrine transporter was 0.877 attomol/cell/sec. HEK-hDAT cells which co-express the D2S receptor, a possible DA autoreceptor, exhibited decreased maximal uptake rates of sequential additions of DA after blockade of the autoreceptor by spiperone. This result suggests that agonist binding to the autoreceptor may increase the maximal transport of the DAT. [Supported by NARSAD (AJE), VA Merit Reviews, grants & contracts from NIDA & NIMH (AJ & KAN) and DA07384 (JOS)].

702.5

METABOLISM OF DOPAMINE BY CATECHOL-*O*-METHYL-TRANSERASE IN CELLS EXPRESSING A RECOMBINANT DOPAMINE TRANSPORTER. A Janowsky*, E Stewart, AK Evenson, KA Neve, & AJ Eshleman. Dept. Physiol. Pharmacol.& Psychiatry, OHSU & VAMC, Portland, OR.

To determine if catechol-*O*-methyltransferase metabolizes dopamine within cell lines used for heterologous expression of the dopamine transporter, thus altering the measured characteristics of dopamine transport, the uptake of [^{3}H]dopamine was quantified in three cell lines that had been transfected with the human dopamine transporter. Tropolone (0.01 to 1 mM), a catechol-*O*-methyltransferase inhibitor, increased the uptake and retention of [^{3}H]dopamine (20 nM) up to 4-fold in C_6 glioma cells, HEK293 cells, and L-M cells, but not in synaptosomes prepared from the mouse neostriatum. In C_6 cells expressing the dopamine transporter, the EC_{50} for tropolone was 18 μM. A second inhibitor of catechol-*O*-methyltransferase, Ro 41-0960, also enhanced the uptake and retention of [^{3}H]dopamine (EC_{50} = 0.28 μM), whereas neither tropolone nor Ro 41-0960 altered the uptake of MPP^+, which is a substrate for the dopamine transporter but is not metabolized by catechol-*O*-methyltransferase. Direct measurement of cellular dopamine by HPLC confirmed that tropolone increased the retention of dopamine in C_6 cells. Saturation analysis of the uptake of [^{3}H]dopamine by C_6 cells expressing the transporter demonstrated that tropolone (1 mM) decreased the apparent K_m of transport (0.33 μM) without significantly altering the maximal velocity of transport. These data suggest that endogenous catechol-*O*-methyltransferase activity in mammalian cells may alter neurotransmitter deposition and thus the apparent kinetic characteristics of transport. MOLECULAR CLONING AND STRUCTURAL ORGANIZATION OF THE MURINE NOREPINEPHRINE TRANSPORTER GENE. L. D. Jayanthi*, J. D. Fritz and R. D. Blakely. Dept. of Pharmacology and Ctr. for Mol. Neuroscience, Vanderbilt University Medical Center, Nashville, TN 37232-6600.

The norepinephrine transporter (NET) provides the primary means of terminating noradrenergic neurotransmission in the CNS and periphery. NET gene expression is restricted to noradrenergic neurons, certain neural crest derivatives and placenta and is regulated by multiple agents including insulin, atrial natriuretic peptide and angiotensin. Presently, the mechanism of cell specific NET gene expression and its regulation are not understood. To gain insight into these issues, a mouse NET (mNET) cDNA clone encoding a region spanning TMDs 2 to 5, was isolated from mouse placenta using PCR and degenerate oligonucleotides designed to encode highly conserved sequences of human NET and GAT1 GABA transporters. The nucleotide and amino acid sequence analysis of the mNET PCR clone revealed 83% and 91% identity, respectively, with the human NET. The mNET PCR clone was used as a probe to isolate two identical genomic clones from a murine 129 BAC library. The identity of the BAC genomic clones with the mNET gene was confirmed by Southern blotting and direct sequencing. The sequence analysis of BAC clones also revealed exon/intron splice sites in the mNET gene in register with those reported for the human NET gene (Porzgen et al 1995). Initial studies using the mNET cDNA clone as a probe suggest that the genomic region coding TMDs 2 to 5 of mNET spans atleast 11 Kb. Progress in these studies should aid in understanding regulatory mechanisms for NET gene expression *in vivo* and the consequences of compromised transporter function in transgenic animals. This work is supported by NINDS 33373 and NARSAD.

REGULATION OF THE FUNCTIONAL ACTIVITY OF THE HUMAN DOPAMINE TRANSPORTER BY PROTEIN KINASE C. M.E.A. Reith*, L.L. Coffey and L. Zhang, Department of Biomedical and Therapeutic Sciences, University of Illinois College of Medicine, Box 1649, Peoria, IL 61656.

The role of protein kinase C (PKC) was examined in the regulation of dopamine (DA) transport in C6 glioma cells expressing the human DA transporter. For all assays, the test system consisted of intact cells attached to culture plates. The PKC activating phorbol esters PMA or PDBu (tested over a range of 1 nM to 100 μM) inhibited [^{3}H]DA uptake dose-dependently with a severity varying between DA transporter preparations. These effects were attenuated by the PKC inhibitor staurosporine (STAU) (0.3 μM) but were unaltered by another inhibitor, chelerythrine (0.02 - 2 μM), or the phosphatase inhibitor okadaic acid (0.3 μM). The potency of PMA (IC_{50} of 30 ± 4 μM) in inhibiting [^{3}H]DA uptake was similar to that (48 ± 3 μM) in inhibiting the binding of the cocaine analog [^{3}H]WIN 35,428 ([^{3}H]CFT) when measured in parallel under identical conditions, and again STAU but not chelerythrine weakened PMA's effect. The reduction in DA transporter activity by PMA (2 μM) was caused by a decrease in the V_{max} (from 108 to 30 pmol/mg/min) opposed by a smaller reduction in K_m (from 2.2 to 0.9 μM), whereas the effect on [^{3}H]CFT binding was caused by a reduction in the B_{max} (from 1.7 to 1.2 pmol/mg) without a change in K_d (9.4 nM). The lower K_m value in the presence of PMA was accompanied by a higher IC_{50} of DA (10.3 versus 1.0 μM in PMA's absence) in inhibiting [^{3}H]CFT binding; the latter effect was attenuated by the co-presence of STAU. The results suggest that activation of PKC (1) reduces the number of functionally active transporters by phosphorylation involving both the DA and CFT binding domain, and (2) reduces the affinity of DA for transporters phosphorylated in a manner that affects the DA but not CFT binding domain.

ACTIVATION OF PROTEIN KINASE C INHIBITS UPTAKE ACTIVITY OF THE HUMAN DOPAMINE TRANSPORTER EXPRESSED IN XENOPUS OOCYTES. S.-J. Zhu and N.R. Zahniser*. Dept. of Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262.

The cloned human dopamine transporter (hDAT) contains two putative consensus sequences for protein kinase C (PKC) phosphorylation. When *Xenopus* oocytes expressing hDAT were pretreated with phorbol 12-myristate 13-acetate (PMA), a PKC activator, [^{3}H]DA uptake decreased in a time- and dose-dependent manner (IC_{50}=8.9 nM), by as much as 80%. The inhibition appeared to be PKC-specific since 1) PMA (0.1 μM) inhibition could be partially blocked by bisindolylmaleimide I (1 μM), a selective PKC inhibitor and 2) incubation with the inactive form of phorbol ester 4α-phorbol-12,13-didecanoate (0.4 μM) did not change the uptake activity. Saturation studies of [^{3}H]DA uptake showed that the inhibition was caused by a decrease in V_{max}, without a change in K_T. PMA pretreatment also resulted in a marked decrease in B_{max} of [^{3}H]mazindol binding to intact oocytes, with little effect on affinity. Preliminary studies of hDAT subcellular distribution using sucrose density gradient assays indicated that the decrease in the uptake activity may be associated with a small shift of hDAT from the cell surface to an intracellular pool, in addition to a loss of total cellular transporters. These studies suggest that the hDAT expressed in *Xenopus* oocytes can be regulated by PKC. The direct and/or indirect mechanisms underlying the PKC regulation are currently under investigation. 702.9

REGULATION OF THE FUNCTIONAL ACTIVITY OF THE HUMAN DOPAMINE TRANSPORTER BY THE ARACHIDONIC ACID PATHWAY. L. Zhang* and M.E.A. Reith, Department of Biomed. and Therapeutic Sciences, Box 1649, University of Illinois College of Medicine, Peoria, IL 61656.

The role of the arachidonic acid (AA) pathway was examined in the regulation of dopamine (DA) transport in C6 glioma cells expressing the human DA transporter. For all assays, the test system consisted of intact cells attached to culture plates. Exogenously added AA (5-160 μM) stimulated [^{3}H]DA uptake when pre-incubated for short times (15-30 min); 160 μM AA inhibited following longer pre-exposures (45-60 min). Under the same conditions, only decreases were observed in the binding of the cocaine analog [^{3}H]WIN 35,428 ([^{3}H]CFT). The reduction in DA transporter activity by AA (at 160 μM for 60 min) was caused by a decrease in the V_{max} (from 202 to 44 pmol/mg/min) opposed by a smaller reduction in K_m (from 1.2 to 0.8 μM), whereas the effect of AA (at 160 μM for 15 min) on [^{3}H]CFT binding was caused by a reduction in the B_{max} (from 1.8 to 1.3 pmol/mg) without a change in K_d (7.2 nM). Upon 15-min exposure, melittin, an activator of phospholipase A_2, and NDGA, a lipooxygenase inhibitor, both expected to cause enhanced endogenous AA, inhibited [^{3}H]DA uptake and [^{3}H]CFT binding with an IC_{50} value close to 1 μM, whereas thimerosal, a reacylation inhibitor, caused similar reductions at the sub-millimolar level. Co-presence of staurosporine (0.3-2 μM), an inhibitor of protein kinase C (PKC), had little or no effect on the melittin- or AA-induced inhibition of [^{3}H]DA uptake suggesting that the effect of endogenous or exogenous AA does not involve activation of PKC. Both the melittin- and AA-induced inhibition of [3H]DA uptake were counteracted by BSA (0.1 and 1 mg/ml) which binds AA.

THE DOPAMINE TRANSPORTER: EFFECT OF PROTEIN PHOSPHORYLATION ON FUNCTIONAL REGULATION.

N. S. Vrindavanam, P. Arnaud, R. Beckstead*, and F.Sallee
Dept of Psychiatry, MUSC, Charleston, SC 29425

The human dopamine transporter (hDAT) is a protein which modulates the action of dopamine (DA) at the synapse of the dopaminergic neurons. It has also been shown to contain binding sites for drugs of addiction and neurotoxins like cocaine and MPP+ respectively. Several putative phosphorylation sites have been postulated on the DAT but direct evidence of protein phosphorylation has not been demonstrated so far. COS-7 cells were transformed with hDAT cloned into the eukaryotic expression plasmid pCDNA3, metabolically labelled with ^{32}P and analyzed for phosphorylation. A Western blot was performed on DAT purified from dog brain striatum using a monoclonal anti phosphoserine antibody. Transformed cells were treated in parallel with phosphorylation promoting agents (forskolin, 8-Bromo cAMP, okadaic acid and nipecotic acid) and assayed for radiolabelled substrate ([^{3}H]DA) uptake and ligand ([^{3}H] WIN) binding. DAT is found to be phosphorylated in its native state and at least one of the phosphorylation sites seem to be a serine. A significant decrease in both substrate translocation and ligand binding was detected. ^{32}P labelling experiments suggest that hDAT may be constitutively phosphorylated and dephosphorylated upon substrate binding. Our studies suggest a significant role for a cAMP mediated system in the functional regulation of the hDAT.

POTENTIAL REGULATION OF DOPAMINE TRANSPORT BY PROTEIN KINASE A. K.K. Yoder*, J.R. Simon, and J.A. Richter. Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46202.

The dopamine transporter contains at least 2 putative protein kinase A (PKA) consensus sequence sites within its intracellular amino acid sequence. To begin to determine if the transporter is regulated by PKA, three drugs that promote phosphorylation by cyclic AMP-dependent kinase were examined for their effects on dopamine uptake in mouse striatal synaptosomes. 8-bromoadenosine 3',5' cyclic monophosphate, forskolin, and isobutylmethylxanthine all produced inhibition of dopamine uptake in a concentration-dependent manner. The most potent agent was forskolin, with an apparent IC_{50} of 156 ± 37.7 μM, followed by isobutylmethylxanthine with an IC_{50} at 574 ± 182 μM, and 8-bromoadenosine 3',5' cyclic monophosphate with an IC_{50} of 1.68 ± 0.31 mM. All three agents significantly reduced the V_{max} of dopamine transport ($p < 0.05$). In addition, isobutylmethylxanthine also significantly increased the K_m for dopamine uptake. 1,9-dideoxyforskolin gave the unexpected effect of inhibiting dopamine transport with an approximate IC_{50} of 66 μM. This may indicate that forskolin may be exerting its effect on dopamine uptake through a non-cAMP-dependent mechanism. The ability of PKI to block the effects of 8-bromoadenosine 3',5' cyclic monophosphate and isobutylmethylxanthine will be studied in order to discern whether or not their inhibition of dopamine uptake is cAMP-mediated. Our observations that pharmacological agents which activate PKA inhibit dopamine uptake suggest that phosphorylation of the dopamine transporter by protein kinase A may be a physiological means of regulating dopamine transport. MUSCARINE INHIBITS CYCLIC AMP-DEPENDENT MODULATION OF MONOAMINE TRANSPORT IN PC12 CELLS N. Nakanishi*, S. Onozawa, S. Katoh Dept. of Biochem., Meikai Univ. Sch. Dentistry, Saitama 350-02, Japan.

We found that cAMP down-regulates cellular uptake of monoamine by inhibiting the amine transport process into the secretory vesicles (J. Neurochem. 64, 600, 1995). Therefore, neuromodulators such as AMP adenosine and VIP, which elevate cellular cAMP, decrease cellular amine uptake and increase extracellular dopamine level in PC12 cell culture, suggesting the antidepressant activity for these agents. In the present study, we examined the effect of muscarine on the amine transport, since muscarinic receptor stimulation was reported to inhibit cAMP accumulation in PC12 cells. Although muscarine (100 μM) alone did not show significant effect on serotonin uptake, the dose-response curve for the uptake inhibition by NECA (adenosine A_2 agonist) shifted in the presence of muscarine. 5HT uptake in the presence of NECA (1 μM), and of both NECA and muscarine were 65%, and 80% that of control value, respectively. The result suggests that acetylcholine also regulates vesicular monoamine transport by interfering with the cAMP-dependent modulation of the monoamine transport. CALMODULIN ANTAGONISTS INHIBIT BINDING TO COCAINE RECOGNITION SITES IN RABBIT BRAIN. Vincent J. Aloyo*, Department of Pharmacology, Medical College of PA and Hahnemann University, Philadelphia, PA. 19129, USA.

The psychoactive drug, cocaine binds to specific recognition sites on monoamine transporters to block neurotransmitter reuptake. The effects of calmodulin antagonists on the binding of the cocaine analogues, [^{3}H]WIN 35,428 and [^{125}I]RTI-55 were investigated. WIN 35,428 binding to the dopamine transporter was performed using a crude membrane fraction prepared from fresh rabbit caudate as previously described (Aloyo et al., JPET, 1995). RTI-55 binding to the serotonin transporter was performed using a crude membrane fraction prepared from fresh rabbit cortex at 25^0 C in 20 mM phosphate pH 7.4 containing 0.32 M sucrose. For both ligands, binding to cocaine recognition sites was defined by 30 μM (-)cocaine. The calmodulin antagonists chlorpromazine, W7 and trifluoperazine dose dependently inhibited [^{3}H]WIN 35,428 binding. In contrast, the sulfoxide congeners of chlorpromazine and trifluoperazine were 40 fold less potent inhibitors of [^{3}H]WIN 35,428 binding. Similarly, several calmodulin antagonists inhibited the binding of [^{125}I]RTI-55. Additionally, the peptide calmodulin antagonist, melittin, also potently and dose dependently inhibited the binding of both cocaine analogues. These data suggest that, as a class, calmodulin antagonists inhibit binding to cocaine recognition sites and therefore may have therapeutic potential in the treatment of cocaine abuse. REGULATION OF HUMAN NOREPINEPHRINE TRANSPORTER (hNET) IN HEK-293 CELLS BY DESIPRAMINE (DMI). M.-Y. Zhu*, R.D. Blakely, and G.A. Ordway. Dept. Psychiatry & Human Behavior, Univ. of Mississippi Medical Center, Jackson, MS; Dept. of Pharmacology, Vanderbilt Univ., Nashville, TN.

Regulation of the level of expression of neurotransmitter transporters induced by exposure to substrates and inhibitors is poorly understood. We used HEK-293 cells stably transfected with hNET to study the regulation of hNET by continuous exposure to the hNET inhibitor, DMI. Levels of hNET and hNET function were measured by (1) generating saturation isotherms for the selective hNET inhibitor, [^{3}H]nisoxetine, in cell homogenates, (2) Western immunoblotting using an hNET antibody, and (3) measuring the uptake of [^{3}H]norepinephrine by hNET in intact cells. [^{3}H]Nisoxetine binding in HEK-293 homogenates was characteristic of binding to native hNET. Exposure of intact HEK-293 cells to 500 nM DMI for 3 days robustly reduced the Bmax (-69%, $p<0.01$), but not the K_D, of [^{3}H]nisoxetine binding to hNETs. Reductions in binding were not affected by extensive washing of cells following DMI exposures. Reductions of the specific binding of [^{3}H]nisoxetine (2.5 nM) following DMI exposures were dependent upon the concentration of DMI (10 nM, -9%, $p>0.05$; 100 nM, -26%, $p<0.05$; 500 nM, -66%, $p<0.01$). [^{3}H]Nisoxetine binding returned to control levels 72 h after the end of a 3 day exposure to 500 nM DMI. Western immunoblots of homogenates of HEK-293 cells confirmed that exposure to DMI reduced hNET protein levels and that hNET protein levels returned to control values following cessation of DMI exposure. Finally, uptake of [^{3}H]norepinephrine by hNET was reduce by 58% ($p<0.01$) following a 3 day exposure to 500 nM DMI. These results demonstrate that continuous exposure to DMI down-regulates hNET expression in HEK-293 cells. Additional studies are required to determine if occupation of the transporter by DMI is required for DMI-induced hNET regulation, and to determine whether hNET regulation occurs at the transcriptional, translational or post-translational level. DECREASED NOREPINEPHRINE TRANSPORTERS (NETs) IN THE LOCUS COERULEUS (LC) IN MAJOR DEPRESSION. V. Klimek*, C.A. Stockmeier, J.C. Overholser, H.Y. Meltzer, S. Kalka, G. Dilley and G.A. Ordway. Dept. of Psychiatry & Human Behavior, Univ. of Mississippi Med. Ctr., Jackson, MS; Depts. of Psychiatry & Psychol., Case Western Reserve Univ., Cleveland, OH.

Most antidepressant drugs have potent acute and/or chronic effects on the neurochemistry of brain noradrenergic neurons, suggesting an involvement of these neurons in the pathobiology of major depression. NETs expressed on noradrenergic neurons are sites of action of many antidepressant drugs, including tricyclic antidepressants. We measured the specific binding of the NET selective ligand, [^{3}H]nisoxetine, to NETs along the rostral-caudal axis of the noradrenergic LC in 16 subjects with major depression and 16 age- and post-mortem interval-matched normal control subjects. Post-mortem toxicology revealed no antidepressants in the blood or bile of any subjects. An uneven distribution of [^{3}H]nisoxetine binding to NETs ($p<0.005$) and an uneven distribution of noradrenergic (neuromelanin-containing) neurons ($p<0.005$) along the rostral-caudal axis of the nucleus had similar topographic patterns for both groups of subjects. There was a significant positive correlation between the number of noradrenergic cells per section and the binding of [^{3}H]nisoxetine at any particular level of the LC from controls ($r^2=0.43$; $p<0.0001$) and from major depressives ($r^2=0.27$; $p<0.0001$). However, [^{3}H]nisoxetine binding to NETs was significantly lower (-31%) in the mid-caudal portion of LC in major depressives compared to controls ($p<0.01$). In contrast, there was no significant difference in the number of noradrenergic cells between major depressives and controls at any level of LC. The low binding of [^{3}H]nisoxetine to NETs in the LC in major depression may result from a compensatory down-regulation of NETs on LC cells in response to an abnormal availability of its substrate (norepinephrine) in the synapse. (Supported by MH 46692 and MH 45488.)

DOPAMINE TRANSPORTER FUNCTION IN MESENCEPHALIC CULTURES AFTER CHRONIC METHAMPHETAMINE EXPOSURE: ALTERATIONS WITH cAMP ADMINISTRATION. B.A. Bennett*, R.S. Martin and C.K. Hollingsworth., Dept. of Physiol/Pharmacol, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27157.

Little is currently known about transporter regulation. While various studies have suggested that second messengers may be important modulators of transporter function, few have examined transporter regulation in neuronal cells. The aim of this study was to examine the effects of acute and chronic methamphetamine (METH) on dopamine (DA) transporter function in midbrain cultures and determine if cAMP alters this response. Initial velocities of uptake were determined as well as experiments designed to examine efflux of DA by reversal of the transporter (with METH challenge). Midbrain cultures were obtained from fetal rat brains (E15) and exposed to 1 and 10 μM METH for 5 days. Sister cultures were exposed to METH plus cAMP (100 μM) or cAMP alone. After 1, 7, or 14 days washout, either uptake or efflux experiments were performed. In METH-treated cultures, DA uptake was reduced at each time point examined compared to control values. In contrast, cAMP-treated cultures showed enhanced DA uptake. Lineweaver-Burke plots were constructed from the initial velocity data for determination of tranporter kinetics. Exposure to METH for 5 days resulted in an increase in the Km for DA, while there was not a significant change in Vmax. Additionally, the efflux of ^{3}H-DA as induced by METH was less than in non-treated cultures, suggesting altered release kinetics as well. Co-administration of cAMP reversed the effects of METH at each time point examined. Our data indicate that chronic METH exposure induces significant alterations in transporter function and may reflect alterations in the phosphorylation state of the transporter. *Supported by NIDA grant DA 05073*

CALMODULIN ANTAGONISTS INHIBIT DOPAMINE TRANSPORT IN MOUSE STRIATAL HOMOGENATES. J.R. Simon*. Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46202.

The synaptic action of dopamine (DA) is terminated by its removal from the synaptic cleft via the dopamine transporter (DAT). In this study, we report alterations in the rate of DA transport in mouse striatal homogenates following exposure to several calmodulin antagonists. Mouse striatal homogenates were preincubated at 30°C for 10 min in the absence and presence of inhibitor drugs. Tritiated DA (final concentration, 100 nM) was then added and uptake was measured for 2 min at 30°C. Calmidazolium, W-7, trifluoperazine and haloperidol all reduced DA uptake. The inhibition of transport produced by these drugs was concentration-dependent and reversible. All drugs tested had similar potencies with IC_{50} values in the range of 2-3 μM. The inhibition of DA uptake produced by haloperidol did not appear to be mediated by DA receptor involvement since another D_2 antagonist (sulpiride) was without effect, and the inhibition by haloperidol was not affected by apomorphine. Preliminary results with calmidazolium suggest that the reduced accumulation of DA is not a result of enhanced efflux. The results suggest that calmodulin-dependent processes may play a role in determining the activity of the dopamine transporter in mouse striatum. THE COCAINE-SENSITIVE DOPAMINE TRANSPORTER: ULTRASTRUCTURAL IMMUNOGOLD LOCALIZATION IN MESOLIMBIC DOPAMINERGIC NEURONS. M. J. Nirenberg*, R. A. Vaughan, G. R. Uhl, M. J. Kuhar, and V. M. Pickel. Div. Neurobiol., Dept. Neurol. and Neurosci., Cornell Univ. Med. Coll., New York, NY 10021, Addiction Res. Ctr.; NIDA; Baltimore, MD 21224; and Neurosci. Div., Yerkes Regional Primate Ctr., Emory Univ., Atlanta, GA 30322.

The termination of dopaminergic neurotransmission is critically dependent upon the uptake of dopamine by the dopamine transporter (DAT). DAT is inhibited by drugs such as cocaine and amphetamines, whose well-known psychoactive effects result largely from the blockade of dopamine uptake into mesolimbic dopaminergic neurons. In the present study, we have used electron microscopic immunogold labeling with an anti-peptide antibody directed against the N-terminal domain of DAT to examine the potential sites for dopamine uptake and cocaine binding within TH-immunoreactive dopaminergic neurons in the rat ventral tegmental area (VTA) and nucleus accumbens (NAc). In VTA perikarya and dendrites, DAT was localized to cytoplasmic surfaces of synthetic organelles and other intracellular membranes. VTA dendrites also contained labeling for DAT along cytoplasmic surfaces of plasma membranes. Axon terminals and unmyelinated axons in the NAc showed extensive labeling for DAT along cytoplasmic surfaces of plasma membranes, and less frequent labeling of electron-lucent vesicles and tubulovesicles. The DAT-labeled segments of plasma membranes in the VTA and NAc were usually distant from recognized synaptic junctions. The observed localization supports the proposed topological model for DAT, and suggests a prominent role for DAT in extrasynaptic dopamine reuptake into axonal and dendritic processes of mesolimbic dopaminergic neurons. The extensive plasmalemmal labeling for DAT in the NAc also provides a cellular basis for the responsiveness of this region to cocaine and other psychostimulant drugs. (Supported by MH40342; DA04600).

DOPAMINE AXON VARICOSITIES IN THE PREFRONTAL CORTEX LACK IMMUNOREACTIVITY FOR THE DOPAMINE TRANSPORTER. SR Sesack,* VA Hawrylak, MA Guido, DS Melchitzky, DA Lewis, AI Levey. Departments of Neuroscience and Psychiatry, University of Pittsburgh, PA 15260; Department of Neurology, Emory University, Atlanta GA 30322.

The dopamine transporter (DAT) plays a critical role in regulating the duration of dopamine's synaptic actions and the extent to which dopamine can diffuse in the extracellular space. We sought to determine whether the reportedly greater diffusion of dopamine in the prefrontal cortex (PFC) compared to the striatum (STR) is associated with a more restricted axonal distribution of the cortical DAT protein. Avidin-biotin peroxidase staining was used to localize a rat monoclonal antibody against DAT in the rat brain. By light microscopy, DAT-immunoreactive (DAT-ir) fibers were sparsely distributed to the deep layers of the prelimbic PFC (Brodmann's area 32), and many of these axons were difficult to visualize without differential interference contrast optics. In contrast, DAT-ir axons were densely localized to the superficial layers of the immediately adjacent dorsal anterior cingulate cortex (CING; area 24) and to the dorsolateral STR. By electron microscopy, DAT-ir processes in the PFC were almost exclusively preterminal axons. Conversely, DAT-ir processes in the CING and STR included both axon varicosities and intervaricose segments. Immunolabeling for tyrosine hydroxylase in adjacent sections of the PFC was also localized to both axons and axon varicosities. Finally, preliminary examination of Walker's prefrontal area 9 in cynomolgus monkeys revealed DAT immunolabeling that was largely restricted to preterminal axons. These findings suggest that extracellular diffusion of dopamine in the PFC may result, in part, from a proximal distribution of the DAT protein relative to synaptic release sites. Support: USPHS MH50314 & MH43784.

703.3

AN IN VIVO VOLTAMMETRIC CHARACTERIZATION OF THE RAT STRIATAL DOPAMINE TRANSPORTER: PHARMACOLOGY, STRUCTURE-ACTIVITY, AND ION DEPENDENCE. S. R. Long* and J. O. Schenk, Dept. of Chemistry,Washington St. Univ., Pullman, WA 99164-4630.

In vitro studies of the striatal dopamine transporter by this laboratory have assessed the sensitivity of transport to pharmacological agents, transporter dependence upon extracellular [Na^+] and [Cl^-] (Biochem. Pharmacol.,**43**, 10, 2189), and structural requirements for substrate transport (J. Neurochem.,**62**, 998). During in vivo experiments designed to be analogous to those in vitro, a pulse of dopamine in physiological buffer was rapidly introduced ca. 200 µm from the site of chronoamperometric pulsing of a carbon-fiber electrode. The disappearance of dopamine represents the combination of diffusion through brain tissue with uptake by the dopamine transporter. Transporter activity is isolated by removing the diffusion component of the signal; uptake thus isolated is reduced ≥93% by either cocaine or RTI-55, and has an apparent V_{max} of 0.48 ± .08 µM/s. Two structural analogs of dopamine were tested; 4-ethylcatechol is transported at a rate 61% that for dopamine and 4-methylcatechol is not transported. The ion dependence of transport was determined by ion selective potentiometry; buffers used in these experiments had reduced [Na^+] or [Cl^-]. Injections of control buffer had no effect on local concentrations of either ion; when [Na^+] is reduced, transport velocities decrease and extracellular [Na^+] decreases over the time of the velocity measurements. Similar results were obtained for Cl^-. The results of this study show that this experimental design allows the investigator to control the composition of extracellular fluid during experiments and make direct comparisons to in vitro results. (Supported by a National Institutes on Drug Abuse (NIDA) grant, DA07384, to J.O.S., recipient of NIDA Research Scientist Development Award DA00184.)

^{18}F-LABELED WIN POSITRON EMISSION TOMOGRAPHY (PET) IN A NONHUMAN PRIMATE: A NOVEL RADIOISOTOPE TO STUDY DOPAMINE TRANSPORTER T Subramanian*, RL Watts, RAE Bakay, GW Miller, AI Levey, B Shi, D Eshima, JT Greenamyre, GW Hubert, MM Goodman, and JM Hoffman
Emory University School of Medicine, Atlanta, GA 30322.

Studies using PET with dopamine transporter ligands have been used to examine the nigrostriatal system in Parkinson's disease (PD). We report the development of a novel ^{18}F-labeled cocaine analogue (^{18}F-WIN) and its use in determining dopamine transporter density and distribution in an adult nonhuman primate brain. These findings were compared with ^{18}F-dopa PET imaging and the actual distribution of dopamine transporter protein using specific anitibodies to the transporter protein. An adult monkey received an injection of ^{18}F-WIN and was imaged using PET. Behavioral ratings at the time of the imaging study did not reveal any abnormalities. Two weeks later, a ^{18}F-dopa PET imaging study was performed. After an additional 2 weeks the animal received 7.1 mCi of ^{18}F-WIN compound i.v. and imaged with PET for 2 hr. Three hr after the injection the animal was sacrificed and the brain was rapidly dissected and 0.4 mm coronal sections were made. Autoradiograms were performed on alternate sections. Tissue punches (0.2x0.2 mm) were obtained from different areas of the brain and ^{18}F-WIN binding measured. The remaining brain sections were postfixed, and 50µm sections examined for tyrosine hydroxylase and dopamine transporter immunoreactivity. The results revealed higher ^{18}F-WIN binding in the striatum compared to other regions by 1) autoradiography, 2) *in vivo* PET imaging studies (striatal to cerebellum S/C ratio increased to 3.5 at 2 hr), and 3) analysis of tissue punches (S/C ratio 30.1). Dopamine transporter immunoreactivity was observed at high levels in the caudate and the putamen and labeled fibers displayed puncta, indicative of nerve terminals. The distribution pattern of ^{18}F-WIN binding appeared similar to the distribution of ^{18}F-dopa uptake and metabolism and the dopamine transporter immunoreactivity in this animal. This study indicates that ^{18}F-WIN PET imaging is a novel method to quantitatively examine dopamine transporter distribution *in vivo* and has significant potential for clinical application in neurodegenerative disorders like PD.

EXPRESSION OF VESICULAR MONOAMINE TRANSPORTER mRNA IN NEURONS OF THE HUMAN BRAINSTEM S.M. O'Donnell*, J.L. Rhodes, M.C. Austin. Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213.

The vesicular monamine transporter (VMAT) accumulates cytosolic monoamines into synaptic vesicles using the proton gradient maintained across the synaptic vesicular membrane. The proper functioning of VMATs are critical for maintaining monoaminergic neurotransmission. Cloning studies have identified two VMATs which exhibit different physiological, pharmacological and anatomical properties. Both the rat and human brain VMAT2 have been cloned. The cDNAs share a high sequence homology except within the large luminal loop between the first two transmembrane domains. A recent study reported the cellular localization of VMAT2 mRNA in human substantia nigra neurons (Gonzalez et al. 1994). The present study was designed to characterize the regional and cellular distribution of VMAT2 mRNA in monoaminergic neurons of the human brainstem. Postmortem human brainstem tissue (N=5) was obtained at autopsy, dissected and frozen. All cases had negative toxicological results and no history of neurologic or psychiatric disorders. Coronal tissue sections (20 µm) were thaw-mounted on gelatin-coated slides and processed for in situ hybridization. Abundant hybridization signal corresponding to VMAT2 mRNA was found in neuromelanin-containing neurons of the locus coeruleus. VMAT2 mRNA was also highly expressed in serotonergic neurons in the median raphe, dorsal raphe and oral pontine nucleus. Pigmented neurons in the various subnuclei of the ventral mesencephalon contained abundant levels of mRNA encoding the VMAT2. In addition, VMAT2 mRNA was found in non-pigmented neurons in the interpeduncular and caudal linear nuclei which presumably represent serotonergic neurons. These findings demonstrate that VMAT2 mRNA is abundantly expressed in monoamine-containing neurons in the human pons and midbrain. The distribution of VMAT2 mRNA-containing neurons in the human brainstem is consistent with the cellular localization of mRNAs encoding the norepinephrine, serotonin and dopamine transporters. THE HUMAN DOPAMINE TRANSPORTER GENE 3' FLANK CONTAINS A NEW GENE EXPRESSED IN BRAIN AND PERIPHERAL TISSUES. Y. Numachi,[1] D.J. Vandenbergh[1], E. Bendahhou[1], & G.R. Uhl[1,2,3]. [1] Molec. Neurobiol. Branch, &[2] Office of Director, DIR, NIDA, NIH; Box 5180, Balto., MD 21224, & [3]Depts. of Neurology & Neuroscience, Johns Hopkins University School of Medicine.

Genomic DNA containing exon 15 of the human dopamine transporter (DAT) gene also contains a gene that is expressed in brain, spleen, kidney, liver, and thymus. Preliminary results suggest brain regional differences in the levels of its mRNA expression. The transcript was identified by sequence match to the Expressed Sequence Tags (EST) GenBank accession #'s N34807, N72874, D19622, and L44337, which are expressed in multiple sclerosis plaques, thymus, and promyelocytes respectively. This gene is located between the 3'-end of the DAT gene and the anonymous marker D5S678, and encodes a small transcript of 700 nt. Further work is necessary to determine whether reported associations between the DAT gene VNTR marker and Attention Deficit/Hyperactivity Disorder [*Am J Hum Genet* 56:993 (95)], and cocaine induced paranoia [*Neuropsychopharm* 11:195 (94)] could be contributed to by alleles of this new gene.

703.7

NEW POLYMORPHISMS AND LINKAGE DISEQUILIBRIUM IN THE HUMAN DOPAMINE TRANSPORTER GENE

D.J. Vandenbergh[1]*, E. Bendahhou[1], Y. Numachi,[1] E. Cook[3], and G.R. Uhl[1,2,4]. [1]Molec. Neurobiol. Branch, & [2]Office of Director, DIR, NIDA, NIH; [3]Dept. of Psychiatry, Univ. of Chicago, & [4]Depts. of Neurology & Neuroscience, Johns Hopkins University School of Medicine, Box 5180, Balto., MD 21224

The dopamine transporter (DAT) is the primary site of action of psychomotor stimulants such as cocaine, amphetamine, and related compounds such as methylphenidate. Taken together with its exclusive expression in dopaminergic neurons, DAT is a candidate gene for several neuropsychiatric disorders. The ability to detect the effects of DAT alleles on inter-individual variability in genetically based disorders depends on knowledge of polymorphisms in linkage disequilibrium within and near the DAT gene. Genetic association studies of unrelated individuals are useful for identifying gene effects in complex, non-Mendelizing disorders. However, it is not clear the extent to which an association at a single marker extends to flanking DNA. New genetic polymorphisms have been identified in and around the human DAT gene, in particular a highly informative marker close to exon 7. Measurement of linkage disequilibrium between these markers generates a highly localized genetic map of the DAT gene. Associations of the DAT gene with Attention Deficit/Hyperactivity Disorder [*Am J Hum Genet* 56:993 (95)], and cocaine induced paranoia [*Neuropsychopharm* 11:195 (94)] can now be tested for replication and for pinpointing possible allelic variants responsible for these associations.

EFFECTS OF PROLACTIN ON EXPRESSION OF FOS PROTEIN IN TYROSINE HYDROXYLASE-CONTAINING NEURONS LOCATED IN SUBDIVISIONS OF THE RAT HYPOTHALAMIC ARCUATE NUCELUS, K. Hentschel, M.J. Eaton*, T.M. Ingram, K.E. Moore and K.J. Lookingland. Dept. Pharm. & Tox., Michigan State University, E. Lansing, MI 48824.

The effects of prolactin were examined on FOS protein expression in subpopulations of tuberoinfundibular dopamine (TIDA) neurons located in the dorsomedial (DM) and ventrolateral (VL) regions of the arcuate nucleus (ARC) using dual immunohistochemistry to quantify the numbers of tyrosine hydroxylase (TH)-immunoreactive (IR) neurons containing FOS-IR nuclei. For comparison, the effects of prolactin on FOS protein expression in non-TH cells in the ARC were also determined. There was no difference in the number of TH-IR neurons located in either the DM (70.2±6.1 cells/section) or VL (65.6±7.5 cells/section) subdivisions of the ARC. Prolactin (10 μg/rat; icv) increased the number of TH-IR neurons containing FOS-IR nuclei in the DM-ARC at 3, 6 and 12 hr after administration. By contrast, prolactin caused a delayed increase (only at 12 hr) in the number of TH-IR containing FOS-IR in the VL-ARC. Prolactin also increased the number of non-TH-IR cells containing FOS-IR nuclei in the DM-ARC at 3 hr, but had no effect on expression of FOS protein in non-TH-IR cells in the VL-ARC. The results reveal that prolactin has differential time-dependent effects on subpopulations of TIDA neurons in the ARC; i.e. TIDA neurons in the DM-ARC are responsive to rapid and prolonged activation, whereas those in the VL-ARC are responsive only to delayed activation. ROLE OF PROLACTIN IN THE LACTATIONAL ANOVULATION IN THE RHESUS MONKEY. T. Ördög, M.-D. Chen, J.R. Goldsmith, M.A. Connaughton, K.T. O'Byrne, J. Hotchkiss and E. Knobil*. Laboratory for Neuroendocrinology and the Department of Integrative Biology, The University of Texas Medical School, Houston, TX 77225.

Earlier studies dealing on the mechanisms underlying the lactational anovulation in rhesus monkeys utilizing indirect indices of the functioning of the hypothalamo—pituitary—ovarian axis suggested that this suckling-induced process could not be accounted for simply by the associated hyperprolactinemia (Biol. Reprod. 25:370, 1981). Electrophysiological access to the gonadotropin-releasing hormone (GnRH) pulse generator has provided the opportunity to re-examine the relative roles of suckling *per se* or of prolactin (PRL) in this phenomenon. Freely behaving, regularly cycling rhesus monkeys were fitted with electrodes chronically implanted in the mediobasal hypothalamus and the electrophysiological correlates of GnRH pulse generator activity monitored continuously by radiotelemetry (Endocrinology 129:1207, 1991). Daily blood samples were taken by venipuncture for the measurement of luteinizing hormone, PRL, estradiol and progesterone. After at least 2 control menstrual cycles, these animals were used as foster mothers to infant monkeys removed from their natural mothers. Lactation, as monitored by manual expression of milk, was induced within 6 days of fostering. Limited supplemental feeding (Primilac) was provided throughout and did not interfere with suckling activity. Suckling arrested GnRH pulse generator activity in all foster mothers with a consequent discontinuation of ovulatory menstrual cycles. To determine the role of PRL in this response to suckling, the foster mothers were treated daily with bromocriptine (0.1 mg/kg) while suckling continued. This regimen, which reduced PRL to undetectable levels, had no effect on pulse generator activity in cycling animals. GnRH pulse generator activity and ovarian cyclicity remained suppressed in the absence of detectable PRL in some but not all of these disparate animals. Changes in suckling intensity, stage of lactation or infant age were not factors in these outcomes. The role of PRL in this phenomenon, therefore, remains ambiguous. (Supported in part by NIH grants HD-17438, HD-08610 and T32-HD-07324-07, and by the Ellwood Foundation.)

***IN VIVO* ACTIONS OF TRANSFORMING GROWTH FACTOR-β1 ON PROLACTIN SECRETION AND LACTOTROPIC CELL PROLIFERATION IN THE PITUITARY GLAND.** S. Minami and D.K. Sarkar*. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164-6520.

Recently it has been shown that lactotropic cells in the anterior pituitary gland produce and secrete transforming growth factor-ß1-(TGF-ß1) peptide. In primary cultures of anterior pituitary cells, TGF-ß1 inhibits basal and estrogen-induced prolactin (PRL) secretion and estrogen-induced lactotropic cell proliferation. TGF-ß1 appears to have no effect on basal secretion of LH, FSH, GH and ß-endorphin in primary cultures of pituitary cells. The *in vivo* actions of this peptide growth factor on lactotropic cells have not been studied. In this study we determined the effects of TGF-ß1 on lactotropic cell function in estradiol-17ß-treated ovariectomized F344 rats. Intrapituitary administration of TGF-ß1 significantly inhibited plasma levels of PRL. In addition, TGF-ß1 decreased estrogen-induced pituitary weight and the DNA synthesis in lactotropes and reduced PRL levels in the anterior pituitary. These results suggest that, as with *in vitro*, TGF-ß1 inhibits PRL secretion and lactotropic cell proliferation *in vivo*, and also suggest the possibility that TGF-ß1 may be a physiological regulator of lactotropic cell function (Supported by NIH Grant CA 56056).

704.4

ROLE OF γ-AMINOBUTYRIC ACID (GABA) IN THE CONTROL OF PROLACTIN (PRL) SECRETION. S.A. Ferreira*[1], D.A. Browning[1], D.E. Kuehl[1], C.J. Scott[2] and G.L. Jackson[1]. [1]Dept. of Veterinary Biosciences, University of Illinois, Urbana, Il 61801. [2]Present address: Prince Henry's Institute of Medical Research, Clayton, Victoria 3168, Australia.

The involvement of GABA receptor subtypes in the regulation of PRL remains controversial. We investigated the effects on PRL secretion of infusing $GABA_A$ and $GABA_B$ receptor agonists (muscimol and baclofen, respectively) via microdialysis into either the medial preoptic area (mPOA) or arcuate-ventromedial region (ARC-VMR) of castrated rams during the non-breeding season. Guide cannulae were implanted bilaterally into either the mPOA (n=7) or ARC-VMR (n=8). Starting at least two weeks after surgery, microdialysis of either artificial cerebrospinal fluid (aCSF) for 4 h followed by aCSF for an additional 4 h (aCSF-aCSF), or aCSF-baclofen (1 mM), or aCSF-muscimol (1 mM in the ARC-VMR and 250 μM in mPOA) was carried out on three separate occasions and in random order. During the 8 h dialysis period, jugular blood was collected at 10 min intervals. Every third plasma sample later was analyzed for PRL. Estimated *in vitro*, the dose of baclofen delivered to each bilateral dialysis site was 7.9 μg while for muscimol it was 1.1 μg and 4.5 μg for the mPOA and ARC-VMR, respectively. The brains were examined histologically to verify probe placement. In the mPOA, baclofen caused a small but significant increase (67 ± 5 vs. 135 ± 18 ng/ml, aCSF vs. baclofen; $p<0.01$) in mean PRL concentration, while muscimol had no significant effect ($p>0.1$). In the ARC-VMR both baclofen (78 ± 8 vs. 231 ± 26 ng/ml, aCSF vs. baclofen; $p<0.001$) and muscimol (88 ± 11 vs. 459 ± 28 ng/ml, aCSF vs. muscimol; $p<0.001$) increased mean PRL, with the response to muscimol being more pronounced. These results suggest that GABA mediates its stimulatory action on PRL release primarily via $GABA_B$ receptors in the mPOA and via both $GABA_A$ and $GABA_B$ receptors in the ARC-VMR. Supported by USPH HD27453.

INCREASED TRANSFORMING GROWTH FACTOR-β2 PROTEIN IMMUNOREACTIVITY IN CASTRATION CELLS OF THE ANTERIOR PITUITARY GLAND. S. Hentges, A. De, S. Fung* and D.K. Sarkar. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164-6520.

Three isoforms of the transforming growth factor ß family of peptides have been identified in mammalian tissues and shown to regulate many aspects of cellular function including cell proliferation, differentiation and gene expression. Two TGF-ß isoforms, TGF-ß1 and TGF-ß3, have been localized in the anterior pituitary tissue and shown to regulate lactotropic cell growth and prolactin hormone secretion. The production and action of TGF-ß2 in the anterior pituitary were not determined. Immunocytochemical localization of TGF-ß2 indicated that a group of anterior pituitary cells was TGF-ß2 immunoreactive (TGF-ß2-ir). The number and intensity of TGF-ß2-ir cells in the anterior pituitary were markedly increased following ovariectomy. The intensely stained TGF-ß2-ir cells were identified as LH-secreting castration cells. Treatment with estrogen resulted in decrease of both castration cells and TGF-ß2-ir cell numbers. The effects of TGF-ß2 on LH, FSH and prolactin secretion were studied in primary cultures of pituitary cells. TGF-ß2 treatment moderately increased the basal secretion of LH but did not have any effect on basal secretion of FSH and PRL from the pituitary cells in primary cultures. These results suggest that TGF-ß2 is also present in the anterior pituitary and may regulate gonadotropic cell differentiation (Supported by NIH Grant CA 56056).

EXPOSURE TO A SHORT PHOTOPERIOD REDUCES PROLACTIN RELEASE FROM PITUITARY FRAGMENT: EFFECTS OF HYPOTHALAMIC FACTORS. Lori L. Badura*, Behavioral Neuroscience, SUNY at Buffalo, Buffalo, NY.

Exposure of Siberian hamsters to nonstimulatory photoperiods induces declines in circulating levels of a variety of anterior pituitary hormones, including prolactin (PRL). The *in vivo* effects of short photoperiod exposure are mirrored by concurrent declines in the ability of cultured pituitary tissue to release PRL, and changes in sensitivity of the pituitary to hypothalamic inhibitory inputs (i.e., dopaminergic tone). The current study investigated whether the same holds true for sensitivity to known stimulating factors. Adult female hamsters maintained either under a long-day (16L:8D) or short-day (10L:14D) photoperiod for 8-10 weeks were sacrificed, the anterior pituitaries rapidly removed, bissected, and each hemi-pituitary placed in a perifusion culture system. In addition, hypothalamic fragments from 10L or 16L animals were inserted upstream from some of the hemi-pituitary fragments. The tissue was perfused with medium 199 for 8 hours (Exp. 1) and fractions of the medium collected every 1/2 hour. In addition, some pituitary tissue alone was cultured with a one hour pulse of varying molar concentrations of vasoactive intestinal peptide (VIP; Exp. 2), a peptide which has been shown to have *in vitro* stimulatory effects upon PRL release.

Overall, 10L pituitaries released less PRL into the medium than 16L pituitaries. For 16L pituitaries, co-culture with hypothalamic fragments from either photoperiod did not alter the amounts of PRL detected. However, for 10L pituitaries, co-culture with 16L hypothalamic fragments significantly increased PRL release. In Exp. 2, 16L tissue was more sensitive to higher doses, and 10L tissue was more sensitive to lower doses, of VIP. Potential photoperiod effects upon hypothalamic stimulatory systems will be discussed. Supported by NSF grant IBN9224804.

HYPOTHALAMIC GABA LEVELS FOLLOWING CHRONIC ADMINISTRATION OF SODIUM VALPROIC ACID. Danelle R. Eshelman*, Peter J. Snyder+, Amanda M. Illig, and Lori L. Badura, Behavioral Neuroscience, SUNY at Buffalo, Buffalo, NY and +Division Neurology, Allegheny General Hospital, Pittsburgh , PA.

Sodium valproic acid (VPA) is a widely prescribed anticonvulsant medication that also interferes with normal pubertal maturation in a small subset of the clinical population. In addition, it delays both reproductive and skeletal growth in seizure-prone mice. While VPA is believed to mimic, or potentiate, GABA actions in the CNS, little is known concerning its mechanisms or sites of action. It is presumably via actions on the endogenous GABAergic system that VPA exerts both it's anticonvulsive and anti-reproductive effects. The current study sought to idenitify potential sites of action on the reproductive axis by quantifying GABA levels in tissue selected from various neural regions in normal and VPA-treated animals.

DBA/2J mice were weaned (14 days of age) and placed on a drinking solution containing either VPA (17 mg/kg/day) or normal tap water. At 6 weeks of age, the animals were sacrificed via decapitation, and the brains rapidly removed and frozen at -80ºC. The brains were then thick sectioned (1000 µm slabs) and tissue from the following regions bilaterally microdissected: caudate, medial preoptic area, arcuate nuclei, and the median eminence. The tissue was homogenized, centrifuged, and the resulting supernatant assayed using HPLC optimized for detection of GABA levels following a 2 min derivitization with OPA. The profiles of the normal control animals in comparison with the VPA-treated animals will be reported.

Supported in part by NSF grant IBN9224804 to L.L.B.

704.8

ADMINISTRATION OF SODIUM VALPROIC ACID DELAYS GNRH CELL MATURATION: A MORPHOLOGICAL STUDY. Amanda M. Illig*, Peter J. Snyder+, Danelle R. Eshelman, and Lori L. Badura, Behavioral Neuroscience, SUNY at Buffalo, Buffalo, NY and +Division Neurology, Allegheny General Hospital, Pittsburgh , PA.

Administration of sodium valproic acid (VPA), an anticonvulsant drug with putative GABAergic actions, delays pubertal reproductive and skeletal maturation in seizure-prone inbred DBA/2J mice. This study investigated whether these effects upon the reproductive axis might reflect abnormalities in the morphological maturation of GnRH neurons in the medial preoptic area. Mice were weaned at 14 days of age and placed upon VPA (17 mg/kg/day) or given control solution (normal tap water; CON). The animals were sacrificed at 18, 21, 24, 28, or 32 days of age and the brains removed and immunocytochemically processed for GnRH. The proportion of immature, bipolar fusiform and mature, spiny unipolar neurons was assessed.

There were no significant effects of gender at any age; thus, the gender variable was collapsed for the remaining analyses. Overall, there was a significant increase in the proportion of spiny unipolar neurons across age for both the VPA and CON groups. Furthermore, within each age, except for the 18 day group, the VPA animals had a greater percentage of immature bipolar neurons than the CON group at all ages. These data indicate: 1) VPA exerts anti-reproductive effects upon the neuroendocrine axis at the level of the GnRH neurons themselves, and 2) GABA may play an inhibitory role on normal pubertal maturation. Supported in part by NSF grant IBN9224804 to L.L.B.

704.9

NMDA RECEPTOR DYNAMICS CHANGE WITH STAGE OF SEXUAL MATURITY. K.M. Flynn*[1,2], E. Yablonsky-Alter[3], S.P. Banerjee[1,3], and M.P. Schreibman[1,2]. Graduate School and University Center[1], Brooklyn College[2], and Sophie Davis School of Biomedical Education[3], City University of N.Y., New York, NY 10031.

This study investigated the quantity and affinity of NMDA type glutamate receptors in immature and mature siblings of a freshwater teleost, the platyfish, *Xiphophorus maculatus*. Previous work in our laboratories has localized the NMDA receptor to neuroendocrine areas of the platyfish brain and indicated an age-related increase in the number of active receptors. We now examined broodmates genetically programmed to reach puberty at two distinct ages, an early maturing genotype (EM) that mature at 4-6 months and a late maturing genotype (LM) that mature at 8-12 months. At 7-8 months of age, when EMs were mature but LMs were not, whole brain preparations were assayed for binding of ^{3}H-MK-801, an NMDA antagonist. Results indicated that maximum binding was 2-3 fold higher in mature animals, suggesting an increase in the functional activity of NMDA receptors. In contrast, affinity at the antagonist site was significantly decreased in the mature group, suggesting that perhaps a population of NMDA receptors with different characteristics emerges at sexual maturity. These results imply that alterations in the NMDA type of glutamate receptor are relative to physiological, rather than chronological, age. This is further evidence of a pivotal role for glutamate in the regulation of maturity in *Xiphophorus*. [Supported by PSC CUNY (665214) to SPB and BARD (IS-2149-92) and NASA (NAGW-1704) to MPS.]

RESISTANCE OF GnRH NEURONS TO GLUTAMATERGIC NEUROTOXICITY IN SIBERIAN HAMSTERS. Francis J P Ebling, Anna Cronin and Michael H Hastings*, Department of Anatomy, University of Cambridge, Cambridge CB2 3DY, UK.

Although many studies provide evidence that glutamatergic pathways regulate the secretion of gonadotropin releasing hormone (GnRH) from the hypothalamus, it is controversial as to whether they act *directly* upon GnRH neurons (e.g. Abbud and Smith, Brain Res. 690:117, 1995). The aim of the current study was to determine whether GnRH neurons are susceptible to the neurotoxic actions of specific glutamate agonists [N-methyl-D-aspartate (NMDA) and kainic acid (KA)], the rationale being that neurotoxic loss of GnRH neurons would provide evidence that they possess specific classes of glutamate receptor. Unilateral injections of 1µl NMDA (0.12M, n=2, 0.012M n=4), KA (0.0025M n=3, 0.0005M n=5) or vehicle/sham (n=4) were stereotaxically directed at the preoptic area (mPOA)/ diagonal band of Broca (dbB) in the region of the OVLT of male adult hamsters (*Phodopus sungorus*). The number and appearance of GnRH neurons was determined immunocytochemically 3-8 days later, and alternate 40 µm sections were stained with cresyl violet to determine the extent of the lesions. In pilot studies, both NMDA and KA caused massive loss of neurons when injected directly into cortical areas and striatum. In the experimental studies, there was no significant evidence of neuronal loss within the mPOA or dbB after either toxin, despite clear neuronal loss in areas adjacent to the injection sites including ventral striatum and olfactory cortex. The morphology of GnRH neurons in the vicinity of the injection sites appeared normal after both KA and NMDA. Moreover, there was no significant decrease in the total numbers of GnRH perikarya identified following NMDA or KA treatments. Thus, GnRH neurons are resistant to the excitotoxic actions of both KA and NMDA. It remains to be determined whether this is a common feature of mPOA and dbB cells or a specific characteristic of GnRH neurons. *Funded by BBSRC (UK) project grant 8/A01646 and by The Royal Society*

OVARIAN STEROID HORMONES DIFFERENTIALLY REGULATE EXPRESSION OF AMPA GLUTAMATE RECEPTOR SUBTYPES IN THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS OF THE JUVENILE FEMALE RAT G. B. Gu*, J. H.Yu, M.C. Zee and R B. Simerly, Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

Glutamate appears to be an important regulator of gonadotropin-releasing hormone (GnRH) secretion during pubertal development, but its sites of action remain largely unknown. The anteroventral periventricular nucleus of the preoptic region (AVPV) plays a critical role in mediating hormone feedback on gonadotropin secretion and appears to provide direct inputs to GnRH neurons. Moreover, ovarian steroids regulate phosphorylation of the cAMP response element binding protein (CREB; Gu et al, J. Neurosci. 1996) in the AVPV, which could influence neuronal responses to glutamatergic activation. In this study we used immunohistochemistry and in situ hybridization to study the distribution and hormonal regulation of glutamate receptor subtypes in juvenile female rats. Neurons that express NMDA receptors are abundant in the AVPV, as are cells that express AMPA receptor subtypes (GluR1, GluR2, and GluR3, but not GluR4-7). Treatment of ovariectomized juvenile rats with exogenous estradiol resulted in a 35% increase in GluR1 mRNA and a 50% increase in the ratio of GluR1/GluR2. However, neither levels of GluR3 mRNA, nor the GluR3/GluR2 ratio, were altered significantly by estrogen treatment. Short term (3 hrs.) treatment of estrogen-primed ovariectomized juvenile rats with progesterone also increased GluR1 mRNA levels in the AVPV, but did not alter the GluR1/GluR2 ratio. However, after an additional 24 hrs. the GluR1/GluR2 ratio fell by approximately 30%. These findings suggest that estrogen may facilitate Ca^{2+} influx in the AVPV by inducing the expression of GluR1 and that progesterone may have the opposite effect. Supported by NIH grants NS26723 and RR00163.

704.12

EFFECT OF *N*-METHYL-D-ASPARTATE (NMDA) RECEPTOR BLOCKADE ON PLASMA CONCENTRATIONS OF LH, CORTISOL AND MELATONIN IN ESTROGEN-PRIMED OVARIECTOMIZED RHESUS MACAQUES. V.T. Garyfallou, D.L. Hess, F.K-Y. Pau, J.C. Rosenfeld, G.A. Dissen* and H.F. Urbanski. Oregon Regional Primate Research Center, Beaverton, OR 97006.

In the rhesus macaque (*Macaca mulatta*), activation of NMDA receptors can markedly stimulate LH secretion. However, it is unclear whether these receptors are physiologically involved in the generation of the preovulatory LH surge; if so, their pharmacological blockade ought to perturb the timing of this surge or attenuate its magnitude and duration. In the present study ovariectomized rhesus macaques were given a s.c. injection of estradiol benzoate (EB; 42 µg/ml BW) to induce a preovulatory-like progression of endocrine events. For the next 72 hours, blood samples were collected remotely from a vascular catheter at 4-hour intervals and assayed for estradiol, LH, cortisol and melatonin. As expected, the EB treatment raised plasma estradiol concentration to ~300 ng/ml and this elevation was maintained for at least 24 hours. A plasma LH peak of preovulatory magnitude (i.e. >300 ng/ml) occurred 48 hours after the EB injection and lasted for ~24 hours. In a second experiment, animals received an identical injection of EB but this was followed immediately by an i.v. injection of MK-801 (1 mg/kg BW), a non-competitive NMDA antagonist; a second injection of MK-801 was administered 24 hours later. In addition, the animals received four i.v. injections of CGP43487 (1 mg/kg BW), a competitive NMDA antagonist, once every 12 hours beginning immediately after the EB injection. As expected, plasma cortisol concentrations doubled during the course of the NMDA receptor antagonism but the circadian pattern of melatonin secretion was not affected. Moreover, plasma LH concentrations showed a surge, which in terms of its timing, magnitude and duration was identical to that observed in the control experiment. The failure of pharmacological doses of NMDA receptor antagonists to influence the estrogen-induced LH surge suggests that these receptors are unlikely to play a significant role in triggering ovulation in primates. *(NIH Grants: HD-29186, HD-18185, HD-16631 & RR-00163).*

CLONING, REGULATION, AND NOVEL 5' FLANKING DNA SEQUENCE OF A RAT OXYTOCIN RECEPTOR GENE. T. L. Bale* and D. M. Dorsa.
Depts. of Pharmacology and Psychiatry and Behavioral Sciences, University of Washington, Seattle, Washington 98195

We have cloned and sequenced a novel segment of 5' flanking DNA of the rat oxytocin receptor which may function in transcriptional regulation of this gene. This novel region is 1.2Kb in length and is located between two large tg-nucleotide repeat segments. PCR amplification using genomic DNA verified that this sequence is present in the rat genome. Sequence analysis of this segment revealed the presence of several regulatory elements of interest, including AP-1, AP-2, AP-3, AP-4 sites, a CRE, and a half-SRE. A near palindromic estrogen response element (ERE) was identified within this new sequence, 4Kb 5' of the translational start site. Mobility gel shift assays indicated that this ERE is active in estrogen receptor (ER) binding. In order to identify potential modes of transcriptional regulation of this gene, transfection experiments were carried out in two different estrogen-sensitive cell lines, MCF7 and SK-N-SH. Three different reporter constructs were used for these experiments, including a full length promoter and two truncated versions. Transcription of the full length promoter construct was induced by PMA or forskolin in both cell lines, and a synergistic (17-fold) effect was noted in MCF7 cells treated with both agents. Estradiol had little effect on the full length construct, but weakly induced transcription (1.7-2-fold) of a truncated construct in which the upstream ERE was in closer proximity to the putative transcription start site. These studies have identified a novel region of the rat OR promoter which imparts phorbol ester and/or cAMP inducibility of OR gene transcription. CENTRAL INTEGRATION OF REPRODUCTIVE FUNCTION VIA A NEURAL CONNECTION BETWEEN HYPOTHALAMIC OXYTOCINERGIC AND OVARIAN NEURAXES. B.H. Lee*, E.A. Kim, K.J. Cho, W.S. Choi, S.H. Baik[1], S.R. Ojeda[2] Dept. of Anatomy, Medical School, Gyeongsang Nat'l Univ., [1]Dept. of Anatomy, College of Medicine, Seoul Nat'l Univ., Republic of Korea and [2]Div. Neurosci.,OR Reg. Primate Res. Ctr, Beaverton, OR 97006

The mammalian ovary is innervated by sympathetic and sensory neurons which contribute to regulating several aspects of ovarian function. The existence of a neural connection between central neurons and the ovary able to integrate ovarian activity to broader neuroendocrine responses has long been suspected, but never unambiguously proven. We have now used a viral transneuronal tracing technique combined with a conventional retrograde labeling and double immunofluorescent staining procedures to demonstrate that oxytocin-producing neurons of the hypothalamus are synaptically connected to the ovary and the connection is formed before the onset of puberty. Although this oxytocinergic innervation is seemed to be maintained before and during the reproductive life, the ratios of the oxytocinergic involvement changed depending on the different reproductive status. In conclusion, this neural connection is likely to provide a direct transsynaptic mechanism by which the central nervous system maintains the state of reproduction that accompanies ovulation in mammals.

HORMONAL PARADIGMS ACTIVATING MATERNAL NEST-BUILDING IN OVARIECTOMIZED (OVX) RABBITS MODIFY HYPOTHALAMIC OXYTOCIN IMMUNOREACTIVITY. [1,2]M. Caba, [1]G. González-Mariscal*, [1]C. Beyer. [1]CIRA, CINVESTAV-Universidad Autónoma de Tlaxcala, México and [2]Centro de Investigaciones Biológicas, Universidad Veracruzana, México.

Maternal nest-building in rabbits occurs close to parturition and is regulated by estradiol (E), progesterone (P), and prolactin. The participation of oxytocin (OT) is suggested by our finding that the number and size of OT-immunoreactive (IR) neurons increases in specific hypothalamic regions near parturition. To further support OT participation in maternal nest-building we explored, in ovx New Zealand white rabbits, the impact of hormonal paradigms that stimulate this behavior on hypothalamic OT immunoreactivity. Females received: I. vehicle (oil) for 20 days or estradiol benzoate (EB; 5 μg/day) and progesterone (P; 10 mg/day) as follows: II. EB for 15 days + P from days 2-15 (EB+P group); III. EB for 20 days + P from days 2-15 (EB+P-P group); IV. EB for 5 days (5 EB group); V. EB for 15 days (15 EB group); VI. EB for 20 days (20 EB group). One day after the last injection, females were perfused with paraformaldehyde and 50 μm sections were incubated with the monoclonal antibody AI-28 against OT and reacted with diaminobenzidine. Cell number increased in the paraventricular nucleus (PVN) of EB+P and 5 EB groups (mean±se=262±15 and 284±19, respectively) compared against the oil group (189±19; $p<0.05$). P withdrawal provoked a decline in cell number (EB+P-P group: 220±17; $p<0.01$). Long-term injection of EB did not significantly modify cell number (208±19 and 185±19 in 15 EB and 20 EB groups, respectively) when compared against the oil group. No significant changes in cell number were found in the lateral hypothalamic area or the supraoptic nucleus. Results show that hormonal paradigms which effectively stimulate nest-building in ovx rabbits (groups II and III) increase the number of OT-IR neurons in the same brain area (PVN) where intact peri-parturient females show similar changes.

IN VIVO PROMOTER ANALYSIS OF THE RAT PROGESTERONE RECEPTOR USING AN HSV VIRAL VECTOR. REM Scott*, S Wu-Peng, MG Kaplitt, and DW Pfaff. Laboratory of Neurobiology and Behavior, Rockefeller University, NY, NY, 10021.

Progesterone receptors (PR) mediate the actions of progestin hormones and act in a sex and tissue specific fashion to mediate a number of reproductive functions. An understanding of the regulation of the gene for this receptor is thus of great importance in relationship to reproductive behavior. We have employed a defective herpes simplex viral vector as a gene transfer vehicle, to examine regulation of a lac Z reporter gene under the regulation of a 2.1 kb fragment of the PR promoter containing 1.4 kb of the 5' promoter region and part of the upstream untranslated region as well as part of the coding sequence. This transcription unit was inserted into the HSV amplicon to create the defective viral vector pHPRp. This vector was stereotaxically injected into the rat pituitary as well as the hypothalamus and caudate. Following treatment with estradiol benzoate (EB) (15ug) or vehicle, animals were sacrificed after 24 hours and brain and pituitary were processed for β-galactosidase activity. In the pituitary, the number of blue cells increased 6-8 fold following EB treatment. In addition, an increase in the density of blue staining in individual cells was observed. Further, an increase in the number of blue cells was seen in the hypothalamus following EB treatment. However, very few blue cells were observed in the caudate, and remained unaffected by EB treatment. This is the first in vivo study of PR promoter regulation and demonstrates that 1.4 kb of the 5' region, as well as ~700 bp of the upstream region is sufficient to allow PR expression and for estrogen regulation in the pituitary and hypothalamus. Supported by an Endocrine Research Training Grant #2T32 DK07313 to REM Scott.

MONOAMINES ARE IMPORTANT IN THE INITIATION OF NATURAL SEX REVERSAL

Earl T. Larson* Department of Environmental, Population, and Organismic Biology. University of Colorado, Boulder, CO 80309.

Many species of fishes have behavioral sex determination, where social structure and interactions in the population can induce an animal to change sex. This requires changes along the hypothalamo-pituitary-gonadal (HPG) axis which result in a total reorganization of the gonad. Gonadal sex reversal is preceeded and accompanied by behavioral sex reversal. *Thalassoma duperrey*, the saddleback wrasse, is a protogynous diandric hermaphrodite from the Hawaiian Islands. The majority of animals begin life as female and naturally switch to male when the ratio of males to females in the population becomes low. When experimentally housed in underwater enclosures with other females in the absence of males, the largest female restructures the ovary into a testis in approximately eight weeks. Isolated females do not change sex. Catecholamines have been shown to be important in controlling the HPG axis of vertebrates. Norepinephrine (NE) has a stimulatory role while dopamine (DA) serves an inhibitory role. Isolated females were treated with IP implants of ephedrine (10mg/kg) or maprotiline (5mg/kg), to increase amounts of NE, or treated with haloperidol (3mg/kg) to block DA action. Animals with increased NE underwent sex reversal. Animals with inhibited DA underwent sex reversal at a increased rate. Control and sham animals did not change sex. These results indicate a role for catecholamines in the initiation of natural sex reversal in this species. Supported by NSF dissertation improvement grant IBN-9412077.

HYPOTHALAMIC-PITUITARY DETERMINANTS FOR PHENOTYPIC VARIATION IN ADULT DEER MICE. **K.R.Lavenburg, A.I. Korytko, S.B.Fountain* and J.L.Blank. Dept. Biol. Sci., Kent State Univ., Kent, OH 44242.**

Individual deer mice *(Peromyscus maniculatus)* exhibit genetically-based differences in reproductive response to inhibitory (short) photoperiod. We exploited this animal model to evaluate the roles played by phenotypic differences in 1) pituitary responsiveness (LH release) to GnRH stimulation and 2) KCL-evoked release of GnRH from superfused hypothalamic tissue in mediating phenotypic differences in reproductive response. Male deer mice were exposed to either long day breeding conditions (LD) or 8 wk inhibitory daylength (SD). In one group of mice on either photoperiod, plasma LH was measured following dose-response treatment with GnRH, or saline (control). In a second group of mice, the hypothalamus (MBH/AH/POA) was removed, placed in Dulbecco's Modified Eagle's Medium, and KCL (45mM)-evoked GnRH measured. Data were analyzed for SD-exposed mice that were either hypogonadal (HPGN) or exhibited normal reproductive function (NORM); LD-housed breeding mice served as controls. Compared to controls, SD caused a 20-fold and 4-fold increase in LH release in HPGN and NORM mice, respectively, indicating that SD modifies pituitary sensitivity in both phenotypes, albeit to different extents. Total GnRH release was greater from superfused tissue isolated from HPGN mice (↑184% from baseline) than NORM mice (↑158%). Total GnRH released from both SD phenotypes was significantly greater than that released from LD animals. These results are consistent with previous published findings that hypothalamic GnRH content is greater in both SD phenotypes compared to LD mice and the hypothesis that SD suppresses GnRH release in HPGN mice. Taken together, these results indicate the utility of this animal model for investigating the molecular and cellular antecedents of GnRH and LH release and their relationship to an animal's phenotype.

OLFACTORY BULB RESPONSE TO VCS ACROSS THE ESTROUS CYCLE IN THE RAT: ELECTROPHYSIOLOGY AND C-FOS EXPRESSION.
R. Guevara-Guzmán*, A. Donatti-Albarrán, B. Barrera-Mera and M.L. Weiss†. Depto. de Fisiología, Facultad de Medicina, UNAM. †Dept. of Anatomy and Physiology, College of Veterinary Medicine, KSU, Manhattan, KS.
Olfactory cues play a role in sexual and maternal behavior. In the female rat, afferent input from the vagina and cervix, which is carried by the pelvic, hypogastric and vagus nerves, is important for the display of reproductive behavior. Here, we identified olfactory bulb (OB) structures which express c-fos after vaginocervical stimulation (VCS) and examine electrophysiological responses of olfactory bulb units during VCS in intact female rats at various stages of the estrous cycle. VCS was carried out using a pediatric urinary catheter inserted into the vagina. The estrous cycle was determined by vaginal smear. Fos immunoreactivity in the nuclei of neurons (Fos labeled cells) was visualized by conventional ABC immunohistochemistry using DAB to visualize labeled cells. Within the OB, the main and accessory olfactory bulbs were analyzed. Stage of the estrous cycle had a significant effect upon Fos expression in the main and accessory olfactory bulb (MOB and AOB, respectively) after VCS with many cells in the MOB and AOB of P-E animals compared to M-D animals. Using conventional electrophysiological methods, extracellular firing rate was recorded with a micropipette located in the mitral layer of the MOB. Animals in P-E responded to VCS with an increase of the firing rate in the OB. In contrast, VCS cause a decrease in the firing rate of M-D animals. These results indicate that the estrous cycle plays a role in the regulation of the OB response to VCS. Supported by DGAPA # IN200594 and American Heart Association (Kansas Affiliate).

ENDOTOXIN DISRUPTS THE FOLLICULAR PHASE OF THE ESTROUS CYCLE IN SHEEP. H.B. Krasa, D.F. Battaglia, J.M. Bowen, L.A. Thrun, C. Viguie and F.J. Karsch*. Reproductive Sciences Prog, Dept of Physiology, Univ of Michigan, Ann Arbor, MI.
Bacterial endotoxin, a potent activator of the hypothalamic-pituitary-adrenal (HPA) axis, disrupts GnRH and LH pulsatile secretion in sheep (Battaglia et al.; Soc. Study Repro. Abstr.,1996). Because pulsatile secretion is necessary for normal folliculogenesis, we hypothesized endotoxin would disrupt the follicular phase of the estrous cycle in intact ewes. Beginning 12 hrs after follicular phase onset, endotoxin was infused (n=8, 300 ng/kg/hr) for 26 hrs; non-infused animals (n=8) served as controls. Blood for assay of LH, estradiol (E_2), and cortisol was sampled and estrous behavior was monitored every 1 to 4 hrs. Endotoxin stimulated cortisol secretion during infusion, confirming HPA activation and endotoxin efficacy (endotoxin vs. control; mean serum cortisol during infusion 43±4 vs. 14±2 ng/ml; $p<0.001$). Coincident with cortisol stimulation, endotoxin suppressed the preovulatory E_2 rise (endotoxin vs. control; mean serum E_2 during infusion; 0.8±0.2 vs. 2.2±0.5 pg/ml; $p<0.05$), and delayed both the LH surge and estrous behavior (endotoxin vs. control; interval to LH peak 79±6 vs. 48±3 hrs; $p<0.001$; interval to estrus 74±6 vs. 40±2 hrs; $p<0.001$). Our results support the hypothesis that endotoxin interrupts the follicular phase, suppressing the preovulatory E_2 rise and delaying both the LH surge and estrous behavior. In the future, we will investigate mechanisms by which endotoxin interrupts the follicular phase through inhibiting GnRH and LH pulsatile secretion and/or blocking the estradiol induced GnRH/LH surge mechanism. Supported by NIH HD-30773.

NEURAL-IMMUNE INTERACTIONS: PATHOLOGY

705.1

FETAL ALCOHOL EXPOSURE (FAE) ATTENUATES THE FEBRILE RESPONSE TO CENTRALLY ADMINISTERED INTERLEUKIN-1B (IL-1).
A.N. Taylor*, D.L. Tio, N.S. Heng and R. Yirmiya. Dept. Neurobiology, UCLA Sch. Med., Los Angeles CA 90095; West Los Angeles DVA Medical Center, CA 90073; Dept. Psychology, The Hebrew Univ. of Jerusalem, Mt. Scopus, Israel 91905.
FAE is associated with impairments of immune functions and decreased resistance to infectious agents. We have reported that the febrile and anorexic effects of systemically administered IL-1 are attenuated by FAE, while IL-1-induced depression of locomotor activity and enhancement of pituitary-adrenal activity remain unaffected by FAE in rats. In order to determine whether the effects of FAE on the febrile response occur centrally, we administered IL-1 via a cannula implanted into the lateral cerebral ventricle. Transmitters for biotelemetric recording of body temperature (BT) were implanted i.p. in normal (N) adult male rats, age- and sex-matched offspring of dams fed a liquid diet supplemented with ethanol (35% caloric equivalent) during the last two weeks of gestation (E) and pair-fed control offspring (P). At 2 weeks after surgery, after 24 hr of baseline recording, rats were injected with IL-1 (20 ng) or saline (10 ul) into the ventricle and BT was recorded for an additional 24 hr. IL-1 produced a 1.5-2.0°C increase in BT above saline levels (±37.2°C) in N and P rats, starting at 1.5 hr and persisting to 8 hr following the injection. Body temperature in E rats increased only 0.8°C, significantly less than in the N ($p=0.001$) and P ($p=0.038$) subjects. These results indicate that FAE acts centrally to impair the pyrogenic effects of IL-1, an impairment that may contribute to some aspects of the decreased resistance to infections observed following FAE. AUTOANTIBODIES AGAINST SCHWANN CELLS IN PATIENTS WITH GUILLAIN BARRÉ SYNDROME. A. Görtzen*[1], S. Gruber[1], and R.W. Veh[2]. [1]Neurol.Abt., St.Josef-Hospital, D-46045 Oberhausen and [2]Inst. für Anatomie der Charité, D-10098 Berlin, FRG.

A potential role for autoimmune mechanisms has been repeatedly implicated in the pathogenesis of a large variety of neurological disorders. To investigate possible autoimmune processes in Guillain-Barré syndrome (GBS), sera and/or cerebrospinal fluids from patients with GBS, other neuropsychiatric diseases (amyotrophic lateral sclerosis, multiple sclerosis, schizophrenia) and healthy volunteers were tested for the presence of autoantibodies against brain and peripheral nerve proteins on Western blots and mildly fixed sections from rat, porcine and human central nervous system.

Sera from GBS patients differed from other disease or control sera in their reactivity against glial cells. Positive staining of astrocytes was found in about 60% and immunoreactivity against Schwann cells in 100% of GBS-patients (17 from 17). Similar reactivities were never seen in patients with other neuropsychiatric diseases nor in healthy controls. The question, whether these autoantibodies are involved in the pathomechanism or whether they just represent an epiphenomenon of the disease, requires further investigation.

MHC EXPRESSION IN SYNGENIC AND ALLOGENIC RETINAL TRANSPLANTS IN THE RAT.
J. Larsson, B. Juliosson, B. Ehinger*. Department of Ophthalmology, Lund University Hospital, Lund, Kingdom of Sweden.
Purpose. MHC class I and II are important in the rejection of transplants. Since the eye is immunopriveliged we wanted to find out how the MHC class I and II were influenced by a retinal transplantation and how this could be correlated to rejection of the transplant.
Methods. Fetal neural retinas of SD-rats were implanted in the subretinal space of adult Lewis and SD rats. After 5 weeks the retinas and the transplants were evaluated with antibodies against MHC class I and II and microglia.
Results. In the syngenic transplants almost no upregulation of MHC class I was seen and only a few MHC class II positive cells could be seen. In the allogenic transplants there was a marked upregulation of MHC class I, most pronounced in the subretinal transplant, but also in the host retina. Numerous MHC class II positive cells were seen in the subretinal transplant but also in the host retina. All of these cells were dendritic and had the typical appearance of microglia. In neither of the two groups could any signs of rejection be seen.
Conclusion. Allogenic retinal transplants seem to grow and thrive just as well as the syngenic transplants, but in the former there is a considerable upregulation of MHC class I and II positive cells. There is obviously an adequate reaction against the allogenic transplants but there is also something that modifies the reaction of the immune system at this level and stops the transplants from beeing rejected

SEX DIFFERENCES IN THE METASTATIC-ENHANCING EFFECTS OF STRESS IN PREPUBESCENT RATS
G.G. Page*, S. Ben-Eliyahu and J.S. McDonald. Ohio State Univ. College of Nursing, Columbus, OH 43210.
We recently reported that there are sex differences in the development of both natural killer (NK) cell activity and susceptibility to the metastasis of NK-sensitive tumor cells in rats from prepubescence through maturity. In these studies, we explored possible sex differences in the immunosuppressive and tumor-enhancing responses to stress in male and female prepubescent (pre, 31-36 day old) F344 rats, and compared such responses to those observed in mature male F344 rats (13.5 weeks). A syngeneic mammary adenocarcinoma cell line, MADB106, was used. After i.v. injection, MADB106 cells metastasize only to the lungs, a process known to be controlled by NK cells, but only during the first 24 h after injection. In Exp 1, mature males, and pre males and females were randomly assigned to the surgery (standard abdominal laparotomy under halothane anesthesia), anesthesia only, or control group. At 5 hours after surgery, all animals were injected i.v. with 4×10^5 radiolabeled MADB106 cells/kg and lungs were removed 16 h later to assess their radioactive content. There was a significant age effect such that the pre rats retained a 10-fold greater percentage of tumor cells compared to the mature rats. Although there were significant increases in tumor cell retention in the anesthesia only and surgery groups in the mature males, there were no such effects in the pre males or females. In Exp 2, the procedure for Exp 1 was repeated except that the pre rats received a 10-fold fewer number of radiolabeled MADB106 cells/kg. Again, the pre rats retained a 10-fold greater percentage of tumor cells compared to the mature males. At these tumor doses however, both the mature male and pre female rats manifested a significant surgery-induced increase in tumor cell retention. Although not statistically significant, the pre male anesthesia only and surgery groups exhibited a pattern of stress-induced increases in tumor cell retention similar to the mature male anesthesia only and surgery groups. MODULATION OF INTERLEUKIN-1β BY REPEATED ENDOTOXICIN LIPOPOLYSACCHARIDE TREATMENT IN THE MOUSE BRAIN AND ENDOCRINE TISSUES. I. Nagano, T. Takao*, T. Takemura, S. Makino, K. Hashimoto. Second Department of Internal Medicine, Kochi Medical School, Nankoku 783, Japan

The cytokine interleukin-1 (IL-1) alters a variety of immune, central nervous system and neuroendocrine activities characteristic of an integrator of the brain-endocrine-immune response to stress. In an attempt to define the regulation of IL-1 by repeated endotoxin lipopolysacchride (LPS) in the mouse, we measured levels of IL-1β using commercial available enzyme-linked immunosorbent assay kit in the hippocampus, hypothalamus, adrenal gland and plasma in male C57BL/6 mice. LPS (30 μg/mouse/0.3 ml) or same volume of saline were injected at 24 h intervals for four consecutive days. The mice were divided into four group, i.e., 1) LPS for 5 days (LL); 2) LPS for 4 days and saline on the day 5 (LS), 3) saline for 4 days and LPS on the day 5 (SL), 4) saline for 5 days (SS). The mice were sacrificed by decapitation at 2 h after the last injection. IL-1β levels in the hippocampus, hypothalamus, adrenal gland and plasma were markedly increased in SL compared with SS group. In addition, repeated LPS treatment (LL) induced robust increase of IL-1β in all tissues than LS group. IL-1β levels in SS and LS were unchanged in all tissues examined. Thus, LPS on the 5th day markedly increased IL-1β levels in the tissues and plasma in both saline-repeated and LPS-repeated mice. These data suggest the important actions of the cytokine in mediating the effects of chronic infectious challenge in brain and peripheral tissues.

NORMAL AND LEUKEMIC HUMAN T CELLS EXPRESS MULTIPLE SOMATOSTATIN RECEPTORS. C. El Ghamrawy, B. Horvat, C. Rabourdin-Combe and S. Krantic*. Lab. Bio. Mol. Cell., ENS Lyon, 69364 cedex 07 France

Neuropeptide somatostatin (SRIF) has been reported to either inhibit (I_{max} = 10^{-11}M) or increase (E_{max} = 10^{-8}M) the proliferation of phytohemagglutinin (PHA) stimulated human T lymphocytes *in vitro*. Previous biochemical studies have revealed one subtype of SRIF receptors (Kd = 10^{-8} M) on activated T lymphocytes and two on spontaneously proliferating human leukemic T cells (Jurkat cells) : high-(Kd = 10^{-12}M) and low-(Kd = 10^{-8}M) affinity binding sites. However, on resting T lymphocytes no specific receptor has been described by this method.

In order to characterize the molecular subtypes of SRIF receptors expressed on human T cells, we performed a Reverse Transcriptase Polymerase Chain Reaction (RT-PCR) by using specific primers pairs for the five presently cloned SRIF receptors (SST1-5). We then compared the expression of SRIF receptors on Jurkat cells and on human T lymphocytes from healthy donors. T lymphocytes were obtained by isolation of mononuclear cells from peripheral blood (PBMC) followed by a passage through nylon columms of the PBMC. The effluent cells were more than 80% T cells.

Our results show that at least SST2, SST3, SST4 and SST5 are expressed on Jurkat cells. Such an expression pattern is not modified by the stimulation with PHA (2 μg/mL) and phorbol ester, TPA, (16 nM) for three days. Likewise, we found that both resting and TPA/PHA activated T lymphocytes express SST2-SST5 receptors.

Therefore, in contrast with what was suggested by previous biochemical data, opposite SRIF actions on T lymphocyte proliferation might be mediated by more than two distinct receptors. It remains to be elucidated whether each of these receptors mediates both inhibitory and stimulatory effects of SRIF or rather has a single function.

This research was supported by ARC grant n° 2401 to Slavica Krantic.

EFFECTS OF LEAD ON CELL SIGNALING. S. Razani-Boroujerdi*, B. Edwards, and M.L. Sopori. Immunotoxicology, Institute for Basic and Applied Research, The Lovelace Institutes, Albuquerque, NM 87108.

Lead (Pb) is a ubiquitous environmental contaminant that has been linked to a variety of psychological as well as physiological abnormalities. Pb affects the function of cells from a variety of tissues, including the nervous system, the microvascular endothelium, the kidney, and the immune system. The manner in which Pb affects cellular function is not clear. We have investigated the effects of Pb on cell proliferation and molecules involved in cell signaling using immune cells. *In vitro* administration of Pb (1 ≥ ppm) increases the uptake of [^{3}H]–thymidine and the progression of spleen cells through the cell cycle. Moreover, Pb augments both allogeneic and syngeneic mixed lymphocyte reactions. To understand the molecular basis of these responses, we examined the effects of Pb on molecules involved in proliferation of immune cells. Our results suggest that, Pb causes a significant rise in the intracellular concentration of inositol 1,4,5, trisphosphate (IP_3) in spleen cells. However, unlike the activation of lymphocytes through the antigen receptors, Pb does not significantly stimulate protein tyrosine kinase (PTK) activity. These observations suggest that Pb, at the concentrations used (1 to 50 ppm), is a stimulatory molecule for lymphocytes. However, this stimulation may activate a signaling pathway(s) independent of the antigen-receptor.

ENDOCRINE STATUS AND MAST CELL NUMBERS IN THE BRAINS OF FEMALE PRAIRIE VOLES. L.J. Kriegsfeld* and R.J. Nelson. Department of Psychology, Behavioral Neuroendocrinology Group, The Johns Hopkins University, Baltimore, MD 21218.

Mast cells are immune cells found in peripheral tissues as well as in the central nervous system. Mast cells are capable of secreting a wide variety of substances including neurotransmitters, biogenic amines, and proteoglycans. A number of factors, including neurotransmitters and steroid hormones, can act on mast cells to cause them to release their contents. Because steroid hormones and neurotransmitters can act on mast cells to cause the release of their mediators, mast cells may represent a unique opportunity to study the interaction among the nervous, endocrine and immune systems.

Recently, it was discovered that mast cells displaying gonadotropin-releasing-hormone-like immunoreactivity (GnRH-ir) move into the central nervous system (e.g., habenula) of male ring doves (*Streptopelia roseogrisea*) following a brief period of courtship. These data suggest that endocrine status may affect mast cell numbers. Based upon this finding, we sought to determine if mast cell numbers increase in discrete brain areas of female prairie voles (*Microtus ochrogaster*) following induction of estrus. Female prairie voles do not exhibit spontaneous estrous cycles. Instead, they are induced into estrus by chemosensory cues found in male urine. Prior to being induced into estrus, female voles have extremely low circulating levels of luteinizing hormone (LH) and estrogen. After exposure to conspecific males, or male urine, female voles experience a rapid increase in serum LH and estrogen levels. In the present experiment, female voles were exposed to either male urine, non-fat dry milk, or water for six days, or were unmanipulated. Brains were removed on the seventh day, sectioned, and stained with toluidine blue. Females exposed to male urine had increased mast cell numbers in the medial habenula and olfactory bulbs relative to control animals exposed to water. There were no differences in mast cell numbers seen in the hippocampus among groups. These data suggest that mast cells may be involved in estrus induction of female prairie voles. Supported by USPHS grant HD22201.

DTH KINETICS TO CSF-ADMINISTERED ALBUMIN IN THE BALB/C MOUSE. JT Park[1], CJ Harling-Berg[2], and PM Knopf*[2], Depts. of Physiol[1] and, of Molec Microbio & Immunol[2], Brown Univ, Providence, RI 02912. (Support: NIH-NS33070)

Previously this laboratory has focused on humoral immune responses to CNS-administered antigens in a rat model with normal blood-brain barrier permeability (Cserr & Knopf, 1992). The CSF route was more immunogenic, inducing significantly higher and persistent antigen-specific serum antibody titers than other routes. We have adapted our techniques to mice to take advantage of the availability of murine immuno-reagents and to characterize the delayed-type hypersensitivity (DTH) response elicited by CNS-administered antigen. In initial studies we detected serum antibody but no peripheral DTH response to a single antigen dose (50ug ovalbumin in 2.5ul) microinfused into CSF. To assess the immune status after a single dose of antigen, we utilized a standard challenge protocol, widely used by those studying immune privilege of the eye. Mice were pretreated with 50ug HSA in 2.5ul saline via CSF or SC (subcutaneous) routes or not pretreated (naive control), and all groups subsequently challenged with an immunizing dose of HSA in adjuvant. A standard ear swelling assay was performed 10 days postchallenge. Serum samples were collected just prior to challenge to assess the humoral response by ELISA. Three pretreatment periods were tested (4, 7, and 14d) to compare kinetics of DTH relative to humoral responses. In 7d SC-pretreated mice, there was significant priming for DTH responses ($p<0.001$) above naive and CSF-pretreated, both which respond. Thus, CSF pretreatment does not significantly prime for nor does it suppress peripheral DTH. The CSF route elicits significantly greater antigen-specific serum antibody responses ($p<0.001$). DTH and antibody responses follow the same trends for the 4d and 14d pretreated groups. These results continue to support the CNS route of administration as preferentially generating a humoral response. However, unlike immune privilege in the eye we find no evidence to support suppression of peripheral DTH in response to CSF-administered serum albumin in the Balb/c mouse.

FLUORESCENT LABELING OF OPIOID RECEPTORS ON FEMALE RAT SPLENIC LYMPHOCYTES: EFFECTS OF *IN VITRO* ETHANOL EXPOSURE. L.C. Band*, T.Y. James and J.R. West. Department of Anatomy and Neurobiology, Texas A&M University, College Station, TX 77843-1114.

Ethanol exposure, both prenatally and in alcoholics, is associated with immune system abnormality and increased susceptibility to infection. The activity of opioid systems have been shown to alter various immune parameters and is thought to mediate a variety of ethanol effects. In order to investigate possible opioid mechanisms for alcohol effects on immunity, we have examined the influence of ethanol administered *in vitro* on opiate fluorescence on splenic lymphocytes.

Naloxone-fluorescein, which labels the three major classes of opioid receptors, was incubated with cell suspensions prepared from the spleens of adult female rats. Flow cytometry was used to determine the proportion of lymphocytes showing greater fluorescence than was observed in the presence of excess unconjugated naloxone (positivity). Splenic lymphocytes displayed dose-dependent, saturable positive labeling, maximal at a 75 μM concentration. Co-incubation for four hours with ethanol concentrations comparable to levels observed in blood following light to heavy drinking reduced positive fluorescence: lymphocytes treated with 1-100 mM ethanol showed corresponding (36-56 %) mean reductions in positivity. The data suggest that ethanol consumption may directly alter opiate-receptor expression on lymphocytes.--supported by AA05523/NIAAA

DEPRENYL PARTIALLY RESTORES THE AGE-RELATED LOSS OF SYMPATHETIC NORADRENERGIC INNERVATION IN THE SPLEENS OF F344 RATS. S. ThyagaRajan*, S.Y. Felten and D. L. Felten. Department of Neurobiology & Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Our laboratory has demonstrated the influence of noradrenergic (NA) fibers in the spleen and lymph nodes (LN) on cell-mediated immune responses. Such responses are diminished in young animals following experimental sympathectomy and in older animals accompanying a decline in the NA fibers in the spleen and LN. The purpose of this study was to determine whether treatment with deprenyl, an irreversible MAO-B inhibitor, will hasten the process of splenic reinnervation in chemically sympathectomized (SyX) young rats and reverse the age-related loss of sympathetic NA fibers in the spleen of old rats. To examine the effects of deprenyl in young SyX rats, 3 mo-old male F344 rats were treated with 6-hydroxydopamine and administered 0, 0.25, 1.0, 2.5, or 5.0 mg of deprenyl/kg BW for 1, 15, or 30 days. In another study, 21 mo-old male F344 rats were treated with 0, 0.25, or 1.0 mg of deprenyl/kg BW for 9 weeks. At the end of the treatment period, spleens were removed and stored for histofluorescence, immunocytochemistry, and measurement of norepinephrine (NE) by HPLC. In the spleens of both the young SyX and old rats, deprenyl treatment revealed a moderate to intense fluorescence around the central arteriole and in the periarteriolar lymphatic sheath of white pulp. In contrast, young SyX and old rats treated with saline showed severe loss of such innervation compared with young unlesioned animals. Deprenyl treatment in both the age groups revealed punctate and linear tyrosine hydroxylase-positive fibers around the central arteriole and in other compartments of the white pulp of the spleen. The concentrations of NE in the spleens of young SyX rats showed a tendency to increase due to deprenyl treatment in comparison to SyX saline-treated rats. In old rats, deprenyl treatment increased the concentration of NE in the hilar region of the spleen. The results from these two experiments provide evidence for neurorestorative properties of deprenyl on sympathetic NA innervation of the spleen. ALTERATIONS IN SYMPATHETIC INNERVATION OF THYMUS IN AGED MICE. M. E. Maida, K. S. Madden* and D. L. Felten. Department of Neurobiology and Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, NY USA

The present study examines the role of noradrenergic (NA) innervation in thymic T cell development in 2-month to 24-month BALB/c mice histologically, neurochemically and immunologically. In the thymus of 2-mo animals, NA fibers, detected by fluorescence histochemistry for catecholamines, distribute along blood vesssels and intralobular septa to subcapsular, cortical, medullary and cortico-medullary vascular regions. Only sparse fibers were observed in the parenchyma. With increasing age and thymic involution, NA plexuses progressively increased in density, with a significant number of fibers found traversing the parenchyma, including cortical regions. Thymic norepinephrine (NE) concentration (per mg wet weight) showed a three-fold increase in 12-mo vs. 2-mo animals and a 10-fold increase in 24-month vs.. 2-month animals. Total thymic NE (per thymus) remained constant across age groups, suggesting that NA innervation is maintained as the thymus involutes. In young animals, compartmentation of NA innervation suggests that NE may primarily influence migration and proliferation of stem cells in the subcapsular region, and proliferation and emigration of mature T cells in the cortico-medullary junction. Receptor-ligand binding studies from our laboratory indicate ß-adrenoreceptors on unfractionated thymocyte populations are not detectable at any age. This finding suggests that cortical CD4+CD8+ T cells, which comprise 80% of the thymocyte population, do not express the number of ß-adrenoreceptors that mature T cells express. Others have shown that single positive T cells in the thymus do possess detectable ß-receptor expression and that NE in the thymus can suppress proliferation and enhance differentiation. The increase in density of NA innervation with age suggests that NE may have a progressively greater influence on thymocyte maturation as the animal ages. NE may contribute to the thymic microenvironment in T cell selection in the thymus.

TUFTSIN IN CENTRAL NERVOUS SYSTEM OF MAMMALS: MYTH OR REALITY. I.A.Grivennikov*, E.L.Arsenieva, O.V.Dolotov, I.Yu.Nagaev, V.N.Nezavibat'ko, V.I.Skvortsova, D.A.Zaitzev, N.F.Myasoedov. Institute of Molecular Genetics RAS, Moscow 123182, Russia.

It is known that tuftsin (Thr-Lys-Pro-Arg) which represents a fragment of heavy chain of immunoglobulin G (residues 289-292) can influence on some functions of CNS of mammals. Recently we have shown the presence of two binding sites for tuftsin in the brain. To elucidate the presence of this peptide in CNS we tried to detect it in cerebrospinal fluid (CSF). CSF was received from healthy human volunteers in aseptic conditions. Usually 4 mL of CSF was lyophilized and then dissolved in 100 µL of 0.2% trifluoroacetic acid (TFA). Tritium labelled tuftsin (65 Ci/mmol) was synthesized and added (10 µCi) to solution as a reference. This solution was applied on Superose 12 column and then eluted by 0.2% TFA. Fractions containing radioactivity were pooled, lyophilized and applied on Hibar 100-RP column (4.6x250 mm, Merck, Germany). Chromatography was carried out in gradient of methanol 20-80% in 20 mM sodium octansulfonate. Fractions containing radioactivity were pooled and lyophilized. Analysis of these fractions by amino acid analysis revealed the presence of four amino acids: Arg, Lys, Pro, Thr. The presence of tuftsin in the samples of CSF was confirmed by the determination of amino acid sequence. The quantity of tuftsin in our samples as determined by isotopic dilution varied from 400 to 500 µg/mL. Monoclonal antibodies to this peptide was obtained to develop method for its detection in CSF and other biological fluids in normal and pathological conditions. Our data suggest that tuftsin is really exists in CSF of humans and can influence on some functions of CNS. (Supported by ISF N69000 & N69300 and RFFI 96-04-49025).

REVERSIBLE CONDUCTION BLOCK OF RAT SCIATIC NERVE BY NITRIC OXIDE GENERATING COMPOUNDS. A.W. Custer, D. Mattson and P. Shrager*. Neuroscience Graduate Program, Box 603, Univ. of Rochester Medical Center, Rochester, NY 14642

Nitric oxide (NO) is a free radical produced in response to pro-inflammatory cytokines by activated macrophages, and is thought to be pathogenic in autoimmune diseases. We have tested for the ability of NO to alter conduction in peripheral nerve axons. Sciatic nerves from female Lewis rats were dissected and mounted with the sheath intact in a chamber fitted with pairs of platinum wires for stimulation and recording of the compound action potential (CAP). We applied diethylamine NONOate (DEA-NONOate) to nerves at concentrations of 62 - 2400 μM. At 620 μM the CAP declined in amplitude at 20°C by about 30% in 10-15 min. When the temperature was raised to 37°C, which increased NO release 6-9 fold, the CAP was reduced to zero in 4-5 min. The CAP was restored almost 100% on washing with Locke's solution. Diethylamine (DEA), the precursor and also breakdown product of DEA-NONOate had no effect with a similar protocol. Other NO generating compounds, such as SNAP, SIN-1, and SNP, used in various combinations of slow and fast generators, also reversibly reduced the CAP. NO may thus contribute to loss of function in central and peripheral demyelinating diseases. Supported by NIH and The National Multiple Sclerosis Society.

GM-CSF INTERFERES WITH SCOPOLAMINE-INDUCED AMNESIA IN THE MOUSE : INVOLVEMENT OF INTERLEUKIN-1, Mauro Bianchi, Paola Sacerdote*, Antonio Clavenna and Alberto E. Panerai. Dept. Pharmacology, University of Milano, Via Vanvitelli, 32, 20129 Milano, Italy

Several mediators released from activated immune cells affect brain functions. In this line, we previously observed that the peripheral administration of interleukin-1$_\alpha$ (IL-1) interferes with scopolamine-induced amnesia in mice. A large number of cytokines has been produced by recombinant DNA technology and are available for therapeutic use. Among them, Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF) has been recently approved for clinical use. In the human, it has been observed that the peripheral administration of GM-CSF induces some neurological effects, including lethargy and mental confusion. However, the mechanisms underlying the interaction of this cytokine with brain functions has not been investigated yet. We studied the effects of GM-CSF on the classical behavioral test of scopolamine-induced amnesia for a passive avoidance response in the mouse. The pre-training, peripheral, administration of this cytokine (1.25 to 10 µg/mouse) reduced the amnesic action of scopolamine (1.0 mg/kg i.p.). The administration of the specific IL-1 receptor antagonist (50 µg/mouse i.p.) blocked the effect of GM-CSF. These results suggest that GM-CSF participates, via IL-1, in the modulation of central nervous system functions. Since we previously showed that IL-1$_\alpha$ reduced the hippocampus levels of different amino acids, we are now investigating whether GM-CSF induces similar biochemical modifications at central level .

NALTREXONE ALTERS LIPOPOLYSACCHARIDE INDUCED NITRIC OXIDE SYNTHASE EXPRESSION IN SPLENOCYTES Gabrielle M. Schneider, Donald T. Lysle*. Dept. of Psychology, Univ. of North Carolina, Chapel Hill, NC, 27599.

We hypothesized that the LPS-induced nitric oxide response is modulated through the activation of endogenous opioids. Our prior work *in vitro* has shown that opioids modulate nitric oxide production, and the current work extends this investigation by examining the effect of opioids on LPS-induced nitric oxide production *in vivo*. To determine the parameters of LPS-induced nitric oxide production, the dose and time course were investigated. In the dose response study, LPS was injected in doses of 0, 1, 10, 100 and 1000 µg/kg. In the time course study of inducible nitric oxide synthase (iNOS) expression in response to LPS, animals were sacrificed at 0, 2, 4, 8 and 16 hours post LPS injection. It was found that the maximum effect occurs at 100 µg/kg and that both mRNA and protein expression were detectable at the 4 hour time point, with the peak expression occurring at 8 hours.

To evaluate the involvement of endogenous opioids, the opioid antagonist naltrexone was administered at 0, .1, 1 or 10 mg/kg subcutaneously in combination with LPS. The results from this study show that iNOS mRNA and protein expression are reduced in a dose dependent manner by naltrexone. Given that our laboratory has determined that modulation of nitric oxide via opioid pathways involves central opioid receptors, further studies are in progress to investigate whether endogenous opioids acting centrally alter iNOS mRNA and protein expression in response to LPS. N-methylnaltrexone will be administered intracerebroventricularly to determine the role of the central nervous system in the modulation of nitric oxide production *in vivo*. This research expands our knowledge of nitric oxide and extends our examination of the central nervous system's role in modulating nitric oxide production.

STRESS RESPONSE TO ANTIGENIC CHALLENGE: SEX DIFFERENCES REFLECT THE MATING SYSTEM OF THE SPECIES. S.L. Klein* and R.J. Nelson. Johns Hopkins Univ., Dept. of Psychology, Behavioral Neuroendocrinology Group, Baltimore, MD 21218.

Detection of antigenic stimuli by the immune system constitutes a stress response (i.e., increases glucocorticoid secretion and sympathetic activity). The degree to which males and females respond to stressful stimuli may depend on their life histories. For example, polygynous males of many species are subjected to extreme stressors associated with the competition for mates. These "competition" stressors are generally reduced among monogamous males and females of both polygynous and monogamous species. The purpose of the present study was to determine whether sex differences in response to antigenic challenge are dependent on the mating system of the species. Male and female meadow voles (i.e., a polygynous species) and prairie voles (i.e., a monogamous species) were immunized with 150 µg of KLH and blood samples were obtained on days 0, 5, 10, and 15 post-immunization. Sex differences in humoral immunity were only observed among the polygynous meadow voles, in which males produced more anti-KLH IgM than females. No sex differences were observed among either species in production of anti-KLH IgG. We speculated that steroid hormones may underlie the observed sex difference in humoral immunity among the polygynous, but not the monogamous species. Serum estradiol levels did not differ between female meadow and prairie voles, or between pre- and post-immunization samples for either species. Serum testosterone levels declined from pre- to post-immunization samples among male meadow voles, but not among prairie voles. Because antigenic stressors have been reported to suppress reproductive hormones in polygynous species (e.g., rats and mice), we speculate that testosterone levels among male meadow voles were inhibited by the antigenic challenge and suppressed testosterone levels may be responsible for the observed elevated humoral response. We hypothesize that the inhibition of androgens following immunization among polygynous males may not reflect a "stress response", *per se*; rather, post-immunization androgen suppression may reflect an adaptive physiological response to cope with the high androgen levels necessary to maintain reproductive fitness among polygynous males. UP-REGULATION OF DELTA OPIOID RECEPTOR IN THE DORSAL LATERAL GENICULATE NUCLEUS AFTER VISUAL CORTEX ABLATION IN THE NEONATAL RAT. MJ De Rosa*[1], B Anton[2], C Evans[2] and P Levitt[1]. Dept. Neuroscience and Cell Biology, University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, Piscataway, NJ, 08854[1] and Dept of Psychiatry and Biobehavioral Sciences, UCLA Med. Sch., Los Angeles, Ca 90024[2].

Several studies have demonstrated the effectiveness of opioid receptor (OR) antagonists in preserving neurologic function following head trauma, although the mechanism of these protective effects is not clear. Previous studies in our laboratory have used aspiration of the visual cortex and the concomitant retrograde cell death affecting the lateral thalamus to study immune cell migration into the central nervous system following traumatic injury. These studies demonstrated that an opioid-like peptide is released by affected thalamic cells and that the migration of macrophages activated by exposure to conditioned media from lesioned animals is inhibited by OR antagonists. In the present studies, animals were lesioned on postnatal day 1 (P1) and sacrificed after three days. Immunohistochemical analysis of the brains using antigen affinity-purified antibodies directed against *delta* and *mu* OR demonstrated upregulation of the *delta* OR but not the *mu* OR. The *delta* receptor-like immunoreactivity was evident in the affected region of the lateral thalamus ipsilateral but not contralateral to the lesioned cortex. In addition, antibody labelling with the macrophage marker ED-1 and the astrocyte intermediate filament GFAP failed to demonstrate *delta* OR co-localization with either marker. This suggests that the dying neurons in the dorsolateral thalamus may express the *delta* OR. The receptor expression may play a role in the homing of macrophages to the area or the clearing of cellular debris.

REGULATORY AUTOANTIBODIES (AB) DURING NEUROPSYCHIATRIC DISORDERS.

A.B.Poletaev*,S.G.Morozov[2], N.K.Vabishevich, B.B.Gnedenko,I.A.Zavalishin[3] T.I.Demidenko[3] Fund "Chernobyl-Test", Moscow, [2]Res.Ctr. of Psychiatry & Narcology, Moscow, [3]Res.Inst. of Neurol.,Moscow, Russia.

Background: Evidences are being accumulated, that serum immunoreactivity (IR) to some self-AGs is important physiological characteristic, and its suprathreshold rise as well as declining could be causally related to different forms of pathology. IR deviations may depend on the partial levels of AG-specific idiotypic (AB1) and their antiidiotypic (AB2) counterparts. **Results:** It was found out,that concentrations of AB1 to the brain proteins S100, GFAP, NAP, MP65 (two last are members of integrine superfamily), and ACBP (chromatin's acidic protein), and specific AB2 in healthy adults are surprisingly constant and may change individually at relatively narrow limits. In patients' sera the notable changes of AB1 and AB2 and frequent disbalance between AB1 and AB2 IR are typical. For example, the prominent depression of AB2/AB1 rate in the system of AB to S100 and to GFAP was observed in most cases of epilepsy. In drug-addictors the sharp increase of general IR of AB1 to S100, GFAP, MP65, ACBP and NAP and the proportional increase of IR of AB2 were revealed. In multiple sclerosis the elevation of IR of AB1 to S100, to GFAP and to MP65 was accompanied by the relative decrease of the corresponding AB2 IR. In patients with Parkinson's disease there was found a rise of AB2 counterparts of AB1 to GFAP. The most often feature of schizophrenic patients was a depression of AB2 counterparts of AB1 to S100, to GFAP and to NAP in combination with sharp increasing of IR of AB1 to MP65. **Conclusion:** Different neuropsychiatric diseases are characteri-zed (in general) by peculiar changes in the humoral immunity and especially in the AB1/AB2 rates. Not only increase, but also the abnormal decrease of the serum IR (comparatively to normal values) are often features of such diseases.

NEURAL-IMMUNE INTERACTIONS: INFLAMMATION

706.1

TIME-COURSE OF KYNURENINE-PATHWAY ENZYMES mRNA LEVELS UPON INTERFERON-γ IN HUMAN MONOCYTE/MACROPHAGES (MΦ). M.Mostardini, R.G.Ferrario, C.Caccia, C.Speciale and L.Benatti*. Pharmacia & Upjohn, CNS Research, Nerviano (MI), Italy.

The induction of indoleamine 2,3-dioxygenase (IDO) and other kynurenine-pathway enzymes has been suggested to cause the accumulation of quinolinic acid (QUIN) in the brain and blood of patients with a broad spectrum of inflammatory neurological deseases. MΦ have been proposed as one of the most important source of QUIN synthesis. Using human MΦ we previously reported that 72h interferon-γ (IFN-γ) stimulation caused a strong induction of IDO activity, whereas no changes were observed in the activity of kynurenine 3-hydroxylase and the 3-hydroxykynureninase (3-OH-KYNase). Aim of the present study was to explore in human MΦ both the IDO mRNA expression and the change of IDO activity at different time (2, 8, 24 and 72h) after IFN-γ stimulation in comparison to time-matched untreated cells. An increase of IDO mRNA levels was detected very early (at 2h: ~150% treated vs control) reaching the maximum increase at 72h (~200% treated vs control). The IDO activity was progressively increased starting from the 8h, only in the treated cells, (5, 80 and 300 nmol/h/mg protein at 8, 24 and 72 h, respectively), whereas in control cells was only 2 nmol/h/mg at 72h. We also evaluated the activity and the mRNA expression of the recently cloned 3-OH-KYNase (Toma et al., Soc. Neurosci., 1995). 3-OH-KYNase mRNA levels were increased only at 2h in treated MΦ (~200% vs control), whereas the activity was not modified neither by IFN-γ stimulation nor by the time of culture. In conclusion IFN-γ, a cytokine produced upon immunological stimulation and capable to induce changes in cellular gene expression, caused in human MΦ a time-dependent induction of the IDO activity that we showed to be related to an increase of mRNA levels. This induction might play a crucial role in the activation of the kynurenine pathway in CNS inflammatory diseases.

HUMAN MONOCYTES/MACROPHAGES (MΦ) AS A TOOL FOR STUDYING KYNURENINE PATHWAY METABOLISM. R.G.Ferrario, S.Cavanus, N.Carfagna, E.H.F.Wong*, C.Caccia and C.Speciale. Pharmacia & Upjohn, CNS Research, Nerviano (MI), Italy.

The accumulation of quinolinic acid (QUIN), a neurotoxic metabolite of the kynurenine pathway, has been observed during inflammation-based neurodegenerative processes. Indeed interferon-γ-activated human MΦ can synthesize QUIN, thus they provide a tool to study the metabolism of QUIN in human-derived specimen. During our studies on the modulation of the kynurenine pathway as a strategy for neuroprotection, we tested the novel kynurenine 3-hydroxylase (KYN 3-OHase) inhibitor, (R,S)-3,4-dichlorobenzoyalanine, FCE 28833A, on the human MΦ enzyme activity. The calculated IC_{50} of FCE 28833A and its correspondent R- and S- enantiomers, FCE 29196A and FCE 29191A were 0.35, 8.0 and 0.12 µM, respectively. These values were comparable to the ones determined on rat tissues (Varasi et al., this meeting), proving a similar pattern of inhibition in tissues from two different species. A method for the evaluation of QUIN production in human MΦ from supplied ^{3}H-kynurenine (^{3}H-KYN) was set up. ^{3}H-QUIN was measured both intra- and extracellularly by HPLC coupled to a radiochemical flow detector. ^{3}H-QUIN production was dependent on the concentration of ^{3}H-KYN added to the culture medium (100 nM in routine experiments), and consistent with the linear correlation between cell density and QUIN synthesising enzymes activity (KYN 3-OHase, and kynureninase) previously established (r=0.97 for both extra- and intracellular QUIN). In incubations lasting from 0.5 to 5h, a progressive increase of newly produced ^{3}H-QUIN was selectively detected in the medium (from 0.76 ± 0.08 to 19.6 ± 4.0 pmoles/mg protein, n=6). In experiments testing the pharmacological modulation of QUIN metabolism, 4-chloro-3-hydroxyanthranilate (10^{-5} M) as expected prevented its formation. Studies using KYN 3-OHase inhibitors will evaluate their effects on QUIN production in human MΦ.

706.3

TEMPORAL AND SPATIAL CHANGES OF QUINOLINIC ACID IMMUNOREACTIVITY IN THE HIPPOCAMPUS FOLLOWING TRANSIENT FOREBRAIN ISCHEMIA. S.Barattè, A.Molinari*, O.Veneroni, L.Dho, C.Speciale, L.Benatti and P.Salvati. Pharmacia&Upjohn, CNS Research, Nerviano (MI), Italy.

Quinolinic acid (QUIN) is an endogenous L-tryptophan metabolite with NMDA-like agonistic properties. QUIN is normally present in the brain in nanomolar concentration, although several reports have shown dramatic increase of QUIN levels in the brain following degenerative and inflammatory disorders. In the present study we investigated the cellular localization of QUIN immunoreactivity in the gerbil brain at different times after the neurodegenerative events caused by 10 min bilateral carotid artery occlusion. A new polyclonal antiserum against QUIN was raised in New Zealand rabbits using both protein coupled and gold adsorbed QUIN as immunogen. A competitive solid-phase ELISA assay system was developed to evaluate the efficiency of several potentially interfering compound to displace the binding of the antiserum to the protein-coupled QUIN. Only QUIN resulted active, therefore the antiserum was used without further purification. One, two, four, seven and fourteen days after ischemia, gerbils were anaesthetized and perfused transcardially with a fixative containing 6% carbodiimide. QUIN positive cells were immunohistochemically tagged on frozen cryostat tissue sections using the ABC-peroxidase method. Neurodegeneration was evident in the CA1 and CA2 areas of the hippocampus 4, 7, 14 days after ischemia. QUIN positive cells with microglia-like morphology appeared in the CA1 pyramidal cell layer 4 days after ischemia and extended to the CA2 area at 7 days. QUIN positive cells disappeared at 14 days. Neither neurodegeneration nor QUIN positive cells were detected in sham-operated animals and in ischemic gerbils at 1 and 2 days after ischemia. These findings indicate that microglia-like cells, infiltrating CA1 and CA2 areas of the hippocampus, represent the major source of QUIN synthesis following transient ischemia in the gerbil.

EVALUATION OF A γ34.5 MUTANT OF HERPES SIMPLEX VIRUS (HSV) TYPE 1 AS A VECTOR FOR GENE THERAPY IN THE BRAIN

M.Mary McMenamin[1], Andrew P Byrnes[1], Fenella G Pike[1], Harry M Charlton[1], Alasdair R MacLean[2], S Moira Brown[3] and Matthew J A Wood[1]. [1]Department of Human Anatomy, University of Oxford, South Parks Road, Oxford, OX1 3QX. [2]Division of Virology, University of Glasgow, Institute of Virology, 1 Church Street, Glasgow, G11 5JR; [3]Neurovirology Research Laboratories, Department of Neurology, Southern General Hospital, Glasgow, G51 4TF. SPON: Brain Research Association

Direct injection of viral vectors into the CNS is of value for exploring neural function and as a potential therapy for neural disease. A number of HSV-derived vectors are now being developed for the introduction of foreign DNA into the brain. In this study, we stereotaxically inoculated 10^6 pfu of a non-neurovirulent HSV strain 17 mutant (1716), deleted in the γ34.5 gene, into the CNS of AO rats and C3H mice. In this virus, the β-galactosidase marker gene was expressed under the control of the LAT promoter. We demonstrate that 1) at the site of injection in the striatum, β-galactosidase expression was minimal at all times studied (6 hours to 30 days post injection). 2) There was limited β galactosidase expression at distant sites which contain neurons projecting directly to the site of injection with expression being maximal at 1-2 days and undetectable by one week post injection. 3) Immunostaining with a polyclonal anti-HSV and an anti-UL42 antibody demonstrated that viral gene products could be detected at the injection site as early as 6 hours and up to one week and, also, at several secondary sites not all of which have direct connections with the injection site. 4) In brain sections of rats there was evidence of significant inflammation several days after injection with a proportion of rats showing signs of clinical illness. These findings suggest that γ34.5 negative vectors may require further attenuation before use for gene therapy in the brain. *This work was supported by the Medical Research Council, UK.*

INTERACTIONS BETWEEN EPIDERMAL NERVE FIBERS AND LANGERHANS CELLS: EFFECTS OF DENERVATION ON THE PHENOTYPES OF LANGERHANS CELLS. H.F. Chien, S.-T. Hsieh, Y.B. Li, J.C. McArthur, J.W. Griffin*, Johns Hopkins University School of Medicine, Baltimore, MD 21287

A previous study (Hsieh et al., J. Neurocytol., in press) showed that denervation of the skin produced changes in the epidermis. To investigate the structural relationship between epidermal nerve fibers and Langerhans cells (LC) in the normal glabrous skin of rat foot, we performed double labeling of LC with MRC OX6 (MHC II or Ia Ag) antibody and epidermal nerve fibers with ubiquitin carboxyl terminal hydrolase (protein gene product 9.5 [PGP]) or calcitonin gene-related peptide (CGRP) antibodies. We found that most of PGP (+) nerve fibers were clustering around or impinging on LC. CGRP(+) fibers also had similar pattern in relation to LC, although they were only 20-30% of the total nerve fibers stained with PGP. To ask what changes in LC might be produced by denervation, we evaluated the number and morphology of LC stained with PGP, MRC OX6, and MRC OX1 (leukocyte common antigen) antibodies in the denervated epidermal sheets at 2 d, 7 d, 14 d, and 20 d (N=4, each) after sciatic nerve transection. We observed that the staining intensity of LC by PGP increased after denervation. In addition, there was an increase in the number of round-shaped non-process-bearing MRC OX1(+) LC, especially in 7 d and 14 d groups. We speculated that the increased PGP immunoreactivity reflected increased antigen-presenting function of LC after denervation, since ubiquitin was involved in antigen processing. The increased number of round-shaped LC at the basal layer of epidermis implied more LC traffic across derma-epidermal junction. We concluded that the epidermal nerve fibers are closely related to LC and denervation can induce change of LC phenotypes.

(This study was supported by NIH grant NS14784)

CAPSAICIN-SENSITIVE FIBERS INFLUENCE EPIDERMAL LANGERHANS CELL PHENOTYPE. E. Rowe*, H.F. Chien, Y.B. Li, S.-T. Hsieh and J.W. Griffin, Johns Hopkins University School of Medicine, Baltimore, MD 21287

There is abundant Aδ and C-fiber innervation of epidermis. In addition to their sensory role, it is hypothesized that these fibers have an effector role in the maintenance of epidermal tissue. Recently, denervation of rat skin by sciatic nerve transection has been shown to produce changes in the epidermis (Hsieh et al., J. Neurocytol., in press). This suggests that these Aδ and C-fibers play significant roles in influencing keratinocytes and the phenotypes of Langerhans cells. After sciatic nerve transection, the thickness of the epidermis decreases and Langerhans cells produce both transcripts and gene product of neuronal ubiquitin carboxyl terminal hydroxylase (PGP 9.5). These previous studies have left unresolved the identity of the nerve fibers involved in these effects.

To ask if the changes in epidermal thickness after sciatic nerve transection are due to the loss of capsaicin-sensitive sensory fibers, we injected the plantar skin of the adult rat hind foot with capsaicin, which destroys substance P-positive and calcitonin gene-related peptide (CGRP)-positive fibers. Immunocytochemical studies of preparations confirmed a decrease in epidermal CGRP-positive fibers. By day 3, there was an increase in PGP 9.5 immunoreactivity of Langerhans cells. These data indicate that loss of substance P- and/or CGRP-positive epidermal nerve fibers is sufficient to modify the Langerhans cell phenotype. (Funding: NIH NS14784)

706.7

NORADRENERGIC (NA) INNERVATION OF LYMPHATIC ORGANS AND JOINTS IN EXPERIMENTAL ARTHRITIS (EA). C. Lubahn*, J. Schaller, D.L. Bellinger, and D. Lorton. Sun Health Research Institute, Sun City, AZ 85351 and Dept. of Neurobiol. and Anat. Univ. of Rochester Sch. of med., Rochester, NY 14642.

Previous studies have employed systemic methods of NA denervation to examine the role of NA innervation in modulating chronic inflammatory responses and joint destruction in models of arthritis. This method of denervation destroys NA nerves at several potential sites where norepinephrine (NE) may act, including the joints and lymphoid organs. We have explored the role of NA innervation of the joints versus that of the lymphoid organs by using different routes of administering 6-hydroxydopamine (6-OHDA): (1) local application directly into the fatpads surrounding the draining lymph nodes (DLN) and (2) intraperitoneal (i.p.) injection.

For local application, two 4 µl injections of 6-OHDA (150 µg/ml sterile saline plus 0.1% ascorbic acid) or vehicle were administered bilaterally into the fatpads of lymph nodes that drain the hindlimbs of six male Lewis rats. One day later, animals were given an injection of Freund's complete adjuvant (FCA, 1 mg/0.1 ml mineral oil) at the base of the tail to induce EA. Controls receive vehicle injections. For systemic denervation, 6-OHDA (100 µg/100 g body wt) or vehicle was given i.p. on day 1, 3, and 5 days prior to injections of FCA to induce EA or vehicle and then once a week (n=6). EA was assessed by changes in dorsoplantar width and X-rays of the ankle joints. Local application of 6-OHDA resulted in significant increases in non-denervated arthritic rats. In contrast, systemic denervation resulted in significant decreases in dorsoplantar widths in arthritic rats by day 27 following FCA treatment compared to control arthritic rats. X-ray analysis confirmed these results.

We report that routes of 6-OHDA administration that denervate the lymphatic organs with sparing of the hindlimbs exacerbate EA. In contrast, systemic administration of 6-OHDA which denervate both the joint and the lymphatic organs attenuate EA. This study supports a dual role for NA innervation in modulating the severity of EA by innervation of the joints and the lymphoid organs.

ADRENAL INDEPENDENT CHANGES IN GLUCOCORTICOID RECEPTOR BINDING DURING VIRAL INFECTION A.H. Miller*, B.D. Pearce, T.L. Pisell, C.M. Pariante, C.A.Biron, Emory Univ. Sch. of Med., Atlanta, GA 30322

In the context of a large body of data demonstrating extensive interconnection between the neuroendocrine and immune systems, there has been great interest in the role of glucocorticoids in regulating immune responses to viral infections. Previous work in our laboratories have shown that the neuroendocrine response to viral infection varies as a function of the virus and the immune response to the virus. For example, despite marked immune activation in all viral infections, HPA axis responses in infected animals range from stress levels of corticosterone in the am and pm over several days to no change compared to non-infected animals. Interestingly, in animals infected with lymphocytic choriomeningitis virus (LCMV) clone E350, the minimal corticosterone response to this virus was accompanied by large decreases in glucocorticoid receptor binding in the spleen in the morning and evening on days 3-7 post infection. We hypothesized that these receptor changes may be steroid independent given that related studies using the interferon inducer, poly I:C, decreased cytosolic receptor binding in adrenalectomized animals. To examine the adrenal dependency of LCMV-induced receptor decreases, we infected adrenal intact and adrenalectomized mice with LCMV in the presence or absence of corticosterone replacement via sc implantation of 1.5 mg corticosterone pellets. The mean corticosterone value in replaced animals was 3.16 SE 0.83 µg/dl. LCMV infection led to a 40% decrease in glucocorticoid receptor binding in the spleen of adrenal intact animals (469.5 SE 18.64 fmoles/mg protein in uninfected mice versus 283.5 SE 36.0 fmoles/mg protein in infected mice). Adrenalectomy with or without corticosterone replacement did not reverse the infection-associated decreases in glucocorticoid receptor binding. Although the cytosolic receptor binding assay does not allow differentiation between receptor activation and downregulation, these results indicate that the potential for interactions between the neuroendocrine and immune systems can be modified at the level of the glucocorticoid receptor in the context of an ongoing immune response such as during a viral infection. EXPRESSION AND SECRETION OF INFLAMMATORY CYTOKINES FOLLOWING CENTRAL ENDOTOXIN: POTENTIATION WITH INTERFERON-γ COADMINISTRATION. L. Terreni, F. Mangiarotti, R. Chiesa, G. Forloni and M. G. De Simoni*. Istituto di Ricerche Farmacologiche Mario Negri, Via Eritrea 62, 20157, Milano - ITALIA.

Centrally administered endotoxin (LPS) results in large increase in inflammatory cytokine expression and secretion in the central nervous system (CNS) and in periphery (De Simoni et al., 1995, Endocrinology 136: 897). Since it has been recently shown that interferon-γ (IFNγ) exposure potentiates LPS-induced TNFα production in microglial cultures, in the present study the effect of LPS and IFNγ coadministration was evaluated on inflammatory cytokine induction in vivo. Serum levels of IL-6, measured as hybridoma growth factor on 7TD1 cell line, and of TNFα, measured as cytotoxic activity on L929 cell line, were evaluated 2 and 8 h after LPS (25 μg/rat icv), IFNγ (2.5 μg/rat icv) or after their contemporary administration. In the same experiments, IL-6 and IL-1β mRNA expressions, measured by Northern blot analysis, were evaluated in peripheral tissues (adrenals, spleen and lynphonodes) and in brain areas (hypotalamus, hyppocampus and striatum). Serum IL-6 and TNFα levels were maximally increased by LPS and IFNγ coadministration. In peripheral tissues IL-6 and IL-1β expression were maximal at 2 h, and IFNγ, inactive when administrated alone, significantly potentiated LPS action in the three tissues considered. Also in brain areas, where the maximal cytokine expression was at 8 h, a similar effect was observed. These results show that IFNγ potentiates LPS induction of inflammatory cytokines in vivo.

iNOS gene is Expressed in the Brain during Inflammation. A. Al-Shekhlee[1], M. Wong[1]*, V. Rettori[2], P. B. Bongiorno[1], G. Canteros[2], J. Licinio[1], S. M. McCann[3], P.W. Gold[1]. [1]Clinical Neuroendocrinology Branch, NIMH, NIH. Bethesda, MD 20892-1284; [2]Centro de Estudios Farmacologicos y Botanicos, Buenos Aires, Argentina; [3]Pennington Biomedical Research Center. Louisiana State University, Baton Rouge, LA 70808-4124.

Inducible nitric oxide synthase (iNOS), a transcriptionally regulated enzyme that synthesizes nitric oxide from L-arginine, has a key role in the pathophysiology of systemic inflammation and sepsis. Transgenic animals with a null mutation for the iNOS gene are resistant to lethality and hypotension caused by *E.coli* LPS. The regulation of peripheral iNOS has been well studied in sepsis but little is known about iNOS regulation in the brain during systemic inflammation or sepsis. We show that at baseline there is no detectable iNOS gene expression in the brain, but a detailed neuroanatomical study reveals that early in the course of systemic inflammation there is a profound induction of iNOS mRNA in vascular, glial, and neuronal structures of the rat brain, accompanied by the production of nitric oxide metabolites in brain parenchyma and cerebrospinal fluid (CSF). We propose that the spillover of nitrites into the CSF has the potential to be a diagnostic marker for systemic inflammation and sepsis. Pharmacological interventions aimed to regulate iNOS function in the brain might represent a new treatment strategy in sepsis. Brain iNOS may be relevant to the pathophysiology, diagnosis, and treatment of systemic inflammation and sepsis.

INTRACEREBROVENTRICULAR TRANSPLANTATION DIFFERENTIALLY AFFECTS EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS AND PERIPHERAL INFLAMMATION. B. Misiewicz, M. Poltorak, R. Wright, R. Szczepanowski, W.J. Freed, E.M. Sternberg*. NIMH, Bethesda MD 20892 and NIMH and GW University, Washington, DC 20037.

Compared to inflammatory resistant F344/N rats, histocompatible LEW/N rats are susceptible to experimentally induced autoimmune/inflammatory diseases, including experimental allergic encephalomyelitis (EAE). This difference is related to differential hypothalamic-pituitary-adrenal axis responsiveness. We recently showed that intracerebroventricular (i.c.v.) transplantation of F344/N hypothalamic tissue into LEW/N rats suppresses carrageenan-induced peripheral inflammation by >85%. In the current study, the effect of i.c.v. transplantation of F344/N neural tissue on EAE was examined in LEW/N rats transplanted with F344/N hypothalamus, spinal cord, or striatum. EAE was induced with myelin basic protein four weeks after transplantation. Horizontal locomotor activity in LEW/N rats transplanted with hypothalamic and spinal cord tissue was significantly greater than in non-transplanted EAE rats, and did not differ from non-EAE controls. Total locomotor activity in all transplanted groups and sham operated controls was greater than in non-operated EAE rats. This suggests that i.c.v. transplantation of neural tissue differentially affects horizontal and total locomotor activity. This non-specific effect of i.c.v. surgery on different aspects of locomotion as an index of disease activity contrasts with the more specific effects of hypothalamic transplantation on peripheral carrageenan responses. This suggests that hypothalamic neural mechanisms may have a relatively more specific effect on control of innate peripheral inflammation than on T cell mediated EAE.

IMMUNE SYSTEM IMPLICATED IN REGULATION OF CHOLINERGIC NEURAL FUNCTION. M.T. Ivy*, R. R. Rao, J.G. Postell, M.D. Terry and S. K. Ghosh. Department of Life Sciences, Indiana State Univ., Terre Haute, IN 47809.

Autonomic nerve fibers serve a role in modulation of lymphocyte activity and consequently influence the secretory immune system. Our studies addressed whether stimulation of the immune system exerts similar modulatory effects on the nervous system. In mice topical application into the eye or intraperitoneal (i.p.) injection with a T-cell dependent antigen, Keyhole Limpet Hemocyanin (KLH), elicited significant immune responses locally and systemically regardless of the immunization route. On the other hand, the polysaccharide, Dextran B512 which is a T-cell independent antigen, caused a significant increase in the systemic antibody response subsequent to i.p., but not after topical administration. Following local, but not systemic immunization with KLH, the activities of both acetylcholinesterase (AChE, EC 3.1.1.7), and choline acetyltransferase (ChAT, EC 2.3.1.6) in the mouse lacrimal gland displayed biphasic effects with a low and high dose of the antigen. In contrast, only the high concentration of antigen stimulated conjunctival AChE, but not ChAT. Brain and spleen, being distant from the site of antigenic intrusion, showed no changes in AChE and minimal effects in ChAT activity. After i.p. immunization with KLH, both AChE and ChAT levels were increased dramatically in only the conjunctiva. However, Dextran immunization topically or i.p. elicited no changes in tissue AChE nor ChAT levels. These results suggest that the ocular microenvironment is capable of promoting primarily the T-dependent antigen-induced polyclonal humoral response. Concomitantly, along with this immune response as expected, there are significant changes in cholinergic enzymatic activity. Currently, efforts are directed towards analysis of cytokines evoked by these antigens in situ which may be associated with cholinergic enzymes. Supported by NIH (NEI) grant #EY11025-01.

STRESS AND ANAPHYLACTIC VASCULAR RESPONSE. X. García*, C. Tenorio, V. González, M. García, M. A. Contreras-Barrios, L. Cartas, and E. Gijón, Dept. of Physiology, School of Medicine, UNAM, and Woman's Hospital, SSA. México D. F. 04510, México.

The nervous system influences immune functions and immune mechanisms are involved in the physiology and pathology of the nervous system. Neuroimmunomodulation represents a source of new ideas and investigations at experimental and clinical levels. The aim of this work was to study the anaphylactic response on aortic rings from male guinea pigs actively sensitized to hen egg albumin (EA) and exposed to movement stress or immobilization stress since the first day of immunization by a single subcutaneous injection of 10 mg of EA with complete Freund Adyuvant. Both type of stress induced anaphylactic isometric contraction depression, but being movement stress more effective. Anaphylactic responsiveness followed a temporal course change that may reflect a difference in antibody type produced during sensitization time and/or a difference in stress adaptation.

706.14

DIFFERENTIAL EFFECT OF PLATELET ACTIVATING FACTOR ON ADHESION MOLECULE EXPRESSION BY ASTROCYTES AND MICROGLIA. M.L. Baker*, B.M. Gebhardt, N.G. Bazan. LSU Eye Center and LSU Neuroscience Center of Excellence, New Orleans, LA 70112

Intercellular adhesion molecule-1 (ICAM-1) expression is increased on microglia and astrocytes in inflammatory diseases of the central nervous system (CNS). ICAM expression is important in the entry and activation of mononuclear leukocytes in the CNS, and both microglia and astrocytes are components of the blood-brain barrier. Platelet activating factor (PAF) is a lipid mediator produced during inflammation and is a mediator of neuro-injury caused by stroke and trauma. The **objective** of this study was to look for the presence of ICAM-1 transcripts in microglia and astrocytes treated with PAF. Primary cultures of microglia and astrocytes were dissociated from newborn mouse brains and separated by plastic adherence and filtration through nylon mesh. PAF did not cause an increase in microglial ICAM-1 expression. However, astrocytes did exhibit an increase in ICAM-1 expression when treated with PAF. These results suggest that microglial expression of ICAM-1 is independent of PAF. In that microglial cells synthesize PAF and astrocytes show an increase in ICAM-1 mRNA when treated with PAF, microglia may control astrocytic ICAM-1 expression through PAF excretion during inflammation of the CNS.

KYNURENINE PATHWAY ACTIVATION ALTERS GENE EXPRESSION PATTERN IN MURINE SPLEEN. R.Kori[1]*, I.Rodriguez[2] and M.A.A. Namboodiri[1]. [1] Dept. Biology, Georgetown University, Washington DC 20057, [2] Lab. Ret. Cell Mol. Biol. NEI, NIH, Bethesda, MD 20892.

Activation of kynurenine pathway of tryptophan degradation via induction of the first and rate limiting enzyme, indoleamine dioxygenase (IDO), is a characteristic immune system response in a variety of inflammatory neurological disorders, including neuroAIDS. Our recent studies in several model systems including murine model of AIDS have shown that this response is restricted primarily to dendritic cells and select macrophages. More recently we have found that we can stimulate a selective kynurenine pathway activation in lymphoid tissues by feeding animals with kynurenine in the drinking water. In the present studies, we have examined kynurenine treatment induced gene expression changes in murine spleen using the mRNA differential display technique to understand the physiological significance of kynurenine pathway activation.

Groups of three mice (C57BL/6J, ♂, 20 gms) were treated with L-kynurenine (i.p. 300 mg/kg or in drinking water 10 mM)and were sacrificed at 3 hrs, 6 hrs and 28 hrs. Total RNA was extracted from spleen, DNA contamination removed by DNAse treatment and mRNA differential display performed using the RNAimage kit (GenHunter Corp., TN). The cDNA fragments that appeared to be differentially expressed were cloned and sequenced. Ten cDNA fragments were sequenced so far and 8 were found to be novel sequences. Further studies are under way to confirm these results by Northern analysis and further characterize these sequences in terms of their functional roles in the neuroimmune system.

DIFFERENTIAL EFFECTS OF TRYPTOPHAN AND KYNURENINE ON QUINOLOLINIC ACID IMMUNOREACTIVITY IN RAT.
KJ Blinder*, JR Moffett and MAA Namboodiri. Dept of Biol., Georgetown U., Washington, DC 20057.

Activation of the extrahepatic kynurenine pathway of tryptophan (Trp) degradation via induction (primarily by IFNγ) of indoleamine dioxygenase (IDO) is a characteristic response in a variety of inflammatory neurological disorders, including neuro-AIDS. 2 enzymes can catalyze the first, rate-limiting step of the pathway: hepatocytic Trp dioxygenase (TDO) and the widely-distributed indoleamine dioxygenase (IDO). Only the latter is induced by IFNγ. Its induction during inflammation leads to an increase in plasma kynurenine (Kyn), which is formed by many cells which are unable to synthesize quinolinic acid (Quin). Macrophages and liver cells, unlike most cells, make Kyn, but then convert it via several steps to the potential neurotoxin, Quin.

In the present experiment, we assessed the impact of increased plasma Kyn upon Quin, seeking clues for the physiological significance of the IDO induction and Quin formation of inflammation. S.D. rats were injected *i.p.* with either Trp, Kyn or saline (5 rats each), and Quin-IR was examined in the carbodiimide-fixed liver, spleen, lung and brain. Trp, but not Kyn, increased Quin-IR in hepatocytes, perhaps reflecting differential transport. In contrast, after Kyn loading, increased QUIN-IR was not present in hepatocytes, but was seen in macrophages and dendritic cells of liver, lung and spleen, choroid plexus, and meninges, but not in any parenchymal brain cells. The findings suggest that IDO induction may increase Quin production in macrophages both directly, by inducing macrophage IDO, and indirectly, by increasing plasma Kyn.

ENHANCEMENT OF MACROPHAGE PHAGOCYTOSIS BY CALCITONIN GENE RELATED PEPTIDE.
M.Ichinose*, and M.Sawada.
Department of Physiology, Shimane Medical University Izumo 693, Japan.

Macrophages play important functional roles in the immune system. Macrophages ingest and kill microorganisms, process antigens and present them to T cells. Phagocytosis is the most representative functions of the cells. Phagocytosis of fluorescent latex beads by mouse peritoneal macrophages was examined by flow cytofluorometry. Percentage of phagocytic cells in total macrophages (PP) and phagocytic index (PI), which is defined as the average number of particles ingested per macrophage, were assessed. In the presence of calcitonin gene related peptide (CGRP) during the incubation of macrophages with latex beads, macrophage phagocytosis was enhanced in a dose-dependent manner. CGRP(8-37) also enhanced phagocytosis. These results suggest that CGRP enhances the macrophage function and that CGRP is one of mediators from the nervous system, indicating that the nervous system may modulate the immune system by neural substances.

DEAFFERENTATION ARRESTS DEVELOPMENT OF BRAIN MAST CELLS.
X. Zhuang[1]*, A.-J. Silverman[2], and R. Silver[1,3]. [1]Dept. Psychology, [2]Dept. Anat. & Cell Biol., P&S, 10032, and [3]Barnard College, Columbia Univ., New York, NY 10027.

Mast cell (MC) precursors circulate in the blood and then enter tissues, where local factors influence their phenotypic differentiation. We identified MC precursors in the brain of embryonic day 15 (E15) doves. They lie in the piece of pia that grows into the medial habenula (MH), embedded in the extracellular matrix of the growing capillaries. Ultrastructurally, they contain immature cytoplasmic granules, including small scroll granules and vacuoles with focal deposits of electron dense material. Histochemically, they are not stained with classical MC markers, acidic toluidine blue or alcian blue. By 1 month of age, immature MCs are observed in the neuropil of the MH, where some are weakly positive for low-sulfated glycosaminoglycans. Ultrastructurally, most granules remain immature. Their Golgi apparatus and a few granules are stained by an antiserum against GnRH. These MCs undergo *in situ* maturation in parallel with an increase in cell number. In 6 month old birds, numerous MCs show GnRH-like immunoreactivity, contain highly-sulfated glycosaminoglycans, and possess the full range of granular architecture including homogeneous electron dense granules, which are the most mature.

To explore the role of neural-MC interactions in the maturation process, we transplanted E15 MH into the lateral ventricle. MCs were detected by GnRH antiserum, alcian blue and toluidine blue in the host and transplanted MH, but not in control brain tissue transplanted to the contralateral ventricle in the same animal. MCs in the MH transplant are less mature than either those in the host MH, or in age-matched tissue *in situ*. The results indicate that in the absence of neural connections, MCs survive in the transplanted MH, but that development is arrested. In addition, gonadal steroids which increase MH number in the host MH have no influence on the transplant, indicating that the effect of steroids is not systemic, but involves an action on a CNS site. HISTAMINE, NERVE GROWTH FACTOR AND NEUROTROPHIN-3 RELEASE IS MODULATED BY SUBSTANCE P IN LPS-PRIMED LUNG PARENCHYMA. A.J. Okragly, M.R. Saban, R. Saban, and M. Haak-Frendscho*. Promega Corp., Madison, WI 53711 and Smooth Muscle Laboratory, School of Veterinary Medicine, University of Wisconsin-Madison, WI 53706

There is a growing body of evidence that substance P (SP) is an important mediator of neurogenic inflammation in the airways. Previous studies have demonstrated that SP can induce both histamine and multiple cytokine release from mast cells (MC) following activation. Moreover, MC can synthesize, store, release and respond to Nerve Growth Factor (NGF) by proliferation, enhanced survival and priming for histamine release (HR). In the present study, we investigated the effects of SP on histamine, NGF and Neurotrophin-3 (NT-3) release from lipopolysaccharide (LPS)-primed mouse lung parenchyma. In this model of inflammation, mice were pretreated *in vivo* with LPS (0.5μg, intravesical instillation) alone or in combination with anti-NGF antibody (100μg, i.p.). After 20 hours, isolated lung parenchyma were challenged with 10μM SP and supernatants assayed for histamine, NGF and NT-3 employing 2-site sandwich ELISAs. SP induced identical profiles of histamine and NGF release; levels were significantly increased in the saline and LPS control groups, there was no net release in the Ab pretreatment group, and a marked reduction below basal levels of mediator release was observed in the Ab and LPS pretreatment group. Interestingly, in all groups the NT-3 levels were reduced below spontaneous amounts following SP challenge *in vitro*. Thus the NT-3 response to SP was independent of LPS and Ab pretreatment. Taken together these results suggest a close interrelationship between LPS, NGF, NT-3 and SP during inflammation and mast cell activation.

NERVE GROWTH FACTOR PRIMES MAST CELLS TO ENHANCE THEIR RESPONSIVENESS TO ANTIGENIC AND PEPTIDERGIC STIMULI. L. Facci*, M.P. Cesaroni°, A. Buriani, L. Petrelli, R. Dal Toso, S.D. Skaper and A. Leon. Research*life* S.c.p.A., Castelfranco Veneto 31033 and °L'Aquila 67100, Italy.

Nerve growth factor (NGF) is the prototype of neurotrophic factors. These factors have a critical role in development, maintenance, and survival of neurons throughout the life of the organism. Although neurotrophins are generally described in the context of their actions on neuronal cells, there are many reports of NGF effects on cells belonging to the hemopoietic-immune system and endocrine system. Mast cells, pleiotropic bone marrow-derived cells of immune lineage, not only express the functional NGF receptor TrkA (Horigome *et al.*, JBC, 1993), but also produce and secrete biologically active NGF (Leon *et al.*, PNAS, 1994), suggesting possible autocrine effects for NGF on mast cell function. Because NGF levels are increased in inflammatory disorders and mast cells are likely involved in tissue inflammation, it was of interest to investigate possible interactions between NGF and mast cell activation. Purified peritoneal mast cells, following 10 min exposure to NGF, displayed a 200-300% greater release of either preloaded [^{3}H]serotonin or endogenous histamine, upon subsequent challenge with 30 μM substance P or high-affinity IgE receptor aggregation. The NGF effect was concentration-dependent over 1-100 ng/ml, and was not mimicked by either EGF or BDNF. NGF was not active when added only at the time of mast cell stimulus, nor did NGF trigger mast cell activation per se. Alterations in normal mast cell behaviors may provoke maladaptive neuroimmune tissue responses influencing inflammatory disease states, with NGF acting as a general "alert" molecule to recruit and prime defense processes following insult. Therapies directed against inappropriate mast cell activity might be beneficial in reducing such injury.

SPINAL CORD INJURY (SCI) INCREASES NEUROFILAMENT IMMUNOREACTIVITY AND REDUCES CAPSAICIN-SENSITIVITY OF VISCERAL AFFERENT NEURONS INNERVATING RAT URINARY BLADDER. N. Yoshimura* and W. C. de Groat, Dept. of Pharmacology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261

The afferent innervation of the urinary bladder consists of myelinated Aδ-fiber and unmyelinated C-fiber axons. The former responding to low-threshold mechanical stimuli trigger the normal supraspinal micturition reflex (MR), while the latter which respond to noxious stimuli appear to modulate the MR. After SCI, bladder afferent neurons (B-AN) in rats exhibit an increase in somal size and are more excitable as a result of the plasticity of sodium and potassium ion channels (Soc. Neurosci. Abst. 19: 1726, 1993). In this study, we further examined B-AN plasticity after SCI. Rat B-AN dissociated from L_6-S_1 dorsal root ganglia and maintained in short-term culture (1-2 days) were examined for capsaicin-sensitivity using a cobalt uptake assay and for neurofilament protein immunoreactivity using anti-neurofilament antibody (RT97). B-AN were labeled by axonal transport of a fluorescent dye (Fast Blue) injected into the bladder wall 7-10 days prior to the dissociation. The spinal cord was transected 4 weeks prior to the experiment. In spinal intact animals, 68% of B-AN were neurofilament-poor (ie., C-fiber neurons) and 78% of these cells were sensitive to capsaicin, while only 2% of neurofilament-rich cells (ie., Aδ-fiber neurons) were capsaicin-sensitive. In SCI animals, B-AN had larger diameters (34.2 ± 1.1 μm, mean ± SE, n=126) than those in intact animals (29.2 ± 1.2 μm, n=149). The total number of capsaicin-sensitive neurons was reduced to 38% of B-AN in SCI rats from 55% in intact rats. Immunoreactivity to neurofilament protein which occurred in 32% of B-AN from intact rats was found in a larger percentage (62%) of B-AN from SCI rats. These results indicate that capsaicin-sensitive and neurofilament-poor, C-fiber B-AN change their properties to those of capsaicin-insensitive and neurofilament-rich, Aδ-fiber neurons following SCI. This plasticity coupled with changes in electrical properties of C-fiber B-AN might be responsible for the enhancement of the spinal micturition reflex following SCI. (Supported by NIH grant DK 49430)

AN *IN VIVO* STUDY OF THE EFFECTS OF THE SELECTIVE NEUROKININ A AGONIST β-ALA NKA(4-10) AND THE ANTAGONIST SR48968 ON MECHANOSENSITIVE AFFERENTS ORIGINATING IN THE RAT URINARY BLADDER. A. Kibble, W. Winlow* and J.F.B. Morrison. Department of Physiology, University of Leeds, Leeds LS2 9NQ, UK.

Release of neurotransmitters from 'capsaicin-sensitive' neurones could be involved in modifying the afferent discharge from the urinary bladder. As a tachykinin-mediated, excitatory motor innervation of the rat bladder has been shown in response to nerve stimulation (Meini and Maggi 1994) this study was undertaken to examine a possible role for NK-2 receptors in the bladder by afferent recording *in vivo*. In anaesthetised rats recordings were made from single bladder units in the L_6S_1 dorsal root during distension of the bladder with warm saline. Once control mechanosensitivity had been established the NK-2 agonist β-ALA NKA (4-10) was administered IV (20 nM/kg), and saline distensions performed. In all Aδ and C fibres investigated, the agonist significantly decreased the pressure threshold of the unit, and afferent recordings showed enhancement of mechanosensitivity in a significant proportion of these afferents. The antagonist SR48968 (176nM/kg) antagonised this sensitisation in the majority of units, returning them to levels not significantly different from control. Similarly, the pressure thresholds were returned to control levels. When administered alone (176nM/kg), the antagonist had no effect on the pressure threshold of the afferent, but in the majority of afferents recorded from the antagonist significantly reduced the afferent activity at given bladder pressures.

The existence of NKA and its receptors in the lower urinary tract, together with the evidence in this study raises the prospect of a role for NKA in the control of reflex micturition. The excitatory effect of the NK-2 agonist on bladder afferent activity suggests NK-2 receptors play a positive feedback role in micturition regulation. RETROGRADE AND TRANSGANGLIONIC TRANSPORT OF CHOLERAGENOID, WHEAT GERM AGGLUTININ OR ISOLECTIN-B4 IN PRIMARY AFFERENT NEURONS INNERVATING THE RAT URINARY BLADDER.

H.F. Wang, P. Shortland,* M.J. Park and G. Grant. Dept. of Neuroscience, Karolinska Institutet, S171 77 Stockholm.

In somatic spinal primary afferents, choleragenoid (CTB) and the isolectin B4 are useful markers and tracers for myelinated and unmyelinated primary afferents, respectively, whereas wheat germ agglutinin (WGA) labels both, but predominantly unmyelinated fibers. We have compared the ability of these lectins to retrogradely label primary afferents innervating visceral structures. Eight to 10μl of 0.5% CTB-HRP, 2% B4-HRP or 2% WGA-HRP was injected into the left side of the urinary bladder. Three to 4 days later the L6-S1 dorsal root ganglia (DRG) and spinal cord were processed for HRP or immunofluorescence histochemistry. More DRG cells were labeled with CTB-HRP than with B4- or WGA-HRP. CTB-HRP labeled fibers in lamina I, V-VII, and both the lateral (LCP) and medial collateral (MCP) pathways. The LCP was always intensely labeled and extended into the parasympathetic nucleus. Labeling from both the LCP and MCP extended into the dorsal gray commissure. B4-HRP- or WGA-HRP-labeled fibers, on the other hand, were only seen in the LCP and lateral lamina I. Double staining of DRG sections with the anti-neurofilament antibody, RT97, a marker specific for myelinated afferents, showed that 20%, 5% and 6% of the CTB-, B4- and WGA-immunoreactive cells were RT97+ve.

The results show that CTB/CTB-HRP is an efficient retrograde and transganglionic tracer for visceral afferents from the urinary bladder but is transported mostly by unmyelinated fibers.

RENAL AFFERENT CIRCUITRY: COMPLEMENTARY RESULTS FROM C-FOS AND VIRUS STUDIES. M.L. Weiss* and G.K. Fitch. Dept. of Anatomy and Physiology, Kansas State University, Manhattan, KS 66506-5602

Retrograde labeling studies using the rat indicated that dorsal root ganglion cells from T_8 to L_2 innervate the left kidney. Further, electrical stimulation of renal afferents influences dorsal horn neurons in spinal segments T_{10} to L_1 and nucleus tractus solitarius (NTS) neurons. In the first experiment, we investigated the changes in c-*fos* expression by activation of renal afferents. Renal afferent circuitry was stimulated in various ways, for example by electrically stimulating a left renal nerve. Subsequently, the brain and spinal cord were harvested and free-floating sections were immunocytochemically stained using antibody directed against the Fos protein of the c-*fos* gene. Renal afferent stimulation produced c-*fos* expression in the dorsomedial portion of laminae I and II in the spinal cord dorsal horn and in the NTS. In the second experiment, we investigated the spread of a neurotropic virus after infecting the kidney. The rat's left kidney was injected with pseudorabies virus (PRV, Bartha's K strain). Animals were sacrificed 2-5 days post-infection (PI) by perfusion and the virus was located immunocytochemically. Three days PI, dorsal root ganglion neurons were infected. Starting 4 days PI, infected neurons were detected within laminae I and II of the dorsal horn. Infected neurons were found in NTS five days PI. Our results indicate that information about renal afferent pathways can be obtained by two quite different techniques. Sponsored by the American Heart Association, Kansas Affiliate.

FUROSEMIDE TREATMENT INDUCES C-*FOS* IMMUNOCYTOCHEMICAL LABELING WITHIN THE RAT DORSAL HORN. G.K. Fitch, J.D. Dunn* and M.L. Weiss. Dept. of Anatomy and Physiology, Kansas State University, Manhattan, KS 66506-5602

Retrograde labeling studies using the rat have indicated that dorsal root ganglion cells from T_8 to L_2 innervate the left kidney. Stimulation of renal and ureteral afferents by ureteral ligation activates c-*fos* expression in dorsal horn neurons in spinal segments T_{10} to T_{13} (Fitch and Weiss, Brain Res., in press). The actions of furosemide (FURO), a diuretic-natriuretic drug, have been shown to stimulate feline renal afferents (Genovesi *et al.*, Circ. Res. 73: 906, 1993). To investigate the spinal neurons influenced by renal afferent stimulation, we used c-*fos* immunocytochemistry following FURO treament (5 mg/rat sc) to indicate neuronal activation. Conscious animals received either FURO or 0.9% saline and were placed into urine collection cages for 1.5-2.5 h prior to perfusion. The brain and spinal cord were harvested and histologically processed. Immunocytochemistry using antibody directed against the protein product of the c-*fos* gene was performed on free-floating sections. At spinal levels T_{10} through T_{13}, FURO treatment produced an average of a 250% increase in the number of c-*fos* labeled cells/section in spinal cord dorsal horns relative to saline-injected control animals. Most labeled cells in FURO animals were found in the dorsal horns of spinal segments T_{12} and T_{13}. Our results indicate that FURO can induce c-*fos* expression in the dorsal horn; this induction may be mediated by the activation of renal afferents. MECHANICAL STIMULATION INCREASES $[Ca^{2+}]_i$ IN SPINAL AFFERENTS INNERVATING THE STOMACH IN VITRO. H.E. Raybould*, H. Ennes, T. Lembo, J.M. Gschossmann and E.A. Mayer. CURE Digestive Diseases Research Center, Depts of Physiology and Medicine, UCLA School of Medicine, Los Angeles, CA 90024.

The stomach is innervated by mechanically-sensitive afferents that are stimulated by contraction, distention or movement in the receptive field. The sensory transduction mechanisms are poorly understood. The present study investigated the effect of mechanical stimulation (MS) on $[Ca^{2+}]_i$ in dorsal root ganglion neurons in culture. Methods: DRG neurons innervating the stomach were identified by the presence of a retrograde tracer, dextran-conjugated Texas Red, injected into the stomach wall 2-4 weeks previously (8 x 2 ul of 5% solution). Neurons (T4-L1) were removed, cultured using standard techniques and used in experiments after 24-48 h. $[Ca^{2+}]_i$ was visualized using a video fluorescent microscopic system (Attoflor) in Fura-2 loaded neurons. Increases in $[Ca^{2+}]_i$ were measured in response to MS using a flame polished probe (0.5 sec, 2 um depression). Results: MS of the cell soma increased $[Ca^{2+}]_i$ in around 20% of neurons. The response was markedly reduced by superfusion with zero Ca^{2+} buffer (n=4) or gadolinium (100 or 250 uM; n=8). In Texas Red labelled neurons, MS increased $[Ca^{2+}]_i$ in 3/3 neurons; this response was also abolished by gadolinium. Conclusion: Cell somas of spinal afferents, including those innervating the stomach, express stretch-activated ion channels that mediate an increase in $[Ca^{2+}]_i$. These may be involved in the sensory transduction of mechanical events in the stomach that lead to autonomic and sensory reflexes in response to mechanical stimulation. Supported by NIH DK 41004 (HER) and DK 40919 (EAM).

PROPAGATION OF MECHANICALLY INDUCED CALCIUM WAVES BETWEEN DORSAL ROOT GANGLION (DRG) CELLS AND COLONIC SMOOTH MUSCLE CELLS IN CULTURE

H.S. Ennes, S.H. Young*, H.E. Raybould, and E.A. Mayer.
CURE Dig. Dis. Res. Ctr. / Neuroenteric Biology Group, Depts. of Medicine and Physiology, UCLA and WLA VA Med. Ctr., Los Angeles, CA 90024.

The close interposition of peripheral terminals of primary visceral afferents and smooth muscle cells plays a role in the activation of mechanosensitive afferents in the gut. To study the interaction between colonic myocytes and afferent neurons in vitro, freshly isolated rat DRG cells were plated onto non-confluent rat colonic smooth muscle primary culture. $[Ca^{2+}]_i$ changes were monitored using fura-2 fluorescence videomicroscopy. When cultured alone, 16% of DRG cell somas responded to mechanical stimulation (by a glass rod) with an increase in $[Ca^{2+}]_i$ In some cells, the $[Ca^{2+}]_i$ increase spread down the neurites in form of a Ca^{2+} wave. When co-cultured with smooth muscle cells, 20% of the DRG cells showed an increase in $[Ca^{2+}]_i$ in response to stimulation of the DRG cell body. *Inter*cellular propagation of Ca^{2+} waves from DRG neurites into adjacent myocytes and into adjacent DRG neurites was observed. Mechanical stimulation of myocytes also resulted in intercellular propagation of $[Ca^{2+}]_i$ transients into adjacent neurites. Injection of Lucifer Yellow into the DRG soma or into myocytes was followed by slow dye transfer into the connecting muscle or neuron respectively. Western blots show connexin 43 in the myocytes alone and in the coculture. **Conclusions:** Colonic myocytes and DRG neurites may be coupled via gap junctions. The communication between myocyte and DRG cell may activate neural Ca^{2+}-activated K^+ channels making the nerve terminals less excitable following mechanically induced action potentials. It may play a role in axon-reflex-like communication between multiple effector cells innervated by terminal branches of afferent neurons activated by local mechanical stimulation. *Supported by NIH Grant NIDDK 40919.*

EFFECT OF VISCERAL PAIN ON THE TRANSCRIPTION OF THE GENES ENCODING CRF RECEPTORS IN THE RAT BRAIN. B.Bonaz*, J.Fournet and C.Feuerstein. Dept. of Gastroenterology and INSERM-LAPSEN U318, 38043 Grenoble cedex 09, France.

Intraperitoneal (ip) injection of acetic acid (AA) induces visceral pain and a digestive ileus which is reversed by the CRF antagonist α-helical CRF_{9-41} (1). Aim: 1) to study in the rat brain the effect of AA on the transcription of the genes encoding CRF receptors (CRF-R1 and -R2), 2) the localization of these transcripts in CRF perikarya in the PVN. Methods: male rats received 0.6% AA (10 ml/kg ip) or saline ip and were perfused (4% paraformaldehyde-borax) 1, 2, 3, 4 and 6h later. Brain sections were processed for *in situ* hybridization (ISH) using ^{35}S-labeled riboprobes (2). Localization of these transcripts in CRF perikarya of the PVN was determined by a combination of immunocytochemistry and ISH (2). Results: in AA-treated rats 1) CRF-R1 mRNA was expressed in the PVN. The signal appeared at 2h, peaked at 4h and decreased at 6h. No modulation of this expression was observed in other regions. 2) CRF-R2 mRNA was present in the limbic structures, as in controls, but no increase was observed. 4) CRF-R1 transcript was expressed in CRF perikarya of the PVN. Conclusion: CRF pathways are activated in the PVN by AA-induced visceral pain, and are involved in AA-induced digestive ileus in rats.

MAST CELL MEDIATORS EXCITE THE AFFERENTS OF CAT SMALL INTESTINE. G.N. Akoev, G.N. Andrianov*, L.V. Filippova, and N.O. Sherman. Lab. of Physiology of Sensory Receptors, Pavlov Institute of Physiology, Russian Academy of Sciences, Nab. Makarova 6, St. Petersburg 199034, Russia.

The effect of intra-arterial injections of mast cell mediators on afferent impulse activity of mesenteric nerve of small intestine of the anesthetized cat was studied. 5-Hydroxytryptamine (5-HT) (10^{-8}-10^{-4} M) and histamine (10^{-8}-10^{-3} M) were shown to increase the impulse activity in a dose-dependent manner. Metergolin, the antagonist of 5-HT receptors, suppressed the effect of 5-HT. Clemastine and cimetidine, antagonists of H_1 and H_2 histamine receptors, respectively, distinctly diminished the effect of histamine. Prostaglandin (10^{-3} μg/kg) enhanced the afferent discharges. The data suggest that interaction of antigens with IgE of intestinal mast cells results in their degranulation and release of bioactive molecules which in turn cause excitation of intestinal afferents.

THERMAL SENSITIVITY OF MECHANOSENSITIVE PELVIC NERVE AFFERENTS INNERVATING THE COLON OF THE RAT. X. Su*, J. N. Sengupta and G. F. Gebhart The University of Iowa, College of Medicine, Department of Pharmacology, Bowen Science Building, Iowa City, Iowa 52242

Pelvic nerve afferent fibers innervating the colon that respond to mechanical distension often also respond to chemical stimuli (e.g., bradykinin). There has been no study of thermosensitivity of these afferents in the absence of a change in pressure. In the present study, an approximately 7 cm length of descending colon was isolated to permit intracolonic perfusion with Kreb's solution. To date, 12 fibers in the S1 dorsal root, identified by electrical stimulation of the pelvic nerve, have been studied with fluid distension (FD) of the colon. All fibers gave monotonically incrementing responses to graded FD (5 to 60 mmHg, 30 sec) and responses to repetitive FD at 40 mmHg are reproducible. Intracolonic increases (n=3) or decreases (n=3) in pH of the perfusate failed to produce any change in activity or response to FD. All 8 fibers studied responded to an increase in intracolonic temperature (>40°C); 6 fibers tested did not respond to a decrease in temperature (to 18-20°C), but responses to FD were reduced from 24 to 8 imps/s. The results indicate that mechanosensitive pelvic nerve afferents are also thermosensitive, suggesting that visceral receptors are likely polymodal in character. Supported by NS19912.

ANTIEMETIC EFFECTS OF ETHANOL IN *SUNCUS MURINUS*. Y.Chen, Y.Shitaka*, H.Saito and N.Matsuki. Dept. of Chem. Pharmacol., Fac. of Pharmaceutic. Sci., The Univ. of Tokyo, Tokyo 113, Japan.

A decreased risk of vomiting in regular alcohol comsumers in chemotherapy and early pregnancy suggests that ethanol may have antiemetic effects. We have shown previously that ethanol and its metabolite, acetaldehyde, are emetogenic by stimulating peripheral system. In the present study, effects of subchronic intraperitoneal and acute intracerebroventricular (i.c.v.) administration of ethanol on emesis were investigated in *Suncus murinus*. Subchronic injection of ethanol (20%, 4 mg/kg/day, i.p.) for 3 days caused gradual decrease of vomiting, but 20 mg/kg cisplatin-induced emesis tested on the 4th day was not affected. Pretreatment with i.c.v. injection of ethanol (40%, 3 ml/head) blocked emesis induced by centrally administered nicotine (50 mg/3 ml/head), peripheral ethanol (40%, 4 ml/kg, i.p.) and peripheral acetaldehyde (6%, 4 ml/kg, i.p.), but did not affect emesis induced by peripheral nicotine (5 mg/kg, s.c.) and peripheral cisplatine (20 mg/kg, i.p.). Pretreatment of i.c.v. injection of acetaldehyde (6%, 3 ml/head) showed the similar antiemetic effects as those of ethanol. These results suggested that ethanol and acetaldehyde are antiemetic when administered centrally but the effects depend on the stimuli. EFFECT OF S-NITROSO-N-ACETYLPENICILLAMINE (SNAP) ON CYTOSOLIC CALCIUM IN NODOSE GANGLION NEURONS OF THE RABBIT. M. Sato*, and M. Kawatani. Dept. of Physiology, Akita Univ. Sch. of Med., Akita 010, Japan

To determine whether nitric oxide (NO) stimulates primary sensory neurons, we examined the effect of SNAP, a NO generating agent, on cytosolic Ca^{2+} ($[Ca^{2+}]i$) in primary-culture nodose ganglion neurons (10 hr~4 days) of the rabbit, using a fura-2 microfluorometry. SNAP (5×10^{-6}–10^{-3}M) increased $[Ca^{2+}]i$ dose-dependently in 77% of the neurons (235/304). $[Ca^{2+}]i$ rose immediately after injection of SNAP and the plateau level was maintained in the presence of SNAP. Fifty five percent neurons showed the sustained increase in $[Ca^{2+}]i$ and 45% showed oscillation of $[Ca^{2+}]i$. The SNAP effect was reproducible and the threshold dose of the response was 10^{-5}M. Adding Ni^{2+} (2×10^{-3}M), a N-type Ca^{2+} channel antagonist (5×10^{-4}M Neomycin) or removal of extracellular Ca^{2+} abolished the SNAP (5×10^{-5}M) effect. Tetrodotoxin (10^{-5}M) and L-type Ca^{2+} channel antagonists (10^{-5}M D600 and/or 10^{-5}M nifedipine) did not alter the SNAP effect. A soluble guanylate cyclase inhibitor, 6-anilino-5,8-quinolinedione (LY83583), inhibited the SNAP effect in a dose-dependent manner from 10^{-5}M to 2.5×10^{-4}M. Measurement of NO gas in the solution of SNAP revealed the constant release of 0.03 ppm NO from 5 ml of a 2×10^{-5}M solution. These results suggest that NO generated from SNAP stimulates soluble guanylate cyclase, leading to synthesis of cGMP. The cyclic nucleotide could activate N-type Ca^{2+} channel, and the Ca^{2+} entry should be increased.

IS THE ORTHOTOPICALLY TRANSPLANTED RAT LIVER REINNERVATED BY VAGAL AFFERENTS? AN ANTEROGRADE TRACING STUDY.

A. M. A. Markus, V. Müller, F. Köckerling and W. L. Neuhuber*#

Department of Surgery, University Erlangen-Nürnberg, Krankenhausstr. 12, D-91054 Erlangen; #Deparment of Anatomy, University Erlangen-Nürnberg, Krankenhausstr. 9, D-91054 Erlangen

There is conflicting data on liver reinnervation after transplantation (Dhillon et al., J Pathol 1992, 167:211.216. Boon et al., J Pathol 1992, 167:217-222; Kjaer et al. J Hepatol 1994, 20:97-100). Previous investigations used either general neuronal markers, focused on adrenergic innervation or on functional studies (Wheatley et al., Transplantation 1993, 56:202-206). The vagal reinnervation which is thought to be of great functional significance has never been studied selectively before. Since vagal innervation of the rat liver is almost exclusively afferent (Berthoud et al., Anat Embryol 1992, 186:431-442), we investigated this issue utilizing anterograde tracing from nodose ganglion.To check for possible early reinnervation WGA-HRP was injected into the left nodose ganglion five days post transplantationem and the animals were perfusion fixed one day afterwards. Later stages of persistent denervation or reinnervation were examined using anterograde tracing with DiI. WGA-HRP labeled structures were revealed using TMB histochemisty. DiI labeled fibers were analyzed with confocal laser scanning microscopy.

After 6 to 8 days after orthotopic liver transplantation the organ and the liver pedicle were devoid of labeled vagal afferents. First signs of reinnervation were evident three month post transplantationem. Four month after liver transplantation DiI labeled vagal afferent fibers were seen crossing the anastomosis of the extrahepatic bile duct en route to the graft. Bile duct epithelium was hyperplastic. At this time the pattern of reinnervating axons did not yet resemble to the aborisations as seen in untreated animals.

These results indicate occurring although somewhat delayed reinnervation of transplanted rat liver by vagal afferent neurons.

IS CALCIUM-INDUCED CALCIUM RELEASE (CICR) ESSENTIAL FOR THE SLOW AFTERHYPERPOLARIZATION IN RABBIT VAGAL SENSORY NEURONS? K. A. Moore, R. Bangalore, A. S. Cohen*, J. P. Y. Kao, and D. Weinreich. Dept. of Pharmacology and Experimental Therapeutics, Medical Biotechnology Center and Dept. of Physiology, University of Maryland School of Medicine, Baltimore, MD 21201.

Following a single action potential (AP), a slowly-developing and long-lasting (8 sec) afterhyperpolarization (AHP_{slow}) is observed in 35 % of rabbit nodose neurons. This apamin-insensitive AHP_{slow} is blocked by intracellular BAPTA, suggesting that changes in $[Ca^{2+}]_i$ contribute to its generation. Using fura-2 to monitor $[Ca^{2+}]_i$, we find that a single AP induces a Ca^{2+} transient (Ca_i) of 12 ± 1.2 nM (n=18). The dependence of the amplitude of the Ca_i and the amplitude of the AHP_{slow} current (I_{AHP}) on the number of action potentials are best fit by a rectangular hyperbola. The magnitude of the I_{AHP} is a linear function of the Ca_i magnitude (r = 0.993). Treatment with 10 μM ryanodine or DBHQ abolished AP-induced Ca_i and the AHP_{slow} elicited by up to 8 APs. In the presence of these CICR inhibitors, there is a linear relation (r = 0.945) between number of APs and Ca_i magnitude over the range of 8 - 32 APs. The change in $[Ca^{2+}]_i$ per AP in the presence of these inhibitors is only 2 ± 0.1 nM (n=14). Using whole-cell patch-clamp recording, inward I_{Ca} were evoked by voltage-clamp waveforms of APs previously recorded from a nodose neuron. The amount of charge due to Ca^{2+} entry resulting from each AP averaged 39 ± 2.8 pC and is constant over the range of 1 - 32 APs. The hyperbolic relation between the number of APs and Ca_i or I_{AHP} is therefore not due to decreases in I_{Ca} during a train of APs. Additionally, neither ryanodine nor DBHQ affected Ca^{2+} influx. The AP-induced Ca_i always peaked before the peak of the I_{AHP} and returned to baseline before I_{AHP} returned to baseline. Thus, a CICR pool exists in nodose neurons and can be activated by a single AP. CICR is essential for the development of the AHP_{slow} but is not sufficient to explain the slow kinetics of this afterpotential. (Supported by NIH Grant # NS22069 to DW.)

708.4

SUBSTANCE P REGULATION OF I_K AND I_h DECREASES EXCITABILITY OF FERRET VAGAL SENSORY NEURONS VIA A NK-1 RECEPTOR. M. S. Jafri* and D. Weinreich. Department of Pharmacology & Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD 21201.

We have demonstrated previously that ~80% of ferret vagal sensory neurons (nodose neurons) are hyperpolarized by substance P (SP) through activation of a K^+-current (I_K). This effect could be minimized by activation of a hyperpolarization-activated depolarizing current (I_h) that is present in 65% of these neurons. This study shows that SP reduced I_h by activating the same receptor subtype that mediates the hyperpolarizing SP response.

In acutely dissociated neurons, 200 nM SP reduced the magnitude of I_h elicited by moderate hyperpolarizing stimuli but did not affect the magnitude of I_h elicited by strong stimuli. Tail current analysis indicated that this effect was the result of a shift of the I_h activation curve to more negative membrane potentials. The half-activation potential ($V_{½}$) of I_h shifted from -77 ± 2.1 mV in control to -98 ± 3.2 mV in the presence of 200 nM SP (n=3 for each). The SP effect on I_h, like its effect on I_K, was reversibly blocked by 10 nM CP99,994, an NK-1 antagonist, and was mimicked by 200 nM ASM-SP, an NK-1 agonist. These results show that SP activates a NK-1 receptor coupled to the I_h channel. Thus, NK-1 receptor activation in ferret vagal afferents not only activates a potassium conductance leading to membrane hyperpolarization but it also synergistically enhances this inhibitory effect by decreasing I_h. (Supported by NINDS Grant NS-22069)

SYNAPTIC CURRENTS IN THE RAT NUCLEUS OF THE SOLITARY TRACT EVOKED BY VAGUS NERVE STIMULATION IN VITRO. B.N. Smith*, P. Dou, W.D. Barber, and F.E. Dudek Dept. of Anat. and Neurobiol., Colorado State Univ., Fort Collins, CO 80523.

Amino acid transmission in the nucleus of the solitary tract (NTS) has been demonstrated, but not extensively studied with whole-cell recordings in vitro. We used a brain stem-cranial nerve preparation that allowed whole cell patch-clamp recordings to be made from dorsomedial NTS neurons that were specifically activated by vagus nerve stimulation. Biocytin (0.1%) was used to verify the location of the recorded neurons. We tested the hypotheses that vagal input to NTS neurons was glutamatergic and that local inhibitory circuitry is present in immature (2-5 day old) rats.

Resting membrane potential for NTS neurons was -63 ± 2 mV (mean ± SEM); input resistance was 527 ± 58 MΩ. All neurons responding to vagal stimulation displayed excitatory synaptic responses. Approximately 50% of these also demonstrated multisynaptic, but not monosynaptic inhibitory responses. Evoked EPSCs reversed near 0 mV and were blocked by glutamate receptor antagonists. Glutamate AMPA/kainate receptors mediated most of the response near rest, although NMDA receptors are probably also involved at potentials positive to ~-60 mV. Evoked (but not spontaneous) IPSCs were reversibly blocked by DNQX. The $GABA_A$ antagonist, bicuculline abolished all IPSCs, which reversed near -70 mV.

These data indicate that glutamate mediates the primary response of NTS neurons to vagal stimulation. Local feedforward inhibitory circuits are also functional in the NTS early in postnatal development. Supported by NIH grant NS27972 (WDB).

CARDIAC VAGAL AFFERENTS DEPRESS THE KNEE JERK REFLEX. J.G. Pickar*, Kansas State University, Department of Anatomy & Physiology, Manhattan, KS 66506.

Previous studies demonstrate the presence of a viscerosomatic whose sensory arm originates in the cardiopulmonary region, travels in the vagus nerves and whose efferent arm depresses skeletal muscle activity including the knee jerk reflex (Kalia, M. *Pflug Arch* 343:297-308, 1973; Coast, JR. *J Appl Physiol* 62:2058-2065, 1987). The purpose of the present study was to localize a sensory stimulus to nerve endings in the heart and test the hypothesis that cardiac receptors reflexly depress the knee jerk reflex. Cardiac receptors were stimulated by injecting nicotine (30μg/kg) into the pericardial sac in chloralose-anesthetized cats. The knee jerk reflex was elicited every 1.5 seconds by striking the patellar tendon with a solenoid-driven, light-weight reflex hammer. Nicotine injected intrapericardially (IPC) inhibited the knee jerk reflex by approximately 26.2 ±6.5% in 12 of 15 cats. Isovolumetric saline IPC had no effect on the knee jerk reflex. To confirm that the nicotine-induced depression was initiated by cardiac receptors, procaine IPC was injected 2 minutes prior to nicotine IPC. Procaine IPC abolished the nicotine-induced depression in 5 of 5 cats. To determine whether the nicotine-induced depression was mediated by the vagus nerves, the vagi were cut and nicotine was injected IPC. Vagotomy abolished the nicotine-induced depression in 5 of 5 cats. The data indicate that stimulation of vagally-innervated receptors in the heart can reflexly depress the knee jerk reflex. This reflex may contribute to a negative feedback loop that helps safeguard the heart when excessive demands are placed upon it during physical exertion (Ginzel, KH & Eldred, E. *Proc West Pharm Soc* 13:188-191, 1970). Supported by NIH Grant HL-49221.

708.7

ACTIVATION OF CELLS IN THE C1-C2 DORSAL HORN (DH) BY CARDIOPULMONARY SYMPATHETIC AFFERENT (CPSA) FIBERS IS NOT DEPENDENT ON THE DORSAL COLUMN PATHWAY IN RATS. J. Zhang*, M.J. Chandler, and R.D. Foreman. Dept. Physiology, Univ. of Okla. HSC, Okla. City, OK 73190.

Pain of angina pectoris is referred to the chest, shoulder, arms, neck and/or jaw. Myocardial ischemia activates CPSA and vagal afferent fibers. We have shown in rats that vagal stimulation excites C1-C2 DH cells whose somatic fields include the neck and/or inferior jaw. This study was designed to determine if activation of CPSA fibers, which terminate primarily in upper thoracic segments, also excites C1-C2 DH cells and.to identify the pathway that transmits afferent information to C1-C2. Extracellular action potentials were recorded from 51 C1-C2 neurons in anesthetized rats. CPSA stimulation increased cell activity in 50 cells and decreased activity in 1 cell. Evoked activity increased as stimulus intensity increased. Excitatory somatic fields were found for 37 of 40 cells examined; 15 were HT, 9 were WDR, 11 were LT and 2 were HTi; fields most commonly were on the head, jaw, neck and shoulder. To identify the ascending pathway that carried CPSA input, lesions were made in dorsal columns (DC) in 7 rats and anterolateral funiculi (ALF) in 4 rats at C5-C8. DC lesions did not affect responses, whereas lesions of ALF prevented increased activity after CPSA stimulation. These results showed that sensory inputs from CPSA fibers excited C1-C2 DH cells by activating fibers traveling in ALF, and thus might contribute to the neural mechanisms involved in pain referred to neck and jaw. (NIH HL22732 and Presbyterian Health Foundation)

ENDOGENOUS BRADYKININ ACTIVATES ISCHEMICALLY SENSITIVE CARDIAC SYMPATHETIC AFFERENTS THROUGH KININ B_2-RECEPTOR. S.Tjen-A-Looi, H-L. Pan, and J. C. Longhurst*. Division of Cardiovascular Medicine, University of California, Davis, CA 95616

Activity of ischemically sensitive cardiac sympathetic afferents during myocardial ischemia induces cardiovascular reflexes and angina. Although increased production of bradykinin (BK) has been shown during myocardial ischemia, its role in activation of ischemically sensitive cardiac afferents has not been established. Thus, the present study tested a hypothesis that BK produced during ischemia activates cardiac afferents through kinin B_2 receptors. Single-unit activity of cardiac afferents innervating the left ventricle was recorded from the left thoracic sympathetic chain (T_{1-4}) in anesthetized cats. Intracardiac injection of BK (1μg/Kg, ia) increased the discharge rate of 4 ischemic sensitive afferents from 0.20 ± 0.15 to 0.35 ± 0.16 impulses/sec ($p < 0.05$). Des-Arg^9-BK (1μg/Kg, ia), a kinin B_1-receptor agonist, did not increase significantly the impulse activity of 4 ischemic sensitive fibers (0.02 ± 0.01 to 0.02 ± 0.01 impulses/ sec). Hoe-140 (30 μg/Kg iv), a kinin B_2-receptor antagonist, attenuated significantly the response of 5 afferents to ischemia (0.55 ± 0.33 to 1.24 ± 0.39 vs. 0.60 ± 0.34 to 0.63 ± 0.34 impulses/ sec, post-HOE-140.) These data suggest that BK produced during ischemia contributes to stimulation of ischemically sensitive cardiac sympathetic afferents through kinin B_2 receptors. [Supported by HL36527, HL51428, HL52165, AHA-CA#95-44A].

ROLE OF PROTONS IN ACTIVATION OF ISCHEMICALLY SENSITIVE CARDIAC SYMPATHETIC AFFERENTS. Hui-Lin Pan, Charles L. Stebbins*, and John C. Longhurst. Cardiovascular Medicine, University of California, Davis, CA 95616

Activation of cardiac sympathetic afferents during ischemia causes cardiac pain. The mechanisms underlying activation of cardiac sympathetic afferents during ischemia remain unclear. The present study examined the contribution of protons produced during myocardial ischemia to activation of cardiac sympathetic afferents. Single-unit activity of cardiac sympathetic C-fiber afferents innervating both ventricles was recorded from the left thoracic sympathetic chain and rami communicantes from T_{2-5} in anesthetized cats. Epicardial pH was measured using a pH sensitive needle electrode. Five min of myocardial ischemia decreased epicardial pH from 7.36 ± 0.23 to 7.01 ± 0.22 ($n = 6$, $p < 0.05$). Placement of isotonic neutral phosphate buffer (pH = 7.40) prevented the ischemia-induced decrease in epicardial pH ($n = 6$). Topical application of 10-100 μg/ml of lactic acid dose-dependently stimulated 9 ischemically sensitive afferents, but did not activate 16 ischemically insensitive cardiac afferents. Furthermore, epicardial treatment with isotonic neutral phosphate buffer significantly attenuated the response of 4 afferents to 5 min of myocardial ischemia (0.32 ± 0.09 to 1.29 ± 0.14 pre-treatment vs. 0.36 ± 0.11 to 0.57 ± 0.17 impulses/sec). These data indicate that protons produced during myocardial ischemia contribute to activation/sensitization of ischemically sensitive cardiac sympathetic afferents.

ELECTROPHYSIOLOGICAL PROPERTIES AND CHEMOSENSITIVITY OF ACUTELY ISOLATED RABBIT JUGULAR NEURONS. L. Franca, G. Taylor and D. Weinreich*, Dept. of Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD 21201.

Intracellular recording techniques in conjunction with membrane responsivity to various inflammatory mediators were used to classify neurons in the jugular ganglion of the vagus. The mean cell body diameter was 25±0.7 μm (n=312; range 10 to 70 μm). From a pool of 203 neurons three groups were distinguished on the basis of membrane potential (E_m), input resistance (R_i), action potential width and amplitude of the fast spike afterhyperpolarizations (AHP_f). Group I cells (n=57) possessed E_m values of 67 ± 1 mV, R_i of 54 ± 3.6 MΩ, action potentials widths of 3 ± 1 msec and 15 ± 1 mV AHP_f. All group I neurons expressed a Na_+ current sensitive to TTX (1μM, TTX_s) and a K_+ current sensitive to TEA (5 mM). Group II neurons (n=113) showed E_m values of -65 ± 1 mV, R_i of 63 ± 1 MΩ, action potentials widths of 9 ± 1 msec and 9.5 ± 0.5 mV AHP_f. Only 13% of group II neurons were TTX_s but all had K_+ currents sensitive to TEA. Group III neurons (n=33) revealed E_m values of -65 ± 1 mV, R_i of -67 ± 5 MΩ, action potentials widths of 26 ± 2 msec and 5 ± 1 mV AHP_f. None of group III neurons expressed TTX_s currents but they all had K_+ currents sensitive to TEA. Jugular neurons showed reversible membrane potential changes (4-10 mV) to substance P (SP), serotonin (5-HT), histamine, bradykinin, 1.1-dimethyl-4-phenylpiperazinium iodide (DMPP), γ-amino butyric acid or acetylcholine. Forty percent of the neurons were hyperpolarized (~8 mV) by either SP or 5-HT; neither autacoid produced a measurable membrane depolarization. All three classes of neurons showed hyperpolarizing SP and 5-HT responses; neither membrane properties nor chemosensitivity correlated with cell body diameters. Although neurons were not distinguished by their chemosensitivity properties, three distinct classes of jugular neurons can be recognized according to their electrical membrane properties. The chemosensitivity and electrical properties of these vagal afferents are in marked contrast to those in rabbit nodose. (Supported by Grant # NS22069 to DW and schorlaship from FAPEMA - BRAZIL)

INDUCTION OF FOS-LIKE PROTEIN IN PERIAQUEDUCTAL GRAY (PAG) AFTER ELECTRICAL STIMULATION OF THE SUPERIOR LARYNGEAL NERVE IN ANESTHETIZED CAT. R. Ambalavanar*, Y. Tanaka, M. Damirjian, W.S. Selbie and C. Ludlow. VSS, NIDCD, 10 Center Drive MSC 1416, Bethesda, Maryland, MD 20892-1416.

Vocalization can be elicited in many vertebrates by stimulation in the caudal PAG region. Sensory input from the larynx via the internal branch of the superior laryngeal nerve (ISLN) synaptically excites polysynaptic pathways involving laryngeal and tongue musculature and may play a potential role in vocalization. Previous anatomical studies revealed bilateral connections between the PAG and the nucleus tractus solitarius, the main termination zone of the laryngeal afferents. In the present study we inquired whether there are any functional connections of the ISLN afferents with the PAG using Fos-immunocytochemistry after electrical stimulation of the ISLN. Five experimental and 5 control cats were anesthetized with α-chlorolose (40mg/kg), the ISLN exposed in all 10 cats and stimulated only in 5 experimental cats at 0.5Hz at supramaximal levels (0.6-0.9 volts) with a 0.2 ms pulse for 60 min producing bilateral activity in the TA muscles. Cats were deeply anesthetized 30 min later with pentobarbital (100 mg/kg, i.p) and perfused transcardially with 0.1M phosphate buffered saline (pH 7.4) followed by Zamboni fixative. Serial transverse sections (50μm thick) of the midbrain were cut through the PAG, immunostained for Fos using anti-Fos antibody (Oncogene Sci., Ab-2). Clearly stained nuclei were counted using a commercial image analysis system (Neurolucida). Fos-immunoreactive nuclei were observed bilaterally in the PAG region of both experimental and control cats. Substantially more stained nuclei were found in the experimental cats in the lateral and ventral PAG mainly in the caudal part. The present results suggest the existence of some functinal connections between ISLN afferents and the PAG. Supported by NIDCD, NIH.

SEROTONIN STIMULATES ISCHEMICALLY SENSITIVE SYMPATHETIC ABDOMINAL VISCERAL AFFERENTS THROUGH 5-HT_3 RECEPTORS. L.-W. Fu, H.-L. Pan*, C.A. O'Neill, and J.C. Longhurst. Univ.of Calif., Davis, CA 95616

Abdominal ischemia stimulates sympathetic visceral afferents to reflexly activate the cardiovascular system. In the present study, we evaluated the role of serotonin (5-HT) in activation of ischemically sensitive visceral afferents. Mesenteric lymph and portal venous blood 5-HT levels of 8 cats were measured by high performance liquid chromatography before, during and after 10 min of abdominal ischemia. Single-unit activity of abdominal visceral C-fiber afferents was recorded from the right thoracic sympathetic chain of anesthetized cats. Abdominal ischemia increased the portal venous plasma 5-HT level from 0.45±0.17 to 2.12±0.91 nmol/ml ($p<0.01$). Also, the concentration of 5-HT in lymph fluid increased from a preocclusion level of 0.54±0.15 to 1.98±0.47 ($p<0.05$) during ischemia, and to 3.12±0.90 nmol/ml during reperfusion ($p<0.05$). Intra-arterial injection of 5-HT (20 μg/kg) increased discharge activity of 9 afferents (from 0.33±0.07 to 1.03±0.09 imp/s, $p<0.01$). 2-Methylserotonin (100 μg/kg, ia), a 5-HT_3 agonist, also stimulated 8 out of the 9 afferents and increased discharge activity of these afferents from 0.34±0.05 to 1.09±0.11 imp/s ($p<0.01$). However, a 5-HT_2 receptor agonist, α-Methylserotonin (100 μg/kg, ia) only stimulated 2 out of the 9 afferents (0.19±0.11 vs. 0.72±0.12 imp/s). Furthermore, a 5-HT_1 receptor agonist, carboxamidotryptamine (100 μg/kg, ia) did not alter the impulse activity of these 9 afferents (0.34±0.07 vs. 0.37±0.07). Thus, these data indicate that abdominal ischemia and reperfusion promote the production 5-HT, which may contribute to activation of ischemically sensitive abdominal sympathetic visceral afferents mainly through stimulation of 5-HT_3 receptors. WARM-SENSITIVE ABDOMINAL C-FIBER UNITS *IN VITRO*.
D.W. Adelson*, J.Y. Wei, and L. Kruger. Section of Oral Biology, Dept. of Medicine, and Dept. of Neurobiology, UCLA Medical Center, Los Angeles CA 90095.

Receptive fields of single slowly-conducting afferent fibers were located using a thermal (warm) search stimulus in a rat *in vitro* splanchnic nerve-mesentery preparation. Warm-sensitive receptive fields were punctate, and were densest in the region surrounding the prevertebral ganglia, an area with prominent deposits of brown adipose tissue, where the abdominal aorta branches into the major trunks supplying the abdominal viscera. The majority of warm-sensitive units responded to a rapid warming ramp (42-49°C peak) followed by 10-30 sec at peak temperature with discharge comprising both phasic and tonic components. The remainder responded with only phasic discharge, irrespective of the position from which the stimulus was applied. Some warm-sensitive units were also responsive to either punctate mechanical (< 10 mN) stimuli or to bradykinin (BK). BK-induced sensitization to warming, lasting 5-10 minutes after focal application of microliter volumes of 9-90 nM BK, was apparent in a number of units as a significant increase in the number of impulses evoked by a post-BK warming trial. Changes in background activity, thermal threshold, mechanical sensitivity, BK sensitivity and BK-induced sensitization were noted in various units over the course of prolonged observations, suggesting that these indices may not reliably distinguish unit type, but may instead indicate the functional state of the sense organ. The thermosensitivity of splanchnic afferent neurons may be relevant to abdominal thermoregulation, nociception, and/or vascular effector functions of peptidergic afferent terminals.

AFFERENT SIGNALLING OF VERTEBRAL DISPLACEMENT IN THE NECK OF THE CAT.
P.S. Bolton* & C.T. Holland Neuroscience Group, Faculty of Medicine & Health Sciences, University of Newcastle, Callaghan, 2308 Australia.

Previous studies suggest that afferents arising from muscles spindles in dorsal neck muscles attaching to the head and deeper neck muscles contribute to neck evoked reflexes. We tested if afferents innervating deep intervertebral muscles and zygapohysial joint tissue can signal vertebral motion in the neck. The skin and dorsal neck muscles were denervated (C1-C4) in anaesthetised cats and recordings of multi and single unit activity were made from the dorsal rootlets (dr) of C2 (n=8) and C3 (n=16) spinal nerves, the medial branch of the dorsal primary rami (mDPR) of the C3 spinal nerve (n=4) and putative articular branches (pA) to the C2/C3 zygapophysial joint (n=6) during displacement of C2 vertebra. The firing rate of spontaneous units in the dr and mDPR responsive to mechanical stimuli or succinylcholine (0.14ug in 0.1ml saline i.m.) applied to the ipsilateral semispinalis cervicis or semispinalis dorsalis muscles increased when the C2 vertebra was displaced in one direction and decreased when displaced in the other. Response characteristics of most units were similar to those described by others in afferents activated by muscle spindles in dorsal neck muscles. On occasion, otherwise silent units with receptive fields in intervertebral muscles were activated during the displacement of the C2 vertebra (n=2) or were activated when probing/puncturing the ipsilateral C2/C3 zygapophysial joint capsule (n=6), with 3 exhibiting after discharges. Notably we have not found unitary activity in the pA, mDPR or dr with receptive fields in the C2/C3 zygapophysial joint activated by displacement of the C2 vertebra. Our data indicate vertebral displacement may be signalled to the central nervous system by afferents arising from deep intervertebral neck muscles. Further, afferents innervating the C2/C3 zygapophysial joint are unlikely to make a major contribution to signalling vertebral displacement.

Ionic Components of Action Potentials in Muscle Afferents.
M.A. Rizzo*, T. Oyelese, S.G. Waxman, and J.D. Kocsis. Dept. of Neurology,Yale School of Medicine, New Haven, CT and Neuroscience Research Center, VAMC, West Haven, CT 06516.

A series of experiments designed to characterize the kinetics and pharmacology of ionic channels particular to muscle afferents was performed. Muscle afferent dorsal root ganglion (DRG) neurons were identified by retrograde labelling with fluorogold in order to study action potential properties, sodium current expression and the ionic mechanisms underlying the action potential in this class of sensory neurons. Action potential duration (at 50 % max amplitude), presence or absence of an inflection on the downslope and duration and amplitude of the afterhyperpolarization were examined. The action potentials in muscle afferents were brief in duration (0.68 ± 0.05 ms) and 82 % of neurons studied lacked an inflection on the downslope of their action potentials. Noninflected action potentials exhibited sensitivity to 200 nM tetrodotoxin (TTX) while inflected action potentials persisted. In some but not all neurons, the inflection was partially Ca^{++} dependent. Using the whole-cell patch-clamp configuration in the presence of 0.1 mM Cd^{++}, voltage-dependent Na^+ currents were found to consist of two types distiguishable by their kinetics and TTX-sensitivity. An isolated, kinetically fast TTX-sensitive current was present in 12/16 neurons studied, whereas a combination of a TTX-sensitive and a kinetically slower TTX-resistant current was found in 3/16 neurons. One out of 16 neurons studied lacked the fast, TTX-sensitive component. It appears, therefore, that a kinetically slow, TTX-resistant Na^+ current is likely to be responsible for the action potential inflection in a subpopulation of cells. The definitve characterization of Na^+ and Ca^{++} channels particular to muscle afferents may be essential for understanding the molecular pathophysiology of certain diseases where muscle afferent hyperexcitability is implicated, including certain forms of focal dystonia such as writer's cramp. These studies were supported by the NIH, the MS Society, The Eastern Paralyzed Veteran's and Paralyzed Veteran's Associations.

DIFFERENTIAL EXPRESSION OF SPECIFIC PROTEINS FOLLOWING DENERVATION OF RABBIT LACRIMAL GLAND.
M.F. Salvatore,* R.W. Beuerman. Louisiana State University Medical Center, Neuroscience Center of Excellence, New Orleans, LA 70112.

Morphological changes in the cellular constituents of the lacrimal gland have been previously observed following lesions in the corresponding sensory and autonomic nuclei. In this study, complete transection of the lacrimal nerve and the connecting zygomatic branch of the facial nerve at the lacrimal gland itself (representing the sensory/sympathetic and parasympathetic innervation respectively) was conducted on two New Zealand White rabbits. A sham procedure carried out on the contralateral gland included all manipulation, excluding nerve transection. Following surgery, tears were collected from both eyes for one week. Protein concentration was determined in the tear samples and equivalent amounts of tear protein were subject to SDS-PAGE. Significant differences in the expression of five tear proteins were observed. The expression of a 27-kD band was observed to gradually increase in the denervated gland tear output versus the sham gland tear output over one week after denervation. However, other bands at 80, 68, 49, and 40 kD were expressed at significantly higher levels in the denervated gland tears when compared to the sham gland tear output. These findings suggest that the central nervous system has control over the synthesis of specific proteins in the lacrimal gland.

INTRADERMAL INJECTION OF CAPSAICIN IN HUMANS: DIMINISHED PAIN SENSATION ASSOCIATED WITH RAPID DEGENERATION OF INTRACUTANEOUS NERVE FIBERS.
D.A. Simone*[1], M. Nolano[2], G. Wendelschafer-Crabb[2] and W.R. Kennedy[2], Depts. of Psychiatry[1] and Neurology[2], University of Minnesota, Minneapolis, MN 55455.

Application of capsaicin (CAP) to skin results in decreased pain sensation within the CAP-treated area, believed to be due to desensitization of CAP-sensitive nociceptors. We postulated that local injection of CAP might produce morphological alterations of intracutaneous nerve fibers that could account for diminished pain sensation. In human subjects, 20 μl of 0.1% CAP and the vehicle (VEH) was injected into the skin at separate sites on the upper arm. Tactile, cold, pricking and heat pain sensations were assessed at the injection sites before and 24 h after CAP. Injected skin was removed by 2 mm punch biopsy and nerve fibers examined immunohistologically using antibodies for protein gene product 9.5 (PGP), substance P (SP) and calcitonin gene-related peptide (CGRP). In VEH-treated skin, sensation was not affected and both epidermal and dermal nerve fibers had normal appearance. In CAP-treated skin, the magnitude of pricking and heat pain sensation diminished and there was a dramatic decrease in the number of nerve fibers immunoreactive for PGP, SP and CGRP. No fibers were found in the epidermis and fibers in the superficial dermis were sparse. The few remaining fibers had a beaded appearance, suggestive of degeneration. It is possible that degeneration of nerve fibers in the skin may contribute to analgesia produced by CAP. Supported by NIH (NS31223 and NS31397).

709.2

DECREASED SENSATION AND LOSS OF EPIDERMAL NERVE FIBERS FOLLOWING REPEATED TOPICAL APPLICATION OF CAPSAICIN IN HUMANS.
M. Nolano[1], D.A. Simone[2], G. Wendelschafer-Crabb[1] and W.R. Kennedy*[1]. Depts. of Neurology[1] and Psychiatry[2], University of Minnesota, Minneapolis, MN 55455.

Repeated exposure to topical application of capsaicin (CAP) results in diminished pain sensation within the treated area of skin. Indeed, CAP has been used to manage pain associated with a variety of disorders, such as arthritis and post-herpetic neuralgia, and is readily available for clinical use. We examined whether topically applied CAP alters the morphology of nerve fibers in epidermis. Human subjects applied 0.075% CAP cream 4 times each day to a 2-3 cm^2 patch of skin on the upper arm. Before and at various times after application, tactile, cold, pricking and heat pain sensations were assessed within the treated area. To examine nerve fibers in the epidermis, 3 mm diameter suction blisters were made to allow easy removal of the epidermis, and nerve fibers were visualized using immunohistochemical techniques. Blisters were made 1, 3, 8 and 14 days following CAP application. There was a dramatic decrease in the number of fibers immunoreactive for protein gene product 9.5 within 8 days of CAP application. This was accompanied by diminished sensation, particularly heat pain sensation. These findings suggest that topically applied CAP causes degeneration of epidermal nerve fibers and the loss of these nerve fibers may contribute to CAP-induced analgesia. Supported by NIH grants NS31397 and NS31223.

709.3

UPREGULATION OF THE α_{2A} ADRENERGIC RECEPTOR SUBTYPE AFTER PERIPHERAL NERVE INJURY. L.A. Birder* and E.R. Perl. University of North Carolina at Chapel Hill Department of Physiology, Chapel Hill, NC 27599.

After peripheral nerve injury, a population of C-fiber nociceptors develop a novel excitatory adrenergic response mediated by α_2 adrenergic receptors (AR). Our objective was to determine if an α_{2A} AR subtype in DRG neurons is upregulated after nerve injury. One to two weeks after the sciatic nerve was lesioned in deeply anesthetized rats, they were sacrificed under deep anesthesia and DRGs were incubated with an antibody recognizing the α_{2A} protein (Rosin et al.,1993). Immunoreactivity (IR) for the c-jun protein and/or retrograde transport of fluorescent dyes was used to identify axotomized sensory neurons. The α_{2A} AR-like immunoreactivity was visualized as a punctate reaction product localized to the cell membrane, cytoplasm and terminals surrounding individual cells. In animals with partial sciatic nerve lesion (N=4), the α_{2A} AR was substantially upregulated on the ipsilateral side in medium size neurons (avg. dia. 36μm; range 15-58 μm). The greatest increase occurred in ganglia supplying the sciatic nerve (L_4/L_5), with low basal levels and no upregulation of α_{2A} AR detected in more rostral segments and in normal unoperated animals. Only about one-half of the α_{2A} positive cells on the ipsilateral side were colabeled with c-jun IR, indicating upregulation in both uninjured as well as axotomized neurons. Similar results were seen in animals with complete sciatic nerve lesion (N=5), with one-half of α_{2A} AR positive neurons labeled with a fluorescent dye. These experiments provide evidence for increased α_{2A} adrenergic receptors after nerve injury. The size distribution of the soma exhibiting increased α_{2A} AR (mostly medium-large diameter) is inconsistent with C-fiber nociceptors. Instead, the data suggests that an α_{2A} upregulation may correlate with other reported phenomena such as injury induced adrenergic sprouting. This work was supported by grant NS 14899 from the NINDS of the NIH.

CUTANEOUS C-FIBER NOCICEPTORS DEVELOP ALPHA-1 ADRENERGIC SENSITIVITY FOLLOWING L6 SPINAL NERVE LIGATION IN MONKEY. Z.Ali*, M.Ringkamp, H.F.Chien, J.N.Campbell, N.A.Flavahan, and R.A.Meyer, Johns Hopkins University, School of Medicine, Baltimore, MD 21287

The development of adrenergic sensitivity of cutaneous nociceptors has been proposed to account for the pain associated with sympathetically maintained pain. In this *in-vitro* study, we compare the responses to adrenergic agonists of cutaneous C-fiber nociceptors following nerve lesion with responses from control animals. In the anesthetized monkey, the superficial peroneal or radial nerve, together with the skin innervated by the nerve, was dissected and placed in an organ bath where single fiber recordings were made. The α_1 agonist, phenylephrine (PE), and the α_2 agonist, UK 1403 (UK), were applied to the receptive field in increasing concentrations from 0.1 to 100 μM. Each concentration was applied for 5 min, and a 10 min washout period followed treatment with each agonist. Drug order was randomized. Nine C-fibers were studied 2-3 weeks after a tight ligation of the L6 spinal nerve. Two fibers had marked, spontaneous activity before drug application (28 APs/5 min); neither responded to PE or UK. Six of the remaining 7 fibers exhibited an evoked response after administration of PE or UK. At the 10 μM concentration, the mean response to PE (42 APs/5 min; n = 5) was substantially greater than the response to UK (9 APs/5 min; n = 5). C-fiber staining with protein gene product 9.5 revealed an approximately 55% reduction in the number of C-fibers that innervated the epidermis compared to the contralateral limb. Eighteen C-fibers were studied in control animals. None had spontaneous activity. Two of 17 tested responded to PE. One of 14 tested also responded to UK. Thus a significant increase in the incidence of α_1- and α_2-adrenergic sensitivity was observed following nerve lesion (Ψ^2, $p \leq 0.02$; $p \leq 0.01$). In contrast to neuropathic injuries in other species where only α_2-adrenergic sensitivity has been reported, nociceptive C-fibers in primate also develop enhanced α_1-adrenergic sensitivity following a nerve lesion. (NIH, NS-32386)

MECHANICAL SENSITIZATION IS LOCALIZED TO THE REGION OF A MECHANICAL INJURY FOR CUTANEOUS A-FIBER NOCICEPTORS IN THE MONKEY. R.M.Slugg*, R.A.Meyer, and J.N.Campbell. Dept of Neurosurgery and The Applied Physics Lab, Johns Hopkins University, Baltimore, MD 21205

In this study, we sought to determine if primary afferent sensitization contributes to the mechanical hyperalgesia following a cutaneous injury. Standard teased fiber techniques were used to record from eight A-fiber nociceptors that innervated hairy skin in the anesthetized monkey. Force-controlled mechanical stimuli (16 or 32 gm, 1 s) were delivered to the skin via thin (100 μm) blade shaped probes. These stimuli were presented in 100 μm increments along a line through the middle of the receptive field (RF) in order to obtain an RF map. A 1 mm long mechanical injury was produced by delivering controlled force stimuli (128 gm, 10 s) to 10 sequential 100 μm locations within the RF. RF maps obtained before injury were reproducible. Within 15 minutes of the injury, a pronounced mechanical sensitization was observed in the area of injury for all eight fibers tested. The sensitization lasted several hours and was characterized by both an increase in the evoked response and a decrease in latency to first action potential. A change in stimulus transmission was not likely responsible since no change in skin compliance was observed in the area of injury. Sensitization was not observed at distances greater than 600 μm from the injury, suggesting that mediators released by an axon-reflex mechanism are not involved. The restriction of sensitization to the region of injury suggests that primary afferent sensitization to mechanical stimuli contributes to primary but not secondary hyperalgesia. Supported by NS14447 and NS09260.

709.6

TOPICAL CLONIDINE ATTENUATES ONGOING PAIN AND HYPERALGESIA IN PATIENTS WITH SYMPATHETICALLY MAINTAINED PAIN (SMP). U. Wesselmann*[1,2], Z. Ali [2], R. A. Meyer[2] and S. N. Raja[3]. Depts. of [1]Neurology, [2]Neurological Surgery and [3]Anesthesia and Critical Care, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21287.

In a previous unblinded pilot study, topical clonidine was found to relieve hyperalgesia confined to the patch site in patients with SMP; clonidine was proposed to act as an agonist at prejunctional alpha-2 receptors to inhibit the release of norepinephrine, which activated nociceptors and caused pain and hyperalgesia (Davis et al., Pain 47:309, 1991). The aim of the current study was to determine the effects of clonidine on SMP using a placebo-controlled, double-blinded protocol. Nine patients, diagnosed as having SMP based on pain relief after a local anesthetic sympathetic ganglion block, were enrolled in the study. Seven of these patients also reported pain relief with an intravenous phentolamine infusion (1mg/kg). Two skin patches were applied 1-2 cm apart to a uniformly hyperalgesic area. One patch contained clonidine (0.3 mg), the other patch contained no drug and served as a placebo control. Patients used a 0 to 10 scale to rate ongoing pain and pain to mechanical and cold stimuli before and three days after the application of the patches. Seven of the nine patients reported a significant decrease of the ongoing pain and hyperalgesia. A decrease in pain and hyperalgesia was observed at both the clonidine and the placebo sites, but the decrease was greatest at the clonidine site. Although pain relief was observed over a relatively large area that was centered on the clonidine site, pain relief was not observed over the entire affected extremity and thus a systemic effect of the drug is unlikely. These data support a localized site for the action for clonidine. We hypothesize that clonidine acts at a peripheral site to decrease ectopic activity in nociceptors. The resulting decrease in central sensitization may explain the widespread area of decreased ongoing pain and hyperalgesia. HYPERRESPONSIVENESS OF C-FIBERS TO MECHANICAL STIMULATION IN A RAT MODEL OF VINCRISTINE-INDUCED PAINFUL PERIPHERAL NEUROPATHY. K. D. Tanner*, D. B. Reichling, and J. D. Levine. Depts. of Med., Anat., Oral Surg., and Prog. Neurosci., Univ. of California, San Francisco,CA 94143

Vincristine, a chemotherapeutic agent that exerts its antineoplastic effects by depolymerizing microtubules, produces peripheral neuropathy in humans characterized by painful paresthesias and dysesthesias. We have established a rat model of vincristine-induced painful neuropathy (Aley et al., *Neuroscience*, in press, 1996) in which mechanical hyperalgesia develops and persists 11 days following the final dose of vincristine. To test the hypothesis that alterations in C-fiber function contribute to vincristine-induced hyperalgesia, we performed *in vivo* extracellular recordings of single primary afferents from the saphenous nerve of vincristine-treated rats during maximal hyperalgesia. Mean conduction velocities of A-fibers and C-fibers in vincristine-treated rats were significantly slower than those in control rats ($p<0.001$), consistent with the clinical presentation of the neuropathy. The proportion of A-fibers and C-fibers present in the nerve was similar in both groups. Interestingly, in contrast to other models of painful neuropathy, we did not find a significant increase in the percentage of spontaneously active neurons in vincristine-treated rats. Most notably, 45% of vincristine-treated C-fiber nociceptors showed a marked hyperresponsiveness (124±5 AP, n=9) to sustained mechanical stimulation (10g, 1 min) as compared to control C-fibers (59±4 AP, n=21). This hyperresponsive population was significantly different from both control C-fibers ($p<0.0001$), as well as the other population of vincristine-treated C-fibers (50±4 AP, n=11, $p<0.0001$). In contrast, mechanical activation thresholds of vincristine-treated C-fibers (5.1±1.9 g, n=38) tended to be higher than those of control C-fibers (2.4±0.6 g, n=44). The mean heat activation thresholds of C-fibers and the distribution of C-fibers among subclasses (e.g. C-MH) in vincristine-treated rats were not different from those in control rats. The mechanical hyperresponsiveness seen in C-fibers could contribute to the hyperalgesia in vincristine-treated rats and to the paresthesias and dysesthesias in patients receiving vincristine. PRIMARY AFFERENT SENSORY NEURONS THAT RELEASE SUBSTANCE P IN THE NORMAL, TRANSECTED, AND INFLAMED RAT. B.J. Allen, J. Li, D.A. Simone, S.D. Rogers, J.R. Ghilardi, C.M. Kotz*, A.I. Basbaum, and P.W. Mantyh. Mol. Neurobiol. Lab. (151), VA Med. Cntr., Mlps., MN 55417; Depts. of Psychiatry & Med., Univ. Minn., Mlps., MN 55455; Dept. Anatomy, UCSF,SF, CA 90024.

The neuropeptide substance P (SP), which is synthesized and released from primary afferent neurons, appears to be intimately involved in nociceptive transmission in the spinal cord. Recent studies have suggested that although C-fibers are the main type of primary afferent neuron that synthesizes SP in the normal animal, large myelinated fibers that project to the dorsal column nuclei (DCN) have been reported to express SP following nerve injury. To examine whether there is an altered pattern of SP release by primary afferent sensory neurons following nerve injury or peripheral inflammation, we stimulated the sciatic nerve electrically at intensities sufficient to excite various populations of afferents. This was verified by recording the sural nerve compound action potential simultaneously. Using internalization of the substance P receptor (SPR) as an indicator of SP release in the spinal cord, we found that activation of A-beta fibers only, did not evoke SPR internalization in spinal cord neurons. In contrast, activation of A-beta *and* A-delta fibers together evoked SPR internalization in the superficial laminae (I and II) of the dorsal horn but not in the deeper laminae (III-VI) whereas activation of A- and C-fibers evoked massive SPR internalization in laminae I through III but not in the deeper laminae (IV-VI). These studies suggest that both A-delta and C-, but not A-beta, fibers contain and release SP upon activation in the normal animal. We are currently examining the changes that occur in the spinal cord and DCN following nerve transection or inflammation. These data should shed light on the changes in the neurochemistry of the primary afferent and spinal cord neurons that occur in response to peripheral nerve injury or inflammation. Supported by NIH NS23970, NS31223, NS14627, and VA Merit Review.

709.9

CONFOCAL IMAGING OF SUBSTANCE P (NEUROKININ-1) RECEPTOR EXPRESSION IN THE NORMAL, NERVE INJURED AND INFLAMED SKIN

S.D. Rogers, A.L. Van Erem, J.R. Ghilardi, S.R. Vigna, P.W. Mantyh*. Mol. Neurobio. Lab (151), VAMC, Mpls., MN 55417; Dept. of Psychiatry, Univ. of Minnesota, Mpls., MN 55455.

Substance P (SP), which is synthesized and released from sensory neurons, has been hypothesized to modulate the proliferative, reparative and inflammatory processes in the skin. To define the cells that SP directly acts upon in the skin we have examined the expression of the substance P receptor (also known as the neurokinin-1 receptor (NK-1R)) in the normal, nerve injured, and inflamed skin. The models we used included the skin of the normal rat hindpaw and the hindpaw of rats that were denervated (via unilateral sciatic nerve transection)or inflamed (induced via injection of Complete Freund's Adjuvant (CFA)). In the normal animals, cells expressing high levels of NK-1R include keratinocytes located in the stratum basale, spinosum, and granulosum, capillaries in the epidermis, nerve fibers in the dermis and epidermis and smooth muscle cells of dermal arterioles. Following sciatic nerve transection (7-14 days) there is an approoximately 50% reduction in the thickness in both the epidermis and dermis with a decrese in NK-1R expression by the epidermal keratinocytes. Following injection of CFA the most marked change is a dramatic increase in mononuclear inflammatory cells expressing the NK-1R which invade both the dermis and hypodermis. These results suggest that SP and NK-1R can modulate the proliferative, reparative, and inflammatory processes of the skin. Additionally, the rat hindpaw appears to be an excellent model system for examining the function and therapeutic potential of using the transdermal modulation of the NK-1R to aid the repair and regeneration of skin. Supported by NIH 23970 and VA Merit Review.

EXCITATION OF DORSAL ROOT GANGLION CELLS BY INFLAMMATORY MEDIATORS AND GLUTAMATE IN NERVE–INJURED RAT. X.-J. Song, J.-M. Zhang and R. H. LaMotte*. Department of Anesthesiology, Yale University School of Medicine, 333 Cedar Street, New Haven, CT 06510

Injury of sciatic nerve increases the excitability of dorsal root ganglion (DRG) cells and induces cutaneous pain and hyperalgesia. Inflammatory mediators and excitatory amino acids play an important role in nociception. However, the effects of these substances on the responses of nerve–injured ganglion cells have not been evaluated.

Experiments were performed on 25 male Sprague–Dawley rats, 180–400g. The right sciatic nerves in 20 rats were loosely ligated at least 2 weeks before electrophysiological recording. An *in vitro* nerve–DRG preparation was used in which the L_4 or L_5 DRG with its nerve and dorsal root attached was removed from the rat, placed in a recording chamber and perfused with oxygenated artificial cerebral spinal fluid (ACSF, pH 7.3). Microfilament recordings were made from the dorsal root of L_4 or L_5. C and A fibers were identified by electrical stimulation of the sciatic nerve. Glutamate (Glu, 10^{-2}M) or inflammatory soup (IS), containing bradykinin, histamine, serotonin and prostaglandin E_2, all in 10^{-5}M, were applied to the DRG. The results showed that: 1) in nerve–injured rats, 9 of 18 C fibers were spontaneously active with a discharge rate of 0.06–1.0 impulses/sec. Twelve of 18 C fibers, 8 having spontaneous activity (SA), responded to IS with increased discharge rates. One of 4 C fibers with SA was excited by Glu; 2) 4/9 and 4/6 Aδ fibers, 5/6 and 2/4 Aβ fibers were excited by IS and Glu, respectively; 3) in normal rats (n=5), of the 4 C fibers and 11 Aβ fibers tested, only one Aβ-fiber weakly responded to either IS or Glu. Thus, it is possible that endogenous inflammatory mediators and glutamate excite the nerve–injured DRG and contribute to pain or hyperalgesia after nerve injury. CURRENTS EVOKED BY VANILLOIDS AND THEIR MODULATION IN TRIGEMINAL GANGLION NEURONS

T.K. Baumann*[1,2], M.E. Martenson[1], J.H. Arguelles[1] and K.-J. Lee[1]
Division of Neurosurgery[1] & Department of Physiology and Pharmacology[2], Oregon Health Sciences University, Portland, OR 97201

In a previous study (Baumann and Martenson, Soc. Neurosci. Abstr. 21, 1159, 1995) we have demonstrated that adult rat trigeminal ganglion (arTG) neurons respond to both piperine (10 μM) and capsaicin (100 nM) with a relatively slowly activating, sustained inward current (whole-cell patch-clamp recordings, holding potential alternating between -60 and -70 mV). In some neurons the sustained current is preceded by a transient inward current. The prolonged current is strongly enhanced in acidified physiological salt solutions (pH 6.3). The piperine- or capsaicin-activated currents are blocked by capsazepine, and so are the low-pH-enhanced currents. In the present study we examined the responses of arTG neurons to the vanilloids in more detail. In particular, we sought to determine how the low-pH enhancement of the slow inward current depended on the ionic composition of the recording solutions. Enhancement by protons was not evident in extracellular solutions based on cesium chloride or N-methyl-D-glucamine. These findings demonstrate that the enhancement of vanilloid responses by low-pH can be manipulated by changing the ionic composition of the extracellular solution. ENDOGENOUS OPIOIDS ACTIVATE A THIRD OF CUTANEOUS C-FIBRE POLYMODAL RECEPTORS IN THE RAT HAIRY SKIN. H.A. Martin*. Div. of Neurobiology, Univ. Sch. of Med., Newcastle upon Tyne NE2 4HH, UK.

Endogenous opioids, including β-endorphin (β-END), dynorphin (DYN) and Met-enkephalin (ENK) are released by dermal immunocytes upon interleukines activation. We have recently reported that IL-2 activates a third of cutaneous C-polymodal receptors (see Martin and Murphy, 1995; Martin 1996) but the mechanisms remain hypothetical. Opioids are potent mast cells degranulators and potentiate histamine-induced itch independently of histaminergic mechanisms or prostaglandin formation. Yet, it is not clear whether these opioids can activate cutaneous sensory neurones to produce pruritus, in addition to their antinociceptive effects in inflammation.

Activity of single units was recorded in an *in vivo* saphenous nerve preparation. Units were identified by their physiological characteristics. Test agents were injected (3µl) into individual mechanical receptive fields. Increase doses of one opioid were tested at 10 min intervals, respectively in this order: 0.1, 1, 10 and 100 µM. Then, mechanical and thermal thresholds were re-assessed. Response to bradykinin (BK, 100 ng) and acetic acid (H^+) were recorded at the completion of the drug study.

Opioid peptides activate a third of cutaneous C-polymodal receptors that are chemosensitive to BK and H^+. Concentration thresholds were circa 1 µM and responses did not increase at concentration above 10 µM. Desensitisation to mechanical and thermal stimuli was commonly observed. Cross-reactivity between test agents was not assessed due to experimental limitation.

We conclude that endogenous opioids and IL-2 activate a third of cutaneous C-polymodal receptors that are chemosensitive to BK and H^+ and produce inflammatory pruritus resistant to antihistamines.

TENSION AND COMPRESSION SENSITIVITY OF NOCICEPTORS IN RAT HAIRY SKIN. **PS Khalsa*, RH LaMotte , P Grigg. Dept. Physiology, University Of Massachusetts Medical School, 55 Lake Ave., Worcester, MA 01655, *Dept. Anesthesiology., Yale University School of Medicine**

Nociceptor afferent neurons can be activated by pushing a probe into the skin. This causes compressive stresses and strains in the skin. If the skin overlies soft tissue, it will also create tensile stresses and strains. This study was designed to determine the relative contribution of tensile and compressive stresses and strains to activation of fine (slowly conducting) afferent neurons. Isolated innervated skin from rat hindlimb was stretched by pulling along its edges, resulting in tensile stresses and strains. The receptive field of an isolated nociceptor was compressed using a force controlled indenter. The skin was supported by a hard, flat platform. Indentation stress ranged from 0 to 350 kPa. Compressive strains were measured from the displacement of the indenter after contact with the skin. C and Aδ afferents were recorded from teased filaments of a branch of the saphenous nerve innervating the skin. Activity was recorded while combinations of compression and tension were systematically applied. 91 afferents (18 Aδ and 73 C) were recorded in 12 experiments. Afferents were classified by their conduction velocity, and response to heat (38^0 and 52^0 C) and cold (ice chips). 16 of the 18 Aδ and 50 of 73 C afferents were mechanically sensitive. Overall, mechanically sensitive C and Aδ afferents demonstrated remarkable sensitivity to tensile loading. All of the C afferents sensitive to both cold and mechanical stimuli were equally activated by tensile and compressive stress. Activation thresholds for tension were often lower than those for compression. Among other C afferents (i.e., CM and CMHs), approximately half were activated by both tension and compression. When subjected to compression loading over soft substrates (e.g., muscle or fat), a significant component of their response may arise from the tensile loads developed during indentation. **Supported by NIH Grant NS10783.**

A *Herpes simplex* VIRUS REPLICATION PRODUCT INHIBITS SODIUM CURRENTS IN ADULT RAT DORSAL ROOT GANGLION NEURONES *IN VITRO*. NM Storey[1*2], DS Latchman[1] & S Bevan[2*]. [1]Dept of Molecular Pathology, University College London Medical School, 45 Cleveland Street, London W1A 6DB & [2]Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN

Herpes simplex virus (HSV) is known to affect the electrophysiological properties of dorsal root ganglion (DRG) neurones *in vitro*. Action potentials in HSV infected DRG neurones are characteristically broader and smaller in amplitude than control cells. It has been suggested that a decrease in sodium conductance underlies the electrophysiological changes (Fukuda, J *et al Brain Research* **262**,79-89, 1983). We have examined effects of HSV on voltage gated sodium currents (I_{Na}) in DRG neurones. Whole cell voltage clamp recordings were made from neurones isolated from adult rat DRGs infected with HSV *in vitro*. Sodium currents were isolated by blocking K^+ and Ca^{2+} currents with appropriate solutions and channel blockers. I_{Na} was evoked by a 10ms step depolarization from a holding potential of -80mV to +10 mV. 24 hours after HSV infection most DRG neurons showed no I_{Na}. The normalised peak I_{Na} (max current/cell capacitance ± s.e.m.) in control DRG neurons (0.187±0. 02nA/pS, n=23/23) was significantly larger than the normalised current remaining in the HSV infected neurons (0.024±0. 006nA/pS, n=34/119, p<0.05). TTX-resistant (TTXr) and TTX-sensitive (TTXs) I_{Na} were separated on the basis of their different activation properties. Both TTXr and TTXs normalised I_{Na} were significantly reduced 24 hours after infection with HSV (TTXs control 0.159±0. 020nA/pS, HSV infected 0.080 ±0.018nA/pS, TTXr control 0.041±0.007nA/pS, n=28, HSV infected 0.0157± 0.003nA/pS, n=13, p<0.05). Addition of 50µg/ml cycloheximide did not affect the normalised peak I_{Na} (I_{Na} 0.153±0.012nA/pS, n=82, p<0.05), but did inhibit the effect of HSV infection (I_{Na} 0.180±0.016nA/pS, n=37, p<0.05). Addition of 50µM acyclovir inhibited the effects of HSV infection in DRG neurones (p<0.001, n=38). Results demonstrate that the electrophysiological effects of HSV infection in DRG neurones are not caused by viral host shutoff proteins, which inhibit host cell protein synthesis, or by a virion component. HSV DNA replication and HSV protein synthesis in DRG neurones is required for the loss or reduction of TTXs and TTXr sodium currents.

EFFECT OF TETRODOTOXIN (TTX) ON CUTANEOUS AFFERENT FIBERS IN ADULT RAT IN THE SKIN-NERVE *IN VITRO* PREPARATION.

M. Schneider*, C.L. Stucky, K.V. Toyka and M. Koltzenburg *Dept. of Neurology, University of Würzburg, D-97080 Würzburg, Germany.*

TTX blocks voltage-gated sodium channels and isolated dorsal root ganglion neurons exhibit differential sensitivity. Many studies have addressed the effects of TTX on the cell soma of sensory neurons *in vitro*, however, little is known about the effects of TTX on the peripheral terminal of primary afferent neurons *in situ*. Here, we used neurophysiological techniques to investigate whether TTX, applied to the peripheral receptive field of primary afferent fibers, selectively blocks conduction in functionally characterized sensory fibers. The saphenous nerve with innervated skin was dissected from adult rats and placed in a organ bath superfused with oxygenated, modified synthetic interstitial fluid (Reeh 1986). Extracellular recordings were made from single afferent fibers *in vitro* (n=40). Fibers were characterized by their conduction velocity and response to controlled mechanical and thermal stimuli. The receptive field of each fiber was covered with a self-sealing metal ring which allowed superfusion with test solutions. Receptive terminals were electrically-stimulated with super-maximal square wave pulses using isolated tungsten microelectrodes. Approximately two thirds of the large myelinated fibers (conduction velocities > 12 m/sec) were blocked by 0.1 µM TTX. However, among the C-fibers (conduction velocities < 1.2 m/sec), less than 50% were blocked by 0.1 µM TTX. All fibers were blocked by 10 mM lidocaine. These studies indicate that the majority of fibers with fast conduction velocities are blocked by TTX, whereas some fibers with conduction velocities in the C-fiber range exhibit resistance to TTX. CONCURRENT EXPRESSION OF 5-HT$_3$ RECEPTOR AND GFP IN DRG NEURONS. D. Taneliaan*, R. Berry and G. Smith. Dept. Anes. and Pain Mgt., UT Southwestern Med. Ctr., Dallas, TX 75234-9068

In order to selectively visualize single DRG neurons during growth and development, we used adenoviral gene technology to transfect neurons in co-culture with green fluorescent protein (GFP). Low light epifluorescent imaging and whole cell patch clamp techniques were used for the electrophysiology experiments. Adenovirus encoding GFP infected 9.5% (37/389) of the DRG neurons, resulting in two populations of viral exposed neurons: non-fluorescent (NF) and fluorescent (F). In addition, normal non-viral exposed neurons were used as a control (C). The GFP fluorescence was observed in neuronal cell bodies and processes as they grew over several weeks. After transfection, morphological and electrophysiological analysis was done to compare C, F, and NF neurons. Analysis of the data reveals no difference in the morphology or electrical properties (AP threshold, duration, or amplitude; or whole cell resistance) of the different neuron populations. Next, neurons were infected by recombinant virus expressing GFP and a 5-HT$_3$ receptor (gift of J.Yang, M.D., Ph.D., UT Southwestern). Again, approximately 10% of the neurons became fluorescent and both F and NF neurons were whole cell patch recorded from to determine if functional receptor had been expressed. Both populations of neurons were voltage clamped at Vh=-70 mV and 10^{-3} M 5-HT was applied to the neuronal cell bodies by spritzing the ligand via microelectrodes visually positioned near the neuron. All fluorescent cells tested (n=3) responded vigorously to application of 5-HT with a mean inward current of 1710 pA. None of the non-fluorescent cells (n=3) demonstrated any response to 5-HT. We conclude that this approach offers a powerful method for the study of sensory neuron development and function both in vivo and in vitro.

MEASUREMENT OF CONDUCTION VELOCITY, CELL SIZE, RESTING AND THRESHOLD POTENTIALS WITH PATCH CLAMP RECORDING IN THE INTACT GANGLION. J.-M. Zhang*, D. F. Donnelly[1], X.-J. Song and R. H. LaMotte. Dept. of Anesthesiology & Pediatrics[1], Yale University Sch. of Med., 333 Cedar Street, New Haven, CT 06510

Patch clamp recordings from dorsal root ganglion (DRG) are traditionally performed on dissociated cells that are structurally altered and unable to interact with each other. Furthermore, dissociation eliminates the axon process thereby eliminating the ability of obtaining a measurement of conduction velocity(CV). A preparation was developed, *in vitro*, from an intact ganglion/peripheral nerve which allowed for assessment of CV in conjunction with cellular parameters. The L_4 and L_5 DRG with sciatic nerve attached were excised from Sprague-Dawley rats (9-15d). The ganglion sheath was carefully removed, and the connective tissue was dissolved by exposure to dilute collagenase (1mg/ml) solution for 30min before transferring to the recording chamber which was perfused with HEPES-buffered saline. The soma of individual cells was exposed by gentle surface cleaning through a perfusion micropipette. Cells were classified as small, medium or large based on the cross-sectional area (μm^2), ≤500, 501-1000 and >1000. Following seal formation and establishment of whole-cell recording, resting potential (Vm) was measured. Threshold potential (Vth) was measured in the current clamp mode during increasing steps of depolarizing currents. CVs ranged from 0.3-0.6 m/s for small cells to 1.0-8.0 m/s for large cells. The Vm was similar in all 3 groups (Small: -60.0 ± 1.9 mV, n=32, Medium: -60.1 ± 1.6 mV, n=32, Large: -65.3±2.2 mV, n=11). Vth occurred at a significantly more positive potential in small ganglion cells (-21.2±2.7 mV, n=23) compared with large (-33.7 ± 3.8 mV, n=7) and medium cells (-31.8±2.1 mV, n=24). The results demonstrate the feasibility of patch clamp recording of intact DRG cells, *in vitro*, which may be useful for studies requiring a physiologically intact preparation (Supported by PHS grants NS14624 and NS10174).

SOMATIC AND VISCERAL AFFERENTS: MECHANORECEPTORS

PERIPHERAL NERVE ANASTOMOSES IN THE RACCOON FORELIMB; IMPLICATIONS FOR CORTICAL PLASTICITY. E.F. Johnson*, C.X. Li, D.A. Rasmusson[1], and R.S. Waters. Dept. of Anatomy and Neurobiology, UT, Memphis, [1]Dept. of Physiology and Biophysics, Dalhousie University.

At the previous meeting of the society of Neuroscience, we reported the anastomoses of peripheral nerves in the forelimb of cat and squirrel monkey, and suggested that these findings are important for any definitive interpretation of cortical plasticity. We tested the hypothesis that anastomosis is a common feature of mammalian forelimb nerve organization. The current effort involves the examination of the pattern of ulnar, median, and radial nerve innervation in the forearm/paw of adult raccoon.

Six forelimbs from adult raccoons were surgically removed and fixed in 10% formalin for several weeks. The skin, superficial and deep fasciae, as well as radial, ulnar and median nerves were grossly dissected. Peripheral nerve courses were visually observed via a dissecting microscope. Particular attention was given to determine the presence of anastomosed and/or overlapping of contiguous peripheral nerves. The nerve patterns were photographed, digitized, and reconstructed using a 9500 Macintosh Computer. Using these methods, the following results were observed:

1. Single or multiple anastomotic tributaries of the dorsal branch of the ulnar and superficial radial nerves were observed in the dorsal metacarpal region , proximal to the web between third and fourth digits and fourth and fifth digits
2. A single trunk or plexus of anastomotic fibers were observed between median and ulnar nerves on the glabrous surface of the paw in all animals (six forelimbs).
3. Anastomoses of peripheral nerves were not observed in the forelimb of the raccoon.

These results support the hypothesis that anastomoses are common and frequently occur in various patterns among peripheral nerves in the upper extremity of mammals. (Supported, in part, by NINDS, Grant No. NS-25824 and NSF, Grant IBN-9400318)

710.2

A CONCENTRIC DUAL LEAD ELECTRODE FOR SAMPLING MYELINATED FIBRE AFFERENTS IN HUMAN PERIPHERAL NERVES. **G. Wu, R. Ekedahl & R.G. Hallin*. Dept. Med. Lab. Sci. Technol., Sect. Clin. Neurophysiology, Huddinge Univ. Hosp., Karolinska Institute, Sweden.**

Single units derived from myelinated fibres in man was previously studied with conventional tungsten electrodes. It has been suggested that such electrodes record single unit activity from large sensory afferents intra-axonally. In this study we used concentric needle electrodes with one or two recording surfaces to further investigate the characteristics of units with myelinated fibres in healthy volunteers. 226 units sampled from the median, ulnar or peroneal nerves had different waveform profiles than those encountered in recordings with tungsten electrodes. Among these units, 56 were studied using dual lead electrodes which enabled more reliable unit discrimination than single surface electrodes. The same units had identical waveforms on both surfaces but their amplitudes differed. Sometimes the configuration of the units changed and such changes occurred in parallel on both recording surfaces. In addition, a displacement of a single fibre from one recording surface to the other was often observed when the electrode was slightly repositioned. No cross-talk was found between the two recording surfaces.

Our results strongly suggest that single units from myelinated fibres are recorded extraaxonally at or in the vicinity of nodes of Ranvier. Dual channel recordings combined with interspike interval measurements and template matching analysis of studied neural events substantially enhance data yield in this type of studies.

710.3

INTERSPIKE INTERVAL ANALYSIS AS MEANS TO DISCRIMINATE NEIGHBOURING SENSORY UNITS IN HUMAN PERIPHERAL NERVES WITH OVERLAPPING RECEPTIVE FIELDS IN THE SKIN. R. Ekedahl, G. Wu, T. Carlstedt* and R.G. Hallin. Dept. Med. Lab. Sci. Technol., Sect. Clin. Neurophysiology, Huddinge Univ. Hosp., 141 86 Huddinge and * Dept. of Orthopedics, Karolinska Hosp., Sweden.

In studies with intraneural exploration of human peripheral nerve fascicles using thin caliber concentric needle electrodes pairs of rapidly adapting (RA) and slowly adapting type I (SA I) units in man exhibited overlapping receptive fields in the skin. So did Paccini afferents (PC units) and slowly adapting type II unitary elements (SA II units) with their much larger innervation areas. A new method measuring interspike intervals facilitated unit identification. Fundamental for the procedure was the refractory period of the studied fibres. When neural activity was evoked by different tactile stimuli in the receptive field interspike interval analysis of the recorded responses was performed. In situations when the minimal interspike intervals were longer than the absolute refractory period of a single fibre (1-2 ms) the response derived from one single unit. Responses from at least two units were considered to contribute to the recorded sequences when computer analysis showed that the duration of the minimal intervals were shorter. In this way, the reported procedure facilitated the discrimination of both pairs of RA and SA I units and, in particular, pairs of neighbouring PC or SA II units with overlapping receptive fields in human palmar skin.

The data yield from microneurography recordings can be substantially enhanced using these procedures which also might be applicable in other experimental settings and/or in other parts of the nervous system.

Supported by the Swedish Society of Medicine, Åke Wibergs Foundation and a Wenner-Gren Foundation fellowship to G. Wu.

710.4

THE EFFECTS OF SKIN-SURFACE HYDRATION ON TACTILE PERCEPTION. S.J. Bolanowski*, R.T.Verrillo and F.M. McGlone. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244.

Many previous studies have attempted to define the role that the visco-elastic structure that we call skin has in tactile perception. For example, several models of skin suggest that it's effect should be greater in the spatial than in the temporal stimulus domain, but few studies have been designed to test this hypothesis. Threshold (two-interval, forced choice) and suprathreshold (absolute magnitude estimates of "roughness" and sensation magnitude) sensations were determined using predominantly temporal (vibratory) or spatio-temporal (textured surfaces) stimuli applied to the fingertip with the skin mechanics modified by fully hydrating the skin with various solutions (e.g., distilled water; surfactant/water). The degree of hydration was measured with a Courage/Khazaka corneometer. The results obtained using vibratory stimuli were uninfluenced by the state of skin hydration and thus were not affected by modifications in skin mechanics. However, hydration of the skin caused a significant reduction in the perception of roughness, particularly for the less-rough surfaces. The results suggest that the visco-elastic properties of the skin, in particular the epidermis, play a major role in the perception of spatio-temporal stimuli, but not vibratory stimuli at least in the range tested (1-250 Hz). Furthermore, the results indicate that for spatio-temporal, but not for vibratory stimuli, the skin mechanics must be taken into account when attempting to relate non-human physiological results to psychophysical results obtained on humans. 710.5

TACTILE MECHANORECEPTOR DYNAMIC STIMULUS SENSITIVITY F. J. Looft*, Department of Electrical and Computer Engineering, Worcester Polytechnic Institute, Worcester, MA 01609 USA

The spectral and temporal responses of macaque monkey SA, RA and PC primary afferents were studied using a pseudorandom vibratory indenting stimulus. Isolated afferents were activated with stimulus intensities from near threshold (a *r*oot-*m*ean-square average indentation position eliciting 1-2 impulses-per-second, ≈1.1x**Th**) to a stimulus intensity that was ≈4-5 *x***Th**. During stimulation, stimulus position and impulse event timing were sampled and stored to disc for post-experiment processing.

MMSE power function fits to spectral transfer functions showed that all mechanoreceptors exhibited an increasing dynamic stimulus sensitivity as stimulus intensity was increased. Specifically, SA afferents exhibited a dominant position sensitivity with low intensity stimuli and a slight but significant velocity sensitivity with high intensity stimuli (a slight rise in the transfer function with increasing frequency). RA afferents would only discharge if the stimulus velocity was above a minimum velocity threshold but, once this criteria was satisfied, were primarily sensitive to stimulus position when using low intensity stimuli. With high intensity stimuli RA afferents transitioned to an encoder with a dominant velocity sensitivity. PC afferents were primarily sensitive to stimulus velocity with low intensity stimuli and to stimulus acceleration with high intensity stimuli. Average exponents for low intensity stimuli were -0.19, -0.11 and 1.24 for SA, RA and PC afferents, respectively, and 0.1, 0.33 and 1.52 for high intensity stimuli. There was no statistical difference between the transfer function determined for the indentation, as opposed to the extraction response of a RA or PC dual responding afferent.

The results from a simple neural model showed that the interpretation of spectral transfer functions is significantly enhanced when spectral transfer functions are compared to the results from a temporal analysis of the instantaneous state (pos, vel, acc) of the stimulus at the time of impulse initiation.

710.6

DO THE STIMULATOR AND SKIN DECOUPLE UNDER SINUSOIDAL VIBRATIONS?, J.C. Cohen*, J.C. Makous, B.W. Pietras, and S.J. Bolanowski. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244

Previous experiments (Goodwin, et al., Exp Brain Res. 77:1989) performed on monkey and human fingertip suggested that the skin surface and stimulus probe decouple for sinusoidal displacements applied perpendicularly to the skin surface. From these observations it had been stated that sinusoidal vibration may not be a suitable stimulus for generating models of taction sensation. We repeated these experiments on human observers using stimulus frequencies ranging from 0.5 to 240 Hz and with amplitudes up to 1 mm p-p. The skin-probe movements were measured in the steady-state using stroboscopic illumination and video microscopy. Contrary to the previous results, we found that decoupling did not occur for amplitudes less then 0.5 mm p-p, regardless of stimulus frequency. Decoupling was only observed for stimulus amplitudes greater than 0.5 mm and for frequencies between 5 to 120 Hz. Due to the physical limitations of the vibrator, it was not possible to generate stimulus amplitudes large enough to decouple the probe from the skin for frequencies above 120 Hz. To further investigate this phenomenon, a modified stimulus contactor was used that permitted the measurement of the skin-probe movement using reflected light and fiber optics (Fotonic sensor). In this instance, the vibratory stimuli were applied to the thenar eminence. On the thenar eminence, no decoupling was observed for frequencies ranging from 1 to 300 Hz at 0.25 mm p-p which is well within the range used in most psychophysical experiments performed on this part of the body. We conclude that sinusoidal vibration can be reliably used to stimulate the tactile system and as an appropriate stimulus for developing tactile models of sensation. Supported by NSF/NIMH

710.7

THE EFFECTS OF HEAT PAIN ON VIBROTACTILE SENSITIVITY, G.A. Gescheider*, S.J. Bolanowski, J.L. Niemiec, G.F. Shea and J.L. Tromblay. Dept. of Psychology, Hamilton College, Clinton, NY 13323.

Absolute thresholds, intensity difference thresholds, and magnitude estimations of suprathreshold stimuli were obtained for 10 and 100 Hz vibration applied to the thenar eminence when the subject was experiencing heat pain at the test site and when he/she was not. Heat pain was produced by elevating the surface skin temperature from 30°C to approximately 43°C, a temperature at which the subject reported experiencing moderate pain. Although pain had the effect of reducing tactile sensitivity as determined by both absolute threshold measurements and magnitude estimation it had no effect on the relative difference threshold. The results were interpreted as an indication that pain has the effect of attenuating the tactile afferent input to brain centers responsible for stimulus detection and intensity discrimination. Because of Weber's law, ΔI=Ic, in which discriminable changes in intensity (ΔI) are equal to a constant proportion (c) of intensity level (I), the relative difference threshold, ΔI/I, remains constant when pain reduces the effective intensity of the vibratory stimulus as the absolute threshold is elevated.

ANOTHER LOOK AT APERIODIC STOCHASTIC RESONANCE. J. Müller-Gerking* and D.R. Chialvo. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

Stochastic resonance (SR) is a phenomenon in non-linear dynamical systems wherein the synchronization of the system to a weak sub-threshold signal is enhanced by the presence of random noise. For some non-vanishing levels of noise, the signal-to-noise ratio (SNR) can effectively increase compared to the noise-free system. In neuron models, the best SNR is obtained for a level of noise that in the absence of a signal induces stochastic firings at a rate comparable to the signal's period.

Collins and coworkers have presented simulations and a theory that is claimed to provide SR for aperiodic signals, therefore called aperiodic stochastic resonance (ASR) (Collins et al., 1995). ASR in this form requires signals that change on times-scales much slower than the noise-induced firing rates of the system. In another paper (Collins et al., 1995), the authors suggest that the level of noise does not have to be tuned for optimal performance, if only enough neurons are connected in parallel.

We reexamine their suggestions by numerical simulations of the Fitzhugh-Nagumo equations and propose a revised view of this phenomenon. We show that ASR is in fact simple frequency modulation of the firing rate. In the system, as presented by the above authors, the noise does not contribute to a resonance phenomenon, but leads to a linearization of the system's transfer function (i.e., input vs. firing rates). Furthermore, ASR, as described by the authors, lacks the fundamental features of "bona-fide" SR, namely the "skipping" of cycles, and location of the SNR maximum at a Kramers' rate of the same order as the time-scale of the signal. Supported by MH50064.

710.9

FREQUENCY AND CATEGORY DEPENDENCE OF TOUCH RECEPTOR MODULATION BY NOISE, C.M. Ivey[1], D.R. Chialvo[2], A.V. Apkarian*[1], Dept. Neurosurgery[1], SUNY HSC; Syracuse, NY and University of Arizona[2], Tucson, AZ.

Enhancement of signal transmission by noise for bistable nonlinear elements (stochastic resonance; SR) has been demonstrated in a number of biological and simulated neuronal systems. Here we study the SR properties of touch receptors and, for the first time, demonstrate the frequency dependence of this phenomenon.

Isolated single fiber recordings were done from the tibial nerve in anesthetised rats. The most sensitive portion of the receptive field of a given fiber was mechanically stimulated by uniformly distributed noise (low pass filtered to 2000 Hz), by sinusoidal modulation, and by various amplitude combinations of both. The tuning curve as a function of frequency was determined. Receptor categories (slowly adapting; SA, or rapidly adapting; RA) were also determined based on the tuning curves and responses to square waves. Periodic histograms were generated for various sine plus noise stimuli, and the total spike count was calculated.

The total spike count was independent of the presence of the sine wave. However, the periodic histograms showed preferential frequency modulation during sine plus noise trials, indicating SR. In both RA and SA neurons, the signal to noise ratio (SNR) changes with increased input noise were highly frequency dependent. This dependence was different for each receptor type. In the SA, the SNR exhibited a monotonic increase and decrease around the best frequency, but at higher frequencies the increasing phase was narrower and then quickly saturated. In the RA, the SNR exhibited a monotonic increase and decrease for frequencies below the best frequency, although the peak SNR decreased as the sine wave frequencies approached the best frequency.

The distinct frequency dependence in SR properties indicate that the underlying transduction mechanisms are different for the two types of touch receptors.

SHAPE ENCODING BY SPATIAL POPULATION OF MECHANORECEPTORS IN MONKEY FINGERPAD. RM Friedman*, PS Khalsa, P Kenins, C Lu, AJ Fuglevand#, MA Srinivasan+, and RH LaMotte. Dept. of Anesthesiology, Yale University School of Medicine, New Haven, CT 06510; #John B Pierce Laboratory, New Haven, CT; +MIT, Research Lab of Electronics, Cambridge, MA

The neural representation of shape by a population of neurons in the fingerpad has been previously inferred with the use of spatial event plots (SEPs). While recording from a single neuron, the SEP is obtained by stroking an object along a series of laterally shifted, parallel, linear trajectories over the fingerpad. The validity of this hypothesis was tested by comparing shape representation obtained from SEPs with that obtained from an actual population of neurons. Responses of single units innervating the fingerpad were recorded from median nerve in anesthetized monkeys. Units were recorded from teased filaments using standard electrodes for SEPs and by percutaneous microneurography for the actual population. An object was repeatedly stroked (10 mm/s) across the fingerpad by a servocontrolled stimulator with constant contact force (10 gm). The toroidal objects had a radius of 5mm on the major axis, and a radius of 1, 3, or 5mm on the minor axis. The actual population response was obtained by stroking the object perpendicular and parallel to the long axis of the finger over a central point, and similarly varying the orientation of the object. SA and RA units recorded with microneurography had receptive fields distributed over most of the fingerpad, while units recorded for SEPs were not uniformly distributed. For both SEPs and the actual population: 1) the object shape was represented non-isomorphically in the shape of the spatial discharge rate profile (SDR); 2) the maximum SDR in RAs and SAs increased with increasing shape eccentricity. The number of units in the actual population activated at any instant in time by the object decreased with increasing distance away from the object. The mean total spikes increased with shape eccentricity, which was related to greater indentation stress. The inferred population response from SEPs was similar to that obtained by the actual population of neurons. (Supported by NS 15888)

HUMAN MECHANORECEPTORS SERVING TACTILE DIRECTIONAL SENSIBILITY H. Olausson*, N. Kakuda, and J. Wessberg. Dept. of Physiology, University of Göteborg, Medicinaregatan 11, S-413 90 Göteborg, Sweden.

Tactile directional sensibility, i.e. the ability to recognize the direction of an object's motion across the skin, is an easily observed sensory function which is of clinical interest since it is sensitive to disturbances of the peripheral and central nervous systems. In psychophysical experiments on healthy subjects it has been shown that tactile directional sensibility may depend on the parallel processing of two different types of sensory information. One consists of spatial data expressed as a function of time, and the other consists of direction specific patterns of skin stretch caused by friction between the moving object and the skin. The objective of the present study was to identify peripheral afferents that may transmit these two types of information.

Using the microneurography technique we recorded from 31 myelinated afferents with low threshold mechanoreceptors located in the human forearm skin. The units were classified into one of four types, i.e. field (n=4), hair (n=6), SAI (n=9), and SAII (n=12). All units responded to movements with the probe that was used in the psychophysical experiments, and were possible candidates for signalling spatial information to the CNS. 11 of the SAII units decreased their spontaneous activity when the probe approached the body of the receptor, and/or increased their activity when the probe moved away from the body of the receptor. Thus, SAII units responded to changes of skin stretch, and information about patterns of skin stretch could be signalled by a population of SAII units.

MESENTERIC AND TACTILE PACINIAN CORPUSCLES (PC) ARE PHYSIOLOGICALLY COMPARABLE. L. Pawson, S.J. Bolanowski, C.M. Checkosky* and J.C. Makous. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244.

Much of what is known about transduction by tactile receptors is based on anatomical and physiological studies performed on cat mesenteric PCs. For example, the location of tactile receptors within the skin precludes the recording of receptor potentials. Although PCs found in the mesentery are shown to be anatomically identical to those found in cat and primate skin, the physiological responses of tactile and mesenteric PCs seldom have been compared. Action-potential rate-intensity and frequency characteristics (10 Hz -1 KHz), as well as interval (IH) and peri-stimulus-time (PST) histograms in response to sinusoidal displacements were obtained from mesenteric PCs and from PC fibers innervating cat glabrous skin. The rate-intensity characteristics obtained on both preparations showed similar response profiles including equal slopes for low stimulus intensities (approximately 10 spike ratios/20 dB displacement) and one-and-two spikes/cycle entrainment. The frequency characteristics of both groups were U-shaped with similar low-frequency slopes (-12.5 dB/octave) and bandwidths (Qs=1.3). Although the best frequencies were lower for the tactile PCs (200 Hz) when compared to the mesenteric PCs (250 Hz), the results are expected based on differences in recording temperature. The IHs showed (sub)multiple entrainment and the PSTs showed neither transient responses nor adaptation. Thus the mesenteric PC is an adequate model for tactile receptors. Furthermore, since the frequency characteristics of the two PC types are similar, it is concluded that the skin, while attentuating stimulus intensity, does not impart mechanical filtering of vibration in the frequency range tested. THE EFFECT OF DIAZINON PLUS ON RAPIDLY ADAPTING RECEPTORS IN THE RABBIT. C.T. Kappagoda, H.C. Campbell, K. Ravi, E. Bravo and, A.C. Bonham*, University of California, Davis, CA 95616

Effects of the peticide, diazinon PLUS, on the activities of rapidly adapting receptors (RARs) and stretch (SAR) receptors of the airways were investigated in rabbits anesthetized with pentobaritone (25 mg/kg). The animals were also artificially ventillated. Effects on both baseline activity and the responses to stimulation by increasing left atrial pressure were examined. Action potentials were recorded from the left cervical vagus nerve. The compound was administered as an aerosol (particle size 3 μm) generated by a miniHeart Nebulizer. We observed that an aerosol of diazinon PLUS (1/10 v/v dilution in normal saline) decreased the baseline RAR activity ($n = 10$) significantly ($P < 0.05$) from 209 ± 77 impulses/min to 120 ± 40 impulses/min and decreased significantly to 131 ± 52 impulses/min ($P < 0.05$) following a second exposure of diazinon PLUS (undiluted) aerosol. Aerosols of normal saline in the control state did not produce a significant change in the RAR activity. A group of SARs ($n = 8$) were examined under similar conditions and was found that only the exposure to diazinon PLUS (undiluted) aerosol decreased the activity significantly ($P < 0.05$) from 11536 ± 206 impulses/min to 1367 ± 182 impulses/min. The effect of diazinon PLUS on the response to increasing left atrial pressure was examined in 7 RARs. In the control state RAR activity increased significantly ($P < 0.05$) during elevation of mean left atrial pressure. This response was abolished after exposure to diazinon PLUS. These findings suggest that diazinon may interfere with airway defense mechanisms by reducing the activity of RARs. Supported by NIHLB HL52165.

INTERSTITIAL CYSTITIS SECONDARY TO HERPES MYELITIS: FURTHER EVIDENCE FOR A NEUROGENIC MECHANISM.

Luc Jasmin[1,2]*, Richard Schmidt[4], Anu Iyer[1], Samuel Rabkin[1,3]. [1]Neurosurgery, [2]Cell biology, [3]Microbiology, Georgetown University, Washington DC. 20007. [4]Urology, University of Colorado, Denver CO 80262 .

We recently reported a model of interstitial cystitis that appears five days after pseudorabies virus (PRV)-Bartha injection of a tail muscle (10^5 pfu in 20µl). This cystitis was found to be neurogenic since sympathectomy or removal of small fiber primary afferents innervating the bladder prevented its appearance. It remains to be shown, however, that the cystitis is not a neuro-immune response to local invasion by the virus. Fresh bladders, urine and spinal cords were harvested from animals at various survival times after injection of PRV in a tail muscle. Tissues were isolated from 18 animals under anesthesia, quickly frozen and stored at -80°C prior to assay. The presence of infectious PRV was determined by plaque assay on monolayers of Porcine kidney (PK15) cells. Samples were freeze-thawed and sonicated to release virus and tissue samples were further homogenized. No infectious PRV was detected in the urine or bladder of animals from 2 to 5 days post-tail-inoculation under conditions where 100 pfu/ml was detectable. In order to demonstrate that there were no inhibitory factors present in the bladder or urine, PRV was incubated with the samples for 10 min. at room temperature and then titered. Effects range from none to an approximately 2-fold decrease in PRV titer after such treatment. Spinal cord (lumbar) specimens from animals 5 days post-tail-inoculation contained significant amounts of infectious virus (10^4-10^5 pfu). This correlates with the number of infected cells in the spinal cord as detected immunohistochemically. Finally, at no time point was any PRV immunoreactivity found in the bladder despite its presence in the spinal cord as early as 48 hrs post-inoculation. We conclude that PRV is absent from the inflamed bladders and that the cystitis is likely to be purely neurogenic. NIH RO1 DK47523-01; MRC (Canada).

Local Injection of Nerve Growth Factor (NGF) Triggers Degranulation of Mast Cells in Rat Paw.

Michael Tal*, The Hebrew University, Dep. of Anatomy, School of Medicine, Jerusalem, Israel.

Several lines of evidence indicate that NGF plays a role in hyperalgesia and inflammatory pain states.

We have shown previously (IASP 1996) a direct sensitization and small excitatory response of cutaneous nociceptors after NGF and other inflammatory agent's treatment. Lewin et al (1994) suggested that the initial rapid component of thermal hyperalgesia evoked by NGF is attributable to a peripheral mechanism, involving mast cells. Here, we show directly, using histological staining, that degranulated mast cells are present following treatment with NGF and inflammatory mediators. Intracutaneous injection to the rat's paw (50µl) of NGF (1-100 µg/ml) evoked a dose-depended hyperalgesia to heat as measured by paw withdrawal latency to noxious heat. An even more intense hyperalgesia was induced by "inflammatory soup" (10µm BK, 5HT, PGE2 and histamine) was stronger than the NGF.

Mast cells counts in the dermis were performed on coded slides under X100 magnification after fixation in Carnoy's solution and staining with toluidine blue (pH 0.5). The ratio of degranulated mast cells over nonactive cells after injection of the 3 concentrations of NGF (1, 10, 100, µg/ml) was significantly higher ($p>0.01$) than after saline injection. No significant differences were found among the three concentrations of NGF. The effect of inflammatory soup was similar to that of the NGF.

The results demonstrate that NGF activates mast cells and releases tissue mediators in the acute phase of NGF-induced hyperalgesia in the rat's paw.

CHARACTERIZATION OF CARRAGEENAN-INDUCED HINDPAW INFLAMMATION IN THE MOUSE

L. M. Aanonsen[§*], J. D. Richardson[†], R. Nakkash[§], J. Knoll[§], K. M. Hargreaves[†] and R. Whitehead[§]. [§]Biology Dept., Macalester College, St. Paul, MN 55105; [†]Depts. of Restorative Sciences and Pharmacol., Univ. of Minnesota, Mpls., MN 55455

Although a few laboratories have reported using carrageenan (carra) to induce an inflammatory response in the hindpaws of mice, there has not been to date, characterization of carra-induced hyperlagesia in this animal. The purpose of the present study was to characterize the development of hyperalgesia, edema and leukocyte infiltration in mouse hindpaws that were intraplantarly (ipl) injected with carra. Prior to carra injection, baseline responses to a thermal nociceptive test (hotplate, 52°C) were determined and paw thickness was measured using a digital calipers. Ten µl of 6% carrageenan (or saline) was then bilaterally injected into the intraplantar surfaces of the mouse hindpaws . Paw width and hotplate latencies were again determined at 30, 60, 90 and 180 min after carra. Carrageenan produced a significant nociceptive response at 30 min after injection which was blocked by indomethacin (10mg/kg, ip.). A significant increase in paw width was evident in the carra group throughout the time course when compared to the saline control. At the peak of the hyperalgesic response (30-60 min), the plantar tissue was removed, fixed and processed for light and electron microscopy (EM). Tissue from the carra group had a higher concentration of neutrophils when compared to the saline group. EM was used to verify the presence of neutrophils and also revealed numerous mast cells (some degranulated), occasional macrophages and eosinophils, and a profuse scattering of RBCs in connective tissue, all of which was absent in the control tissue. The hyperalgesia, edema and infiltration of immune cells observed in this preliminary study confirm that carra induces an acute inflammatory response in mice. This work was support by a grant from the Howard Hughes Medical Foundation.

711.4

EFFECTS OF HINDPAW INFLAMMATION ON HYPERALGESIA AND CUTANEOUS LEVELS OF iCGRP.

C.A. Harding-Rose, S. Kilo, K.M. Hargreaves*, Lab. of Neuropharmacology, University of Minnesota, Minneapolis, MN 55455.

Although numerous studies have evaluated the effects of carrageenan (carra) on hyperalgesia and inflammation, relatively few studies have determined the effects of carra on neuropeptide content and release. In the present study, we determined time-response curves for carra-induced alterations in thermal hyperalgesia, edema, and cutaneous levels of immunoreactive calcitonin gene-related peptide (iCGRP).

Male Sprague-Dawley rats (n=6/time point) were injected ipl with carra (2 mg) in one hindpaw. Thermal hyperalgesia was measured by paw withdrawal latency to a beam of radiant heat; edema was measured by tissue weight of a 30mm biopsy of skin; and cutaneous levels of iCGRP were measured by RIA. Both ipsilateral and contralateral measures were collected at 0-72 hr after carra injection. Data were analyzed by ANOVA and Duncan's test.

Paw withdrawal latencies decreased from baseline values after carra injection, with peak differences observed at 3hr (ipsi:contra of 3.4 ± 0.6 vs 12.1 ± 1.4 sec; $p<0.05$), and recovery to baseline values observed by 72hr (ipsi:contra of 9.2 ± 1.0 vs 9.8 ± 0.7 sec; p=NS). Edema, as measured by tissue weight, was evident by 3hr (ipsi:contra 383 ± 14 vs 216 ± 16 mg/biopsy; $p<0.05$) and peaked at 24hr after injection (ipsi:contra 472 ± 13 vs 220 ± 7 mg/biopsy; $p<0.05$). Tissue levels of iCGRP declined from baseline levels, with maximal effects observed at 12hr (438 ± 24 vs 323 ± 27 fmol/biopsy) and levels returning to nearly baseline values by 72hr (478 ± 16 fmol/biopsy).

Collectively, these data indicate that carra induces time-dependent changes in hyperalgesia, edema and tissue levels of iCGRP. The effect of carra on tissue content of iCGRP suggests that peptidergic fibers are activated by inflammatory mediators leading to altered rates of synthesis, transport and release. Current studies are evaluating these alternative hypotheses.

FUNCTIONALLY ADAPTIVE CHANGES ARE INDUCED BY COLLATERAL SPROUTING OF NOCICEPTIVE NERVES, BUT NOT BY NGF-INDUCED HYPERALGESIA.

J.Diamond*, E. Pertens, M. Holmes, B. Urschel, and R. Pal. Dept. of Biomedical Sciences, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5

We find the collateral sprouting of spared, undamaged nociceptive axons into adjacent denervated rat skin to be temporally associated with (i) sprouting of the central projections of the nociceptive neurons in the ipsilateral dorsal horn (revealed by HRP back-filling), and (ii) an increase in their drive of second order neurons (increased number of c-fos-expressing neurons induced by a standard mechanonociceptive stimulus). Prevention of peripheral sprouting by anti-NGF treatment disallows both intraspinal changes. We now find an interesting functional correlate of these sprouting-related phenomena. The localised reflex contraction of the *cutaneus trunci* muscle (CTM) evoked by a pinch of the overlying skin is enhanced; however, rather than hyperalgesia (reduced reflex threshold) or an increase in response intensity, there is an *expansion* of the responsive area of the fully-innervated CTM. We interpret this as a central adaptation to the expansion of the cutaneous nociceptive field brought about by collateral sprouting. No equivalent adaptation occurs during acute NGF-induced hyperalgesia; the areas both of the nociceptive fields and of the reflexly evoked muscle responses, are unchanged; unexpectedly, in preliminary studies there appears to be an absence of recruitment of second order neurons in our standard mechanonociceptive stimulation paradigm. When we evoke nociceptive nerve sprouting by daily systemic NGF injections, we find that a minimum of 6 days administration is required for the sprouting to become functionally detectable in the skin. We predict, therefore, that in conditions of *maintained* increases in NGF levels, e.g. in chronically inflamed target tissues, the acute hyperalgesic state could well extend into one characterised by the sprouting-related events described above.

RESPONSES OF NOCICEPTIVE AFFERENTS TO THERMAL AND MECHANICAL STIMULI BEFORE AND DURING ZYMOSAN-INDUCED INFLAMMATION OF THE RAT HINDPAW.

A. Randich*[1] and S.T. Meller[2]. [1]Dept. of Psychology, Univ. of Alabama at Birmingham, Birmingham, AL 35294, [2]OTC-HCTD Procter and Gamble Co., Cincinnati, OH, 45239

Single unit recordings were made of primary nociceptive afferents before and during zymosan-induced inflammation of the ipsilateral (left) hindpaw of the rat. Stimulus-response functions were generated for either mechanical (0.27-190 g) or thermal (36-50° C) stimuli during a control period and 1, 2, and 3 h after inflammation.

The mean thermal response threshold of C-mechanoheat (CMH) units decreased significantly within 1 h of inflammation and remained at that level during testing. In contrast, the mean thermal response threshold of A-mechanoheat (AMH) units increased significantly across post-zymosan testing. Thermally-evoked total discharge frequency either increased or remained the same in CMH units, but significantly decreased in AMH units.

The mean mechanical response threshold of C-mechanonociceptor (CMN) units significantly decreased after zymosan administration, while those of low threshold mechanoreceptor (LTM), A-high threshold mechanoreceptor (HTM), AMH, and CMH units remained either unchanged or significantly increased. Mechanically-evoked total discharges of CMN units significantly increased after zymosan, while those of LTM, HTM, AMH, and CMH units remained either unchanged or significantly decreased.

These data demonstrate that zymosan inflammation results in selective sensitization of CMH units to thermal stimuli and CMN units to mechanical stimuli. These results demonstrate that the afferents mediating primary hyperalgesia to thermal and mechanical stimuli during zymosan-induced inflammation are different.

NEUROPATHIC PAIN AND SYMPATHETIC SPROUTING IN THE DORSAL ROOT GANGLION: THE EFFECT OF PARTIAL NERVE INJURY AND NGF. M.S. Ramer and M.A. Bisby*. Department of Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

We have investigated the influence of the degenerating distal stump of a partially injured nerve on pain-related behaviour and abnormalities of sympathetic innervation of the dorsal root ganglion (DRG) in rats and mice with a peripheral mononeuropathy. This condition is characterized by thermal hyperalgesia and mechanoallodynia that occur between 4 days and 1 week following constriction. Monoaminergic pericellular baskets (absent from naïve animals) begin to become apparent by 4 days following CCI, but after a sciatic resection, where the proximal and distal stumps are isolated from one another, sprouting was delayed until 14 days following injury. As evoked pain requires a connection to the periphery, we are currently determining whether these sprouts occur preferentially around axotomized or spared DRG neurons. We also asked if it is NGF which influences (a) the development of neuropathic pain-related behaviour and (b) sympathetic innervation of the DRG. Transgenic mice expressing NGF under the GFAP promotor (which experience more severe hyperalgesia and allodynia) show enhanced sympathetic hyperinnervation of the DRG following a CCI when compared to age-matched non-transgenic controls with the same injury. We conclude that NGF plays a role in neuropathic pain and sympathetic sprouting in the DRG and may serve as a target for the treatment of neuropathic pain.

NEUROPEPTIDE EXPRESSION IN PRIMARY SENSORY NEURONS AFTER PARTIAL AND COMPLETE SCIATIC NERVE INJURIES. W. Ma* and M. A. Bisby, Dept.of Physiology, Queen's University, Kingston, Canada K7L 3N6

The aim of the study was to compare the effects of partial and complete sciatic nerve injuries on neuropeptide expression by primary sensory neurons. Complete transection (CSNL), half transection (PSNL) and chronic constriction injury (CCI) were made on the sciatic nerves of three groups of rats at high thigh level. All animals were allowed to survive for 2 weeks. Immunocytochemistry for substance P (SP), galanin (Gal) and neuropeptide Y (NPY) was carried out on L4-5 DRG, L4-5 spinal cord and lower brainstem sections. SP immunoreactivity (IR) in ipsilateral DRG neurons and the superficial dorsal horn was significantly decreased after CSNL, but not significantly different after PSNL and CCI. Some very dark SP-IR DRG neurons of the lesioned side were observed after PSNL and CCI, but not after CSNL. In all three types of injuries, Gal- and NPY-IR were significantly increased in the ipsilateral DRG neurons, the dorsal horn and the gracile nuclei. However, in PSNL and CCI, the numbers of Gal-IR DRG neurons were significantly higher, and more medium size Gal-IR neurons were detected in PSNL and CCI than in CSNL. Gal-IR was also observed in deeper laminae of the dorsal horn of partial injury animals. More Gal-IR was observed in the gracile nuclei of PSNL and CCI than CSNL. No significant differences of NPY-IR in DRG, the dorsal horn and the gracile nuclei were found between partial and complete injury models. SP and Gal expression in primary sensory neurons seem to be differentially regulated following partial and complete sciatic nerve injuries; this may be related to the different pain responses following the two types of injury. 711.9

ADRENALINE-SENSITIVITY INDUCED AT THE RECEPTIVE TERMINALS OF UNDAMAGED SENSORY NEURONS AFTER PARTIAL NERVE INJURY. Y. Choi, H.C. Shin, J.W. Leem and H.K. Shin*. Depts. of Anesthesiology, Ulsan Univ. Col. Med. & of Physiology, Hallym, Yonsei & Hanyang Univ. Col. Med., Korea.

The aim of this study is to see if sensory neurons, when their peripheral receptors remain intact after peripheral nerve injury, become sensitive to adrenaline.

Using rats that received a unilateral ligation of one or two of L4-L6 spinal nerves 10-15 days previously, dorsal roots with unligated spinal nerves on the injury side were cut near the root entry zone, and the recording was made from afferents in microfilaments teased from the distal cut end of dorsal roots. Sensitivity of the recorded afferents to adrenergic agonists or to sympathetic stimulation was examined.

Some afferents that responded mainly to noxious mechanical stimulation of their somatic receptive fields were responsive to epinephrine, but not to isoproterenol, or to sympathetic stimulation. These afferents were conducting in the Aδ- and C-ranges, and their adrenergic responses were blocked by subcutaneous infiltration with lidocaine or by cutting the spinal nerve.

The results suggest that after partial peripheral nerve injury, a portion of sensory neurons with intact fine axons become sensitive to adrenaline at their receptive terminals by the mediation of alpha-adrenoceptors. (Supported by KOSEF 961-0701-008-2)

ACTION OF EPINEPHRINE AND OTHER ADRENERGIC AGONISTS ON C-FIBER POLYMODAL NOCICEPTORS AFTER PARTIAL NERVE INJURY. K.D. O'Halloran, V.K. Shea & E.R. Perl*, Department of Physiology, University of North Carolina at Chapel Hill, Chapel Hill 27599-7545, USA.

Partial injury of a peripheral nerve induces excitatory responses in some remaining C-fiber cutaneous polymodal nociceptors (CPM's) to sympathetic stimulation (SS) and norepinephrine (Sato & Perl, Science 251, 1991). These observations have been implicated as possible factors in sympathetically related pain syndromes such as causalgia. The endogenous catecholamine, epinephrine (EPI), exerts similar physiological actions to norepinephrine, but the effects of EPI on the characteristics of CPM's following partial nerve injury have not been investigated.

Single-unit recordings from fine filaments of the great auricular nerve were obtained in adult, deeply anesthetized rabbits, intact and 14-27 days after partial lesion of this nerve. Receptive field organization, mechanical and thermal thresholds and conduction velocities were not different between intact and operated animals.

Unilateral SS and close arterial injections (through a small collateral of the great auricular artery) of EPI (50ng) did not activate any CPM's (n=23) from intact animals. In contrast, 11 of 35 units from injured animals were excited by SS (4-17 impulses) and/or EPI (1-20 impulses) in the 60 seconds immediately following each trial. Responses were reversibly antagonized by selective α_2-adrenoceptor blockade with yohimbine (0.6-1.0mg/kg) or rauwolscine (1.0mg/kg). When tested, some EPI responsive units were also excited by norepinephrine (50ng) and guanabenz (10μg) but were unaffected by clonidine (3μg) and BHT-933 (3μg).

We conclude that circulating EPI, acting via an α_2-adrenoceptor subtype, could be a factor in the development of aberrant pain syndromes following partial nerve injury.

AN INCREASE IN MYELINATED FIBERS FOUND IN THE L5 DORSAL ROOT FOLLOWING SPINAL NERVE LIGATION IN THE RAT. H.A. Lekan*, K. Chung, Y.W. Yoon, J.M. Chung and R.E. Coggeshall. Marine Biomedical Institute, The University of Texas Medical Branch, Galveston, TX 77555-1069.

An experimental peripheral neuropathy was induced in rats by ligating the L5 and L6 spinal nerves distal to the dorsal root ganglia. Previous behavioral and electrophysiological studies indicate that these animals consistently exhibit heat hyperalgesia and mechanical allodynia for a period of at least one month. Additionally, recent anatomical findings indicate that myelinated Aβ fibers sprout into a region of the dorsal horn normally occupied by small diameter fibers subserving pain and temperature. To address the question of the origin of these sprouting fibers as well as the fate of unmyelinated small diameter fibers in this neuropathy model, the axons of the L5 dorsal root were counted at various times post-ligation (2, 6, 12 and 32 weeks). The results of this study indicate a significant increase in myelinated axons by 32 weeks post-ligation. Although the myelinated fibers were not quantified by diameters, there appeared to be more small diameter fibers present following neuropathy upon visual inspection. There was a trend towards a decrease in unmyelinated fibers, but these changes were not found to be statistically significant. These results suggest that the origin of the increase in Aβ fibers in the dorsal spinal cord originate in part from sprouting of these fibers in the roots. This work was supported by NIH grants NS11255, NS1061, NS31680 and NS 07185.

711.12

PERIPHERAL NERVE TRANSECTION PRODUCES Ca^{2+}-DEPENDENT ACTIVATION OF THE NITRIC OXIDE SYNTHASE IN THE PRIMARY AFFERENT NEURONS, WHICH MEDIATES NON-PEPTIDERGIC AND NON-IMPULSIVE SIGNAL TRANSMISSION IN THE SOMATOSENSORY PATHWAY

T. Honda, N. Ozaki, Y. Tonosaki, K. Nishiyama, and Y. Sugiura* Dept. of Anatomy, Fukushima Medical College, Fukushima, 960-12, Japan.

We have provided that Fos expression in the lumbar spinal cord induced by the sciatic nerve transection was unaffected by the several analgesic treatments, i.e.,the topical application of lidocaine to the sciatic nerve or the systemic treatment of capsaicin (Pain Res., 10, 11-20, 1995). Our additional studies provided that topical pretreatment of colchicine to the sciatic nerve prevented this capsaicin-resistant Fos expression in the superficial layer of the lumbar spinal cord. These previous results suggested a possibility that nerve transection produced a defined transmitter in the primary afferent neurons. This transmitter was not capsaicin-sensitive and released by a process unrelated to the membrane depolarization of the primary afferent neurons.

An immunohistochemical or an enzyme-histochemical studies provided that the neuronal type of nitric oxide synthase (nNOS) sequentially expressed in the lower lumbar dorsal root ganglion and the dorsal horn of the lumbar spinal cord following the sciatic nerve transection. Capsaicin-resistant Fos expression evoked by nerve transection was suppressed by capsaicin application combined with L-NAME, an inhibitor of NOS. In addition, topical pretreatment of EDTA to the nerve-transected part markedly reduced the capsaicin-resistant Fos expression evoked by the sciatic nerve transection in the lumbar spinal cord. Our present results strongly suggested that the nerve transection made the primary afferent neurons to synthesize NOS which acted as a neurotransmitter. Newly synthesized NOS in the primary afferent neurons may be activated by Ca^{2+} influx into soma through the membrane-disrupted part of the peripheral nerve, and possibly mediates the non-peptidergic and non-impulsive signal transmission in the somatosensory pathway.

711.13

CGRP AND SP LEVELS IN ADJUVANT-INDUCED INFLAMMATION OF THE RAT TMJ. **R. Spears, R.P. Harper, R.J. Hinton, and B. Hutchins*. Dept. of Biomedical Sciences, Baylor College of Dentistry, Dallas, TX, 75246.**

Research indicates that inflammation occurring at various body joints results in elevation of calcitonin gene-related peptide (CGRP) and substance P (SP) levels. Few data exist on the role of these inflammatory mediators within the temporomandibular joint (TMJ), hence, this study was designed to determine CGRP and SP trigeminal ganglion levels in adjuvant-induced inflammation of the rat TMJ. Thirty male Sprague-Dawley rats (200-250 gm) were anesthetized and a mixture of complete Freund's adjuvant (50 µl) and radiopaque fluid (20 µl) was placed within the left TMJ. The contralateral joint received vehicle only. Placement of the injections were verified with X-rays. Animals were sacrificed at 6 h, 24 h, 48 h, 10 days and 4 wks. Trigeminal ganglia were removed and CGRP and SP levels quantified via RIA. The results indicated CGRP levels were significantly elevated on the adjuvant-injected side for the first 24 h post-injection, declining to a plateau at 10-28 days. All time periods were significantly greater than the control. SP levels were significantly elevated on the adjuvant-injected side for all time periods, but no difference existed between intervals. These results indicate that adjuvant-induced inflammation of the TMJ produces a chronic elevation (4 wks) of CGRP and SP levels in the trigeminal ganglion. This research was supported by NIH NIDR DE07270 and Baylor College of Dentistry Research Funds.

FORMALIN CAUSES "ANESTHESIA DOLOROSA" WITH BIPHASIC NOCICEPTOR DISCHARGE IN RAT SKIN, IN VITRO; B. Riedl and P.W. Reeh* Inst. of Physiology and Exp. Pathophysiology, Universitaetsstrasse. 17, D-91054 Erlangen, Germany

Recently, Puig and Sorkin (Pain 64, 345-355, 1996) published evidence for primarily peripheral origin of the distinctly biphasic pain related behaviour of rats injected with formalin. This is in full agreement with observations made in our lab, using controlled formalin application to rat cutaneous nerve endings, in vitro: Low formalin concentrations (1 and 10 mM) applied for 3 min evoked monophasic „injury" discharge in all slowly conducting fibers with unmyelinated endings and led to partial desensitization and sensitization. Higher concentrations (30, 100 and 300mM) exited and completely desensitized all units of every fiber class, but only C and Aδ fibres showed a second phase of vigorous discharge, which typically lasted for about 80 min.

We now have extended this previous work to study the effect of 30mM (=2.5%) formalin, known as the lowest concentration to evoke biphasic pain related behaviour in rats. All 10 polymodal C fibers responded with clear-cut biphasic discharge periods, separated by an inactive period of 3-15 min duration (median 4.5 min). Averaged responses showed no significant difference between phase 1 and 2 activity in respect to the magnitude of discharge (using several different bin-widths). In late phase 2, all units turned out to be completely desensitized to any physical stimulus applied.

We conclude, that the formalin pain model induces a condition resembling "anesthesia dolorosa". Its superior performance in pharmacological screening tests may be due to exclusively nociceptive activity in phase 2. Quantitatively, there is not much need left for neither peripheral inflammation nor spinal sensitization to explain phase 2 of pain related behaviour.

QUANTIFICATION OF CALCIUM INFLUX THROUGH CAPSAICIN- AND PROTON-ACTIVATED ION CHANNELS IN ADULT RAT DRG NEURONS H.U.Zeilhofer*, D.Swandulla, P.W.Reeh, and M.Kress. Dept. of Pharmacology and Dept. of Physiology , Univ. of Erlangen-Nürnberg, D-91054 Erlangen, Germany.

Capsaicin and protons have long been known as potent algogens and excitatory stimulants of primary nociceptive afferents. Both agents activate a rather non-specific slowly inactivating cationic current in about 40 % of adult DRG neurons.

Here we have quantified the fractional contribution of Ca^{2+} to the total current activated by acidic solutions (pH 5.1) and capsaicin (3 µM) by combining the whole-cell patch-clamp technique and Ca^{2+} flux measurements with FURA-2. Under conditions where ionic currents are carried exclusively by Ca^{2+} and where all incoming Ca^{2+} binds to FURA-2 we have determined a decrease in the FURA-2 fluorescence (F380), measured at 380 nm, of $3.3*10^{-3}$ units of standard bead fluorescence (BU) per incoming pC of Ca^{2+}. Protons and capsaicin elicited slowly inactivating cation currents and concomitant decreases in F380. In the presence of 1.6 mM Ca^{2+} the contribution of Ca^{2+} to proton- and capsaicin-activated currents (P_f) was 1.7±0.5 % (n=17) and 4.3±0.7 % (n=13), respectively, corresponding to permeability ratios for Ca^{2+} over Cs^+ of 0.55 and 1.35. P_f varied with changes in the extracellular concentration of Ca^{2+} as expected from the GHK equation and increased with decreasing proton concentration of the pH stimuli. Intracellular pH measured with BCECF remained well above the threshold where intracellular acidification affects Ca^{2+} binding to FURA-2 (pH 6.75). Decreasing the extracellular pH from 7.3 to 5.1 for 10 s resulted in an intracellular acidification of only 0.10±0.02 pH units (n=15), measured with BCECF (100 µM).

These results demonstrate that ion channels activated by protons or capsaicin are permeable to Ca^{2+}, which may lead to relevant increases in $[Ca^{2+}]_i$.

SELECTIVE ACTIVATION OF DIFFERENT CURRENT COMPONENTS BY HIGH AND LOW CONCENTRATIONS OF CAPSAICIN IN SENSORY NEURONS. A. Klusch, Fr.-K. Pierau*[‡] and M. Petersen. *Institute of Physiology, Univ. of Würzburg, 97070 Würzburg and [‡]Max-Planck-Institute, Kerckhoff-Institute 61231 Bad Nauheim, Germany.*

Studies of the release of neuropeptides from pulmonary afferents caused by low and high concentrations of capsaicin (CAP) proposed different ion channel mechanisms between both stimuli. We showed in a previous study on isolated rat dorsal root ganglion (DRG) cells with the patch-clamp technique that a prolonged application of 300 nM CAP can evoke an inward current with one or two components in an external solution with a physiological ion composition as well as in an external solution with a high calcium concentration (10 mM) and no sodium. The maximum of the first component occurred at about 8 s and of the second at about 40 s. Both components could be activated independently. To test whether their activation is concentration dependent the occurrence of the distinct components was investigated in response to different concentrations of CAP. Isolated DRG neurons from adult rats were superfused for 60 s with CAP (200 to 1000 nM). Recordings were obtained from short-term cultured small to medium sized neurons with the whole cell patch-clamp technique at -80 mV and in an external solution with high calcium and no sodium. The activation of the first and/or second component was strongly concentration dependent. A low concentration (200 nM) predominantly elicited only the second component (60%), while a high concentration (1000 nM) mainly activated only the first one (75%). At a concentration of 300 nM cells responded predominantly with both components together (60%). The time of the occurrence of the maxima for the different components was maintained regardless of the concentration of capsaicin applied and regardless of whether one or two components occurred. Our findings may account for the different physiological responses evoked by different concentrations of CAP. Supported by DFG Pe 299/3-1.

IMMUNOHISTOCHEMICAL LOCALIZATION OF THE $P2X_3$ RECEPTOR SUBUNIT IN RAT DORSAL ROOT GANGLION (DRG) NEURONS L.Vulchanova*, M. Riedl, S. Shuster, J. Wang, G. Buell[#], A. Surprenant[#], R.A. North[#], and R. Elde. Dept. of Cell Biology and Neuroanatomy, Univ. of Minnesota, Minneapolis, MN 55455, USA and [#]Glaxo Institute for Molecular Biology, Plan-les-Ouates, 1228 Geneva, Switzerland

The $P2X_3$ receptor subunit, a member of the P2X family of ATP-gated ion channels, was cloned from a rat DRG cDNA library. According to *in situ* hybridization studies $P2X_3$ is expressed only in dorsal root, trigeminal and nodose ganglia, and several lines of evidence suggest that this receptor is involved in the processing of noxious stimuli. To further address this question, we used immunohistochemistry to determine whether $P2X_3$ is colocalized with established markers of nociceptive DRG neurons. Antisera were generated against a 15-amino acid peptide corresponding to the C-terminus of $P2X_3$ in both guinea pigs and rabbits, and their specificity was determined by staining HEK293 cells stably transfected with the $P2X_3$ receptor and by absorption controls. In agreement with the *in situ* hybridization results, $P2X_3$ immunoreactivity (-ir) was observed in the dorsal root, trigeminal and nodose ganglia. $P2X_3$-ir was also found in lamina II of the spinal cord and in the nucleus of the solitary tract. $P2X_3$-ir in the spinal cord was not observed on the ipsilateral side after dorsal rhizotomy, and it accumulated at the site of sciatic nerve ligation, suggesting that the $P2X_3$ receptor in DRG neurons is transported both centrally and peripherally. $P2X_3$-ir in DRG was observed in small and medium size neurons. Double-labeling of DRG revealed very little colocalization of $P2X_3$-ir with CGRP-ir and no colocalization of $P2X_3$-ir with SP-ir. Conversely, almost all $P2X_3$-positive DRG neurons also contained peripherin-ir as well as the lectin BSI-B_4. Therefore, $P2X_3$ appears to be expressed predominantly by the subpopulation of small, "non-peptide containing" DRG neurons. Since these primary afferent neurons are thought to function as nociceptors and thermoreceptors, our results support the notion that $P2X_3$ may be involved in the processing of noxious stimuli.

ALTERNATIVELY SPLICED β-ARRESTIN 1 mRNA FORM IN RAT DORSAL ROOT GANGLIA (DRG). N. Komori*[1], H. Matsumoto[1], and K.E. Miller[2]. Dept. of Biochem. and Molec. Biol.[1] & Dept. of Anatomy[2], Univ. of Oklahoma HSC, Oklahoma City, OK 73190

The vast majority of neurotransmitters, neuropeptides, and hormones function through specific G protein-linked 7-transmembrane segment (7-TMS) receptors. Arrestin and β-arrestins have major roles *in vitro* in the desensitization of two well known 7-TMS receptors, rhodopsin and β_2-adrenergic receptor, respectively. We hypothesize that arrestin/β-arrestin gene family members are involved in the desensitization of pain sensation in peripheral afferent neurons. In order to corroborate our previous immunoblot and immunohistochemical results showing the presence of β-arrestins in the rat DRG (Komori, N., et al., Proc. Soc. Neurosci. 20:126, 1994), we have performed reverse transcription-polymerase chain reaction (RT-PCR) to demonstrate the presence of β-arrestin message in the rat DRG. Previously studied tissues, eg. kidney, were used as positive controls. PCR was performed through 35 cycles of denaturation at 94°C for 1 min, annealing at 55°C for 30 sec, and polymerization at 72°C for 1.5 min. DNA sequencing of the PCR product confirmed the presence of β-arrestin 1 mRNA in rat DRG as well as an alternatively spliced form. Supported by Oklahoma Center for the Advancement of Science and Technology (OCAST) HN5-024 to NK, NS27213 to KEM.

STUDIES OF AFTER HYPERPOLARIZATION IN NOCICEPTORS (N cells) OF THE LEECH. G.J. Giesler, Jr.*, Mark A. Masino and Ronald L. Calabrese, & Dept. of Cell Biol. & Neuroanat., Univ. of Minn., Minneapolis, MN 55455 & Dept Biol., Emory Univ., Atlanta, GA, 30322

High frequency firing induced by noxious stimuli or intracellular depolarizing pulses is followed by a marked hyperpolarization (>20 mV) of the membrane potential in leech nociceptors (N cells). This after hyperpolarization (AH) can prevent generation of action potentials for more than 2 min. The aim of this study was to determine the ionic currents underlying AH in nociceptors. During AH, membrane conductance was found to increase greatly. Replacement of extracellular Cl^- ions with isethionate ions or injection of Cl^- ions from KCl filled recording electrodes into the cell body of N cells did not obviously reduce AH, suggesting that AH is not the result of increased Cl^- current. AH was virtually eliminated in solutions containing 100 μM Cd^{++}, suggesting that AH is dependent on Ca^{++} entry through voltage-gated Ca^{++} channels. In addition, in solutions containing 0 Na^+ and 1.8 mM Ca^{++}, with outward currents partially blocked using 2M TEA filled electrodes, high-threshold long-duration action potentials were produced by depolarizing stimuli. These action potentials could also be reversibly blocked by 100 μM Cd^{++}, indicating that they were Ca^{++} mediated. In voltage clamp studies, AH was associated with an outward current that reversed at roughly -90 mV, indicating that AH is caused by an increased conductance to K^+ ions. Under voltage clamp, depolarization of N cells in a solution containing Ba^{++} produced a high-threshold (approximately -10 mV), slowly inactivating inward current that could be blocked by 100 μM Cd^{++}. These results support and extend previous findings suggesting that AH in N cells is produced primarily by a Ca^{++} mediated K^+ current. Supported by NS25932 (GJG) and NS24072 (RLC).

PAIN MODULATION: PHARMACOLOGY—INFLAMMATION AND HYPERALGESIA

712.1

TRANSPLANTATION OF AN ENCAPSULATED CELL LINE GENETICALLY ENGINEERED TO RELEASE NGF IN AN ANIMAL MODEL OF PAINFUL PERIPHERAL NEUROPATHY. I. Décosterd[1,2], M. Burki[1], V. Borel[1], N. Gilliard[2], E. Buchser[2], P. Aebischer[1]*. [1]Gene Therapy Center, CHUV. Lausanne University Medical School, [2]Pain clinic, Morges, Switzerland.

NGF induces nociception in naive animals, but has been reported to exert analgesic effect in peripheral neuropathies. In order to decipher the potential dual action of NGF, we are comparing the effect of intrathecal versus systemic NGF delivery on the establishment of pain resulting from a chronic constriction nerve injury (CCI), as the route of NGF administration may also affect the behavioral response. Seven days post-ligation of the sciatic nerve, Sprague Dawley rats were implanted with polymer capsules loaded either with baby hamster kidney (BHK) cells genetically engineered to release NGF (n=6) or with the parent BHK cells (n=5). These capsules were placed in the subarachnoid lumbar space. Animals were tested for both thermal and mechanical allodynia prior to ligation and twice a week for one month post-implantation. All animals developped some degree of thermal and mechanical allodynia following nerve ligation. The cohort receiving NGF implants showed however a significant increase of their allodynia compared to the cohort implanted with the BHK control capsules. This difference tended to disappear starting at 3 weeks. These results suggest that intrathecal delivery of NGF enhances the painful peripheral neuropathy resulting from CCI. We are presently studying the effect of peripheral administration of NGF on established painful peripheral neuropathy.

BEHAVIORAL SIGNS OF CORNEAL HYPERALGESIA AND DIFFERENTIALLY-EXPRESSED GENES IN TRIGEMINAL GANGLION AFTER SYSTEMIC ADMINISTRATION OF NGF IN MICE

G. Davar* and M. Fareed, Molecular Neurobiology of Pain Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, 02115, USA.

This study aimed to examine the frequency of eyeblink responses to thermal and chemical stimuli, and the differential expression of mRNAs in trigeminal ganglion, after systemic administration of NGF.

Using methods previously described (Davar et al., '96), recombinant rat NGF (kindly provided by Genentech, Inc.) (1mg/kg) or saline were administered intraperitoneally to adult Swiss Webster mice(n=12). Eyeblink responses in the 60sec immediately following the application of 5μl of heated (65±1^{0}C) water or 50mM acetic acid were recorded 30min, 4hr, 24hr, and 48hr after administration of NGF or saline. Trigeminal ganglia were harvested and total RNA extracted for analysis of differentially regulated genes using a method of differential display.

Preliminary results of behavioral testing demonstrate significant increases in eyeblink response frequency to thermal stimulation in NGF-treated animals when compared with saline-treated animals (repeated measures ANOVA) at all time points of testing (30min, 24hr and 48hr). Chemical stimulation with 50mM acetic acid did not produce differences in eyeblink response frequency. Preliminary results of differential display demonstrate several fragments in the 150-250 kb range that may be evidence of upregulated mRNAs in trigeminal ganglia from animals treated with NGF. Further efforts will now be directed at the identification of these fragments and functional characterization of their full length clones.

These results may be evidence of an effect of systemic administration of NGF on eyeblink responses to thermal stimulation, and on the differential expression of mRNAs in trigeminal ganglion. Supported by NIH grant 1KO8NS01497

TNFα IN THE PERIPHERAL RECEPTIVE FIELD OR ON THE SCIATIC NERVE TRUNK EVOKES ACTIVITY IN PRIMARY AFFERENT FIBERS W.-H. Xiao*, R. Wagner, R.R. Myers and L.S. Sorkin Dept. of Anesthesiology, UC San Diego, La Jolla, CA. 92093

Blockade of TNFα, a pro-inflammatory cytokine, reduces allodynia in neuropathic rats. We examined the effects of injecting TNFα into the receptive field (RF) or onto the nerve trunk, on afferent fiber activity.

Rats were anesthetized with pentobarbital. Their sural or sciatic nerves were exposed. Spikes from single Aδ or C fibers with RFs on the hindpaw were isolated. TNFα (50 pg in 50 μl) was injected into RFs of sural afferents. Ascending doses of TNFα in 0.1% BSA in saline were applied for 15 min intervals to a restricted portion of the sciatic nerve, distal to the recording site. Activity was assessed during each test interval. Mechanical thresholds were determined every 15 min.

Primary afferent fibers without background activity were unaffected by BSA vehicle. SC injection of TNF-α elicited an ongoing low frequency (≤ 0.2 Hz) discharge. Mechanical thresholds decreased 40-50% from control and remained depressed for at least 60 min following injection. Administration of TNFα (5-7.5 pg/ml) onto the nerve trunk also elicited irregular low frequency activity (0.1-0.2 Hz), with a shorter latency than for SC injections. Concentrations of 10-50 pg/ml resulted in peak responses (1.0-1.5 Hz); higher doses were without effect. Irrespective of dose, RF mechanical threshold was unchanged.

TNFα acting along the nerve trunk can elicit activity in nociceptive primary afferent fibers. In the periphery, TNFα sensitizes receptors as well as elicits discharge. Thus, a nerve passing through inflamed TNFα enriched tissue could be a source of spontaneous pain. Peripheral terminals in such an area could elicit allodynia as well. This work was supported by NS 18715 and AR 42235.

TUMOR NECROSIS FACTOR (TNFα) , BUT NOT INTERLEUKIN 1-β (IL-1-β), ENHANCES THE CAPSAICIN SENSITIVITY OF RAT SENSORY NEURONS. C.M. Pafford, J.C. Lopshire, and G.D. Nicol*. Medical Neurobiology and Department of Pharmacology and Toxicology, Indiana University School of Medicine, Indianapolis, IN 46202.

Since cytokines appear to lower the response threshold of sensory neurons to noxious stimuli, we examined whether these agents altered the excitation produced by capsaicin in rat sensory neurons. Neurons were isolated from the dorsal root ganglia of E16 rat embryos and grown in culture for 4 days. To ascertain capsaicin sensitivity, neurons were either loaded with cobalt in the presence of capsaicin or the whole-cell patch clamp technique was used to record the capsaicin response from a single neuron. Under control conditions, 100 nM capsaicin labelled 15% of the neurons. After a 24 hr treatment, 1 ng/ml TNFα had no effect on the number of labelled neurons whereas 10 and 50 ng/ml produced significant increases of 2.1-fold and 1.6-fold (χ^2, $p<.05$), respectively. IL-1β (10 or 50 ng/ml) had no effect on the number of labelled neurons after a 24 hr exposure. In whole-cell recordings (V_h -60 mV), the focal application of 100 nM capsaicin elicited an average inward current of 610 ± 163 pA (n=8) whereas the bath application of 1 μM capsaicin elicited a maximal inward current of 1701 ± 311 pA. After exposure to TNFα, the current evoked by focal capsaicin increased to 1446 ± 339 pA (n=10) whereas the response to bath capsaicin was unchanged at 1898 ± 387 pA. Normalization of individual responses to focally applied capsaicin to their respective bath applications, indicated that the sensitivity had been increased by greater than two-fold. Pretreatment with 30 μM indomethacin blocked the TNFα-induced sensitization. These results indicate that the pro-inflammatory cytokine, TNFα, enhances the sensitivity of sensory neurons to the chemical excitatory agent, capsaicin, via a cyclooxygenase-dependent pathway. Supported by NIH grant NS30527.

712.5

INTERLEUKIN (IL)-10 REDUCES SIGNIFICANTLY ENDOTOXIN (ET)-INDUCED PERIPHERAL HYPERALGESIA IN MICE. S.A. Kanaan, N.E. Saade*, S.J. Jabbur, S.F. Atweh and B. Safieh-Garabedian. Fac. of Arts and Sci. and Fac. of Med., American Univ. of Beirut, Lebanon.

Previous data from our laboratory has shown that intraplantar injection of ET (1.25µg) in Balb/c mice induced a localized inflammatory hyperalgesia that lasted for 48h as assessed by the paw pressure (PP), tail flick (TF) and hot plate (HP) tests (Kanaan et al., Pain, 1996 in Press). We now report that intraperitoneal (i.p.) injection of IL-10 (Human rDNA) significantly reduces the ET-induced peripheral hyperalgesia in Balb/c mice.

Different groups of mice were injected (i.p.) with various doses of IL-10 (0.75ng, 1.5ng or 7.5ng) in 100µl saline followed, 30 min later, by intraplantar ET injection (1.25µg/50µl saline). One group of mice received ET injections only and control animals received the same volume of saline injection only. All animals were subjected to PP, TF and HP tests for assessment of thermal and mechanical hyperalgesia. IL-10 significantly reduced, and in a dose dependent manner, mechanical and thermal hyperalgesia. At 7.5ng, IL-10 increased the pain threshold latencies of PP (from 62.6% with ET to 82%), HP (from 57% with ET to 90%) and TF (from 76% with ET to 90%) as compared to their control values.

It is known that IL-10 can decrease inflammation and hyperalgesia through its inhibitory action on tumor necrosis factor and IL-1B and we are currently investigating its effect on both of these cytokines.

712.6

EFFECTS OF VARIOUS DRUGS ON ENDOTOXIN (ET)-INDUCED HYPERALGESIA IN RODENTS. S.J. Jabbur*, S.A. Kanaan, B. Safieh-Garabedian, S.F. Atweh and N.E. Saadé. Fac. of Med. and Fac. of Arts and Sci., American Univ. of Beirut, Lebanon.

After establishing intraplantar injection of ET (1.25µg) as a new model for localized and reversible hyperalgesia assessed by tail immersion (TF), paw pressure (PP) and tail flick (TF) tests (Safieh-Garabedian et al., *PAIN*, in Press), we now test the effect of four classes of drugs on this model.

Acetaminophen (12.5mg/kg in rats and 2mg/kg in mice), dexamethasone (200mg/kg in rats and 20mg/kg in mice), indomethacin (4mg/kg in rats and 8mg/kg in mice) and morphine (1.7mg/kg in rats and 7mg/kg in mice) were injected intraperitoneally 24 and 12h *before* ET injection and *just before* each pain test at 3h, 6h, 9h and 24h *after* ET injection. Acetaminophen (aspirin-like analgesic) and dexamethasone (steroidal anti-inflammatory) were the most effective in reducing PP hyperalgesia and least effective on TF hyperalgesia, while indomethacin (non-steroidal anti-inflammatory and inhibitor of cyclo-oxygenase) and morphine (narcotic analgesic) were most effective in reducing TF hyperalgesia with weakest effects on PP hyperalgesia. All four drugs reversed, almost equally, HP hyperalgesia in both rodents.

We conclude that ET-induced hyperalgesia can be mediated by both prostaglandin sensitive and prostaglandin-independent mechanisms.

(Supported by the *DTSabbagh Fund* and the *University Research Board.*)

712.7

THE CYCLIC AMP TRANSDUCTION CASCADE MEDIATES THE PROSTAGLANDIN E_2-INDUCED INHIBITION OF POTASSIUM CURRENTS IN RAT SENSORY NEURONS. A.R. Evans,* M. R. Vasko and G.D. Nicol. Dept. of Pharmacology and Toxicology, Indiana Univ. School of Medicine, Indianapolis, IN 46202.

Prostaglandin E_2 (PGE_2) enhances the excitability of rat sensory neurons and this sensitization may result from an inhibition of a delayed rectifier-like potassium current (IK). Since the sensitizing effects of PGE_2 require activation of the cyclic AMP transduction cascade, we examined whether the PGE_2-mediated inhibition of IK is also cyclic AMP dependent. Neurons were dissociated from the dorsal root ganglia of 15-17 day-old embryos and grown in culture for 4-6 days. The whole-cell patch-clamp technique was used to determine the effects of PGE_2 and CPT-cyclic AMP on the outward IK of sensory neurons. At the end of each recording the cell was exposed to capsaicin; data from only capsaicin-sensitive neurons are reported here. Treatment with 1 µM PGE_2 caused a time-dependent decrease in IK recorded from neurons bathed in N-methylglucamine Ringer's. After 10 and 20 min treatments, G/Gmax was reduced to 0.79 ± 0.04 & 0.69 ± 0.06 (n=6) of the control value. In a similar manner, 100 µM CPT-cyclic AMP decreased G/Gmax to 0.72 ± 0.03 & 0.66 ± 0.03 (n=7) of the control value. Subtraction of the currents remaining after CPT-cyclic AMP from controls revealed that CPT-cyclic AMP inhibited a delayed rectifier-like IK in an manner analogous to PGE_2. Since an increase in cyclic AMP leads to the activation of protein kinase A (PKA), the role of PKA in the PGE_2-elicited decrease in IK was examined. Addition of the peptide inhibitor of PKA (PKI, 20 µM) to the recording pipette abolished the PGE_2-mediated decrease in IK. These data indicate that PGE_2 inhibits potassium current(s) through activation of the cyclic AMP transduction cascade. Supported by NIH grants NS09733, NS34159 and NS30527.

712.8

INVOLVEMENT OF NITRIC OXIDE IN ZYMOSAN-PRODUCED VISCERAL HYPERALGESIA IN THE RAT. S.V. Coutinho* and G.F. Gebhart. Department of Pharmacology, University of Iowa, Iowa City, IA 52242, USA.

We have previously shown that administration of intracolonic zymosan results in significantly enhanced responses to colorectal distension (CRD) in the rat. The present study was aimed at determining whether nitric oxide is involved in mediating the visceral hyperalgesia. The visceromotor response (VMR) to a noxious intensity of CRD (80 mmHg, 20 s) was recorded from the external oblique musculature of awake, chronically instrumented male Sprague-Dawley rats, prior to and three hours following instillation of intracolonic zymosan to establish that the rats were hyperalgesic. Intrathecal administration of L-NAME (100-800 nmol) using a cumulative dose paradigm attenuated the enhanced VMR to CRD in zymosan-treated rats in a dose-dependent manner. Administration of vehicle (saline) or D-NAME was without effect. NADPH-diaphorase histochemical staining of the lumbosacral (L6-S2) spinal cord revealed a significant increase in positive cells three hours post-zymosan when compared to treatment with intracolonic saline. Taken together these findings suggest that spinal nitric oxide is involved in mediating the visceral hyperalgesia produced by intracolonic zymosan. Supported by NS 19912.

ROLE OF NITRIC OXIDE-CYCLIC GMP SYSTEM IN THE SENSITIZATION OF SPINOTHALAMIC NEURONS AFTER INTRADERMAL INJECTION OF CAPSAICIN IN PRIMATES. Q. Lin*, Y.B. Peng, J. Wu and W.D. Willis. Department of Anatomy & Neuroscience, Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77555-1069.

Nitric oxide (NO), an activator of guanylate cyclase, has been reported to be involved in nociceptive signal transduction in the spinal cord. This study was designed to investigate the possible role of NO-cGMP signal transduction system in the development of central sensitization of spinothalamic tract (STT) neurons produced by intradermal injection of capsaicin (CAP). STT neurons were identified by antidromic activation and recorded using a carbon filament electrode in anesthetized young adult monkeys (*Macaca fascicularis*). Responses of STT cells to innocuous and noxious mechanical stimuli delivered in the cutaneous receptive field and the inhibition of these responses produced by electrical stimulation in pariaqueductal gray (PAG) were recorded. Intradermal injection of CAP resulted in sensitization of the responses of STT cells to mechanical stimuli, which was accompanied by a reduction in PAG inhibition. Pretreatment of spinal dorsal horn with 7-nitroindazole, an inhibitor of NO synthase, or 1H-[1,2,4]oxadiazolo[4,3-a]quinoxaline-1-one, an inhibitor of guanylate cyclase, by microdialysis prevented sensitization of STT cells and attenuation of PAG inhibition induced by CAP. On the other hand, sensitization of responses of STT cells to mechanical stimuli and reduction in PAG inhibition were also observed when S-nitroso-N-acetylpenicillamine, a NO source, or 3-Morpholinosydnonimine, a NO donor, was administered into the spinal dorsal horn. Our results suggest that NO plays an important role in the process of central sensitization of spinal dorsal horn neurons, presumably by activating cGMP cascades. Attenuation of the effectiveness of descending inhibition may take place when the sensitization of dorsal horn cells develops. This work was supported by NIH Grants NS09743 and NS11255.

ATTENUATION OF PKC ßII ACTIVITY DURING HYPERALGESIA BY AGENTS ACTING BY DIFFERENT MECHANISMS. O.J. Igwe* and M.B. Filla, Div. of Pharmacology, UMKC Schools of Pharmacy & Medicine, KC, MO 64108.

Thermal hyperalgesia (TH) following unilateral Freund's complete adjuvant (FCA)-induced peripheral inflammation in the rat hind paw is thought to involve Ca^{2+}-mediated central sensitization. Inflammation was characterized by measures of edema and TH. Translocation/activation of Ca^{2+}/phospholipid PKC isozyme(s) following stimulation of excitatory amino acids/neurokinin-1 (NK-1) receptors, has been associated with both development and maintenance of TH. Demonstrable TH was observed from day 1 following FCA treatment. Paw-withdrawal latencies (PWL) were much shorter on the FCA-treated side than on the contralateral side of the FCA and the sham-treated rats ($p \leq 0.01$). There were no statistical differences ($p \leq 0.01$) in the contralateral PWL between day 1 and day 7. Total cytosolic PKC activity in the spinal cord was unchanged on the sides of the spinal cord contra- and ipsi-lateral to the inflammation. Membrane PKC ßII activity was significantly increased ($p \leq 0.01$) on day 7 following FCA treatment on the side of the cord ipsilateral to the inflammation suggesting increased translocation/activation of PKC ßII isozyme related to TH. The sham treated controls had the same membrane PKC ßII activity as the side of the cord contralateral to the inflammation. Membrane activities of PKC α, PKC ßI and PKC γ did not change on the side of the spinal cord contra- and ipsi-lateral to the inflammation. Implantation of 7-day mini-osmotic pumps (one day before FCA treatment) delivering dextrorphan (DEX), a non-competitive NMDA antagonist, L-703,606, a selective non-peptide NK-1 receptor antagonist and GM 1 ganglioside, an intracellular inhibitor of PKC translocation/activation, significantly reduced the hyperalgesic response, and the increase in the activity of PKC ßII on the side of the spinal cord ipsilateral to the inflammation. DEX and GM1 were effective in all doses tested, but L-703,606 was marginally effective only at the highest dose. Drug treatments did not alter the activities of membrane PKC α, PKC ßI and PKC'γ isoforms in the spinal cord section ipsi- and contra-lateral to the inflammation. The present results provide evidence for a pivotal role of PKC ßII isozyme in the molecular mechanism of TH. Supported by USPHS grant AR 41606.

N-(2-HYDROXYETHYL)HEXADECANAMIDE GIVEN ORALLY REDUCES TRAUMATIC NERVE INJURY-INDUCED ENDONEURIAL PLASMA EXTRAVASATION AND MECHANICAL HYPERALGESIA. S. Mazzari*, R. Canella and A. Leon. Research*life* S.c.p.A., 31033 Castelfranco Veneto, Italy.

Hyperalgesic syndrome in experimental models of neuropathic pain is associated with local inflammatory reactions in the nerve trunk. N-(2-Hydroxyethyl)hexadecanamide (LG 2110/1) reduces cutaneous inflammatory extravasation (Mazzari *et al.*, 1996, Eur. J. Pharmacol.) by a mechanism distinct from that of classical NSAIDs and steroidal agents, appearing to act at the peripheral cannabinoid receptor CB2 on mast cells (Facci *et al.*, 1995, PNAS). In addition, LG 2110/1 decreases inflammatory and neuropathic mechanical hyperalgesia (MH) (Mazzari *et al.*, 1995, Soc. Neurosci. Abstr.). We now report that traumatic nerve injury (TNI) (isolation and slight stretch) of rat sciatic nerve causes hindpaw MH and increases local endoneurial plasma extravasation (EPE). LG 2110/1 oral pretreatment (-1 h) dose-dependently reduced both MH and EPE (see table 1) 24 h after TNI.

Table 1: Dose-effect of LG 2110/1 oral pretreatment on MH and EPE 24 h after TNI

	Control	Vehicle	0.1 mg/kg	1 mg/kg	10 mg/kg
MH (§)	251.2±3.4	180.6±8.4	187.1±7.4	201.4±5.5*	225.0±4.6**
EPE (#)	2.2±1.4	177.4±4.8	153.1±8.3*	112.4±8.7**	114.9±5.2**

**p<0.05 and **p<0.001 vs vehicle; n= 7; (§) MH was assessed as reduction o mechanical threshold (g) of hindpaw withdrawal according to Randall and Selitto; (#) Evans blue (50 mg/kg; i.v. at the time of TNI) accumulation in the sciatic nerve endoneurium was evaluated by optical absorbance ($Ax10^{-3}$) at 620 nm.*

Inflammatory alterations of the endoneurial microenvironment thus accompany development of MH following TNI. Importantly, the down-modulation of endoneurial inflammation by LG 2110/1 is functionally associated with a antihyperalgesic effect. N-(2-Hydroxyethyl)hexadecanamide may be of interest in the treatment of neuropathic syndromes associated with traumatic nerve injury.

712.12

TIMING AND ROUTE OF NSAID ADMINISTRATION AFFECTS BASAL AND NMDA-EVOKED SPINAL LEVELS OF PGE2 AND AMINO ACIDS (AA). LS Sorkin*, DL Jones and P Isakson Anesthesiol Res Labs, UC San Diego, La Jolla, CA 92093-0818

Earlier studies showed that 15 min intrathecal (IT, 30 µg) ketorolac (keto) pretreatment blocked spinal PGE2 release evoked by IT NMDA. Basal levels were unaffected. Our aims were to determine if 1) this was true for other NSAIDs and 2) if alterations in timing and route of administration affected basal and NMDA-evoked PGE2 levels.

Rats with previously implanted IT catheters were given microdialysis probes (< 4 mm from end of the IT catheter). Under 1% halothane, 2 basal samples were followed by 3 µg NMDA (IT) and 3 post-NMDA samples; these were all 30 min long. NMDA was preceded (15 min) by IT (R- and S+, 5.6 µg) ibuprofen (ibu), indomethacin 1.8 µg, or keto. Alternatively, keto (30 µg IT or 10 mg/kg IV) was given 60 min before NMDA. PGE2 and AA were assayed, respectively, by RIA or HPLC.

Basal levels of gly and tau, but not PGE2, were reduced by 15 min of indomethacin. Basal PGE2 was equally reduced by 60 min of IT or IV keto, however, only the long IT keto pretreatment reduced asp, tau and citrulline. NMDA-evoked release of PGE2 was blocked by all NSAIDs except R- ibu. S+ ibu also reduced evoked release of glu, asp and gly (taurine and citrulline were not affected). The 60 min IT, but not IV, keto pretreatment blocked evoked release of glu and gly.

These results indicate that evoked release of PGE2 is more sensitive to NSAID treatment than is basal release. Different NSAIDs may have differentially blocked release of other neuroactive substances and spinal administration of NSAIDs may be more efficacious at affecting these alternative pathways. This work was funded by Searle-Monsanto.

PROSTAGLANDIN E_2 ENHANCES THE SENSITIVITY OF RAT SENSORY NEURONS TO CAPSAICIN. J.C. Lopshire* & G.D. Nicol. Medical Neurobiology Program and Department of Pharmacology & Toxicology, Indiana Univ. School of Medicine, Indianapolis, IN 46202.

Prostaglandins (PGs) sensitize sensory neurons to noxious stimuli. This enhanced excitability may result from PG activation of transduction cascades that lead to increased currents through ligand-gated channels. Therefore, we investigated whether PGE_2 treatment enhanced ionic currents elicited by capsaicin, an agent that selectively excites nociceptive-signalling sensory neurons. Neurons were isolated from the dorsal root ganglia of 15-17 day-old embryonic rats and grown in cell culture. In whole-cell patch-clamp recordings, the focal application of capsaicin elicited an inward current, whose amplitude was concentration-dependent with an EC_{50} of 156 nM. Treatment with 1 µM PGE_2 transiently increased the amplitude of currents elicited by 10, 30, and 100 nM capsaicin, having maximal effects at 10-14 min. At this point, the capsaicin response began to decline towards baseline levels at a rate that was inversely related to the capsaicin concentration. The decline, which might be due to desensitization, was maximal with 100 nM capsaicin. Since the capsaicin-elicited current is carried partially by calcium, we examined if lowering extracellular calcium affected this relaxation. Indeed, for currents evoked by 100 nM capsaicin, the half-time of recovery depended on external calcium concentration where the most rapid recovery occurred with 2 mM calcium. $PGF_{2\alpha}$ (1 µM), which lacks a sensitizing action on sensory neurons, had no effect on capsaicin-elicited currents. Our findings indicate that PGE_2 enhances the activity of the capsaicin-gated channel and that the duration of this PGE_2-induced sensitization may be modulated by intracellular calcium levels. Supported by NIH grant NS30527.

MODULATION OF BRADYKININ-INDUCED MECHANICAL HYPERALGESIA IN THE RAT BY ACTIVITY IN ABDOMINAL VAGAL AFFERENTS. S. G. Khasar*, F. J.-P. Miao, W. Jänig[1] and J. D. Levine. Departments of Anatomy, Medicine and Oral and Maxillofacial Surgery, UCSF, CA 94143-0452, USA. [1]Physiologisches Institut, CAU, Olshausenstr. 40, 24098 Kiel, FRG.

We found recently that activity in abdominal vagal afferents inhibits bradykinin- (BK), induced plasma extravasation. In this study, we have tested the hypothesis that activity in abdominal vagal afferents influences another component of the inflammatory response, mechanical hyperalgesia. Surgical bilateral sub-diaphragmatic vagotomy was performed on male Sprague-Dawley rats, 7 days prior to nociceptive testing. Mechanical hyperalgesia, induced by BK, prostaglandin E_2 (PGE_2) and norepinephrine (NE), injected intradermally into the dorsal aspect of the hindpaw of the rat, was quantified by the Randall-Selitto paw-withdrawal method. The dose-response relationship of mechanical hyperalgesia produced by BK in vagotomized rats was enhanced when compared with sham vagotomized rats ($P<0.05$; two way ANOVA). This effect of vagotomy on BK-induced hyperalgesia was mimicked by selectively cutting the coeliac and accessory coeliac but not hepatic and gastric branches of the sub-diaphragmatic vagus nerve. Mechanical hyperalgesia produced by PGE_2, NE or cutting the sympathetic preganglionic neurons to the lumbar sympathetic chain, was not affected by vagotomy.

These results suggest that activity in abdominal vagal afferents attenuate mechanical hyperalgesia induced by BK in the normal rat, hence, removal of these afferents leads to enhancement of BK hyperalgesia. This effect seems specific for BK, is not mediated via preganglionic sympathetic neurons and does not affect hyperalgesia produced by PGE_2 (a direct effect on primary afferents) or NE (an indirect effect via sympathetic postganglionic neurons, as BK).

THE ROLE OF THE CYCLIC AMP TRANSDUCTION CASCADE IN MECHANICAL ALLODYNIA AND HYPERALGESIA INDUCED BY INTRADERMAL INJECTION OF CAPSAICIN IN RATS. K.A. Sluka*, Physical Therapy Graduate Program, The University of Iowa, Iowa City, IA 52242.

Rats were tested for responses to von Frey filaments with bending forces in the both the innocuous and the noxious range as a measure of allodynia and hyperalgesia, respectively, before and after intradermal injection of capsaicin. The threshold to mechanical stimulation with von Frey filaments with bending forces from 0.1-600 mN was tested before and after capsaicin. A microdialysis fiber was implanted into the dorsal horn of the spinal cord for administration of drugs that manipulate the cAMP pathway. Intradermal injection of capsaicin (0.1%, 100 µl) resulted in secondary mechanical hyperalgesia and allodynia manifested as a decrease in threshold to mechanical stimulation. Blockade of adenylate cyclase (SQ 22536) or protein kinase A (H89, PKI (14-22) amide) dose dependently reduces the mechanical allodynia and hyperalgesia. The reduction in the capsaicin-induced allodynia and hyperalgesia by an adenylate cyclase inhibitor can be reversed by activation of cAMP with 8-bromo-cAMP. Thus, the present data support the hypothesis that the cAMP transduction cascade is involved in maintaining mechanical allodynia and hyperalgesia induced by intradermal injection of capsaicin in the rat.

POSSIBLE EFFECT OF PROTEIN KINASE C ON RAT DORSAL HORN NEURON ACTIVITY. Y.B. PENG*, Q. LIN, W. D. WILLIS. Department of Anatomy and Neurosciences and The Marine Biomedical Institute, The University of Texas Medical Branch at Galveston, Galveston, Texas 77555-1069

The effects of a protein kinase C activator, 12-*O*-tetradecanoylphorbol-13-acetate (TPA), on the activity and periaqueductal gray (PAG)-induced inhibition of rat dorsal horn neurons of the lumbar spinal cord were tested. A microdialysis fiber was placed through the dorsal horn for the purpose of local application of pharmacological agents. Extracellular single unit recordings from dorsal horn neurons were made near the microdialysis fiber. TPA was tested on nociceptive dorsal horn cells. There was a significant increase of the background activity and responses to brush with no changes in responses to pressure and pinch stimuli. TPA also significantly blocked the PAG-induced inhibition of responses to brush, press, and pinch. The solvent, which contained dimethyl sulfoxide (DMSO), was also tested for its effect on the responses to peripheral mechanical stimuli and PAG-induced inhibition of the dorsal horn neurons. There were no significant changes. This experiment suggests that activation of the PKC second messenger system may increase the activity of dorsal horn neurons and their responses to peripheral stimuli; in addition, the phorbol ester attenuated the PAG-induced descending inhibition of the dorsal horn neuron activity. It is suggested by this study that PKC is involved in allodynia without taking part in hyperalgesia. Allodynia is probably due partly to attenuation of PAG-induced descending inhibition. This study was supported by NIH Grants NS09743 and NS11255.

INTRATHECALLY ADMINISTERED CYCLOOXYGENASE-2 INHIBITORS ATTENUATE CARRAGEENAN-INDUCED THERMAL HYPERALGESIA IN THE RAT. D.L. Hammond[1]* and S.A. Gregory[2]. [1]Dept. of Anesthesia & Critical Care, University of Chicago, Chicago, IL 60637 and [2]Inflammatory Diseases Res., G.D. Searle & Co., St. Louis, MO 63198.

This study determined whether intrathecal (i.t.) administration of inhibitors of the enzyme cyclooxygenase-2 (COX-2) attenuated thermal hyperalgesia in the rat. Sprague-Dawley rats were anesthetized with halothane and prepared with an i.t. catheter. One week later, baseline paw flick latencies (PFL) to thermal stimulation of each hindpaw were determined. Either vehicle, acetylsalicylic acid or a selective COX-2 inhibitor was then administered i.t. followed 10 min later by s.c. injection of 2 mg of λ-carrageenan (CARRA) in one hindpaw. PFL of both hindpaws was redetermined at fixed intervals over the next 4 hr. Pretreatment with 0.5-250 nmol SC-AA236, 5-50 nmol SC-AA125, or 50 nmol SC-AA984, but not 555 nmol acetylsalicyclic acid, significantly attenuated the ipsilateral decrease in PFL induced by CARRA. These data indicate that i.t. administered COX-2 inhibitors can prevent or delay the occurrence of CARRA-induced thermal hyperalgesia and provide support for the premise that PG release in the spinal cord contributes to thermal hyperalgesia. Supported by G.D. Searle.

DEVELOPMENT AND USE OF A BEHAVIORAL MODEL OF TMJ PAIN IN THE RAT. A.C. Hartwig, A.S. Law, M.O. Urban and G.F. Gebhart*. Dept. of Pharmacology, University of Iowa, Iowa City, IA, 52242 USA

Temporomandibular joint (TMJ) pain is a common but poorly understood phenomenon. While several animal models have been used to study nociception from the TMJ region, there are no behavioral models available. Therefore we have developed a behavioral measure of mustard oil-induced TMJ pain in the rat, and have tested morphine's effects on this model.

Mustard oil injection into the TMJ resulted in significantly more nociceptive behaviors (mean=170 behaviors, n=7) compared with mineral oil-injected rats (mean=45, n=5; $p<0.05$) during the period of observation. 2.5, 5 or 10mg/kg morphine administered prior to mustard oil injection dose-dependently reduced the number of nociceptive behaviors. However, 1mg/kg of morphine resulted in significant facilitation of the mustard oil-induced behaviors (mean=416, n=5; $p<0.05$). The facilitation was reversed by administration (systemic or i.c. injection into the trigeminal subnucleus caudalis) of the CCK receptor antagonist proglumide, but not vehicle.

This is the first report of a behavioral animal model of TMJ nociception. We have shown that preemptive administration of morphine has a biphasic effect on mustard oil-induced nociceptive behaviors, with the low dose facilitating, and the higher doses attenuating, these behaviors. It appears that CCK plays an important role in morphine facilitation in this model. Funded by NIH DA 02879 and DEO21801100.

CHANGES IN MASSETER MUSCLE EMG ACTIVITY AS PREDICTORS OF CHANGE IN LEVEL OF CHRONIC FACIAL PAIN. J. Buxbaum*, A. Eshenaur, N. Myslinski and F. Parente. Dept. of Oral Craniofacial and Biological Sciences, Univ. of Maryland Dental School, Baltimore, MD 21201.

The purpose of this study was to assess the stability of the surface EMG measure, and to assess the validity of the EMG model as a predictor of change in pain. Ten female controls and 12 females with chronic facial pain (FP) participated in the study. This double-blind study utilized a single subject-subject replication design. Treatment conditions included Lodine, Placebo and Rest (no treatment). Pre-treatment EMG was recorded bilaterally over the masseters during 4 modes of activity: clench, right and left chew, and rest. Subjects rated their level of pain on a visual analogue scale (VAS). The EMG and VAS were repeated 3 times. Subjects were then given 1 of 3 treatments. The EMG and VAS were repeated 3 times at both 30 and 60 minutes following treatment. Subjects completed 3 identical study sessions with the exception of different treatment conditions. Six Fourier analyzed EMG parameters were used for statistical analysis. Single case analysis of the VAS scores and the 6 parameters were assessed using ANOVA to determine which of the EMG parameters predicted change in VAS score. Results indicated that Power slope and SP50 intercept appeared to be the most stable and reproducible EMG parameters in the controls. Canonical analysis revealed a strong relationship between the EMG model and type of treatment condition (Rc = 54%). In FP subjects, band width slope consistently predicted change in VAS scores during clench and right chew. The EMG model was able to account for 66% of the variance in the pain measure. Findings suggest that certain EMG parameters may be reliable physiologic correlates of level of perceived chronic pain. Funding was provided by the Univ. of MD DRIF program.

712.20

CHANGES IN EMG ACTIVITY AS PREDICTORS OF CHANGE IN LEVEL OF CHRONIC LOW BACK PAIN. A. Eshenaur *, J. Buxbaum, N. Myslinski and F. Parente. Dept. of Oral Craniofacial and Biological Sciences, Univ. of Maryland Dental School, Baltimore, MD 21201.

The purpose of this study was threefold: to assess stability of surface EMG measures, to assess the validity of the EMG model as a predictor of change in perceived pain, and to determine whether pain changes could be detected from a site that differed from the pain source. Ten controls and 25 subjects with low back pain (LBP) participated in the study. This double-blind study utilized a single subject-subject replication design. Treatment conditions included Lodine, Placebo and Rest (no treatment). Pre-treatment EMG was recorded bilaterally over either the paraspinal muscles or the masseter muscles during several types of movement. Subjects rated their LBP on a visual analogue scale (VAS). The EMG and VAS were repeated 3 times. Subjects were then given 1 of 3 treatments. The EMG and VAS were repeated 3 times at both 30 and 60 minutes following treatment. Subjects completed 3 identical sessions with the exception of different treatments. Six Fourier analyzed EMG parameters were used for statistical analysis. Single case analysis of the VAS scores and the 6 parameters were assessed using ANOVA to determine which of the EMG parameters predicted change in VAS score. Results indicated that Power slope and SP50 intercept were stable and reproducible EMG parameters in controls. There was a strong relationship between the EMG model and type of treatment condition (R=53%). For paraspinal recordings, CF intercept and ZCD slope predicted change in LBP pain during some movements. For masseter recordings, CF intercept predicted change in LBP pain during all movements. The EMG model accounted for 63% of the variance in the pain measure. Funding provided by the Univ. of MD DRIF program.

RETINAL INTRACELLULAR SIGNALLING

MOLECULAR CLONING AND LOCALIZATION OF RHODOPSIN KINASE IN A MAMMALIAN PINEAL. X. Zhao,* J. Huang, R. N. Fariss, A. H. Milam and K. Palczewski. Depts of Ophthalmology & Pharmacology, University of Washington, Seattle WA 98195-6485.

In vertebrate retina, rhodopsin is phosphorylated by rhodopsin kinase (RK) in a light-dependent manner. This phosphorylation reaction is a critical step in the inactivation of the photolyzed receptor that prevents continuous activation of the phototransduction cascade; it is also a first step in the recycling of the receptor to its quiescent form. In addition to retina, RK activity was detected in the rat pineal gland. However, it was unknown if the same enzyme is expressed in both retina and pineal, and what the substrate of this kinase is in pineal. To investigate the RK activity in both tissues, a rat pineal cDNA library was screened with a bovine RK cDNA probe. The deduced amino acid sequence of the cloned kinase shows overall 84% homology and 92% homology in the catalytic region with bovine, RK. Using the PCR primers derived from this clone, we verified that it is identical to rat retinal RK. By immuno-double labeling on human pineal tissue sections, we found that RK and rhodopsin immunoreactivities are co-localized in many of the same pineal neurons. In order to determine if the pineal gland contains rhodopsin, we cloned rhodopsin from rat pineal cDNA by PCR. The PCR product was used to screen a rat pineal cDNA library. Two of the positive clones show highest homology with human blue cone opsin. Our results demonstrate that the mammalian pineal contains RK, rhodopsin, and blue cone opsin. *Supported by USPHS Grant EY08061 and Merck.*

713.2

EFFECTS OF KINASE INHIBITORS OR ACTIVATORS ON THE PHOSPHORYLATION OF AN ~20 kDa PROTEIN PRESENT IN THE MITOCHONDRIAL FRACTION OF THE RAT RETINA. **J. B. Lombardini.* Depts. of Pharmacology and Ophthalmology & Visual Sciences, Texas Tech Univ. Health Sciences Ctr., Lubbock, TX 79430.**

It is documented that all mammalian tissues contain high concentrations of taurine and that taurine is involved in many physiological actions in excitable tissues. However, the mechanism(s) of action at the molecular level for this amino sulfonic acid remains unknown. We previously reported [Biochem. Pharmacol. 46: 1445, (1993)]) that taurine inhibits the phosphorylation of a specific ~20 kDa protein present in a mitochondrial fraction of the rat retina. In this study we tested a number of different kinase affecters for their ability to either stimulate or inhibit the phosphorylation of the ~20 kDa protein. Kinase inhibitors (calphostin C, ISO-H7, H-7, staurosporine, and W-7) had only minimal activity at high concentrations. Surprisingly, chelerythrine chloride stimulated the phosphorylation of the ~20 kDa protein albeit at a very high concentration. Kinase activators (phosphatidylserine, calmodulin, cAMP, and cGMP) had no effect. Addition or deletion of Ca^{2+} to the incubation mixture had no effect. These data suggest that the kinase responsible for the phosphorylation of the ~20 kDa is not likely to be protein kinase C, protein kinase A, protein kinase G, or a calmodulin-dependent protein kinase. (Supported by a grant from the RGK Foundation of Austin, TX.)

G_o MIGHT MEDIATE THE mGluR6 LIGHT RESPONSE OF ON BIPOLAR CELLS. Noga Vardi* and Peter Sterling.
Department of Neuroscience, University of Pennsylvania, Philadelphia PA 19104-6058.

The depolarizing light response of ON bipolar cells is mediated by a metabotropic glutamate receptor (mGluR6) coupled to a G-protein mediated second messenger cascade. The specific G-protein involved is unknown, but G_o is a candidate because it is strongly expressed in the rod bipolar cell. We used an antibody specific for G_o (provided by D. Manning) to further explore its localization and report the following observations: **i)** in primate fovea, where only cone bipolar cells are present, strong staining for G_o in bipolar somas is present in the upper half of the inner nuclear layer, which is the known location of ON bipolar cells; **ii)** in cone pedicles (cat) the central element of the triad is stained, which is the known location of ON dendritic tips; **iii)** both confocal microscopy and EM show that G_o staining is confined to the dendritic terminals of rod bipolar and cone bipolar cells and absent from the axons. Thus, G_o is expressed by ON bipolar cells serving both rods and cones, and within those cells is confined to the dendritic terminals where mGluR6 is localized. This strengthens the hypothesis that G_o couples mGluR6 to its second messenger cascade.

ANALYSIS OF G-PROTEIN-MEDIATED MODULATION OF GAP-JUNCTIONAL INTERCELLLAR COMMUNICATION IN HORIZONTAL CELLS OF THE CARP RETINA. E.-I. Miyachi* and C. Nishikawa. Dept. of Physiol., Fujita Health Univ. Sch. of Med., Toyoake, Aichi 470-11, Japan.

In horizontal cells of the vertebrate retina, dopamine is speculated to activate G-protein and adenylate cyclase to increase cAMP, which blocks gap junctions between horizontal cells through the action of cAMP-dependent protein kinase. To activate G-protein, we injected GTPγS ionophoretically into luminosity-type (H1) horizontal cells of the carp retina. Injection of GTPγS blocked dye-coupling with Lucifer yellow CH. Dye-coupling among horizontal cells was not observed when the inhibitor peptide of cAMP-dependent protein kinase was injected together with GTPγS, indicating that activation of G-protein blocked gap junctions without activation of the cAMP pathway. At the previous Annual Meeting (1995), we reported that the uncoupling effect of cGMP and soluble guanylate cyclase activators, such as nitric oxide (NO), on the gap junctions is through the action of cGMP-dependent protein kinase. To inhibit both cAMP-dependent protein kinase and cGMP-dependent protein kinase, we injected A-3 (Funakoshi) into horizontal cells. Dye-coupling was not observed even when A-3 was injected together with GTPγS. However, dye-coupling was observed when heparin, a IP_3-receptor antagonist, was injected together with A-3 and GTPγS. These findings suggest that gap-junctional intercellular communication among horizontal cells is modulated by G-protein-mediated activation of the IP_3 receptor, in addition to activation of cGMP-dependent protein kinase and cAMP-dependent protein kinase. This work was supported by a Grant-in-Aid from the Ministry of Education , Science and Culture of Japan.

713.5

RETINAL LOCALIZATION OF A 42 KDA INOSITOL 1,3,4,5 TETRAKISPHOSPHATE RECEPTOR PROTEIN AND EXPRESSION AFTER OPTIC NERVE INJURY

G. Reiser*[1], T.M. Böckers[2], B.A. Sabel[3], R. Stricker[1], E. Hülser[1], and M.R. Kreutz[3]
Institut für [1]Neurobiochemie, [3]Medizinische Psychologie, Otto-von-Guericke Universität Magdeburg, Magdeburg, F.R.G. [2]Institut für Anatomie, Westfälische-Wilhelms Universität Münster, Münster, F.R.G.

The expression of an inositol 1,3,4,5-tetrakisphosphate receptor ($InsP_4R$) was investigated in rat retinal cryostat and paraffin sections by in-situ hybridization and immunocytochemistry. $InsP_4R$ mRNA was localized in the retinal ganglion cell layer, the inner nuclear cell layer and the outermost part of the outer nuclear cell layer. For immunocytochemistry an antibody raised against a 19-amino acid peptide obtained from our previous microsequencing of proteolytic fragments of the porcine $InsP_4R$ was used. We found a similar distribution of immunoreactivity in porcine and rat retina. Two cell types, most likely wide field amacrine and retinal ganglion cells, were intensely stained. Prominent immunoreactivity in the on/off sublaminae of the inner plexiform layer and in the optic nerve layer indicates a pre- and/or postsynaptic localization of the protein. Significant $InsP_4R$ expression in the inner segment of photoreceptors points to a putative role of the second messenger $InsP_4R$ in signaling processes related to phototransduction. However, also the endfeet of Müller glia cells in the optic nerve layer of porcine retina showed heavy labelling. Optic nerve crush caused only minor changes in retinal $InsP_4R$ mRNA levels whereas $InsP_4R$ immunoreactivity was attenuated for more than 4 weeks in the photoreceptor inner segments and wide field amacrine cells. Expression in surviving retinal ganglion cells was also reduced and the immunopositive sublaminae of the inner plexiform layer appeared to have shrunken. However, the signal intensity again gradually recovered after 10 weeks. We hypothesize that the $InsP_4R$ might be linked to altered intracellular Ca^{2+} signaling after neuronal injury. 713.6

CLONING AND EXPRESSION OF A RAT CDP-DIACYLGLYCEROL SYNTHASE (CDS) IN THE BRAIN AND RETINA.

S. Saito, K. Goto , H. Sakagami* and H. Kondo. Dept. of Anatomy, Tohoku Univ. Sch. of Med., Sendai 980, Japan.

CDP-diacylglycerol synthase (CDS ; EC 2.7.7.41) is involved in production from CTP and Phosphatidic acid (PA) of CDP-diacylglycerol (CDP-DG) which is used to further synthesize Phosphatidylinositol (PtdIns). Since Drosophila-CDS has recently been suggested to be a key regulator of phototransduction , we undertook to isolate a cDNA encoding mammalian CDS for clarifying the functional significance of the enzyme in mammalian retina and brain . The deduced amino acid sequence from our newly identified cDNA of rats showed a 56.3% homology with Drosophila-CDS . When the cDNA protein was transiently expressed in COS-7 cells , synthetic activity of CDP-DG was clearly detected . By Northern blot analysis a 3.5-kb hybridization band was detected distinctly in testis, eye and brain. By in situ hybridization histochemistory, the expression signals were detected intensely in cerebellar Purkinje cells and pineal gland, and moderately in the cerebral cortex, hippocampus and some thalamic and brain stem nuclei. In the retina, moderate expression signals were detected in the inner segment of photoreceptor cells.

713.7

EXPRESSION OF THE NORPA-ENCODED PHOSPHOLIPASE C-β SUBTYPE II IN THE VISUAL SYSTEM OF DROSOPHILA. S. Kim, D.-M. Chen[+], K. Miller, W.S. Stark[+], and R.D. Shortridge*,
Department of Biological Sciences, State University of New York, Buffalo, NY, 14260, and [+]Department of Biology, Saint Louis University, St. Louis, MO, 63103.

Mutations in the *norpA* gene of *Drosophila* abolish the photoreceptor response and render the fly blind by deleting phospholipase C, a pivotal enzyme in one of the largest classes of signaling pathways known. At least two splice-variant subtypes of phospholipase C are encoded by the *norpA* gene, one of which (subtype I) is expressed abundantly in retina, but not detectable in other tissues, and one that is expressed in a variety of tissues except retina (subtype II)(Kim et al., 1995, *JBC*, 270:14376). The net difference between *norpA* subtype I and subtype II is fourteen amino acid substitutions that are located in a region that is not highly conserved among members of the phospholipase C family of proteins. Transformation of *norpA* mutant with a minigene targeting *norpA* subtype I protein to retina is sufficient to rescue the photoreceptor response concomitant with rescuing the absence of phospholipase C activity observed in mutant (McKay et al., 1995, *JBC*, 270:13271).

The amino acid differences between the two splice-variant subtypes of *norpA* may be a reflection of the need for each subtype to interact with signaling components of different signal-generating pathways. To test this hypothesis, the *norpA* subtype II protein has been expressed in the retina of *norpA* mutant to see if it can substitute for subtype I protein and rescue the lack of photoreceptor response concomitant with rescuing phospholipase C activity. Results of this experiment will be presented.

LOCALIZATION OF CONVENTIONAL PROTEIN KINASE C MESSENGER RNAS IN THE ADULT RAT RETINA.

J. Kosaka*, E. Morii#, S. Nomura# and Y. Fukuda. Department of Physiology and #Department of Pathology, Osaka University Medical School, 2-2 Yamadaoka, Suita, Osaka 565, Japan.

Protein Kinase C (PKC) is known to form a large family with multiple subspecies that have subtle variations of their individual enzymological characteristics. The conventional PKC (α, β and γ) is a calcium ion-dependent protein kinase, and is playing important roles in the regulation of a variety of signal cascades through transmembrane signaling. In the vertebrate retina, anti-PKC antibody is used as a marker for rod bipolar cells. However, which subtype of PKC localizes in rod bipolar cells is still unknown. In the present study, we tried to detect mRNAs for PKC α, β and γ in the adult rat retina by *in situ* hybridization using digoxigenin-labeled isoenzyme-specific probes.

We detected PKCα mRNA in the cells located in the outer margin of the inner nuclear layer, which were strongly suggested as rod bipolar cells. PKCβ mRNA localized in the cells in the ganglion cell layer, some of these cells were suggested as retinal ganglion cells from their large soma size. No signals for PKCγ were detectable in all retinal region. The results demonstrate: (1) α isozyme that has no kinase activity enzymologically at the condition of 0 mM Ca^{2+}, is used in rod bipolar cells. (2) While β isozyme, that still works as PKC under the absence of Ca^{2+}, is transcribed in retinal ganglion cells. We can suggest that the signaling pathways mediating PKCα and PKCβ are modified by Ca^{2+} concentration on the process of signal transductions in both ON bipolar cells and the soma and/or the axon of retinal ganglion cells.

ELEVATING BATH CALCIUM DECREASES THE CALCIUM CONCENTRATION CHANGE INDUCED BY K^+ DEPOLARIZATIONS IN PHOTORECEPTOR INNER SEGMENTS. W. Baldridge, D. Kurenny, M. Wilkinson and S. Barnes*, Neuroscience Research Group, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Divalent cations alter membrane surface charge, affecting the gating of voltage-dependent ion channels. Divalent cations also interact with the permeation pathway of many channels, affecting conductance. We imaged changes in intracellular calcium ($[Ca]_i$) in rod and cone photoreceptors from tiger salamander retina with Fluo-3-AM during mild depolarizations induced by changes in bath K^+ from 1 to 10 or 20 mM. Application of 10 and 20 mM K+ in control solution (3 mM Ca^{2+}) produced increases in fluorescence ($\Delta F/F$) of 4% and 20%, respectively, in photoreceptor inner segments. In 10 mM Ca^{2+} much smaller increases in fluorescence were seen (<1% and 9%, respectively). No change in fluorescence was detected in the outer segments.

The optical assessment of $[Ca]_i$ was then tested in voltage-clamped photoreceptors using perforated patch techniques. No K^+ changes were necessary as membrane potential was strictly controlled, but other conditions were changed (95 mM Cs in the pipette, up to 30 mM TEA and 20 mM HEPES in the bath). We characterized Ca channel currents over a broader range of $[Ca^{2+}]_o$ (0.3, 1, 3 and 10 mM). Although Ca^{2+} conductance was increased 30% when increasing $[Ca^{2+}]_o$ from 3 to 10 mM, large gating shifts occurred. Relative to the control condition (3 mM Ca^{2+}), 10 mM Ca^{2+} shifted activation curves 8 mV positive, reducing channel open probability over a broad range of potentials. Thus, in the imaging experiments, a contest between gating and permeation was won by the elevated Ca^{2+}-induced decrease in channel open probability which proved stronger than the elevated Ca^{2+}-induced increase in conductance.

SODIUM/CALCIUM EXCHANGE IN CATFISH RETINA HORIZONTAL CELLS AND ITS ROLE IN THE REFILLING OF INTRACELLULAR CALCIUM STORES. M.A. Micci* and B.N. Christensen. Dept. Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77555.

Calcium plays a fundamental role in the regulation of intracellular signaling. Intracellular calcium levels are regulated by both the release of calcium from specialized intracellular storage sites and by extracellular calcium influx. Freshly dissociated catfish retinal horizontal cells (HC) are a useful tool to study intracellular calcium regulation as they express both calcium-permeable ionotropic glutamate receptors and voltage-gated L-type calcium channels as well as inositol 1,4,5-trisphosphate-sensitive and caffeine-sensitive intracellular calcium stores. We used confocal microscopy and the calcium sensitive dye fluo-3/AM to characterize the sodium/calcium exchanger in catfish retina HC and its role in the regulation of intracellular calcium. Calcium release from the caffeine-sensitive store was induced by pressure ejection of 10-20 mM caffeine from a nearby pipette. Free intracellular calcium levels and caffeine-induced calcium release were increased by ouabain, a sodium/potassium pump blocker. In addition, reduction of extracellular sodium further and reversibly increased cytoplasmic calcium and the caffeine response in ouabain treated HC. As both these effects were not abolished by the calcium channel blocker nifedipine, it is likely that increasing intracellular sodium by ouabain treatment promotes net extracellular calcium influx through a sodium/calcium exchanger.

We then studied the role of the sodium/calcium exchanger blocker, benzamil, on the caffeine-induced calcium release. Benzamil 500 μM completely abolished the caffeine response in dissociated HC. Caffeine-induced calcium release returned after washout of benzamil.

In conclusion, these results indicate that catfish retina HC express a plasmalemmal sodium/calcium exchanger that is required to refill the caffeine-sensitive intracellular calcium store. Supported by grant NEI-01897 from the NIH.

DIFFERENTIAL CALCIUM REGULATION IN ROD AND CONE INNER SEGMENTS

David Krizaj* and David R.Copenhagen: Depts Ophthalmology and Physiology, UCSF School of Medicine, San Francisco, CA 94143-0730

The fluxes of calcium ions are an important feature of photoreceptor signalling. Previous studies have shown that Ca^{++} ions enter the photoreceptor outer segment through photochannels and are extruded through Na^+/Ca^{++} exchange. This study addresses Ca^{++} regulation in the inner segment which has been much less well characterized.

Enzymatically isolated photoreceptors from tiger salamander retina were loaded with 5μM Fura-2 AM. Cells were depolarized by brief puffs or with long steps of elevated KCl and the changes in intracellular calcium $[Ca^{++}]_i$ were monitored ratiometrically using an intensified CCD camera. Basal levels of $[Ca^{++}]_i$ were 48± 4 nM in rods (n=26) and 32 ±3 nM in cones (n=23). In control saline 200ms puffs or 2-5 min steps of high K raised $[Ca^{++}]_i$ to a few hundred nM or a few μM, respectively. These increases were blocked in 0 Ca^{++}/EGTA saline and by nifedipine or cadmium, suggesting that calcium entry *via* voltage-dependent calcium channels generated a substantial component of the calcium increase. The recovery to baseline of puff-evoked $[Ca^{++}]_i$ increases was well fitted by single exponentials with time constants τ= 18.3 ± 0.9 s and τ=11.0 ± 0.6 s for rods and cones, respectively. Neither the time constant of return to baseline nor baseline $[Ca^{++}]$ were discernably affected by substitution of Na^+ for Li^+ or choline. During steps of KCl, $[Ca^{++}]_i$ remained sustained at an elevated level in rods. In contrast, $[Ca^{++}]_i$ elevations in cones were transient, declining to 36 ± 7 % of the peak in 3min. These results were interpreted as evidence that clearance of calcium loads is faster in cone than in rod inner segments.

In rods, but not in cones, caffeine (10mM) produced transient increases in $[Ca^{++}]_i$ (242 ± 54 nM), which decayed with τ = 41.8 ± 7.0 s, and were blocked by ryanodine. This result suggests that a ryanodine-sensitive intracellular pool contributes to calcium regulation in inner segments of rods but not cones. Acknowledgements: Supported by NIH

CALCINEURIN IS INVOLVED IN ARRESTIN DEPHOSPHORYLATION IN *LIMULUS* PHOTORECEPTORS. S.C. Edwards*[1], L. Kass[2], J. Pelletier[2], R. A. Caicedi[1],and D.Z. Ellis[3]. [1]Depts. of Pharmacol. and Biology and Inst. for Biomolecular. Sciences., Univ. of South Florida, Tampa, FL 33612, [2]Dept. of Zool., Univ. of Maine, Orono, ME 04473, [3]Neuropharmacol. Res. Lab. Harvard Medical School, Mass. Gen. Hosp. Charlestown, MA 02129.

There is evidence that a calcium-calmodulin(CaCAM)-dependent protein kinase type II and a protein phosphatase type 2A are directly responsible for light-dependent arrestin phosphorylation and dephosphorylation, respectively, in *Limulus* photoreceptors. But addition of exogenous, mammalian CaCAM-dependent protein phosphatase, calcineurin (CaN) markedly enhances arrestin dephosphorylation in tissue homogenates, although arrestin is a poor substrate for CaN. We now show that endogenous CaN activity in *Limulus* eye homogenates can be blocked by the immunosuppressant drug, FK 506 (Merck), but not its inactive analogue. FK 506 (Merck), but not its inactive analogue, enhances the level of incorporation of $^{32}PO_4$ into arrestin, in intact, light-, but dark-adapted ventral eyes. Like the CaN inhibitory peptide (Kass et al., 1995), FK506 produces "terraces" in the light-dependent currents and reduces the time of decay of the quantum bump. These results further support the involvement of CaN in the calcium-mediated events in photoexcitation and adaptation. (Supported by NIH EY07570, EY08765)

CALMODULIN-MEDIATED INHIBITION OF WHOLE CELL CURRENTS IN Sf9 CELLS EXPRESSING THE TRANSIENT RECEPTOR POTENTIAL-LIKE (Trpl) PROTEIN. Delanthi Salgado-Commissariat*, William G. Sinkins, William P. Schilling and Diana L. Kunze. Rammelkamp Center for Research, 2500 MetroHealth Drive. Cleveland, OH 44109-1998.

The Drosophila cation channel designated Trpl is thought to be important for phototransduction. Trpl has been cloned and successfully expressed in Sf9 cells. Electrophysiological studies on these Sf9 cells suggest that the *trpl* gene encodes a non-selective cation channel that is constitutively active. The patch clamp technique was utilized to record whole cell Trpl currents from Sf9 insect cells infected with recombinant baculovirus containing cDNA for Trpl. Initially, Trpl currents were 0.11±0.03 nA at 80 mV (n=11). Interestingly, the amplitude of this current increased with time approximately 10-fold to 1.21±0.10 nA at 80 mV. This time-dependent increase in Trpl currents was not observed when the nystatin perforated patch recording technique was applied to these cells (n=3). Therefore, this 'growing' phenomenon of Trpl currents maybe due to the wash out of a cytosolic factor(s). Trpl contains two calmodulin binding sites in the carboxy-terminal domain. To test the hypothesis that the cytosolic substance washed out during whole cell recording is calmodulin, exogenous calmodulin was included in the pipette solution. In the presence of calmodulin (500 nM), the time-dependent increase in Trpl current was only 3-fold (0.12±0.02 nA to 0.34±0.07 nA at 80 mV, n=7). Similar results were obtained when 250 nM calmoldulin was used. These effects of calmodulin were observed in the presence of 2.6 μM free calcium. However, when calmodulin (500 nM) was used in the presence of 150 nM or 10 μM free calcium, the time-dependent increase in Trpl currents was 5-fold its original amplitude. These results suggest that calmodulin inhibits Trpl current in a calcium-sensitive fashion and may explain the time-dependent increase in Trpl currents observed during whole cell recording.

RETINOIC ACID INCREASES ARRESTIN mRNA LEVELS IN THE MOUSE RETINA. E. Wagner, P. McCaffery, F. Farhangfar, M. L. Applebury and U. C. Dräger*, E. K. Shriver Center, Howe Laboratory and Harvard Medical School, Boston, MA, USA

Retinoids serve two main functions: retinoic acid (RA) associates with nuclear receptors and regulates gene expression, and 11-cis retinaldehyde, bound covalently to opsins, forms the visual chromophore. Light causes isomerization of 11-cis to all-trans retinaldehyde, which is released from rhodopsin for regeneration in the retinal pigment epithelium. Since the eye contains high levels of retinaldehyde dehydrogenases, some of the released all-trans retinaldehyde is likely to be intercepted by these enzymes and converted to RA. As such a process would provide a direct way for light to influence gene expression, we are testing whether RA, applied in darkness, can substitute for known effects of light that cannot be explained by light-evoked electric activity. Arrestin, which plays a role in the termination of the visual transduction cascade, is one of several photoreceptor proteins whose mRNA levels are increased by light. We show that RA, injected intraperitoneally into dark-adapted mice, increases the arrestin mRNA levels and mimics the effect of light. Injection of 1 μmol of RA produces a maximal increase in arrestin mRNA levels. The mRNA level reaches its maximum three hours following injection and declines thereafter. The observations suggest that RA mediates the increase in arrestin mRNA produced by light, and they raise the possibility that other known effects of light on mRNA levels of phototransduction proteins are similarly mediated by RA. ALDEHYDE DEHYDROGENASE-POSITIVE AMACRINE CELLS IN THE DORSAL RETINA. A.H. Milam,* D.E. Possin, J. Huang, R.N. Fariss, J.G. Flannery†, and J.C. Saari. U. of Washington, Seattle WA 98195-6485; †U. of California, Berkeley CA 94720.

Retinoic acid (RA) is abundant in retina but does not participate in the visual cycle. A binding protein for RA, cellular RA-binding protein (CRABP), is found in a subset of GABA(+) amacrine cells (ACs). A class 1 aldehyde dehydrogenase (ALDH) catalyzes oxidation of retinaldehyde to RA in bovine retina. A mAb against the ALDH was found to react strongly with a class of ACs that were restricted to the dorsal half of the retina. The ALDH(+) ACs had somata on both sides of the inner plexiform layer (IPL) and processes ramifying in two IPL strata. Double immunolabeling with antibodies against AC neurotransmitters and associated enzymes revealed that the ALDH(+) ACs in the adult retina were not immunolabeled with anti-CHAT, -somatostatin, -TH, -serotonin, or -substance P. Most ALDH(+) were (-) for GABA (~99%) and glycine (~95%). The ALDH(+) ACs were also (-) with anti-CRABP, which labeled a different subset of ACs. No ALDH-immunoreactivity was present in fetal bovine retinas from 2.7-5.5 months, but specific AC labeling was present at 5.6-7.8 months that closely resembled the pattern in adult retina. The ALDH(+) ACs appear to be novel, having a distribution restricted to the dorsal retina. This study provides additional evidence that cells of the inner retina are involved in retinoid metabolism.

IMMUNOREACTIVITY FOR CALCIUM-BINDING PROTEINS DEFINES CELL CLASSES IN THE CLAUSTRUM OF THE MONKEY. J. S. Baizer* and K. Reynhout. Department of Physiology, University at Buffalo, Buffalo, NY 14214.

The claustrum receives projections from multiple sensory and motor areas of cortex, and sends projections back to those areas. However, little is known about anatomicl organization within the claustrum itself. We have determined the distribution, density and morphological characteristics of cells in the claustrum immunoreactive for the calcium-binding proteins parvalbumin, calbindin and calretinin. We found four morphologically distinct populations of cells; each was distributed throughout the entire dorsoventral and anterior-posterior extent of the claustrum. The paravlbumin-ir cells were a single class. They had large (long axis = 19.6μ; s.d. = 4.8; short axis = 12.0μ; s.d. = 3.4; n = 86) darkly stained cell bodies, which often resembled cortical pyramidal cells in shape. Calretinin-ir cells were oval in shape (long axis = 12.8μ; s.d. = 2.8μ; short axis = 8.1μ; s.d. = 1.8μ; n = 29) with two processes emerging from the cell body on opposite sides. They were often seen in groups with cell bodies and processes parallel. Calbindin-ir cells fell in three distinctly different classes. The first class consisted of cells similar to the cells labeled by parvalbumin. The second class had oval, small, (long axis = 11.5μ; s.d. = 3.6μ; short axis = 8.3μ; s.d. = 2.3μ; n = 61) darkly staining cell bodies with fine processes which arborized close to the cell. The third class of cells were fusiform in shape, larger (long axis = 17.4μ, s.d. = 4.2μ; short axis = 7.8μ; s.d. = 1.8μ; n = 309), with two processes emerging from both ends of the long axis of the cell. The processes showed little branching and traversed relatively long distances. The results suggest that morphologically distinct neurons in the claustrum belong to different functional groups. SUBCORTICAL CONNECTIONS WITH THE DORSOMEDIAL VISUAL CORTICAL AREA (DM) IN PROSIMIAN, NEW WORLD, AND OLD WORLD PRIMATES. Pamela D. Beck* and Jon H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

The dorsomedial area (DM) is a proposed subdivision of visual cortex that appears to exist in all primates. In the present study, subcortical connections of the DM region were investigated in prosimian galagos, New World squirrel monkeys, and Old World macaque monkeys in an effort to obtain further evidence on the existence of the area across primate taxa. Injections of WGA-HRP and fluorescent tracers were placed in the DM region, and DM was later identified by myeloarchitecture. In all primates, the major thalamic connections of DM were with the inferior (PI) and lateral (PL) divisions of the pulvinar. In monkeys, most of the PI label was localized in the intermediate (Pli) and central (Plc) nuclei. In all primates, at least a few labeled neurons were found in the LGN, but many more were found in galagos. In all primates, WGA-HRP injections revealed projections to the superior colliculus. We conclude that the thalamic connections were similar enough to be from a homologous area, DM, in the three primates. The results also reveal a clear but species-variable direct contribution of the LGN to DM. (Supported by EYO2686 and MH10761).

714.3

ARCHITECTONIC SUBDIVISIONS OF THE INFERIOR PULVINAR IN NEW WORLD AND OLD WORLD MONKEYS
I. Stepniewska* and J.H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

The architecture of inferior pulvinar, PI, was examined in New World owl monkeys (*Aotus*), and squirrel monkeys (*Saimiri*) and Old World macaque monkeys (*Macaca*). Brain sections through the pulvinar were processed for cell bodies (Nissl stain), histochemically for cytochrome oxidase (CO) and acetylcholinesterase (AChE), and immunocytochemically for Cat-301 and calbindin (Cb). PI has four disctinct subdivisions or nuclei. The posterior (Plp), medial (Plm) and central (Plc) nuclei have been previously described. However, we found that the large Plc constituting most of the traditional inferior pulvinar, has two distinctive nuclei, a larger Plc "proper" nucleus and a smaller medial portion we distinguished as an intermediate nucleus (Pli), between Plc laterally and Plm medially. In coronal brain sections Pli stands out as CO and AChE light oval, between AChE and CO dark Plc and Plm. In addition, Pli is darker than Plc and Plm in Cb preparations. Finally, Cat-301 is densely expressed in Pli, but not in Plc or Plm of squirrel monkeys. Plp is distinct as a dark region in Cat-301, CO and AChE preparations. The four nuclei are also apparent, but less distinctive in fiber and Nissl preparations.

We conclude that the inferior pulvinar of both New and Old World monkeys have four subdivisions or nuclei with obvious differences in chemoarchitecture. These nuclei also appear to have different patterns of connections with visual cortex and the superior colliculus, and thus they have a different functional roles. Supported by NEI Grant EY- 02686.

THE CAT PULVINAR/LP COMPLEX: A CORTICOCORTICAL GATEWAY?
Bickford, M.E.*, Godwin, D.W. and Erisir, A. Dept. of Anatomy and Neurobiology, University of Louisville*, & Dept. of Neurobiology, SUNY at Stony Brook.

It has previously been reported that corticothalamic terminals in the pulvinar and lateral posterior (LP) nuclei of the cat originate from layer V cells in cortical areas 17 and 18, and both layer V and layer VI cells in extrastriate areas. These two cells types presumably account for two classes of cortical terminals in the pulvinar/LP complex: small (type I) terminals and large (type II) terminals. To examine the connections made by these two morphologically distinct terminals, we placed small injections of biocytin, which spanned layers I through VI, into cortical areas 17, 18, or 21 of 3 cats. We then examined the distribution of cells and terminals labeled by the retrograde and anterograde transport of biocytin. Following injections in areas 17 or 18, type I labeled corticothalamic terminals, known to originate from layer VI cortical cells, were distrubuted in the lateral geniculate nucleus (LGN) in a column that overlapped the distribution of labeled thalamocortical cells. In contrast, only patches of type II labeled terminals were found in the LP nucleus. This confirms the layer V origin of type II terminals. Following area 21 injections, both type I and type II terminals, as well as thalamocortical cells, were labeled in the pulvinar/LP complex. The distribution of labeled cells and type I terminals overlapped in the LP nucleus, while labeled type II terminals were distributed in isolated patches in the pulvinar nucleus. Thus, while layer VI corticothalamic terminals form *feedback* connections in the LGN and pulvinar/LP complex, it appears that layer V terminals form *feedforward* connections. Electron microscopic examination of labeled corticothalamic terminals in the pulvinar/LP complex revealed that type II terminals participate in complex synaptic arrangements similar to other primary thalamic inputs, e.g. retinal terminals in the LGN. Type I terminals on the other hand, contact small caliber dendritic shafts, similar to layer VI cortical connections in the LGN. Given the similarities in the synaptic organization of the pulvinar/LP complex and the LGN, we propose that cortical layer V connections define the response properties of pulvinar/LP cells, and that input from cortical layer VI, as well as brainstem inputs, are used to modulate or gate the flow of visual information between striate and extrastriate cortical areas. Supported by NINDS R29NS35377.

ULTRASTRUCTURE OF ChAT-IMMUNOREACTIVE TERMINALS OF THE LATERALIS MEDIALIS-SUPRAGENICULATE NUCLEAR COMPLEX (LM-SG) IN THE CAT'S THALAMUS: A DOUBLE LABELING IMMUNOHISTOCHEMICAL STUDY. K. Hoshino* T. P. Hicks[2] & M. Norita[1] Dept. Neurobiology & Anatomy, Niigata Univ. Sch. of Med., Niigata 951 JAPAN[1] and Institute for Biological Sciences, M-54 National Research Concil of Canada, Ottawa, Ont., Canada K1A 0R6[2]

The lateralis medialis-supragenicular nuclear complex (LM-Sg) contains neurons responsive to a variety of forms of physiological visual stimulation, and receives numerous inputs from the superior colliculus, brain stem and spinal cord as well as from certain area of extrastriate visual cortex, suggesting a relation to visuomotor function. In this study, the ultrastructure of ChAT-positive terminals in LM-Sg was examined using a double antigen immunohistochemical method to determine the type of transmitter-positive profile that is present, and retrograde transport of HRP was combined with immunohistochemistry to identify the transmitter of PPT-projection neurons to LM-Sg as well as LM-Sg-projection neurons to visual cortex. It has been confirmed that LM-Sg receives cholinergic inputs from the pedunculopontine tegmental nucleus (PPT) in the brainstem by retrograde HRP combined with ChAT-immunohistochemistry. ChAT-immunopositive terminals form asymmetrical synaptic contacts with glutamate-immunopositive dendrites of projection neurons and/or GABA-immunopositive dendrites of interneurons. These results suggest that cholinergic inputs may be important for modulating visuomotor information in both the extrinsic and intrinsic circuitries of LM-Sg. Supported by a Grant-in-Aid (06680731) from the Japanese Ministry of Education, Science and Culture (to MN) and NISSAN SCIENCE FOUNDATION (to MN) and NIH grant 1R15EY10156-01 (to TPH).

REDUCTIONS IN NAAG AND GAD_{67} IN THE RAT VISUAL SYSTEM AFTER OPTIC NERVE TRANSECTION, J.R. Moffett*Dept. of Biology, Georgetown University, Washington, DC 20057-1229.

The distributions of N-acetylaspartylglutamate (NAAG) and the large isoform of the GABA synthesizing enzyme, glutamic acid decarboxylase (GAD_{67}), were compared in the visual system of pigmented and non-pigmented rats. In retinorecipient zones, NAAG and GAD_{67} immunoreactivities were observed in distinct populations of neurons, and in dense networks of strongly immunoreactive fibers and synapses. Dual labeling immunohistochemistry indicated that principle retinorecipient neurons were stained for NAAG, while local interneurons were stained for GAD_{67}. Ten days after unilateral optic nerve transection, three responses were observed in contralateral retinal terminal zones. First, the number of NAAG immunoreactive fibers and synapses was dramatically reduced in both albino and pigmented rats in all retinorecipient areas. Second, in some denervated areas, such as the lateral geniculate, the level of GAD_{67} immunoreactivity was slightly reduced in interneurons. Third, in many denervated retinal targets, NAAG immunoreactivity was elevated in principle neurons. In addition to these direct and transynaptic changes in NAAG and GAD_{67} levels, the ipsilateral and contralateral divisions of the retinal projections were apparent in NAAG stained sections after unilateral optic nerve transection. For example, in the dorsal lateral geniculate nucleus contralateral to the cut nerve, most remaining NAAG immunoreactive synaptic terminals were confined to the core of the nucleus, while the core was synapse-poor in the ipsilateral geniculate. This arrangement of ipsilateral and contralateral retinal projections, demonstrated by NAAG immunohistochemistry, supports the presence of a rudimentary lamination in the rat lateral geniculate which conforms to the basic mammalian pattern for binocular vision. (Funded by The National Eye Institute: EY09085).

RETINAL AFFERENTS TERMINATE, AND RETINAL EFFERENTS ORIGINATE, IN THE SAME REGION OF THE DORSAL RAPHE NUCLEUS IN RATS. K. V. Fite, W. Foote, L. Bengston, and J. Cosentino, Neuroscience & Behavior Program, University of Massachusetts, Amherst, MA, 01003

Previous studies have provided evidence for a serotonergic centrifugal projection to the retina in rats originating from the dorsal raphe nucleus (DRN) (Villar, et al., 1987). More recently, a direct retinal projection to the DRN has been described in rats (Shen & Semba, 1994). In the present study, both anterograde and retrograde transport of cholera toxin (subunit B) conjugated to HRP (CTB-HRP) has shown that retinal axons terminate in an area of the DRN that also contains retrogradely labelled neurons projecting to the retina.

Intraocular injections of 4 µl of 0.2% CTB-HRP into the posterior chamber of anesthetized rats were folowed by a postinjection survival time of 5 days. Serial, coronal, 50 µm thick, frozen sections throughout the entire mesencephalon and caudal brainstem were reacted using the tetramethyl-benzadine HRP protocol. An extensive rostro-caudal region that included the rostral, central and caudal DRN contained anterogradely labelled retinal terminals. In addition, a diverse population of about 50 retrogradely labelled neurons occurred within a more restricted region, primarily in the lateral portions of the rostral DRN. A variety of cellular morphologies were observed with large, medium or small perikarya, ranging from 50-65 µm, 25-35 µm, or 10-18 µm in diameter, respectively. The retinal projection to the DRN is contralateral, while the centrifugal DRN projection is ipsilateral.

The functional signficance of this retino-DRN-retinal circuit remains unknown at present, although retinal sensitivity, circadian rhythmicity and arousal levels may be modulated via this loop. (Supported by a grant from the University of Massachusetts and Baystate Medical Center).

CONNECTIONS BETWEEN SUBCORTICAL VISUAL NUCLEI: ANTERO- AND RETROGRADE ANALYSIS. J Blanchard* and LP Morin. Dept. Psychiatry, HSC, Stony Brook Univ., NY 11794.

The circadian rhythm system is not isolated from the rest of the visual system. We have previously shown pervasive retinal projections to subcortical visual nuclei (Soc.Neurosci. '95, 21:654), including the intergeniculate leaflet (IGL) of the circadian system, and that the IGL projects to the pretectum (Vis.Neurosci. '95, 12:57). The present study more fully evaluates the interconnections between pretectal, tectal and certain thalamic visual nuclei of the adult male hamster.

Iontophoretic injections of the anterograde tracer, *Phaseolus vulgaris* leucoagglutinin, and the retrograde tracer, cholera toxin B fragment, were made into each of the following retinorecipient areas: thalamus--IGL, VLG, DLG, lateral posterior n.; pretectum--posterior limitans n., anterior n., n. optic tract, olivary n., posterior n., medial n., commissural n.; and tectum.

Patterns of innervation observed with anterograde tracing confirmed the patterns observed with retrograde methods. Most of the above nuclei are reciprocally connected by extensive, largely unilateral projections. The DLG and lateral posterior thalamic nuclei are exceptions which generally do not connect with the others. In contrast to the connections of most of the other nuclei, those of the IGL are bilateral.

Functionally, many of the nuclei are involved in oculomotor regulation or responsive to multiple sensory modalities. Their interconnectivity suggests that the IGL may also modulate oculomotor function or that, through its connection to the suprachiasmatic n. circadian clock, the IGL may serve as a final common path by which non-photic stimuli may modify circadian rhythm phase. Supported by NS22168 to LPM.

WHAT PROCESSING OCCURS IN THE INPUTS TO THE NUCLEUS OF THE OPTIC TRACT PRIOR TO MOTION DETECTION? M.R. Ibbotson* and R.F. Mark. Developmental Neurobiology, Research School of Biological Sciences, The Australian National University, Canberra, Australia.

This investigation examines the effects of signal pre-processing on the motion detecting system feeding into the nucleus of the optic tract (NOT) of the wallaby, *Macropus eugenii*. We recorded from the two classes of neurons in the NOT, those maximally sensitive to high image speeds (fast cells) and low image speeds (slow cells). The fast and slow cells were tested for their responses to apparent motion stimuli generated by presenting sequential brightness changes in two juxtaposed vertical stripes (28° high, 0.7° wide). Cells were also tested for their responses to stimulation of each stripe alone. The motion-dependent components of the responses were obtained by subtracting the responses obtained by independent stimulation of the stripes from those evoked by apparent motion. Slow cells elicited positive motion-dependent responses during a sequence of brightness increments in the preferred direction and negative responses during a sequence of brightness increments in the anti-preferred direction. No responses were elicited by brightness decrements showing that slow cells receive a half-wave rectified input from 'ON-type' neurons. In fast cells, sequences of both brightness increments and decrements led to positive motion-dependent responses for simulated motion in the preferred direction and negative responses for motion in the opposite direction. The motion-dependent responses were inverted in sign when the polarity of sequentially presented brightness changes in neighbouring stripes was different. The results suggest that the polarity of brightness changes are preserved at the processing step prior to motion detection. These results contradict theories suggesting that the input signals to the fast cells are full-wave rectified.

CYTOCHROME OXIDASE AND NADPH DIAPHORASE ACTIVITY IN THE NUCLEUS OF THE OPTIC TRACT, THE DORSAL TERMINAL NUCLEUS AND OTHER NUCLEI OF THE ACCESSORY OPTIC SYSTEM OF THE OPOSSUM. C.D.Vargas*, F.L.R. Bittencourt, A.O. Sousa, C.M. Santos, R.F. Bernardes, C.E. Rocha-Miranda and E. Volchan. Lab. of Neurobiology, Federal University of Rio de Janeiro, Rio de Janeiro, 21949-900, Brazil.

The pretectal nucleus of the optic tract (NOT) and the dorsal terminal (DTN), medial terminal (MTN), lateral terminal (LTN) and interstitial nucleus of the superior fascicle, posterior component (INFSp) of the accessory optic system (AOS) have been implicated in the generation of the optokinetic reflex in many mammalian species. To investigate the presence and distribution of the enzymes cytochrome oxidase (CO) and nicotinamide dinucleotide phosphate (NADPH) diaphorase in these nuclei, two adult opossums (*Didelphis marsupialis aurita)* were deeply anaesthetised and perfused with 4% paraformaldehide. Alternate coronal sections were histochemically reacted for CO and NADPH diaphorase (indirect method). The outlines of the nuclei under scrutinity as revealed by CO histochemistry (COH) coincided with those following histochemistry for NADPH diaphorase. The NADPH diaphorase labelling in the soma was faint, while CO-positive cells were usually strongly labelled. In the pretectum, the CO-positive cells were much more numerous than NADPH diaphorase cells. In the AOS nuclei, their number was about the same. A third animal, reacted for COH, had been previously injected in the region of the inferior olives (IO), with retrograde labelling of cells in the aforementioned nuclei. Analysis of alternate sections showed that the region occupied by CO labelled cells in the NOT-DTN superimposed with the one defined by the IO labelled cells. Comparison of the distribution of CO positive and IO labelled cells along the NOT-DTN extent showed that the number of the former exceeds that of the latter, the ratio being almost twice in the rostral half of the complex. These results indicate that the NOT-DTN and other AOS nuclei can be identified by these methods alone. The application of COH has, besides, revealed that these nuclei have a high metabolic activity.

THE LATERAL LINE OF THE SWORDTAIL, XIPHOPHORUS HELLERI: ITS NEUROPHYSIOLOGY AND NEUROANATOMY. V. N. Rush, E. Debski*, and H. Y. Yan. T. H. Morgan School of Biological Sciences. University of Kentucky, Lexington KY 40506.

The swordtail fish *Xiphophorus helleri*, is an excellent model system for examining the functional correlates between behavior and neurophysiology. Males display to females by rapid undulations of their bodies within two body lengths of the female, close enough for the lateral line to detect the particle motion. Female swordtails prefer males with larger bodies and longer extensions to their caudal fin (the sword). The male body movement reaches rates of 15 cycles per second based on video analysis (G. Rosenthal pers. comm.). Therefore both visual and mechanosensory stimuli may be important cues in how females choose males. This study examines response properties of the females lateral line for correlates to male mating behavior. Recordings were done from the cut lateral line nerve of 5 females. Wave particle stimuli were presented using a minishaker attached to a frequency generator and amplifier. Stimulus-response curves were determined for frequency stimuli between 10-150 hertz in 10 hertz increments and a tuning curve was calculated from the resultant data. Female swordtails respond best to frequencies between 30-80 hertz. These results indicate that the female lateral line is not tuned to the male mating display. We did tract tracing of the lateral line nerve using rhodamine dextran dyes to determine the brain centers involved in processing the lateral line stimuli. Preliminary results of neuroanatomical tracing indicate that one major brain center for integration of lateral line stimuli is the torus semicircularus. Support for this work was provided by NIMH training grant T32 MH19917-01A1 to V. N. Rush, US Geological Survey grant 14-08-001-G2021 to H. Y. Yan and CEEB grant to H. Y. Yan.

INTERPORE SPACINGS ON CANALS MAY DETERMINE DISTANCE RANGE OF LATERAL LINE SYSTEM. S. Coombs. Parmly Hearing Institute, Loyola University of Chicago.

In most teleost fish examined to date, there is a single sensory organ (neuromast) between every two lateral line canal pores. The response of any given neuromast to fluid motions inside the canal is proportional to the external pressure gradient across the two pores. Thus, the excitation pattern across neuromasts can be predicted by the pressure gradient pattern across pores, which, in turn, will depend on the spatial interval between pores. To determine how interpore spacing might vary, we measured the distance between consecutive pairs of pores on the trunk lateral line canal of 12 teleost species from six different orders. Mean interpore distances (IPD's) were computed for the trunk canal on one side of the fish for at least two individuals per species. Mean IPD's were strongly correlated with fish standard length (SL) both within and between species and varied from 0.8 mm for a blind cavefish (*Astyanax mexicanus*, SL = 40 mm) to 16 mm for an alligator gar (*Lepisosteus spatula*, SL = 1040 cm). Thus, mean trunk IPD's were nearly a constant fraction (between .01 and .02) of fish SL. To determine how lateral line excitation patterns might vary for different IPD's, we also modeled the pressure gradient patterns expected from a small (6 mm diam) 50 Hz dipole source. For a 2 mm IPD and source distances less than 80 mm, excitation patterns contained information about both source location and distance. At distances greater than 80 mm, the excitation pattern was relatively flat, meaning that this information was lost. For a 20 mm IPD, the excitation pattern did not flatten out until source distances greater than 160 mm. These results suggest that the distance range of the lateral line system depends on IPD and as such, depends ultimately on fish SL in widely divergent taxa. (Funded by grants from NIDCD and ONR).

FREQUENCY DISCRIMINATION LIMEN IN WATER WAVE SUPERPOSITION IN THE CLAWED FROG, XENOPUS. A. Elepfandt*, Inst. of Biol., Humboldt-Univ, D-10115 Berlin, Germany.

Xenopus can by means of its lateral-line system distinguish between water surface waves of different frequency. We have tested its limen of frequency discrimination when two waves are presented simultaneously so that they overlap at the frog. The frog was trained to discriminate between two monofrequent waves (3 s long with 1.5 s rise and fall times) of different frequency impinging simultaneously from 45° left and right, respectively. When this was learned the frequency difference was reduced stepwise until the limen was attained.

Except at 5 Hz, discrimination acuity was found to be better than in tests when only one wave had been presented (Elepfandt et al., J. Comp. Physiol. A 157:255,1985). Between 16-20 Hz, the relative discrimination limen was less than 4 %. This is a frequency difference below 0.6-0.8 Hz. The stimulus at the lateral-line organ under such conditions is a wave that beats with that frequency. The input from the individual organ does not enable the discrimination. Detection of the frequency difference between the component waves, therefore, requires the beat input from several lateral-line organs to be compared. Such comparison of wave beats is known in electric fish, where detection of beat frequencies of 1-2 Hz is demonstrated by the jamming avoidance response. Electroreception has evolved from the mechanoreceptive lateral-line system. It appears, thus, that the ability to detect component frequencies in a beat might be not specific for electroreception, but inherited from the ancestral mechanoreceptive lateral-line system.

A RESIDUAL END ORGAN RESPONSE PERSISTS FOLLOWING SEMICIRCULAR CANAL PLUGGING IN THE TOADFISH, *OPSANUS TAU*. R. D. Rabbitt*[1,4], R. Boyle[2,4], A. Yamauchi[1] and S. M. Highstein[3,4]. [1]Dept. Bioeng. Univ. Utah, Salt Lake City, UT; [2] Dept. of Otolar. and Physiol., OHSU, Portland, Oregon; [3]Dept. Otolar., Anat. and Neurobiol., Wash. Univ., St. Louis, MO; [4]Marine Biological Laboratory, Woods Hole, MA.

The horizontal semicircular canal of the toadfish was surgically plugged by compressing the membranous endolymphatic duct firmly against the cartilaginous bone using a 1.2 mm dia. glass rod. To insure that the manipulation did not damage the transduction apparatus, afferent responses to sinusoidal mechanical stimulation were continuously monitored during plugging. It was found that successful plugging must proceed slowly over a time. Occluding the canal at an average rate >3 µm/sec invariably damaged the system and eliminated afferent modulations. The lack of response in such cases was presumably due to cupula damage. Six canals were successfully plugged without apparent damage. Following plugging, individual afferents were tested for sensitivity to micromechanical indentation of the utricle (J. Neurophysiol. 73: 2237-60). All plugged canals showed a response to this stimulus. These data imply the existence of endolymph movement in the ampulla, which is consistent with the hypothesis that the labyrinthine wall distends in the region located between the cupula and the canal plug. To test this hypothesis we measured the distentional impedance of the labyrinth using micro-pressure measurement and mechanical stimuli. Impedance data show that flexibility of the labyrinthine wall is sufficient to account for the residual neural responses. To further study the influence of distensability, a morphologically descriptive model of the flexible-wall canal was developed, validated using the mechanical stimulation data, and subsequently applied to simulate head rotation. The model predicts a residual cupula deflection for plugged canals that is negligible below 0.01 Hz of angular head oscillation. In sharp contrast, plugged canals are predicted to have nearly the same gain as normal canals at frequencies above 10 Hz. The phase for the plugged canal leads the normal canal by ~90° at 0.1 Hz and by ~60° above 10 Hz. [sponsored by NIH NIDCD DC01837]

CORRELATION BETWEEN SACCULAR HAIR CELL ORIENTATION PATTERN AND DIRECTIONAL RESPONSE PROPERTIES OF SINGLE, SACCULAR AFFERENTS IN A TELEOST FISH. Z. Lu*, J. Song and A. N. Popper. Dept. of Zoology, Univ. of MD, College Park, MD 20742.

Mechanisms underlying sound localization by fish are not well understood. It has been hypothesized that fish determine the axis at which a sound wave is propagating by encoding acoustic particle motion at the auditory periphery (Dijkgraaf 1960, Proc. R. Soc. Lond B 152: 51-54; Fay 1984, Science, 225: 951-954). The present work examined the ear structure and investigated neural encoding of this acoustic particle motion in the sleeper goby (*Dormiator latifrons*). The focus was the correlation between ear structure and neural encoding.

The goby's saccular sensory epithelium lies perpendicular to the horizontal plane and about 30° to 40° off the sagittal plane. The saccular hair cell orientation pattern is similar to the standard pattern of the teleost fish (Popper and Fay 1993, Brain, Behav. and Evol., 41: 14-38). The orientation of the saccule predicts that most saccular afferents should have their best response axes in azimuth, about 30° to 40° off the fish's longitudinal axis.

A stimulus control apparatus, modified from Fay (1984), was used to provide linear accelerations to simulate underwater acoustic particle motion. Extracellular recordings were obtained from 70 single saccular afferents in response to these linear accelerations along six axes with 30 degrees separation in azimuth. Responses were plotted as a function of axis to determine the best response axes for individual saccular afferents. In general, single saccular afferents responded to the stimuli in a highly directional manner. Strikingly, we found that the distribution of best response axes of saccular afferents correlates with the orientation patterns of saccular hair cells. In azimuth, it appears that the saccule is mainly responsible for the detection of acoustic particle motion 30° to 40° off the fish's longitudinal axis.

SENSORY HAIR CELL ARRAYS IN LUNGFISH INNER EARS SUGGEST RETENTION OF THE PRIMITIVE PATTERNS FOR BONY FISHES. C. Platt* and A. N. Popper. Dept. Zoology, Univ. Maryland, College Park MD 20742.

Otolith organs in the inner ears of two lungfish genera contain sensory hair cells organized into regions of opposing directional orientations. Sensory tissues from African Protopterus and South American Lepidosiren were routinely fixed, dried, and examined by scanning electron microscopy. The mechanosensory ciliary bundle on individual hair cells seems large relative to those in many other fishes, but shows the usual asymmetric kinocilium at one side of the tuft of stereovilli, giving each cell a directional orientation. Hair cell orientations were mapped for each of the three otolith organs, the utricle, saccule and lagena. The dished utricular macula (epithelium) has most bundles oriented rostrolaterally outward in a fan-shaped array, except for a broad rostrolateral band where bundles are oriented inward from the macular edge; a curved line can be drawn to divide the two populations, and the opposing orientations are toward the line. The saccular macula is a long strip curving from the medial wall up the rostral wall of the large sacculo-lagenar pouch, and its hair cells are oriented away from a central longitudinal dividing line. The lagenar macula also lies on the medial wall of this pouch, more caudally, as a small vertical strip; it can be divided vertically into a rostral region where hair cells are oriented dorsally, and a caudal region where they are oriented ventrally, so orientations are antiparallel along the dividing line. Some bony fishes that are considered to retain many primitive characters share these features of ear morphology. These lungfish lagenar patterns, in particular, are like those of Polypterus (Popper A.N. 1978, J. Comp. Neurol. 18: 117-128) and the coelacanth Latimeria (Platt C, 1994, J. Morph. 220 :381), and are quite unlike lagenar orientation patterns reported for tetrapods. Comparisons with the remaining lungfish genus, the Australian Neoceratodus, will be useful to understand better the relationships of the ear between lobe-finned fishes, ray-finned fishes and tetrapods. DIFFERENCES IN CYTOCHROME OXIDASE IN HAIR CELLS OF THE UTRICLE: A COMPARATIVE STUDY. W. M. Saidel*, J. A. Crowder and T. V. Rivera. Dept. of Biology, Rutgers University, Camden, NJ 08102

The vestibular epithelia in vertebrates contain two classes of receptor cells. In mammals, the two types are strictly characterized by a vase-like or columnar cell shape. In teleost fish, two general classes of columnar-shaped hair cells have been distinguished by various morphological and physiological characteristics. Utricular epithelia of each were treated for cytochrome oxidase (CO) reactivity and examined at the light and electron microscopic levels. Mitochondria in hair cells of the striola were always more reactive than outside the striola. In the rat, CO staining of both types of hair cells appears to depend on the spatial position of the hair cell in the utricular epithelium. Reactivity in mitochondria appeared progressively reduced as a given type I or type II cell was located further from the striola.

CO-staining in mitochondria of teleost utricular hair cells differed. In particular, the so-called type I-like hair cells are only found in the striola of the epithelium. Mitochondria of these cells revealed intense CO reactivity. Type II hair cells expressed a difference in the reactivity within mitochondria located directly beneath the cuticular plate. Staining within these particular mitochondria was reduced or absent in the extrastriolar region, not just decreased as in the rat.

These results imply two conclusions: I) despite the difference in the inertial component of the utricle (the otoconia of mammals vs. the otolith of teleosts), the striola apparently defines an area of focused stimulation; and ii) the evidence of any phylogenetic relationship between striola hair cells of teleosts and type I striolar hair cells of mammals remains lacking.

EXTENDING THE AUDITORY DYNAMIC RANGE OF A BASILAR MEMBRANE SECTION BY POOLING FUNCTIONS DESCRIBING SINGLE UNITS.

L. Nizami* and B. A. Schneider. Psychology Dept., Erindale Campus, U. of Toronto, 3359 Mississauga Rd., Mississauga, Canada L5L 1C6

The cat's hearing range (≥ 100 dB) far exceeds the average dynamic range of 8th-nerve fibers (≤ 40 dB). A logistic function, with dynamic range, unit threshold, spontaneous rate, and saturation rate as explicit parameters fits well to individual rate-level curves; a double-logistic function well describes sloping-saturating units. Distributions for these parameters in a pool of units serving a restricted locus on the basilar membrane were derived from single unit measurements obtained by a variety of investigators. We investigated whether a simple summation over these logistic functions could extend dynamic range. First, the pool was split into three spontaneous rate (r_s) groups due to differences in parameter distributions. Intensity discrimination was computed using a signal detection model (W. S. Hellman and R. P. Hellman, J. Acoust. Soc. Am. 87, 1255-1265 [1990]) for a count period of 50 ms. For the critical band at 8 kHz (938 units), a single channel provides an effective dynamic range of 7-89 dB SPL where the upper and lower limits are those intensities at which the JND drops below 3 dB. Two independent channels (low r_s units, and all others) extend the upper range by only 3 dB. When more conservative estimates of the means and variances of the dynamic ranges in the high- and mid-r_s channels are used, the single channel range becomes 3-81 dB SPL, and employing two independent channels extends the upper limit to 92 dB. Treating sloping-saturating units as a separate upper channel does not increase this range. However, by splitting four channels into seven along unit-threshold criteria, and by combining channels optimally, the upper limit is extended to 101 dB SPL, which is only 3 dB less than a 938 channel ideal computer. For a wide dynamic range we need only a few channels even before considering olivocochlear feedback.

NITRIC OXIDE MODULATES AUDITORY EVOKED RESPONSES FROM THE GERBIL COCHLEA. M. D. McGinn* and K. R. Henry. Department of Otolaryngology and Department of Psychology, University of California, Davis, California 95616

Auditory evoked compound action potentials (CAPs) and auditory nerve responses (neurophonics) to f_2-f_1 difference tones (ANNs) were recorded from the round window niche of the gerbil cochlea. L-arginine (L-ARG), the precursor for the bio-synthesis of nitric oxide (NO) by nitric oxide synthase (NOS), and L-N^G-nitroarginine (L-NOARG), an NOS inhibitor, are both polar compounds permitting cochlear administration by diffusion through the round window membrane. When instilled into the round window niche, L-ARG (100 µM, 1 mM, 10 mM in artificial perilymph) enhanced amplitudes and reduced thresholds to both ANNs and CAPs. In contrast, the instillation of the same concentrations of L-NOARG into the round window niche reduced amplitudes and elevated thresholds to both ANNs and CAPs. Artificial perilymph alone, instilled into the round window niche as a control, had no effect on either ANNs or CAPs. These results suggest that NO acts within the cochlea to enhance auditory responses, perhaps to sharpen neural tuning.

HAIR CELL MORPHOMETRY IN THE BULLFROG AMPHIBIAN PAPILLA CORRELATES WITH TONOTOPY. C. Bertolotto*, D. D. Simmons, M. Pajouhi, and L. Tseng, Depts. of Physiological Science, Program in Neuroscience, and Brain Research Institute, UCLA, Los Angeles, CA 90095.

The amphibian papilla (AP) is one of two auditory endorgans in the bullfrog (*Rana catesbeianna*) inner ear. Intracellular dye-injection studies of afferent fibers demonstrate that the AP is tonotopically organized: nerve fibers innervating hair cells in the rostral region respond best to low frequency sounds while fibers innervating hair cells in caudal regions respond best to increasingly higher frequencies (Lewis et al. J. Comp. Physiol. 145:437-445, 1982). The purpose of this study was to investigate the morphological gradients found in hair cells in the bullfrog AP and compare this to its tonotopic map.

Serial sections of plastic embedded inner ear labyrinths were taken at 2 µm. The entire AP was reconstructed such that the caudal pole represents the 0% distance location and the rostral pole represents the 100% distance location. In the caudal third of the AP, the mean length of the hair cell body was 30 µm (±5 µm). In the middle third, the mean length was 44 µm (±15 µm). In the rostral third, the mean length was 51 µm (±15 µm). Plots of hair cell length and stereociliary bundle height versus AP location from caudal (0%) to rostral (100%) reveal steeply increasing measurements over the caudalmost 10% distance region, and then slightly decreasing to slightly increasing measurements from 10% to 60%. The tallest hair cells and the longest stereocilia were found between the 70% and 80% region. Hair cell length and stereociliary bundle height precipitously decreased between the 80% and 100% distance locations.

These morphometric data are strongly correlated with the tonotopic map of the bullfrog AP: hair cell length and stereociliary height are inversely related to the best excitatory frequencies of nerve fibers. Thus, the direction of hair cell gradients near the rostral pole predicts that there would be a deviation in strict tonotopy.

AUDITORY SYSTEMS: CENTRAL PHYSIOLOGY—HEARING LOSS

716.1

AN ANIMAL MODEL OF TINNITUS ASSOCIATED WITH SOUND-INDUCED HEARING LOSS. P.J. Jastreboff*, S. Hu, M.M. Jastreboff, and H. Song Dept. of Surgery, Univ. Maryland Sch. of Medicine, Baltimore, MD 21201.

In clinical practice the predominant type of the auditory phantom perception, tinnitus, is related to high frequency hearing loss. On the basis of our animal model of salicylate-evoked tinnitus, we have created a behavioral animal model for hearing-loss related tinnitus, which allows for evaluating, in individual rats, the extent of tinnitus induced by exposing animals to intense sound.

Rats were divided into groups: (1) exposed to high intensity pure tone of various parameters; (2) control with conductive hearing loss; (3) with salicylate administration. All rats were behaviorally evaluated for the presence of tinnitus, hearing threshold (frequency specific ABR), and the function of outer hair cells (otoacoustic emission distortion product measurements).

The paradigm detected tinnitus disregarding the extent of hearing loss, as conductive hearing loss did not induce behavioral manifestation of tinnitus, while creating hearing loss similar to that observed in animals subjected to tone overstimulation.

Salicylate treatment as a model for tinnitus investigated with the 2-deoxyglucose method.

E. Wallhäusser-Franke*, S. Braun, and G. Langner, Institute of Zoology, Technical University Darmstadt, 64287 Darmstadt, Germany

Salicylate is known to produce tinnitus in humans and animals. Therefore effects of salicylate on the auditory system of gerbils (Meriones unguiculatus) were investigated with the ^{14}C-2-deoxyglucose (2-DG) method.

On 4 consecutive days, gerbils received i.p. injections of either sodium salicylate dissolved in saline (n=6) or saline as a control (n=6). 2 hours after the last injection, the animals were injected with the radioactive 2-DG, transferred to a soundproof chamber and left there for 90 min. Then brains were removed, sectioned in the transverse (brainstem) or horizontal plane (cortex) and exposed to Kodak NMB-films. Autoradiographs were screened for 2-DG uptake. Salicylate treatment reduced activity in inferior colliculus (IC), especially in the high frequency part, whereas high activation along some isofrequency contours was observed in auditory cortex. In contrast, in saline controls IC was active but not the auditory cortex.

These results suggest that the sensation of subjective tinnitus may be generated within auditory brain structures. The 2-DG method may be used to objectively measure tinnitus in an animal and also to evaluate tinnitus treatments.

716.3

TIME COURSE OF SALICYLATE INDUCED CHANGES IN SPONTANEOUS NEAR-FIELD POTENTIALS OF SITES IN INFERIOR COLLICULUS OF GERBILS, R.W. Ward Tomlinson * and Gerald Langner, Zoological Institute, Technical University of Darmstadt, D-64287 Darmstadt, Germany.

Injestion of large doses of salicylates in humans almost always gives rise to a sensation of ringing in the ears, or tinnitus. Behavioral experiments provide evidence that the same phenomenon also exists in rodents. Mongolian gerbils were anesthetized with urethane, an opening made in the skull over the cerebellum, and placed in an electrically-shielded, sound-attenuated chamber. Near field potentials were measured at physiologically identified frequency regions in the inferior colliculus with low impedance platimun-iridium microelectrodes. Data was collected over a period of four to six hours and stored digitally on video tape. After recording baseline potentials for a period of one half to one hour, an injection of sodium salicylate (300 mg/kg) was made intraperitoneally and the animal left in quiet. Control experiments with injections of physiological saline were also carried out to proved a basis for comparison. After termination of the experiment, the electrodes were left in place and the tips anatomically localized. The recordings were analysed by performing a spectral analysis using Fourier transforms, and averaging over epochs of 1.5 minutes (256 spectra). These averaged spectra were calculated for the entire duration of the experiment. From these, difference spectra with respect to the initial state were computed, as well as their statistical significance. For a period 1.5 to 3 hours after salicylate injection, spectra of brain potentials taken from regions responding best to 7.5 kHz tones show increased energy above 1000 Hz, indicating an increase in spontaneous discharge of neurons in the region - a possible neuronal substrate for tinnitus.

716.4

AN ANIMAL MODEL OF TINNITUS THAT REFLECTS SOME OF THE QUALITATIVE FEATURES AND THE PERSISTENCE OF THE DISORDER. T.J. Brozoski*, M. Wyder, and C.A.Bauer. Dept. of Psychology, Grinnell College, Grinnell, IA 50112.

An attempt was made to develop an improved animal model of tinnitus ("ringing in the ears") that: (1) reflected the persistent chronic nature of the disorder; (2) captured the qualitative tonal characteristics of the *drug-induced* disorder; (3) demonstrated that subjects were not simply suffering from hearing loss. Tinnitus was drug induced, with the drug delivered in home-quarter drinking water: group 1 received quinine sulfate (0.8 mg/ml), group 2 sodium salicylate (4 mg/ml), and group 3 normal tap water. The 3 groups of 8 rats each were trained to lever press on a VI 20 schedule for food pellets, in the presence of low-level white noise (60 dB, SPL). Once fully trained, subjects were presented with 8 randomly scheduled 60 s warning stimuli (WS) in daily sessions. Half of the WS were silence and half were pure tones. WS tone frequencies were either 10, 12, 14, or 20 kHz (equal-loudness matched to 10 kHz @ 50 dB, SPL). In any given session, only one frequency, plus silence, was tested. Conditioned suppression was induced by terminating 25% of the WS with a mild (0.5 ma, 1 s) foot shock. Subjects displayed their perception of the WS by suppressing responding during the WS periods. Foot shocks were given only when subjects failed to meet suppression criterion level (suppression ratio ≤.2). The salicylate group suppressed more to the silence and 20 kHz WS, than controls, and more to the silence than to the tone. These results indicate that the salicylate subjects did not have altered auditory thresholds, because they suppressed better to 20 kHz WS than controls. Also by suppressing better than the controls to the silent WS, it is clear that the salicylate subjects were hearing something other than silence, presumably their tinnitus. Finally, because the salicylate group suppressed more strongly to 20 kHz than other WS tone frequencies, qualitatively their tinnitus was likely to be more like that tone than others. Support: Grinnell Coll. & Am. Tinnitus Assn.
