REDUCTIONS IN THE ACTIVITIES OF ANTIOXIDANT ENZYMES IN THE INFERIOR COLLICULUS WITH AGING. K.R. Gawai[1], R.H. Helfert[2,1]* and V. Ramkumar[1]. Depts. of Pharmacology[1] and Surgery[2], Southern Illinois University School of Medicine, Springfield, IL 62702.

The inferior colliculus (IC) is a major auditory processing center located in the midbrain. Previous studies have shown that neurons in the central nucleus of the IC undergo an age-related loss of dendrites, which is matched by a similar loss of presynaptic terminals. It is possible that the loss of synaptic terminals is linked to the dendritic loss. In this study, we determined age-related differences in the activity of antioxidant enzymes as an initial step to delineate the mechanism(s) underlying these phenomena. Spectrophotometric determination of the activities of superoxide dismutase (SOD) and glutathione peroxidase (GSH.Px) in the IC showed significant reductions with age. SOD activities in the 19 and 24 month age group declined to 54.2 ± 15.6% and 45.8 ± 8.7% of 3 month-old activity, respectively. The respective activities of glutathione peroxidase GSH.Px were 86.2 ± 18.4% and 59.2 ± 20.1% of the 3 month-old activity. The decline in activities of antioxidant enzymes were reflected by increased age-related lipid peroxidation, as measured by malondialdehyde (MDA) levels. MDA levels in the 18 and 24 month old animals were 158 ± 15% and 159 ±12% of 3 month-old level, respectively. These data provide evidence of increased oxidative stress in the IC accompanying the aging process. We speculate that increased oxidative stress might explain, at least in part, the deficit in the synaptic changes and the loss of GABA observed in the IC during aging.

CENTRAL PROCESSING IN A PATIENT WITH RESIDUAL HEARING CONTRALATERAL TO COCHLEAR PROSTHESIS

DM Daly* and FD Owens, Box 210855, Dallas, TX 75211; 3600 Gaston Ave. Ste 1103, Dallas, TX 75246

Because of locations and orientations of auditory cortex, studies of central processing in man typically exploit psychophysical phenomena or disease altered structure/functioning. Cochlear implants afford a view of central processing through sparse, specifiable peripheral transfer functions. We have used sets of computer synthesized sounds to characterized aspects of central auditory processing in an adult deaf in the left ear since birth and who had radiographically confirmed right acoustic neuroma. At time of initial testing the patient had a fully functioning 22 electrode device (Cochlear) in left cochlea; patient's right ear had fluctuating hearing loss (pure tone thresholds sloping from: -20dB 250 Hz, to -45dB 3,4,6,8 kHz). Patient described sounds through the processor/implant as 'having holes in them'. Patient distinguished 'being aware of' sounds in the left hemi-environment from 'hearing' sounds in the right hemi-environment; patient denied experiencing vertigo or detecting gross discontinuities as objects/sounds moved within a hemifield or across hemifield boundaries. Patient classified sets of synthetic vowels (ile) significantly more consistently when presented at right ear than directly through processor. With sounds at right ear patient classified brief time varying transients in GY and BW consistently ($p<0.001$ re composite of 65 normal hearing individuals) but was did not distinguish among higher rates of frequency changes in BDG. Through processor, patient distinguished GY and BW at extremes of the stimulus range, but did not distinguish - and was unaware of - direction of frequency change either when BW and GY sets were mixed or among BDG. Processor results are consistent with findings in a group of six bilaterally deaf patients with unilateral muiltichannel implants (Daly et al. *JASA* 86:1,S95 1989) and affirm the importance of including appropriate spectral information particularly in the representations of brief transients.

BEHAVIORAL CORRELATES OF HEARING-LOSS-INDUCED (HLI) PLASTICITY IN C57BL/6J MICE: INCREASED EFFECTIVENESS OF TONES IN PRODUCING FEAR-POTENTIATED STARTLE, J.F. Willott*, S. Carlson, W.A. Falls, J.G. Turner, and S.E. Webster. Dept. Psychol., Northern Illinois Univ., DeKalb, IL 60115.

C57BL/6J mice possess a gene that results in progressive, high-frequency hearing loss of cochlear origin between age 1 month (young adulthood) and 6 months. Earlier neurophysiological studies have shown that, in the inferior colliculus and auditory cortex, the loss of high frequency hearing (>20 kHz) is accompanied by enhanced neural responses to middle frequency tones (especially 12-16 kHz), referred to as hearing-loss induced (HLI) plasticity. In order to assess behavioral correlates of HLI plasticity, we used the fear-potentiated startle (FPS) paradigm: after a conditioned stimulus (CS) has been paired with electric shock, the acoustic startle response is potentiated in the presence of the CS. Because one or both auditory structures exhibiting HLI plasticity are probably in the neural circuit for FPS, we hypothesized that 12 kHz tones would become superior CSs in hearing-impaired C57 mice.

We used 12 kHz, 70 dB SPL tones as CSs in groups of C57 mice aged 1- or 6-months. Experimental groups (N=10) received CS+shock pairings during training for FPS; control groups (N=10) received unpaired tones and shocks. Experimental mice of both age groups exhibited statistically significant FPS, but FPS was significantly greater in the hearing-impaired, 6-month-olds. After conditioning, startle amplitude increased by 41% when the CS was present in 1-month-old experimental mice, and by 115% in 6-month-olds. Control mice exhibited no significant FPS for either age group (startle amplitudes with the CS present did not change significantly). Additional experiments indicate that these results are not due to a general improvement in conditioning ability in the older mice. For example, FPS was not better in 6-month-olds than in 1-month-olds when the CS was 4 kHz, a frequency which is less affected by HLI plasticity. The findings suggest that HLI plasticity can increase the behavioral salience of tones in fear conditioning.

EFFECTS OF ACOUSTIC STIMULATION ON THE BEHAVIORAL SALIENCE OF SOUNDS IN DBA/2J MICE WITH PROGRESSIVE HEARING LOSS, J.G. Turner* and J. F. Willott. Dept. Psychol., Northern Illinois Univ., DeKalb, IL 60115.

DBA/2J mice provide a unique animal model of adolescence-onset, progressive hearing loss. They possess genes that result in hearing loss of cochlear origin beginning during adolescence (age 3-4 weeks) and becoming severe by 5-months. Previous research from our laboratory evaluated developmental changes in behavioral responses to sound in DBA mice using the prepulse inhibition (PPI) paradigm: a moderately intense tone "prepulse" stimulus (S1) presented 100 msec before an intense startle-eliciting sound (S2) causes a reduction in the amplitude ("inhibition") of the startle response evoked by S2. The degree of PPI provides a measure of the behavioral salience of the S1. Our earlier research showed that by 2-months of age, S1s of 24 and 16 kHz had become less effective whereas the salience of 4, 8 and 12 kHz S1s remained stable or even improved. This study used PPI to determine how the salience of sounds is affected by moderately increased levels of acoustic stimulation as high frequency hearing loss progresses.

Mice were exposed to 10 consecutive 12-hr nights of broad-band noise bursts (70 dB SPL, 200 msec duration, 10 msec rise-fall, 2 Hz rate) during one of three age periods, 25-35, 35-45, or 45-55 days. Litter-mate controls were not exposed to the noise. PPI was measured before and after the 10 day period using S1s of 4, 8, 12, 16, and 24 KHz (70 dB SPL). Auditory brainstem response (ABR) thresholds were obtained for tone pips of the same frequencies.

For the 25-35 group, PPI was significantly **worse** after exposure than before exposure; by comparison, there was no change in the control mice. For experimental mice of the 35-45 and 45-55 groups, the results were reversed: PPI became significantly **better** after exposure. Noise exposure clearly affected the course of developmental change but the effects were dramatically influenced by age-related factors and/or severity of hearing loss during exposure. Changes in PPI and ABR thresholds were not related in a consistent manner, suggesting that acoustic exposure may have altered central mechanisms of PPI.

DEAFNESS-INDUCED CENTRAL AUDITORY SYSTEM PLASTICITY. S.C. Bledsoe, Jr.* Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109.

Mechanisms associated with central auditory system plasticity induced by cochlear ablation are not known. We reported that 21 days of bilateral deafness in adult guinea pigs and rats greatly reduced the number of neurons in the central nucleus of the inferior colliculus (CIC) which respond with suppression to contralateral electrical stimulation of cochlea. In vivo microdialysis also revealed a marked decrease in γ-aminobutyric acid (GABA) release from the CIC cells in deafened animals. Here, we report on data obtained from guinea pigs deafened for 1, 7, 14, 21, 28 and 90 days. All animals were bilaterally deafened by intracochlear injections of 10% neomycin. After a specified survival, they were anesthetized, a monopolar stimulating electrode implanted in the basal turn of the cochlea and single-units recorded in the CIC in response to 100 Hz sinusoidal electrical stimulation.

In a sample of 224 cells from normal animals, 42% were suppressed by contralateral electrical stimulation. However, after 21 days of deafness, only 5% of 242 units showed suppression. There was no significant difference in response threshold between the two groups but 21 day deaf animals had a significantly lower mean spontaneous discharge rate. The percentage of suppressed cells at 1, 7, 14, 28 and 90 days post deafening was 21%, 50%, 26%, 1.3% and 33%, respectively. This suggests that the decrease results from a time-dependent change in the central auditory neuraxis and that it is reversible. The results provide evidence for deafness-induced changes in inhibitory processes occurring in the adult central auditory system. They have important basic implications for our understanding of plasticity in the CNS, and clinical implications for the reintroduction of hearing in deaf patients with the cochlear prosthesis.

Rate-place representation of /ɛ/-like steady-state vowels in cat auditory nerve is lost after noise-induced hearing loss. R.L. Miller*, B.M. Calhoun, J. Yu, J. Wong and E.D. Young. Center for Hearing Sciences, The Johns Hopkins Sch. of Med., Baltimore, MD 21205.

The response properties of large populations of auditory nerve fibers were studied in cats with severe hearing loss to determine what deficits in the neural code for speech sounds might accompany acoustic trauma, other than loss of audibility. We used four forms of an /ɛ/-like steady-state vowel (F1= 0.5 kHz, F3= 2.5 kHz). The second formant was varied (F2= 1.4, 1.5, 1.7, 2.0 kHz) to allow investigation of discriminability of spectral shape. Conley and Keilson have previously shown a clear rate-place difference for vowels differing in F2 by only 0.1 kHz in normal-hearing cats (JASA **98,** 3223-34).

The rate-place representation of the difference between these vowels was lost subsequent to acoustic trauma in the F2 region (4 hour exposure to 108 dB SPL noise centered at 2 kHz, 0.05 kHz bandwidth, minimum 54 day recovery period). Three levels of amplification were tested (70, 90 and 110 dB SPL), but impaired fibers did not show a rate-place difference for vowels differing by even 0.6 kHz. Tuning curves for fibers in the F2 region were very broad and showed a nominal sensitivity loss of 45 dB at BF, indicating damage to OHCs. This broad tuning increased sensitivity to spectral features below BF and allowed F1 to dominate the response of fibers which normally encode F2 features. Responses to F2, the contrasting spectral cue, were only a fraction of that seen in the normal cochlea, making the damaged cochlea unable to encode the differences between the stimuli on the basis of firing rate.

A MODEL OF THE ENCODING OF SPEECH IN THE VENTRAL COCHLEAR NUCLEUS COMPARING NORMAL COCHLEAR FUNCTION TO COCHLEAR IMPLANTS. D. R. Kipke*, Bioengineering Program, Arizona State University, Tempe, AZ 85287-6006

Cochlear implants are effective in helping profoundly deaf people regain some degree of hearing. However, the neural mechanisms by which an implant provides acoustic information to the central auditory system are not well known. We are investigating the activation of neural networks in the auditory brainstem resulting from electrical stimulation of the deaf cochlea and comparing this to normal activation resulting from acoustic stimulation of an intact cochlea. The objective of the present study was to compare the encoding of selected speech segments by acoustic and electrical stimulation in the ventral cochlear nucleus (VCN).

A computational model of the implanted cochlea was developed to simulate auditory-nerve spike activity driven by electrical stimulation through a speech processor. In addition, a model of the intact cochlea was implemented to simulate normal auditory-nerve spike activity driven by acoustic stimuli. Each of these cochlear models were used to drive a separate network model of several hundred VCN bushy, octopus, and stellate cells. Simulations were ran to investigate how steady-state vowels and consonants were encoded by the VCN network model using both the intact and implanted cochlear models.

The effects of electrode site spacing, current spread, and stimulation rate were examined in terms of making VCN responses to the implanted cochlea closely match responses to the intact cochlea for the same speech stimuli. The effects of these implant parameters were found to be interdependent, and there was less variability in the VCN responses using the implanted cochlear model compared to the intact cochlear model. Ongoing investigations are looking at the effects of additional implant and network parameters on VCN network responses.

SPEECH RECOGNITION IN NOISE AND PRESBYCUSIS: Neural Bases, D.R. Frisina and R.D. Frisina*. Rochester Institute of Technology, Rochester, New York, 14623 and Otolaryngology Division, University of Rochester Medical Center, Rochester, New York, 14642-8692, USA

Previous speech recognition experiments with presbycusic subjects have suggested changes in the cochlea and central auditory pathways. This study is part of a multi-discipline effort to determine the role of the central auditory system in presbycusis. Linguistic materials with three degrees of difficulty were presented at supra-threshold levels to determine speech recognition in noise performance. Performance by three groups of old subjects with hearing loss (n=30) was compared to that of a group of old normal-hearers (n=10). The study sought to determine how three defined gross loci, of the auditory system and brain, might be implicated in speech recognition problems. Main findings: 1) peripheral auditory system pathologies contribute to heightened speech reception thresholds in quiet, and to reduced speech recognition performance in noise at supra-threshold levels; 2) cognitive function reflected in sentence context benefit, indicated that cortical portions of the central speech/language nervous system were not responsible for speech recognition dysfunction; 3) when reduced audibility was compensated for, speech recognition in noise dysfunction remained, thus indicating auditory brainstem and/or auditory cortical spectral resolution problems; and 4) results from previous studies comparing young and normal-hearers (such as the control group here) suggest that when audibility and cognitive functioning are not affected, speech recognition in noise dysfunction remains in old subjects, thus, implicating auditory brainstem or auditory cortex temporal-resolution dysfunction.

REFLEX INHIBITION BY PARTIALLY FILLED GAPS IN DEVELOPING AND AGED MICE: ONTOGENETIC CHANGES IN PROCESSING EFFICIENCY, NOT TEMPORAL ACUITY OR AUDIBILITY. J. Ison*, E. Gutierrez, P. Agrawal, J. Pak, & W. Vaughn. Brain & Cognitive Sciences, U. of Rochester, Rochester NY 14627.

A reduction in noise level (from 70 to 60, 50, 40 or 30 dB) just prior to an acoustic startle reflex elicited by a 115 dB noise burst inhibits the reflex to a degree determined by the S/N ratio of the gap and its duration. Inhibition was examined in mice (the CBA/Ca, C57Bl/6J, and their F1 cross) variously ranging in age from 1 month to 3 years. Baseline startle increased from 1 to 3 m. of age, then declined in the 6 m. old C57, and the 18 m. and 2 y. old CBA and F1. Asymptotic inhibition: 1) increased with S/N ratio and 2) with age from 3 w. to 3 m; but 3) decreased with hearing impairment (in the 6 m. C57) and with age (in the 18 m. and 2 y. CBA and F1) to levels below the youngest mice. The time course of inhibition did not vary with S/N ratio or age: Time constants approximated 3 ms. In addition, we show that asymptotic inhibition depended on the carrier level when the noise floor was at nominal zero, but not for a constant S/N ratio, save at high levels of 90 dB, when immediate facilitation from a depressed baseline was seen, rather than inhibition.

In their showing that gap detection is reduced with noise in the gap, increases in early development, and is diminished in the aged, our data agree with those found in humans. They are significant in showing that all effects derive from variation in the efficiency with which the gap is processed, and not from any variation in intrinsic temporal acuity or in the audibility of the signal carrier.

AGE-RELATED CHANGES IN THE NEURAL PROCESSING OF GAPS IN BACKGROUND NOISE IN THE CBA MOUSE INFERIOR COLLICULUS, J.P.. Walton, K. Barsz and G.J. Thomas*. Otolaryngology Div., Neurobiology & Anatomy Dept., U. Rochester Medical Ctr., Rochester. NY, 14642-8629, USA.

Perception of complex sounds requires analysis of rapid, ongoing fluctuations in frequency and intensity. A common complaint of elderly listeners is difficulty understanding speech in background noise. One of the reasons for this degradation is that temporal acuity is compromised due to smearing of the temporal waveform. Similarly, psychoacoustic gap detection thresholds increase when background noise is added to the carrier (Forrest and Green, JASA 82:6,1987). To further elucidate the neural mechanisms underlying age-related declines in temporal resolution we compared minimal gap thresholds (MGTs) in quiet and in background noise from inferior colliculus (IC) neurons measured in young (2-4 mon) and old (>24 mon) CBA mice. Neurons were characterized by their best frequency, rate/intensity functions, first spike latency and MGT obtained in various levels of background noise. "Gap series" typically consisted of gaps 0 (control) to 96 ms, presented at 65 dB SPL. MGT was quantified by comparing (Wilcoxon nonparametric test) spike counts in time windows around the gap. Neural gap coding was dependent on a unit's temporal discharge pattern. Recently, we have reported that roughly 50% of *phasic* neurons encountered in young animals show an unambiguous onset response to the gap, and the MGT is comparable to that for quiet. That is, they appear specialized for encoding gaps in adverse listening conditions. These specialized *phasic* neurons are encountered much less frequently in old animals. If these specialized neurons are important in coding rapid changes in sound amplitude in background noise, the decline observed in older animals may represent a fundamental age-related neurophysiological temporal processing deficit.

AGE-RELATED PLASTICITY IN INPUTS TO A FUNCTIONALLY-CHARACTERIZED REGION OF THE INFERIOR COLLICULUS OF THE CBA MOUSE MODEL OF PRESBYCUSIS. M.A. Lynch-Armour, R.D. Frisina, J.P. Walton and E.L. Lynd-Balta*. Otolaryngology Div., Univ. Rochester School of Medicine, Rochester, NY 14642-8629, USA.

Explorations of the neural basis of presbycusis have implicated changes in the inner ear and brain. We have discovered that the proportion of neurons capable of encoding short noise gaps (1-2 ms) in the dorsomedial inferior colliculus (IC) of old CBA mice declines relative to young adults, for both quiet and background noise conditions (Walton *et al., Companion Abstr.*). To start to ascertain why this occurs, injections of HRP were made following these recordings in dorsomedial IC in the 18-24 kHz region of CBA mice, 3 ages: Young adult, 2-4 mon (N=5); Mid age, 14-16 mon (N=4); Old, 22-27 mon (N=5). Retrogradely-labeled perikarya and anterogradely-labeled bouton endings were found in the brainstem. Analyses revealed: 1) The density of HRP in retrogradely-stained perikarya declined with age in some areas; 2) The number of labeled cells in nuclei such as the superior olivary complex (SOC), nuclei of the lateral lemniscus, and the contralateral IC remained stable with age. Statistically significant reductions in retrogradely-labeled cells occurred in all 3 contralateral cochlear nucleus (CN) divisions and in the ipsilateral anterolateral periolivary nucleus of SOC. Analyses of output regions are currently being performed. Declines in inputs from the CN and other areas may underlie physiological and perceptual degradations in temporal and speech processing that are characteristic of presbycusis.

CALBINDIN IMMUNOREACTIVITY IN THE DORSAL DIVISION OF THE MEDIAL GENICULATE BODY OF YOUNG AND OLD CBA AND C57 STRAINS OF MICE. S. Haider, M.L. Zettel*, W.E. O'Neill, and R.D.Frisina. Otolaryngology Div. and Dept. of Neurobiology and Anatomy, Univ. of Rochester Sch. of Medicine and Dentistry, Rochester, NY 14642, USA.

Previous studies by our group have shown a significant decrease (23-25%) in the number of Calbindin (CaBP)-positive cells in the commisural nucleus of the inferior colliculus of old CBA/CaJ and C57/Bl mice. We expanded our study to examine whether this central aging effect was also evident in the thalamus.

Following measurement of ABR audiograms and behavioral gap detection thresholds, the brains of young (3-9 mon.) and old (>24 mon) CBAs, and young (3 mon) and old (>26 mon) C57s were immunoreacted with a monoclonal antibody against calbindin (Sigma C-8666). The ABR audiograms of old CBA mice showed an average flat loss of 20 - 30 dB from 4 to 80 kHz, and gap detection thresholds lengthened, consistent with a loss of central inhibition involved in temporal processing. The old C57 mice were totally deaf, but had normal hearing when tested at 3 mon.,similar to young CBA's.

Many cells in the dorsal division of the MGB were densely CaBP+ and the darkly stained neuropil made this division easy to distinguish from the remaining regions of MGB. Each 300 x 300 µm grid (n=10) on a 30 µm-thick section yielded an average of about 200 CaBP+ cells. These cells appeared to be oval stellate cells with somatic diameters from 7 to 15 µm. Analysis of variance showed no significant change in the number of CaBP+ cells in the dorsal MGB in relation to strain or age.

While some regions of the central auditory system show a loss of CaBP+ cells with age, it is obvious from this study that it is not a system-wide loss. This may indicate that some regions such as the IC are effected by aging, or compensate more for age, than do others such as the dorsal division of MGB. *Supported by NIH-NIA Grant P01 AG09524 and the Intl. Center for Hearing and Speech Research, Rochester, NY*

OLFACTORY SYSTEMS: OLFACTORY RESPONSES

717.1

VOLATILE ODORS FROM INACCESSIBLE ESTROUS FEMALES ARE NECESSARY AND SUFFICIENT TO ACTIVATE A SPECIES-TYPICAL SEXUAL RESPONSE IN MALE RATS. B. D. Sachs.* Dept. of Psychology, U-20, Univ. of Connecticut, Storrs, CT 06269 U.S.A.

Male rats exhibit a rather stereotypic pattern of penile erection and grooming when exposed to inaccessible estrous females, but not when given free access to bedding soiled by estrous females or by copulating rats (Sachs et al., Physiol. Behav. 55:1073; 1994). Other modalities may participate in mediating these noncontact erections (NCE), but the ineffectiveness of soiled bedding did not preclude a role for olfaction. Sexually naïve males were tested with an estrous female upwind or downwind in a chamber that prevented direct contact between animals. Airflow was regulated by a quiet fan drawing ~0.68 m^3/min of air through the 0.33 m^3 chamber; barriers between animals were clear or opaque (C/O). 11/20 males displayed NCE with females upwind, vs. 1/20 males with females downwind (p=0.001). There was not a reliable C/O effect, and retesting after two copulatory experiences did not alter the pattern of results. Apparently (1) volatile odors from inaccessible estrous rats are necessary to evoke NCE from males, and (2) visual and auditory stimuli from estrous rats are not sufficient to evoke NCE. Half the males were later tested with opaque barriers and anesthetized females upwind; 6/10 males had NCE in response to estrous females, vs. 1/10 with anestrous females (p=0.02), indicating that volatile odors from estrous females are sufficient for NCE. This may be the first evidence for a volatile mammalian pheromone activating not just orientation and approach, but a sexual response with the characteristics of a fixed action pattern.

EFFECT OF MALE MOUSE PHEROMONES ON CYCLIC AMP ACCUMULATION IN FEMA LE MOUSE VOMERONASAL CELLS. A.-W. Zhou and R. L. Moss*. Department of Physiology, University of Texas Southwestern Medical Center, Dallas, TX 75235.

The signal transduction cascade in vomeronasal (VN) cells has been shown to involve G proteins that are known to inhibit adenylyl cyclase (Berghard and Buck, 1996; Halpern et al., 1995). Two chemosensory ligands, namely, dehydro-*exo*-brevicomin (DHB) and 2-(*sec* butyl)-4,5-dihydrothiazoline (SBT) have been extracted from male mouse urine and have been shown to modulate reproductive and social behaviors as well as to decrease the net membrane conductance in isolated VN neurons in the female mouse (Jemiolo et al., 1986; Novotny et al., 1985; Moss et al., 1996). The present study was designed to investigate whether the action of these chemosensory ligands (pheromones) at the level of VN cells involved the second messenger molecule cyclic adenylyl monophosphate (cAMP). *In vitro* cAMP accumulation assays were performed on VN tissue of female mice (n = 6~8) in presence and absence of the chemosensory ligands either individually or together. The results showed that the cAMP level in mice decreased significantly after stim ulation by the ligands: 25 ppm (1ppm = 6.5 µM) DHB or SBT treatment resulted in decreasing the cAMP content to 76.5± 12.2 or 55.7 ±7.0 percent of the basal level respectively. In addition, a combination of equal amounts of DHB and SBT initiated a drop in cAMP level to 53.6± 13.8%. If 0.5 mM IBMX , a potent inhibitor of phosphodiesterase (PDE) was included along with the ligands in the incubation media, the cAMP levels decreased to levels similar to those of the ligands alone. These results suggest both ligands can reduce the levels of cAMP in mouse VN cells and that this reduction is probably mediated through decreasing the activity of adenylyl cyclase and not through the inhibition of the PDE. We conclude that the cAMP second messenger system is involved in the signal transduction pathways in the mammalian VN receptor neurons. Research supported by NIH grant DC 02120.

CHEMOATTRACTANTS PRODUCE C-FOS EXPRESSION IN THE VOMERONASAL (VN) SYSTEM OF FEMALE MICE. J. Guo, C.A. Dudley*, and R.L. Moss. Depart. Physiology, UT Southwestern Medical Center, Dallas, TX 75234.

Cyclicity can be induced in crowded, non-cycling female mice by exposure to a male mouse or male-soiled bedding. A mixture of two substances extracted from male mouse urine, dehydro-*exo*-brevicomin (DHB) and 2-(*sec*-butyl)4,5 dihydrothiazoline (SBT), has also been demonstrated to induce cyclicity in crowded female mice (Jemiolo et al.,1986). The present experiments were designed to determine if male-soiled bedding and/or DHB and SBT could modulate cell activity in the VN system as measured by c-fos expression.

C57BL/6 females were housed 10/cage and vaginal cytology was monitored daily to insure that cyclicity was disrupted. In the first experiment, females were exposed to male-soiled bedding (n=7) or clean bedding (n=4) for two hours and tissues were processed immunocytochemically to detect the c-fos protein. Elevations in c-fos expression were found in the mitral and granule layers of the accessory olfactory bulb after exposure to male-soiled bedding. None of the other VN areas examined demonstrated clear elevations in c-fos.

In the second experiment, a more sensitive measurement of c-fos expression was obtained by performing Northern blot for c-fos mRNA. Non-cycling females (n=5 per group) were exposed to male-soiled bedding, clean bedding, a mixture of DHB and SBT (5 µl of a 5ppm solution placed on the oral nasal groove every 10 min), or distilled water (5 µl every 10 min. on the oral nasal groove) for 30 min. Northern blot analysis revealed that c-fos mRNA was highly elevated in the VN organ and slightly increased in the AOB after exposure to the mixture of DHB and SBT. Exposure to male-soiled bedding increased c-fos mRNA in the AOB and medial amygdala. Furthermore, the effects of male-soiled bedding were inhibited by removal of the VN organ. The results indicate that the female VN system is activated by specific substances found in male urine and that the non-cycling mouse is a useful model for the study of chemosensory influences on the VN system. Supported by MH 41784 and DC 02120.

NASAL MUCUS POTENTIATES THE ABILITY OF VOMERONASAL CHEMOSENSORY LIGANDS TO DECREASE NET MEMBRANE CONDUCTANCE. Robert L. Moss, Jiming Shi, Xin-ming Shen, and Gregory Goldmakher*. Department of Physiology, University of Texas Southwestern Medical Center, Dallas, Texas 75235-9040.

Recently it has been shown that mouse major urinary protein (MUP) selectivity binds dehydro-*exo*-brevicomin (DEB) and 2-(*sec*-butyl)4, 5 dihydrothiazoline (SBT). MUP is structurally similar to odorant binding protein (OPB III) which is expressed in nasal and vomeronasal (VN) glandular tissue suggesting that in addition to their clear functional and behavioral effects, DEB and SBT also have a possible means of obtaining access to the VN organ.

To test the hypothesis that the nasal mucus may facilitate the action of the chemosensory ligands on VN receptor neurons, cells from the VN organ were dissociated as previously described and whole-cell voltage clamp recordings were obtained. The chemosensory ligands, DEB and SBT and the mucus were puffed directly onto the dendritic knob of the VN neuron as was KCl and control bath solution. Mucus was collected from female mice by lavage of the nasal passages with a small volume of bath solution. Experiments conducted under steady-state current conditions at a holding potential of -70 mV with a leak subtraction, revealed that the ligands evoked an outward current while the application of KCl initiated an inward current and bath and mucus had no effect. However when the mucus was combined with either DEB or SBT, the amplitude of the evoked outward current increased by 50 %. Further studies under similar conditions indicated that the ligands decrease net membrane conductance and that this decrease was amplified in the presence of nasal mucus. It was further demonstrated that boiling the mucus eliminated the potentiation effects. Finally, experiments conducted under conditions with no leak subtraction revealed that DEB and SBT reduced inward current and that mucus potentiated this action. These findings support the notion that nasal mucus contains a protein that facilitates the binding of the ligands to receptor cells of the VN organ. Supported by NIH grant DC02120.

NESTIN EXPRESSION BY RAT VOMERONASAL ORGAN AND OLFACTORY EPITHELIUM TRANSPLANTS IN RAT BRAIN, J.C. Dennis and E. E. Morrison*. Department of Anatomy and Histology, Auburn University, AL 36849-5518.

The intermediate filament protein nestin is expressed by cells in the neuronal lineage prior to expression of other neural specific markers and is therefore a marker for neuronal precursors and possibly of stem cells. Nestin is expressed in early postnatal rat vomeronasal organ epithelium (VNO) but at very low levels or not at all in postnatal main olfactory epithelium (OFE). We examined nestin expression in VNO and OFE transplants (20-90 days survival time) using immunohistochemistry (rat-401, Developmental Studies Hybridoma Bank, University of Iowa). The tissue was fixed in Bouin's, paraffin embedded, serial sectioned at 7 microns, and mounted on glass slides. The antibody binds to cells in both transplant types but the distribution of signal differs between the two. Epithelial structures in VNO transplants display weak signal but no cells below the epithelium are nestin positive. Conversely, OFE transplants show no signal in sensory epithelium but have small numbers of strongly positive cells below the epithelium. These observations suggest that nestin expression in transplanted VNO epithelium continues for at least two months longer than expression in in situ epithelium. Also, expression of nestin by OFE transplant epithelial cells is either very low or nonexistent similar to in situ epithelium, however, OFE transplants do contain a small population of nestin positive cells located within the lamina propria.

THE ACCESSORY OLFACTORY SYSTEM DOES NOT MEDIATE PHEROMONE INDUCED FOS EXPRESSION IN THE MeP, BNSTpm AND MPNmag. J.M. Swann*, T. Bijak, J.M. Gabriel and A. Davis Department of Biological Sciences, Rutgers University, Newark, NJ. 07102.

In male Syrian hamsters exposure to female hamster vaginal secretions (FHVS) stimulates anogenital investigation and copulatory behavior. While detection of this pheromone is mediated by both the vomeronasal and olfactory systems the latter appears to play the greater role. Using fos as a marker for neuronal stimulation, we have shown that 1) exposure to FHVS induces an increase in the number of fos neurons in the posteromedial bed nucleus of the stria terminalis (BNSTpm), posterior medial nucleus of the amygdala (MeP) and the magnocellular medial preoptic nucleus (MPN mag) of gonadally intact male hamsters following exposure to FHVS, and that 2) this increase is mediated by the main olfactory system. The present experiment examines the role of the vomeronasal system in FHVS-induced fos expression. Male, Syrian hamsters were screened for sexual behavior and subjected to vomeronasal organ removal (VNOX), treated with zinc sulfate (which destroys receptors in the main olfactory system) and subjected to VNOX (ZN-VNOX) or left intact. Mating behavior was affected by the surgery - half of either treated group failed to mate after surgery while the majority of the intact males continued to mate. 24 hours after mating tests half of each group was given no stimulus while the other half was given FHVS - all were perfused one hour later. Brains were removed, sectioned and processed for c-fos immunocytochemistry. Exposure to FHVS increased fos expression above control levels in the MeP, BNSTpm and MPN mag in intact and VNOX hamsters but failed to induce these levels in ZN-VNOX males. Thus, vomeronasal organ does not mediate pheromonally induced fos expression in the MeP, BNSTpm and MPN mag of male hamsters. In addition, our results support the hypothesis that fos expression is not required for the expression of male mating behavior. Supported by NIH R29HD28467.

FOS EXPRESSION IN VOMERONASAL PROJECTIONS AFTER icv LHRH INJECTION IN MALE HAMSTER, M. Meredith* and K.A. Veillette. Neurosci. Prog., Florida State University, Tallahassee, FL 32306

Reproductive behavior impaired by vomeronasal organ removal (VNX), in inexperienced male hamsters can be substantially restored by intracerebroventricular (icv) LHRH injection. Vomeronasal pheromone stimulation, or mating with/without vomeronasal stimulation, induces characteristic patterns of *c-fos* expression in central vomeronasal projections, especially medial amygdala (anterior and posterior: MeA, MeP), and in caudal medial preoptic area (MPOA). We studied FOS-protein expression in these regions after icv LHRH injection (50 ng LHRH in 2 uL saline, or 2 uL saline) via cannulae inserted in guide tubes implanted 5 days earlier in the left lateral ventrical of intact- or VNX- inexperienced male hamsters. Males were placed with a receptive female and allowed to mate for 45 min or left alone for 45 min, then anesthetized and perfused after a further 45 min. Vibratome sections (50um) were reacted with anti-FOS antibody (Cambridge) and ABC (Vector). ANOVA analysis of FOS-labelled nuclei in the 3 areas shows an insignificant effect of LHRH injection on FOS expression in unstimulated males but an increased expression in LHRH injected, compared to saline injected, males that mated. Among control unstimulated animals, VNX males had lower FOS expression than intact males, especially in MeP. Among males that actually mated, intact and VNX males were not significantly different in FOS expression but there was a significant increase in expression in LHRH-compared with saline- injected animals.

OLFACTORY SEARCH BEHAVIOR OF RATS IN A WIND TUNNEL. C. Chee-Ruiter*, S. Wu, and J. M. Bower. Computation and Neural Systems Program, Division of Biology 216-76, Caltech, Pasadena, CA 91125

Localizing an odor source in a complex environment is a problem commonly faced by foraging animals. One difficulty posed by chemical cues is that they are inherently non-directional. Thus, olfactory-based searching must integrate multiple modes of sensory information (e.g., olfactory, visual, and/or mechanosensory), acquired via a single or possibly several search strategies. By controlling the physical and chemical parameters of an odor stimulus in a low-speed wind tunnel, it is possible to identify an animal's search strategies, to study what information a search strategy provides and how olfactory information is integrated with information from other sensory modes for the animal to successfully locate an odor source.

Rats were initially trained in a light-shielded T-maze to follow a commercially-available odorant (citral) to a sugar-water reward. Subsequently, olfactory search behavior was examined in a 4' X 10' wind tunnel in a darkened room. Animals followed a citral "plume" to one of three possible release sites, where they received a sugar-water reward. Non-odorized air and plain water were used as controls for the other sites. The behavior of the animals was videotaped using infrared cameras.

In the initial phase of training, the performance of the rats was found to be dependent on both odorant quality and concentration. In the wind tunnel, four search phases were identified, independent of how often an animal performed the task: (1) a possibly non-olfactory exploration phase, (2) an initial "detection" phase where the animal ran perpendicular to the airflow once, (3) a highly variable "localization" phase characterized by multiple perpendicular runs and high activity levels away from the edges of the tunnel, and (4) a "target approach" phase. Our results suggest that olfactory search is among a hierarchy of behaviors, and may itself consist of a stereotyped sequence of behaviors. Further, odor quality and concentration, wind speed and direction, and spatio-temporal patterns of the odor plume all appear to be important cues used by rats in odor localization tasks.

CHOLINERGIC MODULATION OF SYNAPTIC INHIBITION IN THE PIRIFORM CORTEX. M.M. Patil* and M.E. Hasselmo, Dept. Psychology Harvard University, Cambridge MA 02138

The modulatory effects of acetylcholine in cortical structures have been previously studied in this laboratory and by others, using both experimental and computational tools (Hasselmo & Bower, J. Neurophys, 67:1222). Cholinergic modulation in the piriform cortex shows laminar selectivity in suppression of excitatory synaptic transmission at the intrinsic but not afferent fibre synapses, and may set the dynamics for recall and storage of information. Present work addresses the effects of cholinergic modulation on inhibitory synaptic transmission, by using intracellular recordings from pyramidal neurons and stimulating afferent (Ia) and intrinsic (Ib) layers of the piriform cortex.

Perfusion of the slices with 50μM carbachol during intracellular recordings resulted in a decrease in the inhibitory potentials evoked from the intrinsic layer by about 82.1 ± 8.4% (n=21), but IPSPs evoked from the afferent layer remained relatively unchanged (decreased by 9.84 ± 5.34%, n=17). Putative miniature spontaneous IPSP activity (as observed by Pitler, & Alger, J. Physiol, 450:127) was recorded on slice exposure to carbachol (n=12). Carbachol exposure also decreased the firing threshold for orthodromic stimulation of layer 1a. Also, as has been previously documented, carbachol depolarized the membrane potential (by 12.7 ± 5.6 mV), increased input resistance, and decreased amplitude of the EPSP (by 54.2 ± 11.38%) evoked by stimulation of intrinsic layer, whereas the afferent EPSP decreased by 16.5 ± 7.45%. Currently the factors that may account for the decrease in the IPSPs are being investigated.

CAJAL-RETZIUS-LIKE CELLS IN ANTERIOR PIRIFORM CORTEX MEDIATE FAST FEEDFORWARD INHIBITION IN A LARGE AREA OF THE PIRIFORM CORTEX, ANTERIOR OLFACTORY NUCLEUS, AND OLFACTORY TUBERCLE. J.J. Ekstrand*, D.M.G. Johnson, S.L. Feig, and L.B. Haberly, Neurosci. Training Prog., MD-PhD Prog. and Dept. of Anatomy, Madison, WI 53706.

Previous anatomical studies in the opossum piriform cortex (PC) demonstrated distinctive large horizontal cells with thick dendrites in the afferent fiber zone (layer Ia) and long appendages on somata reminiscent of those on embryonic Cajal-Retzius cells (Haberly, JCN 213:163; Haberly & Feig, JCN 216:69). Like Cajal-Retzius cells in certain regions of neocortex (Imamoto et al, Neurosci Res 20: 101), these neurons stain with antisera to GABA and GAD (Haberly et al, JCN 266:269). A unique feature was that tritiated GABA was not taken up from the neuropil, suggesting a lack of the high affinity GABA uptake characteristic of other GABAergic cells in PC.

In the present studies in the rat, similar cells were observed in layer Ia, deep to the lateral olfactory tract (LOT) where they could be excited at brief latency by myelinated afferents. As in the opossum, somata were positive for GABA and GAD. Physiological studies with whole-cell patch pipettes in slices revealed fast, non-adaptive spiking as in most other GABAergic cells in layer I (Ekstrand & Haberly, Neurosci Abs 21:1186). Intracellular staining with Neurobiotin showed that dendrites arborize largely in layer Ia, but unlike the opossum, somatic appendages are absent. Tiny extracellular injections of biotinylated dextran amine *in vivo* revealed that axons are large in diameter (the largest yet observed in olfactory cortex) and project over long distances in the anterior PC , olfactory tubercle (OT), and anterior olfactory nucleus (AON). In anterior PC and AON, these axons give rise to distinctive, downwardly directed branches with clusters of large synaptic terminals in layers Ia and Ib. These appear to correspond to large synaptic terminals that are stained in this region with GABA and GAD antisera. In the lateral part of the OT axonal arbors are particularly exuberant--filling large regions with a profusion of synapses.

Based on anatomical and physiological indicators for GABAergic function; dendritic arbors that are largely confined to the afferent fiber layer, and large diameter axons, it is concluded that these cells mediate a fast feedforward inhibition. The apparent lack of high affinity uptake of GABA in the opossum suggests that this inhibition may have distinctive properties. Supported by NS19865 to LBH.

SUPPORT FOR THE KINDLING HYPOTHESIS IN MULTIPLE CHEMICAL SENSITIVITY SYNDROME (MCSS) INDUCTION. L.M. Kay*. Biophysics, UC Berkeley, Berkeley, CA 94720

Multiple Chemical Sensitivity Syndrome (MCSS) is characterized in the sufferer by progressive and generalized sensitivity to environmental toxins and can be precipitated by periodic low dose exposure, often following a single toxic exposure. It has been suggested that MCSS kindles in the limbic system similarly to experimental epilepsy. Others have observed 20 Hz oscillations in the olfactory bulb (OB) and dentate gyrus (DG) of rats upon exposure to toluene or a predator odor. In the present study, field potential recordings from the rat olfactory-limbic tract indicate that exposure to toluene causes seizure-like activity, consisting of narrow band, high amplitude oscillations in the 15-30 Hz range throughout the system, initiating in most cases in the prepyriform cortex. In one animal exposure was followed by epileptiform activity originating in the hippocampus and spreading to the olfactory areas. These phenomena were also seen to a lesser degree in response to mint odor, and not seen to any significant degree in response to non-trigeminal affecting odors, such as vanilla and orange, nor without an odor stimulus. Unit responses are presently being recorded from the OB simultaneously with the field potential throughout the olfactory-limbic tract during exposure to these odors and to formaldehyde. The presence of seizure-like activity in response to toxic stimuli supports the kindling hypothesis and examination of MCSS as a dynamical disease. DYNAMICS AND COHERENCE OF OSCILLATORY ACTIVITY IN CENTRAL OLFACTORY PATHWAYS IN RATS. N. Ravel, P. Chabaud, A.M. Mouly, D.A. Wilson[1] and R. Gervais*. Physiol. Neurosensorielle, UCB Lyon I, CNRS ERS 5643 and EP 100, Villeurbanne, 69622 France ; (1) Univ. Oklahoma, Norman , 73019 OK USA

In mammals, each central olfactory structure generates a prominent populational oscillatory activity. There are few descriptions of the dynamic range of different levels along olfactory pathways and how the different levels interact during odor presentation in awake animals. This question was addressed in rat by recording simultaneous activity in: the olfactory bulb (OB), the anterior and posterior part of the piriform cortex (APC, PPC) and the entorhinal cortex (EC) through chronically implanted monopolar electrodes. Oscillatory activities were recorded through local field potential (LFP) signals.

In absence of odor, Fast Fourier Transform analysis revealed a progressive reduction of the median of the spectrum from the OB to the EC. Odor-induced changes appeared as power changes within classically defined frequency bands (mainly α, β) and/or as a shift in frequency of the maximum of power within a band (mainly γ). Interestingly, for both resting and odor-induced activities, APC and PPC differed in many aspects. The analysis of coherence and phase of LFP signals suggests olfactory information processing is based on complex dynamic interactions rather than on a sequential activation within the network. Current experiments explore the effect of olfactory learning on these interactions.

MULTIPLE OLFACTORY ACTIVITY IN THE HUMAN NEOCORTEX IDENTIFIED BY MAGNETIC SOURCE IMAGING. B. Kettenmann*, H. Stefan and G. Kobal. Dept. of Experim. and Clin. Pharmacol. and Dept. of Neurol., Univ. of Erlangen-Nuremberg, 91054 Erlangen.

In this study we localized neuronal activity following olfactory stimulation by using magnetic source imaging. The evoked magnetic fields from ten healthy volunteers to the two odorants hydrogen sulfide and vanillin were recorded. The olfactory stimuli were delivered within a humidified and temperature controlled constant air flow to the nasal cavity without altering the thermal conditions at the mucosa. The stimulus sequence consisted of 200 ms pulses once every 40 s. Cortical responses were recorded with a 37 channel neuromagnetometer (Krenikon^R, Siemens) in a magnetically shielded chamber. Additionally, to compare timing between magnetic and electric responses, olfactory event-related potentials (OERPs) were recorded from the vertex (Cz/A1). The functional magnetoencephalographical information was combined with anatomical data from magnetic resonance imaging. The peak latencies of the olfactory event-related magnetic fields (OERMFs) corresponded to the ascending and descending slopes of the major electric deflections of the OERPs P1, N1 and P2. At these events we obtained consistent activation of parts of the insular cortex, the superior temporal plane and the superior temporal sulcus which is known for cognitive function. Our results show that cortical structures are activated bilaterally during the first 700 ms after stimulus onset and emphasize the role of the insula and temporal lobe structures in human olfactory function.

GPI ANCHORED PROTEINS IN PARAMECIUM CHEMORESPONSE. J. L. Van Houten*, C. Paquette, and A. Bush. Department of Biology, University of Vermont, Burlington, Vt 05405.

GPI anchored proteins are associated with transport and signal transduction. These proteins can be cleaved from the surface of cells by phospholipases. We present evidence that the very large surface glycoprotein of *P. tetraurelia* is a GPI-anchored protein, as it is in other *Paramecium* species. It can be cleaved from the cell surface, or removed with an ethanol wash. Along with the surface glycoprotein, there are other proteins of smaller molecular weight that can be harvested from the cells with the same procedures. The antisera made primarily against the surface glycoproteins A and B (kindly provided by J. Forney) recognize these smaller proteins in addition to the large surface glycoproteins on Western blots of PLC liberated proteins. We have suspected that some of the chemoreceptors of *Paramecium* are GPI anchored and thus it was possible that the antiserum contained antibodies against these receptors. Tests of mutant cells that lacked the A and B surface antigens (kindly provided by J. Forney) showed that antiserum treatment blocked chemoresponse behavior to folate, and glutamate, but not the responses to acetate and ammonium. It is interesting to consider that lipid domains with GPI anchored proteins are thought to have other transduction proteins, including the plasma membrane calcium pump, which we believe is part of the signal transduction pathway for folate, cAMP and glutamate.

GAP JUNCTION PROTEINS IN RAT VALLATE TASTE BUDS. J. Roach and S. D. Roper*. Department of Physiology and Biophysics, University of Miami School of Medicine, Miami, FL 33146

Synapses between cells in taste buds are believed to mediate lateral interactions. This suggests that "cross talk" or information processing occurs in taste buds prior to signals being transmitted to higher brain centers. There is strong evidence for electrical synapses between taste cells, as revealed by dye-coupling and by measurements of junctional resistance between electrically-coupled taste cells (Bigiani & Roper '93, '95). We have speculated that electrical coupling may play a role in acid (sour) taste transduction; the conductance of gap junctions is modulated by cytosolic acidification which may occur during acid taste (Bigiani & Roper '94). However, to date there have been few morphological correlates of electrical coupling, *i.e.* gap junctions, in taste buds. We have used immunocytochemistry to investigate whether gap junction proteins, connexins (Cx's), are found in rat taste buds. We report here that 2 members of the family of gap junction proteins, Cx26 and Cx32, are expressed in rat vallate taste buds. A 3rd member, Cx43, is expressed in surrounding, non-taste epithelial cells but is absent in taste buds. Immunostaining for Cx32 is particularly robust. The majority, if not all taste cells are immunoreactive for anti-Cx32 and anti-Cx26, and all taste buds in each section were equally immunostained. Curiously, unlike punctate immunostaining (*i.e.*, gap junctions) on plasma membranes of cells in control tissues (liver, salivary glands, epithelial cells), anti-Cx immunostaining in taste cells was cytosolic and uniform. Punctate immunostaining was not visible on the plasma membrane of taste cells. We speculate that the cytosolic anti-Cx immunostaining might imply that taste cells express connexins but only insert few into the membrane to form functional cell-cell junctions. This would be consistent with measurements of junctional resistance, at least in *Necturus* taste buds (Bigiani & Roper '95). Support: NIH PO1 DC00244

A SLICE PREPARATION FOR PATCH CLAMPING RAT VALLATE TASTE CELLS. E. Trepakova, N. Chaudhari*, and S. D. Roper. Dept. of Physiol. Biophysics, Univ. of Miami School of Medicine, Miami, FL 33146

Electrophysiological properties of mammalian taste cells have been studied with patch clamp recordings from isolated taste buds and taste cells. These studies have yielded important information about ion conductances and responses elicited by taste stimuli in gustatory receptor cells. In most cases, enzymatic treatment has been used to obtain taste buds and cells for recording. This raises the concern that taste cell properties might be compromised by the isolation procedures. Furthermore, synapses between taste cells might well be interrupted by isolating taste buds, and obviously are missing in single cell preparations. Thus, we have devised a new approach for patch recording from taste cells, using thin (100-150 μm) slices of rat lingual tissue that include the vallate papilla. This preparation avoids the use of enzymatic treatment of the tissue. Additionally, this preparation makes it possible to investigate synaptic interactions in relatively intact vallate taste buds. Data from the lingual slice preparation indicate that voltage-gated and resting membrane properties are well-preserved in the taste cells. Furthermore, voltage-gated K currents are significantly larger when compared with enzymatically-isolated preparations. For example, I(K) was > 2700 pA @60 mV in 27% of taste cells in the slice preparation, but was this large in only 5% of cells from enzymatically-isolated rat vallate taste buds. In most cells (61%) in the slice preparation, I(K) was 600-1300 pA @60 mV. In contrast, the majority (65%) of enzymatically-isolated taste buds had I(K) @60 mV = 300-600 pA. Serotonin affects I(Ca) and is believed to be a neuromodulator in amphibian taste buds (Nagai *et al*, *Chem. Senses* in press). Serotonin immunoreactivity also is found in rat taste buds (Kim & Roper '95). However, to date we have been unable to observe any responses to serotonin (≤ 100 μM) in isolated rat taste buds or in the rat vallate slice preparation. Supported by NIH RO1 DC00374.

INHIBITION OF INWARDLY RECTIFYING POTASSIUM CURRENTS BY G-PROTEIN ACTIVATION IN RAT TASTE RECEPTOR CELLS. M. Scott Herness*, Xiao-Dong Sun and Yushe Chen, Indiana University School of Medicine, Muncie, IND. 47306.

We have previously characterized inwardly rectifying potassium currents in dissociated rat taste receptor cells using the patch clamp recording technique in the whole-cell configuration. These currents appear to be ubiquitous in taste cells and have about half maximal conductance at the resting potential. In other cells these channels are often directly activated by G-proteins. We tested this hypothesis in taste cells by adding 500 μM GTPγs to the pipette solution (ICF). GTPγs resulted in a profound and irreversible inhibition of Kir; currents were inhibited up to 50% when recorded in 100 mM external KCl after a latent period of about 10 minutes. Control experiments without GTPγs showed no inhibition over the same time course (up to 40 minutes). To test whether this inhibition required second messenger, application of 50 μM or 100 μM 8-CPTcAMP, a cAMP analogue that can penetrate cell membrane, was tested. No effect on Kir was noted for this analogue. Application of 50 μM forskolin, which stimulates adenylate cyclase and inhibits outward potassium currents, was without effect on Kir. Moreover, application of extracellular saccharin (1mM) or norepinephrine (50 μM) were similarly without effect on Kir. GTPγs also inhibited outward potassium currents up to 80% with a similar time course to that of Kir inhibition. These results suggest G-protein may directly inhibit inwardly rectifying potassium currents without an intervention of second messenger. This inhibition would serve to depolarize the membrane potential.

VOLTAGE-GATED ION CURRENTS OCCURRED ONLY ON BASOLATERAL MEMBRANES IN MOUSE TASTE BUDS CELLS. H. Furue, K. Sugiyama* and K. Yoshii. Dept. of Biochemical Engineering And Science, Kyushu Inst. of Tech., Iizuka, 820 Japan, Dept. of Physiology, Kurume Univ. Sch. Med. Kurume, 830 Japan.

To investigate the localization of voltage-gated ion channels in mouse taste bud cells under voltage clamp conditions, we applied various ion channel blockers to either of the membranes of the taste bud cells in peeled tongue epithelium that prevented the leakage of blockers to the other. Taste bud cells elicited voltage-gated Na currents, several outward K currents, inward rectifier K currents, and L and T type Ca currents. Blockers such as 1 μM TTX, 10 mM TEA and 4-AP applied on the basolateral membranes blocked these voltage-gated currents. However, they were ineffective when applied on the receptor membranes. L and T type Ca currents were recorded only when the basolateral membranes was perfused with 105 mM $BaCl_2$. Voltage-gated ion channels play an important role in taste signal transduction and hence it is understandable that they are in basolateral membranes where ionic environments as are stable.

GLUTAMATE RECEPTORS MEDIATE SYNAPTIC RESPONSES IN THE PRIMARY GUSTATORY NUCLEUS IN GOLDFISH. C.A. Smeraski*[1], T.V. Dunwiddie[2], L.H. Diao[2], K.R. Magnusson[3] and T.E. Finger[1]. [1]Dept. of Cellular and Structural Biology, [2] Dept. of Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262, and [3]Dept. of Anatomy and Neurobiology, Colorado State University, Ft. Collins, CO 80523.

The vagal lobe of the goldfish is a laminated structure homologous to the gustatory part of the nucleus of the solitary tract in terms of receiving input from primary gustatory afferents of the vagus nerve (X). The in vitro slice preparation of this dorsal medullary structure permits pharmacological access to the gustatory nerve terminals in the CNS. We sought to characterize pharmacologically the neurotransmitters that may be involved in sensory processing, beginning with excitatory amino acids.

Electrical stimulation of small fascicles of the primary gustatory nerve produces two negative-going population responses from local regions in the sensory layers (within layers VI-VIII) of the vagal lobe. Absence of the responses following removal of $Ca^{++}$from the bathing medium indicates that these responses observed are due to synaptic currents. These responses were abolished or reduced at different times following application of a broad spectrum glutamate antagonist, kynurenic acid (final concentration=100 μM). Complete blockade of the responses was achieved by adding a combination of antagonists that block NMDA and non-NMDA receptors selectively (APV, 50 μM and DNQX, 10 μM). These results indicate that the synaptic responses in the vagal lobe are sensitive to both NMDA and non-NMDA antagonists, and therefore are likely to involve an excitatory amino acid neurotransmitter.

Autoradiographic studies showing the presence of AMPA, kainate, NMDA and metabotropic type 2 binding sites further support the involvement of excitatory amino acid neurotransmitters in this system.

MONOSODIUM GLUTAMATE AND GUANOSINE 5'-MONOPHOSPHATE RESPONSES IN RAT FUNGIFORM TASTE CELLS. W. LIN, AND S. C. KINNAMON*. Dept. of Anat. and Neurobiol., Colorado State Univ., Fort Collins, CO 80523 and The Rocky Mountain Taste and Smell Center, Denver, CO 80262.

Monosodium glutamate (MSG) and guanosine 5'-monophosphate (5'-GMP) are the main components for the unique umami taste. However, the mechanisms involved in the transduction of these compounds are largely unknown. We examined the responses of individual cells in isolated rat fungiform taste buds to MSG and 5'-GMP with patch-clamp recording. In whole cell voltage-clamp configuration (holding potential = -80 mV), bath application of 1 mM MSG induced three types of responses: a decrease in inward holding current; an increase in inward holding current; and a biphasic response, with an initial increase followed by a sustained decrease in holding current. 5'-GMP (0.1 mM) induced similar responses. Further, the responses to MSG and 5'-GMP may occur in the same or different cells: of the 60 cells tested with both MSG and 5'-GMP, 27 cells responded to both, 9 cells responded to MSG only, and 11 responded to 5'-GMP only. This suggests that different receptors may be involved in transducing MSG and 5'-GMP. Simultaneous bath application of MSG and 5'-GMP resulted in a synergistic response in some cells, an important property of umami taste. Recently, a glutamate receptor, mGluR4, has been shown to be specifically expressed in rat taste cells (Chaudhari, et al., J. Neuroscience, in press). Since activation of mGluR4 in brain decreases the intracellular cAMP level, we examined the effect of cAMP on these responses. Bath application of 8-bromo cAMP (2 mM) reduced the response to MSG in most cells tested. The synergistic response between MSG and 5'-GMP was also decreased by 8-bromo cAMP, suggesting that cAMP may be involved in the transduction of MSG and the synergism between MSG and 5'-GMP.

Supported by NIH grant DC01959.

CASCADE OF ADRENOCEPTOR, G-PROTEIN, AND cAMP INHIBITS OUTWARD POTASSIUM CURRENTS IN RAT TASTE RECEPTOR CELLS. Xiao-Dong Sun* and M. Scott Herness, Indiana University School of Medicine, Muncie, IND. 47306.

The whole-cell patch clamp technique was used to investigate the possible modulation of ionic currents by adrenoceptors, G-protein and cAMP on dissociated rat taste receptor cells. Two types of adrenoceptor agonists, norepinephrine (NE) and isoproterenol (ISP), were used to activate α- and β- receptors on the taste cell membrane. The results showed that both agonists at 50 μM significantly reduced outward potassium current, 50% for NE and 30% for ISP, and the development of the current inhibition was dependent upon the perfusion time. Propranolol, a nonspecific β-receptor blocker, at 2 μM diminished the inhibitory effect of ISP. To investigate possible involvement of G-protein in potassium current inhibition, GTPγs, 500 μM, was added to pipette solution (ICF). The amplitude of outward currents began to decrease time-dependently upon formation of the whole-cell recording mode and was reduced by 70% after 40 minutes. When cells were exposed to 50 μM or 100 μM 8-CPTcAMP, a cAMP analogue that can penetrate cell membrane, outward potassium currents decreased dramatically to 60% of control. None of these data were reversible with washout of the bathing solution. These results indicate that adrenoceptor stimulation in rat taste receptor cells, as in other cell types, may shut down potassium channels through elevating intracellular cAMP level.

SEROTONIN INHIBITS CALCIUM-ACTIVATED POTASSIUM CURRENTS IN RAT TASTE RECEPTOR CELLS. Yushe Chen*, Xiao-Dong Sun and M. Scott Herness, Indiana University School of Medicine, Muncie, IND. 47306.

The actions of serotonin (5-HT) were studied on dissociated rat taste receptor cells from foliate and circumvallate papillae using patch-clamp techniques in whole cell configuration. Potassium currents were measured as TEA sensitive outward currents elicited by depolarizing voltage steps from a holding potential of -70 mV to +40 mV. Bath application of 5-HT (20 - 1000 μM) reduced this current in 5 to 10 minutes by about 10 - 15% (n=8). However, if this same step were taken from a holding potential of -50 or -40 mV, which we have previously demonstrated to inactivate most of the delayed rectifier potassium current leaving the apamin-sensitive calcium-activated potassium current (K_{Ca}) enriched, bath application of 5HT now reduced the outward current by approximately 40 - 60% (n=10). To ensure that these results were not indirectly due to "run-down" of calcium currents, cells were recorded in the absence of 5-HT and tested for K_{Ca}. After control periods of 30 to 45 minutes, only small diminution of the current was observed. Subsequent application of 5-HT caused large inhibitions. 5-HT also resulted in a shift to the left in the inactivation curve of the potassium currents by approximately 5 mV. No measurable effects of 5-HT were noted on inwardly-rectifying potassium currents. These results suggest a previously unrecognized action of this neurotransmitter on a specific set of potassium channels in taste receptor cells.

MOLECULAR CLONING OF DELAYED RECTIFIER POTASSIUM CHANNEL EXPRESSED IN TASTE BUDS OF CHANNEL CATFISH. J. Kang, J. H. Teeter* and R. B. Puchalski. Monell Chemical Senses Center, Philadelphia, PA 19104

Taste responses to L-arginine in the channel catfish are mediated, in part, by direct gating of nonselective cation channels, resulting in taste cell depolarization (Caprio et al. 1993). However, in about 50% of the L-arginine-sensitive taste cells, L-arginine induces hyperpolarizing responses (Teeter et al. 1994; Miyamoto et al. 1995), consistent with the possibility that K^+ or Cl^- channels may be involved in the taste responses to L-arginine. To identify K^+ channels potentially involved in L-arginine-taste responses, we isolated several partial length cDNAs encoding delayed rectifier K^+ channels using PCR. Degenerate oligonucleotides corresponding to the highly conserved amino acid sequences of different subfamilies of the delayed rectifier K^+ channels were used to prime the PCR. The cDNA was synthesized by reverse transcription of total RNA isolated from catfish maxillary barbels and used as a template for PCR. PCR products of the predicted size of 800bp were subcloned. DNA sequence analysis reveals that one clone is 75-80% similar to one subfamily of delayed rectifier K^+ channels. Preliminary *in situ* hybridization analysis indicates that the clone is expressed specifically in the taste buds of the channel catfish.

GUSTATORY NEUROTOMY OF THE SEVENTH CRANIAL NERVE OR AMILORIDE ADULTERATION DISRUPT TASTE-GUIDED LICKING AVOIDANCE OF NaCl IN RATS. A. C. Spector*. Dept. of Psychology, Univ. of Florida, Gainesville, FL 32611.

Although transection of the chorda tympani nerve (CT) has pronounced effects on NaCl detection thresholds and on salt discrimination performance in rats, it does not affect unconditioned licking avoidance to hypertonic NaCl concentrations, nor does transection of the glossopharyngeal nerve (GL) or combined neurotomy of the two lingual taste nerves. The present study examined if removal of the collective gustatory input of the seventh cranial nerve would compromise licking of NaCl. Water-deprived rats were tested in a gustometer for their licking responses to repeated and randomly delivered 10 s trials of water and various concentrations of NaCl (.03, .1, .15, .3, 1.0 M) during 3 consecutive 40 min sessions before and after surgery. All groups monotonically decreased licking as a function of NaCl concentration both before and after surgery. Rats significantly (ps<.05) increased their licking to all NaCl concentrations above 0.03 M after combined bilateral transections of the greater superficial petrosal nerve (GSP) and the CT (n=7). Sham surgery (n=7) had no effect. An additional group that had the epithelial sodium channel blocker amiloride (100 μM) placed in all of the solutions after sham surgery, significantly increased licking to all NaCl concentrations except for 0.1 (p=.054) and 1.0 M (p=.49). In conclusion, narrowly tuned sodium-responsive gustatory afferents contribute to avoidance responses at low and mid-range NaCl concentrations. The more broadly tuned sodium-responsive units found in the CT, GSP, and GL also contribute to taste-guided NaCl avoidance behavior especially at high concentrations of the salt. The contributions of the superior laryngeal and lingual trigeminal nerves also cannot be dismissed.

In vivo EXTRACELLULAR AND INTRACELLULAR RECORDINGS FROM RAT GENICULATE GANGLION CELLS. S. I. Sollars[1]*, W. E. Renehan[2] and D. L. Hill[1]. [1]University of Virginia, Charlottesville, VA 22903 and [2]Henry Ford Hospital, Detroit, MI 48202.

The geniculate ganglion is the site of cell bodies for primary taste neurons innervating the anterior tongue (chorda tympani nerve) and the nasoincisor ducts and soft palate (greater superficial petrosal nerve). In order to characterize both physiological and neuroanatomical aspects of these neurons, we recently developed a technique to obtain extracellular and intracellular recordings from geniculate ganglion cells *in vivo*. Ganglia were surgically exposed through the ventral aspect of the bulla. This approach provided a high degree of ganglion tissue stability since the underlying petrosal bone remained intact. Glass micropipettes were advanced through the ganglia and taste stimuli applied to the tongue as search probes for taste responsive cells. Once extracellular taste responses of individual neurons to stimulation (NH_4Cl, NaCl, sodium acetate, HCl, sucrose and quinine) of the anterior tongue and/or the palatal taste receptor fields are attained, the electrodes can be advanced to record responses intracellularly and subsequently inject neuronal tracers. Taste response profiles of geniculate neurons appear similar to those determined through electrophysiology of single chorda tympani nerve fibers. Therefore, the present technique allows us to examine both the electrophysiological responses to tastes and the central neuroanatomical profiles of these primary taste afferents. In addition, this approach allows us to attain previously unexamined single-neuron responses and morphologies of the greater superficial petrosal nerve.

RELATIONSHIPS OF CELL-SURFACE MARKERS TO GUSTDUCIN EXPRESSION IN TASTE BUD CELLS. D.W. Pumplin, C. Yu*, J.D. Boughter, Jr. and D.V. Smith. Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, MD 21201-1509.

To define further the molecular phenotypes of taste-bud cells, we compared the distributions of several surface carbohydrates with that of gustducin, a G-protein implicated in the transduction of responses to sweet- and bitter-tasting substances. Previous studies have shown that the human blood group antigens A, B, H and $Lewis^b$, which are differentiation antigens in mammalian epithelia, are differentially expressed in rat taste-bud cells. The A and $Lewis^b$ antigens are expressed on small subsets of taste cells, whereas the H and B antigens are more widely distributed. We prepared cryostat sections from several taste-bud regions of rats fixed by perfusion with formaldehyde. Sections were double labeled for indirect immunofluorescence with monoclonal antibodies to the A and $Lewis^b$ carbohydrate moieties and a polyclonal antibody to gustducin, then examined by confocal microscopy. Gustducin and the $Lewis^b$ and A blood group antigens were present only on spindle-shaped cells whose apical processes reached the taste pore. Basal cells and surrounding epithelial cells did not express these markers. A subset of gustducin-positive cells expressed the $Lewis^b$ antigen, but all $Lewis^b$-positive cells expressed gustducin. The fraction of $Lewis^b$-positive cells was lower in taste buds of the geschmäcksstreiffe than in those of vallate papilla or the nasoincisor duct. In the vallate papilla, some cells expressed both gustducin and the A antigen, whereas others expressed only one of these markers.

Supported by NIDCD Program Project Grant DC00347.

MORE TASTE-BUD CELLS EXPRESS GUSTDUCIN IN AREAS SENSITIVE TO SWEET- AND BITTER-TASTING SUBSTANCES. J. D. Boughter, Jr., D. W. Pumplin, C. Yu and D. V. Smith*. Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, MD 21201-1509.

Gustducin is a taste-cell specific G-protein similar to rod transducin and has been implicated as a component in the transduction of responses to bitter- and sweet-tasting substances. To gain further insight into the function of gustducin, we examined the distribution of cells expressing gustducin in taste buds from different regions of the rat's oral cavity. We prepared cryostat sections from several taste-bud regions, and stained them for indirect immunofluorescence with an anti-gustducin antibody. Nuclei were stained with propidium iodide for cell counting. In all regions, gustducin was evenly distributed in the cytoplasm of spindle-shaped taste-bud cells whose apical processes extended to the taste pore. In vallate papilla, only light cells (Type II) have this characteristic shape. Taste buds in fungiform papillae, a region primarily sensitive to salt and acid stimuli, contained relatively few cells expressing gustducin (1.8 ± 0.9 / bud; n = 11). Taste buds in the vallate papilla, a region relatively sensitive to bitter- and sweet-tasting stimuli, contained many cells expressing gustducin (10.3 ± 2.9 / bud; n = 41). Taste buds found within the geschmäcksstreiffe or lining the nasoincisor duct, areas especially responsive to sweet-tasting stimuli, also contained many cells expressing gustducin (8.7 ± 2.6; n = 10 and 11.6 ± 4.6; n = 14, respectively). The distribution of taste-bud cells expressing gustducin is consistent with its proposed role in the transduction of responses to both sweet- and bitter-tasting substances.

TONIC GABA INHIBITION OF TASTE-EVOKED RESPONSES IN THE NUCLEUS OF THE SOLITARY TRACT. C.-S. Li* and D.V. Smith. Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, MD 21201-1509.

The rostral portion of the nucleus of the solitary tract (NST) receives gustatory afferent fibers from the VIIth, IXth and Xth nerves. Neurons in this area form an obligatory relay in the afferent processing of gustatory information. Immunohistochemical studies have shown that cells in both caudal and rostral portions of the NST contain γ-aminobutyric acid (GABA) or its principal degradative enzymes, suggesting the possibility of a GABAergic network within the gustatory region of the NST. Previous *in vitro* studies in both hamsters and rats have demonstrated that GABA inhibits many cells within the gustatory region of the NST, where there appears to be a tonic GABAergic inhibitory network. Although *in vitro* studies provide valuable information about the biophysical properties of NST neurons, it is not possible to determine their gustatory properties. In the present study we investigated the mechanisms of tonic inhibition on taste-evoked responses in the NST *in vivo*. A three-barrel glass pipette assembly was used to apply bicuculline methiodide (BICM) into the vicinity of an NST cell and to record single-unit activity in response to gustatory stimulation. The taste stimuli were 0.1 M sucrose, 0.1 M quinine hydrochloride, 0.1 M NaCl and 0.01 M citric acid, presented to the anterior tongue before and after application of BICM into the NST. BICM (2 and 10 mM) increased taste-evoked responses in a dose-dependent fashion, although there was no effect with 0.2 mM BICM. Responses to all classes of tastants appear to be under GABAergic modulation. Additional studies will investigate sources of this control.

TASTE-RESPONSIVE NEURONS IN THE NUCLEUS OF THE SOLITARY TRACT OF THE HAMSTER ARE EXCITED BY SUBSTANCE P. B. J. Davis* and D. V. Smith. Dept. Anatomy, Univ. Maryland Sch. Medicine, Baltimore, MD 21201-1509.

The rostral gustatory portion of the nucleus of the solitary tract (NST) in the hamster contains substance P (SP) immunoreactive neurons and also receives extrinsic SP immunoreactive afferent inputs. *In vitro* slice studies indicate that SP excites about 70% of the cells in the gustatory portion of the NST in both rats and hamsters. Although *in vitro* studies provide valuable information about the biophysical properties of NST neurons, it is not possible to determine their gustatory properties. Here we assessed the influence of SP on taste-responsive neurons in the rostral NST *in vivo*. A micropipette containing SP (0.5-1.0 mM) was glued to the shaft of a tungsten microelectrode about 125 μm from the recording tip. Taste stimuli (0.032M NaCl, 0.1M sucrose, 0.01M quinine-HCl, 0.0032M citric acid) were flowed over the anterior tongue to characterize the baseline response profiles of single gustatory neurons. About 30 nl of SP was then delivered by pressure injection and the battery of stimuli was repeated after 1, 10, 20 and 30 min. SP increased the spontaneous activity of NST neurons and their responses to gustatory stimulation. There was no generalized excitation, i.e., the effect of SP was specific to the stimuli that normally excite the cell. Both spontaneous activity and the specific enhancement returned to baseline in about 30 min. These studies demonstrate that SP has a selective excitatory effect on the response profiles of taste neurons *in vivo*. Further studies will examine whether SP preferentially excites different classes of gustatory neurons.

CLASSIFICATION OF GABAERGIC TERMINALS IN rNST USING POSTEMBEDMENT IMMUNOHISTOCHEMISTRY. N. L. Leonard, B. Wetherton, C. Hearn, W. E. Renehan and L. Schweitzer* Dept. of Anat. Sci. and Neurobiol., Univ. of Louisville Sch. of Med., Louisville, KY 40292 and Div. of Gastroent., Henry Ford Hosp. Detroit, MI 48202

In order to provide a framework for analyzing the distribution of synapses onto physiologically-characterized cells we characterized 152 terminals in the rostral nucleus solitarius (rNST) from two rats and grouped them using cluster analysis. The analysis defined six terminal types characterized by the presence or absence of dense core vesicles, the density of vesicles (vesicles per sq. μm) and vesicular area. Form factor (shape) of the vesicles and the size of the synaptic apposition were not significant determiners of terminal type. Following this analysis, postembedment immunohistochemical techniques with colloidal gold were used to investigate GABAergic terminals. Fifty six GABAergic terminals were photographed throughout the rNST of the four rats and were then classified according to the criteria that proved useful in the cluster analysis. Forty-two of these terminals (75%) fit into criteria that defined "group 5", confirming the validity of the cluster analysis for defining terminal types. This group is defined by having few dense core vesicles, average vesicular size and low density of vesicles. These terminals did not fit terminal types previously used to classify terminals in the nucleus -- 53% were type MP, 25% were type SP and 22% were primary-like. Most (82%) of the GABAergic terminals synapsed with dendrites, the remaining synapsed with profiles containing vesicles resembling primary-like terminals and thus likely provide a presynaptic inhibitory action onto these terminals. NIH Grant RO1 DC01074-05.

INDUCTION OF C-FLI IN THE NTS AND PBN AFTER THE EXPRESSION OF A CONDITIONED TASTE AVERSION. C.L. Wyvell and K.C. Berridge*. Department of Biopsychology, University of Michigan, Ann Arbor, MI 48109.

We assessed c-Fos like immunoreactivty (c-FLI) in the nucleus of the solitary tract (NTS) and the parabrachial nucleus (PBN) after the expression of a conditioned taste aversion. Previous investigators have reported increased levels of c-FLI in the intermediate NTS after the expression of a conditioned taste aversion (Swank and Bernstein, 1994; Houpt et al., 1994). One group has also described distinctive patterns of c-FLI in the PBN (Yamamoto et al., 1994). Male Sprague Dawley rats were trained to develop a discriminative conditioned aversion to one sweet solution (15% fructose or 15% maltose) by associative pairings of that solution with LiCl administration (the other solution was paired with NaCl). Levels of c-FLI were then compared between animals that received the aversively conditioned taste (CS+) on the test day to animals that received the safe taste (CS-). The animals given the CS+ had significantly more c-FLI in the intermediate and caudal NTS. Significantly higher levels of c-FLI were also found within a specific region of the PBN, located in the medial quadrant of the dorsal PBN (immediately distal to the medial tip of the brachium conjectivum). Overall c-FLI was much lower in the PBN, however, than in the NTS. These data represent the first quantitative demonstration of increased c-FLI in the medial dorsal PBN after the acquisition of a conditioned taste aversion.

FOS EXPRESSION IN THE INSULAR CORTEX TO CONDITIONED AN UNCONDITIONED TASTE STIMULI. P. A. Bryant* and I. S. McGregc Dept. Psychology, University of Sydney, NSW, 2006, Australia.

The insular cortex (IC) receives gustatory inputs from thalamic and brainstem nucl and electrophysiological studies suggest that taste and visceral stimuli activat neurons in this cortical area. The present series of experiments examined fos-lik immunoreactivity (FLI) in the IC to tastes that have different unconditioned propertie and tastes which have acquired conditioned properties by a pairing with lithiur Chloride (LiCl).

In an initial experiment, rats were assigned to one of six conditions where they wer given 30min access to a maximum of 10ml of either distilled water (control), 3 sucrose (sweet), 0.024% quinine (bitter), 0.9% sodium chloride (salt), 0.36 hydrochloric acid (sour) or 2.8% monosodium glutamate MSG (umami). All tast stimuli were novel to the rats. All tastes except for quinine induced significantly mor FLI in the IC than distilled water alone. While MSG, salt and sucrose intakes wer significantly higher than distilled water, amount of intake did not appear to correlat meaningfully with differences in IC FLI. In addition, HCl intake was equal to that water but resulted in significantly higher FLI in the IC. A second experimer examined FLI induced by ingestion of 0.1% saccharin which had either bee previously paired with injection of LiCl (20ml/kg, 0.15M) or NaCl (0.9%, 1 ml/kg Two days following this pairing rats were re-exposed to a maximum of 2 ml saccharin. Results showed that saccharin which had been paired with LiCl induce significantly less FLI than unpaired saccharin. Again, differences in saccharin intak across the two conditions did not appear to account for the FLI data.

The fact that the FLI in the IC induced by a taste changes once that taste has bee paired with illness is consistent with previous research from our laboratory showin that IC lesions cause impairment in conditioned taste aversion learning. Thes results taken together provide evidence that the IC is involved in not only the gener processing of taste information but in more complex taste guided tasks such a conditioned taste aversion learning and memory.

GUSTATORY NEURAL CODING IN THE MONKEY CORTEX: MIXTURES. C.R. Plata-Salamán and T.R. Scott*. Dept. Biol. Sci. and Dept. Psychol., Univ. Delaware, Newark, DE 19716, U.S.A.

We recorded the activity of 48 neurons in primary taste cortex in response to the oral application of each of the four basic stimuli, their six possible dyads, the four triads, and the tetrad of all four. Stimuli were maintained at a constant intensity in all mixtures by increasing their concentrations as the number of components rose. Glucose was the most effective basic stimulus, followed by quinine HCl, NaCl, and HCl. The mean response to dyads was suppressed by 50% from the sum of responses to the two unmixed components. The response to triads was 62% lower than the sum of responses to their three components, and activity evoked by the tetrad was suppressed by 74% from the sum of all four individual responses. Taste quality, as indexed by correlation coefficients among profiles of activity, was quite predictable for dyads, typically falling midway between the profiles of the two components. The profiles generated by triads and the tetrad were less predictable. A comparison was made between the contributions of each basic component to the perception of a mixture by humans, and to the electrophysiological response to that mixture in macaques. The only difference was that the acid component was generally less effective in the macaque, and the sugar more so. Supported by NSF IBN-9120611.

STIMULATION OF THE LARYNGEAL OPENING WITH TASTE STIMULI INCREASES FOS EXPRESSION IN RAT BRAINSTEM AND FOREBRAIN NUCLEI. J.A. Cook* and R.D. Sweazey. Dept. of Anatomy, Indiana Univ. Sch. of Med., Fort Wayne, IN 46805.

Information about the central neural pathways that underlie the laryngeal chemoreflex, a reflex elicited by application of chemical stimuli to the laryngeal opening, is currently lacking. Using Fos immunohistochemistry, we examined the distribution of neurons involved in processing laryngeal chemosensory information.

Rats were anesthetized and a tube positioned at the laryngeal opening. Four hours later, a stimulus solution containing 0.5 M KCl and 0.01 N HCl dissolved in distilled water was infused into the laryngeal opening. The mixture was applied to the receptor area for 1 min and then removed by rinsing with saline. This sequence was repeated 10 times over a 30 min period, and then repeated twice at 15 min intervals for the next 60 min. The animals were overdosed and sacrificed 30 min after the completion of the stimulus protocol. Brains were removed from the skull, sectioned and processed for the demonstration of Fos immunoreactivity.

Stimulus application produced increased Fos expression relative to controls in several areas of the rat brain. In the medulla, significant increases in the number of Fos-positive nuclei were observed in the interstitial and ventrolateral subnuclei of the nucleus of the solitary tract, and in the paratrigeminal area. In the pons, increased Fos expression was observed in the external medial subnucleus of the parabrachial pons, a region that receives caudal oral cavity taste information, and in the Kölliker-Fuse nucleus. At more rostral levels, increases in Fos expression were observed in the central nucleus of the amygdala, hypothalamus, and bed nucleus of the stria terminalis. These data suggest that in the rat, laryngeal chemosensory information is transmitted to brain regions involved in the control of respiration and visceral functions, and to nuclei involved in processing taste information.

This research supported in part by NIH Grant DC00735 to R.D.S.

CORTEX: TRANSFORMATIONS

719.1

TEMPORAL CHANGES IN THE EFFECT OF ARM ORIENTATION ON DIRECTIONAL TUNING OF CELLS IN MONKEY PRIMARY MOTOR (M1) AND DORSAL PREMOTOR (PMd) CORTEX DURING REACHING. **S.H.Scott* and J.F.Kalaska CRSN, Dépt. de Physiologie, Univ. de Montréal, Montréal, PQ, Canada H3C 3J7**

The directional tuning of cells in M1 and PMd during reaching movements with similar hand trajectories is altered by changes in arm orientation (Scott and Kalaska, J. Neurophysiol., 73:2563-2567, 1995; Neurosci. Abst. 21:2074, 1995). The present study looked at whether there was any temporal variation in the sensitivity of cell directional tuning to arm orientation. We compared the directional tuning of cells between arm orientations during a 70 ms sliding time window for trials aligned to the onset of movement. We found a gradual temporal change in the sensitivity of discharge to arm orientation. In general, the directional tuning of the earliest task-related activity in both M1 and PMd (prior to 100 ms from movement onset) showed significantly smaller differences between arm orientations than for their subsequent activity during the rest of the reaction time, during movement, or while the monkey maintained constant arm postures at the peripheral targets. The average difference in directional tuning of the early activity was similar in M1 and PMd, but was greater in M1 than PMd for later activity. These results suggest that neuronal activity in both M1 and PMd may reflect different types of information at different times during the planning and execution of movement. The earliest responses of M1 and PMd cells after target appearance may be more related to extrinsic aspects of the task, such as target location or movement direction, whereas the later discharge, especially in M1, may reflect an increasing prominence of information about intrinsic aspects of the motor task. Supported by MRC Group Grant in Neurological Sciences (JFK), & MRC Post-Doctoral Fellowship (SHS).

719.2

EXTERNAL LOADS IN DIFFERENT DIRECTIONS PRODUCE MINOR CHANGES IN PRIMATE MOTOR CORTEX (M1) DIRECTIONAL TUNING. J.F. Kalaska*. CRSN, Physiologie, U. Montréal, Montréal, PQ Canada H3C 3J7

When monkeys make reaching movements along similar handpaths using 2 different arm orientations, there is a change in the directional coupling between extrinsic and intrinsic movement attributes. In these conditions, the directional tuning of single M1 cells during movements in the two arm orientations is similar for their earliest task-related responses (mean diff. 19° at 210-140 msec before movement onset), but often gradually diverges at later times in the trial (mean diff. 42° at 70-0 msec before movement; see accompanying abstract - Scott & Kalaska). Therefore, the directional tuning changes in M1 may reflect a progressive temporal shift from activity that is initially related more to extrinsic aspects of the task, to later discharge that is more strongly influenced by movement parameters that covary with the intrinsic geometry and mechanics of the arm. Alternatively, the tuning shifts could be due to factors unrelated to arm geometry, such as an artifact of changes in discharge level with arm orientation, or successive processing of different extrinsic movement parameters (Fu et al. (1995) J Neurophysiol 73:836).

The same analysis was used on M1 activity recorded during reaching movements against different directions of external loads (Kalaska et al. (1989) J Neurosci 9:2080), which caused large changes in the level of cell discharge but not in handpaths or arm orientation. The directional tuning of single cells between unloaded and loaded movements did not show increased divergence with time (mean diff. 20° at 210-140 msec before movement, and 14° at 70-0 msec before movement). Therefore, the progressive divergence of directional tuning in the other study appears to be related to the change in arm orientation, and not other factors. Temporal divergence of tuning was not evident in the activity across different load conditions because they did not alter limb orientation, and so presumably did not require the same change in the coupling between extrinsic and intrinsic movement attributes that occurred for movements with different arm orientations. Supported by the MRC Group Grant in Neurological Sciences.

719.3

SIMULTANEOUS RECORDINGS OF MOTOR CORTICAL NEURONS ALLOW ESTIMATION OF MOVEMENT DIRECTION FROM SMALL NUMBERS OF NEURONS. E.M. Maynard[1], N.G. Hatsopoulos[2], C.L. Ojakangas[2], B.D. Acuna[2], J.N. Sanes[2], R. Normann[1], J.P. Donoghue[2]*. [1]Dept. Bioengineering, U. Utah 84112, [2]Dept. of Neuroscience Brown University 02912.

Single unit recordings in monkey motor cortex (MI), have indicated that a cluster of about 200 neurons is required to encode movement direction (Georgopoulos et al. 1996; J.Neurosci. 8:2928). This estimate may be inaccurate because of variability introduced by using populations comprised of neurons collected over multiple behavioral sessions. By contrast, simultaneous recording methods allow examination of neural populations recorded during identical behavioral conditions and should permit an improved estimate of the number of cells necessary for direction encoding. Using the Utah multielectrode array we recorded up to 21 MI cells simultaneously during a radial direction arm reaching task. Of these cells, 12 showed cosine direction tuning ($r^2 > 0.5$) and were included in further analyses. Calculation of the neural population direction vector using a standard weighted averaging formula of preferred directions provided a reliable prediction of movement direction. Errors in movement direction predicted by the neuronal population vector averaged 22° but were as low as 2° for some directions. Larger direction errors appear to be attributable to under representation of certain preferred directions. In conclusion, simultaneous recordings of 12 MI neurons are sufficient to encode movement direction, suggesting that fundamental cortical operations may occur within small networks of neurons. Supported by NIH NS25074, NSF IBN94-24509.

719.4

POPULATION VECTOR ANALYSIS OF THE RELATIVE TIMING BETWEEN MOVEMENT KINEMATICS AND CORTICAL ACTIVITY IN BOTH PRIMARY AND PREMOTOR CORTICES. **D.W. Moran*, A. Kakavand and A.B. Schwartz. The Neurosciences Institute, 10640 John J. Hopkins Drive, San Diego, California 92121.**

During coordinated arm movements, the population vector algorithm has been shown to provide a high-fidelity relationship between cortical activity and hand velocity. A temporal comparison between hand velocity vectors and corresponding population vectors for various tasks was performed in order to elicit timing characteristics in the brain.

A rhesus monkey was trained to perform a 2D center->out task on a computer touchscreen. In addition, the animal was trained to trace smooth spiral figures while single-unit cortical activity was recorded. We have used these two tasks to compare the encoding of direction and speed. Each movement of the center->out task is essentially straight such that only speed varies as a function of time during the task. Conversely, spirals are drawn with a time-varying directional component and a near constant speed component.

Primary motor cortical cells (133) were recorded from one hemisphere and dorsal premotor cells (142) from the other in a single monkey. Time varying population vectors were generated for each task using ensembles from each cortical area. Results suggest that for arm movements, primary motor cortical cells operate as a single ensemble which encode both direction and speed independently with time lags that vary with the curvature of movement. Results from dorsal premotor cells suggest that there are two separate ensembles, operating in parallel, with very different timing characteristics with respect to the movement. Supported by Neurosciences Research Foundation.

719.5

DYNAMIC CORRELATIONS OF MOTOR CORTICAL ACTIVITY WITH KINETIC AND KINEMATIC PARAMETERS OF HAND MOVEMENT.
A. Kakavand*, D.W. Moran and A.B. Schwartz. The Neurosciences Institute, 10640 John J. Hopkins Drive, San Diego, California 92121.

3D arm movements were used to study the relationship between motor cortical activity and movement parameters. A rhesus monkey looked through stereographic goggles and drew computer generated objects in free space. The 3D position of the monkey's hand and arm were tracked in real time and used to move a virtual representation of the monkey's hand. The monkey performed a center-out task in which it moved from the center of a cube to the eight corners.

Joint torques were calculated from a 3D, seven degree-of-freedom dynamic model of the monkey arm. Spike activity of motor cortical cells was regressed against hand velocity , joint angles, joint torques and muscle activity during the task. This regression was done in a two-step process. First, the spike activity was regressed separately against each parameter (e.g., joint torques). This regression was done in a 350 ms sliding window from approximately 200 ms before to 100 ms after the movement. Each set of parameter coefficients were recorded at the lag that provided the best fit (r^2) to the model. A vector of these coefficients termed the "preferred" vector was calculated for each parameter. At each instant of time, the inner product between the "preferred" vector and the actual time-varying vector was calculated for each parameter. The inner products for each parameter were combined into a single equation and regressed against discharge rate.

Our preliminary results show that most of the variability in discharge rate is explained by kinematics. Kinetic parameters account for less variability and have a time course that is less predictive. However, both kinematic and kinetic parameters are represented in motor cortical activity. Supported by Neurosciences Research Foundation.

SEQUENTIAL PROCESSING OF NEURONAL ACTIVITY FOR PREPARING AND EXERTING ISOMETRIC FORCE IN THE MONKEY DORSAL PREMOTOR CORTEX. T. Fukushi*, T. Sawaguchi, and K. Kubota. Dept. of Behavioral and Brain Sciences, Primate Res. Inst., Kyoto Univ., Inuyama, Aichi 484, Japan.

We recently reported that neurons in the monkey's dorsal premotor cortex (PM) show positively or negatively correlated activity before an exertion of isometric force, with forthcoming force produced by wrist flexion (Fukushi et. al, 1996, Jap. J. Pysiol.). To further address neuronal mechanisms of the dorsal PM in preparing for and exerting isometric force, we examined time courses of the neuronal correlations with isometric force in a visually guided wrist-flexion task. In this task, the monkey was required to exert one of two magnitudes of force ("larger", 3.7-5.2 N, "smaller", 1.7-3.2 N) by isometric wrist flexion after a fixed preparatory period (3 s); the magnitude was instructed by means of a visual cue throughout the preparatory period. We sampled 73 neurons from the dorsal PM whose locations were estimated by stereotaxic coordinates and ICMS. The neurons showed correlated activity after the onset of the visual cue. In the earliest phase of the preparatory period, positively correlated neurons were dominant (positive vs. negative, 3.3:1). In the middle phase, numbers of negatively correlated neurons increased (1.7:1), and in the last phase it became comparable to those of the positively correlated neurons (0.8:1). During the reaction period, from the onset of a visual "go" signal to the onset of force exertion, both positively and negatively correlated neurons contributed relatively equally to the coding of force magnitude (1.2:1). Thus, the exertion of a fixed-sized isometric force can be prepared for in the preceding phase of force exertion by changing the number of the dorsal PM neurons with positive or negative correlation, initially by positively correlated neurons and then by both positively and negatively correlated neurons.

TARGET SIZE MODULATES ACTIVITY OF DORSAL PREMOTOR CORTEX (PMd) BUT NOT ARM EMG. J.E. Gomez*, Q.-G. Fu, D. Flament, and T.J. Ebner. Depts of Neurosurgery & Physiology, Univ. Minnesota, Minneapolis, MN 55455.

We used an accuracy-direction arm reaching paradigm to study the characteristics of dorsal premotor (PMd) cortical neurons and arm muscles. In two primates, we recorded the activity of PMd neurons and 16 arm muscles during a task involving a multijoint reaching movement in the horizontal plane from a centrally located start box to 8 radially arranged square targets of 6 possible sizes (0.25, 0.56, 1.0, 1.56, 2.25, 3.06 cm^2). Multiple regression analysis was employed to assess the contribution of accuracy (i.e., target size) to the firing rate of neurons in the PMd and to the rectified EMG evoked from various arm muscles. The regressions were performed in time, using 20 ms bins.

Based on this analysis, the majority of cells (99/150, 66%) had significant periods of activity (>100 ms consecutively) correlated with target size. A greater percentage of cells (134/150, 89.3%) showed significant periods of coding for direction, while fewer (83/150, 55%) displayed significant periods of coding for mean hand velocity. Mean peak partial R^2 values were 0.49, 0.33, and 0.36 for direction, target size and mean velocity respectively. The onsets of the correlations were temporally segregated with accuracy generally following direction, but the relations with accuracy and velocity were statistically coincident. Mean onset times were -769 ms, 375 ms, and 81 ms for direction, size, and mean velocity respectively.

After performing the identical analysis on the EMG, we failed to find any statistically significant relations for either target size or mean velocity while all muscles showed significant modulation with direction (mean peak R^2=0.65).

In conclusion, there are cells in the dorsal premotor cortex of the monkey whose firing rate is correlated with accuracy either alone or more commonly in combination with other parameters. These relations were not seen in the output of muscles, however. Supported by NIH grants NS-31530 and GM-15595.

IMPAIRMENTS IN TRAJECTORY CONTROL IN REACHING PRODUCED BY INACTIVATION OF ROSTRAL MOTOR CORTEX. B. Kably, J.H.Martin*, C. Ghez. Ctr. Neurobiology & Behavior, Columbia Univ. and NYS Psychiatric Institute, New York, NY 10032

We have previously shown that reversible inactivation of rostral motor cortex (MCr) in the cat produced systematic trajectory end-point errors and defects in reaching above an obstacle. In the present experiments, we conducted a kinematic and dynamic analysis to investigate the role of MCr in trajectory control by examining deficits in the performance of a reaching task produced by muscimol injection. Animals reached into a narrow food well at various heights, distances and inclinations to grasp a small piece of beef.

Normally, animals reached to targets of increasing height by increasing the angle of inclination of the initial phase of the trajectory and by scaling elbow flexion. During MCr inactivation, reaches to all targets were over-shot by a relatively constant amount, confirming our earlier report. Compared with control reaches, the initial trajectory inclination of reaches to targets of increasing heights was similar and more variable. Elbow scaling to target height, however, was preserved. Inactivation produced a prolongation in the duration of the flexor phase of motion and a delay in the onset of and a reduction in the amount of extensor residual (i.e., muscle) torque.

Our findings suggest that the initial trajectory change produced by inactivation may reflect an impairment in the transformation from an extrinsic to an intrinsic coordinate system in hand-path planning. The over-reaching may result from an impairment in the braking action of the extensor (ie, antagonist) phase of reaching, similar to what has been proposed for cerebellar hypermetria. (NSF IBN942-1582)

REACHING AND INTER-JOINT COORDINATION AFTER REMOVAL OF PARIETAL AREAS 5 AND 7B. M.F. Rushworth, H. Johansen-Berg, P.D. Nixon, S. Young, R.E. Passingham (SPON: Brain Research Association) Department of Experimental Psychology, University of Oxford, Oxford OX1 3UD.

Area 7a is important for visuospatial behaviour. A spatial representation is constructed by cells that take into account position of both eye and head. Areas 5 and 7b may provide an analogous proprioceptive-motor map.

Six cynomolgus macaques were trained to reach to targets in the dark. The animals never saw the position of the targets and so were forced to encode their position in terms of proprioception and efference copy from the limb. The parietal cortical areas 5 and 7b were removed in three of the animals. They were retested and compared with controls. Performance was recorded at 25 frames/s on videotape and hand and joint positions measured with computer software.

1) We measured accuracy of reaching by comparing the hand trajectory with the direct distance from start to finish. Lesions caused an impairment when reaches were made from different starting positions as opposed to repetitions from the same starting position. This condition requires a spatial representation of the target.

2) Forelimb elevation (FE) depends on the coordination of the elbow and the shoulder. FE was correlated with the hand's position during reaching. FE velocity and the tangential velocity of the hand were, however, only poorly correlated after the lesion suggesting an impairment of inter-joint coordination.

3) Coordination of reaching and grasping was disrupted by the lesion – grasping movements were initiated when the hand's velocity was lower.

4) Joint angle range, and joint and hand velocities were unaffected.

Supported by a Wellcome Trust Program Grant (038041/Z/93).

TRANSFORMATION INTO THE JOINT-RELATED COORDINATE SYSTEMS IN THE MOTOR CORTEX. S. Tanaka*. Dept. of Electrical Eng., Sophia Univ., Tokyo 102, Japan.

The primary motor cortex receives direct and indirect proprioceptive input. The objective of the present study is to analyze the usage of the proprioceptive signal to code directional information in the arm-centered, joint-related coordinate systems proposed previously (Tanaka 1994). Interestingly, Caminiti et al. (1990, 1991) recorded from monkey motor cortical neurons that the amount of rotation of the preferred directions was distributed widely. I proposed that the wide distribution of the preferred directions is attributed to weak convergence of the proprioceptive input to each motor cortical neuron (Tanaka 1996). This would indicate that the input to the motor cortex is poorly tuned. The numerical simulation based on the population coding theory shows that, nevertheless, the motor cortex can code internally represented direction accurately for various postures of the arm.

The population vector is defined for each joint-related coordinate system. The relationship between the population vectors represented in the joint-related coordinate systems and the population vector represented in the body-centered coordinate system is described as rotation. The amount of the rotation of the population vector is obtained, for a two-joint model arm, from the joint-related coordinate system hypothesis. This would be the substrate for the coordinate transformation from the body-centered to the arm-centered (joint-related) coordinate systems. The numerical simulation suggests that the transformation is made with high accuracy regardless of the distributed (or poorly tuned) input of the proprioception as long as the standard deviation of the input is less than about 50°.

PERIPHERIN IN THE VESTIBULAR NUCLEI OF GERBILS. G.A. Kevetter* and R.B. Leonard. Departments of Anatomy & Neurosciences and Otolaryngology. Marine Biological Institute. Univ. TX Medical Branch, Galveston, TX 77555.

We are characterizing the chemical staining properties of neurons within the vestibular nuclei, as well as afferents to the vestibular nuclei, in order to study their morphophysiological properties. Our goal is to correlate these biochemical markers with anatomical and physiological properties to better understand the biology of the vestibular control systems. Peripherin staining is confined to small neurons of Scarpa's ganglion. When the area of peripherin-positive somata are compared with the distribution of cell area of Nissl stained ganglion cells, it is evident that the peripherin-stained population is restricted to the smallest neurons. A number of thin peripherin-positive fibers enter the vestibular nuclear complex through the vestibular nerve root. In the more lateral portions of the vestibular nuclear complex, most of the fibers appear to be traveling elsewhere, as there are few branches, ramifications, or bouton-like swellings. Fibers are present in all vestibular nuclei, except the dorsal portion of the lateral. In the magnocellular portion of the medial vestibular nucleus (where many large calretinin-stained afferent fibers terminate) relatively straight, unbranched fibers traverse towards the parvocellular division. Fibers, fiber clusters, and bouton-like terminals are concentrated in the parvocellular medial and rostral superior vestibular nuclei, where many vestibulo-ocular neurons are located. Terminals are not as evident with peripherin as they are with other markers that stain larger fibers. Lesions of the vestibular ganglion eliminate staining within the vestibular nuclei. Therefore, we conclude that primary aferents are the sole source of peripherin input to the vestibular nuclei and that they are restricted to afferents with the smallest somata and the thinnest fibers, probably bouton-only endings. Peripherin also stains the vestibular efferent nucleus, cell group e, adjacent to the genu of the facial nerve. These neurons are densely stained, including long, intertwining dendrites. The efferent bundle in the vestibular nerve root is peripherin-positive. (Supported by DC00052, Deafness Research Foundation).

CALRETININ AND PERIPHERIN STAIN SEPARATE, NON-OVERLAPPING POPULATIONS OF VESTIBULAR AFFERENTS. R.B. Leonard* and G.A. Kevetter. Departments of Anatomy & Neurosciences and Otolaryngology. Marine Biological Institute. University of TX Medical Branch, Galveston, TX 77555.

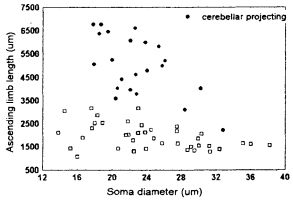
Sections through Scarpa's ganglion were stained with antibodies to peripherin and calretinin. The area of the ganglion cells where the nucleus and at least one of either the central or peripheral nerve process was present was measured. The measures were compared with a student t-test and the stained populations were significantly different ($P<0.0001$). We compared these measures with values of ganglion cell areas obtained in normal Nissl stained tissue. The calretinin-positive neurons were among the largest and the peripherin-positive cells were among the smallest. These data support our hypothesis that different populations of vestibular afferents can be differentiated by their distinct chemoarchitecture. When canal cristae are stained with antibodies to peripherin, many fibers and boutons are visible throughout the crista. When the focus is on the slopes of the crista (i.e., the central and peripheral zones) many fibers and boutons are present. Also present are many extremely fine fibers and terminals at the apex of the crista and fibers coursing over the planum semilunatum. The staining reflects both bouton-only afferent endings and vestibular efferents. Thus far, in 6 cristae that have been examined, we have seen only one calyx ending. When we have stained cristae with antibodies to calretinin, by contrast, only calyx-endings are labeled, and their position is limited exclusively to the apex of the crista. When the cross sections are subsequently cut, the exclusive distribution of the labeled calyxes to the apex in the central portion of the crista is confirmed. Although peripherin-stained afferent and efferent terminals overlap in the crista, and therefore cannot be readily distinguished, peripherin stained endings centrally are confined to a specific subpopulation of vestibular afferent fibers. These data support the hypothesis that these antibodies stain separate, non-overlapping populations of afferents. (Supported by DC00052 & Deafness Research Foundation)

720.3

IDENTIFICATION OF POSTERIOR CANAL AFFERENTS TO THE CEREBELLUM. J.A. Huwe* and E.H. Peterson. Neurobiology Program, Ohio U., Athens, OH 45701.

Canal afferents project to cerebellar cortex. We used two strategies to determine their type (bouton, calyx, dimorph) and peripheral epithelial location in a turtle, *Trachemys scripta*.

In some experiments we injected horseradish peroxidase into the posterior ampullary nerve to visualize central axons of single posterior canal afferents. Twenty-two out of 62 reconstructed axons projected to cerebellar cortex. Eighty six percent of these (19/22) occupy a restricted range of the total soma size distribution, suggesting that they represent a specific afferent type or peripheral epithelial location.



To test this, we applied biotinylated dextran amine (BDA) to the cerebellum, which labels afferents in the posterior crista. All BDA-positive terminals were bouton-type (except for 3 calyx-bearing afferents). They occurred along the full length of the crista, typically outside the calyx-bearing central zone.

Our results suggest that a subset of afferents, probably bouton afferents, relays posterior canal signals to the cerebellum in *Trachemys*. Because the response dynamics of turtle bouton afferents vary with distance from the wall to the center of the canal, our results suggest that signals reaching the cerebellum encompass the full range of bouton response dynamics.

PROJECTIONS OF VESTIBULAR NERVE TO VESTIBULAR NUCLEAR COMPLEX AND CEREBELLUM: AN HRP STUDY IN RAT H.Li*, D.A.Godfrey, and A.M.Rubin. Dept. of Otolaryngology-Head and Neck Surgery, Med. Col. of Ohio, Toledo, OH 43699-0008.

The distribution of vestibular nerve terminations in the rat brain was studied 2-4 days after introducing HRP-VI into Scarpa's ganglion, which was surgically exposed by a translabyrinthine approach. The majority of anterogradely labelled vestibular fibers projected into the vestibular nuclear complex (VNC) via an entry zone between the inferior cerebellar peduncle (ICP) and spinal trigeminal tract, although a few of them passed dorsally between the ICP and dorsal cochlear nucleus at the level of the spinal vestibular nucleus (SpVN). From the entry zone, vestibular afferent fibers fanned out dorsomedially to all the VNC regions. Labelled fine fibers and puncta appeared to be denser in medial (MVN) than in superior (SuVN) vestibular nucleus, followed by SpVN and lateral vestibular nucleus (LVN). However, the densities of labelled fine fibers and puncta in three areas, i.e., the ventrolateral part of LVN near the entry zone, the area between ICP and LVN, and the lateral part of SpVN, were comparable to that in MVN. Labelled fine fibers could also be recognized in group Y, but not clearly in group X. Most fine fibers appeared to be ends of axons in MVN and SuVN, while those in LVN and SpVN appeared as short branches of passing axons. In most VNC regions, the fine fibers were predominantly loosely spiraling and contained varicosities. However, in LVN and SpVN, especially in the region near the entry zone, plexuses of highly twisted fine fibers and puncta were observed. No labelling was observed in the contralateral VNC. In the cerebellum, sparse fine fibers were observed in the ipsilateral interpositus and fastigial nuclei. Clusters of label appeared bilaterally in the flocculus and in the nodulus, in the Purkinje cell body layer and the deep part of the molecular layer. Suggestions: 1) Each vestibular nerve fiber may terminate with several patterns. 2) Vestibular nerve fibers may terminate on Purkinje cell perikarya and apical dendrites. *(NIH grant R01-DC2550)*

PROJECTIONS TO THE CEREBRAL CORTEX BY VESTIBULAR BRAINSTEM NUCLEI TRANSNEURONALLY LABELED BY PSEUDO-RABIES VIRUS. B.A. Metts*[1], G.D. Kaufman[1], A.A. Perachio[1,2]. Departments of Otolaryngology[1], Physiology and Biophysics[2], Anatomy and Neurosciences[2], Univ. TX Medical Branch, Galveston, TX 77555-1063.

In order to identify the anatomical connections of the vestibular nuclei and other functionally related brainstem nuclei such as the prepositus to the visual cortex, we employed a retrograde, transneuronal labeling method. It is hypothesized that the visual cortex projects polysynaptically to the prepositus as well as to the vestibular nuclei, based on ample evidence that vestibulo-ocular responses are altered by visual input. The methods involve the injection of the Bartha strain of alpha-Herpes virus (pseudo-rabies virus) into the visual cortex of Mongolian gerbils. After an incubation period, the animals were sacrificed and the tissue was prepared for histologic examination using an antibody to the viral coat and an avidin-biotin reaction to amplify and visualize the virus *in situ*. Visual cortex injections labeled connections originating in the nucleus prepositus as well as the medial vestibular nucleus projecting transneuronally to the visual cortex. Other nuclei known to project to visual cortex such as the dorsal and ventral lateral geniculate nuclei, and the superior colliculus, were also labeled. Injections of HRP were performed in order to verify retrograde transport. Injections in adjacent cortices served as further controls. For example, injections in the limbic cortex resulted in retrograde labeling of the anterior nucleus of the thalamus, the hippocampus, and other limbic areas with the absence of labeling in visual associated structures. Connections between the brainstem and the visual cortex likely play an important role, serving as the substrate for visual influences on vestibular responses during head motion. INFERIOR OLIVE ABLATION DOES NOT AFFECT NODULUS PROTEIN KINASE Cδ RESPONSES TO UNILATERAL LABYRINTHECTOMY. C.D. Balaban* and G.G. Romero. Depts. of Otolaryngology and Pharmacology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15213

Previous studies have shown that Purkinje cell (PC) Protein kinase Cδ (PKCδ) expression becomes asymmetric in a sagittal band in the rat nodulus within 6 hr after unilateral labyrinthectomy (UL), with an increased number of PKCδ-positive PCs contralateral to the lesion. This asymmetry disappears within 24 hr post-UL. This study tested the hypothesis that intact climbing fibers are essential for the initial change in PKCδ expression. The inferior olive was ablated in adult male Long-Evans rats by successive i.p. injections of 3-acetylpyridine (75 mg/kg), harmaline (+3 hr, 15 mg/kg) and nicotinamide (+4.5 hr, 300 mg/kg). Five days later, either surgical UL (n=9) or sham (SH) operations (n=5) were performed under Innovar anesthesia, reversed postoperatively with naloxone. The rats were euthanized 6 hr post-operatively with a pentobarbital overdose, perfused and frozen sections reacted immunohistochemically for PKCδ (Gibco/BRL primary antibody) with standard avidin-biotin methods (Vectastain Elite) and a diaminobenzidine chromagen. Labyrinthectomies were verified histologically. The results were the same as reported previously in rats with an intact inferior olive. PKCδ was distributed symmetrically in nodulus PCs in SH rats, with no evidence of sagittal bands. In the UL group, an increased number of PKCδ-immunopositive PCs was observed contralateral to the lesion in an intermediate band. These findings suggest that intact climbing fibers are not essential for early, transient changes in nodulus PKCδ expression after UL. It is hypothesized either retrograde chemical communication in PCs or direct PC activity may produce these changes in PKCδ expression. (Support: USPHS R01 DC02559)

DISTRIBUTION OF PROTEIN KINASE C-δ IN CEREBELLAR PURKINJE CELLS FOLLOWING UNILATERAL LABYRINTHECTOMY IN RAT. Z.-Y. Qian* and N.H. Barmack. R.S. Dow Neurol. Sciences Inst., Portland, OR 97209.

Protein Kinase C-δ, a calcium-independent isoform of PKC, is found in sagittal bands in the cerebellum of rat. Using immunohistochemical staining for PKC-δ we have investigated changes in the distribution of PKC-δ within nodular Purkinje cells following unilateral labyrinthectomy (UL). ULs caused no change in PKC-δ labeling of Purkinje cell bodies in the ipsilateral nodulus. However, the labeling of Purkinje cell terminals within the ipsilateral medial vestibular nucleus and nucleus prepositus hypoglossi was reduced. Western blots of the vestibular nuclei showed a decrease in membrane-bound PKC-δ on the side of the UL. These changes were specific for PKC-δ. They were not seen for PKC-γ or for Zebrin-II, two other proteins also found in nodular Purkinje cells. Using hybridization histochemistry, we detected no change in PKC-δ mRNA in nodular Purkinje cells following a UL.

The transport of PKC-δ from Purkinje cell body to the axon terminal was studied following micro-injections of the ^{32}p-ATP into the nodulus. Autophosphorylated PKC-δ was detected in the vestibular complex within 6-12 hours post-injection. PKC-δ translocates from the cytosol to the membrane following its activation. We injected a PKC activator, phorbol 12-myristate 13 acetate (PMA) into the uvula-nodulus and monitored the amounts of PKC-δ in Purkinje cell body membranes and Purkinje cell axon terminal membranes. Microinjections of PMA increased membrane bound PKC-δ by as much as 45%. Injections of an inactive homolog of PMA, α-PMA, had no such effect.

We conclude that the expression of PKC-δ is constitutive and is not influenced by Purkinje cell activity. Rather, the transport of PKC-δ to Purkinje cell axon terminals within the vestibular complex could reflect the regulation of a protein to which PKC-δ binds. This decrease in PKC-δ transport might, in turn, contribute to vestibular compensation by decreasing the Purkinje cell synaptic release of GABA ipsilateral to the UL. *Supported by NIDCD DC02557.*

TRANSIENT LABYRINTHECTOMY INDUCES FOS EXPRESSION IN VESTIBULOCEREBELLAR AND INTRINSIC VESTIBULAR NEURONS. Dale W. Saxon* and Alvin J. Beitz. Dept. of Vet/Pathobio., Univ. of Minn., St. Paul, MN, 55108. Transient labyrinthectomy using tetrodotoxin (TTX) has previously been demonstrated in the rat (Beitz et al., 1995, Neurosci. Abst.) Following injections (25-50 µl) of TTX in PBS into the middle ear there is a distinct pattern of neuronal activation (as defined by up-regulation of Fos-protein) in various brainstem regions including the vestibular complex (VC). The present study is a continuation of this same theme. Injections of Fluoro-Gold (FG) into the oculomotor nucleus, thalamus, cerebellum and cervical spinal cord were carried out 7 days prior to the administration of TTX. Animals were perfused with 4% paraformaldehyde 2 hrs post-TTX, infiltrated with 20% sucrose overnight and sectioned (30-40 µm) on a sliding freezing microtome. Sections were then processed for Fos immunocytochemistry with a primary antibody concentration of 1:3000. Fos activity was revealed either by development with the ABC method or using a secondary antibody tagged with the fluorescent maker Cy3. Both the ABC and Cy3 protocols produced good results although the sensitivity was slightly higher with ABC. Several series of sections were subsequently processed for NADPH-d histochemistry. Nuclei labeled for Fos were remarkably uniform in size regardless of their location in the brainstem including the VC. The location(s) of retrogradely labeled neurons following each of the injections were consistent with previously reported distributions. In general, Fos positive nuclei in the VC overlapped to varying degrees with the distribution of vestibulo - thalamic, -oculomotor, -cerebellar, and -spinal neurons. Projection neurons labeled with both FG and Fos were rare although some were found in the inferior olive, reticular formation, prepositus hypoglossal nucleus, medial vestibular nucleus and nucleus X following injections into the cerebellar cortex. In sections processed for both Fos-Cy3 and NADPH-d some of the constitutive NADPH-d/NOS neurons in the MVN were double labeled. Using Fos expression as an indicator of neuronal activation the results would suggest that at 2-3 hrs post-TTX there is very little activation of vestibular projection neurons as a result of labyrinthectomy but that neurons, possibly commissural or intrinsic are activated. This work was supported by NIH Grant #NS31318.

ULTRASTRUCTURAL CHARACTERIZATION OF GABAERGIC NEURONS IN NUCLEUS PREPOSITUS HYPOGLOSSI (NPH). G.R. Holstein*, E. Kukielka, G.P. Martinelli and B. Cohen. Departments of Neurology, Cell Biology/Anatomy, Surgery and Physiology/Biophysics, Mount Sinai Sch. Med., N.Y., NY 10029.

We have previously described the GABAergic neurons and processes of the medial vestibular nucleus (MVN) that degenerate following midline medullary section of the vestibular commissure just caudal to the abducens nuclei in one cynomolgus and two rhesus monkeys. Post-lesion, the animals' ability to store activity related to slow phase eye velocity (velocity storage) was lost for nystagmus about any axis, while VOR gains and the ability to hold gaze were unaffected. The purpose of the present study was to characterize the ultrastructural features and synaptology of GABAergic neurons and processes in PPH, and to compare these findings with those in MVN.

Six days after surgery, animals were sacrificed by perfusion with mixed aldehydes. Vibratome sections were exposed to a monoclonal anti-GABA antibody raised in our laboratory, a polyclonal GABA antiserum (Arnel), or a control solution. Subsequently, the unlabeled antibody PAP procedure or a biotin/streptavidin-HRP kit (Vector) was used. At the ultrastructural level, most GABAergic cells were small, with a thin rim of cytoplasm containing many small mitochondria, some flattened cisterns, but a paucity of other organelles. Small indentations were occasionally present in the nuclear envelope, although somal spines were not commonly observed. These cells are dissimilar to the GABAergic neurons of MVN, which typically contain deeply indented nuclei, ample cytoplasm full of organelles, and many somal spines. In contrast to the marked degeneration of cells and processes in rostral and rostro-intermediate levels of MVN, no signs of significant degeneration were present in NPH. Myelinated axons, terminals and synapses all had normal ultrastructural features, and lacked the hyperfilamentosis and dark degeneration characteristic of the neuropil in rostral MVN of midline-sectioned animals. We conclude that (a) GABAergic NPH cells are distnctly different from those in MVN, and (b) NPH cells do not generate velocity storage in primates. EFFECTS OF GABA RECEPTOR AGONISTS ON MEDIAL VESTIBULAR NEURONS IN RAT BRAINSTEM SLICES. Y. Sun[1], H. J. Waller*[2], D. A. Godfrey[1], and A. M. Rubin[1]. Depts. of [1]Otolaryngology and [2]Neurological Surgery, Medical College of Ohio, Toledo, OH 43614.

The inhibitory neurotransmitter γ-aminobutryic acid (GABA) has been strongly implicated in the control of vestibular reflexes. One of its major sites of action is thought to be neurons in the vestibular nuclear complex (VNC). Few in vitro studies have addressed the determination of GABA receptor subtypes in VNC. This study has investigated the effects of muscimol, a specific agonist for $GABA_A$ receptors, and baclofen, a specific agonist for $GABA_B$ receptors, in rat medial vestibular nucleus (MVN). Transverse slices of rat brainstem were cut with a vibratome at 500-550 µm, and action potentials from MVN neurons were recorded extracellularly in an interface chamber. Drugs were applied in the perfusion medium. In some experiments a drug was tested at 2 or 3 different, usually increasing concentrations. All neurons studied showed regular spontaneous discharge patterns typical of MVN neurons. Means of initial firing rates of neurons tested under each condition were not significantly different.

Both muscimol and baclofen caused monophasic, concentration-dependent decreases in firing rate. No neurons increased in rate. The half-maximally effective concentration (reduction to 50% of control firing rate, EC_{50}) of muscimol was 20.2 µM (n=11). The distribution of dose-response values for baclofen suggest two different groups of neurons with either high sensitivity (EC_{50}=0.66 µM, n=10) or low sensitivity (EC_{50}=30.2 µM, n=19) to the $GABA_B$ agonist.

Our data suggest that GABAergic agonists are effective in MVN and that the inhibitory control of MVN neurons involves both $GABA_A$ and $GABA_B$ subtypes.

NORADRENERGIC β_1 AND NOT β_2 RECEPTORS IN THE VESTIBULO-CEREBELLUM OF GOLDFISH ARE NECESSARY FOR ADAPTIVE VESTIBULO-OCULAR REFLEX GAIN CHANGES. L. Z. Williams* and J. G. McElligott. Dept. of Pharmacology, Temple University School of Medicine, Phila., PA 19140.

Adaptation of the vestibulo-ocular reflex (VOR) has served as a model for studying the neurochemistry of learning and memory in a sensori-motor system. Adaptation of this reflex involves a neuroplasitic change within the cerebellum and/or the brainstem. Adaptive gain changes in the cat have been shown to be inhibited following depletion of central nervous system norepinephrine (NE) by 6-hydroxydopamine (6-OHDA) (Keller and Smith, 1983; McElligott and Freedman, 1988). Other work in rabbits demonstrated that the non specific β-blocker, sotalol, when injected into the vestibulo-cerebellum also inhibited VOR adaptation (van Neerven, et al. 1990). Studies from our own lab confirmed this finding in the goldfish. Propranolol, another non specific β adrenergic antagonist, inhibits the acquisition phase of goldfish VOR adaptation increases. The objective of the study presented here was to determine which β adrenergic subtype, β_1 or β_2, is responsible for the inhibition of VOR adaptation. Adapted VOR gain increases (towards 3X) were produced by presenting visual stimuli at twice the magnitude and 180 degrees out of phase with the vestibular table (1/8 Hz @ +/-20 degrees) over a 3 hour period. Drugs were infused via microdialyisis (1.0 µl/min) or directly microinjected (total volume = 0.50 µl). Infusion of atenolol, a specific β_1 adrenergic receptor antagonist, or ICI-118,551, a highly specific β_2 adrenergic antagonist, prior to adaptation did not alter normal vestibulo-ocular reflex gain in the light or the dark. ICI-118,551 had no effect on adaptive gain increases, when infused into the goldfish vestibulo-cerebellum. Atenolol inhibited the acquisition phase of an adapted VOR gain increase in a dose dependent manner. These results indicate that the β_1 (associated with Purkinje cell), but not β_2 (associated with glial cells and blood vessels) noradrenergic receptors in the cerebellum are involved in adaptive VOR gain changes. (Supported by a grant from NIH-NIDCD # DC 01094)

720.12

DO THE MICROGLIAL CELLS PLAY A ROLE IN THE VESTIBULAR COMPENSATION PROCESS FOLLOWING UNILATERAL LABYRINTHECTOMY IN ADULT RATS ? A.Campos Torres, P.P. Vidal and C. de Waele (SPON: European Neuroscience Association), L.P.P.A. CNRS-Collège de France, Paris, France

Vestibular compensation is a suitable model to study the mechanisms underlying post-lesional plasticity in the adult central nervous system. The static postural and oculomotor deficits which follow unilateral labyrinthectomy largely disappear with time in all vertebrate species. After about fifty hours, the deafferented vestibular neurons recover a quasi normal resting discharge, which is thought to play a crucial role in the disappearence of the static vestibular syndromes observed at the acute stage. Earlier studies of our team have shown an astroglial reaction during the first stages of vestibular compensation (appearance of vimentin positive cells and increasing of level of GFAP protein and mRNA in the absence of primary vestibular axon degeneration). The aim of this work was to study the vestibular and cochlear microglial reaction after unilateral inner ear lesion by means of immunocytochemical and histochemical methods. The potential microglial reaction was studied in lesioned adults rats at differents post-lesional days (1, 2, 4, and 8) by means of a monoclonal OX42 antibody and lectins (*Griffonia simplicifolia*, B_4 isolectin) labelled with horseradish peroxidase (HRP) or fluorescein. In normal rats only a uniform distribution of the resting microglial cells was observed in the vestibular and cochlear nuclei. As early as 24h after unilateral labyrinthectomy microglia cells were increased in number in the deafferented vestibular and cochlear nuclei. In addition, the cells appeared hypertrophied compared to microglial cells in the contralateral side and in other normal gray matter regions of the brainstem. This microglial reaction persisted for 2 to 3 days following the lesion and disappeared at 8 days in the ipsilateral vestibular nuclei but later in the ipsilateral cochlear nuclei. We thus demonstrated the early presence of reactive microglial cells in the ipsilateral vestibular complex after unilateral labyrinthectomy. The exact role of the reactive microglial cells in the early stages of vestibular compensation process remains to be determined.

IN SITU HYBRIDIZATION STUDY OF AMPA RECEPTORS IN VESTIBULAR AND COCHLEAR NUCLEI OF INTACT AND UNILATERALLY INNER EAR LESIONED RATS. G. Rabbath, A. Campos Torres, P.P. Vidal, C. de Waele*. L.P.P.A, CNRS-Collège de France, Paris, France

In this study, we have investigated by means of in situ hybridization in rat vestibular and cochlear nuclei whether a potential change of the expression of GLUR B (flip and flop) and GLUR C mRNAs could occur following unilateral inner ear lesion (labyrinthectomy and cochleectomy). In the labyrinthectomy model, the vestibular nerve did not degenerate. The central vestibular neurons were thus functionally but not anatomically deafferented. In the cochlectomy model, the acoustic nerve rapidly degenerated and the central cochlear neurons were anatomically deafferented. The central vestibular and cochlear neurons became silent immediatly after the lesion. However, only the deafferented vestibular neurons recovered a sub-normal resting activity three days later. This resting discharge recovery is considered as the key of the vestibular compensation process. Adult rats were thus unilaterally labyrinthectomized and cochleectomized and specific radioactive oligonucleotide were used to probe sections of rat vestibular and cochlear nuclei according to in situ hybridization methods. Levels of labeling for GLUR B flip and flop and GLUR C mRNAs were studied on autoradiograms and on emulsioned sections at different times (5 hours, 1, 3, 8 days) following surgery. In the normal animals, several brainstem regions including the medial, lateral, inferior, superior vestibular nuclei and the dorsal and ventral part of the cochlear nuclei were densely labelled by the antisense oligonucleotide GluR B and Glu R C probes. In the cerebellum the purkinje and the granular layer cells were labelled for GLUR B whereas for GLUR C only the purkinje and the molecular layer cells were stained. This supports the specificity of the hybridization signal obtained. In the inner ear lesioned animals, no assymetry could be detected on the autoradiogramms between the two vestibular and cochlear complexes whatever the stage following the lesion. The number of labelled neurons and the amount of mRNA labelling over individual neurons for each probes are under quantification by means of a BIOCOM image analysis system.

EFFECTS OF ACETYL-LEUCINE (TANGANIL®) ON MEDIAL VESTIBULAR NUCLEUS NEURONS IN GUINEA-PIG BRAINSTEM SLICES. P.-P. Vidal*, N. Vibert and [1]J.-C. Carraro. L.P.P.A., CNRS-Collège de France, 15 rue de l'Ecole de Médecine, 75270 Paris cedex 06, France and [1]Pierre Fabre Médicament, Laboratoires Pierre Fabre, La Chartreuse, 81106 Castres cedex, France.

For at least 40 years, acetyl-leucine has been successfully used in clinical practice to reduce the imbalances and neurovegetative signs associated with acute vertigo crisis. Moreover, in animal models, acetyl-leucine have been shown to accelerate vestibular compensation following unilateral labyrinthectomy, while having only minor effects on normal vestibular function. The cellular mechanisms underlying acetyl-leucine's action are unknown. Using intracellular recordings in slices, we tested whether acetyl-leucine could directly act on the two main types of neurons (type A and type B cells) identified in the guinea-pig medial vestibular nucleus (MVN) according to their distinct membrane properties.

About 20% of type A and 50% of type B neurons were found to be sensitive to bath-application of 1 mM acetyl-leucine. While about half of these cells were hyperpolarized and inhibited by the drug, the other half were in contrast depolarized and excited. Actually, the nature of the response to acetyl-leucine depended on the membrane potential of the recorded cell: the mean potential of the neurons excited by this compound was significantly lower than for non-sensitive cells, whereas the neurons inhibited by acetyl-leucine had higher than normal resting potentials.

Altogether, these data suggest that acetyl-leucine (a) mainly acts on type B MVN neurons, (b) could tend to bring back their membrane potential towards its mean value of about -60 mV following pathological hyperpolarisation or depolarisation. Since abnormal resting potentials of MVN neurons are associated with unilateral labyrinthectomy in animal model, the present study suggest how acetyl-leucine could contribute to decrease acute vestibular disorders. Further studies on the isolated brain are needed to test this hypothesis.

OCULOMOTOR SYSTEM: VESTIBULO-OCULAR AND OPTOKINETIC SYSTEMS

721.1

NADPHDIAPHORASE ACTIVITY IS ASYMMETRICALLY DISTRIBUTED IN THE TURBOT BRAIN DURING THE PERIOD OF EYE MIGRATION. I.K.S.Jansen* and P.S.Enger. Inst. of Physiology and Inst. of Biology, Univ. of Oslo, Norway.

The eye migration during metamorphosis in flatfish leads to a misalignment of visual and vestibular frames of reference. The process is associated with a major reorganization of vestibulo-ocular pathways in the brain. In attempts to identify the processes which might be involved we have examined the NADPH diaphorase activity histochemically in larval and juvenile turbots.

Before eye migration there is very little NADPH diaphorase reactivity in the brain. As the larvae start tilting to the right side and the right eye begins its dorsal migration, we find diaphorase activity in several regions related to the vestibulo-ocular system. In two of these, the reactivity is asymmetrically distributed between the right and the left sides during the period of eye migration. In the optic tectum, the earliest reactivity is detected predominantly on the left side, about at the time the eye migration is initiated. A few weeks later, at the climax of metamorphosis, the reactivity in the corpus cerebelli is similarly asymmetric, and most intense on the left side. In juveniles, after the eye migration, the NADPH diaphorase reactivity is equal on the two sides in both structures.

NADPH diaphorase activity is commonly used as a histological marker for Nitric Oxide Synthase. The present observations suggest that Nitric Oxide might be involved in the reorganization of the vestibulo-ocular pathways during eye migration in flounders.

ANATOMY AND PHYSIOLOGY OF VESTIBULAR AND INTERNUCLEAR NEURONS RESPONSIBLE FOR NASALLY-DIRECTED EYE MOVEMENT IN TELEOSTS. H. Suwa* and R. Baker. Department of Physiology and Neuroscience, New York University Medical Center, 550 First Avenue, New York, New York 10016.

Selective unilateral MLF inactivation in teleosts, either by lidocaine or lesion, blocks all nasally-directed movement of the ipsilateral eye. To determine the neuronal structure and function necessary for regulating medial rectus motoneurons (MR Mns), intra-axonal records were obtained from the MLF in closely related cyprinids (goldfish, zebrafish) and a distantly related perciform (sunfish) during horizontal visuo-/vestibuloocular reflexes and saccadic eye movement. Electrical stimulation of the horizontal canal nerve produced disynaptic (1.5 ms) EPSPs in ipsilateral MR Mns, but IPSPs were not detected in contralateral MR Mns. Identified second order excitatory vestibular neurons (EVNs) exhibited both head/eye velocity and position signals. Biocytin labeling demonstrated the EVNs to be concisely located in the ventrocaudal anterior octaval nucleus directly below the VIIth nerve and lateral to the gustatory tract. Axons of EVNs entered the ipsilateral MLF, ascended without collaterals and distributed 1-3 branches to terminate with discrete butons on 6-12 MR Mns. Hence, teleosts possess a homologue of the Ascending Tract of Deiters exhibiting physiological signals similar to those described in mammals, but with an axonal pathway within the lateral border of the MLF. Robust eye velocity and eye position sensitivity was found to originate exclusively from internuclear (Int) Ns in the ventral hindbrain. The parent axon of each Int N formed a calyx-like ending on a single MR Mn and then radiated 1-3 branches that terminated on 3-6 other MR Mns. All the axon collaterals and terminals of Int Ns and EVNs were therefore confined within the MR subdivision. Int Ns were located in two separate subgroups axially contiguous with, but dorsolateral to, the rostral and caudal abducens Mn subgroups. Biocytin labeling of single Int axons in the MLF lightly-labeled other Int somata in either the rostral or caudal, but not Abd Mn, subgroups. Transneuronal label of presynaptic axon arbors suggests transport through gap junction located on lateral Int dendritic bundles. These data document the ubiquitous and dominant role Int Ns play in producing parallel symmetric horizontal movement of both eyes. We suggest that this symbiotic pattern of horizontal canal related vestibular and internuclear premotor organization is remarkably well conserved in vertebrates. Nonetheless, while hindbrain Int and EVN subgroups appear anatomically identical between members of the same family (cyprinids), the eye movements and position/velocity signals can still differ for closely related species. OCULOMOTOR PERFORMANCE AND ADAPTATION IN THE ZEBRAFISH AND CLOSELY RELATED CYPRINIDS. E. Gilland*, E. Marsh, H. Suwa, and R. Baker. Department of Physiology and Neuroscience, New York University Medical Center, 550 First Ave, New York, NY, 10016

Eye movements in the genus *Danio* (*D. rerio* and *aequipinnatus*) were quantified using the scleral search coil technique and compared to the goldfish (*Carassius auratus*), a closely related cyprinid. In the danios, a continuous pattern of spontaneous scanning eye movements occurred at 0.5 Hz consisting of single large eccentric steps in eye position, alternating temporal and nasal, followed by a rapid position decay towards the center of the oculomotor range at a rate of 2-7°/s. In goldfish, the decay was much slower (<1°/s) and often exhibited perfect velocity to position integration. Combined optokinetic (OKR) and vestibuloocular (VOR) reflexes were elicited by vestibular and visual sinusoidal stimuli from 0.06-8.0 Hz at 32°/s peak velocity. In the danios at 0.125 Hz, peak eye velocity ranged from 20-28°/s with an average gain of 0.75 (eye/head velocity); however, VOR gain in the dark was 0.5 with a phase angle of 0°. At 1 Hz, VOR gain increased to 1.0 with a 40° phase lead. At 3 Hz, the resonant frequency, gain peaked at 2.0 with a phase lead of 70° and then decreased, reaching 1.0 with a 20° lead by 8 Hz. Comparable Bode plots in goldfish were nearly flat from 0.06-8 Hz (gain of 1.0, 0° phase) with the resonant frequency observed at 1.5 Hz. Vestibular step stimuli of 4 s duration, produced steps of eye velocity in danios with a latency of 13 ms. Maximum eye velocity was reached by 100 ms and then decayed towards zero with a time constant <1.5 s which was an order of magnitude faster than the 15 s decay for the velocity storage integrator in goldfish. In danios and goldfish, OKR gain was 0.5 at 0.125 Hz and decreased to 0.2 at 1 Hz. The VOR could be adapted to a gain of either 2.0 or 0 with visuo-vestibular training. OKR gain also increased after visual training, however, unlike in goldfish, eye velocity was never entrained to the stimulus period. The oculomotor behavioral repertoire of the danios differed significantly from goldfish despite a fundamentally identical pattern of visuo- and vestibuloocular neurons and circuitry. We therefore suggest that differences in the intrinsic properties of neurons essential for velocity to position and velocity storage integration are responsible for the disparate VOR and OKR behaviors in zebrafish and goldfish. (NIH EY02007 & NS13742)

721.4

SEGMENTAL ARRANGEMENT OF VESTIBULOOCULAR NEURONS IN THE HINDBRAIN OF ADULT ZEBRAFISH AND CLOSELY RELATED CYPRINIDS. R. Baker*, H. Suwa, E. Marsh and E. Gilland. Department of Physiology and Neuroscience, New York University Medical Center, 550 First Avenue, New York, NY 10016.

The hindbrain of all vertebrate embryos is segmentally organized into a series of conspicuous rhombomeric segments (rhs 1-8) that can often be identified in adults by the locations of iteratively homologous reticulospinal neurons and cranial motor nuclei IV-XII. Intra- and extracellular biocytin labeling along with electrophysiological analysis were utilized to distinguish the putative rhombomeric segmental identities for all vestibuloocular neurons with axons ascending within the MLF in the genus *Danio* (*D. rerio* and *aequipinnatus*) with outgroup comparison to goldfish (*Carassius auratus*). Excitatory vestibular neurons (EVNs) projecting to contralateral inferior oblique (IO) and superior rectus (SR) motoneurons (Mns) form compact, but separate, ventromedial and dorsolateral anterior octaval subgroups located in rhs 2. Inhibitory vestibular neurons (IVNs) to the ipsilateral IO and SR Mns and those to the ipsilateral inferior rectus (IR) and trochlear (TRO) Mns appear more caudal in two subgroups overlying the gustatory tract spanning rhs 2-3. Ipsilateral EVNs to medial rectus Mns were tightly clustered, caudal and lateral to, the IVNs at the level of the Mauthner cell in rh 4. EVNs, comprising the entire tangential nucleus extend across rhs 5 and project to contralateral IO, SR, IR and TRO Mns. EVNs to the contralateral abducens (Abd) Mns and internuclear (Int) Ns to contralateral MR Mns were also located in rhs 5-6. EVNs to contralateral TRO and IR Mns were observed in the ventral descending octaval nucleus dorsolateral to the caudal subgroup of Abd Int Ns in rhs 6. Non-vestibular ventromedial subgroups situated in rhs 7-8 contained the horizontal eye velocity and position integrators presumed to target Abd Mns and Int Ns. We conclude that vestibuloocular subgroups are readily distinguishable within five rhombomeric segmental locations. We therefore suggest a segmental origin of their neuroepithelial precursors in embryonic rhombomeres 2-6; however, by patterning mechanisms likely different from those giving rise to either reticulospinal or motoneurons. The structural similarity of this vestibuloocular pattern within Cyprinidae and the equally striking resemblance with birds and mammals argues that the zebrafish model can be used to establish the role of particular gene products in rhombomere-specific vestibulooculomotor development. SENSORY-MOTOR COORDINATE TRANSFORMATION IN THE HORIZONTAL VOR OF THE FROG. C. Pantle and N. Dieringer*. Dept. Physiology, Pettenkoferstr. 12, 80336 München, Germany.

The pulling direction of the lateral rectus eye muscle and the plane of the horizontal semicircular canal of frogs deviate by an angle of 16°. To make a compensatory horizontal VOR possible the basic vestibular input from the horizontal canal to abducens motoneurons has to be transformed. Therefore we studied the maximal activation direction (MAD) of the abducens nerve of decerebrated, immobilized frogs. Multi-unit abducens nerve responses were evoked by oscillations around an earth-vertical axis. With respect to this rotation axis the static head position was systematically changed in pitch and in roll. To determine the MAD we used the null point technique and searched for response reversal points (minimal amplitude and 180° phase shift).

The plane of the abducens MAD was not coaligned with the plane of the horizontal canal, but suggested a contribution from the vertical canals. Complete cerebellectomy or ipsilateral labyrinthectomy did not alter the abducens MAD significantly. Thus, the abducens MAD depends entirely on the inputs from contralateral canals. After a section of the contralateral anterior canal nerve the abducens MAD was significantly changed and closely aligned with the plane of the horizontal canal. Consequently, the abducens MAD is composed of inputs from the contralateral anterior and horizontal canals in a ratio of 1 : 3.7. Because of this convergence the abducens MAD plane and the lateral rectus pulling direction are very closely coaligned.

TARGETS OF FLOCCULAR ACTION IN THE GUINEA PIG'S IN VITRO WHOLE BRAIN PREPARATION. A.Babalian, N.Vibert, A.Grantyn* and P.-P.Vidal. L.P.P.A., CNRS-Collège de France, 15 rue de l'Ecole de Médecine, 75006, Paris, France.

In experiments on the isolated in vitro whole brain of the guinea-pig the effects of stimulation of the flocculus were studied at the level of: (a) oculomotor nerve and nucleus; (b) abducens nerve and nucleus; (c) abducens motoneurons; (d) second order vestibular neurons. In addition, the integrity of the cerebellar network was confirmed by recordings of characteristic field potentials in the floccular lobe following stimulation of the inferior olive and vestibular nerve.

Activation of the flocculus had no effect on the responses in the oculomotor and abducens nerves and nuclei evoked from the contralateral (with respect to the stimulated flocculus) vestibular nerve. On the other hand, activation of the flocculus significantly reduced discharges of oculomotor nerves on both sides following ipsilateral vestibular nerve stimulation. In the same conditions of the ipsilateral vestibular nerve stimulation, floccular action did not influence the discharge in the contralateral abducens nerve, while it depressed inhibitory response in the ipsilateral abducens nerve. At the level of ipsilateral abducens motoneurons this action of the flocculus was manifested as a depression of disynaptic IPSPs elicited from the ipsilateral vestibular afferents.

Some of second order vestibular neurons, monosynaptically activated by vestibular afferents, received short-latency inhibition from the flocculus and were thus characterized as floccular target neurons (FTN). All these neurons recorded so far belonged to the type B vestibular cells, previously identified on slices and in the in vitro whole brain preparation.

Different paradigms of long-term (hours) pairing of the vestibular nerve and floccular stimulations did not modify output responses of the oculomotor nerves evoked by activation of vestibular afferents.

Floccular Region Purkinje cells during pursuit & VOR in head-free Squirrel monkey. T. Belton* & R.A. McCrea. Comm. on Neurobiology, Univ. of Chicago, 947 E. 58 th St., Chicago, Ill. 60637.

The activity of Purkinje Cells (Pkc) in the flocculus and ventral paraflocculus of squirrel monkeys was recorded during head-free and head-restrained target pursuit and whole-body rotation using 0.5 and 2.3 Hz stimuli. Monkeys had 90 degrees of head movement in the yaw plane by means of an occiput-attached rod that extended upward coaxially with the c1-c2 juncture, which could be clamped to permit simple changeover to a head-restrained condition. Of 89 neurons recorded during pursuit, the modulation of virtually all was reduced when the animal was free to use combined eye and head movements as compared to eye movements alone to track the target. Most all Pkcs did not encode the gaze velocity related to head-free pursuit. The reduction seen in the free-head condition was explainable by the reduction of the eye velocity seen during head-free pursuit in one-half of the cells. The peak firing rate modulation during head-restrained pursuit was usually larger than that recorded during cancellation of the VOR at 0.5 Hz by an averaged ratio of 3.5 to 1.0 sp./sec. During cancellation of the VOR at 2.3 Hz the modulation re. the turnatable was either unchanged from that at 0.5 Hz, in one-half of units, or was increased. In VOR tests, Pkcs modulated in phase with eye velocity, due to the predominant eye velocity signal of our recorded units, and during head-free VOR tests, in which the monkey generated a compensatory head-on-shoulders movement rather than solely eye movements to fixate the target, Pkc modulation was very reduced or non-existent.

Vergence Related Changes in the Firing Behavior of Ascending Tract of Deiters Neurons during Combined Angular and Linear Head Rotation.

Chiju Chen-Huang* and Robert A. McCrea The Committee on Neurobiology, University of Chicago, Chicago, IL 60637.

The ascending tract of Deiters is a central vestibulo-ocular reflex pathway from the vestibular nuclei to the medial rectus subdivision of the oculomotor nucleus. The firing behavior of horizontal canal related secondary vestibular neurons whose axons project into the ipsilateral ascending tract of Deiters (ATD) was recorded in alert squirrel monkeys. The monkeys were trained to fixate small, earth stationary or head stationary LED targets and to pursue small moving targets projected onto a tangent screen. During experiments monkeys were seated on a vestibular turntable with their head fixed in the plane of the horizontal semicircular canals. Different combinations of angular and linear accelerations were applied by changing the position of the monkey, and the axis rotation, on the turntable. Ascending tract of Deiters secondary vestibular neurons (ATD neurons) were identified by their short latency orthodromic response following electrical stimulation of the ipsilateral vestibular nerve, their antidromic response following electrical stimulation of the ipsilateral ATD, and their sensitivity to head rotation in the plane of the horizontal semicircular canals.

The response of ATD neurons to vestibular stimuli was dramatically affected by the oculomotor behavior circumstance. Most ATD cells fired in phase with ipsilateral head velocity during angular table rotations (AVOR) when the monkey fixated distant targets and in phase with ipsilateral eye velocity during smooth pursuit. During VOR cancellation the response of most ATD cells reversed, and their firing rate was in phase with contralateral head velocity. During fixation of far earth fixed targets the firing rate of most ATD neuron was weakly related to linear head velocity. This linear velocity sensitivity increased inversely as a function of target distance. Considered together, the change in sensitivity of ATD neurons to linear velocity as a function of target distance was proportional to the change in the gain of the eye movements.

In sum, ATD neurons carry signals related the HVOR, the LVOR and eye movements. The pathway appears to provide signals that are appropriate, and possibly sufficient, for producing the changes in eye velocity gain of medial rectus motoneurons related to the angular and linear VORs during vergence. VISUAL ENHANCEMENT OF THE HUMAN VOR AT HIGH FREQUENCIES OF HEAD ROTATION V.E. Das, A.O. DiScenna, A. Feltz, S. Yaniglos, A.Z. Zivotofsky, J.S. Stahl, and R.J. Leigh*
Ocular Motor Lab., VA Medical Center and Case Western Reserve Univ., Cleveland OH 44106

We recently demonstrated that if human subjects are rotated horizontally at a constant frequency of 2.8 Hz, but at different head velocities, the gain of the VOR during visual fixation (VVOR) is adjusted so that retinal slip is held below ~5 deg/sec, and vision remains clear and stable. Such changes in VOR gain do not occur if subjects imagine a stationary target in darkness. We set out to determine whether visually mediated eye movements could contribute to modulation of the VOR at high frequencies. Three subjects viewed a stationary target either directly, or through an optical stabilization device that required eye movements to be twice the amplitude of head movements in order to maintain foveation. Subjects were rotated at 5 frequencies between 0.2 and 3.5 Hz, with peak head velocity of up to 50 deg/sec. Results: With direct viewing, we confirmed that VVOR gain increased at higher peak head velocities at each frequency. With stabilized viewing, VVOR gain declined as a function of the frequency of head rotation, (*not* peak head velocity, or acceleration). For head rotations at 3.5 Hz, with stabilized viewing, the 3 subjects' gains were increased by 7, 8, and 23% compared to corresponding values from the direct-viewing eye. Thus, visually-mediated eye movements are involved in supplementing the gain of the VOR at high frequencies.

OTOLITH-DEPENDENT ADAPTATION OF EYE-POSITION-DEPENDENT VERTICAL SKEW. I.S. Maxwell* and C.M. Schor, University of California, Berkeley, CA 94720.

The relative participation of the vertical recti and obliques changes with horizontal and vertical eye position - due to orbital mechanics - and with head tilt - due to otolith stimulation and to counterroll. The coordination of muscle forces is plastic and prior experiments have demonstrated eye-position-dependent (EPD) and head-position-dependent (HPD) adaptation of binocular vertical eye alignment (skew). The present experiments examined the interdependence of EPD and HPD adaptive mechanisms. During a one hour training period, subjects attempted to fuse vertical visual disparities that changed as a function of both vertical eye position and head position. An 8% afocal magnifier was in front of one eye with the head rolled 45 deg to the right and front of the other eye with the head rolled 45 deg to the left. This created increasingly right-over-left vertical disparities as a function of eye elevation when the head was tilted to one side and increasingly left-over-right disparities when the head was tilted to the other side. Vertical phoria (binocular alignment in the absence of a stimulus for fusion) was tested using a version of the Lancaster test before and after training. Following training, each subject showed EPD changes in their vertical phorias that were in opposite directions at the two head positions. EPD and HPD adaptive mechanisms, therefore, are integrated and not independent processes. Additional experiments suggested that the EPD aftereffect was not tuned specifically to the head position at which training was obtained but was proportional to the output of the otoliths.

DEVELOPMENT OF THE OPTOKINETIC SYSTEM IN MACAQUE MONKEYS C. Distler[*1], K.-P. Hoffmann[1], F. Vital-Durand[2], [1]Allgemeine Zoologie & Neurobiologie, Ruhr-Universität Bochum, Postf. 102148, D-44780 Bochum, Germany [2]INSERM U371 Cerveau et Vision, F-69500 Bron, France

Using electrooculography we for the first time quantitatively investigated the development of the horizontal optokinetic nystagmus (OKN) in baby monkeys. Six macaque monkeys (Macaca fascicularis) were studied longitudinally on a weekly basis during the first four months of life. Eye movements were recorded during monocular and binocular wholefield stimulation with bright dots of varying size moving in clockwise or counterclockwise direction at velocities ranging from 10°/s to 120°/s. The data were compared to findings in two normal adults measured in the same setup.

At low stimulus velocities (10°/s and 20°/s), monocular OKN was largely symmetrical already at about 3 weeks of age, i.e. stimulation from nasal to temporal (null-direction) was almost as effective as stimulation from temporal to nasal (preferred direction). By contrast, steady state monocular OKN was much more asymmetric at higher stimulus velocities (40°/s-120°/s), i.e. temporal to nasal stimulation elicited higher gain OKN than stimulation from nasal to temporal. Symmetry at higher stimulus velocities was reached at 3-4 months of life. This increase in symmetry was largely due to a stronger increase of eye velocity in response to stimulation in the null-direction. The gain of OKN continued to increase slightly especially at higher stimulus velocities even at the end of the period investigated. The largely symmetrical OKN at low stimulus velocities can be explained by the bilateral retinal input to the subcortical OKN pathway present in primates. By contrast, the slower development of symmetry at higher stimulus velocities may be related to the maturation of the cortical pathway for motion analysis.

THE OPTOKINETIC RESPONSE TO VELOCITY STEPS AND UNDER STROBOSKOPIC ILLUMINATION IN MONKEYS. J. Kröller* and F. Behrens Freie Universität, Physiol. Institut, Arnimallee 22, 14195 Berlin, Germany.

In two awake untrained squirrel monkeys the horizontal optokinetic nystagmus (OKN) was studied. We focussed on the buildup of the slow-phase eye velocity during the first two seconds and on the time after OKN interruption. Using an optokinetic drum of black and white stripes, a paradigm was designed to achieve abrupt changes between a pattern appearing stationary or rotating. Velocity steps from zero to 14 to 73 deg/s and back to zero could be achieved.

OKN onset: The mean latency between pattern movement onset and onset of slow-phase eye movements was 82.8 ± 16.5 ms. The initial velocity increase could be approximated by a straight line (slope 103 ± 67 deg/s^2). Eye movement velocity at the end of the linear part (duration on average 300 ms) increased linearly with drum velocity(slope 0.59). When after OKN elicitation by the rotating pattern, the pattern was suddenly illuminated stroboscopically the monkeys showed two modes of respose: (1) the OKN ceased when the preceeding rotation period was short or (2) the monkeys continued with OKN as before when the stimulation period was longer. The threshold stimulation interval between these modes was 5-7 s. This indicated that a time-consuming process for accumulating activity in the velocity storage was necessary for the monkey's capability to continue with nystagmus under stroboscopic light.

OKN-offset: After OKN under strobe light a well devellopedOKAN in darkness could be elicited. The influence of a fully charged OKN velocity storage mechanism on eye movements after a sudden exposure of a stationary surround was studied in 23 recording sessions. After OKN interruption the velocity decay commenced after an interval of 83.5 ± 16.6 ms. On average the slope of decay was -195.4 ± 83.6 deg/s^2. During the initial 5.8 ±0.98 s of presenting a stationary surround, a slow afternystagmus in the direction of the OKN could be observed.

SPINAL CORD AND BRAINSTEM: ANATOMIC ORGANIZATION

722.1

ANATOMY OF THE DISYNAPTIC FLEXION REFLEX CIRCUITRY IN CAT SPINAL CORD. R.G. Durkovic, J.E. Hoover, A.R. Light and B. Taylor-Blake*. SUNY Health Science Center, Syracuse, NY 13210 and University of North Carolina, Chapel Hill, NC 27599.

The flexion reflex, historically considered as strictly an oligosynaptic reflex, has been shown neurophysiologically to have significant disynaptic components (e.g., Leahy and Durkovic, J. Neurophysiol. 66:450, 1991). Using neuroanatomical techniques the present studies revealed potential spinal circuitries for such disynaptic connections for cutaneous evoked reflexes of the hindlimb. First, transganglionic transport of HRP/WGA-HRP was used to examine spinal projections of saphenous (S) and superficial peroneal (SP) nerves. One cat exhibited transsynaptic labeling of interneurons in L_{5-6} in laminae IV-VIII and X for each nerve, a greater ventral distribution of interneurons receiving direct cutaneous inputs than expected.

Other animals received an injection of fluorescent-labeled latex microspheres into the region of hindlimb flexor motoneuron pools. Weeks later the S or SP nerves were stimulated electrically and the spinal cords processed for c-*fos* expression. Interneurons labeled retrogradely with fluorescent beads that also expressed c-*fos* are putative last-order interneurons of the flexion reflex. Such cells were found in L_{4-7}, rostral to the injection site in laminae V-VII and X. Caudal to the L_7 or S_1 injection site such cells were also observed in laminae I, II and IV.

The common locations of interneurons receiving direct inputs from cutaneous afferents (HRP data) and last-order flexion reflex interneurons (double-labeling data) suggest that laminae V-VII and X interneurons in L_{5-6} are part of the disynaptic flexion reflex circuitry. In addition certain rostrally projecting interneurons in laminae I, II, IV-VII and X and other double-labeled L_{4-7} neurons represent potential disynaptic inputs to flexor motoneurons should they receive direct inputs from cutaneous afferents. Supported by NSF Grant IBN9220206 and NIH Grant NS16433.

CLASSICALLY CONDITIONED *C-FOS* EXPRESSION IN SPINAL CAT M.L. Nguyen and R.G. Durkovic.* Dept of Physiology, SUNY Health Sci. Ctr., Syracuse, NY 13210.

Our study was designed to utilize *c-fos* immunohistochemistry to help define the neural circuits related to associative long-term potentiation (LTP) of spinal reflexes. Cutaneous nerve stimuli were applied to the unanesthetized, decerebrate spinal cat preparation in a manner typical of classical conditioning paradigms. The only operative procedures were T_{10} spinal transection, exposure of two cutaneous nerves in the left hindlimb, and decerebration, all done under halothane anesthesia. Conditioning procedures began 2 hrs after spinal transection. For conditioning animals, saphenous nerve stimulation (10 Hz/1.5 sec) served as the conditioned stimulus (CS). The onset of the unconditioned stimulus [(US): superficial peroneal nerve stimuli (30 Hz/0.5 sec)] overlapped the last 0.5 sec of each CS. Stimuli were supramaximal for Aß and Aδ fibers, but below threshold of C fibers. Such paired stimuli were given every 2 min for 30 trials. Each "paired" animal was matched with a control animal studied the same day. Sensitization control animals received 30 "unpaired" CSs and USs that were alternately presented at 1 min intervals. Following the 1 hr stimulation periods, a 2 hr period passed before the animals were perfused, and the spinal cords were processed for the presence of *c-fos*-like immunoreactivity.

Nearly double the number of *c-fos* labeled neurons were observed in the paired compared to the unpaired stimulus paradigm. In addition, the two nerve stimulation paradigms produced different *c-fos* distributions within the laminae of the lumbro-sacral segments of the spinal cord. For the paired paradigm, the number of labeled nuclei in dorsal laminae (I-II) were more than double for the paired than for the unpaired paradigm. The number of *c-fos* labeled cells in laminae IV-VII was lower than in the dorsal laminae but was also often higher in paired compared to the unpaired control animals. The present results suggest primary involvement of laminae I and II neurons in the long-term reflex enhancement of Aδ cutaneous nerve activated reflex circuits, the circuitry that exhibits potentiation in the classical conditioning paradigm employed (Durkovic, Neurosci. Letters 39:155). Supported by NSF Grant IBN9220206.

Descending projections of the lateral paragigantocellular nucleus (LPGi): possible anatomical basis of role in lumbosacral reflexes

G.E. Hermann*, G.M. Holmes, R.C. Rogers, M.S. Beattie, and J.C. Bresnahan, Depts. Cell. Biology, Neurobiology, and Anatomy, and Physiology, Ohio State University, Columbus, OH 43210

The autonomic and somatic motoneurons (MNs) which innervate the smooth and striated muscles essential for normal eliminative and sexual reflexes are located in the lumbosacral segments of the spinal cord. Although segmental circuitry is capable of reflexive regulation of these functions, descending control of this spinal circuitry is evidenced by the loss of coordinated control demonstrated by spinal cord injured individuals. Possible sources of this descending influence include the nucleus raphe obscurus (nRO) and lateral paragigantocellular nucleus (LPGi). Our previous electrophysiologic and anatomic studies (SNS 1993-'95) demonstrated that the nRO is capable of modulating the activity of pudendal motoneurons. The nRO sends descending fibers which arborize in the thoracic and sacral intermediolateral cell column and lamina IX in the lumbosacral cord with apparent direct connections with these MNs. Similar anatomic studies were used to simultaneously label ("fluororuby") LPGi projections to the spinal cord and retrogradely label (fluorogold) MNs innervating the external anal sphincter, bulbospongiosus, and the ischio-cavernosus muscles. In contrast to the discrete distribution patterns of descending fibers and arborizations from the nRO, the LPGi maintains a significantly more widespread and robust distribution and arborization pattern in the lumbosacral cord. Apparent contact with labelled pudendal MNs was more intense than that seen with nRO fibers. These suggest that, compared with the nRO, descending influences from the nLPGi may have a more generalized impact on spinal sexual and eliminative reflexes. (Support: NS-31193; Paralyzed Veterans of America SCRF 1254)

PUDENDAL MOTONEURON FUNCTION IN INTACT AND CNS INJURED RATS: ALTERATIONS FOLLOWING BRAINSTEM LESIONS AND SPINAL TRANSECTION. M.S. Beattie*, G.M. Holmes, G.E. Hermann, R.C. Rogers, J.C. Bresnahan. Depts. of Cell Biology, Neurobiology, and Anatomy; and Physiology. The Ohio State University, Columbus, OH 43210.

In the rat, motoneurons innervating the external anal sphincter (EAS) and bulbospongiosus (BS) muscles receive descending input from both the nucleus raphe obscurus (nRO) and lateral paragigantocellular nucleus (lPGi). In normal, unanesthetized rats, the recto-anal reflex (RAR) is readily elicited by transient, small (3-5mm) distentions of the distal rectum and EAS. This fictive passage of a fecal bolus results in EAS muscle contractions which are anesthesia sensitive. Therefore, these studies must be conducted in awake animals. The RAR of intact animals, consists of brief (200-1000 msec), low level activity in the EAS that occurs during and/or after anorectal distention. In spinally transected animals, EMG activity was profoundly increased, but limited to the period of time immediately following the termination of distention. Rats with lesions of the nRO, also exhibit elevated RAR activity 2 days post-lesion. However, the duration of the bursts are not significantly elevated. By 7 days post-nRO lesion, all measures of RAR activity return to within normal ranges. Lesions of the lPGi do not produce the post-lesion hyperreflexia seen in nRO lesioned males. Instead, the EAS appears unable to maintain closure of the orifice following distention. These data provide further evidence of multiple descending pathways regulating reflexes involving pudendal motoneurons and suggest that the nRO and lPGi may regulate different aspects of EAS reflex function. (Support: NS-31193; Paralyzed Veterans of America, SCRF 1254).

IN-VIVO MICRODIALYSIS IN THE RAT LUMBAR SPINAL CORD: ALTERATIONS IN ENDOGENOUS 5-HT RELEASE FOLLOWING BRAINSTEM STIMULATION. G.M. Holmes*, J.C. Bresnahan, R.C. Rogers, M.S. Beattie, R.L. Stephens, Jr. Depts. of Cell Biology, Neurobiology, and Anatomy; and Physiology. The Ohio State University, Columbus, OH 43210.

In the rat, motoneurons (MNs) innervating the external anal sphincter (EAS) and bulbospongiosus (BS) muscles are located in the dorsomedial nucleus (DM) of the L5-L6 spinal cord and receive descending input from both the nucleus raphe obscurus (nRO) and lateral paragigantocellular nucleus (lPGi). There is ample evidence that nRO and lPGi projections contain serotonin (5-HT) and neuroactive peptides. Using chloral hydrate anesthetized male rats, a concentric microdialysis probe (1mm length, 240μ OD, 20kDa cutoff) was placed at a 30° angle between the L5 and L6 root entry zones within the DM (depth: 1.5mm). A midline metal electrode (bregma: -13.5mm, depth: -8.5mm) was positioned within the nRO. Following 1.5h recording of basal 5-HT release (15min collections), stimulation trains (15min, 20-100μA, 20Hz, 1s on/off) were initiated at 45min intervals. Higher (80-100μA) stimulation intensities increased endogenous 5-HT release (measured by HPLC-EC) during the corresponding collection period (181% basal). Mean basal values for 5-HT dialysates were 616 fg/5μl. In subsequent periods, 5-HT levels appear to be suppressed for periods of greater than 1hr following stimulation (80-100μA). This suppression may mimic the reduction in spinal 5-HT release seen after intrathecal 5-HT (48% basal). These data provide evidence of physiological relevance of brainstem serotonergic output onto L5-L6 motoneurons. (Support: NIH, NS-31193; Paralyzed Veterans of America, SCRF 1254).

DESCENDING PROJECTIONS FROM THE CAUDAL VENTROLATERAL MEDULLA TO THE LUMBOSACRAL CORD OF THE MALE HAMSTER: POSSIBLE ROLE IN REPRODUCTIVE BEHAVIOR.
P.O. Gerrits*, L. Kerstens, V.G.J.M. VanderHorst and G. Holstege.
Department of Anatomy and Embryology, University of Groningen, Oostersingel 69, Medical School, 9713 EZ Groningen, The Netherlands.

Recent findings in the cat indicate that the nucleus retroambiguus (NRA), a compact column of premotor interneurons located in the ventrolateral tegmental field of the caudal medulla, projects contralaterally to distinct motoneuronal cell groups of the lumbosacral cord. Comparable studies carried out in the rat suggest a similar pathway. These NRA projections to the lumbosacral cord are thought to form the common pathway for reproductive behavior (VanderHorst and Holstege, 1995). No information is known concerning the NRA-lumbosacral pathway in the hamster.

In this study descending projections from the NRA to the lumbosacral cord were studied in male hamsters (mesocricetus auratus; 130-150 g). They were injected with WGA-HRP (2.5% solution; 50 nl) unilaterally in the area of the NRA. To avoid descending ipsilateral projections from reticulospinal fibers adjacent to the NRA, spinal cord hemisections were made at the level of the T2 spinal cord segment.

The results of the present study show that fibers originating in the NRA cross the midline at the level of the NRA and descend within the lateral and ventrolateral funiculi and terminate mainly in discrete lumbosacral motoneuronal pools of the contralateral spinal cord, probably innervating hindlimb, axial, and pelvic floor muscles. As these muscle groups are probably active during reproductive behavior, the NRA may play a role during copulation.

722.7

DESCENDING PROJECTIONS FROM THE CAUDAL VENTROLATERAL MEDULLA OF THE MALE RAT SELECTIVELY INNERVATE DISCRETE MOTONEURONAL POOLS WITHIN THE LUMBOSACRAL CORD: POSSIBLE ROLE IN REPRODUCTIVE BEHAVIOR. A.Z. Murphy*, M.T. Shipley, V.G. VanderHorst, and G. Holstege Univ. of Groningen, Dept. of Anatomy, Gronigen, The Netherlands, and Univ. of Maryland School of Medicine, Dept. of Anatomy, Baltimore, MD.

Recent findings in the cat indicate that the nucleus retroambiguus (NRA) in the caudal ventrolateral medulla projects contralaterally to distinct motoneuronal cell groups of the lumbosacral cord. However, little information is known regarding the NRA-spinal pathway in the male rat. The present study was conducted to examine the termination pattern of NRA fibers in the lumbosacral cord. Male Wistar rats (250-400 g) were injected with either WGA-HRP (2.5% solution) or BDA (10% solution) unilaterally in the NRA. A cord hemisection was performed at the T4 level to eliminate the contribution of ipsilaterally projecting reticulospinal fibers from adjacent medullary structures. NRA descending fibers crossed the midline at the level of origin and descended within the lateral and ventrolateral funiculi to terminate predominantly within the contralateral spinal cord. Rostral to the lumbar enlargement (T10-T12), dense anterograde labeling from the NRA was confined primarily to motoneuronal pools that innervate the abdominal muscles. In the rostral lumbar enlargement, NRA efferents terminated within motoneuronal pools that innervate axial and hindlimb musculature. Most striking was the dense anterograde labeling present within the motoneuronal pools innervating the iliopsoas. At the L6/S1 levels, dense anterograde labeling was present within the dorsomedial and dorsolateral subnuclei of the ventral horn. These motoneuronal pools innervate the external anal and bulbospongiosus muscles, and the external urethral and ischiocavernosus muscles respectively. The results of these studies show that NRA-spinal projections provide selective input to discrete lumbosacral motoneuronal pools. As these muscle groups are all utilized during mating, the NRA may play a role in copulatory behavior.

722.8

THE NUCLEUS RETROAMBIGUUS IN THE FEMALE RAT PROJECTS TO SEVERAL DISTINCT MOTONEURONAL CELL GROUPS IN THE LUMBOSACRAL CORD: POSSIBLE ROLE IN LORDOSIS BEHAVIOR. L. Kerstens, V. G. J. M. VanderHorst and G. Holstege*. Dept. Anatomy and Embryology, Faculty of Medicine, University of Groningen, The Netherlands.

In the cat VanderHorst and Holstege (1995) have shown that the nucleus retroambiguus (NRA), an interneuronal cell group in the caudal ventrolateral medulla, projects contralaterally to distinct motoneuronal cell groups in the lumbosacral cord. The authors suggested that this projection might be involved in lordosis behavior. The question arises whether such a pathway also exists in the rat.

Ovariectomized female Wistar rats were injected with 2.5% WGA-HRP in the area of the NRA (1.5-2.5 mm caudal to obex). To eliminate the contribution of ipsilaterally projecting reticulospinal fibers from adjacent structures, hemisections were made at the level of the T4 spinal segment.

The results show that the NRA descending fibers cross the midline at the level of origin and descend primarily within the lateral and ventrolateral funiculi to terminate mainly within the contralateral spinal cord. Rostral from the lumbosacral enlargement dense anterograde labeling was found in the motoneuronal cell groups of the abdominal muscles. In addition, in the rostral half of the lumbosacral enlargement fibers were found to terminate in axial and hindlimb muscle motoneuronal cell groups. In the caudal enlargement dense anterograde labeling was found in the dorsolateral nucleus, which in the female rat mainly contains motoneurons of the external urethral sphincter. Caudal to the enlargement anterogradely labeled fibers were found to terminate ventrally in the ventral horn, where the motoneurons of the tail muscles are located.

The results show that the NRA in the female rat projects to several axial, hindlimb, pelvic floor and tail muscle motoneuronal cell groups. Possibly, this projection represents the final common pathway for lordosis behavior.

Organization of projections from the brainstem to the first cervical segment of the cat. L. Zhou, H. Matsumoto, P.K. Rose, F.J.R. Richmond*. MRC Group in Sensory-Motor Neuroscience, Queen's University, Kingston, ON, Canada K7L 3N6

Motoneurons supplying neck muscles are widely distributed from C1 to C6. The goal of the present study was to describe the distribution of neurons in the brainstem that project to C1 where motoneurons that supply suboccipital muscles predominate. The distribution of neurons stained by injections of Fluororuby or Fluorogold into the ventral horn and adjacent white matter of C1 was compared to previous studies in which the cells of origin of descending spinal tracts were retrogradely stained by labelling axons that projected past C2 or terminated in C2 (eg. Holstege, in Neuroanatomy of the Oculomotor System 1988). The distribution of some cell groups (eg. vestibulospinal, trigeminospinal) was common to both studies, but other cell groups in the medullary and pontine reticular formation were stained much more frequently following C1 injections. These cells were located in nucleus reticularis dorsalis and parvicellularis and the dorsal part of the paramedian nucleus, nucleus reticularis ventralis, and gigantocellularis. Many labelled cells were also found in the rostro-medial quadrant of the superior colliculus. This region contained few stained cells after injection of tracers in C2.

These results indicate that some neurons in the brainstem may selectively innervate regions of the upper cervical spinal cord and may therefore be involved primarily in the control of small head movements by contraction of suboccipital muscles. (Supported by MRC of Canada)

THE ORGANIZATION OF ACROMIODELTOID AND SPINODELTOID MOTOR NUCLEI IN THE RAT. J. E. Hoover*, J. Y. Choi, and J. S. Green. Dept. of Biology, Millersville Univ., Millersville, PA 17551.

We have used the retrograde intraaxonal transport of fluorescent dyes to identify the motoneuron populations that innervate two shoulder muscles, acromiodeltoid (Ad) and spinodeltoid (Sd), in the rat. Both muscles were injected in each animal (n=4) with one of two tracers that fluoresce different colors (e.g., 5-15 μl of 10% Bisbenzimide or 2% Nuclear Yellow). After a 2-5 day transport period, transverse spinal cord sections were cut, mounted, and examined using epifluorescent microscopy. Each muscle injection labeled an average of 30-40 motoneurons, distributed between spinal segments C5 and C7. Both Ad and Sd motor nuclei occupied positions in ventrolateral portions of the ventral horn, in central regions of Rexed's lamina IX. Although there was considerable overlap among the motoneuron populations, the center of the Ad motor nucleus was consistently located more rostral and medial than that for the Sd motor nucleus. These experiments demonstrate that the use of multiple fluorescent tracers is of great advantage for resolving the morphological relationships among adjacent and overlapping motoneuron pools.

JAW-MUSCLE SPINDLE AFFERENT FEEDBACK TO THE CERVICAL SPINAL CORD. D. Dessem* and P. Luo. Department of Oral and Craniofacial Biological Sciences., University of Maryland, Baltimore, MD 21201.

Putative synaptic contacts between jaw-muscle spindle afferents and descending brainstem neurons were studied in rats by combining retrograde and intracellular neuronal labeling. Spinal cord projecting neurons were retrogradely labeled via injection (0.2μl) of horseradish peroxidase (HRP) unilaterally into the cervical spinal cord (C2-C5). Twenty-four hours later, 1-5 jaw-muscle spindle afferent axons were physiologically identified and intracellularly stained with biotinamide (Neurobiotin) on each side of the brainstem. Horseradish peroxidase-labeled neurons were found bilaterally in the supratrigeminal region (Vsup), trigeminal principal sensory nucleus (Vp), parvicellular reticular nucleus (PCRt) and it's alpha division (PCRtA), spinal trigeminal subnucleus oralis (Vo) and interpolaris (Vi) and the medullary reticular formation. Retrogradely-labeled neurons (n=1906) were most numerous in Vo (28%), PCRt (22%) and the ventral part of Vi (10%). These neurons had fusiform (33%), triangular (35%) and multipolar (32%) perikarya and were predominately (58%) medium-sized neurons (20-30μm). A few HRP-labeled neurons were also present in the trigeminal mesencephalic nucleus (Vme) and spinal trigeminal subnucleus caudalis. Appositions between jaw-muscle spindle afferent boutons and labeled spinal projecting neurons were found in the Vsup, dorsomedial part of Vp (Vpdm), dorsomedial part of Vo (Vodm), PCRtA and PCRt. Ninety-two of these labeled neurons (92/918,10%) were approximated by 247 stained spindle afferent boutons. These close appositions (n=92) were predominantly located in the PCRt (40%) and Vodm (29%). Fifty-five percent (136/247) of stained spindle afferent boutons were juxtapositioned with the somata of HRP-labeled neurons while 45% (111/247) closely apposed labeled dendrites. These spinal cord projecting neurons (n=92), approximated by spindle afferent boutons, had multipolar (40%), triangular (33%) and fusiform (27%) cell bodies with maximum diameters of 12-38μm ($\bar{x}$=24.07; SD=5.62). These results indicate that some proprioceptive feedback from Vme reaches the cervical spinal cord (C2-C5) directly and suggests that jaw-muscle spindle afferent feedback reaches this region predominately via relays in Vodm and PCRt. It is hypothesized that these pathways are involved in trigemino-neck reflexes and the coordination of jaw and head movement. Supported by NIH DE10132.

MEDULLARY AFFERENT PROJECTIONS TO ORAL MOTONUCLEI: AN ANTEROGRADE (PHA-L) STUDY IN RABBITS Ying-Hui Yu*, WP Gai and W.W. Blessing Centre for Neuroscience, Flinders University, Bedford Park, SA 5042, Australia.

We have investigated neuronal inputs to hypoglossal, facial and trigeminal motoneurons in rabbits using anterograde transport of *Phaseolus vulgaris* leucoagglutinin (PHA-L), deposited in the dorsomedial medullary region with similar projections in rats (1). In New Zealand White rabbits (3-3.2 kg) anesthetised with 1% halothane in oxygen, PHA-L was iontophoretically applied to the dorsal medulla, just ventral to the rostral portion of the nucleus tractus solitarius and medial to the spinal nucleus of the trigeminal nerve. After 10-12 survival days, rabbits were deeply anaesthetised with sodium pentobarbitone, and perfused transcardially with fixative. The brain was removed, postfixed, sectioned and processed immunohistochemically to demonstrate PHA-L (Vector goat anti-PHA-L, 1 in 5000). Bundles of PHA-L immunoreactive fibbers were found to project into the hypoglossal, facial (especially the ventral and dorsal intermediate subdivisions) and motor trigeminal nuclei, bilaterally with mild ipsilateral predominance. The projection was very discrete and selective for these target regions. These findings suggest that neurons in the injected region may play an important rule in regulating orofacial motor activities such as chewing and swallowing in the rabbit.

RETRUSOR MOTONEURON ORGANIZATION IN THE HYPOGLOSSAL NUCLEUS OF RAT. J. R. McClung, Y. Guo* and S. J. Goldberg. Dept. of Anat., Virginia Commonwealth Univ., MCV, Richmond, VA 23298-0709.

Studies have shown the motor innervation of the rat tongue to be organized with regard to the retrusor and protrusor muscle groups. However, the precise organization of the individual retrusor muscle motoneuron pools in the dorsal aspect of the hypoglossal nucleus has not previously been demonstrated. The current dissection and histological study of the retrusor muscles of the tongue allowed the precise labeling of individual muscles.

We have focused on 1) the microsurgical isolation of the extrinsic bellies of the styloglossus and hyoglossus muscles and, 2) study of the lateral hypoglossal nerve branches in the body of the tongue. Injections of cholera toxin HRP into the isolated muscles revealed separate populations of hypoglossal nucleus motoneurons (MNs). The styloglossus MNs were closely packed in the rostral quarter of the dorsolateral hypoglossal nucleus. The hyoglossus MNs were found between the dorsal and ventral subdivisions of the hypoglossal nucleus throughout the caudal three quarters of the dorsal nucleus. In addition, intrinsic tongue muscles innervated by axons carried in the lateral (retrusor) branch of the hypoglossal nerve had MNs found throughout the central two thirds of the nucleus. These intrinsic muscle MNs are the dominant cell type in the dorsomedial aspect of the hypoglossal nucleus.

Current studies are focused on the innervation ratios and cell sizes in each of the motoneuron pools involved in tongue retrusion.

RETROGRADE TRANSNEURONAL TRACING WITH RABIES VIRUS OF NEURONAL CIRCUITS INVOLVED IN CONTROL OF BUCCOLABIAL FACIAL (VII) MOTONEURONS G. Ugolini*. Lab. de Génétique des Virus, Centre National de la Recherche Scientifique (CNRS), 91198 Gif-Sur-Yvette, FR.

Retrograde transneuronal transfer of rabies virus allows a specific tracing of synaptically linked neurons in absence of neuronal damage, local spread or symptoms of disease (Ugolini 1995, J. Comp. Neurol. 356:457). In the present study, this method was exploited to characterize the neuronal circuits mediating descending control of facial motoneurons (VII MN) to buccolabial muscles. In rats, rabies virus (CVS strain) was injected unilaterally into the buccal and marginal mandibular branches of the VII nerve. The CNS distribution of virus was studied immunohistochemically at sequential 12 hr intervals from 2 to 4 days post-inoculation (p.i.). Virus transfer was time-dependent. At 2 days, labelling involved only retrogradely infected MN in the intermediate and lateral divisions of the ipsilateral VII nucleus (n.). Positive MN showed the same distribution at all times explored. At 2.5-3 days p.i., labelling appeared in CNS cell groups that can be regarded as second-order in view of their projections to intermediate-lateral VII (e.g. n. reticularis parvocellularis, dorsalis, ventralis, gigantocellularis, parabrachial, Kölliker-Fuse bilaterally; spinal trigeminal n. ipsilaterally; tectum and cerebellar medial n. contralaterally). Other cell groups were visualized at 3.5 days p.i. (e.g. n. reticularis magnocellularis, specific regions of cerebellar and trigeminal nuclei, red nucleus, tectum, substantia nigra and cerebral cortex). In addition to second-order, these cell groups can be regarded as higher-order buccolabial-related, since they are involved in control of buccolabial MN and/or project to second-order cell groups infected earlier. The results confirm the specificity of rabies transneuronal tracing, and show that buccolabial-related neurons have some similarities in organization, but also differences, with respect to hypoglossal-related neurons labelled transneuronally with rabies virus (Supported by CNRS UPR9053).

722.15

GABA AND SEROTONIN IMMUNOREACTIVE AXONS CONTACTING TRIGEMINAL MOTOR NUCLEUS NEURONS IN THE RAT. O. TAKAHASHI*, T. SATODA, C. MURAKAMI AND T. UCHIDA. Dept. Oral Anatomy II, Hiroshima University School of Dentistry, Hiroshima 73400, Japan

It appears to be established that various types of afferent inputs exert effects on the trigeminal motor nucleus (Vm) neurons. This study was undertaken to examine quantitatively GABAergic and serotonergic projection to Vm neurons. After injection of cholera toxin B subunit (CTb) into the masseter (Ma) or the anterior digastric (AD) muscles of female Wistar rats, a substantial number of retrogradely labeled neurons were found in ipsilateral Vm. Sequential double immunofluorescence histochemistry for transported CTb and GABA/serotonin (5-HT), revealed that the numbers of GABA-like immunoreactive (-LI) boutons contacting AD motoneurons were twofold as many as those contacting Ma motoneurons. On the other hand, the numbers of 5-HT-LI boutons contacting Ma motoneurons were more than twofold as many as those making contacts to AD motoneurons. It is conceivable that jaw opener motoneurons receive mainly GABAergic afferent inputs, while cells of jaw closer motoneuron group chiefly receive afferents of serotonergic axons. Supported by a Grant-in-Aid for Scientific Research (07771612) from Japanese Ministry of Education, Science and Culture.

722.16

TRIGEMINAL PREMOTOR NEURONS RECEIVING JAW-MUSCLE SPINDLE AFFERENT INPUT. P. Luo* and D. Dessem. Department of Oral and Craniofacial Biological Sciences., University of Maryland Dental School, Baltimore, MD 21201.

Brainstem pathways conveying proprioceptive feedback from the muscles of mastication were studied in rats by combining retrograde and intracellular neuronal labeling. Initially, horseradish peroxidase (HRP) was iontophoresed unilaterally into the trigeminal motor nucleus (Vmo). After 2 days, 1-5 jaw-muscle spindle afferent axons were physiologically identified and intracellularly stained with biotinamide. Following histochemical processing, numerous retrogradely labeled trigeminal premotor neurons were found bilaterally in the parvicellular reticular nucleus (PCRt) and it's alpha division (PCRtA), dorsomedial portions of the spinal trigeminal subnucleus oralis (Vodm) and interpolaris (Vidm) and ventrolateral to the hypoglossal nucleus. Fifty-five percent of these neurons (n=734) were located ipsilaterally while 45% (n=589) were located contralaterally. HRP-labeled neurons were also present contralaterally in the: supratrigeminal region (Vsup); dorsomedial trigeminal principal sensory nucleus (Vpdm); Vmo and the peritrigeminal zone. Stained spindle afferent axon collaterals and boutons were predominantly distributed in Vsup, Vmo, Vpdm, PCRtA, Vodm, PCRt and Vidm. Appositions between spindle afferent boutons and labeled premotor neurons were found in Vsup, Vpdm, Vodm, PCRtA, Vidm and PCRt. Twelve percent of labeled premotor neurons (68/542) were contacted by 165 stained spindle afferent boutons. Contacts were particularly frequent in Vidm where 29% (10/34) of labeled premotor neurons were approximated by 1-8 spindle afferent boutons. In PCRtA, 18% (19/103) of labeled premotor neurons were contacted by 1-5 spindle afferent boutons. Approximately 65% (108/165) of stained spindle afferent boutons approximated labeled premotor neuron dendrites while 35% (57/165) approximated their somata. These interneurons had fusiform (21/68,31%), triangular (24/68,35%), multipolar (18/68,27%) and ovoid (5/68,7%) perikarya with maximum diameters of 13-40μm ($\bar{x}$=24.73; SD=7.88). These results suggest that jaw-muscle spindle afferent feedback reaches the Vmo via numerous pathways and that premotor neurons in Vidm and PCRtA receive particularly strong input from jaw-muscle spindle afferents. Supported by NIH DE10132.

TOPOGRAPHICAL ORGANIZATION OF THE SPINAL INPUT TO THE PERIAQUEDUCTAL GRAY: AN ANTEROGRADE TRACING STUDY IN THE CAT. L. J. Mouton* and G. Holstege. Dept. Anatomy and Embryology, Faculty of Medicine, University of Groningen, The Netherlands.

The mesencephalic periaqueductal gray (PAG) plays an important role in nociception, cardiovascular control, vocalization, lordosis and micturition. To accomplish these functions the PAG receives somatosensory information directly from the spinal cord. Several studies in rat, cat and monkey showed that this ascending system is predominantly contralateral and terminates in the ventrolateral and lateral PAG (vl+lPAG). They suggested a somatotopic organization, i.e. the lumbosacral cord projects to the caudal PAG and the cervical cord to the more rostral PAG. In the present anterograde tracing study in the cat the precise topographical organization of the spino-PAG pathway is studied.

In 10 cats WGA-HRP was injected in the spinal cord, each at a different spinal level. In most cases, prior to the injection a hemisection was made rostral to the injection site. From the brainstem every fourth transverse section was incubated with the TMB method and the anterograde labeling in the PAG was studied.

The results demonstrate that the somatotopic organization of the spino-PAG pathway is **not** predominantly rostrocaudal but medio-lateral. Many neurons in the sacral cord project to those regions of the vl+lPAG which directly border the aqueduct. In the lumbar injected cases labeling was also found in the vl+lPAG, but not in the areas immediately bordering the aqueduct. In addition, much labeling was found in the lateral part of the lPAG and in the laterally adjacent tegmentum. In the C2-C3 injected case labeling was most dense in the outer regions of the vl+lPAG and in the laterally adjacent tegmentum. After injections in the lower cervical and thoracic cord scattered labeled fibers were found within the vl+lPAG and in the adjacent tegmentum.

722.18

THE CORTICOMESENCEPHALIC PROJECTION FROM THE CINGULATE MOTOR CORTEX TO THE PERIAQUEDUCTAL GRAY IN THE RHESUS MONKEY. C.M. Schroeder and R.J. Morecraft*,. Dept. of Anatomy and Structural Biology, University of South Dakota School of Medicine, Vermillion, SD 57069

The midbrain periaqueductal gray (PAG) is a complex structure that is involved in many behaviors ranging from the integration of various somatic and visceral motor responses to pain modulation. Our current understanding of the PAG arises from an enormous body of literature detailing the subcortical connections of the PAG and the various functional affiliations of these pathways. In comparison, the structural and functional relationship between the cerebral cortex and PAG is not as well established. We investigated the corticomesencephalic projection from the cingulate motor cortex (area 24c or M3 and area 23c or M4) to the PAG complex using the anterograde tracers biotinylated dextran amine and tritiated amino acids in 8 Rhesus monkeys. We discovered a direct and strong ipsilateral projection from areas 24c and 23c to the lateral and ventrolateral subsectors of the PAG. Area 24c also projected lightly to the ventromedial subsector where labeling spread to involve the adjacent parabrachial complex. In contrast, area 23c projected lightly to the dorsolateral subsector where labeling spread to involve the adjacent inferior colliculus. In the contralateral PAG, areas 24c and 23c gave rise to terminals ending in the lateral and ventrolateral subsectors exclusively. In general, PAG labeling formed longitudinal columns along the rostrocaudal axis. Finally, a light bilateral projection from areas 24c and 23c ended in the raphe nuclei. Our observations are consistent with the concept of longitudinal PAG organization and suggest that the cingulate motor cortex-PAG projection forms a direct pathway linking part of the cerebral cortex involved with higher-order voluntary motor behaviors to a subcortical site mediating autonomic responses, motor behaviors related to basic physiological drives, pain and analgesia and vocalization.

IDENTIFICATION OF DISTINCT CAUDAL MEDULLARY RAPHE CELLS BASED ON THEIR CENTRAL AND PERIPHERAL INPUTS, AND THE EFFECT OF SEROTONIN. V. Fenik, R.O. Davies and L. Kubin*. University of Pennsylvania, Philadelphia, PA 19104.

Individual medullary raphe cells send axons to functionally distinct regions of the brainstem and spinal cord. Some of them contain serotonin (5HT) and are most active during wakefulness and least active during desynchronized sleep. To elucidate functions of caudal raphe cells, we began to determine the relationship between their selected central and peripheral inputs and axonal projections. In decerebrate, paralyzed, artificially ventilated cats, we recorded extracellularly from spontaneously active cells located on the midline of the ventral half of the medulla (0-3.5 mm rostral to the obex) and studied their sensitivity to tactile and noxious stimuli applied to the hindlimbs, iontophoretic administration of 5HT, and the presence of antidromic responses evoked from spinal cord (T3-6) and/or medullary hypoglossal and solitary tract nuclei. The 25 cells studied to date fell into three groups: type I (n=9), excited or not affected by 5HT, excited by tactile and sometimes acoustic (n=4) stimuli, and weakly responsive to noxious stimuli; type II (probably serotonergic, n=6), inhibited by 5HT, no tactile input and excited during painful stimulation of muscle and/or joint receptors leading to blood pressure and motor tone increases; the remaining 10 cells had weak and mixed responses to the studied inputs. Spinal axonal conduction velocities were 12-41 m/s for type I cells (n=3), and < 2.5 m/s for the other two groups (n=5). Type I and II cells, having opposite responses to 5HT and different central and peripheral inputs, probably play distinct roles in states associated with peripheral sensory and central cardiorespiratory/motor activations, respectively.

LOCALIZATION OF THE GLYCINERGIC NEURONS PROJECTING TO THE RAT LOCUS COERULEUS, DORSAL RAPHE AND TRIGEMINAL MOTOR NUCLEI C. Rampon, C. Peyron, D. Gervasoni, R. Cespuglio, P. Fort* and P-H Luppi INSERM U52, 8 Avenue Rockefeller, 69373 Lyon cedex 08, France

It is well known that the noradrenergic and serotonergic neurons fire tonically during wakefulness, decrease their activity during slow wave sleep and cease firing during paradoxical sleep (PS). Based on anatomical and physiological studies, we hypothesized that these neurons might be inhibited by the population of glycinergic neurons hyperpolarizing the motoneurons during PS. To test this hypothesis, we compared the origin of the glycinergic innervation of the locus coeruleus (LC), dorsal raphe (DRN) and trigeminal motor nuclei (Mo5). For this purpose, we developed a double staining method combining cholera-toxin b subunit (CTb) as a retrograde tracer with glycine immunohistochemistry. To obtain reliable injections of CTb in the nuclei under study, we realized electrophysiological recordings through the glass micropipette containing the tracer. Monoaminergic or motoneurons were identified by their discharge properties. Iontophoretic injections allowed us to obtain small sized sites (300 µm diameter). After CTb injections in the LC, a moderate number of double-labeled cells was observed in the ventrolateral part of the periaqueductal gray (CGLV), ipsilateral to the injection site. A few double-labeled neurons were also found in the alpha (GiA) and ventral gigantocellular (GiV) reticular nuclei. Following CTb injections in the DRN, a small number of double-labeled cells was localized in the CGLV. After CTb injections in the Mo5, a large number of double-labeled cells was observed bilaterally in the parvocellular nucleus alpha lateral to the descending branch of the facial nerve. A substantial number of double-labeled cells was also localized in the more caudal parvocellular nucleus. Only a few double-labeled neurons were found in the GiA and GiV. These results indicate that the glycinergic innervation of the Mo5, LC and DRN arises from distinct populations of neurons. It is therefore unlikely that a single group of glycinergic neurons might hyperpolarize simultaneously the motoneurons and the monoaminergic neurons during PS.

THE DOPAMINERGIC SYSTEM IN THE LAMPREY BRAIN WITH SPECIAL REFERENCE TO STRIATUM. M. A. Pombal*, A. El Manira and S. Grillner. Nobel Institute for Neurophysiology, Department of Neuroscience, Karolinska Institutet, 171 77 Stockholm, Sweden.

The basal ganglia play an important role in different types of behavior. In mammals, the striatum, which represents the major input nucleus, receives a dense dopaminergic projections from the mesencephalon. In the lamprey, a lower vertebrate, we have demonstrated dopaminergic projections to striatum using immunohistochemical techniques. Dopamine immunostaining shows a very dense DA-immunoreactive (DA-ir) fibers in the neuropile of striatum. DA-ir cells are present in the telencephalon in the internal granular layer of theolfactory bulb and the nucleus of the anterior commissure. The largest number of DA-ir cells is located in the diencephalon (preoptic region, nucleus of the postoptic commissure, ventral thalamus, hypothalamus, nucleus of the postinfundibular commissure and nucleus of the posterior tuberculum). These cells appear to be the source of the ascending and descending dopaminergic fiber systems that project to the striatum, and the brainstem and rostral spinal cord, respectively. In the mesencephalon only a few small cells were detected in the optic tectum. In the rhombencephalon, DA-ir cells were observed in both the rostral part (isthmic region) and caudal part. Cells in the nucleus of the posterior tuberculum were retrogradely stained following injection of fluorescein-coupled dextran amine (FDA) in striatum. This suggests that this nucleus could be the origin of the DA projections to striatum, thus representing a homologous structure to the mesostriatal dopaminergic system of other vertebrates.(Supported by the Swedish MRC, Project No 3026).

Tm: Ho: LuAG LASER AT 2.1 µM INDUCED THERMAL NECROSIS IN THE BRAINSTEM M.E. Reynolds,[1] K. Sentrayan, [1,2] Y. Chen, [2] V. Kushawaha, [2] S.C. Rapisardi,[3]* and C.O. Trouth[2]. 1. Depts. of Physiology and Biophysics, 2. Physics, 3. Anatomy, Howard University, College of Medicine, Washington, D.C. 20059.

Recently, the midinfrared Holmium lasers at 2.1µm has attracted the surgical community due to its strong absorption in water for sift-tissue ablation. The availability of robot, high power, high repetition rate operational quartz fibers offers additional advantage for precise endoscopic microsurgery. In the present investigation, we have used a free running (200µs pulse duration) Tm: Ho: LuAG laser (λ = 2.1µm) to produce lesion in the brainstem of a rat. A series of focused laser pulses (1-25) with energy fluence ~ 14J/cm2/pulse different sites of ventral medullary surface (VMS). The brainstem was then frozen in dry ice and 20 µm coronal sections (-18°C) were sequentially cut and mounted on cold gelatin subbed slides. The slides were then stained with cresyl violet, NIH Image Program on an AV Power Macintosh with an AO trinocular microscope and a CCD camera. No lesion was observed at low energy fluence of the laser indicating a threshold for ablation. The width of the necrotic zone was in the range of 460 µm - 1 mm and increased with increase in the number of pulses deposited in the same site. The variation in the depth of penetration with laser energy fluence suggests that the absorption coefficient and the penetration depth are no more a constant and varies due to the temperature elevation of the tissue. Structural changes in the tissue may also modify the scattering characteristics. At higher energy fluences of the laser, some degree of damage to the surrounding tissue structures doe to thermal damage was observed and can be avoided using a ns Q-switched laser pulse.

CHRONIC ACTIVATION OF A HETEROGENEOUS MUSCLE CONVERTS THE MUSCLE BUT NOT ITS MOTONEURONS TO A HOMOGENEOUS POPULATION. JB Munson*, T Gordon and LM Mendell. University of Florida (JBM), University of Alberta (TG) and SUNY at Stony Brook (LMM).

This work tests two hypotheses: (1) that the properties of muscle can be determined completely by activity, and (2) that signals from muscle can alter motoneuron properties. Chronic activation of cats' heterogeneous medial gastrocnemius (MG) muscle (by stimulation of the muscle nerve with 2.5s trains @ 20Hz, 1/5s, 24h/d for 2-3 mos) alters both muscle and motoneuron properties: muscle units become exclusively type I histochemically and type S mechanically; motoneuron electrical properties migrate toward those of fatigue-resistant motor units (Gordon et al., Soc Neurosci Abstr 19, 20). Were activity the sole determiner of muscle-unit contractile properties, then those properties should exist within a very narrow range following common chronic activation. However values of fatigability, tetanic force and twitch time-to-peak of chronically activated MG units were found to exist over the full ranges for normal MG type-S units. Although all muscle units were converted completely to type-S/type-I phenotype, most motoneurons could be classified into one of two types, based on rheobase, input resistance and afterhyperpolarization: original type-S and original type-F. Muscle units of the original type-F motor units, although slowed and weakened by stimulation, were typically faster and/or more powerful than those of the original type-S motor units. Thus although chronic stimulation greatly altered both muscle and motoneuron properties, confirming effects of activity, matching between motoneuron and muscle-unit properties endured, indicating intrinsic regulation as well. These results suggest an orthograde effect of activity, altering muscle properties, and a retrograde effect from muscle, altering motoneuron properties. Supported by Canadian MRC (TG) and NIH/NINDS (LMM and JBM).

THE COMPLEX STRUCTURE OF A SIMPLE REFLEX CHANGE. J.R. Wolpaw*, Wadsworth Center, NY State Dept of Health & State Univ of NY, Albany, NY 12201.

Monkeys and rats can gradually increase or decrease the triceps surae (TS) H-reflex (HR), the electrical analog of the spinal stretch reflex, when reward is based on that amplitude. The reward contingency causes long-term alteration in descending control over the spinal arc of the HR. Over time, this alteration produces a larger (HRup mode) or smaller (HRdown mode) HR. This operantly conditioned behavioral change is associated with a complex pattern of physiological and anatomical modifications in the spinal cord (J Neurophysiol 61:563-572, 72:431-442, 73:867-871; 73:1365-1373; Feng-Chen & Wolpaw, PNAS, in press), including changes in TS motoneuron firing threshold, axonal conduction velocity, F terminal diameter and active zone coverage, and C terminal diameter and number in each C complex; possible changes in group Ia EPSPs and group I oligosynaptic inputs; and undefined change in the contralateral spinal cord. The mechanisms of these changes and their contributions to a larger or smaller HR are unknown. It is clear that other changes remain to be found, and that the mechanisms of HRup and HRdown conditioning are not simply the inverse of each other. This presentation attempts to relate what is known about the complex spinal cord plasticity to HR change, and discusses the potential origins of the complexity.

The most viable hypotheses are: 1) HRdown conditioning is due to a positive shift in firing threshold and a modest decrease in the Ia EPSP, and the threshold shift and the decreased conduction velocity are both due to a positive shift in Na^+ channel activation voltage; and 2) HRup conditioning is due to a change (increased excitation and/or decreased inhibition) in disynaptic group I input. While these hypotheses can explain the HR changes, they cannot account for all aspects of the functional changes seen with HR conditioning.

Even the simplest behavioral change is likely to be associated with three classes of plasticity: intended (here responsible for the HR change), compensatory (needed to preserve behaviors disturbed by the intended plasticity), and reactive (results of the changes in neuronal activity produced by the first two classes). DORSAL COLUMN TRANSECTION IN RATS ABOLISHES CAPACITY FOR OPERANTLY CONDITIONED H-REFLEX DECREASE. X.Y. Chen* and J.R. Wolpaw, Wadsworth Center, NY State Dept Health and SUNY, Albany, NY 12201.

Both monkeys and rats can gradually increase or decrease H-reflex (HR) amplitude in response to an operant conditioning paradigm that induces long-term change in descending control over the spinal arc of the HR (J Neurophysiol 57:443-459, 1987 & 73:411-415, 1995). Over time, this change modifies the spinal cord physiologically and anatomically (e.g., J Neurophysiol 72:431-442, 1994; Feng-Chen & Wolpaw, PNAS in press) and produces a larger (HRup mode) or smaller (HRdown mode) HR. We seek to learn which spinal cord pathways are needed for this process. In an initial study, we are exploring the role of the corticospinal tract in HRdown conditioning.

Female Sprague-Dawley rats (250-300 g) are implanted with EMG electrodes in soleus muscle and nerve cuff stimulating electrodes on posterior tibial nerve. Electrodes connect to a head-mounted tether cable. When background EMG remains in a specified range for a randomly varying period, stimulation at M response threshold elicits the HR. Under control mode, no reward occurs. Under the HRup or HRdown mode, reward occurs 200 ms later if HR amplitude is above (HRup) or below (HRdown) criterion. After 10-20 control-mode days, the rat is anesthetized (ketamine and xylazine) and the dorsal columns (which contain the main corticospinal tract) are cut at T8 by electrocautery. Rats recover well. After an additional 22-50 days of control-mode exposure, the rat is exposed to the HRdown mode for 50 days.

In 4 rats studied to date, DC transection itself had little lasting effect on background EMG or HR. However, all 4 failed to achieve successful HRdown conditioning (defined as a decrease of ≥20%). This result is significantly different ($P<0.01$ by Fisher exact test) from earlier studies of uninjured rats, in which 12 of 14 (86%) were successful at HRdown conditioning.

These results suggest that the corticospinal tract is necessary for HRdown conditioning. Further studies, including assessment of the role of dorsal column ascending pathways, are needed. 723.4

SYNAPTIC TERMINAL POPULATIONS ON DENDRITES OF PRIMATE TRICEPS SURAE MOTONEURONS AFTER OPERANT CONDITIONING OF H-REFLEX. D.M. Maniccia*, K.C. Feng-Chen, and J.R. Wolpaw. Wadsworth Center, NY State Dept of Health and State Univ of NY, Albany, NY 12201.

Operant conditioning of the primate (Macaca nemestrina) triceps surae (TS) H-reflex changes F terminals and C terminals on the cell bodies and immediately adjacent dendritic segments of TS motoneurons (Feng-Chen & Wolpaw, PNAS, in press). We are now studying terminals on more distal dendritic segments, where the majority of primary afferent terminals are located. TS motoneurons from animals in which one leg's TS H-reflex has been increased (HRup mode) or decreased (HRdown mode) are labeled retrogradely with cholera toxin-HRP, and labeled dendritic segments are studied electron microscopically.

To date we have classified 3852 terminals from the trained sides of 5 HRdown animals and 5 HRup animals. Classes are: F (flattened vesicles), S (round vesicles), C (subsynaptic cistern and associated rough endoplasmic reticulum), M (postsynaptic Taxi bodies), P (presynaptic to M or S). The table shows the percentages for F, C, M, and S terminals and for M and S terminals contacted by P terminals.

Mode	F	C	M	M w/P	S	S w/P
HRup (n=1924)	62.0	3.4	3.5	0.8	31.1	2.2
HRdown (n=1928)	59.6	2.7	4.4	1.7	33.1	1.7

The percentages of C and M terminals, combined with measurements of segment diameter, indicate that both proximal and distal segments are represented. Measurements of membrane and terminal lengths, now underway, should provide estimates of terminal diameters, frequencies, and coverages, and thereby reveal whether the conditioned changes found on the cell body and proximal dendritic segments are present more distally and whether additional changes (e.g., in M or P terminals) are present. (Supported by NIH NS22189.)

723.5

GABAERGIC & GLYCINERGIC TERMINALS ON PRIMATE MOTONEURONS. K.C. Feng-Chen* & J.R. Wolpaw. Wadsworth Ctr, NYS Dpt Hlth, Albany, NY 12201.

Operant conditioning of the primate triceps surae (TS) H-reflex changes F terminals on motoneurons (PNAS, in press). To further define this effect, we are using postembedding methods to identify GABAergic and glycinergic F terminals.

Adjacent ultra-thin sections containing CT-HRP retrograde-labeled TS motoneurons of Macaca nemestrina are treated with GABA or glycine antisera and immunogold (Chemicon), and photographed with a Philips 301 electron microscope. Terminals are classed as labeled if their gold-particle density is ≥5x average postsynaptic density.

To date, 155 terminals on 3 cells from 3 naive (i.e., unconditioned) animals have been studied. The table shows results for each terminal type (i.e., F (flattened vesicles), S (round vesicles), C (subsynaptic cistern and associated rough endoplasmic reticulum), G (many dense-core vesicles), P (presynaptic to an S)).

Type (#)	GABA only	Glycine only	Both	Neither
F (98)	5%	37%	48%	10%
S (44)	9%	0%	7%	84%
C (8)	0%	0%	0%	100%
G (4)	0%	0%	0%	100%
P (1)	0%	0%	100%	0%

The glycine labeling density of F terminals was positively correlated with terminal area ($R=0.32$, $P<0.002$). This was not true for GABA ($R=0.06$, $P>0.5$). For S terminals, no correlations between area and labeling were detected.

These initial results were comparable across the three animals. They are consistent with the presumed primarily inhibitory function of F terminals and excitatory function of S terminals, and with data from other species. (Supported by NIH NS22189.)

723.6

MONO- AND POLYSYNAPTIC PSPS IN SPINAL MOTONEURONS OF NEONATAL RATS IN VITRO. J.S. Carp*, Wadsworth Laboratories, New York State Department of Health and SUNY, Albany, NY 12201.

Oligosynaptic inputs to motoneurons have been proposed to be the substrate of operantly conditioned H-reflex increase (Carp and Wolpaw, J. Neurophysiol. 73: 1365-73, 1995). Previous studies in decerebrate rats in vivo suggested that PSPs elicited by stimulation of low-threshold afferents contain both mono- and polysynaptic excitatory components. In the present study, polysynaptic contributions to PSPs are further characterized in vitro with the interneuron blocker mephenesin (MP).

Spinal cords of 3-8 day old rats were isolated, hemisected, and superfused with artificial CSF. Compound PSPs were recorded intracellularly during stimulation of the L4 or L5 dorsal root (0.016-8.0 Hz, 1.5-10 times PSP threshold (xT)) in motoneurons antidromically activated from the homonymous ventral root in the absence and presence of MP (1 mM). Highly frequency-dependent late PSP components (latency>100 ms) were decreased by MP. Earlier components (latency=5-50 ms) were transiently increased, and subsequently decreased by MP. The duration of the PSP increase was greater at high (>3xT) than low (<2xT) stimulus intensity. Short latency components (<2 ms latency) were depressed by MP, but to a lesser degree than the late components.

These data suggest that polysynaptic input contributes to PSPs throughout their entire time course. They also suggest that both excitatory and inhibitory oligosynaptic (in addition to monosynaptic) inputs to motoneurons contribute to determining whether a motoneuron reaches firing threshold. (Supported by NIH NS22189.)

INESCAPABLE SHOCK DISRUPTS SPINAL LEARNING: EVIDENCE FOR SPINAL MEDIATION AND NALTREXONE REVERSIBILITY. J.W. Grau*, R.L. Joynes & H. Penland. Dept. of Psychology, Texas A&M University, College Station, TX 77843.

Prior work suggests that spinal neurons can support a simple form of operant learning. In a typical experiment, spinal rats (Exp.) are given shock to one hind leg whenever the leg is extended. Yoked subjects experience the same amount of shock irrespective of leg position. Rats in the Exp., but not the Yoked, group learn to maintain a flexion response. In a subsequent test phase, all subjects receive controllable shock. Rats in the Exp. group show facilitated learning (positive transfer), while subjects that previously experienced inescapable shock fail to learn (a learned helplessness-like interference effect).

Experiment 1 examines whether operant training of one hind leg affects learning when shock is applied to the contralateral leg. Spinal rats (N=36) received 30 min of controllable shock, uncontrollable shock, or no shock. Half the subjects then received 30 min of controllable shock applied to the ipsilateral leg, while the other half were trained using the contralateral leg. Prior exposure to inescapable shock disrupted learning irrespective of whether the ipsi- or contralateral leg was tested. An analysis of the data collected during the first 3 min of testing indicated that prior exposure to controllable shock facilitated learning when shock was applied to either hind leg. These results rule out a variety of peripheral explanations of the transfer effects and suggest that both depend on spinal neurons.

Experiment 2 looked at whether inescapable shock undermines learning by inducing an opioid mediated antinociception. Spinal rats (N=36) were given saline or the opioid antagonist naltrexone (14 mg/kg) followed by 30 min of escapable, inescapable or no shock. All subjects then received 30 min of testing with controllable shock applied to the same leg. Exposure to inescapable shock produced a small; but significant, antinociception. Naltrexone attenuated the antinociception observed after training and eliminated the interference effect during testing. Supported by MH48994 to J.W.G.

CONTRIBUTION OF L-TYPE CALCIUM CHANNELS TO PROLONGED SENSORY-EVOKED EXCITATION OF THE SCRATCH REFLEX IN THE *IN VITRO* TURTLE SPINAL CORD. S.N. Currie*, Dept. Neuroscience, Univ. of California, Riverside, CA 92521.

We have developed an *in vitro* preparation of the turtle spinal cord that expresses fictive pocket scratch motor patterns in response to electrical stimulation of an identified cutaneous nerve (Currie and Lee, J. Neurophysiol. 75: in press, '96). The ventral-posterior pocket (VPP) cutaneous nerve contains afferents innervating a small patch of skin in the pocket scratch receptive field; electrical stimulation of this nerve in intact, low-spinal animals elicits intense fictive pocket scratch motor patterns (Currie and Stein, J. Neurophysiol. 60:2122, '88). In the present study, we isolated 1 - 3 segments of the spinal cord hindlimb enlargement along with the attached VPP cutaneous nerve and several identified muscle nerves. *In vitro* pocket scratch motor patterns display a long-lasting excitation after brief sensory input similar to that previously demonstrated *in vivo*. A single electrical pulse delivered to the VPP nerve *in vitro* increased the excitability of the pocket scratch network for several seconds: single pulses delivered at 5-10 s intervals evoked strongly summating scratch motor output. Previous results showed that this sustained excitation was greatly reduced by the NMDA receptor antagonist APV (Currie and Lee, '96). In the present study, we found that sustained, sensory-evoked excitation was also reduced by nifedipine (10-50μM), a blocker of L-type, voltage-gated Ca^{2+} channels. L-type Ca^{2+} channels have been associated with plateau potentials and "wind-up" in turtle dorsal horn neurons (Russo and Hounsgaard, Neuroscience 61:191, '94). These results support the hypothesis that L-type Ca^{2+} channels contribute to the storage of sensory-evoked excitation in the pocket scratch neural network. DIFFERENTIAL PRESYNAPTIC MODULATION OF DESCENDING ORIGIN EXERTED ON ASCENDING AND SEGMENTAL COLLATERALS FROM SINGLE MUSCLE AFFERENTS. J.N. Quevedo*, J. Lomelí, P. Linares and P. Rudomin. CINVESTAV-IPN, México, D.F. 07000.

A previous study has shown that during reversible spinalization, the inhibition produced by cutaneous and joint afferents on the PAD of group I fibers is increased (J. Neurophysiol. 70:1899, 1993). We have now investigated the extent to which tonic descending influences affect, in a differential manner, transmission in pathways mediating the PAD of one segmental and one ascending collateral, both from a single muscle afferent fiber. In barbiturate anesthetized, paralyzed and artificially ventilated cats, stimulating current pulses were delivered in alternation through two micropipettes, one placed at L3 in Clarke's column and the other at L6 in the intermediate nucleus. Tests for refractoriness were made to ensure that antidromic responses were produced from collaterals of the same afferent (gastrocnemius) fiber. PAD in each collateral was inferred from intraspinal threshold changes. In 10/11 fibers, PBSt nerve conditioning (4 shocks, 300 Hz, applied 25 ms before the testing pulse), with strengths 1.25-2.85 xT, produced a larger PAD in the collateral ending at L6 than in the collateral ending at L3. This asymmetry was maintained during the thoracic spinal cold block. In 8/9 fibers, SP nerve conditioning (1 shock, applied 50 ms before the testing pulse) with strengths 2-10 xT, produced a larger inhibition of the PBSt-induced PAD in the L3 than in the L6 collateral. After the spinal cold block, the asymmetry in the inhibition of PAD was reversed. Namely, in most fibers (6/9) the inhibition became larger in the L6 than in the L3 collateral. No clear reversals in the asymmetry of the inhibition of PAD were observed following stimulation of sural and joint afferents. At present, the results support the existence of a descending tonic differential control exerted on the pathways mediating PAD from SP to group I muscle afferents. *Partly supported by grants NIH NS09196 (USA), CONACyT 039-N91107 and SNI (México).*

EFFECTS OF NERVE CONDUCTION BLOCKADE ON THE MONOSYNAPTIC REFLEX IN THE RAT. K.L. Seburn and T.C. Cope. Dept. of Physiology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

We have investigated the effects of tibial nerve conduction blockade on the monosynaptic reflex (MSR). Tetrodotoxin (TTX) was delivered by an osomotic pump to a silastic cuff assembly on the left tibial nerve for periods up to 10 days. The effectiveness of tibial nerve blockade was confirmed by the presence of toe-spread and absence of ankle extension. MSR's were recorded bilaterally (L5) following stimulation of the tibial nerve at 1.5-2x group I strength. Comparison of changes in the MSR amplitude between the treated and untreated side were made under two different paradigms. First, we monitored decreases in MSR amplitude in response to pulse-trains delivered to the tibial nerve at different frequencies (6 pulses @ 0.1 to 20 hz) (rate-sensitive depression). The amplitude of composite 1a motoneuron EPSPs recorded intracellularly in motoneurons of untreated animals was unchanged at stimulation frequencies up to 100hz, consistent with the assertion that rate-sensitive MSR depression, observed at frequencies as low as 1hz, is mediated by interneuronal circuits. Secondly, we measured decreases in MSR amplitude recorded following a conditioning pulse-train (200ms @ 200 hz) to the sural nerve at varied delays.

Nerve conduction blockade for 2-3 days, known to induce significant increases in Ia-motoneuron EPSP amplitude (Manabe et al., *J.Neurosci.*,1989), had no effect on the extent of rate-sensitive depression. However, preliminary results suggest that this depression is more prounounced with longer durations of blockade. These findings may indicate that the early changes in synaptic efficacy observed at the Ia-motoneuron connection in response to inactivity, do not occur at other connections made by these afferents. The change in MSR amplitude with sural conditioning did differ between the left and right sides after 2-3 days of TTX blockade. Whether these changes are due to alterations on the treated side or a compensatory response on the untreated side is currently being investigated. Supported by NIH grant R01 31563

COCHLEAR AND TRIGEMINAL CONTRIBUTIONS TO THE STARTLE REFLEX. R.Brown*, B.W.Scott, P.W.Frankland and J.S. Yeomans, Psychology, Univ. Toronto, Canada M5S 1A1.

Moveable stimulating electrodes were placed above the cochlear nucleus (CN) in rats. Current thresholds for evoking startle-like responses were determined every 300 um. The lowest thresholds were found in the antero-ventral CN near the VIII nerve. Much lower thresholds were found for tracks located medially in the principal sensory trigeminal nucleus and the sensory root of the trigeminal. At low threshold sites, acoustic stimulation (110 dB) was followed by electrical stimulation at C-T intervals of 0-4 ms. Although summation between the stimuli for startle was strong in all sites, collision-like effects were observed for only a few ventral CN sites, but not trigeminal sites. Trigeminal activation, therefore, powerfully evokes startle-like responses, but is not involved in acoustic startle. When the acoustic stimulus was presented contralateral to a CN site, no collision was observed. In each case, the maximum collision was centered 2.0 ms after the acoustic stimulus. CN stimulation paired with PnC stimulation in two cases produced electric-electric collision at C-T intervals of 0.8-1.2 ms. Therefore, the acoustic startle reflex is mediated by action potentials that pass through the ipsilateral ventral CN 2.0 ms after the acoustic stimulus. This acoustic activation is then relayed to the PnC 0.8-1.2 ms later.

EFFECTS OF PEDUNCULOPONTINE NUCLEUS (PPN) STIMULATION ON PONTINE AND MEDULLARY RETICULAR FORMATION NEURONS. E. Garcia-Rill*, T. Hayashi, H. Miyazato and R.D. Skinner. Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205

Stimulation of the PPN (part of the reticular activating system and known to modulate the startle response) is known to induce locomotion via projections to the reticular formation. We recorded the activity of neurons in the medioventral medulla (MED), an area known to induce locomotion, and in the caudal pontine region (PnC), an area known to modulate the startle response, in the paralyzed decerebrate cat following auditory stimulation and after electrical stimulation of the PPN. Neurograms were recorded from hindlimb nerves to determine motor responses. Auditory stimulation (5 click 1KHz train 103 dB) did not activate MED neurons (n=52) but excited 12/106 PnC neurons at latencies of 4-20msec. Auditory stimulation elicited excitation of flexor neurograms at a 15msec latency and 5msec duration, an effect which may correspond to the "fictive startle response". PPN stimulation excited 13/52 MED neurons at a latency of 6.1+3.2msec, while inhibiting 7 MED cells for 50-100msec. PPN stimulation activated 21/106 PnC cells at a latency of 7.5+2.3msec, while inhibiting 17 cells for 50-100msec. When repetitive stimulation of PPN was used to elicit locomotion (<100uA amplitude, 0.5msec duration pulses at 60Hz), activated PnC neurons responded with a tonic excitation outlasting the stimulation. If stimulation was continued, the tonic activation was replaced by a 1Hz bursting rhythm. This rhythmic activity was present whether or not the neurograms were cycling. These results show the presence of the fictive startle response in the decerebrate cat and of PnC neurons which are recruited into a rhythmic pattern by PPN stimulation. These findings suggest the presence of rhythmic activity in the reticular formation in the absence of a spinal cord locomotor rhythm.

THE EFFECTS OF INTRATECHAL CLONIDINE ON THE LOCOMOTION OF INTACT CATS. N.Giroux, F. Lebel, J. Provencher, T. A. Reader* and S. Rossignol. Neuroscience Res. Center, Physiologie, Université de Montréal, Montréal (Québec) Canada H3C 3J7.

Clonidine, an alpha-2 noradrenergic agonist, can initiate hindlimb locomotion on a treadmill within the first week after a spinalisation at T13 in adult cats. After a few weeks, when cats regain spontaneous locomotion, clonidine can, for 4-6 hours, increase the step cycle, the joint excursions and the amplitude and duration of the flexors bursts as well as increase the threshold of cutaneous reflexes. On the other hand, in cats with massive bilateral ventral and ventro-lateral lesions, clonidine markedly deteriorates the four-legged locomotion. Since clonidine exerts quite dramatically opposed effects in both the complete and incomplete spinalized cats, we studied the effects of clonidine injected through an intrathecal canula (tip at L4-5) in two intact cats chronically implanted with EMG electrodes. In the first cat, 5 injections (25 to 100µg/100µl) were performed whereas, in the second cat, 2 injections (100µg/ 100µl) were done. With the largest doses, the first cat had pronounced central effects of drowsiness and could hardly walk at speeds higher than 0.2 m/s, at least within the first half hour. This behavior improved thereafter and, after an hour or so, both cats could reach speeds similar to control values, and had a rather normal walking behavior although the reflex threshold to electrical stimulation of nerve cuffs placed on cutaneous nerves remained elevated. The step cycle duration, for the same speed of the treadmill, was the same or even shorter. In flexor muscles, the most preeminent effect was an increased delay between the knee flexor and the hip flexors, often leading to a segmentation of the swing phase, and sometimes to an increase in its duration. The extensors of the knee, but not of the ankle, had a smaller amplitude and duration which might explain the shorter steps after clonidine. These results thus suggest that the more pronounced effects observed with clonidine on cats with spinal lesions is probably related to changes in receptor sensitivity and/or to effects of clonidine on important compensating mechanisms, such as spinal reflex transmission, which are crucial to maintain locomotor performance after lesions of descending tracts.

PATTERNS OF SYNCHRONIZATION AMONG HINDLIMB MOTOR NUCLEI DURING FICTIVE LOCOMOTION IN THE CAT. V.Turkin and T.M. Hamm*. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Previous work from this laboratory has employed coherence spectra to demonstrate synchronization between motor nuclei of hip and ankle extensors during fictive locomotion (McCurdy and Hamm, Soc. Neurosci. Abst. 19:540, 1993). We have extended this analysis to examine a broader range of motor nuclei, including those innervating ankle stabilizers and those controlling actions at the toes. Experiments were performed in unanesthetized decerebrate cats, and fictive locomotion was produced by stimulation of the mesencephalic locomotor region. The activity of motor nuclei was determined from rectified neurogram recordings from several muscle nerves. We confirmed our previous observations that synchronization in the discharge of motor nuclei occurs at frequencies up to 200 Hz between several motor nuclei that discharge in phase during fictive locomotion. Synchrony among motor nuclei bursting in phase is absent in some cases, suggesting that the coherence peaks at higher frequencies are contributed mainly by presynaptic synchronization. Synchrony has been observed during flexor activity: significant peaks have been observed in the coherence functions between posterior biceps femoris (PBF), semitendinosus (ST), and the anterior and posterior branches of tibialis anterior (TAa and TAp). The ankle stabilizer peroneus longus may be synchronized with ST, PBF, and TAa. Despite patterns of activity that were largely in phase with these motor nuclei, coherence between the activity of extensor digitorum longus and these other motor nuclei was weak or absent. Our results suggest that a synchronization of interneuronal pools presynaptic to motoneurons may occur during fictive locomotion and that commands from these interneuronal pools are distributed differently to motor nuclei that control actions at the toes in comparison to other motor nuclei.

PONTINE CONTROL OF MEDULLARY RHYTHMIC NEURONS: A PATCH CLAMP STUDY IN VENTRAL HORIZONTAL SLICE OF THE NEWBORN MOUSE. F. Kato*, V. Borday, J. Champagnat, Biologie Fonctionnelle du Neurone, Institut A. Fessard, CNRS, 91198, Gif-sur-Yvette, France. *, Dept. Pharmacol., Jikei Univ., Tokyo, 105, Japan.

To elucidate the neuronal mechanisms underlying descending control from the ventral pons, we have developed a ventral horizontal slice (500 μm) of newborn mouse in which both the medullary respiratory network and the caudal part of pontine reticular formation (cPR) are conserved. The spontaneous and pontine stimulation-evoked synaptic potentials or currents of the neurons in the medullary respiratory network were recorded with patch pipettes in the whole-cell configuration. Spontaneous respiratory-like rhythmic EPSPs and EPSCs (6-10 min^{-1}, 0.5 s duration) were recorded from the neurons in the facial nucleus and the pre-Bötzinger region. These rhythmic EPSPs and EPSCs were reversibly abolished by CNQX (100 μM). The neurons in these regions showed 1) an EPSP after a single stimulation of cPR, 2) a hyperpolarization during a continuous stimulation, 3) a long-lasting depolarization which outlasted the termination of a continuous stimulation, 4) synchronization of the spontaneous rhythm to a periodic stimulation and 5) an inhibition of the spontaneous rhythm after a continuous stimulation. This novel preparation retains rhythmogenic network of the medulla and pontomedullary afferents. It reveals distinct descending synaptic controls by caudal ventral pontine areas of neurons of the medullary respiratory network. Supported by CNRS and DRET n°95091.

PREPARATORY MOTOR ACTIVITY IN THE RETICULAR FORMATION OF THE MONKEY DURING REACHING. J.A. Buford*[1] and M.E. Anderson,[1,2] Depts. of Rehabilitation Medicine[1] and Physiology & Biophysics.[2], Regional Primate Research Center, University of Washington, Seattle, WA 98195

Reticulospinal neurons receive corticospinal collaterals largely from premotor cortex (PM) and supplementary motor area (SMA) (Kievit and Kuypers 1981). Why is the reticulospinal system so closely associated with these advanced cortical motor areas? Perhaps the reticular formation also is associated with motor set and the preparation for movement.

Reticular formation neuronal activity has been recorded in *Macaca fascicularis* during a delayed instruction arm-movement task. To date, about two-thirds of the cells studied have had activity related to the movement but no cue-related or preparatory activity. One third of the cells, however, have had preparatory activity reminiscent of the patterns reported in the literature for premotor cortical areas such as PM and SMA. We have recorded eye movements and designed the task to control for eye-movement related activity, and the preparatory activity in these cells appears related to the preparation of arm movement, not just a consequence of corollary eye movements. Indeed, many of the cells responded specifically to manipulation of the arm but not to visual stimuli that elicited oculomotor responses. Further, electrical stimulation in the vicinity of some cells produced specific movements of shoulder muscles. Therefore, these reticular formation cells have patterns of activity that implicate them for involvement in the preparation as well as the execution of arm movement.

A better understanding reticular formation control of normal reaching is expected to lead to better strategies for rehabilitation of individuals suffering from stroke and other brain injuries that may place a greater motor control responsibility on the reticular formation when cortical cooperation is lacking.

ACTIVATION OF MEDULLARY RETICULOSPINAL UNITS BY ROSTRAL PONTINE ELECTRICAL STIMULATION THAT INDUCES GENERALIZED ATONIA IN DECEREBRATE CATS. J. Kohyama*, Y. Y. Lai and J. M. Siegel. Dept. of Psychiatry, UCLA School of Medicine, Neurobiology Research (151A3), Sepulveda VAMC, North Hills, CA 91343.

The pontomedullary region is responsible for the muscle tone suppression of REM sleep and the cataplexy seen in narcoleptics. This work was undertaken to identify the medullary output neurons mediating muscle atonia.

Trains of 3 pulses (0.2 ms, 330 Hz, 20-150 μA, train duration 6.1 ms) unilaterally applied to the rostral pons (P 2.4±0.5, L or R 2.2±0.6, H 5.1±1.1) caused bilateral suppression of neck and hindlimb muscle tone in precollicular decerebrate cats. Mean latency-to-onset, latency-to-peak, and duration of this suppression for neck muscle in 10 cats were 18.5 ms, 37.1 ms and 39.0 ms, and those for soleus muscle was 37.5 ms, 58.9 ms and 40.7 ms, respectively. One hundred-forty reticulospinal units were identified antidromically in the nucleus reticularis gigantocellularis (NRGc; 75), nucleus reticularis magnocellularis (NRMc; 35) and in the nucleus reticularis paramedianus (NRPm; 30) by stimulating L1 spinal cord. Seventy-six units were activated orthodromically by pontine stimulation (NRGc; 32, NRMc; 21, NRPm; 23). Thus, pontine stimulation inducing generalized atonia activated 54.2 % (76/140) of the medullary reticulospinal units we identified. According to the orthodromic latency, 72.4 % (55/76) of these atonia related units were activated via mono- or oligosynaptic pathways from the rostral pons. We identified a group of neurons [55.3 % (42/76)] that remained active for a mean duration of 22.5 ms after the cessation of the stimulation.

We hypothesize that the maintained activity of medullary reticulospinal neurons after the end of the 6.1 ms stimulus train is responsible for the induction, maintenance and cessation of muscle atonia we observed.

EFFECTS ON SHOULDER, ELBOW, WRIST, DIGIT AND INTRINSIC HAND MUSCLES FROM MICROSTIMULI APPLIED TO THE RED NUCLEUS IN THE MONKEY. A. Belhaj Saïf, E. E. Samson* and P. D. Cheney Smith Mental Retardation & Human Development Center and Dept. of Physiology, Kansas Univ. Medical Center, Kansas City, KS 66160

Cheney et al (J. Neurophysiol., 66:1978, 1991) have shown that magnocellular Red Nucleus (RNm) preferentially facilitates extensor muscles, using: Spike Triggered Averaging (SpTA) and Stimulus Triggered Averaging (StTA) to study simple wrist movements. To further understand the function of RNm in motor control, we used StTA: 1) to test the extensor muscle preference at different joints, during complex movements and, 2) to assess the control of distal and proximal muscles by RNm. Two Rhesus monkeys were trained to perform two forelimb tasks: 1) a reaching and prehension task, and 2) a targeted push pull task. RNm stimulation (20µV at 20Hz) was delivered throughout the movement. EMGs of 24 muscles of the forelimb (5 shoulder, 6 elbow, 5 wrist, 6 digit and 2 intrinsic hand muscles) were recorded and digitized; and averages were compiled for 60ms epoch (20ms before the trigger to 40ms after it). From 85 microstimulation sites in the RNm, a total of 372 poststimulus effects was obtained, with 241 poststimulus facilitation effects (PStF) and 131 poststimulus suppression effects (PStS). Of the PStF effects, 21% were in shoulder muscles, 27% in elbow muscles, 47% in wrist and digit muscles, and 5% in intrinsic hand muscles. Of these effects, the majority at each joint was in extensors: shoulder (92%), elbow (71%), and wrist/digits (84%). Both distal and proximal muscles were facilitated together at 46% of RNm sites tested. In conclusion, this data: 1) supports the work of Cheney et al (1991) and Sinkjær et al (Exp. Brain Res., 102:546, 1995) that the RNm actions on distal muscles are predominantly excitatory to extensors, 2) shows that a similar extensor preference exists for RNm output to proximal muscles, and 3) reinforces the possible importance of the RNm in control of coordinated multi-joint movements of the arm. MIDBRAIN NON-EPILEPTIC SEIZURES IN THE RAT, O.J. Andy*, X-B Qian, M. Lundien, C. Dearman, J. Andy, R. Rockhold and M. Andrews. Departments of Neurosurgery, Pharmacology and Toxicology, and Preventive Medicine. University of Mississippi Medical Center, Jackson, MS 39216

The objective of this study was to develop a model of brainstem seizures in the rat. Lesions of the midbrain, following electrode implant and DC stimulation, were used to kindle seizures in the brainstem reticular system. Method: Sixty one adult rats were used. Nine treatment groups were formed; lesions and cocaine alone and in various combinations. Under general anesthesia, chronic bipolar electrodes were placed in the bilateral midbrain. In freely moving subjects, the behaviors and EEG were simultaneously recorded. Histology of electrode placements was done. RESULTS: There were 4 different brainstem EEG seizure discharge patterns. Forty five sensory-motor behaviors were recorded. In comparison to cocaine alone, the greatest number of behaviors occurred when lesion and drug were combined ($p=0.0001$). Next greatest was with lesion alone ($p=0.01$). Conclusion: Midbrain seizures in the rat consist of non-epileptic sensory-motor behaviors, generated in the reticular formation. Support: Department of Neurosurgery.

ANATOMICAL AND PHARMACOLOGICAL EVIDENCE FOR GLYCINERGIC CONTROL OF URETHRAL SPHINCTER MOTONEURONS IN CAT. M.J.Espey*, R.Buss,D.M.Nance[1],M.Sawchuk,P.Carr[2] & S.Shefchyk Depts. of Physiol. and Path.[1], Univ. of Manitoba, Canada R3E 0W3; Lab of Neural Control, NIH[2]

During micturition, external urethral sphincter (EUS) motoneurons hyperpolarize due to an active chloride conductance (Fedirchuk & Shefchyk,J.Neurosci.1993,13:3090). The neurotransmitters mediating this postsynaptic inhibition are unknown. While Ramirez et al. (J. Chem Neuroanat. 1994,7:87) demonstrated GABAergic terminals on cells in Onuf's nucleus, nothing is known about the inhibitory neurotransmitter glycine in this system. The present study uses anatomical and pharmacological methods to examine the involvement of glycine in EUS control. In decerebrate or chloralose-anesthetized cats, antidromically-identified EUS motoneurons were recorded intracellularly and filled with tetramethylrhodamine-dextran (TMR-D,depolarizing current 20-51 nA x min). Cats were then transcardially perfused with 4% paraformaldehyde. After post-fixation and cryoprotection, lumbosacral spinal tissue was sectioned and immunohistochemistry for gephyrin, a protein associated with membrane-bound glycine receptors was performed. Three-dimensional images of TMR-D-filled cells with glycine receptor immunoreactivity were generated using confocal microscopy. Both the soma and dendrites of EUS motoneurons were heavily covered with glycinergic receptor immunoreactivity.

Glycine's contribution to the decreased EUS activity seen during micturition was examined by observing the effects of a glycinergic receptor antagonist, strychnine, on activity in the urethral motor branch of the pudendal nerve during distension and pontine micturition centre- evoked micturition in decerebrate, paralyzed cats. Strychnine (0.10-0.2375mg/kg, i.v.) abolished tonic sphincter inhibition and facilitated normally-suppressed phasic-evoked pudendal reflexes during micturition. The presence of glycinergic receptors on sphincter motoneurons, coupled with the ability of a glycinergic antagonist to block sphincter inhibition during micturition, suggests that glycine contributes to EUS inhibition during micturition. *Supported by the MRC and Rick Hansen Man in Motion Foundation.*

GENITOURINARY RESPONSES TO MICROSTIMULATION OF THE SACRAL SPINAL CORD, W.M. Grill* and N. Bhadra, Dept. Biomed. Eng., Case Western Reserve Univ. Cleveland OH 44106-4912

The objective of this study is to determine the physiological responses in the genitourinary system to electrical stimulation of discrete regions of the sacral spinal cord. Penetrating activated iridium microelectrodes (exposed surface area ~ 200μm^2) were used to generate stimulation maps in male cats anesthetized with α-chlorolose. The sacral cord was exposed by laminectomy, and vertical dorsal-to-ventral penetrations (increment=200μm) were made at multiple mediolateral locations (increment=250μm) in the middle of the segment generating the largest bladder pressures on stimulation of the ventral root (presumably S2). The pressures generated in the bladder and the urethra were recorded in response to trains of pulses (100μA, 100μsec, biphasic pulses applied at 20Hz for 1s). Bladder pressures could be generated by stimulating over a widespread region of the S2 segment. However, the largest pressures (30-40cmH_20) were generated with electrodes in the dorsolateral aspect of the ventral horn, consistent with the location of the axons of the preganglionic parasympathetic motoneurons innervating the bladder. Bladder pressures could also be generated by stimulation within the dorsal horn, presumably by transynaptic activation of preganglionic motoneurons via afferent terminals and/or interneurons. This interpretation is consistent with bladder responses generated by stimulation of the S2 dorsal root. Electrode locations in the ventral horn generated direct activation of urethral and pelvic somatic musculature, consistent with the location of pudendal motoneurons. At these locations there was co-activation of the bladder and the pelvic musculature, consistent with responses generated by stimulation of the S2 ventral root. These results indicate that regions of the sacral spinal cord can be identified that yield selective activation of the detrusor, and generate pressures as high as physiological voiding pressures.

This work was supported by NIH NINDS NS-5-2331 to WMG.

SPINAL CORD AND BRAINSTEM: RESPONSES TO INJURY

724.1

Differential growth of dendrites of axotomized neck motoneurons in the cat. P.K. Rose* and M. Odlozinksi. MRC Group in Sensory-Motor Neuroscience, Queen's University, Kingston, ON, Canada K7L 3N6

In contrast to limb motoneurons, the surface area of the dendritic trees of neck motoneurons increases following long term permanent axotomy. The objective of the present study was to identify the changes in dendritic structure that contributed to the increase in surface area. Five motoneurons with a permanent (11-16 weeks) axotomy were intracellularly stained and their dendritic trees were reconstructed using a computer-base data acquisition system. Increases in dendritic size were the result of two mechanisms: (1) an increase in process length, either by simple extension or the formation of complex tangles of short branches on distal dendrites, and (2) an increase in the diameter of distal dendrites. These changes were not distributed uniformly within the dendritic tree of a single motoneuron. Most of the distal dendrites of one primary dendrite from three motoneurons had exceptionally large diameters (greater than 3.0 μm). These dendrites were often stained in a nonuniform fashion and followed a meandering path that ended in the ventral or lateral funiculi. Other primary dendrites had an unusually high incidence of dendrites that projected more than 1630 μm from the soma (for intact motoneurons, only 1% of the total dendritic length exceeded this distance). The lengths and diameters of distal dendrites of other primary dendrites appeared normal. These results indicate that expansion of neck motoneuron dendrites following axotomy is controlled at the level of individual primary dendrites. (Supported by MRC of Canada)

MEDULLARY RETICULAR FORMATION MODULATION OF EJACULATORY CIRCUITRY IS DISRUPTED BY CHRONIC T8 CONTUSION. R.D. Johnson* & C.H. Hubscher. Dept. Physiol. Sci., Univ. Florida, Gainesville, FL 32610.

Ascending sensory pathways from the penis, urogenital tract and perineal skin project to the medullary reticular formation (MRF) and may contribute to ejaculatory reflexes. In 16 urethane-anesthetized rats, the MRF was microstimulated bilaterally to (i) determine the effects of descending projections on pudendal motoneuron circuitry (N=10) and (ii) determine the effects of a severe clinically-relevant 30-day T8 spinal cord contusion injury on these projections (N=6). Two microelectrodes were set for bilateral penetration of MRF, in the same anterior/posterior plane and equidistant from midline. A systematic tandem tracking matrix through the medulla was designed to completely envelope MRF. Monopolar current pulses were passed through one or both microelectrodes in order to unilaterally or bilaterally microstimulate MRF regions. Pudendal motoneuron reflex discharges (PMRD) were recorded simultaneously on both sides in response to stimulation of the dorsal nerve of the penis (DNP) and pelvic nerve (PN) before, during and after MRF microstimulation. Microstimulation produced a decrease in amplitude and an increase in latency of the DNP-elicited PMRD; no effect on the PN-elicited PMRD was found. Bilateral microstimulation was always more effective than unilateral microstimulation, although the latter produced both ipsilateral and contralateral PMRD depression. The most robust reflex depression was produced from the lateral paragigantocellular reticular nucleus and regions just medial to it. No reflex modulation was obtained in the rostral part of the tracking matrix. Thus, our data demonstrate a discrete area within the caudal brainstem that is capable of robust modulation of DNP-elicited PMRD. This modulation, however, was significantly reduced following severe chronic contusion injury. Thus, disruption of this MRF-pudendal circuitry likely contributes to reproductive abnormalities that occur following spinal cord injury. Supported by Am. Paralysis Assoc. and the Florida Brain & SCI Rehab. Fund.

724.3

EFFECTS OF CHRONIC PARTIAL MID-THORACIC SPINAL CORD INJURY ON THE NEURAL CIRCUITRY MEDIATING MALE SEXUAL FUNCTION.

C.H. Hubscher* and R.D. Johnson. Departments of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610.

Ascending and descending spinal projections between the medullary reticular formation (MRF) and the lumbosacral spinal circuitry that controls male sexual reflexes are compromised following clinically relevant chronic mid-thoracic contusion injury. The present electrophysiological study was designed to assess the location of these spinal projections in ten male rats following a 30-day recovery period from either dorsal (DHX) or lateral (LHX) mid-thoracic hemisection. Terminal bilateral recording/stimulation experiments (urethane anesthesia) included searching for (1) single MRF neurons responsive to bilateral electrical stimulation of the dorsal nerve of the penis (DNP) and (2) effective microstimulation sites in MRF for modulation of DNP-elicited pudendal motoneuron reflex discharges. DHX eliminated MRF neuronal responses to DNP stimulation as well as MRF microstimulation-induced modulatory depression of pudendal motoneuron reflex discharges. In contrast, after LHX, MRF neurons on both sides of the brainstem responded to bilateral stimulation of the DNP. However, responses to stimulation of the DNP ipsilateral to LHX were greater in magnitude than those for DNP contralateral to LHX. In addition, microstimulation of MRF produced a decrease in amplitude and increase in latency for bilateral DNP-elicited pudendal motoneuron (both left and right) reflex discharges, but were limited to effective MRF regions located contralateral to LHX. Thus, only DHX is severe enough to damage a high percentage of ascending and descending axons between the spinal circuitry controlling male sexual reflexes and MRF, implicating the dorsal quadrant of the mid-thoracic spinal cord as the site for both types of projections. Supported by the American Paralysis Association and The Florida Brain &SCI Rehabilitation Fund.

MUSCLE RECRUITMENT AFTER CENTRAL CORD SYNDROME AS TESTED BY TRANSCRANIAL BRAIN STIMULATION.

N. Alexeeva, J. G. Broton, S. Suys and B. Calancie*. The Miami Project to Cure Paralysis, University of Miami, Miami, FL 33136

The central cord syndrome (CCS) resulting from incomplete cervical spinal cord injury is characterized by a greater loss of motor function of the arms (particularly the hands) compared to the legs. An injury to the corticospinal tract is proposed as a mechanism of the syndrome (Levi et al. 1996). Since projections of long motor tracts to spinal neurons can be assessed by transcranial magnetic stimulation (TMS) of the motor cortex, we used this non-invasive method of brain stimulation to analyse muscle recruitment after CCS. TMS-evoked response distribution and latency in upper and lower extremity muscles affected by the lesion were tested in 14 CCS and 20 able-bodied (AB) subjects for comparison. Cortical stimuli were delivered during a weak voluntary contraction of an individual muscle. CCS subjects showed a normal high probability of "Well-defined" responses (> 150 μV) in both upper and lower extremity muscles. The post-injury preservation of muscle responses may reflect the source of innervating proximal and distal musculature by ventral and lateral tracts, respectively. In contrast to TMS-evoked response distribution, motor response latency was significantly prolonged ($p<0.05$) after CCS. The latency delays did not increase progressively from muscle to muscle with increasing central conduction distances. Based on normal peripheral conduction latency after traumatic spinal cord injury, these results are consistent with unmyelinated central conduction through a focal lesion. As revealed by repeated measurements of TMS-responses in the same subjects, central motor conduction did not "improve" (i.e. shorter latency) with post injury time.

724.5

MOTOR UNIT ACTIVITY DURING ISOMETRIC AND DYNAMIC CONTRACTIONS PERFORMED BY SPINAL CORD INJURED SUBJECTS.

C. K. Thomas* and V. B. Esipenko. The Miami Project to Cure Paralysis and Dept. of Neurological Surgery, Univ. of Miami Sch. of Med., Miami, FL 33136.

Most studies to date have examined changes in motor unit firing patterns during isometric contractions. However, most daily tasks require movement and therefore changes in muscle length. The aim of the present study was to examine triceps brachii whole muscle and motor unit activity during repeated isometric, concentric and eccentric contractions performed by individuals with chronic cervical spinal cord injury (SCI) and control subjects. Subjects performed 50% maximum voluntary isometric contractions (MVC) for 6s followed by 4s rest until unable to reach the target force. On a different day, dynamic contractions against 50% maximum load were performed using the same duty cycle until the subject was unable to perform the task. Surface and intramuscular EMG were always recorded while force or elbow joint angle were measured during isometric or dynamic contractions respectively. During isometric contractions, motor unit firing rates tended to rise during fatigue. During dynamic contractions performed by control subjects, motor unit firing rates tended to rise during the concentric phase and fall during the eccentric phase of the cycle. In SCI subjects, motor units fired: 1) in a similar pattern to control units, 2) only during the end of the concentric phase but not during the eccentric phase, or 3) with two firing rate peaks, one immediately at contraction onset and another near the transition from the concentric to the eccentric phase. Given that SCI subjects were significantly weaker than control subjects, the latter motor unit firing pattern may reflect a different force control strategy during fatiguing dynamic contractions. Substantial modulation of motor unit firing rates versus motor unit recruitment may predominate in SCI subjects with reduced numbers of motor units left under voluntary control.

ULTRASTRUCTURE OF CGRP TERMINALS IN CAT SACRAL SPINAL CORD, WITH EVIDENCE FOR SPROUTING IN THE SACRAL PARASYMPATHETIC NUCLEUS (SPN) AFTER SPINAL HEMISECTION.

Q. Li*, M.S. Beattie, and J.C. Bresnahan, Dept. of Cell Biol., Neurobiol., and Anat.; and Neurosci. Prog., The Ohio State Univ., Columbus, OH 43210.

CGRP is contained within visceral and small diameter primary afferents in the sacral cord. CGRP-afferents have been implicated in regeneration and sprouting after spinal cord injury . CGRP-immunoreactive (-IR) terminals were identified using sequential light (LM) and electron microscopy (EM). In the sacral cord, CGRP-IR terminals were seen in Lissauer's tract, laminae I, II,V, lateral VII (SPN), dorsal gray commissure (DGC) and rarely in IX. Ultrastructurally, terminals (n=388 from 4 cats) contained clear vesicles (78.7% round; 22.9% pleomorphic; 3.4% flat) and most (89%) also contained dense core vesicles (DCVs; range 1-76/terminal; mean=7.3). Overall, 67.8% of the CGRP-IR terminals formed synaptic contacts with terminals in I&II having the highest probability of synapsing (71.6% with contacts) while in the SPN and DGC only 54.6% and 56.8% of the terminals exhibited synaptic contacts. The post-synaptic targets were predominantly distal dentrites (67.4%), with proximal dendrites (13.1%), axon terminals (11.7%) and cell bodies (7.8%) being less common. CGRP was also observed in cell bodies in the SPN and in motor neurons in the ventral horn.

Following T10 spinal hemisection, apposition of CGRP-IR terminals to SPN neurons was quantitatively assessed at the LM level for twenty-five somata/side/case (n=4 cats/group). In the 2 day survival group, 18.3% $\pm$ 3.5% (SD) vs 21.9%$\pm$4.5% of the cell surface was apposed to CGRP terminals on the control vs. hemisected side ($p>0.05$ whereas after 6 weeks, 19.4% $\pm$ 2.9% vs. 33.6%$\pm$ 4.8% of the cell surface was apposed to CGRP terminals on the control vs. hemisected sides ($p<0.05$). This suggests either synaptic sprouting of CGRP terminals or upregulation of CGRP in primary afferent inputs to the SPN cell somata. (Supported by NS-10165 and NS-31193)

EXPRESSION AND REGULATION OF GLUCOSE REGULATED PROTEIN 78 kDa CAUDAL TO A LOW THORACIC SPINAL CORD HEMISECTION

A. Schmitt[1,2], U.E. Olazábal[2]*, W. Nacimiento[1], G. Brook[1], J. Noth[1] and G.W. Kreutzberg[2]. [1]Dept. of Neurology, Technical Univ.Sch. of Med., 52057 Aachen and [2]Dept. of Neuromorphology, Max-Planck-Institute for Psychiatry, 82152 Martinsried, Germany.

Cellular heat shock proteins are induced in response to various stresses, including neurotoxicity and mechanical injury. We studied the expression of glucose regulated protein 78 kDa (GRP78) in the spinal cord caudal to a low thoracic hemisection. Segments ipsilateral and contralateral of L1, L3 and L5 were removed at 3d, 7d and 14d after hemisection (N=3 per group), prepared in SDS sample buffer and normalized with respect to total protein content. Immunoblotting was performed with a polyclonal antibody against GRP78 (BIP) and detected using enhanced chemiluminescence. No regulation of GRP78 was observed 3d and 14d after hemisection. In contrast, 7 day-hemisected animals demonstrated an up-regulation of GRP78, evident ipsilateral and caudal to the lesion in L1- and L3-segments and to a lesser degree in L5. In the same animals, immunofluorescence analysis using confocal laser microscopy from L2 and L4 segments revealed increased GRP78 labeling in ventral horn neurons on the operated side. OX-42 immunostaining at this time point showed reactive microglia. Some scattered cells were also GRP78 double-labeled, indicating a minor glial component to the GRP78 induction. Taken together, these results demonstrate a transient increase of the metabolic state primarily in ventral horn neurons caudal to hemisection.

EFFECTS OF NORADRENERGIC (NE) & SEROTONINERGIC (5-HT) AGONISTS ON THE LOCOMOTION OF ADULT CATS AFTER BILATERAL VENTRAL AND VENTROLATERAL SPINAL LESIONS

E. Brustein*, F. Lebel, J. Provencher, and S. Rossignol, Ctr. Rech. Sci. Neuro., Université de Montréal, Qc, Canada.

The effects of NE and 5-HT drugs, administered intrathecally, were studied in two chronically implanted cats after large, bilateral ventral and ventrolateral spinal lesions, performed through an opening in the pedicles at T13. Our former studies (Soc. Neurosci. Abstr: 21, 420, 1995) have shown that, after these lesions, cats recuperated voluntary quadrupedal locomotion but suffered from major long-term deficits such as poor weight support and inconsistent interlimb coordination leading to an inability in maintaining regular walking. NE and 5-HT drugs were chosen to try and improve these locomotor deficits because they are known to initiate and/or modulate the locomotor pattern of complete chronic spinal cats. EMGs synchronized to video images were taken during treadmill locomotion at different speeds and were compared before and after the drug application. NE (50-150μg/100μl) was found to increase weight support, maintenance and regularity of walking and, during early days post lesion, also improved cats walking speed. Clonidine (alpha-2 NE agonist, 25-150μg/100μl), which can initiate locomotion in complete spinal cats, caused deterioration of the locomotor performance manifested as a reduced weight support, a disorganization of the movement and a decrement of EMG activity and joint angular excursions. On the other hand, Methoxamine (alpha-1 NE agonist, 50-150μg/100μl) increased EMG amplitude and step cycle regularity resulting in an better locomotor stability and regularity. 5-HT agonists, such as Quipazine (50-100μg/100μl), also improved the walking by increasing the step cycle duration and regularity, result from a more consistent interlimb coupling. The effects of Methoxamine and Quipazine in combination were additive. Our results thus show that the effects of some drugs depend on whether or not the spinal lesion is complete. However, more importantly, the effects of the drugs can be integrated into the residual voluntary locomotor control to improve walking, probably by changing the excitability of spinal neurons involved in locomotion. NEUROTRANSMITTER RECEPTOR MODULATION CAUDAL TO COMPLETE SPINAL TRANSECTION

S.Croul*, A. Radzievsky and M.Murray
Depts of Pathology and Anatomy/Neurobiology, The Medical of College of Penna. Phila.,Pa. 19129

Serotonergic input to the spinal ventral horn may serve to depolarize motoneurons and facilitate reflexes. Following spinal transection, serotonergic agents can induce bipedal locomotr behavior. To clarify someserotonergic receptor modulations that occur distal to spinal transection, we have employed the ligand 125 I DOI and performed receptor binding autoradiography for 5HT1c/2 receptors.

Following complete thoracic transection of adult female rats, spinal cords were harvested both rostral and caudal to the transection site from 1day to 20 weeks following surgery. Binding densities for 125I DOI showed no changes rostral to the transection, but were increased 1.5 to 2 times controls at 2 and 8 weeks.

These results are suggestive of increased 5HT1c/2 expression and possibly supersensitivity in the spinal segements caudal to the transection. They suggest that pharmacotherapies which stimulate these receptors may be useful in enhacing locomotor function.

THE TRANSNEURONAL SPREAD PHENOTYPE OF HERPES SIMPLEX VIRUS TYPE I INFECTION OF THE MOUSE HIND FOOTPAD J.P. Engel, T.C. Madigan, G.M. Peterson*. Departments of Medicine/Anatomy & Cell Biology, East Carolina Univ Sch Med, Greenville, NC 27858.

The mouse hind footpad inoculation model has served as a standard laboratory system for the study of the neuropathogenesis of herpes simplex virus type 1 (HSV-1) infection. The temporal and spatial distribution of viral antigen, known as the transneuronal spread phenotype, has not been described, nor is it understood why mice develop paralysis in an infection that involves sensory nerves. The HSV-as-transneuronal-tracer experimental paradigm was used to define the transneuronal spread of HSV-1 in this model. A new decalcification technique (EDTA) and standard immunocytochemical staining of HSV-1 antigens enabled a detailed analysis of the time-space distribution of HSV-1 in the spinal cord and brain stem. Mice were examined at days 3, 4, 5, and 6 post-inoculation (p.i.) of a lethal dose of wild-type HSV strain 17 *syn+*. Viral antigen was traced anterograde into first order neurons in dorsal root ganglia at day 3 p.i., to the dorsal spinal roots at days 4 and 5 p.i., and to second and third order neurons within sensory regions of the spinal cord and brain stem at days 5 and 6 p.i. HSV-1 antigen distribution was localized to the somatotopic representation of the footpad dermatome within the dorsal root ganglia and spinal cord. Antigen was found in the spinal cord gray and white matter sensory neuronal circuits of nociception (spinothalamic tract) and proprioception (dorsal spinocerebellar tract and gracile fasciculus). Because motor neurons were not involved, we postulate that hindlimb paralysis resulted from intense infection of the posterior column (gracile fasciculus), a region known to contain the corticospinal tract in rodents.

DIFFERENTIAL REGULATION OF VAMP-1 AND VAMP-2 GENE EXPRESSION IN SPINAL MOTONEURONS AFTER AXOTOMY. G. Jacobsson, F. Piehl and B. Meister*, *Department of Neuroscience, Karolinska Institute, S-171 77 Stockholm, Sweden.*

*V*esicle-*a*ssociated *m*embrane *p*rotein (VAMP; synaptobrevin) participates in the regulation of transmitter release. VAMP-1 and VAMP-2 are two isoforms that are encoded by different genes. We have axotomized the rat sciatic nerve in order to study the regulation of the two isoforms. Using *in situ* hybridization, the mRNA levels in spinal motoneurons of VAMP-1 and VAMP-2 were studied in parallel with mRNA levels for choline acetyltransferase (ChAT) and α-calcitonin gene-related peptide (α-CGRP). In normal animals, there was a strong hybridization signal for VAMP-1 mRNA and a weak hybridization signal for VAMP-2 mRNA. After axotomy, VAMP-1 mRNA levels decreased and VAMP-2 mRNA levels increased in motoneurons belonging to the sciatic pool. VAMP-1 mRNA levels decreased rapidly until 1 week after axotomy, to further decrease at 2 and 3 weeks. In contrast, VAMP-2 mRNA levels increased until 2 weeks, to show a decrease at 3 weeks. Comparison of VAMP-1 and ChAT mRNA levels showed a similar pattern until 1 week, with an initial decrease, whereafter the levels of ChAT mRNA showed an increase. Both VAMP-2 and α-CGRP mRNA expression increased, although VAMP-2 mRNA levels increased more and reached its maximum later than α-CGRP mRNA levels. The results suggest that VAMP-1 and VAMP-2 genes are differentially regulated in spinal motoneurons after sciatic nerve axotomy and may have different roles in exocytotic events.

SEROTONIN MODULATES NMDA RECEPTOR-MEDIATED INTRINSIC VOLTAGE OSCILLATIONS IN NEONATAL RAT LUMBAR MOTONEURONS AND INTERNEURONS. J.N. MacLean*, K.C. Cowley, and B.J. Schmidt. Depts. of Medicine and Physiology, University of Manitoba, Winnipeg, MB, Canada R3E 0W3.

Mammalian motoneurons (MNs) and interneurons (INs) are capable of generating intrinsic voltage oscillations in the presence of NMDA and TTX (*Hochman et al. J. Neurophysiol. 72(2) and 72(4) 1994*). These properties may contribute to the rhythmic activity underlying certain behaviors such as locomotion. In the present series, 5-HT receptor antagonists (methysergide 160 μM, mianserin 150 μM, or cyproheptadine 80 μM) blocked NMDA- or acetylcholine-induced rhythmic hindlimb activity in 7/7 bilaterally intact *in vitro* neonatal rat spinal cord preparations. We then obtained whole cell recordings of MNs and INs, in order to test the effect of 5-HT receptor activation and blockade on intrinsic oscillations. In some neurons rhythmic NMDA-induced sinusoidal oscillations (0.8 Hz) were blocked by TTX (1-2 μM). All but one of these cells displayed a linear response to injected current ramps. In contrast, other neurons were capable of generating intrinsic oscillations after suppression of synaptic activity with TTX; these cells displayed a non-linear response to current ramps. MN oscillations averaged 20 mV in amplitude and were morphologically unchanged after TTX, although slower in frequency (0.5 Hz). In one MN, NMDA-induced oscillations were abolished by TTX but the ramp response was non-linear; these oscillations were restored by 5-HT. After application of the 5-HT receptor antagonist mianserin (80--150 μM) MN and IN intrinsic oscillations were replaced by long-lasting, arrhythmic, abrupt depolarizing and hyperpolarizing shifts of membrane potential averaging 26 mV. This bistable behavior was resistant to shifts in holding potential between -60 and -30 mV, while below and above this range cells remained tonically hyperpolarized or depolarized, respectively. These preliminary observations suggest that 5-HT may have a role in the modulation of NMDA receptor-dependent oscillatory activity in lumbar MNs and INs. (Supported by: HSCF, MHRC and NCE)

NON-NMDA- AND GLYCINE-MEDIATED MINIATURE SYNAPTIC CURRENTS IN SPINAL MOTONEURONS OF IMMATURE RATS. B.-X. Gao*, G. Cheng, and L. Ziskind-Conhaim. Dept. of Physiology and Ctr. for Neuroscience, Univ. of Wisconsin, Madison, WI 53706.

The frequency of miniature excitatory and inhibitory postsynaptic currents (mEPSCs and mIPSCs) increases by 5-7-fold between embryonic days 17-18 and 1-3 days after birth (Gao and Ziskind-Conhaim, Soc. Neurosci., 1995). In embryonic motoneurons in thin spinal cord slices (150 μm), the frequency of non-NMDA-mediated mEPSCs was 3-fold higher than that of NMDA-mediated mEPSCs. Similarly, the frequency of glycine-mediated mIPSCs was 3-fold higher than that of GABA-mediated mIPSCs. After birth, the frequencies of non-NMDA- and glycine-mediated miniature currents significantly increased, but the frequencies of NMDA- and GABA-mediated currents remained low. Consequently, the ratio of non-NMDA- to NMDA-mediated mEPSCs increased to 14, while the ratio of glycine- to GABA-mediated mIPSCs increased to 47. One explanation for these findings was that non-NMDA- and glycine-mediated synapses were located on proximal motoneuron dendrites, while NMDA- and GABA-mediated synapses were located on distal dendrites, which were probably severed in the thin spinal cord slice. To test this possibility, whole-cell voltage clamp experiments were carried out in thick spinal cord slices (350 μm) using infrared video microscopy. In postnatal motoneuron, the ratio of non-NMDA- to NMDA-mediated mEPSCs was 6, and the ratio of glycine- to GABA-mediated mIPSCs was 5. These findings suggested that non-NMDA- and glycine-mediated synapses were dominant on motoneurons, and they were probably located on more proximal dendrites than NMDA- and GABA-mediated synapses. Supported by NIH grant NS23808 to L.Z-C.

HORMONE-DEPENDENT PHENOTYPIC CHANGES IN A MOTOR NEURON HYBRID CELL LINE TRANSFECTED WITH THE HUMAN ANDROGEN RECEPTOR. B.P. Brooks, H.L. Paulson, D.L. Kolson, D.E. Merry, E.F. Salazar-Grueso,* A.O. Brinkmann, and K.H. Fischbeck. University of Pennsylvania, Dpt. of Neurology, Phila., PA 19104

The androgen receptor (AR) is normally expressed in motor neurons. Androgens have been shown to promote the survival of these cells and to accelerate the rate of axonal regeneration after axotomy. In order to study the mechanisms by which androgens exert these effects we have stably transfected a motor neuron-neuroblastoma hybrid cell line with the human AR cDNA. Expression of the AR has been confirmed by Western blot, ligand binding, immunofluorescence, and hormone-dependent reporter gene activation. These cells can be differentiated into postmitotic neuron-like cells that express several neuronal markers (choline-acetyl transferase, acetyl cholinesterase, and neurofilament proteins) and continue to express AR. When differentiated in the presence of androgen, AR-expressing clones display an altered phenotype, characterized by a fusiform appearance and an increase neurite diameter. These androgen-treated cells continue to express neuronal markers and show enhanced survival under low serum conditions. Control cell lines differentiated in the presence or absence of androgens do not exhibit such phenotypic changes. We believe these cells are a useful model system for studying the role of the androgen receptor in motor neurons.

A COMPARTMENTAL MODEL OF BISTABLE AND COMPLEX FIRING PATTERNS OF VERTEBRATE MOTONEURONS

V. Booth, J. Rinzel* and O. Kiehn†. Math. Research Branch, NIDDK, NIH; †Sect. of Neurophysiology, University of Copenhagen, Copenhagen, Denmark.

In contrast to the limited response properties observed under normal experimental conditions, motoneurons generate complex firing patterns in the presence of certain transmitters and channel blockers. For example, Ca^{2+}-dependent regenerative responses are uncovered by TEA when Na^+ currents (I_{Na}) are blocked with TTX (Hounsgaard, Kiehn and Mintz, J. Physiol. (1988) 398:575-589) and bistable repetitive firing modes and plateau potentials are induced by 5-HT presumably by blocking a Ca^{2+}-dependent K^+ current (I_{KCa}) (Hounsgaard and Kiehn, J. Physiol. (1989) 414:265-282). These complex firing patterns are believed to depend on a nonuniform distribution of conductances between the soma and dendrites. We investigate the roles of specific ionic currents and their distribution in generating these firing patterns with a quantitative model consisting of two compartments. The soma compartment, representing the soma and proximal dendrites, contains Hodgkin-Huxley-like I_{Na} and delayed rectifier K^+ current (I_{Kdr}), an N-like Ca^{2+} current (I_{Ca}) responsible for the transient influx of Ca^{2+} during action potentials and I_{KCa} underlying the slow after-hyperpolarization. The dendrite compartment, representing the lumped distal dendrites, contains, in addition to N-like I_{Ca} and I_{KCa} as in the soma, a persistent L-like I_{Ca}. When the action of pharmacological agents are simulated, the model reproduces similar changes in action potential profile and regenerative responses as observed experimentally. That is, plateau potentials are induced by the reduction of I_{Kdr} (mimicking the effect of a high concentration of TEA) and I_{KCa} (corresponding to the effect of apamin or 5-HT). Pure calcium spikes could also be obtained. We additionally investigated 5-HT effects on several conductances located in both compartments.

DENDRITIC PLATEAU POTENTIALS AND BISTABLE FIRING IN SPINAL MOTONEURONS: COMPUTER SIMULATION STUDIES. R.H. Lee* and C.J. Heckman, Department of Physiology, Northwestern University Medical School, Chicago IL, 60611.

A computer simulation of the adult spinal motoneuron was constructed to investigate the role of somatic vs. dendritic conductances in the generation of bistable firing in spinal motoneurons. The hypothesis was that our voltage clamp experimental data (see accompanying abstract by Heckman and Lee) could be simulated by adding dendritic compartments with persistent inward Ca channels to a single compartment model of motoneuron rhythmic firing. The somatic compartment included Na and K channels for the spike, a Ca-mediated K channel for the AHP, an H channel, and a persistent Ca channel. A pump and buffer system controlled Ca concentration. Parameters for somatic channels were set via a goal-seeking algorithm that sought to match a large set of normal motoneuron behaviors.

A single dendritic compartment allowed simulation of the depolarization-dependent amplification of Ia effective synaptic current and development of Ia tail currents during clamp of the somatic compartment. Hysteresis in the cell's i-v function also developed as in the experimental data. The hysteresis was due to differential polarization of the dendrites vs. the soma during the rising and falling phases of the triangular voltage command. Inclusion of multiple, parallel dendritic compartments each with slightly different coupling conductances, representing multiple dendritic branches, produced a more gradual N shape during the falling phase than did the single dendritic compartment. These results are consistent with a dendritic origin for plateau potentials in motoneurons.

DENDRITIC PLATEAU POTENTIALS AND BISTABLE FIRING IN SPINAL MOTONEURONS: *IN VIVO* VOLTAGE CLAMP STUDIES. C.J. Heckman* and R.H. Lee. Department of Physiology, Northwestern University Medical School, Chicago IL, 60611.

In the presence of the noradrenergic α-1 agonist methoxamine, spinal motoneurons in the decerebrate cat preparation tend to exhibit bistable firing (i.e. sustained firing evoked by a brief synaptic input). Previous work (e.g. Bennett et al., Soc. Neurosci. Abstr. 21, p. 145, 1995) suggests that this behavior is in part due to plateau potentials in the dendrites. We utilized the single electrode voltage clamp technique to further investigate this hypothesis.

A 1.5 s period of steady synaptic input in muscle spindle Ia afferents was evoked in triceps surae motoneurons by vibration of the Achilles tendon. During voltage clamp at depolarized holding potentials, Ia effective synaptic current during vibration underwent enormous amplification (~5-fold) and a prolonged tail current was present after vibration ceased. The duration of the Ia tail current correlated with the duration of bistable firing in each cell (r=0.82, n=15). Studies of the motoneuron i-v relation based on a slow triangular command voltage (40 mV amplitude; 10 s total duration) revealed a strong "N" shape during both the rising and the falling phases. However, the N for the falling phase occurred at a substantially lower membrane potential and also tended to be more gradual than the N during the rising phase.

Because the voltage clamp held the behavior of active conductances at the soma constant, all of these phenomena (the amplification of Ia current, the Ia tail current, and the hysteresis in the i-v function) were likely to have originated in regions electrically distant from the clamped soma - i.e. the dendrites.

THE FORM OF MOTONEURON DENDRITES: OPTIMALITY, FRACTALITY, AND PARSIMONY W. B. Marks* Lab. of Neural Control, NINDS, Bethesda, MD 20892

This is a search for a form factor which is maximal for natural dendrites and cannot be exceeded by any other dendrite morphology. In *Soc Neuro Abstr* 21: 145, 1995 I suggested that the form of motoneuron dendrites tends to maximize the ratio F; the connectivity-weighted extracellular volume invaded divided by the dendrite volume: $F = V/v$, with $V = \Sigma\, m(x)\, dV(x)$, and v = dendrite volume. The sum is over all points x along the dendrite, dV(x) are extracellular volume elements within about 200 μM of x, and m(x) is the fraction of current injected at x that reaches the stem. The distribution of F is reasonably constant over a wide range of sizes for natural dendrites.

A parametric model that fitted motoneuron branch lengths (Burke, Marks, and Ulfhake, *J Neurosci* 12:2403, 1992) was augmented with branch angles, and the parameters were varied to maximize F. For branch length parameters somewhat different those of natural ones, model dendrites attained an F about twice that of natural ones. However these had straight dendrites, whereas natural dendrites meander. For most motoneuron branches, the Euclidian distance between two points on the branch compared with the path length between them fitted the relation, distance = path^H, where H = approx .95. Thus the path is fractal, with dimension D = 2 - H = 1.05. Model dendrites which meandered by this amount approached natural ones in optimal parameter values and the value of F. Plots of F against branch angles, branch lengths, branch diameters, and dendrite size were also comparable to their occurrence among motoneurons, with some interesting discrepancies. Absent those exceptions we have a parsimonius description: the form of a motoneuiron dendrite is any shape that maximizes F.

DYNAMIC RESPONSES OF MOTONEURONS TO CURRENT TRANSIENTS STUDIED WITH THE WHITE NOISE METHOD. A.V. Poliakov*, R.K. Powers, and M.D. Binder. Department of Physiology & Biophysics, University of Washington, Seattle, WA 98195.

Motoneurons generally perform a linear transformation of input currents to output firing frequency under steady-state conditions. However, their responses to transient inputs has a substantial nonlinear component. To derive a generalized expression for the input-output function of motoneurons, we used the *white noise* method of systems identification on both rat hypoglossal motoneurons *in vitro* and on cat lumbar motoneurons *in vivo*. A series of 40 s currrent steps with superimposed zero-mean random processes were injected into the motoneurons. We then estimated the first three Wiener kernels using the cross-correlation technique (Bryant & Segundo *J. Physiol.* 260: 279, 1976). For both neuron types, the input-output transform can be well described by a second-order Wiener model, which in turn can be approximated with a cascade of a linear filter followed by a static nonlinearity. However, the time course of the Wiener kernels in rat hypoglossal and cat lumbar motoneurons was substantially different. This suggests that the pattern and duration of firing-rate modulation produced by synaptic inputs is quite different in these two types of motoneurons. We also studied the effects of a number of factors (temperature, neuromodulators, toxins etc.) on the dynamic and static firing properties in motoneurons. (Supported by NINDS grants NS31925 and NS26840)

725.9

MODELING THE CONTRIBUTION OF AHP SUMMATION TO SPIKE-FREQUENCY ADAPTATION IN MOTONEURONS. R.K. Powers*, J.R. Musick, and M.D. Binder. Dept. of Physiology & Biophysics, Univ. of Washington, Seattle, WA 98195.

A calcium-activated potassium conductance produces the afterhyperpolarization (AHP) following an action potential in a motoneuron. The intial phase of spike-frequency adaptation in response to a step of injected current is thought to reflect the summation of the AHP conductance produced by successive action potentials (cf. Baldissera et al. *Brain Res.* 52:382,1973). To better understand the relationship between initial adaptation and AHP summation, we attempted to replicate the discharge behavior of individual cat and rat motoneurons using neuronal models of varying complexity .

We measured a number of sub- and suprathreshold behaviors in individual motoneurons in order to fix certain model parameter values and constrain others. We initially varied parameter values to provide an optimal fit to the time course of the AHP following 1 to 6 directly-evoked spikes at various interspike intervals. We then tested the ability of a given model to replicate repetitive discharge following suprathreshold current steps of various amplitudes. The simplest of these models, which featured a fixed spike threshold and an exponentially-decaying AHP conductance, underestimated the extent of spike-frequency adaptation and failed to reproduce its time course. More complete models that included a variable spike threshold as well as an explicit representation of calcium entry and buffering, produced better matches to the observed patterns of discharge behavior. (Supported NIH grants NS 31925 and NS 26840)

725.10

AHP SUMMATION AND SPIKE-FREQUENCY ADAPTATION IN RAT HYPOGLOSSAL MOTONEURONS. J.R. Musick, R.K. Powers and M.D. Binder*. Dept. of Physiology & Biophysics, Univ. of Washington, Seattle, WA 98195.

The intial phase of spike-frequency adaptation following the onset of a step of injected current in motoneurons is thought to be due to summation of a calcium-activated potassium conductance (Gkca) underlying the post-spike afterhyperpolarization (AHP: e.g. Baldissera et al. *Brain Res.* 52: 382, 1973). We studied the quantitative relationship between AHP summation and initial adaptation based on *in vitro* intracellular recordings from rat hypoglossal motoneurons. Gkca summation was estimated from the peak magnitude of AHPs following 1 - 6 spikes evoked either by 1 ms suprathreshold current pulses at a fixed interpulse interval or by a constant current step of fixed magnitude and variable duration. We then measured repetitive discharge evoked by 2 s current steps of different amplitudes. Measurements were made both in control perfusate and in a solution containing 1 mM TEA (which acts to broaden the spike and increase calcium influx).

We quantified initial adaptation as the decrease in the slope of the frequency-current relation (f/i slope) between the first and second interspike intervals. The average decrease in f/i slope was 59% in control conditions versus 28% in TEA. The increase in AHP amplitude from 1 to 2 spikes was 58% in control conditions and 20% in TEA. These data indicate a rough correlation between the amount of AHP summation and intial adaptation. Further study of this relationship is on going using additional pharmacological manipulations to affect calcium entry and buffering. (Supported by NIH Grants NS31925 & NS 26840)

725.11

PERIODIC FIRING AND INTERACTIONS OF SPINAL INTERNEURONS OF AWAKE BEHAVING MONKEYS. Y. Prut, S.I. Perlmutter*, E.E. Fetz. Dept. Physiology & Biophysics & Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195

Activity of pairs of C7-T1 spinal interneurons was recorded with single electrodes in 3 macaques producing isometric, ramp-and-hold flexion-extension torques at the wrist. The firing rate of one or both cells of each pair was modulated during the task. 10/70 pairs exhibited synchronous firing, identified by peaks in their cross-correlation histogram. Delayed peaks for 3 pairs (mean onset =1.5 ms, width=4 ms) suggested a serial connection between the units. 7 pairs had symmetric peaks straddling the origin (mean width=18 ms), suggesting shared or synchronous inputs to the 2 cells. The duration of these peaks was comparable to that of synchrony effects in spike-triggered averages of forearm muscle EMG from spinal interneurons (12 ms). The presence or strength of synchrony between units was often modulated during the task.

15 cells had oscillatory autocorrelograms. A running estimator was developed to detect episodic oscillations in spike trains. The estimate quantified the deviation of spike times from a grid of 4 Gaussians recurring at a given frequency. This method revealed that 34 interneurons had periods of regular firing of 25-65 Hz. Most of these cells (n=22) fired rhythmically only for torques in the direction that activated the cell, although many fired bidirectionally. Other cells (n=4) had bi-stable periodicity, oscillating at different frequencies in different phases of the task. The frequency and phase of these oscillations were not consistent across cells, including paired cells. These results suggest that rhythmic firing is common in spinal interneurons. The source of this periodicity is unknown, but the wide range of frequencies, long duration of periodic firing and lack of correlated oscillations in pairs suggest they are not driven by a cortical source. A SUBPOPULATION OF CHOLINERGIC SPINAL CORD NEURONS IN LAMINA VII POSSESS L-TYPE CALCIUM CHANNELS. S.C. MacDonald*, M.A. Sawchuk, and L.M. Jordan. Department of Physiology, University of Manitoba, Winnipeg, MB, CANADA, R3E 0W3

Acetylcholine plays an important role in locomotion, and it has been previously shown that cholinergic neurons in Rexed's lamina VII are active during locomotion (Carr et al. Brain Res. Bull. 37:213). There is also reason to believe that L-type Ca^{2+} channels are involved in the control of locomotion as they have been previously shown to sustain plateau potentials in spinal motor neurons. A population of turtle commissural neurons has also been shown to possess plateau potentials and L-type Ca^{2+} channels (Hounsgaard and Kjaerulff, Eur. J. Neurosci, 4:183). To explore the possibility that plateau potentials might contribute to the control of locomotion, our goal was to determine whether interneurons in the cat spinal cord possess L-type Ca^{2+} channels.

Lumbar spinal cord sections from 3 cats were fixed in 4% paraformaldehyde and subsequently processed immunohistochemically for choline acetyltransferase (ChAT) and the α_2- subunit of the dihydropyridine receptor, which is associated with L-type Ca^{2+} channels (Ahlijanian et al. Neuron, 4:819).

Preliminary results have shown that a population of neurons exists in lamina VII near the central canal which is positive for ChAT and the α_2- subunit of the dihydropyridine receptor. These neurons were stellate in shape and possessed a mean soma diameter of 29.7± 9.8 μm (n=14). They comprised 36% of the cholinergic neurons in medial lamina VII.

These results demonstrate the presence of a population of spinal cord neurons in lamina VII which are cholinergic and possess L-type Ca^{2+} channels. It is possible that this population is capable of plateau potentials and may play an important role in spinal rhythmic activity

TARGETING FUNCTIONAL POPULATIONS OF SPINAL NEURONS WITH FLUORESCENT RECEPTOR LIGANDS IN A SLICE PREPARATION: THE BIOGENIC AMINES. S. Hochman*, M. Sawchuk, & L. Song. Dept. Physiology, Univ. of Manitoba. Winnipeg, MB, Canada R3E 0W3.

The strength of the CNS slice preparation lies in a reliable cell identification *in situ* coupled to electrophysiological, pharmacological and imaging approaches that elucidate synaptic and cellular function. Unfortunately, in spinal cord, morphologic and topographic criteria are often insufficient for neuron identification. Thus, characterization of subpopulations of spinal neurons requires an alternate approach.

The biogenic amines exert pronounced actions in the spinal cord that include modulation of the synaptic/cellular properties associated with nociception, segmental reflex pathways, and locomotion. Histochemical studies have revealed an overlapping but differential distribution of amine receptor subtypes and suggest that neurons express a limited subset of amine receptors in a function-specific manner. Hence, we have used high-affinity fluorescent receptor probes to cholinergic, dopaminergic and adrenergic receptor subtypes to identify sub-populations of living spinal neurons.

To date, antagonists to the muscarinic M_1 (BODIPY 558/568 pirenzipine), the adrenergic α_1 (BODIPY-FL prazosin) and the dopaminergic D_1 receptor (BODIPY FL SCH23390) (0.1-1.0 μM for 5-15 minutes) have been applied to 'ultrathin' slices of neonatal rat spinal cord (30-50 μm). Following reperfusion with control ACSF, only a small fraction of neurons within the spinal cord retained the receptor-bound probes, and were markedly fluorescent. Cells exhibiting D_1 receptor-selective labeling were localized to the dorsal horn while M_1 and α_1 receptor probes identified small populations of neurons with a diffuse distribution. Cell viability was confirmed using complementary fluorescent live/dead cell stains. Future studies are aimed at an electrophysiological characterization of these receptor-selective neurons.

FUNCTIONAL AND MORPHOLOGICAL PROPERTIES OF THE MAUTHNER SYSTEM IN THE ADULT ZEBRAFISH. K. Hatta[1], G. Rao[2], and R.C. Eaton[2] and H. Korn*[1]. [1]Institut Pasteur, Inserm U261, Paris, France; [2]Dept. of Biology, Univ. of Colorado, Boulder, CO.

In the zebrafish (ZF) as in the goldfish, which has become a reference for studies of the Mauthner (M-cell) this neuron is characterized by the presence of the "axon cap," (AC) a peculiar structure which surrounds the initial segment of the M-axon. The high resistivity of the AC accounts for an unusual amplification of the fields generated within and around it. Extra- and intracellular recordings were performed with KCl and KAc filled microelectrodes in the brain of anaesthetized (MS222) and immobilized (Pavulon, 1 μg/g body weight) adult ZF continuously perfused through the mouth. Overall, our data indicate that the properties of the M-cell and of its afferent networked are essentially the same as in the goldfish, and that inhibition controls at all time their function. Specifically, the M-cell extracellular field is large (10-20 mV) close to the axon hillock and the latency of intracellular antidromic spikes (RP, -70 to -80 mV; input resistance: ~0.5 MΩ) is short (0.2-0.5 msec), confirming a high conduction velocity of the M-axon. The "EHP" which signals firing of presynaptic cells as well as the collateral inhibition (and its associated conductance changes) decrease at frequencies of spinal stimulation > 5/sec, suggesting a similar organization of the recurrent collateral network as in the goldfish. The time course of evoked and spontaneous unitary IPSPs recorded from the soma and in the lateral dendrite parallels that of the underlying IPSCs recorded in voltage clamp; their decay is short (τ = 4-6 msec), i.e., in the range of glycinergic ones in the goldfish and of the mean open time of glycine activated channels in the ZF embryo. As in goldfish IPSPs are highly voltage-dependent, since their decay time constant is increased by depolarizations. The spontaneous IPSPs are due to the random firing of presynaptic glycinergic neurons which are numerous in the vicinity of the axon cap and can be identified by their PHP (2-6 mV). Sensory responses, such as mixed (electrical and chemical) sound evoked dendritic EPSPs (latency ~2.4 msec, at 500 Hz), can fire the M-cell with short delays and hence, trigger the escape reaction of the ZF.

POSTNATAL DEVELOPMENT OF $5HT_{1A}$ RECEPTOR-MEDIATED RESPONSES AND $5HT_{1A}$ RECEPTOR EXPRESSION IN RAT HYPOGLOSSAL MOTOR NEURONS E.M. Talley, N. Sadr and D.A. Bayliss*. Dept. of Pharmacology, Univ. of Virginia, Charlottesville, VA 22908.

We compared the electrophysiological responses to 5-HT of neonatal and adult rat hypoglossal motor neurons (HMs) using intracellular recording techniques in a brainstem slice preparation. 5-HT caused a decrease in the amplitude of spike afterhyperpolarization (AHP) in neonates (≤ P8) but not in adults (≥ P21). 8-OH-DPAT, a $5\text{-}HT_{1A}$ agonist, has been shown to mimic this effect in neonates, suggesting that the response is mediated by a $5HT_{1A}$ receptor. The 5-HT-induced inhibition of the AHP caused a substantial increase in minimal firing frequency (F_{min}) in neonates. In adult HMs, 5-HT did not change F_{min}; however, intracellular injection of the long-lasting GTP analog, GTPγS, induced an agonist-independent increase in F_{min} similar to that seen in neonates after 5-HT. This implies that intracellular mechanisms which mediate effects on the AHP downstream of the $5\text{-}HT_{1A}$ receptor are present in adults. It further suggests the hypothesis that age-related differences in these effects of 5-HT may be due to developmental regulation of the $5HT_{1A}$ receptor. To test this hypothesis, we performed ligand binding autoradiography using [^{3}H]8-OH-DPAT and *in situ* hybridization using oligodeoxyribonucleotide probes specific for $5HT_{1A}$ receptor mRNA. With both techniques, higher levels of receptor expression were observed in the hypoglossal nucleus of neonates than adults. Maximal binding and hybridization occurred between postnatal day zero (P0) and seven (P7), with very low levels by P28. *In situ* hybridization revealed higher levels of $5\text{-}HT_{1A}$ receptor mRNA in ventral HMs, which innervate tongue protruder muscles. Finally, immunohistochemistry for 5-HT showed that the developmental regulation of the $5HT_{1A}$ receptor in HMs was coincident with substantial increases in serotonergic innervation of the hypoglossal nucleus. SEROTONERGIC NEURONS IN THE NEONATAL RAT CAUDAL MEDULLA: INTRINSIC PROPERTIES, NEUROMODULATION AND SYNAPTIC INPUTS. Y.-W. Li,* E.M. Talley and D.A. Bayliss. Department of Pharmacology, University of Virginia, Charlottesville, VA, 22908.

Serotonergic neurons in raphe obscurus and pallidus are important in regulation of motor and autonomic functions, yet little is known about their intrinsic properties, neuromodulation or synaptic inputs. Whole-cell recordings were made from visually identified raphe neurons in medullary slices (150 μm) of neonatal rats (P2-P6) at room temperature. Recorded neurons were filled with Lucifer Yellow and stained for tryptophan hydroxylase immunoreactivity. Serotonergic neurons (n=20) displayed irregular spontaneous discharge (1.2±0.1 spikes/s) and had an input resistance of 1.6±0.1GΩ at "resting potential" (-48±0.4mV). Action potential amplitude and duration were 78.5±1.1mV and 6.2±0.1ms. Serotonergic neurons showed a decrementing discharge pattern in response to current injections. Discharge rate at the beginning of a 2-s current pulse (instantaneous) was maximal and declined to a steady-state (3-4 spikes/s). Larger depolarizing current pulses increased instantaneous discharge, but had minimal effects on steady-state discharge rate. In voltage clamp, both 5-HT (1-5 μM) and noradrenaline (10 μM, in the presence of α_1 and β adrenoceptor antagonists) decreased high-voltage activated Ca^{++} currents (n=10), but only 5-HT increased inwardly rectifying K^+ currents (n=7). Electrical stimulation (0.1-0.2 ms, 5-25 V) of single raphe neurons evoked excitatory postsynaptic currents (EPSCs) in 9/12 raphe cells (including 5 histologically-recovered serotonergic neurons). EPSCs had a latency of 3.0±0.1 ms and amplitude of 55±4.4 pA (n=9). τ_{on} and τ_{off} were 2.8±0.3 ms and 6.2±0.6ms (n=9), respectively. Kynurenic acid (0.5 mM) attenuated or blocked EPSCs. These results indicate that: 1) serotonergic neurons in the caudal raphe are intrinsically active *in vitro* with an adapting firing pattern; 2) 5-HT and α_2 agonists have differential effects on these cells; and 3) serotonergic neurons receive glutamate/asparate-mediated fast excitatory synaptic inputs from adjacent raphe cells. AN ELECTROPHYSIOLOGICAL STUDY OF BRAINSTEM PROJECTIONS TO TRIGEMINAL MOTONEURONES IN LAMPREYS. **D. Petropoulos, J.P. Lund* and R. Dubuc,** *Dép. de kinathropologie, Université du Québec à Montréal, H3C 3P8 and CRSN, Université de Montréal, H3C 3J7 and Faculty of Dentistry, McGill University, Québec, Canada H3A 2B2*

Feeding behaviour (Kawasaki and Rovainen, *Brain Behav. Evol.* 32:317, 1988), and the topographical representation of muscles in the trigeminal motor nucleus (mot V) (Homma, *Brain Res.* 140:33, 1978) have been previously studied in lampreys. However, little is known about the brainstem networks that control the activity of these motoneurones. As a first step, Huard et al. (*Soc. Neurosci. Abstr.* 21:142, 1995) identified several populations of brainstem neurones that project to mot V, with anatomical methods. To verify that these neurones make synaptic connections with trigeminal motoneurones, we carried out electrophysiological experiments in the *in vitro* isolated brainstem preparation of young adult lampreys, *Petromyzon marinus.* Glass-coated tungsten microelectrodes were used for stimulation of all the brainstem sites that had been shown to contain projection neurones. Synaptic responses were recorded intacellularly in trigeminal motoneurones. Microstimulation of all sites elicited excitatory synaptic responses, which were significantly attenuated by adding CNQX (10μM) and 2-AP5 (200μM) to the perfusate. Microstimulation of the contralateral mot V, the principal sensory trigeminal nucleus (sensibilis), and ipsilateral regions caudal to mot V elicited large amplitude responses with a short latency and a sharp onset. An early electrical component of these responses persisted in Ca^{+2} free Ringer's. In summary, our data suggest that the anatomically identified brainstem premotor neurones excite trigeminal motoneurones via electrotonic and excitatory amino acid chemical synapses. NMDA-DEPENDENT PLATEAU POTENTIALS AND CALCIUM RESPONSES INDUCED BY CUTANEOUS INPUTS IN LAMPREY RETICULOSPINAL NEURONES. **G. Viana Di Prisco*, R. Robitaille and R. Dubuc,** *Dép. de kinanthropologie, Université du Québec à Montreal, H3C 3P8 and CRSN, Université de Montréal, Montréal, Québec, H3C 3J7 Canada.*

Reticulospinal (RS) neurones integrate sensory inputs and trigger motor outputs. We have combined electrophysiological and calcium imaging techniques to study the response of RS neurones to mechanical stimulation of the skin and/or electrical stimulation of the trigeminal nerves. Experiments were performed in larval lampreys (*Petromyzon marinus*) using an isolated brainstem-spinal cord preparation with the skin covering the snout. The preparations were pinned down to a chamber and perfused with oxygenated cold Ringer's. Intracellular recordings were done with sharp micropipettes (4M KAc). A linear relationship between the stimulus strength and the synaptic response was observed with small intensities. However, with stronger intensities or with repeated stimulation, non-linear sustained depolarising responses appeared which lasted several seconds. These plateau potentials were decreased by adding 2-AP5 (200 μM) to the perfusate, suggesting the activation of NMDA receptors. For Ca^{2+} imaging, RS neurones were preloaded retrogradely *in vitro* (48hrs) with Ca^{2+} Green-Dextran (10,000 MW). The images were recorded with an intensified CCD camera at a rate of 1-2 images per second. A large Ca^{2+} response, which decreased with 2-AP5, was observed in RS somata and axons. A smaller component of the Ca^{2+} response was due to the release from internal stores since locally applied glutamate could still elicit a response in Ca^{2+}-free conditions. A tight coupling of the Ca^{2+} influx to the membrane sustained depolarisation was confirmed with simultaneous recordings. We therefore hypothesize that the depolarizing plateaux, which are due at least in part to NMDA receptor activation, and are accompanied by a rise in intracellular Ca^{2+} , mediate a switch from a sensory response to a motor-related activity in RS neurones. ANATOMICAL STUDY OF CENTRAL PROJECTIONS TO THE OCTAVO-MOTORII NUCLEI IN THE LAMPREY. **J-F. Pflieger* and R. Dubuc,** *Dép. de kinanthropologie, Université du Québec à Montréal, H3C 3P8 and CRSN, Université de Montréal, Montréal, Québec, Canada, H3C 3J7.*

Vestibulospinal (VS) neurones of lamprey are located in the posterior (OMP) and intermediate (OMI) octavomotorii nuclei. They are innervated by primary vestibular afferents and relay incoming vestibular information about the orientation and movements of the head to reticulospinal and spinal neurones. The activity of VS neurones as well as vestibular transmission to reticulospinal neurones is phasically modulated during locomotion (Bussières & Dubuc, Brain Res., 575:174, 1992 and Brain Res., 582:147, 1992). However, brainstem and spinal neurones which project to VS neurones, and may be involved in this modulation, remain unknown. To identify these projections, cobalt-lysine was injected in the OMP-OMI region in one side of the *in vitro* brainstem-spinal cord preparation of young adult lampreys (n=5, 17-25cm). Transport times ranged from 48 to 72 hrs. The labelled brains were viewed in wholemount. In the rhombencephalon, scattered neurones were retrogradely labelled in the contralateral area octavolateralis ventralis. Other neurones were observed, forming a column laterally and ventrally to the posterior rhombencephalic reticular nucleus, on either side of the brainstem. A more densely packed group of neurones was labelled in the contralateral lobus auricularis, within the ithsmic region. The latter neurones also appeared to send an axonal collateral to the basal mesencephalon. Dorsal cells were retrogradely labelled in the ipsilateral spinal cord. A few scattered neurones were also observed in the spinal grey. Labelled neurones were not observed in the mesencephalon nor more rostrally. In summary, our results indicate that several groups of brainstem and spinal neurones project to the lamprey octavomotorii nuclei. Whether these neurones make synaptic contacts with VS neurones remains to be determined by using electrophysiological techniques. (Funded by a Group grant from the Canadian MRC and FCAR Québec. PNC NEURONS IN BRAIN SLICES: ELECTROPHYSIOLOGICAL PROPERTIES AND SYNAPTIC CONNECTIONS. T. Wagner*. Tierphysiologie, Univ. Tübingen, Auf der Morgenstelle 28, D-72076 Tübingen, Germany.

The giant neurons of the caudal pontine reticular nucleus (PnC) are the sensorimotor interface of the acoustic startle response in the rat. They receive afferent projections from auditory brainstem nuclei and project with their axons directly to motoneurons in the spinal cord. In the present study PnC neurons were recorded intracellularly using acute rat brain slices. Bipolar stimulation electrodes were inserted into afferent auditory structures to elicit postsynaptic potentials (PSPs). The morphology of the recorded neurons was revealed by intracellular injection of biocytin and subsequent staining using the ABC-System and a horseradish peroxidase / diaminobenzidine process. Pharmacology of elicited PSPs was tested by bath application of transmitter antagonists.

Short-latency excitatory PSPs were elicited after stimulation of afferent auditory structures in a large proportion of neurons recorded. Most effective were stimulations in the lateral superior olive (LSO). Application of the AMPA receptor antagonist NBQX resulted in a complete and reversible disappearance of these PSPs. A large proportion of the neurons recorded showed a low input resistance and a sustained AP-response to depolarizing current pulses. They were morphologically identified as giant neurons. Others showed high input resistances and differed in their responses to intracellular current pulses. This type of neurons showed rarely PSPs after stimulation of afferent auditory structures. Presumably these neurons resemble the small cells of the PnC.

The present study revealed that several structures - including the LSO - of the auditory brainstem elicit short-latency excitatory PSPs in PnC giant neurons. These projections are presumably glutamatergic using receptors of the AMPA-type. This raises the question if an excitatory glutamatergic input from more than one structure of the auditory brainstem is necessary to elicit a behavioral response to an auditory startle stimulus.

A STUDY IN INTRACELLULAR RECORDING AND LABELING IN THE NATURALLY SLEEPING CAT SHOWS ORDER OF REM SLEEP FIRING RECRUITMENT CORRELATES WITH SOMA SIZE OF PONTINE RETICULAR FORMATION NEURONS.

K.Ito*, M.Yanagihara, H.Imon, L.Dauphin, & R.W.McCarley. Lab. Neurosci.,Dept.Psych., Harvard Med. Sch./VAMC,Brockton MA 02401.

Acute intracellular labeling studies in our laboratory have examined the projections of giant cell field pontine reticular formation (FTG) neurons. Type I neurons had primarily reticulo-spinal projections, relatively few collaterals, and most had soma diameters $\geq$ 47.5 μm. Type II neurons projected to brainstem reticular sites, often had collaterals, and had soma diameters < 45.7 μm. The present study used intracellular recording and intracellular labeling (PhAL, biocytin, or neurobiotin) in naturally sleeping, chronic male cats to determine if the "lead time" of onset of markedly increased discharge rate prior to REM was correlated with soma size. Soma diameter was determined from digitizer measurements of cross-sectional area (inter- and intra-rater variation < 5%), and done blind to the physiology. RESULTS: Diameters of the 33 labeled neurons ranged from 43 μm to 88 μm (soma size range: $\approx$1500 - 6000 μm^2). Within this range there was a strong positive linear correlation between diameter and "lead time", which ranged from near zero minutes to about six minutes. That larger neurons had longer "lead times" was contrary to our expectation that smaller neurons, which might be Type II neurons with abundant reticular projections, would show earlier recruitment. It was also expected from the inverse size dependence of recruitment order in alpha motoneuronal pools. Earlier recruitment of larger neurons may reflect a stronger cholinergic excitatory input. *This research is supported by the Veterans' Administration (R.W.M) and NIMH 39,683 (R.W.M.).*

A 4-AP SENSITIVE SUSTAINED OUTWARD CURRENT CONTROLS DISCHARGE PROPERTIES IN TRIGEMINAL MESENCEPHALIC SENSORY NEURONS (MES 5) OF NEONATAL RAT.

Christopher A. Del Negro*, Scott H. Chandler, and Andrew M. Lapin. Dept. of Physiological Science, University of California Los Angeles, Los Angeles, CA 90095-1568.

The mesencephalic trigeminal sensory nucleus (Mes 5) is composed of sensory neurons innervating jaw-closer muscle spindles and periodontal mechanoreceptors. Their somata are located in the CNS and these neurons project to motoneurons and premotoneurons of the brainstem which control jaw musculature. Therefore Mes 5 constitutes an integral part of the neuronal circuitry for oral-motor pattern generation.

Current and voltage clamp experiments were performed on cells obtained from neonatal rat thin brainslices (age 1-7 days, 200 µm) using whole-cell patch clamp recording. Cells were visualized using infra red video-enhanced microscopy.

In current clamp, cells rapidly accommodated in response to depolarizing current injection. During 4-aminopyridine (4-AP) application (50 µM - 2 mM) similar stimuli evoked sustained repetitive spiking. In voltage clamp, 4-AP application (100 µM) revealed a small magnitude outward current ($I_{4\text{-}AP}$) which activated between -60 and -30 mV and exhibited sustained kinetics. Application of tetraethylammonium (TEA, 10 - 20 mM), to block other sustained outward currents, did not cause repetitive firing in current clamp.

$I_{4\text{-}AP}$ in Mes 5 ensures that rapid adaptation normally occurs in response to depolarizing current injection. The pharmacological reduction of $I_{4\text{-}AP}$ or its reduction potentially by neuromodulation can cause the cell to fire repetitively. This may indicate one way in which Mes 5 neurons could function as central interneurons in the CNS.

Funded by NIH-NIDR DE 016193.

724.23

TEA-SENSITIVE SUSTAINED CURRENT AND TRANSIENT OUTWARD CURRENTS INFLUENCE DISCHARGE PROPERTIES IN TRIGEMINAL MESENCEPHALIC SENSORY NEURONS (MES 5) OF NEONATAL RAT.

Scott H. Chandler*, Christopher A. Del Negro, and Andrew M. Lapin. Dept. of Physiological Science, University of California Los Angeles, Los Angeles, CA 90095-1568.

The complement of outward currents in Mes 5 neurons control excitation such that cells normally adapt rapidly to depolarizing current injections. However, removal of a 4-AP-sensitive sustained current allows sustained fast spiking behavior to emerge, as we discuss in our other presentation. Our goal in this study was to characterize the contributions of other outward currents to the control of excitation in these neurons.

Current and voltage clamp experiments were performed on cells obtained from neonatal rat thin brainslices (age 1-7 days, 200 µm) using whole-cell patch clamp recording. Cells were visualized using infra red video-enhanced microscopy.

When the membrane potential was held at hyperpolarized levels (< -55 mV), cells rapidly accommodated in response to depolarizing current. Adjusted to levels above -55 mV, cells discharged repetitive spike bursts which lasted ~100 ms or longer. This behavior can be explained by the presence of a transient A-like outward current which is available from hyperpolarized membrane potentials, preventing excitation from these levels.

In addition, a large magnitude TEA-sensitive sustained current was identified which activated between -40 to +40 mV and was responsible primarily for repolarization of action potentials. Removal of this current allowed Ca^{++}-mediated action potentials and plateau potentials to emerge.

HUMAN LOCOMATION

726.1

EYE, HEAD, AND TRUNK PHASE RELATIONSHIPS DURING TREADMILL LOCOMOTION WHILE VIEWING VISUAL TARGETS AT DIFFERENT DISTANCES.

B.T. Peters, J.J. Bloomberg, C.S. Layne, P.V. McDonald, W.P. Huebner*. Neuroscience Movement and Coordination Laboratory, NASA-Johnson Space Center, Houston, TX 77058.

We have previously demonstrated that ocular fixation of a near target (30 cm from the eyes) during treadmill locomotion utilizes synergistic eye and head movements to compensate for the vertical translation of the trunk to stabilize gaze (Bloomberg, 1992). However, it is not known whether a different compensatory strategy emerges when maintaining gaze on a target at optical infinity during locomotion. As part of a larger study investigating the effect of space flight on head and gaze control during locomotion, seven subjects visually fixated an eye-level, earth-fixed target at distances of 2 m (FAR) and 30 cm (NEAR) while locomoting on a treadmill at 6.4 km/hour. A video-based motion analysis system was used to obtain vertical trunk translation and head pitch data. Vertical eye movement and heel strike data were measured via DC-electrooculography and foot pressure switches, respectively. The vertical trunk translation, head pitch, and vertical eye movements were averaged per step cycle and the temporal relationships of the maxima and minima from each signal were used to calculate their phase relationships. During the NEAR target condition vertical eye movements were compensatory for vertical trunk translation, confirming our earlier results. Conversely, during the FAR target condition this relationship was modified and the vertical eye movements tended to compensate for pitch head movements. These results demonstrate that eye-head-trunk coordination strategies that occur during locomotion can be appropriately altered to contend with changes in visual target fixation distance. Importantly, the NEAR/FAR paradigm can be used to investigate space flight related changes in goal-directed eye-head-trunk coordination strategies that occur during locomotion.

VISUAL SEARCH PATTERNS AS WE APPROACH AND STEP OVER OBSTACLES IN THE TRAVEL PATH.

A.E. Patla* and J. Vickers. Department of Kinesiology, University of Waterloo, Waterloo, Ontario N2L 3G1, and Faculty of Kinesiology, University of Calgary, Calgary, Alberta T2N 1N4 Canada.

Gaze behaviours during locomotion in a cluttered environment were the focus of this study. Subjects (N=8) were required to travel along a 10 m pathway and step over obstacle (height: 1, 15 or 30 cm) located within the 4 to 6 m region. We examined the frequency and duration of three types of gaze behaviours with respect to the subjects stepping patterns using a mobile monocular corneal reflex eye tracker unit: obstacle fixation (ObsFix); travel fixation (TravFix) (when the eye is transported along with the locomotor apparatus) and fixation in the 4 to 6 m region (Fix4-6). During the approach phase to the obstacle, subjects fixated on the obstacle for ~ 20% of the travel time; TravFix duration was ~32% and Fix4-6 duration was ~4% of the travel time. Only Fix4-6 duration was modulated as a function of obstacle height (1 cm - 8.3 %; 15 cm - 2.6 %; 30 cm - 0.52 %) by regulating the frequency (1 cm - 0.8; 15 cm - 0.38; 30 cm - 0.1) and reflected the increased time needed for detection of the small low contrast obstacle in the travel path. Frequency of ObsFix increased significantly as a function of obstacle height (1 cm - 0.95; 15 cm - 1.45; 30 cm - 1.92) and reflects visuo-motor transformation needed for limb elevation control. Subjects did not fixate on the obstacle as they are stepping over, but did the planning in the steps before. In fact the frequency of ObsFix was zero in the one step before and step over the obstacle. TravFix duration and frequency was constant while Fix4-6 duration was higher in the step before and step over the obstacle reflecting visual search of the landing area for the lead limb following obstacle avoidance. These results clearly show that environmental information provided by vision is used in a feedforward rather than on-line control mode to regulate locomotion. Information about self motion acquired through optic flow and potential time to contact with the obstacle from retinal image expansion acquired during travel fixation can be used to control velocity and foot placement before the obstacle.

CHALLENGES TO HEAD STABILITY AFTER SPACE FLIGHT. P.V. McDonald*, M.A. LaFortune, C.S. Layne, and J.J. Bloomberg. Neuroscience Movement & Coordination Laboratory, NASAJohnson Space Center, Houston, TX 77058.

During locomotion, the initial foot-ground contact is characterized by an impact force. The shock created by this impact have been shown to travel through the body eventually reaching the head. We wished to determine whether the ability to attenuate this shock wave was changed as a result of adaptation to weightlessness, and to evaluate the influence of this shock wave on head and gaze stabilization. Before and after flight we measured the ground reaction forces (GRF) and head accelerations generated during overground locomotion while two crew members from one Shuttle flight were asked to walk toward, and fixate gaze on a target located at head height at the end of a 6m walkway. Our focus was on axial accelerations (vertically through the body) in a period of 256ms following heel strike.

Temporal domain analyses of the ratio of peak head shock and initial spike in the GRF illustrated a pronounced reduction of this ratio immediately after flight. Frequency domain analyses in the form of a transfer function between these same signals revealed reduced gain at frequencies between 4 and 32 Hz and more attenuation at frequencies between 32 and 60 Hz on landing day. For one subject these changes had disappeared 2 days after flight. However, the second subject showed a gain in the 16-32 Hz range which exceeded the preflight values, and which persisted even 4 days postflight.

These data reflect changes in the shock attenuation properties of the musculo-skeletal system, especially in the 2-4 hours immediately after flight. It is possible this departure from nominal gain/attenuation is directly related to the oscillopsia frequently reported by astronauts. Certainly the observed changes at the lower end of the spectrum fall within the traditionally identified operating bandwith of the vestibular system and thus we may anticipate correlated changes in dynamic visual acuity. However, is there any reason to speculate that the observed increase in attenuation in the 32-60Hz range will affect sensorimotor control? Future work will address these questions directly.

726.4

FRONTAL PLANE HEAD STABILIZATION DURING LOCOMOTOR TASKS. R.L. Cromwell*. Dept. of Physical Therapy, Temple University, Philadelphia, PA 19140.

Head stabilization has been investigated in the horizontal and sagittal planes (Cromwell, Soc. Neurosci. Abstr., 1994, 1995). Frequency analysis of head on trunk motion in these planes showed subjects to use compensatory motion at higher frequencies where head movements were challenged. This study examined four locomotor tasks in the frontal plane: normal walking (normal), arm swings at twice the normal frequency (frequency), large amplitude arm swings (amplitude), and arm swings 180° out of phase (phase). Angular velocities of head and trunk were collected. Data were integrated to obtain angular position. Standard deviations (SDs) of angular position provided an indication of head stability as compared to the normal condition. There was no significant difference ($p>.05$) between the SDs of head motion across all conditions. While head stability was similar in each condition, various head on trunk movement patterns were used to maintain head stability. Frequency analysis of angular velocity data demonstrated head on trunk motion that was both compensatory and non-compensatory at frequencies below 3 Hz. Above 3 Hz, head stability became challenged particularly in the frequency condition, showing frequencies as high as 15 Hz. At these higher frequencies, the head tended to move with the trunk indicating that subjects locked head on trunk to maintain head stability. One purpose for maintaining head stability is to facilitate gaze stability. Ocular counter-roll in the frontal plane compensates for only 50-70% of head movement (Collewijn et al., Exp. Brain Res., 1985). Perhaps the inability of the eye to perfectly compensate the head in this plane caused locking of the head on trunk at higher frequencies as a final effort to maintain head stability.

THE EFFECTS OF LOAD ON THE HUMAN STEP CYCLE. M.J. Stephens*, J.F. Yang, Division of Neuroscience and Department of Physical Therapy, University of Alberta, Edmonton, Canada T6G 2G4

Unloading of the limb in the stance phase is thought to be an important prerequisite for the inititation of the subsequent swing phase in walking (e.g., Duysens & Pearson, Brain Res 187:321-332, 1980). Feedback from group Ib afferents in extensors are thought to mediate this response by reinforcing extensor activity during walking (e.g. Conway et al., Exp Brain Res 68:643-656). Yet, our previous experiments with putative group Ib reflexes in the human indicated that the effects were very small. A realistic convergence of load information may be important to elicit the response in intact humans. Thus, in this study, subjects walked under 3 load conditions: normal load, and either an increase or a decrease in load equivalent to 30% body weight. Loading resulted in a small, but consistent increase in both the magnitude and duration of the extensor activity and a delay in the onset of the flexor activity. Two to three steps were needed to adjust to the new load. The stance phase duration was prolonged with sustained loading, by an average of 40 ms, and the swing phase duration shortened by roughly the same amount, so that the total cycle duration was unchanged. Unloading had the opposite effect. These effects are qualitatively consistent with animal work, but the size of the effects are small. It remains to be seen whether the larger effects of load seen in cats are a characteristic of the reduced preparations.

LOCUS OF DYNAMIC BALANCE CONTROL IN RESPONSE TO A FORWARD SLIP AT HEEL STRIKE DURING HUMAN WALKING. P-F. Tang*, M. H. Woollacott, R. K-Y. Chong. Inst. of Neuroscience and Dept. of Exercise and Movement Science, University of Oregon, Eugene, OR 97403.

Control of the upper body alignment through the activation of trunk musculature at heel strike and toe-off is crucial for maintaining dynamic balance during human walking. The present study investigated whether proximal muscles continue to be the locus of balance control when a person experiences a slip occurring at heel strike during walking. Thirty-three healthy young adults (20-35yrs) performed 48 free-speed walking trials across a 5m-long walkway equipped with two movable platforms. Slips were simulated by an unexpected 10cm translation (10cm/s) of the right platform in the forward or backward direction timed to heel strike, midstance, or late stance phase. Twelve trials of no-slip normal walking were first given in block, followed by randomized trials of 12 anterior- and 12 posterior-slip (4 trials/phase), and 12 additional no-slip trials. Onset latencies and burst durations of the first burst of muscle responses from the trunk and legs to the anterior slip at heel strike were analyzed over the 4 trials of this condition. Results from the first trial of 6 subjects (27.2±3.6 yrs) showed that the right tibialis anterior (TA) reacted to the slip first at 113.2 (±32.7) ms, followed by the right rectus femoris (RF) at 194.0 (± 61.1) ms and right abdominals (ABD) at 190.8 (± 80.6) ms. The mean burst durations for TA, RF, and ABD of the first trial were 86.2 (± 25.4) ms, 141.1 (± 37.9) ms, and 75.1 (± 3.7) ms, respectively. While the TA activity occurred in all 4 trials of this condition for all subjects, the ABD activity either did not occur (1 subject) or occurred only once in the first trial (5 subjects). Thus, the ABD activity adapted quickly. Comparison between the first and fourth trials of these 5 subjects showed a mean reduction in TA onset latency by 38.9 ms and in RF onset latency by 60.1ms, and a decrease in TA and RF burst durations by 56.3% and 56.5%, respectively. The results indicate that the locus of control during a forward slip at heel strike resides in the distal leg musculature, which shows early onset, long burst duration, and adaptive but persistent activity after multiple exposures. GAIN MODULATION OF EVENT-RELATED POTENTIALS TO RAPID WHOLE-BODY TRANSLATIONS. W.R. Staines*, W.E. McIlroy[1] and J.D. Brooke. Department of Human Biology and Nutritional Sciences, University of Guelph, Ontario, N1G 2W1, and [1]Sunnybrook Health Science Centre, Toronto, Ontario, M4N 3M5, Canada.

Discharge from vestibular and muscle afferents travels to the cortex along similar rostral paths. In both systems, third order neurons project from the same thalamic nucleus (VPL) to specific cortical areas (3a). Convergence of these two modalities is important in control during instability. We hypothesized that the gain of vestibular and somatosensory pathways would be reduced as a result of muscle spindle discharge in knee extensors. Event-related potentials (ERPs) were evoked by rapid translations of subjects strapped in a chair on a movable platform. ERPs were recorded from standard international 10-20 sites (C3, C4, P3, P4, F3, F4, T3, T4, and Cz) referenced to the left earlobe during passive translations with and without prior vibration of the patellar ligament. Somatosensory evoked potentials, referenced to Fpz, and soleus H reflexes from tibial nerve stimulation, were attenuated immediately following vibration. ERP gain was also reduced to a similar level (approx. 50% of stationary control) following vibration. Gain reduction in these pathways may arise from muscle spindle discharge in knee extensors. The importance of this sensory interaction with regards to instability control invites further exploration. Supported by NSERC (Canada) and Sunnybrook Trust.

RAPID RESPONSE OF WHOLE-LEG MUSCULATURE TO SUDDEN PERTURBATIONS DURING WALKING IN HUMANS. J.E. Misiaszek*[1], K.G. Pearson[1], M.J. Stephens[2] and J.F. Yang[2]. Dept. of Physiology[1] and Dept. of Physical Therapy[2], University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Disturbances applied to the support surface during standing or walking in humans produce rapid responses of the musculature of the leg which act to re-establish a stable base of support for the body center of mass. However, the postural adjustments in response to disturbances at the torso, rather than the support surface, are not well described during walking. We investigated the response of the leg musculature to a sudden force pulse applied at the pelvis of 6 consenting male volunteers. The subjects were equipped with a belt that fitted snuggly at the level of the iliac crest. A pair of cables were fastened to the belt and fed through pulleys secured to a treadmill. Pulling the cables produced a force that acted down and back such that during late stance the force vector acted parallel to the long axis of the leg. While walking on a treadmill at 0.9 m/s, brief force pulses (approx. 500ms duration, 50-70%body weight) were delivered to the pelvis of the subject during late stance of the left leg. Random perturbations were also delivered throughout the gait cycle to avoid anticipation. In 4 of the 6 subjects the initial response to the perturbation was a rapid contraction of all leg muscles monitored. The earliest response was a co-contraction of soleus and tibialis anterior with latencies of 65.5±5.0 ms and 60.0±2.8 ms respectively. A co-contraction of vastus lateralis and biceps femoris soon followed with latencies of 98.7±17.5 ms and 99.3±22.7 ms respectively. It is important to note that the onset of the early responses occurred well before any disturbance in the kinematics of the ankle or knee joints. Subsequent, longer latency responses (>300ms) were not consistent between subjects. The longer latency responses likely represent a pattern of activity arising from descending sources. We suggest that the early activation is a triggered response that acts to increase the total stiffness of the leg and reduce the displacement of the center of mass. It is not yet clear what gives rise to this early response. Supported by MRC and AHFMR.

ENHANCEMENT OF ANTICIPATORY POSTURAL ADJUSTMENTS DUE TO AN ELECTROCUTANEOUS REACTION STIMULUS FOR STEP INITIATION AMONG ELDERLY HUMAN SUBJECTS. M.W. Rogers*, T.D. Cain, T.A. Hanke. Programs in Physical Therapy, Department of Physical Medicine and Rehabilitation, Buehler Center on Aging, and Institute for Neuroscience, Northwestern Univ., Chicago, IL 60611

During forward step initiation, anticipatory postural adjustments involve an initial shift in the foot-ground center of pressure (CoP) backwards and towards the stepping limb to accelerate the body forward and laterally prior to step onset. The lateral response is dictated by an increase in vertical loading beneath the step limb and contralateral unloading. We examined these events for possible differential effects of age on sensorimotor channels which trigger reaction time (RT) step initiation.

Twenty medically screened female subjects (62 to 86 yrs) initiated forward stepping with the right leg during 3 randomly sequenced simple RT conditions involving warning-reaction stimuli: sound-light (SL), light-sound (LS), sound-touch (ST). The tactile stimulus was a just perceptible single electrocutaneous square pulse (1ms) at the right retromalleolar sural nerve region. Electromyographic data, ground reaction forces (GRFs), and kinematics were recorded.

Overall, there were no differences in the RT latencies of postural responses or stepping as detected by changes in GRFs. However, a significant effect for stimulus condition (ANOVA $p<.05$) and post-hoc analyses indicated a greater anticipatory peak loading beneath the stepping limb for ST (25% bodyweight +/- 1.4% SE) than for SL (20.5% +/- 1.4%) and LS (21% +/- 1.3%). This effect was mirrored by an increase in the initial lateral CoP excursion which reduced the ratio of the foot referenced posterior/lateral CoP change for ST (1.93 +/- .11SE) vs SL (2.51 +/- .21) and LS (2.39 +/- .14).

These findings suggested an enhancement of the anticipatory postural component among older subjects due to a somatosensory stimulus trigger. This effect may have been mediated by a transient facilitation of neuronal circuitry shared by convergent descending and peripheral pathways. *Supported by NIA K01 AG 00581.*

STRATEGY OF CO-ORDINATION OF TWO-JOINT RECTUS FEMORIS AND HAMSTRINGS MUSCLES DURING THE SWING PHASE IN RUNNING.
B. I. Prilutsky and R. J. Gregor*. Dept. Health and Performance Sciences, The Georgia Institute of Technology, Atlanta, Georgia 30332-0110.

It has been hypothesized (Jacobs and van Ingen Schenau, J. Physiol., 457, 611-626, 1992) that the input from the skin receptors of the foot may play an important role in the control of biarticular muscles and subsequently the direction of an external force (or the distribution of the resultant moments among leg joints) in leg extensions. The control of the distribution of joint moments may be provided by the two-joint rectus femoris (RF) and hamstring (HA) muscles, since a high correlation coefficient was found between the difference in electromyographic activity (EMG) of RF and HA (RF_{EMG} -HA_{EMG}) and the difference in the resultant moment at the knee and hip (M_k-M_h). In the present study we examined the co-ordination of RF and HA during the swing phase of running, where no external force is applied to the foot. Five subjects ran on a treadmill at a speed of 3.6 m/s. EMG activity of RF and HA and coordinates of the main leg joints were recorded by surface electrodes and by a high speed video system (120 Hz, Peak Performance), respectively. The EMGs were rectified, integrated over 50 ms, and normalized with respect to the peak averaged EMG in a given trial. An inverse dynamics analysis was used to calculate the resultant moments at the knee and hip. Correlation coefficients were calculated between (RF_{EMG} -HA_{EMG}) and (M_k-M_h) taken every 5% of the swing phase. The results demonstrated that the correlation coefficients calculated between (RF_{EMG} -HA_{EMG}) and (M_k-M_h) during the swing phase were typically higher than 0.80. Since the coordination of the RF and HA in controlling the distribution of the hip and knee moments was not substantially changed in the absence of the external force applied to the foot, we suggest that the input from the skin receptors in the foot may not play an essential role in the system employed to control joint moment distribution and external force direction. CORTICAL CONTROL DURING THE SWING PHASE OF HUMAN WALKING. C. Capaday, H. Barbeau*, M. Bonnard and B.A. Lavoie. Centre de Recherche en Neurobiologie, Université Laval, Québec, (Qc) Canada, G1J 1Z4

Focal transcranial magnetic stimulation of the human motor cortex was used to determine the extent of cortical control during a voluntary motor task requiring attention compared to the 'automatic' act of walking. The quantitative method developed by Devanne et al. (1995) to determine the extent of cortical control during human motor tasks was used in this study (Soc. Neurosci. Abstr. 21:1075). For each subject, the entire input-output (I/O) curve – integral of the evoked motor response (EMR) vs. stimulus strength – was measured during a prescribed tonic voluntary contraction of the tibialis anterior muscle and at various times during the swing phase of walking. For both tasks the I/O curves were measured at matched levels of background EMG. The I/O data points were fitted by the Boltzmann sigmoidal function, which accounted for at least 80% of total data variance. In all subjects there was no statistically significant difference between the I/O curves measured in each task. Furthermore, there was no significant difference in the relation between the coefficient of variation and the amplitude of the EMRs measured in each task. This shows that the responses obtained during walking were no more variable than those obtained during the voluntary task. Finally, stimulation of the motor cortex just before, or at any time during, the swing phase of walking did not reset the step cycle. On the assumption that the cortical stimuli evoke motor responses that reflect intracortical excitability, we conclude that the motor cortex is equally well linked with the segmental motor circuits during the swing phase of walking as during voluntary and attentive motor activity. POSTURAL STABILITY IN GENETICALLY DISTINCT AUTOSOMAL DOMINANT CEREBELLAR ATAXIAS. J.H.Anderson*, L.P. Ranum, L.J. Schut, and C.M. Gomez. Depts. of Otolaryngology and Neurology, Univ. of Minn., Mpls., MN 55455.

The autosomal dominant cerebellar ataxias (ADCA) are a genetically heterogeneous group of disorders characterized by degeneration of brainstem and cerebellar neurons in patterns that might be correlated with the different genes that are involved and the corresponding pathophysiology. We hypothesized that there would be unique functional deficits affecting postural stability for different genetic varieties. This was studied by using dynamic posturography in subjects with clinically and genetically defined spinocerebellar ataxia (SCA) types 1, 3, and 5 and in others with clinical signs of SCA 2, 4, and 6. Quantitative testing was done with the Equitest system, using some modified protocols. Postural sway in the sagittal plane was estimated with the subjects standing on a fixed or compliant platform, which was controlled with both positive and negative sway-referencing. The center of force and the position and orientation of the head in space was measured. Using a sway-referencing gain of +1.0, all groups had a very significant vestibular deficit (fell or very low sway score on conditions 5, 6), but there were different profiles across the other conditions. In SCA 1 and 3 there were low scores on conditions 1-4, with condition 2 having the lowest score, indicating a somatosenory deficit. In SCA 2 and 4 there were mildly low scores on conditions 2-4, indicating both a somatosenory and visual deficit. In SCA 5 there were normal or slightly low sway scores on conditions 1-4, but very low or falls on conditions 5 and 6, indicating a profound vestibular but not a somatosenory or visual dificit (with respect to the stimulus conditions that were used). These results indicate that there are definite physiological differences in motor behavior among the SCAs. Additional subjects need to be tested to further quantify the different profiles in sway, to correlate the postural deficits with oculomotor behavior, and to establish the time course for the pathophysiology. EMG ANALYSIS OF LONG-LATENCY POSTURAL REFLEXES IN A SUBJECT WITH CONGENITAL MIRROR MOVEMENTS.
D.J. Beckley*, E.A. Franz, B.R. Bloem, I.L. Kwee, V.P. Panzer, and M.P. Remler, Dept. of Neurology, U.C. Davis, CA, USA and University Hospital, Leiden, The Netherlands.

Subjects with mirror movements (MM) provide a unique opportunity to study the circuitry involved in long-latency (LL) reflexes. Bilateral LL responses have been previously reported during unilateral stretch in the upper extremities. To date, no comparable studies have been described in MM subjects with respect to lower extremity LL postural reflexes. Therefore, we studied both upper and lower extremity LL reflexes in a subject with familial congenital mirror movements (male, age 22) and 6 controls (2 male; $\bar{x}$ age 42.0 $\pm$ 8.6 S.D.). Normalized EMG activity was recorded with surface electrodes from the flexor carpi radialis (FCR) and extensor digitorum communis (EDC) from both upper extremities and, separately, the tibialis anterior (TA) and medial gastrocnemius (MG) from both lower extremities in response to a series of 4° upward tilts of a forceplate at 50°/sec. Stretch to the upper extremities was done under both 'resist' and 'yield' conditions. Lower extremity reflexes were tested with a) both legs on the platform b) one leg on and the contralateral off, but weight bearing and c) one leg on and the contralateral off and non-weight bearing. Similar to previous reports, the MM subject, unlike controls, showed bilateral LL responses in the upper extremities to unilateral wrist stretch. In the lower extremities, like controls, MM showed bilateral LL responses in conditions a) and b) and unilateral responses (stretched leg only) during condition c). These findings are consistent with the notion that either LL lower extremity postural responses are not transcortically mediated and/or, that reduplication of LL circuitry is confined to the upper extremities in subjects with mirror movements. *Supported by NIA Grant#202-23676

MULTIVARIATE EMG PATTERN ANALYSIS. A.Wojciechowski, M.Hulliger, K.G.M. Gerritsen[1], I. O'Callaghan, G. Bishop & W. Baldridge*. Dept. of Clinical Neurosciences & Human Performance Lab[1], Calgary, AB, Canada T2N 4N1.

Quantification of global (multivariate) EMG patterns is a non-trivial problem, especially in the case of pathological EMG. While characteristic constellations of multiple EMG profiles may be recognized by eye, such patterns have proven to be difficult to quantify. We investigated whether principal component analysis, a method which has previously been used successfully for quantification of multivariate kinematic gait patterns (J. Motor Behavior 26, 83-102, 1994), could be applied in modified form for data reduction and subsequent pattern analysis of global (multi-channel) EMG signals.

Surface EMG recordings were made from 8 leg muscles on one side while normal subjects and stroke patients walked at a comfortable speed. Principal components (PCs) were calculated as optimally weighted sums of rectified and low-pass filtered EMG signals. For PC analysis to be a useful tool, it has to meet minimally five criteria: it should permit significant data reduction (1); PCs should be consistent within subjects (2) and between subjects (3); PC analysis should capture alterations in global EMG patterns in pathological gait (4); and EMG PCs should be interpretable, functionally (5).

Results so far indicate that by calculating the first 4 (of maximally 8) PCs appreciable data reduction could be achieved with limited loss of information (10-20%). PC waveforms were generally consistent both within and between (normal) subjects, featuring reproducible profiles of the 8 EMG weight factors. Preliminary analysis of hemiplegic EMG patterns yielded distinctly different yet consistent PC waveforms, indicating that the pathological alterations of the hemiplegic patterns were mostly captured in the PC representations. However, the functional interpretation of PC waveforms is not straightforward. Judging from the weight factor profiles it is evident that individual PCs do not reflect simple anatomical (e.g. flexor/extensor) synergies. Instead they appear to represent functional fractional synergies of anatomically heterogenous muscle groups. Attempts are under way to determine whether useful kinematic equivalents of EMG PCs can be identified, using a mathematical model of gait. **Supported by NCE Canada, AHFMR and NSERC.**

PARKINSON'S DISEASE MODIFIES THE INTERACTION BETWEEN THE FLEXION REFLEX (FR) AND DYNAMIC TILT-EVOKED RESPONSES IN STANDING.
C.W.Y. Hui-Chan* and N. Paquet. School of Physical and Occupational Therapy, McGill University, Montreal, Canada H3G 1Y5.

We found that PD patients exhibited abnormal lower limb muscle coactivation during whole head-and-body tilt (WHBT; *Paquet and Hui-Chan, Soc. Neurosci. Abstr. 1996*). This could be due to a defect in the sensorimotor integration during balance control. In order to explore this hypothesis, we developed a method thereby we examined the interaction of the FR with tilt-evoked responses (*Paquet and Hui-Chan, Soc. Neurosci. Abstr. 1994;20:1752).* Our objective was to determine the effect of PD on this reflex interaction.

Eight PD patients in stage 3 of the desease and 11 age-matched normal subjects were blindfolded and stood fixed to a tilting apparatus with straps and a neck collar. They underwent sudden whole head-and-body tilts of 20° in the forward direction, around an axis co-linear with the ankle joint. The mean peak of head acceleration was 0.7g, as measured with a linear accelerometer mounted on a dental bite. FRs were elicited with electrical stimulation (ES) of the right tibial nerve behind the medial malleolus during standing (ES_{alone}) and tilting (Tilt+ES). The background contraction of the ipsilateral tibialis anterior (TA) muscle was kept at 10-20% of the maximum voluntary contraction in order to prevent habituation of the FR. The ES was delivered as a train of 1 ms pulses at 200 Hz during 30 ms at about 3-5 times the sensory threshold. EMGs were recorded from the TA, soleus (SO), biceps femoris (BF) and vastus lateralis (VL) muscles bilaterally.

During ES_{alone}, the frequency of FR occurrence and the FR area were increased by 167% and 386% respectively, in PD patients relative to age-matched subjects ($p<0.01$ and $p<0.05$), despite similar level of background contraction. A proportion of 55% of the age-matched subjects manifested a change in the FR occurrence or FR area during Tilt+ES in comparison with ES_{alone}. In contrast, only 25% of the PD patients manifested a modulation of the FR during WHBT.

Our results indicate that with PD, the FR excitability was enhanced in standing, and that the FR was less modifiable when it interacted with tilt-evoked responses during WHBTs. Our findings suggest that PD could involve a defective integration between sensory inputs and/or with central programmes during the control of dynamic tilts of the head-and-body. *Project financed by Parkinson's Foundation of Canada and a MRC studentship for N.P.*

727.5

TILT-EVOKED RESPONSES ARE MORE FACILITATED THAN SOLEUS H-REFLEX DURING DYNAMIC HEAD-AND-BODY TILTS IN PARKINSON'S DISEASE (PD).
N. Paquet* and C.W.Y. Hui-Chan. School of Physical and Occupational Therapy, McGill University, Montreal, Canada H3G 1Y5.

One manifestation of impaired balance control in PD patients is the enhanced "destabilizing" responses in leg muscles to rotation or translation of the standing platform (*e.g. Schieppati and Nardone, Brain 114: 1227-44, 1991*). Our objectives were 1) to characterize lower limb muscle responses to whole head-and-body tilts (WHBT) in PD patients; and 2) to investigate the relationship between tilt-evoked responses in the soleus (SO) muscle and the modulation of SO H-reflex during WHBT.

Ten PD patients in stage 3 of the disease and 10 age-matched normal subjects were blindfolded and stood fixed to a tilting apparatus with straps and a neck collar. They were suddenly and unexpectedly tilted forward for 20° with an axis of rotation co-linear to the ankle. The mean peak of head acceleration was 0.7g (±15%), as measured with a linear accelerometer mounted on a dental bite. Forty H-reflexes were elicited in the right SO muscle at 30-190 ms intervals after head acceleration onset, and compared with 25 control reflexes obtained during quiet standing. During WHBTs, the M response was kept at ±15% of control M. EMGs were recorded from the SO, tibialis anterior (TA), biceps femoris (BF) and vastus lateralis (VL) muscles bilaterally.

Three main findings emerged: *First,* PD patients showed an abnormal co-activation of the SO, BF and VL muscles at 100-111 ms after head acceleration onset. *Second,* they exhibited an increase by 413% in the area of tilt-evoked responses in the SO muscle in comparison with age-matched normal subjects ($p<0.01$). *Third,* this excessive responsiveness to WHBT was accompanied by an increase of only 14% in the amplitude of SO H-reflex ($p<0.05$).

Our results suggest that the hyperexcitable tilt-evoked responses observed in PD was not likely due to motoneuronal hyperexcitability and/or decreased presynaptic inhibition of the group Ia terminals involved in the mainly monosynaptic H-reflex pathway. The control of spinal *interneurons* involved in the tilt-evoked responses might be defective in PD.

Project financed by Parkinson's Foundation of Canada and a MRC studentship for N.P.

727.6

RHYTHMIC ENTRAINMENT OF GAIT PATTERNS IN HUNTINGTON'S DISEASE PATIENTS. M. H. Thaut*[1], H. W. Lange[2], R. Miltner[2], C. P. Hurt[1], V. Hoemberg[2]. [1]Center for Biomedical Research in Music, Colorado State University, Fort Collins/Colorado, USA. [2]Neurologisches TherapieCentrum, Heinrich-Heine University Duesseldorf, Germany.

Rhythmic entrainment of gait patterns was studied in a group of 26 Huntington's disease (HD) patients (mean age=47=/-11 years; 13 male/13 female). After assessing gait baseline for normal walking tempo rhythmic auditory stimulation (RAS) via metronome (MT) and rhythmic music (MS) cues was delivered at 10% slower and 10 to 20% faster rates than baseline step frequencies to study rhythmic synchronization ability. Exact RAS rates were determined based on each patient's individual walking ability. Patients were able to significantly ($p<0.001$) change their gait velocity using RAS-MT: baseline mean=51.1 m/min; slow MT=40.9 m/min; fast MT=61.6 m/min. Changes with music cuing were not significant (54.4 m/min, $p<0.16$). Ability to adapt velocity was graded by severity of disease (chorea/impairment) and completely lost in the severe group with music. RAS-rate and step cadence showed large percentage deviations (slow MT: 10.4%; fast MT: 9.9%; fast MS: 9.5%). Asynchrony deteriorated with severity of disease: 3.2% for the mild group, 9.2% for the moderate group, 12.5% for the severe group.

In conclusion, HD patients in mild and moderate stages of the disease adjusted gait velocity and cadence as cued by RAS. However, velocity changes appeared mediated by responding to general speed impulses rather than rhythmic synchronization. Disturbed synchronization ability was already evidenced in mildly affected patients and became more deficient with disease progression. Also, rhythmic tracking of the music was lost more rapidly than the metronome with severity of the disease, pointing to progressive deficits in complex sensory perception in HD. (Funded by German Research Council DFG/SFB 194)

ADAPTATION OF THE WALKING PATTERN TO GRADED WALKING IN NORMAL AND SPINAL CORD INJURED SUBJECTS. A. Leroux , A. Pépin, J. Fung* and H. Barbeau. School of Physical & Occupational Therapy, McGill Univ., Montreal, QC H3G 1Y5.

This preliminary study investigated the strategies to adapt to uphill and downhill treadmill walking (0, 5, 10 and 15°) in 3 normal and 2 incomplete spinal cord injured (SCI) subjects. EMG activity of lower limb muscles (vastus lateralis (VL), semitendinosus (ST), soleus (SOL), medial gastrocnemius (MG), tibialis anterior (TA)) and angular displacements of the hip, knee and ankle joints were measured. Results from joint angular displacements in the sagittal plane showed that both normal and SCI subjects used similar patterns to adapt to uphill walking, although the knee and hip angles became more in phase during swing in the SCI subjects. As the treadmill slope increased from 0 to 15°, there was a gradual increase in hip and knee flexion and in ankle dorsiflexion during late swing and early stance. When the slope decreased from 0 to 15° downhill, hip flexion progressively decreased while there was a gradual increase of knee flexion in stance. For all subjects, the ankle angle at initial foot contact changed progressively from dorsiflexion to plantarflexion as the slope changed from uphill to downhill. In general, EMG activities of normal subjects were increased in the uphill condition and decreased in the downhill condition, except for VL which was increased in the downhill condition. In SCI subjects, the activities of proximal muscles (VL and ST) were similar to those of normal subjects across the different conditions. However, the activation patterns of distal muscles (SOL and MG) differed in that there was a prolongation of the EMG activity and a progressive increase in early activation in uphill condition. In contrast, little change in the EMG amplitude was observed in SCI subjects during the downhill condition, as compared to normal subjects. In conclusion, both normal and SCI subjects can adapt to graded treadmill walking, but different strategies were used by SCI subjects to adapt to the changing locomotor demands.

ABNORMAL REGIONAL CEREBELLAR ACTIVATION DURING BIPEDAL WALKING IN OLIVOPONTOCEREBELLER ATROPHY. M. Mishina[1,2], M. Senda*[2], K. Ishii[2], M. Ohyama[1,2], S. Kitamura[1] and A. Terashi[1]. [1]The Second Department of Internal Medicine, Nippon Medical School, Tokyo, Japan 102, and [2]Positron Medical Center, Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan, 173.

We studied regional cerebellar glucose metabolism associated with bipedal walking in 9 patients with olivopontocerebellar atrophy (OPCA) and 10 control subjects without neurological disease. We quantified the severity of cerebellar ataxia in OPCA patients with a clinical rating scale of Wessel et al. We used 18F-2-fluoro-2-deoxy-D-glucose (18F-FDG) and positron emission tomography (PET) to evaluate glucose metabolism under two different conditions: 30 minutes' treadmill walking and supine resting. The two sets of PET images were three-dimensionally registered to the magnetic resonance images (MRI) in each subject. Then, the PET images were normalized by the global value. The regional cerebellar activation was evaluated by the activation ratio (AR, = [FDG uptake under walking]/[FDG uptake under resting]) for each region as an index free from partial volume effect. We used unpaired t-test for statistical analysis to compare the OPCA patients with the normal control subjects.

The AR of OPCA patients was significantly decreased in the pyramis of cerebellar vermis, but increased in the posterior lobe of cerebellum. In the OPCA patients, AR in the pyramis tended to decrease as the cerebellar ataxia became severer. As the severity was increased, however, AR in the posterior lobe was increased. In the anterior lobe of cerebellum, activation of OPCA patients was equivalent to normals.

We speculate that ataxic gait in OPCA patients is related to the reduction of activation in the pyramis, and that the instability during the ataxic gait increases the inputs from the vestibular, somatosensory and visual systems to anterior and posterior lobe and outputs from these regions to other neural systems. We concluded that the PET activation study can demonstrate the abnormal cerebellar function during ataxic gait in the early phase of OPCA patients.

AUDITORY SCENE ANALYSIS AND FOCAL CORTICAL LESIONS. D.W. Perry*, P.L. Divenyi & A.P. Algazi, Speech and Hearing Research Facility, V.A. Northern California Health Care System, Martinez, CA 94553.

Auditory scene analysis refers to the sensory-cognitive ability responsible for perceptual segregation of one sound event from others in a simultaneous display of multiple events. Typically, the events are complex sounds, each with its own characteristics regarding the "cardinal" dimensions of audition: spectral content, temporal structure, and spatial location. Perceptual segregation has been studied in psychoacoustic experiments with pairs of stimuli differing along two such dimensions, the task being to correctly group the dimensional values – e.g., "the high-pitch sound was to the left of the low-pitch sound". Normal listeners are able to segregate sound pairs in which differences along any of the cardinal dimensions are not larger than just-noticeable differences for single sounds presented in succession, as long as the difference along the other dimension is large. Three patients with focal cortical lesions were also tested: one with right and one with left unilateral CVA-induced lesion in the temporal-parietal junction that included Heschl's gyrus, and one with a vascular malformation in the left caudal orbital-frontal region. *Single*-sound frequency difference limens were normal for the orbital-frontal patient and abnormally large for both temporal-parietal patients. The pattern of single-sound azimuth difference limens was complex and showed larger deficits for the field contralateral to the lesion and for left cortical lesions. Similar trends characterized perceptual segregation of *sound pairs*, although the azimuthal separation required was 20-80% larger than those measured for single sounds. [Supported by the V.A. Medical Service and by NIH grants AG07998, NS21135, and PONS17778.]

728.2

PRE- AND POSTOPERATIVE AUDITORY SPATIAL PERCEPTION IN ANTERIOR TEMPORAL LOBECTOMY PATIENTS. P.L. Divenyi[1], K.D. Laxer[2], N.M. Barbaro[2], J. Walker[2], D.W. Perry[1], I.L. Kwee*[3], A.P. Algazi[1] & K.M. Haupt[1], Speech & Hearing Research, VANCHCS, Martinez, CA 94553 (1), Northern California Comprehensive Epilepsy Center, Univ. of California, San Francisco, CA 94143 (2), Dept. Neurology, Univ. of California, Davis, CA 95616 (3).

Auditory spatial perception was investigated in 10 left and 8 right anterior temporal lobectomy patients before (*Pre*) and after (*Post*) surgery performed to treat epileptic seizures. A battery of psychoacoustic tests measured lateralization thresholds for interaural delays (ITD) in 500-Hz clicks, localization (left or right) of a complex "target" embedded in a spatially-distributed ensemble of 5 simultaneous steady-state sounds, and detection of a sound in one (the "odd") hemifield with 3 to 5 different sounds presented in the opposite hemifield. Peripheral hearing (pure tone thresholds of 40 dB or better at 1 and 4 kHz) and brainstem localization function (masking level difference of 8 dB or better) were normal *Pre* and *Post* in all subjects. *Pre* ITD thresholds were nearly normal in right- and somewhat elevated in left-ATL's, with either no change or a slight improvement *Post*, without regard to hemifield. Target localization *scores* improved slightly *Post* (when unimpaired *Pre*); *bias* of target localization showed an increased attention to the hemifield contralateral to surgery. Detection of sounds in the "odd" hemifield showed increased attention to events in the *right* hemifield, regardless of the side of lesion.

AUDITORY TEMPORAL AND SPECTRAL RESOLUTION IN CHILDREN WITH LANGUAGE IMPAIRMENTS. B.A. Wright, L.J. Lombardino, W.M. King, C.S. Puranik, C.M. Leonard*, and M.M. Merzenich. Keck Center, UCSF, San Francisco CA 94143-0732, and University of Florida, Gainesville FL.

Between three and six percent of children who are otherwise able do not develop normal speech and language. Tallal proposed that such children have a "temporal-processing deficit" which makes them unable to discriminate, within ongoing speech, the brief sounds that identify consonants. The purpose of this study was to determine whether the ability of language-impaired children to detect a brief sound depended upon the temporal, or spectral, position of that sound relative to a longer interfering sound. To address these questions, we used standard psychoacoustic techniques to measure the detection threshold for a 20-ms tone at 1000 Hz presented prior to, during, or following a 300-ms noise masker. The masker spectrum extended across the signal frequency in one set of conditions, but not in another. The masker spectrum level was 40 dB SPL. Our subjects were eight children aged 7 to 8 years, with language impairments and four matched controls. All eight language-impaired children were extremely poor at detecting the brief tone when it was presented prior to the masker (backward masking), requiring that the tone be an average of 45 dB more intense than was necessary for the controls. In contrast, when the tone was presented after the masker (forward masking), the thresholds of the language-impaired children were only an average of 10 dB higher than for the controls. The thresholds of the impaired children were always higher when the masker extended across the frequency of the brief tone than when it did not. These data are consistent with the idea that language impairments result from a deficit in temporal processing, but refine that proposal by demonstrating that the temporal deficit is most severe when a brief sound is rapidly followed by another sound of similar frequency. These results also suggest that language therapy should focus on amplifying information at sound onset.

TEMPORAL PROCESSING AND LANGUAGE COMPETENCE IN BRAIN INJURED PATIENTS AND YOUNG PUPILS. N. v. Steinbüchel, M. Wittmann and E. Pöppel*. Inst. Med. Psych., 80336 Munich Univ., and Research Center (KFA), 52425 Jülich, Germany.

Neuropsychological and psychophysical evidence supports the notion of a strong association of language skills and general temporal processing capacities. With the experimental paradigm of auditory temporal order threshold (OT) temporal processing mechanisms on a high frequency level can be measured (OT = the minimal time interval to indicate the correct temporal order between two acoustic stimuli). OT for young healthy adults lies between 30 to 40 ms. Assessing OT in five different patient groups with acquired focal brain lesions and a patient group without brain injuries (orthopedic control group) the following results are observed: Only patients with left hemispheric posterior lesions with „sensory" aphasic syndromes showed a significantly prolonged mean OT of approx. 130 ms. Patients with left anterior lesions with aphasia (Broca's aphasia), patients with left hemispheric lesions without aphasia and patients with right anterior or posterior injuries were not significantly prolonged. In addition, only patients with left hemispheric posterior lesions with aphasia showed a right ear advantage. This adds evidence to findings of a strong functional relationship between temporal discrimination and language functions located in the temporal lobe. In previous papers (1991, 1995) v. Steinbüchel showed that the highly prolonged OT in aphasic patients can be reduced by functional training to the level of healthy subjects. Not only temporal discrimination but also discrimination of phonemes are significantly ameliorated. These findings of an association of time and language functions and their successful improvement by training have recently also been found in language-learning impaired children (Merzenich et al., 1996). Furthermore we report data on OT, phoneme discrimination, writing and reading ability in approx. 100 children of elementary schools (Supported by BMBF).

HUMAN OSCILLATORY BRAIN ACTIVITY NEAR 40 HZ: CORRELATION WITH COGNITIVE TEMPORAL BINDING AND ALTERATION DURING DYSLEXIA. U.Ribary*[1], S.L.Miller[2], M.Joliot[3], E.Kronberg[1], J.Cappell[1], P.Tallal[2] and R.Llinás[1]. [1]CNM, Dept. Physiology and Neuroscience, New York University Medical Center, New York, NY, 10016, USA; [2]Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ, USA; [3]SHFJ, DRIPP-CEA, Orsay, France.

Spontaneous oscillatory electrical activity in the human brain, at close to 40 Hz, and its reset by sensory stimulation has been reported earlier. Results indicated that such oscillatory activity represents a neurophysiological correlate to temporal cognitive binding of auditory stimuli. In particular, data indicated that the minimal interval required to identify separate auditory stimuli correlates with the reset of the 40-Hz magnetic signal.

A dual 37-channel MEG system (BTi) was used to record magnetic activity from awake human subjects over the auditory cortex (bilaterally) in response to one or a pair of auditory clicks, presented at interstimulus intervals of 6, 12, 15, 18, 21, 24, 30 and 36 ms. Ten healthy controls and ten subjects with language-based learning disabilities (dyslexia) are included in the study. Stimulus pairs were presented at pair intervals of 160 ± 15 ms. 1000 epochs were recorded for each stimulus presentation block using a bandpass of 1-400 Hz and a sample rate of 1041 Hz. Transient responses were averaged and filtered (20-50 Hz) using the onset of the first stimulus as a trigger. Two models were implemented in this study in order to interpret the MEG data. Following magnetic recordings, a perceptual task was performed on each subject, using 6 sets of 2 click presentations with the same interstimulus intervals, and a perceptual threshold was computed. In dyslexics, preliminary results indicate a delayed perceptual threshold of 20-30 msec for the identification of a second auditory stimulus. In addition, our findings indicate a different time interval necessary for the appearance of a second 40-Hz wave. In particular, the data suggest an increased processing latency for incoming stimuli, for the resetting to the first stimulus, and/or resetting to the second stimulus. These results suggest the possibility of a neurophysiological marker for sensory information processing of auditory stimuli in subjects with language-based learning disabilities.

ELECTROPHYSIOLOGY OF INFANT AUDITORY RECOGNITION MEMORY. R. E. Sheehy* & D. W. Shucard. Departments of Neurology and Psychology, SUNY @ Buffalo, 100 High St. (D-6), Buffalo, NY 14203.

The development of the P300 component of the Event Related Potential (ERP) has been studied intermittently in infants since Courchesne (1981) reported a negative component (Nc) in 4-7 month old infants that was higher in amplitude in response to an infrequently presented image of a human face than to a frequently presented one. He believed that this component was the developmental precursor of the adult P300 response. In a series of studies in infants ranging in age from 3 to 12 months, Nelson and colleagues have since isolated a positive component in the visual ERP, occuring between 720 and 1450 ms that they believe is the true developmental precursor of the P300. To date, only one study has investigated this response in the auditory modality (McIsaac & Polich, 1992).

In the present investigation, we recorded ERPs in awake 6 month old infants using a modified oddball paradigm similar to the procedure described by Nelson and colleagues (eg. Nelson and Salapatek, 1986). Following a familiarization condition consisting of single tone stimuli (either 1000 or 2000 Hz) presented in series, stimuli were presented in blocks of 10 consisting of 9 presentations of the familiarized tone, and 1 presentation of a tone not presented during familiarization (novel tone). Results revealed an ERP with at least 6 distinct components for both familiar and novel stimuli. At least 4 of these (two positive-going, and two negative-going) were higher for the novel than for the frequent stimulus. A P300-like component differed from previous reports with infants in that it has a latency that is more similar to that seen in adults. Supported in part by the Department of Neurology Research Fund.

AGE-RELATED CHANGES IN AUDITORY SENSORY MEMORY. C. Alain* & D. L. Woods. Department of Neurology, UC Davis and VA Medical Center, Martinez, CA 94553, USA.

Although older adults show deficits in a variety of auditory selective attention tasks, the nature of the age-related decline in selective attention remains unclear. The current study aimed to evaluate whether the age-related changes in selective attention are secondary to more fundamental deficits in auditory sensory memory. The effects of age on auditory sensory memory were examined using the mismatch negativity (MMN), a component of event-related brain potentials that indexes early cortical processing associated with deviations in the auditory environment. Twelve young (19-29 yrs., mean 23 ± 3 yrs.) and 12 older adults (60-82 yrs., mean 67 ± 6 yrs.) were presented with two different sequences while performing a visual task: (1) a sequence of identical tones that included occasional tones differing in pitch and (2) a sequence of tones alternating regularly in pitch with occasional breaks in the pattern. Deviant stimuli in repetitive and alternating tone sequences elicited a MMN at 140-220 ms post-stimulus. The MMNs elicited by both physically and pattern deviant stimuli were reduced in amplitude in elderly compared with young adults. The age-related changes of the MMN were mainly due to enhanced amplitude of ERPs to frequent stimuli and may reflect a deficit in gating auditory inputs.

MEG Reveals Hemispheric Asymmetries for the Processing of Linguistic Stimuli. JC Edgar, JD Lewine, JT Davis, K Paulson, SL Provencal, D Calvert, V Yorton, E Benzel*, WW Orrison JR. The New Mexico Institute of Neuroimaging, The New Mexico Regional Federal Medical Center, 2100 Ridgecrest Dr, SE, Alb., NM, 87111

Clinical and research data from a wide range of sources converge to demonstrate the existence of significant functional asymmetries in the abilities of the left and right hemispheres for the processing of linguistic information. For right handed subjects (about 90% of the population), the left hemisphere(LH) is dominant for language. In contrast, for left handers, approximately 70% show LH dominance with the remaining 30% showing either right hemisphere(RH) dominance or mixed dominance. The present study used a dichotic stimulation paradigm in conjunction with MEG to evaluate linguistic processing. Data were collected from 26 right handed, 2 ambidextrous and 3 left handed normal subjects using a 122-channel whole-head biomagnetometer system (Neuromag/Picker). At the beginning of the stimulus sequence, fifty 2000 Hz tone pips were presented binaurally, at a rate of 1/3 seconds. This was followed by presentation of 150 word pairs, where each ear was "simultaneously" presented a different word. For 100 of the word pairs, the two items were semantically related, usually as antonyms (e.g., good/bad/, hot/cold, big/small). For 50 pairs, there was no obvious semantic relationship (e.g., good/small, hot/bad, big/cold). The subjects were instructed to identify trials with semantic relationships. Averaged evoked responses for the semantically related word pairs demonstrated a significant language-related response that peaked between 300 and 650 milliseconds post-stimulus for all but three subjects. Of the 23 right handed subjects that demonstrated the signal, the response over the LH was larger than that over the RH in 95.7% of the subjects. There was one right-handed subject with apparently bilateral dominance. The two ambidextrous subjects displayed differing patterns: for one, the language field was clearly strongest over the LH whereas the other had bilateral responses. The three left-handers also displayed differing patterns; two displayed bilateral language fields, while one displayed RH dominance. Although we do not have independent confirmation of language lateralization in these subjects, the data are consistent with expected patterns.

BRAIN DYNAMICS OF CATEGORICAL SPEECH PERCEPTION REVEALED BY MULTIPLE SQUIDS

T. Holroyd, J.A.S. Kelso*, B. Tuller, A. Fuchs, D. Cheyne† and H. Weinberg†. Program in Complex Systems and Brain Sciences, Center for Complex Systems, Florida Atlantic University, Boca Raton FL 33431 and †Simon Fraser University, Burnaby, B.C. Canada.

Magnetic brain activity was recorded using a 66 channel full-head SQuID system (CTF-Systems Inc., Vancouver) while subjects (N=6) were listening to a series of speech stimuli and responding according to what was perceived. The speech stimuli were constructed so that a *transition* from one percept to another took place during each trial. Stimuli were presented binaurally, and responses were performed with the first two fingers of the left hand.

Two words, "say" and "stay," formed the endpoints of a continuum parameterized by the length of a silent gap between a recorded "s" and an artificially generated "ay." Tokens with short gaps are perceived as "say;" tokens with long gaps are heard as "stay." Tokens with intermediate silent gaps are multi-stable, sometimes being heard as "say," and sometimes as "stay." The stimuli were always presented in order of increasing gap duration, and an adaptation paradigm was selected to bias the location of the transition. Magnetic data were recorded for a total of 35 presentations of each token in each bias condition.

Spatiotemporal magnetic field patterns were analyzed by Karhunen-Loève decomposition and projection onto spherical harmonics in order to separate the spatial and temporal aspects of the brain dynamics (e.g., Fuchs, Kelso, & Haken, 1992). We show that a spatial reorganization of power takes place during the category transition, and a reconstruction of the relevant spatial and temporal frequency modes (i.e., those with the most power) reveals spatially coherent patterns whose dynamics are linked to early stimulus properties.

PITCH PERCEPTION AND PLANUM TEMPORALE. G. Schlaug*, B. Martin Bly, V. Thangaraj, L. Jäncke, R.R. Edelman, S. Warach. Depts. of Neurology and Radiology, Beth Israel Hospital, Harvard Medical School, and Dept. of Psychology, Harvard University, Boston, MA 02215, USA; Dept. of Psychology, University of Düsseldorf, D-40001 Düsseldorf, Germany.

In a previous study we found an exaggerated structural asymmetry of the posterior superior temporal plane (PT), in musicians with absolute pitch (AP). In order to assess functional correlates of this structural asymmetry, we investigated interhemispheric differences in PT signal changes using functional magnetic resonance imaging (fMRI) and two auditory tasks. Right-handed AP musicians (n=5) and appropriate non-AP controls (n=7) performed a two-back auditory comparison task involving a series of tones or phonemes. Button press responses were used to indicate "same" or "different". In the control condition subjects performed alternating button presses while attending to scanner noise. Eight contiguous axial functional images (8 mm slice thickness) were acquired during each task performance using a gradient-echo pulse sequence and a 1.5T Siemens Vision EPI-MR scanner. Anatomical images were acquired using a volumetric T1-weighted gradient echo pulse sequence (voxel size: 1x1x1mm). The degree of association between condition and Blood Oxygenation Level Dependent (BOLD) signal changes in the brain were assessed by correlation to a box-car reference function. Reaction time and accuracy of responses were collected inside the MRI scanner and in pretesting. All subjects activated posterior perisylvian regions involving the PT in both tasks. AP musicians showed a pronounced left>right activation of posterior perisylvian areas including the PT in both the tones and phonemes tasks. In contrast, non-AP controls had more bilateral PT activation in the tone task and left>right PT signal changes in the phoneme task. A left>right functional asymmetry in the tone task was only seen in those control subjects exhibiting a structural PT asymmetry similar to AP musicians. These findings suggest that the PT plays a role in the perceptual analysis of auditorially presented stimuli. Structural PT asymmetry may modulate its functional lateralization. The overlap in regional activations in the tone and phoneme tasks suggests a similarity in the perception and early auditory analysis of tones and phonemes.

MAGNETIC AND ELECTRIC RESPONSES TO DEVIANT TONES IN MELODIES DEPEND ON MUSICAL ABILITY. L. Lopez[1,2]*, R. Jürgens[3], V. Diekmann[3], W. Becker[3], S. Ried[3], B. Grözinger[3] S.N. Erné[2]. [1]ITAB, Univ. Chieti, 66100, Italy, [2]Zentralinstitut für Biomedizinische Technik, Univ. Ulm, 89081 Germany, [3]Sektion Neurophysiologie, Univ. Ulm, 89081 Germany.

An oddball paradigm was applied within a set of musical and non musical sequences of auditory stimuli. Twenty subjects were studied: all underwent a pitch discrimination and melody recognition test. Three groups were thus identified: 8 musically ungifted (UNM), 6 musically gifted (MUS) and 6 intermediate. The stimulation protocol consisted of 2 sessions each including 5 paradigms of increasing melodic complexity (NOTE, CHORD, ARPEGGIO, MOZART, BACH), delivered binaurally to subjects in a magnetically shielded room. In each paradigm 30% of the notes were deviants (half tone higher). The subjects were asked to pay attention and count the deviants. EEG and magneto-encephalogram (MEG) were recorded in both sessions. After separate average of standard (STD) and deviants (DEV), the main peaks were characterized in the evoked activity: N100 for bothe STD and DEV; mismatch negativity (MMN) and P300 for DEV. Clear N100 was recorded, for all paradigms, in all subjects; MMN and P300 were also recorded, and their amplitudes and latencies significantly correlated with the musicality score, and with the paradigm's difficulty. We propose that MMN, under these attention-demanding conditions, is elicited not only by the comparison with the preceding sequence of stimuli, but also by a prediction of the forthcoming stimuli, based on a set of pre-learned rules, e.g. involved in musical education.

BRAIN SPACE AND VISUAL BEHAVIOR: II. INTERINDIVIDUAL VARIATIONS IN HUMAN VISUAL ABILITIES. S.D. Halpern, T.J. Andrews and D. Purves*. Department of Neurobiology, Duke University, Durham, NC 27710

We have developed a battery of seven automated tests to assess differences in visual abilities between young adult emmetropes with normal color vision. Our aim was to investigate whether the 2-3 fold interindividual variations in size observed in the components of the human visual system are reflected in corresponding differences in visual performance. The tests examined individual ability in spatial localization, orientation discrimination, luminance-contrast detection, wavelength discrimination, direction-of-motion detection, velocity discrimination and complex form discrimination. These abilities were assessed at 0°, 7.5° and 15° eccentricity. Each test showed strong test-retest reliability of individual performance. Preliminary results from a small group of subjects show that: 1) performances on a given test vary significantly between individuals; 2) scores on the different tests are correlated within subjects; and 3) visual performance decreases at increasing eccentricities, in approximate proportion to the decreased cortical representation of the peripheral visual field. These results indicate that ophthalmologically normal adults differ greatly in their specific and overall visual skills. [Supported by NIH grant NS29187].

BRAIN SPACE AND VISUAL BEHAVIOR: I. INTERINDIVIDUAL VARIATION IN THE SIZE OF THE HUMAN VISUAL SYSTEM. T.J. Andrews*, S.D. Halpern and D. Purves. Department of Neurobiology, Duke University, Durham, NC 27710.

Quantitative morphometric and cytoarchitectonic techniques were used to: (1) determine how the sizes of three related neural centers in the human visual system -- the optic tract, lateral geniculate nucleus and primary visual cortex -- vary among individuals; and (2) assess whether size differences among these visual centers are correlated within individual brains. We thus measured the cross-sectional area of the optic tract, the volumes of the magnocellular and parvocellular regions of the lateral geniculate nucleus, and the surface area and volume of primary visual cortex in both cerebral hemispheres from 15 neurologically normal human brains obtained at autopsy. The main findings were that: (1) the sizes of the optic tract, lateral geniculate nucleus and primary visual cortex vary 2-3 fold among individuals; (2) these variations are not related to differences in overall brain size; and (3) the relative sizes of each of these neural centers are strongly correlated within individuals. The coordinated variation of these major components of the human visual system implies that the development of its different parts is interdependent, suggesting a basis for the substantial differences in overall visual ability found in the human population. [Supported by NIH grant NS 29187].

HEMISPHERIC ASYMMETRIES TO FACES PRESENTED IN THE LEFT AND RIGHT VISUAL FIELDS--AN ERP STUDY T. D. Alvarez[1]*, P. Alvarez[2], and H. J. Neville[3]. [1]UCSD Dept. of Neuroscience, La Jolla, CA 92093, [2]Center for Behavioral Neuroscience, SUNY, Stony Brook NY 11794, [3]Dept. of Psychology, U. of Oregon, Eugene OR 97403.

Previous studies have suggested that face discrimination is supported by specialized cerebral mechanisms different from those involved in other types of visual discrimination. Clinical, behavioral, and electrophysiological studies have also suggested that the right hemisphere is superior for the recognition of upright, but not inverted, faces. In our previous research, we asked subjects to perform an identity matching task on centrally presented pairs of upright and inverted faces. We found that the second face of a pair produced a negative waveform, the N320, which was more negative for mismatched than for matched pairs (Sarfaty, Mills, Knaudt, and Neville, Soc. Neurosci. Abs., 1992). This difference in the ERPs to matched and mismatched pairs was larger over the right hemisphere, but only for upright faces. These findings thus provided electrophysiological support for a predominant role for the right hemisphere in the recognition of upright faces. To further evaluate hemispheric asymmetries in face recognition, we presented face stimuli to subjects' visual hemifields. Event-related potentials were recorded while subjects performed an identity matching task. We observed a negativity from 350-600 msec post-stimulus which was larger for mismatched than for matched stimuli. This match/mismatch difference was larger over the right hemisphere for upright faces presented to the left visual field. However, for faces presented to the right visual field, both hemispheres showed a similar match/mismatch difference. Thus, the right hemisphere appears to be involved in the recognition of upright faces presented in either visual field while the left hemisphere responds to upright faces only if presented in the contralateral visual field. Finally, no hemispheric asymmetries were observed for the match/mismatch difference produced by inverted faces. These findings provide further physiological evidence that the right hemisphere is preferentially involved in the recognition of upright faces. Supported by NIH.

DECREASE IN 35-45 HZ COHERENCE BETWEEN HUMAN FUSIFORM AND LINGUAL GYRI DURING FACE-SPECIFIC PROCESSING. J. C. Klopp*[1], E. Halgren[1,2], K. Marinkovic[1,2], V. I. Nenov[1] [1]Brain Monitoring and Modeling Laboratory, Div. Neurosurgery, and Brain Research Institute, UCLA, Los Angeles, CA 90095; [2]INSERM U97, Paris, France.

Spectral coherence analysis was performed on EEG collected from visual association cortex in four epilepsy patients implanted with depth probes for localization of seizure onset. Delayed recognition tasks were presented using either faces (n=240) or words (n=280) as stimuli. EEG was digitized at 166 Hz with a bandpass filter of 0.1 to 50 Hz. Local evoked potentials were highly specific for faces, especially in the fusiform g from 160-220ms post-stimulus onset (J Physiol [Paris] 88:1-50. 1994).

High frequency (35-45 Hz) coherence estimates between lingual and fusiform contacts in the right hemisphere were calculated for multiple 126 msec epochs from the onset of recording to 300 msec after stimulus presentation, with consecutive epochs offset by 12 msec. Pre-stimulus coherence values were used as controls to determine the statistical significance of event associated coherence fluctuation. Face stimuli in all subjects evoked a statistically-significant ($p<0.005$, uncorrected) decrease in coherence, while word stimuli evoked either no consistent response or a mild increase in coherence. The coherence decrease was maximal at approximately 200-330 msec after stimulus onset. No significant change in 35-45Hz power was found in the fusiform/lingual derivation during the same epoch, nor were consistent coherence changes observed between either lingual or fusiform g and the posterior hippocampus during this period.

In summary, these results indicate that the 35-45 Hz coherence between lingual and fusiform g decreases during the period that these structures are specifically encoding words. This appears to be inconsistent with models of cortical function that posit an increase in high frequency coherence between cortical regions during specific encoding of cognitive stimuli.

THE RIGHT SECOND SOMATOSENSORY CORTEX (S-II) IS IMPORTANT FOR THE RECOGNITION OF EMOTIONAL FACIAL EXPRESSIONS. R. Adolphs*, H. Damasio, D. Tranel, R. Frank, A.R. Damasio. Div. of Cognitive Neuroscience, Dept. of Neurology, Univ. of Iowa Coll. of Medicine, Iowa City, IA52242.

As part of an effort to map neural systems involved in the processing of emotion, we studied 37 individuals with focal cortical lesions on a task of recognition of emotional facial expressions. Subjects were asked to recognize expressions of the basic emotions happiness, sadness, surprise, fear, anger, and disgust. Data were analyzed with a novel technique, based on 3-dimensional reconstruction of brain images, in which anatomical description of lesions and task performance scores were jointly mapped onto a standard brain-space. Through these analyses we determined the maximal anatomical overlap of lesions associated with specific performances, and found that 1. subjects with lesions restricted to left hemisphere recognized all emotions normally; 2. every subject recognized happy emotions normally; 3. some subjects with lesions in right hemisphere were impaired in recognizing fear and sadness ($p<0.005$; ANOVA). Anatomical analysis revealed that subjects impaired in the recognition of fear had lesions in right S-II, or lesions that disrupted visual input to right S-II. We propose that the recognition of specific negative facial expressions, notably fear, relies on a linkage between signals related to visual information about the face expression, and reactivation of pertinent information related to body state. The processing of certain emotions may thus require the participation of neural systems involved in the representation of body states.

A GENOMIC SURVEY OF COGNITIVE ERP'S H. Begleiter*, and B. Porjesz, Neurodynamics Lab., SUNY HSCB, Brooklyn, NY 11203

In recent years a number of different investigators have demonstrated, with the use of the Mz-Dz paradigm, that several electroencephalographic features (EEG-ERP) in humans are highly heritable. As part of a national collaborative study on the genetics of alcoholism we have so far collected EEG and ERP in 2016 individuals belonging to 385 families. While we have obtained several EEG-ERP features today we report our genetic results on the visual P3 component of the ERP. The ERP were recorded from 21 leads of the 10/20 International System. The nose served as reference. Vertical and horizontal EOG were maintained and trials rejected in excess of > 73.3 uV. ERPs were recorded with a bandwith of 0.02-50 Hz sampled at 256 Hz beginning 187 msec prior to stimulus onset and continuning for 1.62 seconds. There were three classes of visual stimuli: Target (the letter X, probability 0.125), non-target (square, probability 0.75), and novel (probability 0.125). Each novel was a different geometric figure.

Stimulus duration was 60 msec and the ISI was 1.6 sec. The subject was asked to press to all target stimuli.

All subjects donated blood from which DNA was extracted. A survey of the entire genome was done using highly polymorphic markers at approximately 20 cm apart. We entered the ERP amplitudes as a quantitative variable using sibpair analysis (Sage-Subpial) in order to establish linkage. Our preliminary results indicate that significant findings are obtained at several chromosomal regions.

WATCHING ACTIONS : A PET STUDY. J. Grèzes, J. Decety*, N. Costes, E. Procyk, M. Jeannerod, F. Grassi, D. Perani, F. Fazio. Inserm U94, F-69500 Bron, France and INB-CNR, Milan, Italy.

Positron emission tomography (PET) with $H_2{}^{15}O$ was used to measure regional cerebral blood flow in healthy volunteers while they were engaged in the observation of meaningful and meaningless hand movements. Subjects were instructed to watch the movements with two aims : either to imitate or to recognize them after the scanner acquisition. We found that the meaning of the movements, irrespective to the strategy used during observation lead to different patterns of brain activity and clear left/right asymetries. Meaningful movements strongly engaged the left hemisphere in frontal regions while meaningless movements involved mainly the right occipito-parietal pathway. Observing with the intent to imitate was associated with activation in the left hemisphere of the dorsolateral prefrontal cortex, the anterior SMA and the cerebellum. In contrast, observation with the intent to recognize activated the right parahippocampal gyrus and the left insula. The right inferior temporal gyrus (Ba 37) was activated during the observation of meaningless movements and the left middle temporal gyrus (Ba 21) was activated during the observation of meaningful movements.

Thus the brain regions that are active during observation of actions are dependent, in part, on the nature of the required executive processing (imitation/recognition) and are strongly modulated by the type of the intrinsic properties of the movement presented.

ASSIMILATION OF A TOOL TO THE HAND: ITS NEURONAL CORRELATES IN MONKEYS. A. Iriki[1,2], M. Tanaka[1], and Y. Iwamura*[1]. [1]Dept. Physiol., Toho Univ. Sch. Med., [2]PRESTO, Res. Dev. Corp. Jpn., Tokyo 143, Japan.

When we use a tool, it becomes extension of the hand in both physical and perceptual sense. The image of a tool is assimilated to that of the hand. To find neuronal correlates of this perceptual experience, we trained macaque monkeys to use a rake to retrieve distant objects, and recorded neuronal activity in the caudal postcentral gyrus where the somato-sensory and visual signals meat. There we found many bimodal neurons which appeared to code the image of the hand. During the tool-use, their visual receptive fields were transformed, so as to include the entire length of the rake or to cover the expanded accessible space. The expansion of the visual RF appeared to be associated with monkeys' intention to use the tool. These neurons were found most heavily in the arm/hand region of the postcentral gyrus but not in the digit region, perhaps reflecting the fact that the rake is an extension of the hand and forearm but not that of the digit in the present experimental situation.

P50 SENSORY GATING AND LATE COMPONENTS OF THE EVOKED POTENTIAL Patricia Tueting* and Nash Boutros University of Chicago, Chicago, IL 60637 and Yale University, New Haven, CT, 06516

When pairs of auditory clicks are presented with a short interval between the two stimuli of the pair, the amplitude of the P50 component of the evoked potential elicited by the second click of the pair is greatly reduced compared to the amplitude elicited by the first. This finding has been interpreted in the context of the theory of sensory gating. According to the gating theory, redundant stimuli are by definition less significant and are gating out at an early stage of information processing. This process spares higher cortical centers for the more complex processing required by stimuli of greater significance that pass by the gate. An important experimental question relates to the extent to which sensory gating measured at 50 msec post stimulus onset is associated with measures of cognitive activity occurring later. Our hypothesis is that sensory gating at 50 msec should be related to N100, P200, N250, and P300, components of the evoked potential that have been widely associated with the significance of the stimulus. The fact that both sensory gating and late component activity are reduced in mental disorders and in normal subjects under stress supports this hypothesis. We designed experiments to more directly address this issue. Three different conditions - paired click, oddball, and stimulus trains - were administered to the same set of 22 normal healthy human subjects. Inhibition as measured in P50 amplitude reduction was observed in all three conditions. Subjects who demonstrated a greater amount of P50 sensory gating were compared on measures of late component activity to subjects showing less early sensory gating.

FACTORS DRIVING INCREASED ATTENTION TO NOVEL STIMULI K Daffner*, L Scinto, M Mesulam, W West, P Holcomb, Harvard Medical School, Boston MA 02215, Northwestern University, Chicago IL 60611, Tufts University, Medford MA 02155

Studies have shown that subjects devote increased attentional resources to "novel" stimuli. It remains unclear whether responses to novel stimuli are due to their infrequency of presentation, deviance from immediate context (as processed by working memory) or unfamiliarity (limited or no previous encounters with the stimulus). These distinctions may have important implications for the role of frontal networks and associative memory systems in responding to novel stimuli. 24 undergraduates participated in 3 experiments that held frequency of presentation of novel stimuli constant while manipulating deviance and degree of unfamiliarity. Each task included a frequent repetitive background stimulus and infrequent "novel" stimuli, randomly presented. Stimuli either came from a set of simple geometric figures or a set of unusual/unfamiliar line drawings (e.g., fragmented or "impossible" objects). In Task A, all stimuli were simple geometric figures; in Task B, all stimuli were unusual line drawings, and in Task C, the background stimulus was an unusual figure and the novels were simple geometric figures. Attentional engagement was operationally defined by the duration of stimulus viewing the subject controlled by button press. Stimuli that deviated from background elicited more attention (longer durations) than background stimuli in all tasks, even when the deviant stimuli were simple and the background stimulus unusual. Deviant stimuli that were unusual/unfamiliar figures elicited more attention than deviant stimuli that were simple geometric shapes. These experiments confirm that novel stimuli attract increased visual attention. Both deviance from background and degree of unfamiliarity influence viewing durations, with the latter seeming to play a greater role in determining the allocation of attentional resources. *Sponsor --NIH (K20MH0137802).*

ALERTING RESPONSE DURING VISUAL SELECTIVE ATTENTION. S. Suwazono, L. Machado, D. Scabini* and R. T. Knight.

Dept. of Neurology and Center for Neuroscience, University of California Davis., Martinez Veterans Medical Center, 150 Muir Rd., Martinez, CA 94553

Visual selective attention encompasses several distinct processes. We recorded reaction time and EEG from young subjects (age 20-37) during a hemifield visual selective attention task to investigate the neural mechanisms subserving the orienting of attention. The stimuli included three categories: standards (upward triangle, 70%), targets (downward triangle, 20%), and novels (240 different color stimuli, 10%). Stimuli were presented randomly to both visual fields 2 degrees from a central fixation (ISI 200-900 msec). Half of the target stimuli were preceded by a novel stimulus delivered equiprobably ipsilateral or contralateral to the subsequent target. Subjects were instructed to press a button immediately after detection of each target. Novel stimuli generated a frontal-central negative potential peaking at 330 msec (amplitude -6.3μV at Cz), which was not observed to standard stimuli ($p<0.001$). There was minimal P3a activity to the novel stimuli following the N330. Target stimuli generated a smaller amplitude N330 and a prominent P3b response. Previous lesion studies in this laboratory have shown that cortical lesions do not reduce the visual novelty N330 (Knight, in press). Target P3b latency was shortened when targets were preceded by novels ($p<0.025$). Reaction times to target stimuli were shortened comparably by both ipsilateral and contralateral novel stimuli ($p<0.01$), but motor potentials were not observed in the interval between novel and target stimuli. These results, including the broad frontal-central scalp distribution of the N330, the lack of reduction by cortical lesions and the behavioral effects on reaction time and P3b latency suggest that the N330 is generated by a subcortical alerting system. FREQUENCY OF TARGETS IN PERCEPTUAL TASKS DOES NOT MODULATE PET ACTIVITY IN THE ANTERIOR CINGULATE CORTEX. M.Corbetta*, G.L.Shulman, F.M.Miezin, D.L.Hunton, and S.E.Petersen.
Dept. Neurol. and Neurol.Surgery, Wash.Univ. Sch.Med., St. Louis, MO.

Current theories of attention propose that the anterior cingulate is involved in the process of target identification. This proposal is partly based on previous findings that anterior cingulate activity increases with the number of targets detected during a semantic monitoring task. We have explored the generality of this finding by manipulating target frequency in three visual experiments that did not involve verbal processing.

Regional cerebral blood flow was measured by PET activation methods during task performance. In expt 1, subjects saw a display consisting of four square windows containing moving colored dots. In the color task, subjects searched for the presence of red-orange dots, in the motion task for the presence of fast moving dots, and in the conjunction task for the combination of red-orange fast moving dots. In different blocks target probability was either .8 or .2. In expt. 2, subjects saw a display containing four differently colored rectangles and searched for targets defined by either a color or the combination of a color and orientation. In different blocks target probability was either .45 or .05. In both expts. 1 and 2 subjects signaled target presence or absence by key-press. The task in expt. 3 was the same as in expt. 2, but target probability was .5 and .05. Also, subjects did not respond on each trial but reported the approximate percentage of targets at the end of each block. No consistent activity difference was noted in the anterior cingulate in any of the three experiments between high and low probability target conditions. Robust cingulate activity was found in expt. 3, but did not differ across target probability. These analyses do not support the claim that the anterior cingulate is involved in target identification across cognitive domains.

ACTIVATION OF PARIETO-OCCIPITAL JUNCTION AND SUPERIOR PARIETAL CORTEX DURING VISUAL SEARCH TASK, S. Miyauchi[1], Y. Sasaki[1], B. Pütz[1], R. Takino[1], H. Imamizu[2], H. Okamoto*[3]. [1]Communications Res. Labs., Tokyo 184, Japan; [2]ATR Human Info. Processing Res. Labs., Kyoto, Japan; [3]Fujitsu Labs. Ltd., Kanagawa, Japan

We studied which brain areas are activated when subjects are performing two types of visual search tasks, one in which a target "pops out" from the background and can be found effortlessly (parallel search), and one in which a target is defined by a conjunction of features and the detection is effortful (serial search). In intervals of 0.75 s arrays of 36 simple shapes (crosses or circles) were displayed in three concentric circles around the fixation point. In the first experiment (pop-out), one of the shapes (target) differed from the other 35 in the test condition, while all shapes were identical in the control condition. In the second (conjunction-passive) and third (conjunction-search) experiments, the shapes were defined by a conjunction of features (shape and color) for the test condition, and again uniform for the control condition. The subjects were required to see the arrays passively in the first and second experiments, and to detect a target which was indicated at the center of the array as a fixation in the third. MR Images were acquired on a Siemens Vision scanner (1.5 T) equipped for echo planar imaging (TE: 66 ms, TR: 3 s, FA: 90°, resolution: 1.6 x 1.6 mm, slice thickness: 3 to 5 mm). Data were analyzed using voxel-by-voxel cross-correlation. No activation was found in the primary visual cortex in all experiments. Spatially restricted, but robust activation was found in the superior parietal cortex and areas in the parieto-occipital junction (areas around the intraparietal sulcus and the transverse occipital sulcus) in the pop-out experiment. In the conjunction-search experiment, strong additional activation was observed in the superior frontal cortex. Of these areas, the superior parietal cortex and the superior frontal cortex have been shown to be activated by visuospatial attention (Corbetta et al. 1993). Thus, it is suggested that areas in the parieto-occipital junction play an important role in feature analysis during visual search, and that the passive/parallel "pop-out" mechanism and the mechanism for voluntary/serial feature analysis share common neural circuits.

HEALTHY AGING SLOWS DYNAMIC ADJUSTMENT OF THE SCALE OF THE ATTENTIONAL FOCUS. P.M. Greenwood* & R. Parasuraman, Cognitive Science Laboratory, The Catholic University of America, Washington, DC 20064

Both healthy aging and Alzheimer disease reduce the benefit of precise location precues in visual search (Parasuraman, Greenwood & Alexander, 1995). Based on this, we hypothesize that the age-related selective slowing of "disengagement" of visuospatial attention following an invalid location cue in a non-search task (Greenwood & Parasuraman, 1994) may arise from difficulty maintaining a target-sized focus of attention while shifting attention to the target. This study sought to examine the effect of aging on the ability to flexibly control the scale of the focus of visuospatial attention by manipulating the size and location of both precues and targets in a consonant-vowel discrimination task presented to healthy young (15) and old subjects (15). Cues were rectangles appearing at one of 12 locations on the screen and were valid, invalid or neutral in predicting target location. When the cue was valid for size, it matched the target at one of three sizes. When the cue was invalid for size, it could either be smaller than the target, hypothesized to require expansion of the attentional focus, or larger than the target, hypothesized to require constriction of the attentional focus. RTs were longest when the cue was both (a) at an invalid location and (b) larger than the target. When the location of the cue was valid, aging slowed discrimination of large targets following smaller cues ($p<.05$). When the location of the cue was invalid, aging slowed discrimination of small targets following larger cues. These results indicate that aging slows both the constriction and expansion of the attentional focus. Supported by NIA grant AG12387-03 to P. Greenwood.

VISIOSPATIAL ATTENTIONAL SELECTION EXAMINED WITH FUNCTIONAL MAGNETIC RESONANCE IMAGING. M. Worden and W. Schneider*. Dept. of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

Functional Magnetic Resonance Imaging (fMRI) was used to examine endogenous modulation of early visual areas in human occipital cortex relating to spatial attentional selection. An oscillatory task design was used in which subjects switched attention periodically (every 11.52 s) between stimuli in the lower-right and the lower-left visual quadrants for the duration of a trial period lasting approximately 196 s. Sixty-four images of nine 3-mm thick slices were acquired during each trial using a fast spiral K-space pulse sequence. Areas of attentional modulation were determined using a Fourier-based F-statistic to identify regions showing significant oscillatory activity at the frequency of task alternation relative to background frequencies (noise). The subjects performed a target-search task at the attended locations which required a response to a target stimulus which was imbedded in a serial stream of distractor stimuli. A variety of different stimulus/distractor configurations were examined, including feature primitives, conjunction stimuli and cluttered stimulus arrays. The areas showing attentional modulation and the degree of modulation was found to vary depending on the particular stimulus configuration used and could be seen as early as area V1 for cluttered displays with confusable distractors and in later stages with less confusable displays. Results suggest that the location of attentional selection is not fixed but varies depending on the task, the nature of the stimuli being selected, and the background against which selection is taking place.

ATTENTION SWITCHING IN AUDITORY AND VISUAL MODALITIES EXAMINED WITH FMRI,
R.L. Wellington* and W. Schneider. Dept. of Psych. U. of Pittsburgh, Pittsburgh, PA 15260

The goal of these experiments was to determine the number, location and specialization of attentional control regions when switching attention in the visual and auditory modalities. Subjects monitored multiple frames wherein the letters were presented in standard alphabetic sequence and responded to an error in the sequence (e.g. A,B,C,D,E,R,G,H....where the "R" is a target). The characters occurred in the lower-left visual field, lower-right visual field, left ear, and right ear. The to-be-monitored sequence could occur in one location, (e.g. left ear) or it could switch between two locations, (e.g. between left and right visual fields or between left visual field and right ear). The to-be-ignored channels included occasional foils to ensure task performance. Behavioral studies were run to practice subjects and determine the stimulus rate which provided good target detection (75%) in all conditions. FMRI was performed using a conventional GE 1.5Tesla scanner with a BOLD contrast imaging sequence using a multi-slice spiral k-space pulse sequence and utilizing an oscillatory paradigm. Results indicate a performance decrement when switching between locations in both modalities (versus maintaining attention in one location). Correspondingly, there was increased activation in the parietal lobe in switching conditions.

CEREBELLAR INVOLVEMENT IN INTRAMODALITY ATTENTION SHIFTING. T.H. Le and X. Hu*. Center for Magnetic Resonance Research. Department of Radiology. Univ. Minn. Med. School, Minneapolis, MN 55455.

Supporting evidences relating to the possible role of the cerebellum in non-motor cognitive function are rapidly accumulating. We present fMRI evidence of the involvement of the cerebellum in rapid shifting of attention as implicated in studies of cerebellar damage and autistic patients (Courchesne et al., 1994.)

Coronal multislice (5mm thick) T2*-weighted EPI [TR/TE: 3.5s/30ms and 0.3mm (volume coil) / 0.15mm (surface coil) inplane resolution] images encompassing the cerebellar and the parietal cortices were repeatedly acquired while subjects (N=13) performed three attention tasks. In each task, the subject was instructed to maintain fixation to a cross-hair displayed in the center of the screen. In the COLOR_ATTN task, the subject responded by pressing a button when a RED object was displayed, ignoring its shape. During the SHAPE_ATTN task, the subject responded by pressing the button when a CIRCLE appeared, ignoring its color. The stimuli consisted of circle and square that were either green or red. In the SHIFT_ATTN task, all stimuli were presented in the same manner as in the other two tasks; however, each subject responded by detecting the first target stimulus in one category (e.g., color) then shift his/her attention to the other category and respond only to the target stimulus of that category (e.g., shape) and continued to alternate between detecting color and shape. Assignment of target stimuli were balanced across tasks. The stimuli were random ordered and 100 ms in duration. The interstimulus interval was 1 s. FMRI maps were generated using the student t-test corresponding to the difference between [SHIFT_ATTN - COLOR_ATTN] AND [SHIFT_ATTN - SHAPE_ATTN] at $p < .01$.

Consistent lateral cerebellar and posterior-superior parietal activation were observed. Activation of the deep cerebellar nuclei was also observed in some of the subjects studied with the higher resolution EPI.

The present study is the first demonstration of cerebellar involvement in rapid attention shifting in normal adults. Our results are concordant with previous findings in patients with cerebellar damage.

DISTINCT COMPONENTS OF COGNITIVE INHIBITION. E. McCormick, E. Carlisle, P.M. Simone*. Department of Psychology, Santa Clara University, Santa Clara, CA 95053.

Many theories exist concerning the phenomenon of negative priming, a paradigm used in the study of selective attention. A dominant theory suggests that negative priming is a result of sustained inhibition, a cognitive mechanism which actively inhibits ignored information (e.g., Tipper, 1985). How this inhibition works is still debated. Our study set forth to examine the important components of inhibition including object location, object identity, and object color in young adults (ages 18-22) using prime/probe trial conditions. Our results challenge Tipper et al.'s (1994) findings that in a "select-what-respond-where" task, inhibition significantly follows location only. In accordance with Milliken et al.'s (1994) study we found inhibition to location to be an underlying mechanism in selective attention. However, by developing other programs which required attention to identity only or color only, we found reliable negative priming to object identity and color as well. Neuroanatonomical correlates of sustained inhibition have been proposed by Connelly and Hasher (1993), i.e separate neural pathways for location (dorsal) and identity (ventral). Specifically, the dorsal projection processes location information through an occipitoparietal pathway while ventral projections process identity information through an occipitotemporal pathway. It appears that identity and color information can reach levels of processing which, like location, require active inhibition depending on the task at hand.

VISUAL SPATIAL ATTENTION SWITCHING IN HUMANS: LATERALIZED PROCESSING OF THE GLOBAL AND LOCAL LEVELS OF PERIPHERAL, HIERARCHICAL OBJECTS. J.M. Shedden*, I.A. Marsman, M.P. Paul, & G.S. Reid. Dept. of Psyc., McMaster University, Hamilton, Ontario, Canada, L8S 1K4.

Perception of a visual scene often involves processing hierarchical (global/local) information (e.g., a pine tree is made of pine cones and branches). Yet the integration of parts does not result in the loss of their individuation. There is evidence that this integration/separation is mediated by the temperoparietal junction (TPJ). Impairment of global/local processing is associated with right/left hemisphere TPJ damage, respectively (Robertson, Lamb & Knight, 1988, J.Neurosci.8:3757). This global/local asymmetry was tested in normal subjects on an attention task that required covert switching between the global/ local levels of hierarchical digit stimuli. Subjects monitored a repeating sequence of ascending digits, responding to errors (e.g., first '8' in sequence: 1,2,3,8,5,6,7,8,9,1,2,3,...). In the following examples, the local stimuli will be represented in subscript font. Stimuli consisted of 10 sets of 10 global digits, made up of all 10 local digits. Thus, the ascending digit sequence 0 through 9 could be presented at either the global or local level. These 100 stimuli were then redesigned to make local and global digits equally salient. Non-digit stimuli provided neutral distractors (e.g., a global digit made up of local boxes). Single stimuli were presented centrally, or two stimuli were presented simultaneously to the left and right of fixation. Attention was fixed at one level, or switched between levels and/or locations. The ascending digit sequence occurred at the attended level, and distractor digits were presented at the other level (e.g., 1_D, 2_D, 3_D, 4_D,...). The ascending digits and the distractor digits alternated between levels in the switching conditions (e.g., 1_D, D_2, 3_D, D_4, 5_D, D_6, 7_D,...). A global/local difference in performance was found for digit, but not neutral distractors. Incompatible digits at the ignored level interfered more than other digits. A disadvantage was found for RH processing of local stimuli, consistent with the evidence from TPJ patients that the RH is more associated with global processing. There was no disadvantage for LH processing of global stimuli. Results from brain-imaging exeriments will also be discussed. Support: Natural Sciences and Engineering Research Council of Canada.

VERTICAL EYE MOVEMENT BIASES DURING MENTAL TASKS: A REPLICATION AND HYPOTHESIS. F.H. Previc* and S.J. Murphy. Armstrong Laboratory, Brooks AFB, TX 78235.

Previous research has shown that vertical as well as lateral eye movements occur during mental tasks, although the neurophysiological basis for such movements remains unclear. Previc (Behav. Brain Sci. 1990;13:519-542) proposed that vertical biases reflect activation of either an upward-biased (ventral-cortical) extrapersonal attentional system or a downward-biased (dorsal-cortical) peripersonal one. In the present study, vertical and lateral eye movements were recorded by means of a video camera from 24 right-handed, right-footed, and right-eyed subjects as they performed each of three mental tasks: a mental arithmetic task, a visuospatial memory task involving a set of nine colored shapes, and a proverb interpretation task. Significant upward biases in the direction of the initial eye movement were observed as subjects answered sets of arithmetic and visuospatial memory questions, with 79% and 83% of subjects who made vertical movements in the respective tasks showing the upward bias. A nonsignificant upward bias was observed following a series of proverb statements that subjects had to interpret. By contrast, no consistent lateral eye movement biases were found in any task. The results of this and previous studies suggest that subjects activate an upward-biased (extrapersonal) attentional system in performing visuospatial memory and mental arithmetic tasks.

EFFECTS OF MEDIAL PREFRONTAL NEURONAL LOSS ON SUSTAINED ATTENTION PERFORMANCE. M. Sarter*, L.A. Holley Miner and M. Ostrander. Department of Psychology & Neuroscience Program, The Ohio State University, Columbus, OH 43210.

The basic cognitive operations of the prefrontal cortex have remained an enigma. Using a task validated for the measurement of sustained attention or vigilance in rats (Psychopharmacol 117:340-357), the effects of bilateral ibotenic acid-induced lesions (5 μg/0.5 μl/hemisphere) of the medial prefrontal cortex were assessed. The task required the animals to discriminate between visual signals (presented for 25, 50 or 500 msec) and non-signals. Compared with sham-lesioned rats, the performance of lesioned rats was characterized by a significant increase in the number of false alarms, i.e., signal responses following non-signal events. The lesion also suppressed the ability to detect the longest signals. Lesioned animals' performance remained insensitive to the detrimental effects of increases in background noise. Collectively, these effects suggest that prefrontal lesions did not affect the mnemonic processing of the stimulus-response rules. However, the lesions completely abolished the ability to discriminate between shorter signals and non-signals. Compared to the exclusive effects of lesions of cortical cholinergic inputs on the detection of signals (Neuroscience 110:247-265), lesions of the medial prefrontal cortex fundamentally disrupt the animals' ability to discriminate short signals from non-signal events.

QUANTITATIVE ANALYSIS OF THE SEQUENCING DEFICITS OBSERVED AFTER FRONTAL LESIONS. M. Lepage* & F. Richer, Labo. Neuroscience Cognition, Université du Québec à Montréal, Montréal, QC, H3C 3P8

Sequential response tasks are sensitive to frontal lobe lesions for reasons that are not well understood. We previously reported (Lepage & Richer, *Brain*, in press) that frontal lesions increase inter-response interference in motor sequences. However, a problem in sequence programming could also contribute to this deficit. A quantitative measure of the efficiency of sequence programming is the decrease in sequence initiation time (SIT) with the predictability of initial responses. We compared 7 patients with a frontal lesion to 6 patients with a temporal lesion and 8 normal subjects in a sequential keypressing task to strings of 4 letters composed of As, Bs, and Cs (e.g. ACBA) with each letter mapped to one of three adjacent keys. In 2 conditions, the predictability of initial responses was manipulated by repeating the first or first three letters of a sequence from trial to trial. In 2 other conditions, the first or first three letters were unpredictable from trial to trial. Frontals were the slowest subjects in all conditions. Normals and temporals showed faster SIT when the three first letters were known compared to only the first while no difference was found between 1 or 3 first unpredictable letters. Frontals, showed the opposite effects; the SIT was longer when the three first letters were unpredictable as compared to only the first one suggesting a susceptibility to programming load, and frontals showed no facilitation effect of the number of predictable initial responses. The fact that frontals were adversely affected by increased initial programming load and did not benefit from a decreased programming load suggest that they cannot use initial predictability to schedule sequence programming optimally. These effects of predictability suggest that part of the sequencing deficits of frontals is a scheduling problem.

THE TASK-SHIFTING DEFICIT AFTER FRONTAL LESIONS: AN EXACERBATED EXOGENOUS INTERFERENCE EFFECT AND LITTLE ENDOGENOUS CONTROL PROBLEM. S. Bédard, F. Richer*. Lab. Neuroscience Cognition, Univ. du Québec, Montréal H3C 3P8.

Frontal lesions have long been associated with problems in task shifting. However, measures of this deficit often lack sensitivity and specificity and rarely permit a quantitative analysis. Above all, the relative contribution of endogenous/voluntary control factors and exogenous/stimulus-driven factors in the frontal shifting deficits has not been determined. We examined these contributions using a predictable task-shift paradigm (Rogers & Monsell 1995) in which the position of the stimulus served as a cue for task shifting. We compared 7 patients with unilateral frontal lobe excision to 7 patients with a temporal excision and 7 controls. In each trial, a stimulus pair was presented in one of the quadrants of the screen and stimuli rotated clockwise from trial to trial, at fixed delays (150 or 800 ms response to stimulus intervals). Stimuli were either letter-digit pairs (A2, 2A, B1, 1B) or pairs in which a neutral (+) sign replaced the letter or the digit. Subjects had to respond to the letter when stimuli were in the upper quadrants, and respond to the digit when stimuli were in the lower quadrants. The shift cost effect can be observed by an increased RT for trials that required changing tasks compared to no-shift trials. Frontals showed an increased RT, both for the shifting and non-shifting trials compared to other groups. Shift cost did not differ between groups. However, the effect of distractors was exacerbated in frontals. These results suggest that the task-shifting problems after frontal lesions are specifically linked to an exogenous susceptibility to interference and not to an endogenous/voluntary switching problem.

DIRECTED ATTENTION AFTER UNILATERAL FRONTAL EXCISIONS IN HUMANS. L. Koski*, T. Paus & M. Petrides. Montreal Neurological Institute, McGill University, Montreal, Quebec, H3A 2B4.

We investigated the ability of patients with frontal-lobe lesions to benefit from advanced information in a simple reaction-time task. The task involved pressing a button in response to the appearance of a peripheral target (visual angle of 11.5°). A cue, presented in the centre of the screen, preceded the target onset by either a short (average 500ms) or long (average 3000ms) interval. In half of the trials, the cue was an arrow indicating the location of the upcoming target (left or right hemifield); in the other half, the cue was an uninformative plus sign (+). In addition to patients with unilateral excisions from frontal cortex (n=15), we tested patients with anterior temporal lobe excisions (n=38) and normal controls (n=8).

The results of a three-way ANOVA (two repeated-measures; one grouping variable) revealed that all subjects were faster in the long-interval trials (long, 416ms; short, 455ms) and faster when given an informative cue (informative, 420ms; uninformative, 451ms). The effect of the cue was greater at long intervals compared with short intervals. However, the three groups were equally affected by the cue and interval manipulations. The latter finding was upheld when the groups were compared using the benefit score calculated for each subject [(plus-signRT - arrowRT) /plus-signRT x100]. The only evidence of uneven distribution of benefits acrôss the three groups, observed in the short intervals, was in the percentage of subjects with benefit scores below the median: 67% (frontal lesion), 47% (temporal lesion) and 13% (normal control)(Chi^2 =6.7, $p<.04$). We conclude that partial unilateral excisions from the frontal cortex need not impair the use of location cues to speed response time.

DIFFERENTIAL EFFECT OF IDAZOXAN (IDZ) IN RATS EXPOSED TO COCAINE PRENATALLY AND CONTROLS: EVIDENCE FOR THE ROLE OF CATECHOLAMINES IN ATTENTIONAL FUNCTION AND DYSFUNCTION.

L.E. Bayer*, S. Kakumanu, C.F. Mactutus, R.M. Booze & B. J. Strupp. Dept. of Psych. & Div. Nutr. Sci., Cornell Univ., Ithaca, NY 14853, & Dept. Pharm., Coll. Med., Coll Pharm., THRI, Univ. of Kentucky, Lexington, KY 40546

The present study was conducted with a dual objective: (1) to test the hypothesis that prenatal exposure to cocaine causes enduring changes in the noradrenergic system & (2) to examine the role of noradrenergic activity in selective attention. Rats exposed to cocaine prenatally and controls were administered the α-2 adrenergic antagonist IDZ (0, .5, 1, 1.5 mg/kg) and tested on a distraction task. This task assessed the ability of the S's to monitor an unpredictable light cue of either .3 or .7 sec duration, and maintain performance when presented with olfactory distractors. Preliminary analysis revealed a specific and differential effect of IDZ in cocaine-exposed and control S's. IDZ (.5 mg/ml) impaired attentional function and increased errors of commission in both groups, specifically under conditions of distraction. This pattern of results rules out nonspecific alterations in performance as the basis of the IDZ effects. Cocaine-exposed S's showed an increased sensitivity to IDZ's attention impairing effects. The nature of IDZ's attentional effect in the cocaine-exposed S's suggested that dopaminergic function may be altered in these animals. These results provide evidence for the hypothesized role of the coeruleocortical NE pathway in selective attention and support the hypothesis that prenatal cocaine exposure causes enduring changes in catecholamine neurochemistry.

NO ATTENTION DEFICIT IN SERIAL REACTION TIME TASK FOLLOWING 192 IgG-SAPORIN LESION.

J.J. Waite*, M.L. Wardlow, A.E. Power & L.J. Thal. Dept. of Neurosciences & Neurology, UCSD & VAMC, San Diego, CA 92161.

Impairment of attentional focusing has been reported after excitotoxic lesions of regions of the cholinergic basal forebrain nuclei. We tested rats in the 5-choice serial reaction time task following a cholinergic basal forebrain lesion produced by 192 IgG-saporin to test whether this more specific lesion would impair attention. Rats received 1.6, 2.6, or 3.3 μg of 192 IgG-saporin, PBS, or 2.0 μg of OX7-saporin in bilateral i.c.v. infusions (10 rats/group), to produce 75, 85, and 90% depletion of ChAT. The OX7-saporin dose was chosen to produce Purkinje cell loss similar to that found with the highest dose of 192 IgG-saporin to control for cerebellar effects on behavior. All rats were trained to nosepoke in response to a light stimulus for a food reward to a criterion of 75% correct prior to being lesioned. Five days of prelesion performance (subsequent to attaining criterion) were compared with 5 days of postlesion performance. On this measure, only the OX7-saporin group was impaired compared with all other groups. All groups reattained criterion and were not significantly different after 10 days of reacquisition. Experimental challenges included reduction of stimulus brightness; shortening and lengthening the intertrial intervals; shortening the stimulus duration; and insertion of a noise distraction before or at the onset of the stimulus. For all experimental challenges, there was no significant effect of group on the percent correct responses. Supported by Alzheimer's Assoc. FSA94019, NIH NS33371 and VA Medical Research Service.

NEURONAL MEDIATION OF DIVIDED ATTENTION: CONTRIBUTIONS OF CORTICAL CHOLINERGIC INPUTS.

J. Turchi* and M. Sarter. Department of Psychology & Neuroscience Program, The Ohio State University, Columbus, OH 43210.

The present experiment represents a continued effort to assess the role of cortical acetylcholine (ACh) in the mediation of processing capacity. A previously characterized crossmodal divided attention task (Psychopharmacology, 115:213-220) was employed to investigate the capacity of rats to process simultaneously competing response rules associated with multiple stimulus types. The immunotoxin 192 IgG-saporin was infused into the basal forebrain to lesion cholinergic projections to the cortex. Lesion-induced cortical cholinergic fiber loss was quantified as described in McGaughy et al. (Neuroscience, 110:247-265). The lesion-induced loss in cortical cholinergic fibers substantially affected the animals' ability to divide their attention between the processing of auditory and visual response rules. While lesioned animals maintained response accuracy, the selective increase in response latencies under the condition of modality uncertainty, as demonstrated on the basis of speed-accuracy trade-off analysis, revealed the decrease in processing capacity produced by the loss of cortical cholinergic inputs. These results will be compared with the effects of combined loss of cortical cholinergic and noradrenergic inputs on divided attention. Collectively, these findings foster further discussion of neural systems subserving divided attention.

JAMES'S THEORY OF CONSCIOUSNESS RECONSIDERED.

Y. Shapiro*. TBD, Portland, OR 97212.

Since Edelman (1989) & Calvin (1989) smuggled "consciousness" into scientific discourse, there has been no shortage in theories that attempt to resolve the mystery of consciousness. James (1890) offered a solution, whose pros and cons will be considered along with his theory - my reconstruction of The Principles. The theory distinguishes between 1) conscious and non-conscious (purposeless) actions of conscious bodies and 2) their "reproductive" (R) and "productive" (P) consciousness (C). RC is species-specific and common to the mammalian brain, whose observable actions it demonstrates, and is fully explained by a) the brain's inertia in obeying the laws of neural habit and neural association and b) cognition that consists in attention and the simple two-term reasoning. PC evolved with "this instrument of possibilities", the human brain; its acts are unobservable. PC breaks the rules of RC: it forgets, disregards, and otherwise selects. PC is explained by a) the ease with which the brain's inertia may be disturbed and by the brain's secondary, internal reactions that break its habits and associations to make the new ones and b) cognitive operations of attention, discrimination, and comparison.

SIGNAL AVERAGING IN COGNITIVE AND MOTOR PET PARADIGMS.

T.M. Ellmore, J.D. Van Horn, G. Esposito, B.S. Kirkby, J. L. Austin-Lane,* D.R. Weinberger, & K.F. Berman. Unit on PET, CBDB, NIMH, Bethesda, MD, 20892.

Multiple presentations of cognitive tasks are increasingly used to better achieve statistically significant neurophysiological signals in cerebral activation studies. The magnitude of statistical effect sizes (e.g. standardized signal-to-noise ratio) is dependent on sample size and number of task repetitions, but little empirical data exist to guide research design. The optimal number of repetitions may vary with different task paradigms. We examined signal strength as a function of number of task repetitions in single-subject and group analyses of two extreme examples within the domain of activation studies, a simple sequential finger movement task and a complex cognitive task, the Wisconsin Card Sorting Test (WCS). For each task paradigm, each of eight healthy subjects completed six activation scans and six control scans with 11-13 mCi of $H_2{}^{15}O$ per scan and PET scanner septa retracted. First, group data were analyzed with Statistical Parametric Mapping (SPM95), averaging all six repetitions; the two most significant foci of activation (i.e. maxima) from the six-repetition group analyses for each paradigm were chosen for exploration in further group analyses in which one, two, three, four, or five repetitions were averaged and the maximum z-score in a 10x10x8mm neighborhood centered around each chosen maximum was determined. Next, in analogous single-subject SPM analyses averaging three, four, five, and six repetitions, z-scores were determined for the two maxima chosen from the group data as well as for two maxima chosen individually from each single-subject six-repetition analysis. In general, activation increased with more repetitions for both paradigms, but was more robust with fewer repetitions for the motor than the cognitive paradigm. In the motor task group analysis, activation in primary motor cortex and cerebellum was highly significant ($p<.001$) with even a single repetition. In the WCS group analysis, significant activation occurred in dorsolateral prefrontal cortex and inferior parietal lobule after three to four task repetitions. In single-subject analyses, motor activations became reliably significant ($p<.001$) with three to four repetitions, whereas at least five to six were required for the WCS. These results may help to delineate the optimal number of task replications needed for various PET activation paradigms, show how reliably group analyses reflect individual patterns of activation and describe the intersubject variability in the locales of activation foci.

THE PLANUM TEMPORALE: A RE-ASSESSMENT OF ITS BOUNDARIES, AREA, & VOLUME USING 3D IN-VIVO MORPHOMETRIC TECHNIQUES

C. Westbury, R.J. Zatorre, A.C. Evans, & D. Klein*, Montreal Neurological Institute, McGill University, 3801 University Street, Montreal Quebec H3A 2B4, Canada.

Uncertainty regarding the posterior and lateral borders of the planum temporale (PT) has made it difficult to assess and unify the literature on its putative hemispheric asymmetry. We present an unambiguous rule-based definition of the problematic lateral and posterior borders of the PT. Our definition emphasizes the topographic continuity between the clear exemplars of the structure (where the ascending and descending rami are easily and indisputably identifiable) and the problematic cases, which often exhibit great apparent anatomic variability. The definition suggests that proper identification of the posterior wall of the descending ramus renders its disputed inclusion as part of the PT unlikely. The previous uncertainty about the lateral and posterior borders is due in part to constraints imposed by the methodologies which have been used to measure the extent of the PT. We used an interactive 3D voxel-painting program (McDonald et al, 1994) to identify and label the PT simultaneously and in real-time in horizontal, sagittal, and coronal planes in MRI scans from 70 normal right-handed volunteers, including 10 subjects with absolute pitch. Scans were transformed into the standardized stereotaxic space of Talairach & Tournoux (1988), to control for individual variation in overall brain shape and size. Using this technique we are able to measure both grey matter volume and cortical surface area of the PT. We present data showing that the hemispheric asymmetry ratio can differ by more than 20% within a single subject, depending on whether the ratio is calculated using grey matter volume or cortical surface area. The functional significance of the disparities in asymmetry quotients using the two different measures is discussed.

FUNCTIONAL VOLUMES MODELING: A STRATEGY FOR SYSTEM-LEVEL MODELING OF HUMAN NEUROIMAGING RESEARCH. P.T. Fox, L.M. Parsons*, J. L. Lancaster. Research Imaging Center, University of Texas Health Science Center at San Antonio, San Antonio, TX 78284-6420.

A systems-level modeling strategy for human functional brain mapping called Functional Volumes Modeling (FVM) was designed, prototyped, and tested. FVM is a means of creating explicit models of the brain activations associated with hypothesized elementary operations in a task. It assumes that many such elementary operations underlie any cognitive task, so tasks are performed cooperatively by multiple brain areas. FVM allows a researcher to decompose a task into elementary operations and assemble a model from location-operation correlations established by metanalyses of published reports with BrainMap™. For a given task, this framework can be used to test a "systems hypothesis": the additive combination of the parts (the elementary operations) is equal to the whole (the task).

The FVM strategy was tested by creating an FVM model of a task vs. control comparison not previously reported and validating it in a PET study of 10 normal volunteers. The task, verb generation, was contrasted here with fixation-point control (rather than higher-order task). Task analysis was adapted from that of Petersen et al, 1988. The Petersen et al. locations (coded as 1.5-cm-radius spheres in Talairach space) were used as seeds for BrainMap searches to identify activation locations and verify task operations. These grouped operation/locations were made into explicit objects by computing the mean location and volume for each functional area, bounding and approximating each as a sphere and embedding it in a 3-D, 2-mm-voxel-spaced data matrix.

This FVM model was compared to the newly observed task vs. control data using logical image analysis. The model matched the new data fairly well: many functional areas were predicted and observed, while a few were observed but not predicted. Thus, in its first evaluation, the Systems Hypothesis has been generally confirmed. Overall, the success of this FVM prototype indicates that FVM modeling and verification may be applied to other functional areas and tasks. (Funded by NIMH grant P20DA52176-01)

Gyral Asymmetries in 3-D Brain Models: Individual Variability and the Importance of Criterion for Asymmetry Jeffrey J. Hutsler*, William C. Loftus & Michael S. Gazzaniga; Program in Cognitive Neuroscience, Dartmouth College & The Center for Neuroscience, University of California, Davis

Previously, we demonstrated that hemispheric asymmetries in the size of individual cortical gyri can appear throughout the brain, but at a population level these gyri are largely symmetric (Hutsler et al., 1993). In the present study we looked for asymmetries in three-dimensional surface models that were constructed from MRI images. These models allow cortical boundaries to be placed directly on the surface of the brain, without the need to plot borders on the original 2-D image set (Loftus et al., 1995). The surface area of two easily identifiable gyri, the cingulate and postcentral, were measured in 12 normal, right-handed males using this improved technique. Several individuals showed asymmetry in the surface area of these regions, however neither region was consistently asymmetric across subjects. Inter-rater reliability scores indicated that surface areas and asymmetry coefficients could be accurately assessed with this method.

Asymmetry coefficients are derived by subtracting the left surface area from the right and dividing by half of their sum. Anatomical asymmetries are typically assessed by choosing an arbitrary criterion for this value that ranges between .1 and .2. We looked for asymmetries at several criterion values and found that agreement between raters varied significantly depending upon the criterion chosen. The presence of individual asymmetries in the absence of population asymmetries argues against using averaged brain templates for locating cortical areas in functional studies; and, arbitrarily defining a criterion for assessing the presence or absence of cortical asymmetries may overestimate the number of asymmetries present in an individual brain.

SOME METHODS FOR DYNAMIC ANALYSIS OF THE SCALP RECORDED EEG. Karl H. Pribram, M.D.*, Joseph S. King, Ph.D., Thomas W. Pierce, Ph.D., and Amanda Warren, B.S. Center for Brain Research and Informational Sciences, Radford University, 423 Russell Hall, Radford, VA 24142

We describe methods for quantifying the spatiotemporal dynamics of EEG. Development of these methods was motivated by watching computer-generated animations of EEG voltage records. These animations contain a wealth of information about the pattern of change across time in the voltages observed across the surface of the scalp. In an effort to quantify this pattern of changing voltages, we elected to extract a single quantifiable feature from each measurement epoch, the highest squared voltage among the various electrode sites. Nineteen channels of EEG were collected from subjects using an electrode cap with standard 10-20 system placements. Two minute records were obtained. Each site was sampled at a rate of 200 per second. Thirty seconds of artifact-free data were extracted from each 2 minute record. An algorithm then determined the location of the channel with the greatest amplitude for each 5 msec sampling epoch. We quantified these spatio-temporal dynamics as scalars, vectors and cluster analytic plots of EEG activity for finger tapping, cognitive effort (counting backwards) and relaxation to illustrate the utility of these techniques. In addition, we are exploring the application of non-linear dynamics to determine whether the paths described by the changing recrudences can be modelled as reflecting their generation by sets of attractors.

FORWARD SOLUTION RECONSTRUCTIONS OF NEOCORTICAL ERP DISTRIBUTIONS FROM LAMINAR CURRENT SOURCE DENSITY (CSD) PROFILES. **C.E.Tenke*, A.D.Mehta and C.E.Schroeder, Dept. Biopsychology, NYS Psychiatric Inst., NY,NY, Dept. Neuroscience, Albert Einstein Coll.Med., Bronx, NY and Progr. Cogn. Neuroscience and Schizophrenia, Nathan Klein Inst., Orangeburg, NY.**

Laminar CSD profiles detail the transmembrane current flow patterns which underlie the local field potential distribution, but do not distinguish between closed- and open-field generators. Only the latter are relevant to the study of the origins and significance of the scalp ERP. We describe an approach to the extraction of waveforms uniquely associated with local open field generators (i.e., regional dipoles). Laminar flash-evoked ERP and derived CSD profiles , sampled (linear electrode array; 150um resolution) from Area 17 in awake macaques, were used to : 1) compute reconstructions of field potential from CSD profiles; 2) compare and contrast empirical and reconstructed profiles using Principal Components Analysis (PCA); 3) evaluate the interpretability of PCA components as indices of local and volume conducting activity in neocortex. "Predicted" field potential contributions of generators described by the CSD (forward solutions) were computed with weighting functions corresponding to uniformly distributed cylindrical generators (Nicholson and Llinas,1971). Solutions were computed for cylinders with .5, 2.5, 5 and 10mm radii(3x 10^{-4}/ohm-mm conductance). Overall, the 2.5mm estimate provided the best fit to the empirical data, although all reconstructed profiles approximated the empirical data. PCA factors were jointly extracted from the empirical and reconstructed data (2.5mm radius) over 0-200ms. Each of the first three components (97.7% variance) included activity coincident with N40. The characteristic lamina 4 sink and deeper source was evident for factors 2 and 3. Factor score profiles were almost identical for empirical and reconstructed data for the first two components (94.5% variance). Weighted sums of the first three components matched empirical profiles at both extreme electrodes, describing the open field properties of striate cortex. However, PCA latency restrictions were required to facilitate direct comparisons with the underlying CSD. (Supported by MH36295 andMH47939)

MISALLOCATION OF VARIANCE IN ERP ANALYSIS SOLVED BY THE TOPOGRAPHIC COMPONENT MODEL. A. Achim*, W. Marcantoni and S. Bouchard. Laboratoire de Neuroscience de la Cognition, Université du Québec à Montréal, Canada, H3C3P8.

Wood & McCarthy (1984) showed that principal component analysis with Varimax (PCA-V) of event-related potentials (ERP) misallocates variance across components, in a context where true components were defined as wave shapes only. We demonstrate that misallocation depends exclusively on imperfect estimation of the component on which the conditions differ, and occurs even if the component to which variance is misallocated is perfectly identified. Möcks' (1988) topographic component model (TCM) differs from PCA-V by identifying the signal space axes based on the assumption that a fixed topography is associated with each component wave shape, rather than based on the PCA-V assumptions of orthogonality and simple structures. Simulated data with a fixed topography associated with each component show that PCA-V still misallocates variance, while TCM decomposes the data correctly. Both TCM and PCA-V assume that components have fixed wave shapes modulated only in amplitude, which is unrealistic in many ERP situations. We explored a dynamic TCM (dTCM) which further allows the component wave shapes to fluctuate in onset and duration times. Simulations show that dTCM is actually solvable. Thus, dTCM could become a very powerful tool for deciphering brain functions.

EFFECTS OF ANESTHESIA ON EVENT-RELATED POTENTIALS AND COGNITIVE PROCESSING IN RATS. J.O. Clifford[1] and B.M. Potter*[2]. [1]NeuroTech Corp., Whitefish, MT 59937; [2]Midlantic BioResearch Corp., Temple Hills, MD 20748.

A novel method for measuring effects of chemical exposure on cognitive function is described. Electrophysiological responses to auditory and visual stimuli presented in oddball paradigms were recorded from 8 rats under varying levels of anesthesia. Surgery was not performed, subject participation was passive, and training was not required. Evoked response potentials (ERPs) were recorded differentially in 3 spatial planes and across time, and vector analysis of dipole movement and magnitude was conducted. Latency and magnitudes of the major brain potentials varied as a function of level of anesthesia, but did not dissociate the stimulus groups presented. 3-D display of voltage trajectories showed a response pattern that varied in a predictable manner in all animals under all levels of anesthesia, and also showed specific electro-anatomical patterns that were unique to the processing of each stimulus group presented at differing levels of anesthesia. This recording method provides a quantitative, spatial characterization of neuronal function following pharmacological manipulation. This same method may be useful to localize abnormal function and/or neuropathology to approximate brain regions, and provide an objective, quantitative, non-invasive means of detecting neurotoxin-induced changes in cognitive processing in the absence of other observable neurological abnormalities.

A COMPUTER PROGRAM TO CALCULATE CRITERIA FOR ABNORMALITY IN TEST BATTERIES USING MULTIPLE MEASURES. C. B. Aiken and L. J. Ingraham*. Lab. of Psychology and Psychopathology, NIMH, Bethesda, MD 20892.

Investigators who use neuropsychological tests and test batteries in their work frequently confront the task of determining whether a pattern of scores on a variety of measures reflects change or impairment. As the number of measures increases, so does the probability that scores on some of the measures will change significantly or score in the abnormal range. In previous work we presented a simple method for setting an overall criterion for abnormality or change when using multiple measures, and suggested an approach for setting criteria when some of the measures are correlated (Ingraham & Aiken (1996) *Neuropsychology, 10*:120-124.). Here, we present a computer program that can be used by investigators to facilitate the calculation of *p* values for various numbers of tests in a battery and for various levels of deviation.

730.10

A COGNITIVE NEUROSCIENCE APPROACH TO THE STUDY OF SEX DIFFERENCES J.S. Janowsky* and P.J. Jennings. Dept. of Neurology, Oregon Health Sciences Univ., Portland, OR 97201 and The Bunting Institute, Racliffe College, Cambridge, MA 02138

The neural mediators of sex differences in cognition are not well understood. We examined sex and hormone effects on the performance of two tasks in young adults. Women at the high estrogen phase of the menstrual cycle perform faster than women at the low estrogen phase on a sequential key pressing task, mediated by the basal ganglia. Estrogen predicted reaction time (RT) in women. RT was unrelated to hormone levels in men. Men and women differed on a global/local visual recognition and attention task mediated by the ventral and dorsal visual systems, respectively. When global and local targets occurred equally often women and men performed similarly. When local or global targets occur more frequently (attentional bias) both men and women responded faster to the biased targets. However men but not women were slower to respond to the low frequency targets. These data suggest a modulatory role of hormones on cognition in adulthood. These results are consistent with the possibility that hormones affect specific aspects of basal ganglia, and parietal lobe function.

MRI MORPHOMETRY OF THE SYLVIAN FISSURE: GENDER DIFFERENCES. A.L. Foundas*, J.R. Faulhaber, J.J. Kulynych, D.R. Weinberger. Dept. Psychiatry and Neurology, Tulane University School of Medicine, New Orleans, LA 70112, and Clinical Brain Disorders Branch, NIMH, NIH Bethesda, MD 20892.

Asymmetries of the sylvian fissure (SF) exist with a predominant leftward asymmetry in consistent right handers. Leftward asymmetries of the sylvian fissure (SF) are more pronounced in the postcentral segment (PSF) than in the anterior segment; PSF asymmetries are also correlated with asymmetries of the planum temporale (PT). Reduced PSF and PT asymmetries have been reported in females (Witelson & Kigar, 1992). We predicted that SF asymmetries derived from in vivo MRI surface renderings in right handed males (n=12) and females (n=12) would demonstrate the predicted leftward asymmetry of the SF with the asymmetry most prominent in the PSF. We also predicted that asymmetries of the PSF would be reduced in females. Across all subjects, leftward asymmetry of the SF was demonstrated, with a significant asymmetry of the PSF ($p < .001$), but not the anterior SF. In addition, asymmetries of the PSF were reduced in females. Similar to Rubens et al (1976) on postmortem brains, there was a corresponding increase in the parietal operculum anterior to the posterior ascending ramus (PAR) in the left hemisphere, and posterior to the PAR in the right hemisphere when SF asymmetries were leftward. Gender differences existed such that asymmetries of the parietal operculum were reduced in females most often due to an expansion of the right parietal cortex anterior to the PAR ($p < .05$). These findings suggest that asymmetries of the SF may be linked to the developmental processes that produce asymmetries of the supratemporal cortex and parietal operculum.

730.12

EFFECTS OF HANDEDNESS AND GENDER ON HIPPOCAMPAL SIZE IN NORMAL CHILDREN: AN MRI STUDY. T.H. Lucas[a], L.J. Lombardino[b], S.N. Roper*[c], & C.M. Leonard[a]. Depts. of Neuroscience[a], Neurosurgery[c] & Communications Processes[b], University of Florida, Gainesville, FL 32610.

Using in vivo magnetic resonance imaging we measured the hippocampus (HIP), midsagittal corpus callosum (CC) area, and indices of the gross brain in 40 normal children between the ages of 5 and 12. We compared these structural data with quantitative handedness indices and a battery of cognitive/behavioral measures. We tested the hypotheses that (1) brain and hippocampal size would change with age, (2) boys would have larger HIP volumes and different patterns of HIP asymmetry than girls, (3) spatial skill would be associated with hippocampal size and (4) handedness would influence these relationships. The results indicated that (1) brain size moderately declined with age, (2) boys had larger brains and absolute HIP volumes than girls--though normalized HIP volumes were indistinguishable and there were no gender differences in asymmetry, (3) performance on the block design subtest of the WISC-III was not associated with left or right HIP volume, and (4) the quantitative handedness coefficient predicted HIP asymmetry. Adextrals had significant rightward HIP asymmetries (coefficient of asymmetry =0.07, $p < 0.005$): 85% (11/13) of adextrals had larger right HIP volumes, whereas dextrals were evenly distributed. These data suggest that the general finding of leftward cortical asymmetry present in righthanders (e.g. planum temporale, pars triangularis, and parietal operculum) may not be present in limbic structures. Factors which influence cortical asymmetries may differentially affect HIP asymmetries. These findings have implications for theories of cerebral laterality. *Supported by grant 96-1021 from the March of Dimes Birth Defects Foundation.*

RELATIONSHIP BETWEEN NUMBER OF GABA NEURONS AND DEGREE OF HAND PREFERENCE. S.F. Witelson*[1], I.I. Glezer[2] and D.L. Kigar[1]. [1]Dept. Psychiatry, McMaster Univ., Hamilton, ON; [2]Dept. Cell Biol. Anat. Sci., CUNY Med. School, N.Y.C.

The number of GABAergic neurons in von Economo's area TA_2 of the superior temporal gyrus was estimated using light microscopic immunocytochemical methods with three calcium-binding proteins (CaBP): calbindin (CB), calretinin (CR), and parvalbumin (PV). The quantitative relationship between number of GABAergic neurons and hemispheric functional asymmetry was examined by studying possible differences between right and left hemispheres and differences related to hand preference, an index of the pattern of functional asymmetry. A sample of 13 brains from 7 men and 6 women who had been tested for hand preference were studied. Previous results showed that a dichotomous classification of hand preference revealed that consistent-right-handers (CRH) had qualitatively more $CaBP^+$ cells than nonCRH, regardless of sex (Glezer, Witelson & Kigar, *Soc NSc Abstr*, 1994). Quantitative analysis revealed no hemispheric differences, but in each sex, the CRH group had more than double the number of each type of $CaBP^+$ neuron. A continuous score of hand preference was also obtained which varied from +12 (CRH) to -12 (CLH). For both the number of $CaBP^+$ neurons under a unit area of cortical surface through the depth of the cortex (columnar number, N_C) and cell packing density (N_V), there was a positive relationship between neuron number and degree of hand preference. Product-moment correlations between N_C (mean of both hemispheres) for each type of $CaBP^+$ neuron and hand preference score (n = 13) were significant beyond $p < .01$ in each case. See Figure. Similar values were obtained for N_V. The results indicate that there are marked individual differences in the number of GABAergic neurons at least in this cortical region, and that the number of GABAergic neurons, which play a key role in cortical inhibition, is related to hemispheric functional asymmetry. WOMEN NAME BOTH COLOURS AND FORMS FASTER THAN MEN. **D. Kimura*, D.M. Saucier and R. Matuk, Psych. U Western Ont., London Canada, N6A 5C2.**

It is well established that women name a series of patches of familiar colours faster than men, a finding usually attributed to enhanced colour processing. To test the specificity of this effect, a page each of 100 colours and 100 forms was presented for rapid naming to 22 women and 24 men. In each task, five stimuli occurred repeatedly, for which correct labels were established prior to naming. Other tests examined articulation speed, and the ability to correctly label, and to match labels to, less familiar colours and forms.

Women named both colours and forms more quickly than men ($F=6.04$, $p=.018$), with a slightly larger advantage on forms than colours; but their ability to label less familiar stimuli of either type was not better than men. Articulation measures neither differentiated the sexes, nor accounted for the difference on the speeded naming tasks. It appears that women may have readier access to standard verbal labels, regardless of stimulus type.

LOWER SPATIAL ABILITY IN LESBIANS: INTERACTION WITH HAND PREFERENCE. C.M. McCormick[1], S.F. Witelson[2] and A.J. McComas*[3] [1]Dept. of Psychology , Bates College, Lewiston, ME; Depts. of [2]Psychiatry & [3]Med., McMaster Univ., Hamilton, ON, L8N 3Z5

Neurobiological factors in the origin of sexual orientation in women were studied with neuropsychological probes. Spatial abilities and performance on fluency tasks were assessed in a group of 31 lesbians and a group of 31 heterosexual women matched for age, education and hand preference. Results were also compared to similar groups of homosexual and heterosexual men. The lesbian group scored lower on each of the three tests of spatial ability than the heterosexual women, but no differences were observed on the two fluency (oral and manual) tasks. A similar pattern of differences was found between the male groups. Hand preference was considered as a factor because in previous work we found an increased prevalence of non consistent-right-handedness (nonCRH) in both homosexual men and women (McCormick & Witelson, *Psychoneuroendoc*, 1991), and some relationship between spatial abilities and hand preference has been reported. In each sex, hand preference was a factor in the relationship between sexual orientation and spatial ability: the difference was among nonCRH groups only. These results are consistent with previous findings indicating an interaction of hemispheric functional asymmetry and sexual orientation. The heterogeneous patterns of correlates of sexual orientation are consistent with the model of a mosaic of neural sexual differentiation (Witelson, *Psychoneuroendoc*,1991). The finding of lower spatial ability in lesbians, as in homosexual men, is not consistent with the generally held view that lesbians are relatively masculinized women. The possibility that lesbians are on the more feminine end of the female axis is proposed. Supported in part by NIH-NS18954(SFW) and NSERC (Canada)(CMM).

730.16

INTRAPERSONAL MOTOR BUT NOT EXTRAPERSONAL THROW ACCURACY IS ENHANCED DURING THE MIDLUTEAL PHASE OF THE MENSTRUAL CYCLE. D.M. Saucier* and D. Kimura, Psych., Univ. Western Ont., London Canada N6A 5C2.

Verbal articulatory speed and small-amplitude manual skills within personal space are usually enhanced during the high-estrogen (E) phases (midluteal and pre-ovulatory) of the menstrual cycle, whereas spatial ability is better in the low-E phase (menstrual). Twenty-two women performed such fine motor tasks (the Box task and Mirror Tracing) in both the midluteal and menstrual phases, along with a spatio-motor task (Targeting) directed at extrapersonal space. The targeting task reliably yields a large male advantage. Saliva samples were assayed for estrogen and progesterone to confirm the appropriate menstrual phase for each test session.

The Box task was performed faster during the high-E midluteal phase relative to the menstrual phase ($F=6.39$, $p=.016$) and Mirror Tracing showed a similar trend toward better midluteal performance. There was no effect of phase on targeting accuracy ($F=0.09$, n.s.). However, for targeting, the right hand was relatively more accurate than the left in the midluteal phase ($F=8.82$, $p=.005$), consistent with earlier suggestions that high levels of E may facilitate left-hemisphere function. Spatial (mental rotation) ability was better in the menstrual phase, and was not significantly correlated with targeting performance.

DO OVARIAN HORMONES PLAY A ROLE IN HUMAN COGNITIVE DEVELOPMENT? FINDINGS FROM PATIENTS WITH TURNER SYNDROME. M. L. Collaer*[1] M. E. Geffner[2], and M. Hines[3,4] Depts. of Psychology[1], Pediatrics[2]& Psychiatry[3], UCLA, Los Angeles, CA 90095, [4]Dept. of Psychology, City University, London, England EC1V 0HB.

Ovarian hormones are typically assumed to have no effect on sexually-dimorphic brain and behavioral development, although recent research suggests alternative views. In contrast, testicular hormones are well known to influence these features in many species. This study investigated the potential contribution of ovarian hormones to human cognitive development in Turner syndrome (TS), a disorder marked by deficient ovarian function.

TS occurs in females as a result of a sex chromosome abnormality. Along with other abnormalities, ovarian regression typically occurs prenatally. Therefore, ovarian hormones, known to be markedly deficient in adulthood, are expected to be reduced during presumed critical periods for neurobehavioral development.

Females with TS show normal verbal intelligence but are impaired on a number of specialized abilities. If ovarian hormones contribute to cognitive development, TS patients would be expected to exhibit greater deficiencies on tasks that show sex differences (i.e., female-superior or male-superior tasks, ones at which females or males, respectively, typically excel) as opposed to tasks that are sex neutral.

Cognitive tasks favoring males, females or neither were administered to 21 patients with TS (12 to 42 yrs) and 21 female matched controls. TS patients differed primarily on tasks that show sex differences. They were most impaired on female-superior tasks but also performed significantly worse than controls on several male-superior tasks. These findings suggest a role for ovarian hormones in cognitive development and may have implications for differences observed between and within the sexes. *Funding source: HD24542*

HIGHER COGNITIVE PERFORMANCE AMONG ESTROGEN USERS R.A. Mulnard*, C.W. Cotman and D.J. Edwards. Institute for Brain Aging and Dementia, University of California Irvine, Irvine, CA 92717-4540.

Estrogen deficiency provides one contributing theory of cognitive decline and the onset of dementia in some post-menopausal females. Several community studies have found support for a decreased incidence of dementia among post-menopausal estrogen replacement therapy (ERT) users, an effect which is enhanced with increasing years of estrogen usage (Kawas, 1995; Mortel, 1995; Paganini-Hill, 1995; Robinson, 1994). Other studies have shown that post-menopausal women experience benefits from ERT including, but not limited to improvements in mood, concentration and memory (Sherwin, 1988). In the current analysis, as part of a large community-based study which examined the relationship between exercise and cognitive functioning among 877 senior citizens, data was extracted on estrogen history and usage for the 675 females within the sample. The cognitive battery was collected over a 40 to 50 minute period of time using a group slide projection technique (test-retest reliability with conventional neuropsych testing was between 0.76 - 0.94). 209 females were current users of estrogen ($\geq$ 1 year) and 466 were non-users of estrogen therapy. The statistical analysis examined the differences in cognitive performance between users and non-users of estrogen replacement therapy. Women currently taking ERT performed significantly better than non-ERT users with respect to measures of expiratory flow volumes, self-efficacy, memory, narrative recall, social support and an overall neuropsychological score.

RELATIONS BETWEEN TESTOSTERONE, AND MORPHOLOGY OF THE HUMAN CORPUS CALLOSUM. S.D. Moffat[1], E. Hampson*[1], J.C. Wickett[1], P.A. Vernon[1] & D.H. Lee[2]. [1]Dept. of Psychol. and [2]Dept. of Diag. Radiol. and Nuc. Med., University of Western Ontario, London, Ontario, N6A 5C2 Canada.

Theoretical speculation in humans (Witelson, 1991) and empirical findings in animals (Denenberg et al., 1991) suggest that testosterone (T) may play a significant role in the development of the corpus callosum (CC). However, there are currently no empirical studies directly relating T concentrations to callosal morphology in humans. The purpose of the present study was to investigate the relationship between free T concentrations, as determined by radioimmunoassay and the mid-sagittal area of the corpus callosum, as determined by MRI. Subjects were 68 young adult (20-35 years), neurologically normal, right-handed males. All subjects underwent MR imaging in a General Electric 1.5 tesla MR unit. Regions of interest included total brain volume, left and right hemisphere volume and regional areas of the CC. CC regions were defined using two different measurement techniques, each dividing the CC into 6 sub-sections. Subjects provided 2 samples of saliva for radioimmunoassay (RIA) of testosterone (T) and cortisol. Anatomical measurements were performed blind with respect to the hormone levels of subjects. Both the RIA and the anatomical measures demonstrated high reliability (all r's>.93). A significant positive correlation between T concentration and cross sectional area of the posterior body of the CC was found. This finding was consistent across the two measurement techniques and was not attributable to individual differences in total brain volume. All correlations between cortisol and CC sub-regions were non-significant. The results of this study are consistent with the notion that T, at an earlier stage in development, may play a significant role in modulating cortical/callosal architecture in humans. MODULATION OF COGNITIVELY-RELATED CORTICAL ACTIVITY BY GONADAL STEROID HORMONES DIRECTLY DEMONSTRATED WITH PET. K. F. Berman*, P.J. Schmidt, D.R. Rubinow, G. Esposito, J.D. Van Horn, J.L. Austin-Lane, M.A. Danaceau, D.R. Weinberger. NIMH/IRP, Clinical Brain Disorders Branch Unit on PET & Biological Psychiatry Branch, Section on Behavioral Endocrinology, Bethesda, MD 20892.

Using the oxygen-15 water PET rCBF method and a cognitive paradigm (the Wisconsin Card Sorting test [WCST] with a matched sensorimotor control task) that, under normal conditions, reliably activates a characteristic neural system including dorsolateral prefrontal cortex, inferior parietal lobule, and inferoposterior temporal lobe, we previously reported in young women that ovarian suppression induced by gonadotropin releasing hormone agonist (Lupron), resulted in marked attenuation of the characteristic pattern, with abolition of prefrontal activation. We further reported that this altered pattern normalized when either estrogen or progesterone was replaced.

With the same cognitive paradigm and the same PET methods, we have now extended this investigation to eight young men studied in a placebo-controlled, cross-over design during gonadal suppression with Lupron and during Lupron plus testosterone replacement. The activation map during treatment with Lupron plus placebo (i.e. in the virtual absence of testosterone) appeared less robust and less extensive than the activation map that resulted when testosterone was added to the regimen, particularly in prefrontal cortex. Direct statistical comparison between the Lupron/testosterone and the Lupron/placebo change maps reached statistical significance at the $p<0.0015$ level in several foci in the three areas important to the task - dorsolateral prefrontal cortex, inferior parietal lobule, and inferoposterior temporal lobe. This series of studies provides some of the first direct neurophysiological evidence in humans of hormonal modulation of regional neural activity in response to cognition. Further work will be necessary to delineate the exact mechanism underlying these findings and to determine whether they represent general phenomena or are specific to tasks like the WCST and the neural systems that subserve them.

PRACTICE RELATED PERFORMANCE CHANGES IN MOTOR LEARNING SHOW DIFFERENT TIME COURSES. H. van Mier*, J.S. Perlmutter, M.E. Raichle and S.E. Petersen. Washington University, School of Medicine, Box 8111, St. Louis, MO 63110.

In previous studies we used PET to measure changes in brain activity as an effect of motor learning. Normal right handed subjects moved a pen with their dominant right hand or non-dominant left hand continuously in a clockwise direction through a cut-out maze as quickly and accurately as possible with their eyes closed. Practice related changes in performance were observed, including increased velocity, a decrease in errors and a decrease in number and duration of stops. These behavioral changes were accompanied by changes in brain activation. Activation shifted from right premotor cortex, right parietal areas, and left cerebellum (mainly activated during initial unskilled performance) to activation of supplementary motor area (SMA), (primarily activated during skilled performance). These results raise questions about the relationship of different performance parameters both to each other and to the timing and order of functional anatomical changes.

Behavioral data of 8 right handed subjects who practiced the maze with their right hand during six separate sessions of 1 min, with intervals of 10 min, showed that above-mentioned parameters did not follow a linear time course. Furthermore, the shapes of the learning curves were different for the behavioral variables. The largest increase in velocity was observed on average between sessions 3 and 4, while the largest decrease in errors and stops was found between sessions 2 and 3. Although differences in learning curves between subjects were observed, in all subjects the decrease in errors preceded the increase in velocity. These findings suggest that specific behavioral measures might be used to parse neural substrates. A PET study in which changes in behavioral data will be directly related to changes in brain activations is in progress to test this hypothesis.

731.2

ACTIVATION OF HUMAN PRE-SMA IN EARLY ACQUISITION OF SEQUENTIAL MEMORY. K. Sakai, O. Hikosaka*, S. Miyauchi, R. Takino, Y. Sasaki, B. Pütz. Department of Physiology, Juntendo University School of Medicine and Communication Research Laboratory, Tokyo 113, Japan

The pre-SMA was identified recently as an area distinct from the SMA, and was shown to receive inputs from the prefrontal cortex and to send outputs to the SMA. It is thought that the prefrontal cortex is involved in working memory, and the SMA in sequential movements. Based on this assumption, we hypothesized that the pre-SMA may play a role in the acquisition of memory for sequential procedures. To test this hypothesis, we performed functional MRI experiments: a time series of 128 gradient-echo echo-planar images was acquired while subjects performed alternating series of test and control tasks. In both conditions, 10 consecutive pairs of targets were presented on the screen and the subjects pressed two corresponding buttons sequentially for each pair. In the test task, subjects had to find out the correct order of each pair by trial-and-error. Subjects became able to perform the whole sequential button presses without any error usually in the latter half of the experiments. In the control condition, button presses in any order were accepted. Activation areas were identified using the correlation of the MR signal time-course with an idealized reference function derived from task sequence. Consistent activation of the pre-SMA was demonstrated, and significantly higher correlation was always observed during the first half of the experiments, when subjects learned by trial-and-error. The test-control difference of the averaged signal intensity in the pre-SMA decreased gradually, and was correlated with the the number of errorneous button presses in the test condition. These results suggest that the pre-SMA plays a role in error correcting processes and early acquisition of memory for sequential procedures. A question still remains whether the pre-SMA is also activated in learning of non-sequential procedures.

EFFECTS OF SMA AND PRE-SMA INACTIVATION ON LEARNING OF SEQUENTIAL MOVEMENTS IN MONKEY. K. Miyashita*, K. Sakai, and O. Hikosaka Dept. of Physiology, Juntendo Univ. Sch. of Med, Tokyo, 113. Japan

To study the role of the supplementary motor area (SMA) and pre-SMA in procedural learning and memory, we injected muscimol (4µl x 5µg/µl) unilaterally into different parts of the SMA and pre-SMA (n=8 for each) of a Japanese monkey. Before the injections, the monkey was trained to perform a sequential button press task, '2x5 task'(*J. Neurophysiol.*74:1652-1661, 1995). On pressing a home key at his own pace, two of 16 (4 x 4) LED buttons (called 'set') were illuminated simultaneously. The monkey had to press them in a predetermined order which he had to find out by trial-and-error. A total of 5 sets ('hyperset') was presented in a fixed order for completion of a trial. A hyperset was repeated as a block of experiment until 10 successful trials were performed. 14hypersets were assigned to be 'learned hypersets' which had been learned daily and the animal could perform them with few errors. After each injection, the monkey performed the learned hypersets and newly generated hypersets using the hand contralateral and ipsilateral to the injection. We found two main effects. (1) By the injections into the pre-SMA, the number of errors increased significantly for new hypersets, but not for learned hypersets. In contrast, the SMA injections produced no significant effects on learning or memory for either new or learned hypersets. (2) Before muscimol injections, the monkey pressed the homekey at his own pace, usually *before* it turned on. Such self-paced initiation became much less frequent, and the effect was more severe after the SMA injections than the pre-SMA injections. These differences were clearer on the right side where neural activities showed clearer differences between the pre-SMA and SMA. These results suggest that the pre-SMA, rather than SMA, is important for learning of new sequences. Instead, SMA, rather than pre-SMA, is critical for internal initiation of action.

CONSOLIDATION IN HUMAN MOTOR LEARNING T Brashers-Krug*, R Shadmehr, and E Bizzi. Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139, and Dept. of Biomedical Engineering, Johns Hopkins Univ., Baltimore, MD 21205.

We have recently developed a psychophysical paradigm in which human subjects learn to make reaching movements in a haptic environment defined by a force field (Shadmehr and Mussa-Ivaldi, *J. Neurosci.* 1994). Here we present psychophysical evidence that learning this motor skill sets in motion neural processes that continue to evolve after practice has ended, a phenomenon known as consolidation. The consolidation of the motor skill was disrupted when subjects learned a second force field immediately after a first field was learned, but not if four hours elapsed between the first and second learning sessions. By training two further groups of subjects in the second motor task after breaks of either 5 minutes or 1 hour, we found that motor skill consolidated gradually over this four-hour period. Previous studies in humans and other primates have found this time-dependent disruption of consolidation only in explicit memory tasks, which rely on structures in the medial temporal lobe (MTL). Our results indicate that motor memories, which do not depend on the MTL, can be transformed by a similar process of consolidation. To our knowledge, this is the first evidence that human motor memory (a type of implicit memory) is rapidly transformed with the passage of time, and in the absence of further practice, from a fragile state to a more solid state. By demonstrating a common principle in declarative and procedural learning tasks, our results suggest the possibility that two distinct systems may have common mechanisms of encoding and storing new experiences. A FUNCTIONAL MRI (fMRI) STUDY OF WORKING MEMORY CENTRAL EXECUTIVE. J.A.L. Smith*, B. Rypma, V. Prabhakaran, J. Desmond, G. H. Glover, and J. D. E. Gabrieli. Depts. of Psychology, Neuroscience, and Radiology, Stanford University, Stanford, CA 94305.

Prior studies have demonstrated activation in left prefontal and posterior parietal areas during verbal working memory tasks. Whereas many of these tasks require that the subject remember varying amounts of information, they generally do not require manipulation of the information and thus may minimally engage working memory central executive. The present study was designed to assess differences in activation associated with manipulation of the information compared to memory of the information alone. The present study utilized variants of the Sternberg working memory task (Sternberg, Science, 153:652, 1966) which required either storage or storage and manipulation of information. In all conditions six letters were presented for 2 seconds followed by a 5 second delay. Subsequently, a probe letter and five place-holders appeared on the screen at which point subjects were required to respond. In the memory task, requirements alternated between remembering one or remembering all six letters. This task employs mainly storage components and thus may minimally engage working memory central executive. In the manipulation task, requirements alternated between remembering the six letters as before, or remembering the six letters and arranging them in alphabetical order during the 5-second delay. This latter condition employs both storage and manipulation components and thus may more fully engage working memory central executive. Brain images were collected in 8 oblique axial planes parallel to the AC-PC line. FMRI was obtained with T2*-weighted gradient echo spiral pulse sequence (1.5T, TR = 720 ms, TE = 40, flip angle = 65 degrees, inter-slice spacing = 1.5 mm, thickness = 6 mm). Preliminary results indicate activation in left prefrontal, premotor, cingulate and insular cortex in the memory condition. These areas have been found to be activated in other, similar studies. In the transformation condition, individual differences were more pronounced and activation was more anterior and bilateral. This research was supported by NSF and NIA grants.

This report is the Wisconsin component of a multi-site consortium examining with functional magnetic resonance imaging (fMRI) the network of cortical activity that supports the execution of a spatial working memory task. We report on regions of cortical activation in a normal right-handed human sample (N = 6) performing a spatial working memory task using echo-planar fMRI.

Whole-brain imaging was acquired while subjects engaged in alternating blocks of dominant-hand button presses corresponding to the current location of the visual presentation of an "X" in one of four positions (motor task) and button presses corresponding to the location of an "X" two positions prior (memory task).

Regions of significant *positive* task-correlated activation were found asymmetrically in right DLPFC and in left supplementary motor cortex (BA 6), and bilaterally in posterior parietal cortex (BA 7). This pattern of activation is interpreted as supporting the working memory, motor planning and visual-spatial integration components necessary to perform the memory task, respectively. In addition, regions of significant *negative* task-correlated activation were found bilaterally in medial prefrontal cortex (BA 10) and posterior cingulate gyrus (BA 30). We discuss the significance of these positive and negative correlations.

Remembering False Events Rather Than True Events Produces Dynamic Changes In Underlying Neural Circuitry: A fMRI Study

M.B. Miller[1], M. Buonocore[4], C.M. Wessinger[2], E. Tulving[2]
L.C. Robertson[2,3]*, and M.S. Gazzaniga[1]
[1]Program in Cognitive Neuroscience, Dartmouth College; [2]Center for Neuroscience, [3]Veterans Administration, [4]Dept. of Radiology, University of California, Davis;

Memory distortions, illusory memories, and false memories have been extensively discussed, but little is known about the underlying brain mechanisms. In this study using the behavioral paradigm described by Roediger and McDermott (1995), we explored brain areas that have correlated activation during the retrieval of false memories versus the retrieval of veridical memories using functional magnetic resonance imaging (fMRI). Before scanning, subjects heard lists of words (i.e., bed, awake, rest) that were close associates of a *critical lure*, a word not presented (i.e., sleep). During the functional scanning, a recognition test was presented auditorily with the studied items (A block) versus critical lures (B block) in the first scan, and studied items (A block) versus nonstudied items semantically unrelated to the lists (C block) in the second scan. We hypothesized that the dorsolateral prefrontal cortex would have more correlated activation during the retrieval of critical lures relative to the retrieval of studied items. The retrieval of false memories and the retrieval of true memories seem to be composed of the same cognitive processes. However, false memories apparently require more effort for some of these processes including over-reliance on semantic retrieval (Metcalfe, Funnell, & Gazzaniga, 1995) and repeated episodic retrieval attempts (Roediger & McDermott, 1995). In our study, preliminary results show correlated activation for the retrieval of false memories bilaterally in the dorsolateral prefrontal cortex relative to the retrieval of true memories. Therefore, it would seem that the correlated activation due to remembering false events relative to true events reflects a change in the dynamics of shared neuronal circuitry. Supported by NIMH/NINDS and the McDonnell-Pew Foundation.

PREFRONTAL ACTIVATION IN VERBAL WORKING MEMORY, M.P. McAndrews*, K. Velanova, D.J. Mikulis. Depts. of Psychology and Neuroradiology, The Toronto Hospital, Toronto, Canada M5T 2S8.

Recent functional neuroimaging studies have demonstrated prefrontal cortical activation during working memory tasks. In one task variant, subjects identify the occurrence of a target from a restricted set of items that are presented many times throughout the procedure. In such cases, activation may reflect a number of processes, including the temporary storage of information in memory, recognition decision processes, suppression of responses to repeated lures, and recency discrimination.

We investigated some of these aspects by comparing two verbal working memory tasks (Item Recognition and Recency Decision) in a continuous decision paradigm in which lures were not repeated. Both were compared with a control task (Detection) that required decisions about physical features of words. Eight subjects underwent fMRI scanning [TR=68ms, TE=46ms, FOV=48mm, matrix 256x128] during the performance of each task. A single 7mm axial slice, oriented along the AP-CP line and centred 3-7mm below the superior margin of the corpus collosum, was obtained.

Significant activation (1-3% increase in signal intensity) was found in the middle and superior frontal gyri (46 and 9) for both the Recency and Recognition tasks compared to the Detection control. The Recency task was associated with more reliable activation in these areas, as was also demonstrated by direct comparison of these conditions. These findings are compatible with previous functional imaging studies on working memory and with other research demonstrating the involvement of dorsolateral prefrontal cortex in memory for temporal order. An unexpected finding was a highly reliable deactivation in the cingulate (24 and 32) for the Recency task in comparison with both other conditions. Although this finding has not been reported in previous functional working memory studies, it may have particular relevance to a direct requirement for temporal order processing and we plan to explore this hypothesis in future work.

This study was funded by the Dept. of Medical Imaging, University of Toronto.

ERPs REFLECT AN INTEGRATED MECHANISM FOR WORKING MEMORY X.L. Zhang, H. Begleiter, and B. Porjesz, R. Cracco* Neurodynamics Lab., SUNY HSCB, Brooklyn, NY 11203

The study of working memory often utilizes a delayed matching to sample paradigm (DMS). Typically in the matching conditions, the test and sample stimuli are identical, raising the possible confound of retinotopic projections for the matching stimuli in contrast to the nonmatching stimuli.

In the current ERP experiment, 65 healthy subjects performed a modified delayed matching to sample task. The stimuli consisted of 60 different sample stimuli (S1) and 60 different test stimuli (S2). Half of the test stimuli were complementary to the sample stimuli (FIT), the other half of the S1 were not complementary (NOFIT). After seeing S2, the subjects had to press one of the buttons to indicate whether or not the test stimulus fit the sample stimulus.

Four principal components and scores were extracted from a PCA with varimax rotation accounting for 80.6% of the variance. Our statistical results indicate that ERPs to sample stimuli differ from ERPs to test stimuli from 150 ms to 780 ms post-stimulus. The ERPs to fitting stimuli were significantly distinguishable from those to nonfitting stimuli from 210 ms to 410 ms poststimulus. These differences in S2 are obtained in the temporal region and the right frontal region.

Our results rule out the retinotopic confound as a potential mediator variable in DMS paradigms, and are in agreement with other neurophysiological studies on memory.

CONTRIBUTION OF STRATEGIC PROCESSES TO SOURCE MEMORY TESTS IN HEALTHY YOUNG SUBJECTS AND PATIENTS WITH FRONTAL LOBE LESIONS. S. L. Reminger, L. A. Monti*, J. D. E. Gabrieli, G. T. Stebbins, B. Mansson, and C. Verees. Dept of Neuro. Sci., Rush Medical College, Chicago, IL 60612, Dept. of Psych., Stanford University, Stanford, CA 94305, and Dept. of Psych., University of Arizona, Tucson, AZ 85716.

Memory for source information of auditory, verbal stimuli has long been regarded as a task mediated primarily by the frontal lobes. Yet, the nature of the strategic processes involved in the higher-order memory task have not been well-defined by the localization literature. In this study, 24 healthy young subjects, and two patients with frontal lesions resulting from anterior communicating artery aneurysms, performed a series of strategic and nonstrategic memory tasks. Strategic tasks included memory for source, listening span and alpha span. Nonstrategic memory tasks included recognition memory for orally presented sentences, and recognition memory for visually presented words. For the healthy young subjects, significant correlations were found between the three strategic memory tasks, and between the nonstrategic tasks, but not across strategic and nonstrategic tasks. These results suggest that memory for source is more strongly mediated by strategic processing than by nonstrategic declarative memory. The frontal lobe patients demonstrated performance that was consistent with this hypothesis. Specifically, they showed impaired performance on the source task, but within-normal performance on the sentence-recognition task. Supported by Alzheimer's Association #IIRG-94-059.

731.11

DIFFERENTIAL EFFECTS OF FRONTAL AND POSTERIOR CORTEX LESIONS ON MEMORY. I. Daum* and A.R. Mayes. Institute of Medical Psychology and Behavioral Neurobiology, University of Tübingen, Germany and University of Sheffield, UK

The present study aimed to investigate whether the memory deficits that are typically associated with the frontal lobes are selective results of frontal cortex damage. Ten patients with frontal lesions (FL) were compared with ten patients with posterior cortex lesions (PL) and ten matched normal control subjects (NC) on a range of memory tasks including verbal and visual free recall and recognition, temporal order memory, memory for spatial locations and prospective memory.

Both patient groups performed significantly more poorly than the NC subjects on verbal and visual free recall, on memory for temporal order and on measures of prospective memory. However, the FL group but not the PL patients showed increased false alarm rates during recognition and an increased number of "confabulatory" responses during all recall tasks, as well as a significant spatial memory deficit. These scores correlated with performance on the Cognitive Estimates Test and on tests of verbal fluency. The results indicate selective effects of frontal lesions which may relate to an impairment in the accurate evaluation of retrieved information.

COGNITIVE STRATEGIES IN PATIENTS WITH FRONTAL LOBE EXCISIONS AND PATIENTS WITH PARKINSON'S DISEASE JL. Iddon*, AM Owen, BJ Sahakian, C Polkey, JR Hodges, B Summers & TW Robbins. *Dept. Exp. Psychology, Univ. of Cambridge, Downing Street, Cambridge, CB2 3EB, UK;

Some of our previous work has suggested that patients with frontal lobe excisions are impaired at generating efficient strategies to complete cognitive tasks. In the present study, a new task was used to test this more explicitly. Spatial strategy learning was assessed in patients with frontal excisions, patients with Parkinson's disease (PD), grouped according to age and medication status, and age and IQ matched normal controls (NC).

The spatial strategy task, which was given to 126 subjects, required the self-generation of an efficient strategy and its implementation. The task was divided into three parts. In part 1 subjects were required to generate as many different four-box sequences as they could from an array of 4 touch sensitive squares (max = 24). Feedback information was given after each sequence. In part 2 subjects were trained to implement the most effective strategy to complete the task, although not explicitly told what this was. In part 3, which was a repeat of part 1, subjects were asked to try to improve on their part 1 score.

Impairments in strategy generation were observed in frontal lobe patients, in PD patients in all age groups and in NC over the age of 55. In addition the frontal lobe group were unique in showing significantly more perseveration throughout the task. These results will be discussed in terms of (i) specific functions of the frontal lobe (ii) the fronto-striatal pathology associated with Parkinson's disease (iii) cognitive flexibility in normal ageing. A number of variations on this task were also carried out and will be presented.

This work was supported by a Programme Grant from the Wellcome Trust.

PRISM ADAPTATION IS NORMAL IN PARKINSON'S DISEASE
M. Mapstone*[1], S. Corkin[1], R.L. Savoy[3], J.J. Locascio[1,2], and J.H.Growdon[1,2]. [1]Department of Brain and Cognitive Sciences and the Clinical Research Center, Massachusetts Institute of Technology, Cambridge, MA 02139; [2]Department of Neurology, Massachusetts General Hospital, Boston, MA 02114; and [3]the Rowland Institute, Cambridge, MA 02139

In order to examine the generality of our finding that subjects with Parkinson's disease (PD) are impaired on a test of sensorimotor rearrangement (mirror tracing), we tested PD subjects on their ability to adapt to prisms that displaced visual images laterally, a task that, like mirror tracing required compensation for changes in visual and proprioceptive input. An early study of prism adaptation in nonhuman primates had found that lesions of the caudate nuclei prevented adaptation to prisms [Bossom, 1965]. The results of studies in humans with PD have been conflicting [Weiner et al., 1983; Stern et al., 1988]. We tested 15 subjects with idiopathic PD and 15 age-matched normal control subjects (NCS) on their ability to adapt to 20 diopter wedge prisms [Paulsen et al., 1993]. Subjects pointed to a vertical line at each of 9 target locations in baseline, exposure, and postexposure conditions, and we recorded the position of the finger after each response. Subjects viewed their hand only in the exposure condition. The measure of adaptation to the prisms was the magnitude of negative aftereffect in the postexposure condition. The groups did not differ significantly in baseline pointing accuracy, and, as expected, both groups showed substantial lateral error in their pointing immediately upon exposure to the prisms. In the postexposure condition, both groups showed a substantial negative aftereffect compared to baseline ($p < .05$), indicating adaptation to the prisms. We found no main effect of subject group and no interactions. These results suggest that PD subjects are able to learn new mappings between visual and proprioceptive spatial dimensions, and that prism adaptation in humans does not depend heavily on basal ganglia function. Studies using subjects with cerebellar lesions indicate that the cerebellum is a more likely neural substrate for prism adaptation [Baizer et al., 1974; Thach et al., 1992; Weiner et al., 1983].

SELECTIVE RETROGRADE AND SELECTIVE ANTEROGRADE AMNESIA WITHOUT OBVIOUS BRAIN DAMAGE - PSYCHOGENIC CAUSES?
H. J. Markowitsch[1], G. F. Fink[2,3], J. Kessler[2], M. Reinkemeier[1], A. I. T. Thöne[1], G.Weber-Luxenburger[2], E. Kalbe[2] and W.-D. Heiss[2,3] (SPON: European Neuroscience Association). [1]Physiological Psychology, University of Bielefeld, [2]Max-Planck-Institute of neurological Research, Cologne, [3]University Clinic of Neurology, Cologne, Germany.

It is well-known that focal bilateral brain damage in limbic-system related bottleneck structures may lead to persistent and severe amnesia in both anterograde and retrograde directions. More recently, cases of focally brain-damaged patients with quite selective memory loss in the retrograde domain have been described. Furthermore, psychogenic retrograde amnesia for autobiographical information with a usually transient character has been found. We here present two cases of probable psychogenic amnesia, one with persistent amnesia confined to the retrograde autobiographical domain, and one with selective, but severe and persistent anterograde amnesia. Both patients had been studied carefully and extensively neurologically, neuroradiologically - including MRI and PET - and neuropsychologically. Both of them did not recover from their amnesia during eight months. Based on neuropsychological test outcomes, evidence for faking seems unlikely. The retrogradely amnesic case provided evidence for altered brain functions when studied with ^{15}O-PET for autobiographical memory ecphory. The brain of the anterogradely amnesic patient had been studied with FDG-PET and did not differ in brain glucose metabolism from those of age-matched control subjects. It is concluded that anterograde and retrograde amnesic states are anatomically and functionally separable and that even persistent amnesic states may occur without obvious brain damage, but probably on the basis of altered brain functions - such as a block of access or a failure of synchrony within anatomical networks necessary for successful encoding, consolidation, and retrieval.

PET STUDIES OF SOURCE MEMORY: ENCODING.
W.M. Kelley*, R.L. Buckner, F.M. Miezin, M.E. Raichle, and S.E. Petersen. Washington Univ. Sch. of Med., Box 8111 St. Louis, MO 63110.

Previous neuroimaging studies have identified brain areas involved in episodic memory encoding and retrieval. This and the next abstract report investigations of a specific kind of episodic memory, that of source memory. This study attempted to identify brain regions that are active during the encoding of source information.

Two different encoding tasks (VISUAL ENCODING and AUDITORY ENCODING) were used to explore activations that were common across tasks as well as activations that were selective for modality specific encoding. During the VISUAL ENCODING scan, subjects passively viewed line drawn and grayscale pictures and were told that they would have to recall information about each picture and its appearance on a later memory test. In the AUDITORY ENCODING scan, subjects passively listened to names of objects that were spoken by either a female or male voice and were told to encode each word and how it sounded for a subsequent memory test. Both conditions were compared to a simple fixation control.

As expected, VISUAL ENCODING revealed multiple bilateral activations in primary and extrastriate visual cortex. Similarly, AUDITORY ENCODING revealed activations bilaterally in primary auditory cortex and auditory association cortex. In both conditions, an activation near the border of left area 6/44 (-41,7,28) was observed. Similar area 6/44 activity has been seen previously in tasks with strong encoding demands, but this activity has often been attributed to response demands. In the present study, no response demands were made to stimuli in either encoding condition.

PET STUDIES OF SOURCE MEMORY: RETRIEVAL.
S.E. Petersen*, W.M. Kelley, R.L. Buckner, F.M. Miezin, and M.E. Raichle. Washington Univ. Sch. of Med., Box 8111 St. Louis, MO 63110.

The preceding abstract identified brain areas that were active during the encoding of source memory. This abstract investigates brain areas involved in the retrieval of source memory. The same subjects described previously were also scanned on two retrieval tasks (VISUAL and AUDITORY RETRIEVAL). In the VISUAL RETRIEVAL task, the names of previously presented pictures were presented visually, and subjects indicated (by a right-handed key press) whether the item was presented as a line drawn or grayscale picture. In the AUDITORY RETRIEVAL task, previously spoken words were presented visually, and subjects indicated (by a keypress) whether the word was spoken by a female or male voice. In both tasks, subjects were encouraged to use recollection of the study episode to make decisions and were successful in classifying these items.

Consistent with previous studies of episodic memory retrieval, both source memory retrieval conditions, when compared to a FIXATION task, revealed activations in anterior prefrontal cortex, bilateral frontal operculum, and anterior cingulate. Additional activations were observed at or near left primary motor cortex, left and right thalamus, several parietal regions, area 9, area 11, and left premotor cortex. This left premotor activation was superior and lateral to the area 6/44 activation observed in the preceding abstract. A direct comparison of VISUAL RETRIEVAL versus AUDITORY RETRIEVAL revealed several areas (areas 19, 37, 11, 11/47, and left posterior parietal) that were selectively active during VISUAL RETRIEVAL that may be preferentially involved in the retrieval of visual information.

NEUROANATOMICAL CORRELATES OF ROUTE LEARNING.
J. Barrash*, H. Damasio & D. Tranel. Division of Cognitive Neuroscience, Dept. of Neurology, University of Iowa College of Medicine, Iowa City, IA 52242.

The neuroanatomical correlates of route learning (RL) were investigated in 96 subjects with focal brain lesions. Based on previous studies of environmental agnosia and our own preliminary findings, we predicted RL would be impaired by lesions in inferior mesial occipital, occipitotemporal, and mesial temporal regions on either the right or the left; and in right inferotemporal and inferior parietal regions. Fifty-five target subjects had lesions in the areas specified above; 41 brain-damaged controls (*BDCs*) had lesions outside the target regions. Targets and BDCs did not differ in gender composition, age, education, or time since lesion onset. No subjects had primary visual defects, recognition defects for objects at the basic object level, severe amnesia, or severe aphasia. Subjects' learning of a standardized real life route was characterized as normal, mildly defective or moderately to severely defective (*msD*) based on age-related norms. RL was defective in 72.7% of the targets (50.9%, msD) and 24.4% of the BDCs (12.2%, msD), $X^2 = 22.9$, $p < .0001$. The target region least consistently associated with defective performance was the right inferior parietal lobule (60%). It is well known that the inferior mesial occipital, occipitotemporal, and inferotemporal regions are critical for form-based visual recognition. The finding that they are important to RL suggests that the ability to learn landmarks is central to RL. The less impressive association of the right inferior parietal lobule to RL suggests that visuospatial processing may not be necessary for RL. These conclusions are supported by a previous study showing that the cognitive ability most highly predictive of RL is the ability to learn and recognize scenes (Barrash et al., 1996). FUNCTIONAL INTERACTIONS BETWEEN HUMAN HIPPOCAMPUS AND VISUAL CORTICES RELATED TO LONG-TERM MEMORY FOR SPATIAL LOCATION AND OBJECT IDENTITY. S. Köhler*, A.R. McIntosh, M. Moscovitch, G. Winocur, and S. Houle. Rotman Research Institute of Baycrest Centre; Clarke Institute of Psychiatry; University of Toronto; Toronto, ON, Canada M6A 2E1

A network analysis was performed on rCBF data from a PET study that examined human visual long-term memory (LTM) for spatial location and object identity. PET data were obtained while subjects engaged in four different tasks: retrieval of spatial location (1) or object identity (2) from LTM, and perceptual matching based on spatial location (3) or object identity (4). Brain regions that were selected for the network analysis included areas in prefrontal cortex, ventral visual cortex (fusiform gyrus), dorsal visual cortex (precuneus, supramarginal gyrus), lateral temporal cortex, and the hippocampus. Correlations of rCBF between these regions were analyzed with structural equation modeling taking into account connections between regions according to primate neuroanatomy. Although the right hippocampus showed no differences in mean rCBF across tasks, its interactions with other brain regions differed across tasks. The functional network for the right hemisphere showed that the hippocampus was positively influenced by dorsal visual cortex regions during retrieval of spatial location but negatively influenced by the same regions during retrieval of object identity. Conversely, the hippocampus was positively influenced by the ventral visual cortex region during retrieval of object identity but negatively influenced by this region during retrieval of spatial location. These differential interactions between visual cortex regions and the hippocampus were observed in the right hemisphere only. They were specific to memory processing in that they were seen during retrieval but not during perceptual matching of spatial location and object identity. The results are consistent with the view that the hippocampus is involved in LTM recovery of information that is represented in domain-specific neocortical storage sites. Supported by an MRC grant to M.M. and G.W.

BRAIN REGIONS ASSOCIATED WITH ENCODING OF NOVEL INFORMATION: A POSITRON EMISSION TOMOGRAPHY STUDY. R. Habib*, M. Wheeler, R. Cabeza, S. Houle, and E. Tulving. Rotman Research Institute of Baycrest Centre, University of Toronto.

We measured regional cerebral blood flow (rCBF) in young healthy subjects during encoding of common words that were either (i) novel, not seen or heard in the experiment, or (ii) familiar, seen or heard before scanning in the experiment. At the time of scanning, subjects made either semantic or orthographic decisions about auditorily and visually presented words which were either novel or familiar. Consistent with previous work, semantic encoding decisions were associated with rCBF increases in left prefrontal, anterior cingulate, and right cerebellum. Brain regions associated with orthographic decisions included the posterior cingulate, precuneus, and right temporal regions. During the encoding of novel words there was increased rCBF in bilateral frontal areas and right thalamus regardless of encoding task or presentation modality. For auditory presentation only, significant novelty-related activations were also observed in the right hippocampus. The right extrastriate cortex was more activated during encoding of familiar words than novel words. Replicating and extending the results of studies concerned with novelty during retrieval (Tulving et al., 1994, Neuroreport, 5, 2525-2528), encoding of novel information was associated with a network of regions comprising frontal, thalamic, and hippocampal areas.

This study was supported by funding from NSERC as well as an endowment from Anne and Max Tanenbaum to E. Tulving.

NEUROPSYCHOLOGICAL TEST PERFORMANCE OF PATIENTS WITH BILATERAL MEDIAL TEMPORAL LOBE DAMAGE INCLUDING AMYGDALA IS COMPARABLE TO THAT OF CONTROL PATIENTS. M. Papka* & M. Berg. Dept. of Neurology, U. of Rochester Med. Ctr., Rochester, NY 14642.

Although the amygdala was once thought to be part of the medial temporal lobe (MTL) memory system, recent evidence suggests that memory impairments are not more severe when MTL damage includes the amygdala. We compared neuropsychological test performance of 3 remarkable patients with bilateral hippocampal and amygdalar damage to that of 3 patients with bilateral hippocampal damage and normal amygdalae. The brain regions affected were documented with high resolution MRI. Patient groups were similar in age (range = 30-45 yrs, M = 37) and education level (M = 12.7 yrs). Pilot testing including standardized tests of motor, visuospatial, language, memory, and executive functions revealed comparable performance across patient groups for all domains. All subjects exhibited moderate impairments in memory and confrontation naming, and mild deficits on measures of executive functioning. Memory impairment was more severe at longer delays. Full-scale IQ was comparable across groups and in the low-normal range (M = 90). These results are consistent with previous reports of selective memory impairment in patients with bilateral MTL damage. These findings further suggest that the amygdala is not a critical substrate of the medial temporal lobe memory system. We continue to explore the specific role of the amygdala in cognitive functioning with ongoing experimental testing of these patients. *Supported by NIA grant AG00107 awarded to P. Coleman; Neurobiology and Anatomy.*

NEURONAL ACTIVITY IN THE HUMAN HIPPOCAMUS DURING DELAYED NON-MATCH TO SAMPLE PERFORMANCE K.A. MacDonald*, I. Fried, C.L.Wilson. Division of Neurosurgery, Departments of Neurology and Psychiatry & Biobehavioral Sciences, UCLA School of Medicine, Los Angeles CA 90095

The hippocampus and its associated structures have long been implicated in human memory function. Primate and rat models of amnesia with lesions of these areas have shown behavioral deficits on delayed non-match to sample (DNMS) tasks. Here we report on neuronal activity in hippocampal and associated areas during DNMS tasks in awake human subjects. Bilateral electrode implantation in 10 patients with intractable epilepsy undergoing intracranial electrophysiologic monitoring to identify a resectable seizure focus yielded extracellular recordings of single unit activity in the amygdala (13), hippocampus (46), and entorhinal cortex and parahippocampal gyrus (29). Magnetic resonance imaging and angiographic stereotaxic techniques were used to place electrodes. Patients were shown a stimulus to be remembered (S), then after a 12-14 second delay containing two distractor stimuli they were given a choice between 2 stimuli, one identical to S and the other a novel non-match stimulus, and required to choose the latter. The activity of 88 units during DNMS tasks revealed neurons which responded preferentially to practically every task phase, including during stimulus and choice presentations as well as the delay. Neurons with preferential responses to particular stimuli such as words or faces were also found. These results suggest stimulus and task-phase specificity of neuronal activity in human hippocampal and associated areas during performance of memory tasks.

DOES INCREASING DELAY INTERVAL OF RECOGNITION MEMORY TASKS INVOKE STRATEGIC MEMORY PROCESSES: A STUDY OF PATIENTS WITH PARKINSON' S DISEASE. G.T. Stebbins*, J.D.E. Gabrieli, F. Masciari, L. Monti, S. Reminger. Dept. of Neuro. Sci., Rush Medical College, Chicago, IL 60612, and Dept. of Psych., Stanford University, Stanford, CA 94305, Dept. of Psych., University of Arizona, Tucson, AZ 85716.

Patients with Parkinson's disease (PD) are impaired on tests of strategic memory (SM) (free and cued recall, self ordered pointing, temporal ordering), but relatively intact on tests of nonstrategic declarative recognition memory (DM). This pattern of performance appears to be caused by a disruption of a fronto-striatal system in PD which supports working memory and processing, two mechanisms which underlie SM, and a sparing of a temporal-diencephalic system which is sufficient for DM. The dissociation between SM and DM is not at the task level per se, but rather is based on the demands a given task places upon SM processes. One way to increase SM demands of a recognition memory test might be to increase the delay between study and recognition, which was the purpose of this study. Seven mild PD patients and 12 age- and education-matched controls (PDNC) were administered a test of processing speed, SM tests (free and cued recall, self-ordered pointing, and temporal ordering), and immediate and delayed (1/2 hr.) recognition tests. PD patients were impaired on all SM tests and on the delayed recognition test. PD patients were not impaired on the immediate recognition memory test. When processing speed was introduced as a covariate, group differences between PD and PDNC on SM tasks and delayed recognition were eliminated. These results suggest that the introduction of a delay between study and recognition increases the role of SM processes. Supported by ONR # N00014-J-184.

HIPPOCAMPAL BUT NOT CORTICAL VOLUMES DISTINGUISH AMNESIC AND NONAMNESIC ALCOHOLICS. E.V. Sullivan*, L. Marsh, P.K. Shear, K.O. Lim, A. Pfefferbaum. Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine and Psychiatry Service, and Palo Alto VA Health Care System Center, Palo Alto, CA 94304.

Diencephalic and thalamic pathology is implicated in alcoholic Korsakoff's Syndrome (KS). However, the relevance of limbic and cortical abnormalities to the amnesia of KS is not fully established, even though both brain regions show structural volume loss in nonamnesic chronic alcoholics (ALC). To examine this issue, regional cortical and ventricular volumes were measured on axial spin-echo MRI in 9 KS, 18 ALC, and 26 age-range matched normal controls (NC) (50 to 71 years); hippocampal and temporal horn volumes were derived from coronal images, available for 5 KS, 11 ALC, and 25 NC. MRI measures were corrected for normal variation due to intracranial volume and age, based on a larger group of 73 controls, 21 to 70 years old. The groups did not differ significantly in premorbid intelligence, estimated by the NART IQ. The KS demonstrated dense amnesia; the IQ-General Memory Index difference of the KS was 42.8±13.8, whereas the comparable difference in the ALC was -2.6±13.6 and in the NC was -5.9±11.7. Relative to the NC, the KS and ALC had significantly and comparably smaller gray matter volumes in all 6 cortical regions measured; the white matter volume deficit was confined to the prefrontal region. Similarly, the two alcoholic groups had abnormally larger volumes of the third ventricle and cortical sulci, except the frontal-temporal sulci. Both ALC and KS had significantly larger lateral ventricles and temporal horns and smaller anterior hippocampi than NC, and these structures were even more abnormal (by at least 1 SD) in KS relative to ALC . Together with our previous observation that amnesic and nonamnesic alcoholics share a similar degree of mammillary body shrinkage, these results suggest that extensive hippocampal volume deficits may contribute to alcohol-related amnesia. *Supported by AA05965, AA10723, MH30854*

LOCALIZED HIPPOCAMPAL DAMAGE IMPAIRS ACQUISITION, BUT NOT REVERSAL, OF A SPATIAL DISCRIMINATION IN HUMANS. C. Myers*[1], M. Hopkins[2], R. Kesner[3], B. Ermita[1], & M. Gluck[1]. [1]Center for Molec. & Behav. Neurosci., Rutgers Univ., Newark NJ 07102; [2]Dept. of Hyperbaric Med., LDS Hosp., Salt Lake City UT 84143; [3]Dept. of Psych., Univ. of Utah, Salt Lake City, UT 84112

Subjects with hypoxic brain injury show significant cell loss in the hippocampus, but generally not in the parahippocampal gyrus nor temporal lobes. Such relatively localized hippocampal damage can be compared to populations with broader medial temporal damage, to investigate the specific contributions of the hippocampus in learning and memory. Here, a computer-based task, adapted from Daum et al. (*Cortex*, 1991), was used to study acquisition and serial reversal of a left-right discrimination in 12 hypoxic patients and 12 matched controls. The hypoxics showed a strong impairment at acquisition of the original discrimination, but no impairment at 3 successive reversals of this discrimination. In combination with the Daum et al. (1991) data, which show that broad right but not left medial temporal lesions also disrupted acquisition, these results suggest that the right hippocampus itself selectively mediates this learning. Additionally, the hypoxics in the current study showed a different pattern of reversal errors than the matched controls, tending to perseverate significantly before changing strategy; this occurred in the absence of any frontal damage or frontal syndrome. These results suggest that although the hypoxics learn the reversals as quickly as controls, they may be using different strategies to do so.

ODOR LEARNING AND MEMORY IN PATIENTS WITH EXCISION FROM RIGHT OR LEFT TEMPORAL LOBE STRUCTURES. L.A. Dade* and M. Jones-Gotman. Montreal Neurological Institute, Montreal, Quebec, Canada, H3A 2B4.

We studied odor learning and memory in epileptic patients with surgical excision from left or right temporal lobe. Recognition memory was tested after the first exposure, again after the 4th trial, and after 24 hours. To construct the memory test, 4 stimuli were taken from each of 12 categories (e.g., fruity, woody), and the odors were tested for discriminability from one another. Those best discriminated were chosen as targets, with the remaining 3 used as foils for the three recognition trials. This was expected to decrease the effectiveness of using a verbal (category) label to assist in recognition.

Healthy Ss achieved a mean score of 80% correct after a single exposure, and improved to 92% after four trials; some forgetting occurred over the delay interval (82% recognition). Contrary to expectation, both left and right temporal-lobe lesion groups were deficient compared to the control Ss after a single exposure, and although they showed learning over the 4 trials, they did not attain the level of the control Ss. Forgetting was also observed over the 24-hr delay interval in both patient groups.

This study was supported by the Medical Research Council of Canada, FCAR and the donation of stimuli from Givaudan-Roure.

FACIAL AFFECT PROCESSING ABILITIES FOLLOWING UNILATERAL TEMPORAL LOBECTOMY. A. K. Anderson, K. S. LaBar* and E. A. Phelps. Department of Psychology, Yale University, New Haven, CT 06520.

There is neuropsychological evidence to suggest that recognition of facial identity and facial affect are behaviorally dissociable (e.g., Young et al., 1993). Recent studies have revealed bilateral damage of the amygdala results in a narrow impairment of facial affect processing, selective for fearful faces. (Adolphs, et al., 1994; Young, et al., 1995; but see Hamann et al., 1996). In addition, a considerable amount of research has revealed a more general right hemisphere (RH) dominance for emotional face processing (see Etcoff, 1989).

In order to more closely examine the relationship between RH dominance and amygdala contributions to emotional processing, the present study investigated facial affect identification abilities of patients with unilateral temporal lobe resections for intractable epilepsy, which included damage to 70-80% of the amygdala. Although these patients are known to have spared visual perceptual functions, the present experiment suggests that patients with right temporal lobe excisions show an impaired ability to process facial affect, as indexed by identification performance using the Ekman and Friesen (1975) pictures of facial affect. Further, different patterns of emotion-specific performance are found in unilateral temporal lobectomy patients with right vs. left damage and age matched controls. These results are in contrast with a recent study of Adolphs et al. (1995), that did not reveal such an impairment following unilateral temporal lobe damage.

DISTRACTION DISRUPTS DISCRIMINATION AND REVERSAL OF EYEBLINK CONDITIONING IN HUMANS. M.C. Carrillo[1]*, J.D.E. Gabrieli[2], & J.F. Disterhoft[1]. [1]Dept. of Cell & Molecular Biology, Northwestern University Med. Sch, Chicago, IL. 60611; [2]Dept. of Psychology, Stanford University, Stanford, CA, 94305.

Eyeblink conditioning is an associative task presumed by many to occur in an unconscious manner, that has been extensively studied in both humans and animals. A distraction typically used in human eyeblink conditioning is a silent movie that does not disrupt acquisition and alleviates boredom. More complex forms of eyeblink conditioning such as trace and reversal have been shown to be hippocampally dependent in animals and humans. The goal of this study was to examine three levels of distraction in 600-ms delay, 500-ms trace, and discrimination-reversal paradigms to evaluate the contribution of attention to eyeblink conditioning. The distraction groups included a no-distraction control, a silent movie group, and a verbal shadowing task group in which participants repeated simultaneously a story read to them.

Delay eyeblink conditioning involved the presentation of an 85 db, 700-ms 1 kHz tone that coterminated with a 100-ms, 3 psi corneal airpuff to the right eye (n=27, M age=27.3). Trace eyeblink conditioning involved the presentation of an 85 db, 100-ms, 1 kHz tone, followed after a 500-ms silent trace interval by a 100 ms, 3 psi corneal airpuff to the right eye (n=33, M age=27.6). Sessions consisted of 60 paired tone-puff conditioning trials and 30 tone-alone extinction trials. Discrimination-reversal was a delay conditioning task involving the presentation of 1 and 5 kHz tones, in 60 discrimination conditioning trials (30 CS+, 30CS–), and 60 reversal conditioning trials in which the significance of the tones was reversed (n=48, M age=29.3).

No difference was observed in the delay or trace paradigms across all distraction groups. Discrimination and reversal were successfully acquired in the no-distraction control (C) group, but were disrupted in the silent movie (MV) and verbal shadowing (VS) groups (p<.001) (See Table). These data suggest that more complex forms of eyeblink conditioning in the human are not automatic and involve cognitive processing and attention. (Supported by GM 17223 to MCC & AG 08796 to JFD.)

IMPAIRED TRACE EYEBLINK CONDITIONING IN SEVERE MEDIAL TEMPORAL LOBE AMNESICS. J.F. Disterhoft[1]*, M.C. Carrillo[1], R.Q. Hopkins[2], J.D.E. Gabrieli[3], & R.P. Kesner[4]. [1]CM Biology, Northwestern University Med. Sch, Chicago, IL. 60611; [2]Dept. of Hyperbaric Med., LDS Hospital, SLC, UT, 84143; Depts. of Psychology, [3]Stanford University, Stanford, CA, 94305 & [4]Univ. of Utah, Salt Lake City, UT, 84112.

Studies of eyeblink conditioning in hippocampomized rabbits have shown that delay eyeblink conditioning is not hippocampally dependent, while the 500-ms trace paradigm is impaired and characterized by short latency, non-adaptive responses (Moyer, et al., 1990). A recent study also showed that medial temporal lobe amnesics are not impaired in the delay eyeblink conditioning task as compared to normal matched controls (Gabrieli, et al., 1995). The present study examined 500-ms trace eyeblink conditioning in 11 medial temporal lobe amnesics divided into two groups, moderate (n=6; WMS-R GMI=85.0, SD=7.44; M age=35.0) and severe (n=5; WMS-R GMI=70.4, SD=17.4; M age=46.4) who have experienced an hypoxic episode and demographically matched controls. Etiologies of the hypoxic events included cardiac and respitory arrest or CO poisoning that resulted in decreased blood flow and/or oxygen supply to the brain, resulting in medial temporal lobe damage, confirmed by MRIs. The goal of the study was to compare performance of severe vs. moderate amnesics to normal controls in the 500-ms trace paradigm.

Eyeblink conditioning involved the presentation of an 85 db, 100-ms, 1 kHz tone, followed after a 500-ms silent trace interval by a 100 ms, 3 psi corneal airpuff to the right eye sufficient to elicit reliable unconditioned responses. Sessions consisted of 60 paired tone-puff conditioning trials and 30 tone-alone extinction trials. A comparison of mean percent conditioned responses (%CRs) in the severe (33.7%) vs. moderate (73.0%) amnesic groups resulted in an unexpectedly large difference (p<.01). Mean %CRs for the severe amnesic group and controls (60.0%) was also significantly different (p<.05). Analysis of CR latency suggests that CRs in the amnesic population were short latency, non-adaptive responses compared to normal controls. These data demonstrate hippocampal involvement in 500-ms trace eyeblink conditioning that is dependent on the severity of the amnesia as would be predicted from animal studies. Supported by AG 08796 to JFD, GM 17223 to MCC.

IMPAIRED TRACE EYEBLINK CONDITIONING IN ALCOHOLIC KORSAKOFF'S AMNESIA. C.M. Brawn[1], R. McGlinchey-Berroth[1,2], M.C. Carrillo[3], J.D.E. Gabrieli[4], F.B. Gershberg[1]*, L.S. Cermak[1], J.F. Disterhoft[3].
1 Memory Disorders Research Center, Boston VAMC, Boston, MA; 2 Geriatric Research, Education and Clinical Center, Brockton/W. Roxbury VAMC, W. Roxbury MA ; 3 Northwestern University, Chicago, IL; 4 Stanford University, Stanford, CA.

Past research has demonstrated that amnesic and non-amnesic alcoholics are impaired in delay eyeblink conditioning (McGlinchey-Berroth et al., 1995). It is predicted, therefore, that diencephalic damage will disrupt both the patient's and the recovered alcoholic's acquisition in a trace paradigm compared to normal individuals.

Trace eyeblink conditioning was examined in 5 amnesic Korsakoff's (K) patients and two groups of age- and VIQ-matched control subjects, consisting of 5 recovered alcoholics (AC) and 7 normal individuals (NC). Sixty conditioning trials were presented using a 100 ms, 1000 Hz, 85 db tone (CS) presented binaurally through headphones. The unconditioned stimulus (UCS) was a corneal airpuff (3 psi), 100 ms in duration, delivered to the right eye, which followed the CS after a 500 ms trace period. Thirty extinction trials, which included only the CS, followed. A conditioned response was defined as a departure from baseline of ≥ 4 sd during the CS-UCS interval, ≥ 100 ms after CS offset.

The mean percentages of conditioned responses were 24.67 for Ks, 48.33 for ACs, and 58.33 for NCs. An ANOVA with Group (K, AC, NC) and Trial Block (1-12) revealed a significant effect of Group (p<.02), confirming a significant impairment in the Ks compared to the NCs and ACs. As predicted from previous results in delay eyeblink conditioning, these data indicate impaired acquisition of trace eyeblink conditioning in Korsakoff's amnesia. There is a trend toward a lower acquisition rate in ACs as compared to NCs, however, the difference was not significant (p>.3). The deficit displayed in the Korsakoff's patients may be attributable to the cerebellar degeneration generally associated with long-term alcohol abuse (e.g. Harper, 1982, 1990). FUNCTIONAL IMAGING OF BRAIN REGIONS INVOLVED IN PAVLOVIAN FEAR CONDITIONING IN HUMANS. D.C. Knight[1]*, F.J. Helmstetter[1,2] & E.A. Stein[2] Department of Psychology[1], University of Wisconsin-Milwaukee and Deparment of Psychiatry[2], Medical College of Wisconsin, Milwaukee, WI 53201

Pavlovian fear conditioning has been successfully used for years in various model system approaches to understanding the neural substrates of learning, memory and emotion in laboratory animals. However, relatively little is currently known about the functional neuroanatomy of this type of learning in humans. In the present study we used functional magnetic resonance imaging (FMRI) in healthy volunteers that were exposed to a conditioning procedure in which presentations of a flashing light (CS+) were followed by brief electrical stimulation (UCS). Images were collected using a 3T/60 Bruker Biospec scanner equipped with a 3-axis local gradient coil and endcapped quadrature birdcage RF coil using a gradient-echo echo-planar pulse sequence. Eight contiguous 8mm axial slices were collected (TR=2s, TE=27.2msec, FOV=24cm) throughout each series of stimulus presentations. Activated regions were identified based on correlation with an ideal function representing the temporal pattern of stimulation. Control subjects received unpaired lights and shocks. Paired training with light and shock produced large stimulus-related changes in signal intensity in several brain regions. Notably, occipital and inferotemporal visual cortical areas showed enhanced responses to the paired light compared to light or shock presentations alone. These changes appeared to develop as a function of repeated pairings. There were also learning-related changes in anterior and posterior cingulate cortex as well as in other coritcal areas.

HABIT LEARNING IN H.M.: RESULTS FROM A CONCURRENT DISCRIMINATION TASK. K. L. Hood, B. R. Postle, S. Corkin*. Dept. of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139.

Habit learning has been described as a slow or incremental process that results when automatic connections develop between a stimulus and a response (Mishkin et al., 1984). Tests of concurrent discrimination (CD) learning, in which subjects learn to choose the rewarded object of a pair, have been used to test habit memory. Normal performance by monkeys with bilateral medial temporal-lobe lesions on CD tasks suggests that CD learning occurs independently of explicit memory. Squire et al. (1988), however, reported that humans with Korsakoff's syndrome show impaired learning on a CD task, and that any learning that occurred was correlated with subjects' explicit knowledge of the reward contingencies. In the present study, we tested the amnesic patient H.M and 5 normal control subjects (NCS) on a 10-object pair CD learning task. Because of the severity of H.M.'s explicit memory deficit, we reasoned that any learning we observed would be due to implicit, or habit, memory. We presented 10 object pairs in each of 6 testing blocks per day; blocks were separated by 1-2 hours. The same object in each pair was always rewarded with a dime, which subjects retrieved by displacing the correct object. Left-right position of the target object varied pseudorandomly. We tested NCS for 4 consecutive days, and H.M. for 6 consecutive days. NCS learned the task to 100% accuracy within 3 days of testing (3 out of 5 reached an asymptotic level of performance on Day 1). Mann-Whitney tests revealed that H.M.'s scores were significantly lower than those of each NCS ($p=.0001$). However, a linear regression analysis revealed that H.M. was able to learn over time ($p<.04$), increasing from a mean percentage correct of 4.2% on Day 1 to 6.2% on Day 6. By the end of Day 1, all NCS were aware that the same object in each pair was consistently rewarded. In contrast, H.M. had no explicit knowledge of the reward contingencies at any point during testing; therefore, his learning could only have occurred implicitly, and may be an example of habit memory. Further testing with H.M. and other amnesic subjects with severe explicit memory impairments will seek to clarify this result. *NIH Grant AG-06605.*

THE RELATIONSHIP BETWEEN MEMORY FUNCTION AND TEMPORAL LOBE PATHOLOGY IN CHILDREN. S.J. Wood[1], D.G. Gadian[2], E.B. Isaacs[1], J.H. Cross[1], C.L. Johnson[2], A. Connelly[2], and F. Vargha-Khadem[1]. [1]Neurosciences Unit and [2]Radiology and Physics Unit, Institute of Child Health, London WC1N 1EH UK. (Sponsor: European Brain and Behaviour Society)

The lateralization of verbal and nonverbal cognitive function in patients with temporal lobe epilepsy (TLE) has been well documented in adults but not in children. To study this question, we assessed 34 young ($X=12.7$ years), right-handed, TLE cases with both magnetic resonance (MR) techniques and cognitive tests. MR measures included T2 relaxometry ($N=26$) to assess hippocampal pathology, and MR spectrocopy ($N=27$) to assess diffuse temporal lobe pathology (19 cases underwent both). All the children were given tests of language, executive function, and verbal and nonverbal memory. Scores on verbal memory tests considered to be sensitive to left temporal lobe damage correlated with measures of left temporal, including hippocampal, pathology. However, memory tests believed to be sensitive to right temporal lobe damage (e.g. memory for an Emergent Complex Figure[1] and Face Recognition) showed a tendency to correlate not with right temporal pathology but with left. Indeed, two patients with severely damaged right temporal lobes were unimpaired on these and other nonverbal memory tests. Nonmemory scores showed no correlations with the pathology measures. The results suggest that, in children, some forms of nonverbal memory depend at least as much on the left as they do on the right temporal lobe.

DEVELOPMENTAL CHANGES IN AN ELECTROPHYSIOLOGICAL MEASURE OF SHORT TERM AUDITORY MEMORY. H. Gomes, E. Sussman, W. Ritter, D. Kurtzberg, N. Cowan, H. G. Vaughan, Jr.*. Neuroscience & Neurology, Albert Einstein College of Med., Bronx, NY 10461

In behavioral studies, children's memory for pitch has been found to persist for less time than adult's (Keller & Cowan, 1994). It is difficult to determine, however, if this developmental change is due to attentional mechanisms or due to changes in auditory memory. Mismatch negativity (MMN), an auditory event related potential, is thought to reflect auditory discrimination and the underlying transient memory upon which it depends. Further, it is considered to be preattentive and automatic and relatively insensitive to attentional mechanisms. This study examined the MMNs of 6-7, 8-10 and 11-12 year old children and adults. Subjects were presented with trains of stimuli, each beginning with either a standard (1000 Hz) or a deviant (1200 Hz) tone with trains separated by either 1 or 8 sec. of silence. All four groups of subjects exhibited MMNs after delays of 1 second, but only the adults and oldest children exhibited MMNs after 8 seconds. Maturational changes in the duration of auditory memory have important implications for the acquisition of language.

ASPIRATION LESIONS OF THE AMYGDALA DISRUPT RHINAL CORTICAL EFFERENTS TO THE MEDIODORSAL NUCLEUS OF THE THALAMUS IN RHESUS MONKEYS. S. Goulet*, F.Y. Doré and E.A. Murray, Laboratory of Neuropsychology, NIMH, NIH, Bethesda, MD 20892.

Behavioral studies in nonhuman primates have shown that although combined removal of the amygdala (A) and hippocampus (H) by aspiration severely disrupts visual recognition memory, combined removal of these structures using the excitotoxin ibotenic acid does not. It now appears that, within the medial temporal lobe, damage to the rhinal cortex (i.e. entorhinal and perirhinal cortex), the region ventrally subjacent to the A and rostral H, is both necessary and sufficient to produce the severe impairment in visual recognition. It has been proposed that aspiration lesions of the amygdala result in inadvertent transection of the perirhinal efferent fibers that course just lateral and dorsal to this structure, thereby accounting, at least in part, for the recognition deficit that follows aspiration lesions of the A plus H. To test this idea rhesus monkeys with aspiration lesions of the amygdala in one hemisphere received bilaterally symmetrical injections of the fluorescent retrograde tracer Fast Blue into the medial portion of the mediodorsal nucleus of the thalamus (MDmc), another structure implicated in visual recognition. In the 2 cases examined, there was a paucity of labeled cells in the rhinal cortex of the amygdalectomized hemisphere relative to the intact hemisphere. By contrast, retrogradely labeled cells in the hypothalamus were equally abundant in both hemispheres. We conclude that aspiration lesions of the amygdala in rhesus monkeys disrupt rhinal cortical efferents to MDmc, and perhaps to other sites as well. The behavioral effects of aspiration lesions of the amygdala in nonhuman primates should be interpreted with caution. EFFECTS OF ASPIRATION VS NEUROTOXIC LESIONS OF THE AMYGDALA ON EMOTIONAL REACTIVITY IN RHESUS MONKEYS. M. Meunier*, J. Bachevalier, E.A. Murray, L. Malkova and M. Mishkin. Lab. Neuropsychol., NIMH, Bethesda, MD 20892.

Aspiration lesions of the amygdala (A(ASP)), which include the rostral portion of the rhinal cortex, yield both memory loss and emotional changes (Aggleton, TINS, 1993, 16:328). Some memory deficits after A(ASP) lesions result from damage to the rhinal cortex rather than to the amygdala (see Murray, Sem. Neurosci., 1996, 8:13). To test whether a similar conclusion holds for the emotional changes, we prepared 6 monkeys with selective neurotoxic amygdala lesions made with ibotenic acid (A(IBO)), which spare the rhinal cortex, and compared their emotional reactivity to that of 3 monkeys with A(ASP) lesions and 6 normal controls. The stimuli used were a toy snake, a taxidermic monkey head, a human wearing a mask, and an object concealing a food reward, which were shown for 20 sec each on each of 3 days. Animals were videorecorded and frequency and duration of 30 behavioral categories were scored by two observers. Relative to controls, monkeys with A(IBO) lesions displayed a loss of fearful reactions (i.e. freezing responses), fewer aggressive responses (i.e. head lunges, mouth threats), and an increased tendency to examine objects, often orally. These significant changes in emotionality were similar to those found after A(ASP) lesions, although in some behavioral categories, such as aggressivity, the magnitude of the changes was less. Thus, selective damage to the amygdala is sufficient to produce notable changes in emotional reactivity.

AMYGDALA MODULATION OF MULTIPLE MEMORY SYSTEMS M. G. Packard* & L. A. Teather, Dept. of Psychol., Univ. New Orleans, & LSUMC Neurosci. Center of Excellence, N.O., LA, 70148.

In exp. 1, rats received an 8-trial training session in either a spatial or cued water maze task, followed by post-training intracerebral (hippocampus, caudate nucleus, or amygdala) injections of d-amphetamine (d-amp; 5 ug or 10 ug/0.5 ul) or saline (0.5 ul). Prior to a retention test 24 hour later, rats received intracerebral injections (hippocampus, caudate, or amygdala) injections of lidocaine (2%; 0.5 ul) or saline. On the spatial task, post-training intra-hippocampal (10 ug), but not intra-caudate injections of d-amp enhanced memory, and pre-retention test intra-hippocampal injection of lidocaine blocked the memory enhancing effect of post-training intra-hippocampal d-amp injections. On the cued task, intra-caudate (10 ug), but not intra-hippocampal injections of d-amp enhanced memory, and pre-retention intra-caudate injection of lidocaine blocked the memory enhancing effect of post-training intra-caudate d-amp injections. Intra-amygdala injections of d-amp (5 ug) enhanced memory in both tasks. However, pre-retention intra-amygdala injection of lidocaine did not block the memory enhancing effect of post-training intra-amygdala d-amp injections on either task. In exp. 2, rats cannulated in two brain structures (amygdala-hippocampus or amygdala-caudate) received training in the spatial or cued tasks, followed by post-training injections of d-amp into the amygdala (5 ug), and simultaneous post-training injections of lidocaine into the hippocampus (spatial task), or caudate nucleus (cued task). In the spatial task, intra-hippocampal lidocaine blocked the memory enhancing effects of intra-amygdala d-amp. In the cued task, intra-caudate lidocaine blocked the memory enhancing effects of intra-amygdala d-amp. The findings indicate 1) the effects of post-training intra-hippocampal and intra-caudate injections of d-amp on memory are task-dependent, and likely involve consolidation of memory *within* these structures, and 2) post-training intra-amygdala injections of d-amp enhance both hippocampal- and caudate-dependent memory processes, and this modulatory effect is likely due to a direct action on these two memory systems.

CONTRIBUTIONS OF THE HIPPOCAMPUS AND THE AMYGDALA TO THE RESPONSE TO REWARD REDUCTION. J.A. Salinas* & N.M. White, Department of Psychology, McGill University, 1205 Dr. Penfield Avenue, Montreal, Quebec H3A 1B1, Canada.

It has previously been shown that post-training amygdala inactivation impairs, but does not abolish, memory for reward reduction in rats. In the present study we compared the effects of pre-training radio frequency fimbria-fornix (Fx) and electrolytic lateral amygdala (La) lesions on the response to reward reduction. Lesioned and unlesioned rats were trained to run a straight alley (6 trials /day) for either a large or small food reward with a 3 minute intertrial interval. After reaching asymptotic running speed rats trained on the large reward were shifted to the small reward. Shifted unlesioned animals displayed a characteristic large decrease in runway speeds compared to unshifted controls. In contrast, shifted Fx lesioned rats displayed runway speeds indistinguishable from unshifted Fx lesioned animals. Shifted La lesioned rats slowed but returned to preshift performance by the second postshift day. Our data support the view that the *initial* aversive emotional reaction elicited by the unexpected reward is dependent upon a hippocampal memory system and the *subsequent* alteration in behavior is directed by an amygdala-dependent associative mechanism. The complete behavioral response exhibited by shifted unlesioned rats in the runway may therefore depend upon a cooperative interaction between these two structures.

THE ROLE OF THE AMYGDALA IN CONDITIONED FEAR AND REMEMBERING REWARD SIZE. R.S. Astur*, A. Koerner, F.M. Barrington , R.J. McDonald, A.Y. Gonzales, C. O'Brien & R.J. Sutherland. Dept. of Psych. & Physiol., UNM, Abq. , NM 87131.

A series of experiments was designed to assess the contributions of the amygdala to reward and punishment processes. In addition to the amygdala often being cited as contributing to conditioned fear, it also may be necessary to attach an appropriate positive valence to a particular cue. To examine these ideas, 6 rats received neurotoxic damage to the amygdala and 6 served as controls. They were placed into a specific context and received a series of tone-shock pairings. When tested for conditioned fear to the context, the amygdala rats displayed significantly less freezing than the control rats. They were then trained in a differential magnitude of reinforcement task in which they were presented with 2 different images on a computer screen. Pressing one image resulted in a 4-pellet reward, while pressing the other image resulted in a 1-pellet reward. The amygdala rats did not differ from the control rats in learning this task. Finer discriminations with cues signaling 5 vs 3-pellet rewards and testing in a paradigm similar to a "gambling task" suggests that the amygdala is part of a complex interconnected memory system that collectively contributes to reward and punishment processes. Supported by UNM's SRAC, RAC, and MBRS funds.

EFFECTS OF AMYGDALA LESIONS ON TWO AVERSIVELY MOTIVATED TASKS O.F.A. Bueno*, E.B. Gugliano, G.F. Xavier and N.S. Canteras Dept. Psicobiologia, UNIFESP-EPM, São Paulo,SP, Brasil,CEP 04023-062.

Several studies suggest the participation of different neuroanatomical structures on contextual (CL) and conditioned fear (CF) learning. One such structure that appears to have an essential role on the process of emotional learning is the amygdala. Lesion to this structure impairs aversively motivated tasks. The present study sought to examine whether lesions on specific amygdala nuclei produce differential effects on CL and CF tasks. Rats were submitted to bilateral electrolytic lesion on either basolateral or central nuclei of the amygdala, or to bilateral ibotenic acid-induced basolateral nucleus lesion. The animals were trained in a step-through inhibitory avoidance apparatus comprised of a dark shock compartment interconnected with a white safe compartment. After entering the dark box they received 5 paired tone (90dB/1sec)-shocks (1 mA/1sec) 15 sec apart. Twenty-four hours later half the animals were submitted to the step-through inhibitory avoidance test in the same apparatus (a measure of CL), and the other half was placed in a new environment (open-field arena) where freezing time was measured for 8 min. During the 4th min the same tone as presented during training sounded. Freezing after the tone was a measure of CF and before sound of unconditioned fear (UF). Neither eletrolytic or restricted neurotoxic lesions to the basolateral nucleus resulted in significant changes in CL and CF tests. Lesion to the central nucleus of the amygdala caused an impairment on both tasks but not on UF. Our results indicate the participation of the central, but not of the basolateral nucleus, on the process of aversive learning.

DISSOCIATION OF THE EFFECTS ON CONDITIONED TASTE AVERSION AFTER IBOTENIC ACID LESIONS TO THE CENTRAL AND BASOLATERAL AMYGDALA IN RATS. S. Frey*, R. Morris, and M. Petrides. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada.

Recent findings in our laboratory have implicated the basolateral nucleus of the amygdala (BLA) as a critical structure in the learning of a conditioned taste aversion (CTA). In the present study the role of the central amygdala (Ce), one of the relays along the gustatory pathway, was examined. Rats with ibotenic acid (IBO) lesions restricted to either the BLA or the Ce were tested for their ability to acquire an aversion to a sucrose solution paired with lithium chloride toxicosis. When compared to normal controls, impairments were only seen on the CTA when the lesions were restricted to the BLA. The fibers coursing through the amygdala were assessed in both groups of lesioned animals, using a tract-tracing technique, and were shown to be spared. This study therefore confirms the role of the BLA in taste aversion learning. Additionally, these data argue that lesions to the Ce are insufficient in producing a deficit on the CTA and that fibers running through the amygdala do not appear to subserve CTA learning.

LEARNING AND MEMORY FOR TASTE INFORMATION: ROLE OF THE AGRANULAR INSULAR CORTEX. M.E. Ragozzino* and R.P. Kesner, Department of Psychology, University of Utah, Salt Lake City, UT 84112.

The present experiment examined whether a neurotoxic lesion of the agranular insular cortex impairs memory for food reward magnitude and acquisition of a flavor-preference test. Rats were first tested for memory for food reward magnitude using a go-no-go procedure. During the study phase, rats received a cereal piece containing either 20% or 50% sugar. One cereal was designated as the positive stimulus and the other as the negative stimulus. In the test phase, a positive stimulus was always followed by a food reward under an object, whereas the negative stimulus was not. Performance was assessed as the latency to displace the object. After reaching criterion, rats received, under anesthesia, either bilateral injections of quinolinic acid (125 mM) or saline into the agranular insular cortex. Compared to controls, lesioned rats exhibited significant performance deficits, with greater deficits at longer retention delays.

The same rats were then given a flavor-preference test. Rats received a cherry-flavored solution or a grape-flavored solution on alternating days for a total of 6 days during the acquisition phase. One solution contained 3.4% sucrose, whereas the other solution contained no sugar. Two days following acquisition, rats were simultaneously presented both solutions unsweetened. Controls showed a significant preference for the previously sweetened solution, whereas the lesioned rats did not exhibit a preference for either solution. The findings indicate that agranular insular cortex lesions impair memory for food reward magnitude and learning of a flavor preference, suggesting a role for the agranular insular cortex in processing affect information related to taste.

CONTRIBUTION OF INSULAR CORTEX TO THE CONDITIONED EXPRESSION OF c-FOS IN NTS FOLLOWING TASTE AVERSION LEARNING. G. E. Schafe* and J. L. Bernstein. Department of Psychology, Univ. of Washington, Seattle, WA 98195.

The induction of c-Fos-like immunoreactivity in the intermediate division of the nucleus of the solitary tract (iNTS) is a reliable cellular correlate of the acquisition and/or behavioral expression of a conditioned taste aversion (CTA). Recently, we have shown that electrolytic lesions of the amygdala (AMYG) eliminate both the behavioral expression of a CTA and accompanying c-FLI in iNTS. In the present study, rats were given either unilateral or bilateral electrolytic lesions of insular cortex (IC) or SHAM operations. For comparison, a group with unilateral AMYG lesions was also included. Following surgery, paired animals were conditioned by the pairing of intraoral infusion of 0.15% saccharin (CS) with LiCl (0.15M, 20 ml/kg, i.p.). Unpaired controls received a non-contingent saccharin-LiCl presentation. At testing, unilateral-lesioned groups and SHAMs rejected the CS taste, whereas rats with bilateral lesions of IC showed no evidence of learning. Unilateral IC lesions significantly attenuated, but did not eliminate, conditioned c-FLI ipsilateral to the lesion, whereas bilateral IC lesions attenuated c-FLI bilaterally. These results are consistent with the interpretation that both AMYG and IC are necessary, but not sufficient, for the behavioral expression of a CTA. Alternatively, results could indicate that an ipsilateral projection from IC to iNTS, which passes through or near AMYG, is necessary for behavioral expression of a CTA and that the effects of electrolytic lesions of AMYG are due, at least in part, to interruption of this pathway. NIH DC00248

CONTRIBUTION OF THE AMYGDALA TO THE CONDITIONED EXPRESSION OF c-FOS IN NTS FOLLOWING TASTE AVERSION LEARNING. J. L. Bernstein* and G. E. Schafe. Department of Psychology, University of Washington, Seattle, WA 98195

The induction of c-Fos-like immunoreactivity (c-FLI) in the intermediate division of the nucleus of the solitary tract (iNTS) has been shown to be a reliable cellular correlate of the acquisition and/or behavioral expression of a conditioned taste aversion (CTA). We have been using immunostaining for c-FLI in combination with localized lesion techniques to begin to define neuroanatomical structures and pathways that are critically involved in CTA learning. In the present study, rats were given either unilateral or bilateral electrolytic lesions of the amygdala or SHAM operations. Following surgery, paired animals were given a single conditioning trial consisting of intraoral infusion 5 ml 0.15% sodium-saccharin (CS) followed by injection with LiCl (0.15M, 20 ml/kg, i.p.). Unpaired controls received saccharin followed by an equivalent volume of 0.15M NaCl. At testing, unilateral-lesioned animals rejected the CS taste, but increases in c-FLI were evident only on the side of iNTS contralateral to the lesion. Rats with bilateral lesions showed no evidence of having acquired a CTA and no increases in c-FLI in iNTS relative to unpaired controls. These findings are in agreement with previous reports that the amygdala is involved in CTA learning and are consistent with the hypothesis that a lateralized connection between amygdala and iNTS is necessary for the behavioral expression of a CTA. Alternatively, results may reflect the contribution of projections from agranular insular cortex to iNTS, which are known to pass through or near amygdala, or the contribution of both structures. NIH DC00248

CONDITIONED IMMUNOENHANCEMENT IS DISRUPTED BY INSULAR CORTEX AND AMYGDALA NMDA INDUCED LESIONS. V. Ramírez-Amaya*, B. Alvarez-Borda and F. Bermúdez-Rattoni. Depto. de Neurosciencias, Instituto de Fisiología Celular, UNAM, México, D.F. 04510.

It has been demonstrated that the immune system can be activated through a Pavlovian conditioning. A reliable conditioned increase of antibody production resembling a secondary immune response can be obtained in male Wistar rats that receive the pairing of a gustative stimulus with an antigen. In our laboratory, we are interested in the neural substrates of conditioned immune responses. Previously, we have demonstrated that the insular cortex and the amygdala are involved in conditioned immunosuppression. In this study, we evacuate the effect of insular cortex, amygdala and hippocampal NMDA induced lesions, that were made before the acquisition of a conditioned enhancement of antibody production. The conditioning is obtained by the pairing of saccharin with Hen Egg Lysozyme as the antigen. After the end of the primary immune response (25 days later), rats were reexposed to the gustative stimulus alone, and 4, 8, 12 and 16 days after reexposure blood samples were taken and the serum was analyzed with ELISA by using anti rat IgM and IgG peroxidase conjugated antibodies. Adequate controls were used to ascertain the effect of conditioning. The results showed that insular cortex and amygdala but not hippocampal lesions disrupted the conditioned increase of IgM and IgG antibody production. These data further support the idea that insular cortex and amygdala are involved in the neural mechanisms underlying the conditioning of immune responses. Supported by DGAPA IN201993

BASOLATERAL AMYGDALA LESIONS BLOCK THE MEMORY-ENHANCING EFFECT OF GLUCOCORTICOID ADMINISTRATION IN THE DORSAL HIPPOCAMPUS. B. Roozendaal* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory, and Departments of Psychobiology and Pharmacology, University of California, Irvine, CA 92717-3800.

Extensive evidence indicates that glucocorticoids can influence memory storage via activation of adrenal steroid receptors in the hippocampal formation. We previously reported that lesions of the basolateral nucleus of the amygdala (BLA) block the memory-modulatory effects of systemically administered glucocorticoids. Together, these findings suggest that the BLA may interact with the hippocampus in mediating these glucocorticoid effects. These experiments examined, in male Sprague-Dawley rats, the effects of bilateral amygdala nuclei lesions on modulation of memory storage induced by bilateral intra-hippocampal microinfusions of glucocorticoids. Posttraining infusions of the glucocorticoid receptor (GR or Type-II) agonist RU 28362 (3.0 or 10.0 ng) enhanced inhibitory avoidance retention and infusions of the GR antagonist RU 38486 (3.0 or 10.0 ng) administered shortly before training in a water maze spatial task did not affect acquisition, but impaired retention. In both tasks, neurochemically induced lesions of the BLA, but not of the central amygdala (CEA) blocked the memory-modulatory effects of the intra-hippocampal infusions of the drugs affecting GRs. Lesions of the CEA alone impaired inhibitory avoidance retention, but BLA lesions alone did not affect acquisition or retention in either task. These findings provide further evidence that the BLA is a critical area involved in regulating glucocorticoid effects in other brain regions involved in memory storage.

GLUCOCORTICOID-INDUCED MEMORY MODULATION DEPENDS ON NORADRENERGIC NEUROTRANSMISSION IN THE BASOLATERAL AMYGDALA. G. L. Quirarte*[3], B. Roozendaal[1] and J. L. McGaugh[1,2]. 1. Center for the Neurobiology of Learning and Memory; 2. Departments of Psychobiology and Pharmacology, University of California, Irvine, CA 92717-3800 and 3. Faculty of Medicine, National University of México, México 04510.

Stress hormones of the adrenal glands, released in response to aversive training, can influence memory storage. Extensive evidence indicates that the memory-modulatory effects of the adrenomedullary hormone epinephrine are mediated via activation of β-adrenergic mechanisms in the amygdala. We previously demonstrated that the effects of systemic posttraining administration of the synthetic glucocorticoid dexamethasone are blocked in rats with lesions of the basolateral nucleus (BLA), but not the central nucleus (CEA) of the amygdala. The present study examined whether glucocorticoid-induced memory enhancement also depends on the integrity of β-adrenergic elements in the BLA. Posttraining injections of dexamethasone (0.3 mg/kg, s.c.), in male Sprague-Dawley rats, enhanced inhibitory avoidance retention. Bilateral microinfusions of propranolol (1.0 μg in 0.2 μl), a β-adrenergic receptor antagonist, given into the BLA 10 min prior to training, blocked the glucocorticoid-induced memory enhancement. Propranolol alone did not affect retention performance. These findings indicate that noradrenergic mechanisms in the BLA are critically involved in regulating glucocorticoid effects on memory storage.

EFFECTS OF DIFFERENT FOOTSHOCK INTENSITIES AND OPIOID PEPTIDERGIC DRUGS ON NOREPINEPHRINE RELEASE WITHIN THE AMYGDALA. R. Galvez, G. L. Quirarte, J. L. McGaugh*. Center for the Neurobiology of Learning and Memory and Department of Psychobiology and Pharmacology, University of California, Irvine, CA 92717-3800.

Extensive evidence suggests that the amygdala plays a major role in modulating memory storage of emotionally arousing events through the release of norepinephrine (NE). Pharmacological evidence suggests that opioid peptidergic drugs influence memory storage by altering the release of NE within the amygdala. The first part of the study examined NE levels in the amygdala of freely moving rats in response to different footshock intensities (comparable to those typically administered during inhibitory avoidance training) to determine an optimal footshock level. Male Sprague-Dawley rats were implanted unilaterally with guide cannulae aimed at the amygdala. One week later a microdialysis probe was inserted into the guide cannula. Thirty min prior to collecting the first sample, the rat was placed into a box containing a grid floor from which a footshock could be delivered. The flow of the artificial cerebrospinal fluid was 1.0 μl/min and the samples were collected every 15 min. After establishing a stable baseline, the rats were given either a high (1.2 mA), mild (0.7 mA), or low (0.3 mA) footshock stimulation. In the second experiment, the rat received systemic injections of naloxone (1 mg/kg) or ß-endorphin (1 μg/kg) immediately following the footshock stimulation, and NE levels in the amygdala were determined by HPLC. NE levels increased significantly in response to naloxone and did not deviate significantly from baseline in response to ß-endorphin. These findings are consistent with previous pharmacological evidence suggesting that opioid peptidergic drugs modulate memory by mediating the release of NE within the amygdala.

AN INVESTIGATION INTO THE ROLE OF THE TRANSCRIPTION FACTOR c-FOS IN MEMORY CONSOLIDATION. J.F. Guzowski* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory, and Department of Psychobiology, University of California, Irvine, CA 92717-3800.

Because the immediate-early gene c-Fos has low basal expression and is rapidly induced, techniques to detect c-Fos RNA and protein have gained widespread use as markers of neuronal "activation" in behavioral research. Despite this, the functional relevance of this dynamic upregulation to the cellular mechanisms underlying memory consolidation is not clear. To investigate the role of c-Fos in long-term memory formation, we have initiated studies in which antisense oligodeoxynucleotides (ODN) to c-Fos mRNA are infused into the rat hippocampus and the effect on learning and memory are compared to mismatch ODN control groups. Tasks used in these studies are the hidden platform water maze and continuous multiple trial inhibitory avoidance (CMIA). These functional antisense studies are conducted in parallel with studies examining c-Fos expression following training. Preliminary immunoblot analyses show that 90 minutes following training in both tasks, hippocampal c-Fos protein levels increase by approximately 30% relative to caged controls. Additional preliminary findings indicate that pretraining c-Fos antisense ODN infusions impair retention performance in CMIA but not in the water maze task and that the antisense treatment does not affect acquisition in either task. These data suggest that although the induction of c-Fos expression in the hippocampus may be involved in memory consolidation for some tasks, it may not be a global indicator of neuroplastic changes related to long-term memory formation. Ongoing studies are designed to characterize further these initial findings.

MULTIPLICATIVE COMPUTATION WITH A TEMPORAL NEURAL CODE BY A SINGLE NEURON EXHIBITING SUBTHRESHOLD OSCILLATIONS. T. Fukai*. Dept. of Electronics, Tokai Univ., Hiratsuka, Kanagawa 259-12, and Lab. for Neural Modeling, Institute of Physical and Chemical Research (RIKEN), Wako, Saitama 350-01, Japan.

It is shown that a single neuron displaying the subthreshold oscillation can perform multiplication of two inputs in terms of a temporal neural code. Here the temporal neural code implies that an analog variable X is represented by a time advance δ of action potential generation from a peak time of the oscillation. Psychophysical experiments on perception of stimulus intensity suggest $\delta = a\log(X/X_0)$. Then if two stimulus sequences given at phases δ_1 and δ_2 elicite action potentials at $\delta_{out} \approx \delta_1 + \delta_2$ in each oscillatory cycle, multiplication of the inputs is achieved: $X_{out}/X_0 \approx \exp(\frac{\delta_1+\delta_2}{a}) = (X_1/X_0)\cdot(X_2/X_0)$. A Hodgkin-Huxley type model neuron which exhibits such a response is presented. In the model, the post-inhibitory rebound caused by the low threshold Ca^{++} current plays a crutial role. Possible functional roles of this multiplication are discussed for memory and learning in the rat hippocampus.

METHODS FOR IMPROVING DISCRIMINATION OF DIGITALLY SAMPLED SPIKES. J.L. Kubie*, M. Stead, A.A. Fenton, and R.U. Muller. Dept of Physiology, SUNY. H.S.C. Brooklyn, NY 11203.

The collection of spike waveforms with digital methods inevitably results in a loss of accuracy about the original waveform. For example, the apparent peak of a spike is generally less than the true peak since, at reasonable digitization rates, it is unlikely that a sample point will be taken exactly at the time of the peak. We have decided to use cubic splines to generate continuous representations of digitized spikes. The splined representation is immediately useful for extracting information about the amplitude of various parts of the waveform. Next, the time at which the spike crossed the trigger level for spike acceptance is determined. The time axis is then shifted so that t = 0 corresponds to the trigger time, a process referred to as "realignment". Information about the time of important parts of the spike (peak time, zero crossing, time of minimum) is then extracted. Finally, the splined representation is "resampled" such that the data points are relative to the threshold. The effects of this procedure can be seen in the figure below, in which the distinctions among a set of 3 waveforms are apparently enhanced. It is our impression that the realignment and resampling scheme improves our ability to recognize spike clusters; we are currently using algorithmic methods to test if our impression is correct.

INJECTION OF ARC ANTISENSE OLIGONUCLEOTIDES SELECTIVELY BLOCKS HIPPOCAMPAL LTP MAINTENANCE IN VIVO. G.L. Lyford^, G.D. Stevenson~*, C.A. Barnes~, P.F. Worley^. Dept. Neuroscience & Neurology, Johns Hopkins University, Baltimore, MD 21205^ and ARL NSMA, University of Arizona, Tucson, AZ 85724~.

Neurons respond to synaptic activity by increasing the transcription of specific genes, and this genomic response is essential for the establishment of long-term plasticity. The focus of our research has been to identify and functionally characterize these induced genes as a means to understand the molecular basis of plasticity. Arc is a recently described immediate early gene (IEG) which encodes a 50 kDa protein that possesses modest homology to the cytoskeletal protein spectrin and binds to preparations of F-actin (Lyford et al., Neuron, 1995). Arc is unique among IEGs in that the mRNA is present in neuronal dendrites. To examine its role in synaptic plasticity, we have developed an *in vivo* electrophysiological recording preparation that permits delivery of oligonucleotide probes to the hippocampus of chronically implanted rats. Antisense (AS) probes, which combine hybrid phosphorothioate and phosphodiester linkages, were identified that are effective in selectively blocking the expression of Arc in hippocampal granule cells. AS and scrambled control (SC) probes were delivered to opposite hemispheres of the same rats 2 hrs prior to administration of a high frequency LTP-inducing stimulus. Group data from a total of nine bilaterally-implanted rats indicates that the oligonucleotides had negligible effect on baseline synaptic transmission, and that initial induction of LTP is virtually indistinguishable in AS and SC hemispheres. Interestingly, LTP decayed more rapidly in the hemispheres to which antisense probes were administered. These results therefore suggest a role for Arc in the maintenance phase of LTP. AGE-RELATED DECREASE IN THE SCHAFFER COLLATERAL EVOKED EPSP IN CHRONICALLY IMPLANTED F-344 RATS. G. Rao*, G.D. Stevenson, C.A. Barnes, B.L. McNaughton and K.L. Weaver. ARL NSMA, University of Arizona, Tucson, AZ 85724.

In old F-344 rats, we have previously shown that the Schaffer collateral evoked CA1 EPSP and the population currents evoked to applied AMPA are both smaller relative to the presynaptic fiber volley, even though the unitary EPSP recorded intracellularly does not change in old age. These results suggest that there are fewer CA3-CA1 synapses in old animals; however, given that tissue prepared from old rats may be particularly vulnerable to certain aspects of the hippocampal slice preparation, such as periods of anoxia or prolonged incubation in the slice chamber, it is important to verify the evoked response changes in a chronic preparation, free from such effects and without anesthesia. F-344 rats (n=10, 28 mos old; n=10, 9 mo) were tested in the Morris water task, and subsequently bilaterally implanted with microdrives carrying a pair of nichrome recording and stimulating electrodes. Following the animals' recovery from surgery, the electrodes were slowly advanced into CA1 stratum radiatum to optimize the evoked potential and input-output curves were constructed of the relation between the presynaptic fiber volley and EPSP in the awake rat. As found previously *in vitro*, the presynaptic fiber potential did not differ between age groups (F=0.66, p=0.43), but the EPSP amplitude was significantly smaller in the old rats (F=6.66, p=0.02). These data thus support the overall conclusion that there may be a reduction in the number of synaptic contacts made by a given Schaffer collateral axon. Such changes may contribute to impairments in the performance of spatial tasks by old animals. Supported by AG03376 and MH01227.

PLACE CELL THETA PHASE FIRING PROFILE DIFFERENCES FROM MAZE RUNNING TO REM SLEEP: FAMILIAR VS. NOVEL PLACE FIELDS. G.R. Poe*, B.L. McNaughton, C.A. Barnes, M.S. Suster, K.L. Weaver and J.L. Gerrard. ARL NSMA, University of Arizona, Tucson, AZ 85724.

Hippocampal place cell discharge was studied in relation to theta phase during REM sleep and maze running, to determine whether firing phase during REM sleep varied as a function of the relative familiarity of the prior experience. Such a phase change could be important in light of the finding that synapses can be potentiated when stimulation is given at theta peaks, but previously potentiated synapses are depressed when stimulation is given at theta troughs (Huerta and Lisman, 1995). Hippocampal place cell activity was recorded from 3 rats while they ran on both familiar and novel portions of a figure-8 maze. Hippocampal EEG was recorded from an electrode positioned near the hippocampal fissure for optimal theta activity, and later filtered for theta frequencies (5-10 Hz). The rats were allowed to sleep for a period of approximately 45 min. after maze running. Sleep states were scored during on-line examination of behavior, body position and EEG as well as from off-line examination of movement activity records and hippocampal EEG. Spikes occurring during theta amplitudes which exceeded 200 μV were analyzed for their timing relationship to theta cycle phase. Cells with place fields only in the familiar portion of the maze fired ~180° out of phase during REM sleep compared to their theta phase firing profile during maze running. In contrast, pyramidal cells with fields that formed on the novel portion of the maze fired at the same phase during REM sleep as during maze running ($n = 8$ cells/condition, $p < 0.01$). These data suggest that new spatial firing patterns may be strengthened during REM sleep, whereas highly familiar representations may be weakened. [AG12609, MH01227 and MH46823]

REM SLEEP AND THE REACTIVATION OF RECENT CORRELATION PATTERNS IN HIPPOCAMPAL NEURONAL ENSEMBLES. H.S. Kudrimoti*, W.E. Skaggs, C.A. Barnes, B.L. McNaughton, J.L Gerrard, M.S. Suster and K.L. Weaver. Arizona Research Laboratories Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

During slow wave sleep (SWS) and quiet wakefulness, patterns of correlated neuronal activity that occurred during the preceding behavior are reactivated in the rat hippocampus (Wilson and McNaughton, 1994, Kudrimoti et al., 1995). To test whether this reactivation also occurs during REM sleep, we analyzed 36 recording sessions from 9 rats in which the animal cycled between LIA and REM (82 REM episodes total, range 1-8 episodes/session). Correlations between pyramidal cell-pairs (7,639 pairs total) were computed during behavior and during 20-120 min sleep episodes prior to and after the behavior, separately for LIA and REM periods. In contrast to LIA, for most data sets, there was no significant effect of the correlation structure of the ensemble during behavior on the structure during REM sleep; however, occasionally, strong, significant effects were observed. While the latter result must be regarded as preliminary, overall, the data suggest that, whereas most REM episodes contain information unrelated to the most recent experience, occasional episodes may be strongly focused on it. The possibility remains open that the bulk of the REM activity relates to events in the more remote past which were not recorded in the present experiments. The correlation structure differed between SWS and REM, even though there were no significant differences in the mean firing rates of the cell populations between the two states. Interestingly, during REM, there appeared to be a suspension or slowing of the decay of the behaviorally induced correlations in SWS. Supported by MH46823, MH01227 and AG12609.

REACTIVATION OF HIPPOCAMPAL CORRELATION STATES DURING POST-BEHAVIOR SLEEP IS IMPAIRED IN AGED F-344 RATS. J.L. Gerrard*, H.S. Kudrimoti, C.A. Barnes, B.L. McNaughton, M.S. Suster and K.L. Weaver. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

Firing rate correlations that occur between CA1 neurons, due to the overlap of their place fields during behavior, are reactivated in the hippocampus during subsequent slow-wave sleep (Wilson and McNaughton, 1994; Kudrimoti et al., 1995). It has been suggested that this reactivation could play a role in memory consolidation. The reactivation of correlated neuronal firing was examined in five pairs of young (11-12 mo) and old (25-31 mo) F-344 rats. Populations of up to 62 CA1 neurons were simultaneously recorded during sleep prior to behavior, while the rats ran on a rectangular track, and during sleep following the track behavior. In the young group, the correlated firing of hippocampal neurons with overlapping place fields remained at the same levels as on the maze during the initial stages of the post-behavior sleep, and were significantly higher than the levels observed during pre-behavior sleep. This effect gradually decreased over time as previously described (Wilson and McNaughton, 1994). In the old animals, cells that were correlated on the maze were not significantly more correlated during post-behavior sleep than during pre-behavior sleep. Moreover, there was no change in their mean correlation level over time during post-behavior sleep. These data suggest that old animals have a deficit in the reactivation of traces of recent experience, which may be functionally related to the faster forgetting of spatial memories that occurs in old animals (Barnes and McNaughton, 1985). Supported by AG12609 and MH01227.

INSTABILITY OF SPATIAL REPRESENTATION DURING AGING. M.S. Suster*, B.L. McNaughton, C.A. Barnes, W.E. Skaggs, K.L. Weaver, J.L. Gerrard & H.S. Kudrimoti. ARL NSMA, Univ. of Arizona, Tucson, AZ 85724.

In young adult animals, the hippocampal representation of an environment can be stable for prolonged periods of time (Thompson and Best, 1990). As part of a larger investigation on the properties of place fields in young (12-15 mo) and old (26-31 mo) F-344 rats, stability of place fields were assessed in a familiar apparatus following removal of the animal from the recording room for a one hour period. During this period, the animals were either returned to their home cages in the colony room, or given a series of six blocks of 10 minute exploratory periods in six different rooms. Populations of up to 80 simultaneously recorded pyramidal cells were studied, of which, typically one third to one half exhibited place fields on the experimental apparatus. Consistency of the spatial representation between recording sessions was measured by computing the average spatial correlation of the firing rate distributions for the recorded cells between the two sessions. In the young animals, the mean correlation was consistently high (~0.7). In the old animals, however, there was a clear dichotomous behavior; in some sessions, the correlation was within the normal range of the young animals. In others, the correlations dropped to near zero, indicating a complete rearrangement of the firing rate distributions. The difference between age groups was statistically significant (Chi square $p < 0.02$). Examination of spike cluster distributions during sleep sessions before and after the experiment confirmed the stability of recording. We interpret this finding as indicative of a failure, in old animals, of binding of external sensory inputs to hippocampal coordinate frameworks, leading to the selection of inappropriate maps on initial entry to a familiar environment. This phenomenon may represent a neural correlate of loss of place recognition in old animals. [AG12609 and MH01227]

EFFECTS OF AGE ON THETA RHYTHM AND THETA PHASE PRECESSION IN HIPPOCAMPAL NEURONAL POPULATIONS. J. Shen*, C.A. Barnes, B.L. McNaughton, W.E. Skaggs, M.S. Suster, K.L. Weaver and J.L. Gerrard. ARL NSMA, University of Arizona, Tucson, AZ 85724.

Place specific activity of hippocampal neurons appears in the presence of the 7-12 Hz EEG theta rhythm. O'Keefe and Recce (1993) demonstrated that the phase of the theta cycle at which a pyramidal cell fires advances gradually as the rat passes through the cell's place field. Thus, there is spatial information in the phase of firing as well as in the mean rate. Using parallel recording methods, the effect of age on theta and the phase precession phenomenon has been examined in 6 young (11-12 mo) and 6 old (25-31 mo) F-344 rats, trained to run on a rectangular track in a familiar environment. As observed previously, there was a positive linear correlation between running speed and the theta frequency. The intercept of the regression line, as well as the correlation coefficient, was slightly, but significantly smaller in old rats ($p<0.05$), indicating an intrinsically lower theta frequency in old rats regardless of speed. The phase precession of place cell firing relative to location, however, was significantly faster in old rats ($p<0.05$), while the total phase precession did not differ between groups. In addition, the place fields of old rats were significantly smaller ($p<0.05$). A model for phase precession based on intrinsic connectivity of CA3 (Tsodyks et al., 1996) suggests that the faster phase precession and smaller place fields in old rats may be intimately coupled, and related to a weakening or reduction of intrinsic synaptic connections; while recent data appear to necessitate a revision of the original model (Weaver et al. and Samsonovich and McNaughton, this meeting), the main mechanism is still tenable. The current results are thus compatible with the hypothesis of reduced plasticity of intrinsic connections. [AG12609 and MH01227].

734.10

THETA PHASE PRECESSION IN HIPPOCAMPAL PYRAMIDAL CELLS DOES NOT DEPEND ON VISUAL INPUT. K.L. Weaver, J. Shen, B.L. McNaughton, C.A. Barnes*, W.E. Skaggs, M.S. Suster and J.L. Gerrard. ARL NSMA, University of Arizona, Tucson, AZ 85724.

O'Keefe and Recce (1993) described an interaction between hippocampal place cells and the theta rhythm. As the rat traverses a cell's place field, spike activity advances to progressively earlier phases of the theta cycle. Tsodyks et al. (Hippocampus, 1996) proposed a neural network model for this effect, in which place fields result from synaptic interactions among pyramidal cells and a weakly selective external input. In this model, phase precession is due to spread of activity to cells representing locations ahead of the animal, mediated by intrinsic connections that become asymmetric through experience. The spread occurs in the latter portion of each theta cycle as the extrinsic input declines. At the beginning of the next cycle, the extrinsic input forces the activity back to the neurons representing the current location. The model is crucially dependent on extrinsic input. Without it there is no place field stability; the activity simply spreads in an uncontrolled fashion. We studied the role of visual input in phase precession, using parallel recordings of CA1 neurons from five 9 mo old F-344 rats trained to run ten laps on a rectangular track under moderate illumination, ten more laps in total darkness, and a final ten laps with the lights on again. There were no effects of darkness on either theta phase precession or place field size. Assuming that there is little spatial information apart from that which is available from vision, it appears that an important tenet of the Tsodyks et al. model is not supported. A modification of the model, in which the asymmetry arises from a path integration mechanism, rather than vision, can account for phase precession in darkness (Samsonovich and McNaughton, this meeting). [AG12609 and MH01227]

ATTRACTOR-MAP-BASED PATH INTEGRATOR MODEL OF THE HIPPOCAMPUS REPRODUCES THE PHASE PRECESSION PHENOMENON. A. Samsonovich* and B.L. McNaughton. ARL Division of Neural Systems, Memory & Aging, University of Arizona, Tucson AZ 85724.

If a population of hippocampal place cells is symbolically distributed on a plane ("*chart*") according to their relative place-field locations, then their activity appears as a localized "bump", referred to here as a *soliton*, which moves on the chart in a manner that is consistent with the rat's motion. There may be more than one chart composed of the same units representing different spaces. As a result of the "multichart" architecture (presumably implemented in CA3), each chart becomes associated with a continuous two-dimensional transient set of attractors, or an *attractor map* of the environment. The soliton on a chart is associated with an attractor state and therefore retains its shape regardless of sensory stimuli. The map-based path integrator model (Samsonovich and McNaughton, 1996) assumes that the soliton is driven primarily by the animal's internal representations of head direction and self-motion. This naturally results in oscillations of the soliton in the direction of the head, resembling the "phase precession" of O'Keefe and Recce (1993). A previously proposed model of the phase precession (Tsodyks et al., 1996) appears to be inconsistent with recent experimental findings (Weaver et al., this session). Our numerical simulations based on the integrate-and-fire implementation of the map-based path integrator model reproduce the two-dimensional phase precession phenomenon qualitatively, and may reach quantitative agreement with the experimental data when a combination of AHP and presynaptic facilitation are introduced into the model. The phase precession phenomenon may thus be explained as a byproduct of self-motion integration based on intrinsic mechanisms, independent of exteroceptive stimuli. Supported by NS20331 and ONR.

INTERACTION BETWEEN HIPPOCAMPUS AND NEOCORTEX IN THE REPLAY OF TEMPORAL SEQUENCES DURING SLEEP. Y-L. Qin*, B.L. McNaughton, W.E. Skaggs, C.A. Barnes, M.S. Suster, K.L. Weaver and J.L. Gerrard. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

Evidence from ensemble recording from behaving rats (e.g., Wilson and McNaughton, 1994; Kudrimoti et al., 1995; Qin et al., 1995) supports the hypothesis that events which occur during behavior are reexpressed in both hippocampal and neocortical circuits during sleep, as postulated by some theories of memory consolidation. Recently, Skaggs and McNaughton (Science, 1996) extended these findings by showing that neuronal firing sequence information is also preserved in this reexpression. The purpose of this study was to determine if the same is true for firing order within both cortico-cortical and hippocampo-cortical spike train interactions. Parallel recordings were made simultaneously in both posterior neocortex (HL) and CA1 of rats. Each session involved an initial episode of sleep (S1), a period of behavior on a simple maze (M) and subsequent sleep episode (S2). The measurement of temporal order of firing between cell pairs was based on the temporal bias shown in their cross-correlation histogram, and it was calculated for all pairs of cells, within and between these two areas for each of the three states. The results confirm the hypothesis that temporal order is preserved in neocortical-neocortical interactions in a manner similar to hippocampal-hippocampal interactions; however, the effect was not significant between hippocampus and neocortex. This may be a result of a temporal shift in the interactions between hippocampus and neocortex which would arise if the patterns corresponding to a given event were initiated in neocortex during behavior and in hippocampus during sleep. This possibility is under investigation. Supported by AG12609 and MH01227.

DYNAMICS OF HIPPOCAMPAL MEMORY REACTIVATION DURING SHARP WAVES. W. E. Skaggs* and B. L. McNaughton. ARL Division of Neural Systems, Memory & Aging, University of Arizona, Tucson, AZ 85724.

Sharp waves are brief bursts of activity in the output layers of the hippocampal system, occurring largely during states of sleep or drowsiness, and generated within the CA3 region (Chrobak and Buzsaki, 1994). Previous studies have shown that correlations and temporal sequences from prior behavior are replayed during slow-wave sleep. We investigated sharp-wave-related population activity by analyzing ensembles of 50-100 simultaneously recorded CA1 pyramidal cells and interneurons in sleeping rats. Sharp waves lasted 50-100 msec and led to 5 to 10-fold increases above baseline in pyramidal cell population activity. Interneurons showed variable behavior, the majority increasing their rates, but some decreasing, and others showing complex up-and-down modulations. We compared the peak-times in cross-correlation plots derived from activity during sleep to those derived from prior spatial behavior. Sequences of firing from the prior behavior were replicated noisily during sleep, compressed in time by a factor of about 40. To measure the instantaneous "signal strength" for the replication of correlations, we defined an "event" as any pair of near-simultaneous spikes from different cells, and calculated the mean correlation during prior behavior for cells participating in an event as a function of the time between the event and the nearest sharp wave peak. "Signal strength" increased above baseline during the sharp waves and remained elevated for several hundred msec afterwards. These results support the hypothesis that each sharp wave is due to rapid convergence of the CA3 population from an initially random state to a temporally structured attractor state reflecting information stored in the hippocampal synaptic matrix during prior waking behavior. DYNAMICS OF MISMATCH CORRECTION IN THE HIPPOCAMPAL ENSEMBLE CODE FOR SPACE. K.M. Gothard*, W.E. Skaggs and B.L. McNaughton. ARL NSMA, University of Arizona, Tucson, AZ 85724.

Populations of hippocampal neurons (35-78) were recorded from rats shuttling on a linear track between a fixed reward-site at one end and a movable reward-site, mounted in a sliding box, at the opposite end. While the rat ran from the box toward the fixed reward-site, the box was moved to a different location. After visiting the fixed site, the rat returned to the box in its new position. On the initial part of all journeys, cells fired at fixed distances from the origin, while on the final part of the journeys, cells fired at fixed distances from the destination. Cells firing in the middle of the journey showed transitional behavior. The hippocampal spatial representation at each point of a journey was quantified in terms of population vectors. The effects of the distortion on the population vectors were evaluated by correlating the vectors on the learned (full-length) journeys and the shortened journeys. On the shortened journeys, the population vector showed a process of correction from a representation aligned with the origin of the journey, probably determined by integration of self-motion, to a representation aligned with the destination, probably determined by external cues. The dynamics of this process depended on the degree of mismatch with respect to the initially learned, full-length journey. For small mismatches, the population vector moved smoothly, but in an accelerated fashion, through the intervening coordinates, until the mismatch between the rat's location and the internal spatial coordinate was corrected. For large mismatches, the population vector jumped abruptly to the new coordinate, skipping intervening ones. These data show how path integration and external sensory cues interact competitively to control the firing of hippocampal place cells. Supported by ONR.

RAPID CHANGES IN THE HIPPOCAMPAL POPULATION CODE DURING BEHAVIOR: A CASE FOR HEBBIAN LEARNING IN VIVO. M.R. Mehta*, B.L. McNaughton, C.A. Barnes, M.S. Suster, K.L. Weaver and J.L. Gerrard. Arizona Research Laboratories Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

Although there is abundant evidence for artificially-induced Hebbian synaptic changes *in vitro* and *in vivo*, there is little evidence for such plasticity as a result of behavior. Hippocampal neurons fire in a place specific fashion and the preferred regions of activity are called the place fields. A variety of mathematical models of learning of temporal sequences (Blum and Abbott, 1995; Tsodyks et al., 1996) have predicted that, due to the temporally asymmetric nature of LTP, during repeated traverses of a route in the same direction, the place fields should enlarge and shift in a direction opposite to the direction of movement of the rat. Four young male Fisher rats were trained to run on closed linear tracks and populations of pyramidal neurons were simultaneously recorded. The average location of the populations of place fields shifted progressively backwards with repeated traverses of the route within a session. Moreover, the number of spikes per unit occupancy during the last lap was significantly higher than that during the first lap and the average place field size increased by more than 70%. Most of these changes occurred within the first few (about ten) traversals of the route. These changes occurred every time the rat re-entered a familiar environment after an absence of a day, and also when the rat traversed a novel route immediately after traversing the familiar route. These effects provide indirect evidence for Hebbian learning during behavior, and suggest that the plastic changes occur in the rat hippocampus even when the rat traverses a familiar route after a period of absence. Supported by HFSP LT-553/95, AG12609 and MH01227.

UNSUPERVISED EXTRACTION OF SPATIAL TRAJECTORIES FROM HIPPOCAMPAL INTERNEURON FIRING RATE ENSEMBLES. D.R. Chialvo*, C.A. Barnes and B.L. McNaughton. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

Early reports have indicated that the activity of individual hippocampal interneurons exhibits spatially disperse but distinct and consistent firing patterns when rats run in a spatially extended environment (McNaughton et al., 1983; Kubie et al., 1990). Wilson and McNaughton (1993) showed that it was possible to predict the animal's location given prior knowledge of the spatial firing rate distributions in an ensemble of pyramidal cells. In the present study, however, we enquire whether it is possible to extract the animal's relative spatial trajectory on the basis of firing patterns alone, i.e. without prior knowledge of the animal's actual positions. We analyzed the ensemble activity of from 3 to 7 interneurons recorded simultaneously in the CA1-CA3 region in rats running for food reward on a rectangular (30cm x 80cm) maze. The smoothed firing time series was presented to a self-organizing map (SOM) neural net (Kohonen, 1983). The SOM discovered, without supervision, a topology-preserving mapping which predicted the precise relative spatial location of the rat while it moved on the track. The prediction error was as low as about 1 cm depending on the number of interneurons available for analysis. There are interesting similarities between the architectures of the SOM we utilized and the neural structure to which these interneurons belong, and these similarities lead to the conjecture that a similar dynamic process might occur during the tuning of pyramidal cell place fields that occurs during the first several times the rat traverses the track (see Mehta et al., this session). SPATIAL MEMORY? NEVER WITHOUT THE HIPPOCAMPUS.
V. Bohbot*, Z. Liu[1], S. L. Thurm, L. Nadel, and J. Bures[1]. ARL-NSMA, and Department of Psychology, University of Arizona, USA; [1]Institute of Physiology, Academy of Sciences of the Czech Republic.

In an attempt to explain temporally graded retrograde amnesia in humans, we disrupted hippocampal function in rats at various time intervals after they learned a spatial memory task. If the stored spatial information becomes gradually independent of the hippocampus over time, rats should be able to access this information even while the hippocampus is inactivated.

Results suggest that spatial information does not become independent of the hippocampus up to 20 weeks after learning. During bilateral Tetrodotoxin injection in dorsal hippocampus, a temporal gradient was found while rats were trained in the Morris water task, but it was caused by a decrease in effectiveness of the inactivation procedure: with time, the cortical tissue atrophied and the ventricular space increased, thus changing the injection parameters. A second temporal gradient was found while rats performed a food motivated spatial memory task on a circular platform. In this case, monitoring of hippocampal theta confirmed the successful functional blockade via inactivation of the medial septum (MS) with Tetracaine, but the number of errors measured during the MS blockade decreased proportionally to the number of errors made by the same rats under control performance. We therefore conclude that the temporal gradients obtained are not resulting from spatial information becoming independent of the hippocampus, and that resolving spatial problems can not be achieved independently of the hippocampus. HEAD DIRECTION CELLS RECORDED FROM THE LATERAL MAMMILLARY NUCLEI IN RATS. C.L. Leonhard*, R.W. Stackman, and J.S. Taube. Department of Psychology, Dartmouth College, Hanover, NH 03755.

Previous studies have identified neurons in the anterior thalamic nuclei (ATN) and postsubiculum (PoS) which discharge as a function of the animal's allocentric head direction in the horizontal plane (HD cells). Several anatomical studies have identified projections from the PoS to the lateral mammillary nuclei (LMN) and from the LMN to the ATN. Given this anatomical evidence, the present study determined whether HD cells were also present in the LMN.

Seven female, Long-Evans rats were trained in a food pellet retrieval task in a cylindrical apparatus containing a salient white cue card. Rats were then implanted with moveable recording electrodes directed at the LMN region. Following recovery from surgery, cellular activity was monitored for the presence of directional or other spatial correlates as the rats performed the food-pellet retrieval task. Seven HD cells were identified from animals in which subsequent histological analysis showed the electrodes passed through the LMN. These HD cells discharged with a mean peak firing rate of 72.7 $\pm$ 26.7 spikes/sec (range: 10.4 to 199.3 spikes/sec) and a mean directional firing range of 154.2 $\pm$ 12.2° (range: 88.3 to 180.1°). Rotation of the cue card led to a similar shift in the cell's preferred firing direction. In addition, the cells maintained their preferred firing direction upon removal of the cue card, suggesting that idiothetic cues can support LMN HD cell firing in the absence of landmark cues. A time shift analysis of the spike series indicated that the optimal discharge properties occurred when the cell's spike series anticipated the rat's directional heading by a mean of 10.2 samples (168.8 ms). This value is significantly greater than values reported for ATN and PoS HD cells and indicates that the LMN HD cell signal precedes the HD cell signal in the ATN and PoS. These data suggest a potential contribution of the LMN in the generation of the head direction signal.

TEMPORARY INACTIVATION OF THE VESTIBULAR SYSTEM DISRUPTS HIPPOCAMPAL PLACE CELL ACTIVITY. R.W. Stackman* and J.S. Taube. Department of Psychology, Dartmouth College, Hanover, NH 03755.

The hippocampal formation (HPC) is an integral component of a neural network that supports spatial navigation. It has been hypothesized that HPC place cells are neurophysiological correlates of an internal representation of space. Vestibular input to the HPC through multisynaptic pathways may be necessary for forming a representation of spatial relationships amongst environmental cues (McNaughton et al., 1994). Vestibular stimulation influences HPC place cell firing patterns (Sharp et al., 1995); and procedures used to disorient rats disrupt session-to-session stability of HPC firing fields (Knierim et al.,1995). .In addition, we have shown that vestibular lesions disrupt the directional firing of anterior thalamic head direction cells, a second type of neuron coding allocentric spatial information (Stackman & Taube, 1995). Given the potential contribution of the vestibular system to spatial information processing, we investigated the influence of vestibular inactivation upon HPC place cell activity.

Female Long-Evans rats, trained to retrieve food pellets in a cylindrical apparatus, were implanted with chronic recording electrodes directed at HPC. Upon isolation and recording of the baseline firing pattern of a HPC place cell, the rat received bilateral intra-tympanic injections of tetrodotoxin (TTX) (0.3 mM/side), under brevital anaesthesia. Place cell activity and the rat's behavior were monitored over the course of TTX action. Within 2 hr postinjection, peak deficits in vestibular function, and in the properties of the HPC place field (decreased spatial coherence, decreased information content, and increased background firing) were observed. Recovery of vestibular function and baseline firing pattern were observed by 60 hr postinjection. The recovery of the HPC place cell firing field occurred in congruence with recovery of vestibular function. These data suggest the critical involvement of the vestibular system in maintaining the specificity of HPC place cell firing, and spatial navigation.

HEAD-DIRECTION CELL ACTIVITY MONITORED FOLLOWING PASSIVE TRANSPORT INTO A NOVEL ENVIRONMENT. J.S. Taube*, R.W. Stackman, and P.A. Dudchenko. Department of Psychology, Dartmouth College, Hanover, NH 03755.

Successful spatial navigation is thought to require reliance upon both landmark cue and internally-generated cue (idiothetic, path integration) based systems. The hippocampal formation and related structures comprise an integral neural system that supports spatial navigation. The firing patterns of head direction (HD) cells in the rat anterior thalamic nucleus (ATN) are thought to represent neurophysiological correlates of allocentric spatial information. While HD cells preferentially use stable landmark cues, sensory information from idiothetic cues can support directional firing of HD cells in the absence of familiar landmarks. This experiment examined whether vestibular cues alone could support directional firing properties in HD cells when the rat was passively transported from a familiar environment to a novel one in the dark.

Female Long-Evans rats (n=10) were implanted with driveable recording electrodes directed at the ATN. HD cells were recorded in a dual chamber apparatus consisting of a cylinder attached to a rectangle via a connecting passageway (Taube & Burton, 1995). Following HD cell recording in the familiar cylinder, the rat was placed in a clear plexiglas container on a wheeled cart and passively transported in the dark from the cylinder to the novel rectangle via the passageway. Upon arrival in the rectangle, the room lights were lit and HD cells were monitored while the rat was restricted to the novel rectangle/passageway. During subsequent recording sessions HD cells were monitored as the rat was allowed access to both the cylinder and rectangle. Passive transport into the novel rectangle resulted in a mean absolute shift of 70° in the HD cell's preferred firing direction (PFD), as compared to their respective PFD in the cylinder. In contrast, previous results indicate that the PFD is generally maintained (mean shift=18°) when the rat is allowed to walk into the novel rectangle (Taube & Burton, 1995). These findings suggest that the vestibular cues available during passive transport were insufficient to allow maintenance of the PFD of ATN HD cells.

HEAD DIRECTION CELLS ARE LESS RESPONSIVE TO IDIOTHETIC CUES IN RATS WITH HIPPOCAMPAL LESIONS. E.J. Golob* and J.S. Taube. Department of Psychology, Dartmouth College, Hanover, NH 03755.

Previous studies have shown that neurons in the postsubiculum (PoS) and anterior thalamic nuclei (ATN) discharge in relation to the animal's allocentric head direction in the horizontal plane (HD cells). Both familiar landmark cues and internally-generated, idiothetic cues (e.g., vestibular, proprioceptive, motor efference copy) exert control over the preferred firing direction (PFD) of HD cells (Taube & Burton, 1995). Furthermore, if a HD cell is monitored as an animal locomotes from a familiar environment to a novel one, the cell's PFD changes very little between environments. The maintenance of the cell's PFD under these conditions is believed to be mediated through the use of idiothetic cues. Other studies have shown that hippocampal place cells are responsive to idiothetic cues, and investigators have hypothesized that the hippocampus may be important for the utilization of idiothetic-based cues in navigation (McNaughton et al., 1996). In the present experiments, we tested whether the maintenance of a HD cell's PFD, when an animal moves from a familiar to a novel environment, is dependent on an intact hippocampus.

Six female, Long-Evans rats were trained to retrieve food pellets within a cylindrical chamber containing a prominent white cue card. Following training, bilateral ibotenic acid lesions were made in the hippocampus and an electrode recording array was implanted in the PoS (n=3) or the ATN (n=3). HD cells were later recorded in a cylindrical chamber which served as the familiar environment. A door was then opened, allowing the rat to move into an alleyway which led to a novel rectangular chamber. For the hippocampal lesioned animals the mean absolute difference in PFD between the two environments was 73.0$\pm$ 24.1°. In contrast, studies using intact animals have shown that the mean absolute difference in PFD between the familiar and novel environment was 18.0 $\pm$ 2.8°. These results suggest that without an intact hippocampus, HD cells are unable to accurately process idiothetic cue information. Thus, these findings support the notion that the hippocampus is involved in mechanisms of path integration. Supported by NIMH grants MH48924, MH01286.

CONVERGENT INPUTS OF LATERAL AMYGDALA NEURONS FROM THE AUDITORY THALAMUS AND CORTEX USE DIFFERENT POSTSYNAPTIC RECEPTORS: *in vivo* INTRACELLULAR AND EXTRACELLULAR RECORDINGS. X.F. Li* and J.E. LeDoux. Center for Neural Science, NYU, NY, NY, 10003.

We examined whether individual cells in lateral amygdala (LA) receive inputs from both the auditory thalamus and cortex and whether different postsynaptic receptors contribute to the temporally separated excitations over the two pathways. All studies involved urethane anesthetized rats. *In vivo* intracellular recordings were made in 13 cells. In 12 of the 13 cells, stimulation of either pathways elicited constant latency EPSPs, indicating that these cells receive monsynaptic convergent inputs. In extracellular recordings, similarity of the spike waveforms was used to determine whether an individual cell responded to stimulation of both pathways. The effects of iontophoretic application of NMDA receptor antagonist AP5 (50mM, pH 8.0) and AMPA receptor antagonist CNQX (1mM, pH 9.0) were examined in 7 LA neurons that received convergent inputs. The spikes evoked by stimulation of auditory cortex were antagonized by CNQX in all 7 neurons, whereas AP5 only interfered with the elicited spikes in 1 cell. In contrast, for 6 of the 7 neurons, the responses evoked by thalamic stimulation were blocked by AP5. CNQX also interfered with the spikes evoked by thalamic stimulation in 5 of the 7 neurons. The slow time course of NMDA currents could provide LA cells with a mechanism to integrate the inputs arriving from the fast thalamic and slower cortical pathways. 735.2

ROLE OF NMDA RECEPTORS IN AUDITORY THALAMUS TRANSMISSION TO THE LATERAL AMYGDALA: AN *in vivo* INTRACELLULAR RECORDING STUDY. G. E.Stutzmann *, X.F. Li and J.E. LeDoux. Center for Neural Science, NYU, NY, NY, 10003.

Glutamatergic transmission and NMDA receptor activation are known to be important components of the neural circuitry connecting auditory thalamus and the lateral amygdala (LA), a pathway important in emotional learning. We used *in vivo* intracellular recording in urethane anesthetized rats to examine the role of the NMDA receptor in both LA membrane physiology and synaptic transmission to LA from the auditory thalamus (medial division of the medial geniculate body and posterior intralaminar nucleus). Baseline/control measurements were recorded from intracellularly impaled neurons. Following this, MK-801, a non-competitive NMDA receptor antagonist that crosses the blood-brain barrier, was administered systemically (i.v. or i.p., 1 mg/kg) and the same measurement series were repeated, allowing each neuron to serve as its own control. In the presence of MK-801, a 5-20 mV hyperpolarization occurred in most cells, and action potentials normally evoked by depolarizing current pulses (0.05-0.7nA) were blocked with the exception of some high threshold (possibly Ca++) spikes. Input resistance and rectification properties were not significantly affected. Electrical stimulation of the auditory thalamus evoked postsynaptic potentials in LA neurons at latencies of 4-13 msec. These were abolished or diminished in the presence of MK-801. These results provide direct evidence of NMDA receptor activation in the thalamo-amygdala circuitry, and provide insight into NMDA-dependent properties of LA neurons. SIMULTANEOUS RECORDINGS IN THE AUDITORY THALAMUS AND LATERAL AMYGDALA: EFFECTS OF FEAR CONDITIONING ON SPONTANEOUS AND TONE EVOKED ACTIVITY. J.C. Repa, S.J. Williamson*, and J.E. LeDoux. Center for Neural Science, New York University, NY, NY 10003.

Prior studies have shown that neurons in both the auditory thalamus and lateral nucleus of the amygdala (LA) exhibit enhanced responding to tones previously paired with aversive stimuli. However, because these studies have only recorded from one region at a time, the relation between neuronal plasticity in the auditory thalamus and LA is not well understood. We examined this relationship by recording, in the anesthetized rat, simultaneously from multiple single units in the LA and in regions of the auditory thalamus that project monosynaptically to the LA, namely the posterior intralaminar nucleus (PIN) and the medial division of the medial geniculate nucleus (MGm). Preliminary findings suggest that while neurons in both the auditory thalamus and LA exhibit short-latency (<30ms) enhanced responding to tones following fear conditioning, neurons in the thalamus may additionally develop longer-latency (over 100 ms) alterations of tone responses. Furthermore, by investigating when neurons in LA spontaneously fire with respect to neurons in the auditory thalamus, we have seen evidence that fear-conditioning may disrupt time-locked oscillatory firing properties between the two regions, the net result of which may be to enhance the transfer of information from the thalamus to the amygdala. 735.4

A COMPARISON OF LATERAL AMYGDALA AND AUDITORY CORTEX NEURONS DURING FEAR CONDITIONING. G.J. Quirk*, J.L. Armony and J.E. LeDoux. Center for Neural Science, New York University, NY, NY 10003.

Previous work from our laboratory has examined the conditioned responses of lateral amygdala (LA) neurons during fear conditioning in freely moving rats (Quirk et al., 1995). In order to investigate the contribution of the auditory cortex (ACx) to fear conditioning, we have used identical procedures to record from the region of auditory cortex that projects to the lateral amygdala. A total of 42 neurons were recorded and compared to previously collected data in LA. A tone CS (5 KHz, 2 sec) was either unpaired (control) or paired with a footshock US (last 500 ms of tone). ACx cells were tone responsive in similar proportions to LA and showed early tone responses (10-20 ms following tone onset). Like LA, these short latency responses showed associative plasticity. Unlike LA, a late onset conditioned response leading up the time of shock onset (500-1500 ms) was observed. Further analysis of LA neurons showed that conditioned responses occurred at tone onset and offset only. This suggests that LA may signal changes in the occurrence of a threatening stimulus, while the cortex may maintain sustained attention to the stimulus while it is present. Following 30 extinction trials, the short latency conditioned responses of LA neurons extinguished, while responses of ACx were not significantly attenuated, suggesting that ACx may be a storage site for extinction-resistant memories.

AMYGDALA CONTROL OF CORTICAL PLASTICITY IN FEAR CONDITIONING. J.L. Armony*, G.J. Quirk and J.E. LeDoux. Center for Neural Science, New York University, NY, NY 10003.

In auditory fear conditioning, pairing of a neutral acoustic conditioned stimulus (CS) with an aversive unconditioned stimulus (US) results in an enhancement of neural responses to the CS in the auditory cortex and amygdala. It is not clear, however, whether cortical plasticity governs neural changes in the amygdala or vice versa, or whether learning in these two structures is determined by independent processes. We examined this issue by recording multi- and single-cell activity in the auditory cortex of freely–behaving, amygdalectomized rats using a movable bundle of microwires. Lesions were confirmed histologically and behaviorally (by absence of any conditioned fear responses). Responses to the CS presentation, without the US, after conditioning were compared to sensitization trials (unpaired CS and US). Lesion of the amygdala did not interfere with auditory processing in the cortex, but had significant effects on some aspects of cortical plasticity. Whereas cortical cells in unoperated animals developed conditioned increases in their response to the entire duration of the 2 sec CS, cells in amygdalectomized rats only exhibited conditioned increases shortly after tone onset (< 250 ms) and immediately preceding the time when the US would have occurred (1500 ms after tone onset). These results suggest that the amygdala activates (either directly or indirectly) the cortex during fear learning and enables sustained neuronal responses to a threatening stimulus.

SHORT-TERM AND LONG-TERM HABITUATION OF THE ACOUSTIC STARTLE RESPONSE IN RATS AS A FUNCTION OF STIMULUS RISE TIME. P. K. D. Pilz and R. N. Leaton*. Tierphysiologie, Universität Tübingen, Tübingen, Germany and Department of Psychology, Dartmouth College, Hanover, NH 03755.

Short-term habituation (STH) of the acoustic startle response (ASR) appears to be intrinsic to the underlying neural circuitry, which includes the caudal pontine reticular nucleus (PnC). ASR threshold and amplitude and firing rates of PnC neurons are inversely related to stimulus rise time. Therefore, STH should be sensitive to stimulus rise time. Long-term habituation (LTH) of ASR is believed to be an extrinsic process, and its predicted relation to stimulus rise time is less obvious. We tested the effect of stimulus rise time on STH and LTH of ASR.

Albino rats were tested in a standard acoustic startle apparatus using 10-kHz, 105-dB SPL acoustic stimuli with duration of 100 ms plus the rise/fall time. In Experiment 1 rats were tested for their responsiveness to a .4-ms rise-time stimulus (RTS) following 100 presentations of either a 72-ms RTS or a .4-ms RTS. Rats were significantly less responsive to the .4-ms RTS following training with the .4-ms RTS as compared with the 72-ms RTS. In Experiment 2 rats were tested for responsiveness to a .4-ms RTS after training with either a 300-ms RTS or a .4-ms RTS. One group received the rise-time change within a session to assess STH, and one between sessions to assess LTH. A continuous .4-ms RTS was used for comparison. Trials with the 300-ms RTS produced little or no reduction in responsiveness to the .4-ms RTS in the within-session tests. However, trials with the 300-ms RTS did reduce responsiveness to the .4-ms RTS between sessions. We conclude that STH is an inverse function of stimulus rise time, as expected for an intrinsic process. LTH appeared to be independent of rise time under these test conditions, occurring even to a stimulus that produced no STH. The LTH could involve habituation of startle, per se, and/or habituation of sensitization.

NEUROTOXIC-INDUCED LOSS OF GIANT NEURONS IN THE CAUDAL PONTINE RETICULAR NUCLEUS ATTENUATES THE STARTLE RESPONSE AND THE FREEZING PROVOKED BY AN ACOUSTIC STIMULUS IN RATS. R. N. Leaton, M. Koch, P.K.D. Pilz, and H-U Schnitzler*. Department of Psychology, Dartmouth College, Hanover, NH 03755, and Tierphysiologie, Universität Tübingen, Tübingen, Germany.

Sudden, loud acoustic stimuli provoke a short-latency startle response (ASR), but such stimuli also induce a fear-like state that can be indexed by freezing. Although there is some disagreement in detail, the caudal pontine reticular nucleus (PnC) is a critical part of the neural circuitry mediating the ASR. PnC receives direct auditory input from the cochlear nucleus complex, the superior olivary complex, and from parts of the inferior colliculus. We know nothing of how the startle-eliciting stimulus reaches the neural circuitry that promotes the fear-like responses, but we do know that lesions to rostral structures like the amygdala and the periaqueductal gray attenuate these responses without affecting the basic ASR.

In the present experiment we tried to separate the startle circuit from the fear circuit early in the ASR pathway. Bilateral neurotoxic lesions were made with quinolinic acid in PnC. ASR and freezing (measured as the absence of movement in video observations) were recorded in a standard startle apparatus in adult male rats to presentations of a 107-dB SPL, 20-ms, white-noise stimulus. Lesions were evaluated by counting the number of giant cells in the PnC. Both startle amplitude and time spent freezing were significantly and positively correlated with the number of giant cells in PnC, that is to say, the lesions effectively attenuated the startle response and reduced the freezing provoked by the auditory stimulus. This laboratory previously showed, using neurotoxic lesions, that the number of giant cells in PnC is strongly correlated with startle amplitude. It now appears that both the startle-inducing and fear-inducing aspects of an auditory stimulus depend upon the integrity of the giant neurons of the PnC.

ASSOCIATIVE AND NON-ASSOCIATIVE LEARNING INDUCED BY CONTEXTUAL FEAR CONDITIONING OF C57BL/6J MICE. Jelena Radulovic*, Snezana Milanovic, Olgica Laban, Oliver Stiedl and Joachim Spiess. Dept. Mol. Neuroendocrinology, Max Planck Inst. Exp. Med., 37075 Goettingen, Germany.

The present experiments were carried out with the objective to evaluate freezing and locomotor activity in male C57BL/6J mice after contextual fear conditioning. For acquisition of learning, mice were exposed to a single pairing of contextual cues (box 1, 180 s) and electric foot shock (0.7 mA, 2s). A control group was exposed to context without foot shock. The retention test was performed by exposure to the distinctive (box 1) or the altered (box 2) context 24 hours or 6 days after acquisition. Habituation was investigated in mice subjected to an identical conditioning paradigm, and then daily exposed on 5 consecutive days to altered context (box 2, 180s). On day 6, mice were exposed to distinctive (box 1), habituated (box 2) or novel (box 3) context. Non-shocked mice were habituated in an identical manner and then behaviorally tested in the habituated and novel context. Re-exposure of mice to the conditioning context (box 1) 24 hours after acquisition resulted in a significant increase of freezing and decrease of locomotor activity in comparison to non-shocked controls, but their behavior did not differ significantly from conditioned mice exposed to altered context (box 2). Behavioral tests performed 6 days after conditioning also revealed high freezing in box 1 and box 2. However, freezing of the conditioned mice in box 1 was interspersed with hyperactivity. Because of these hyperactivity intervals, the mean activity scores were increased to values observed with mice exposed to context only. Conditioned mice exhibited significantly lower activity and higher freezing in the first 3 days of habituation when compared to mice exposed to context without foot shock. The habituation procedure completely abolished freezing after exposure of conditioned mice to novel context (box 3), whereas exposure to the distinctive context resulted in high freezing scores. These results suggested that behavior induced in C57BL/6J mice by the fear conditioning procedure was characterized by both associative and non-associative (sensitization) learning, and that interference by sensitization can be eliminated by habituation in an environment lacking stimulus-associated cues. A 20-Hz NEURAL OSCILLATOR UNDERLIES THE ACQUISITION OF CONDITIONED EYELID RESPONSES. J.A. Domingo, A. Gruart* and J.M. Delgado-García. Lab. de Neurociencia, Fac. de Biología, 41012-Sevilla, Spain.

The nictitating membrane/eyelid response is an excellent model for the study of the acquisition of new motor skills in mammals. The appearance and consolidation of conditioned nictitating membrane and/or eyelid responses is a progressive process that builds up following the repeated presentation of paired conditioned and unconditioned stimuli (CS-US). The search coil in a magnetic field technique allows the precise recording of lid movements for the quantitative analysis of the frequency components of learned eyelid responses.

Experiments were carried out in cats following the European Union and Spanish legislation for the use of animals in chronic experiments. Animals were implanted bilaterally with search coils in the upper lid and with EMG electrodes in the orbicularis oculi muscle. Trace and delayed conditioning paradigms were used. The US always consisted of a 100 ms, 3 Kg/cm^2 air puff applied to the left cornea. The CS consisted of 350 ms tones or of short (20 ms) and weak (0.8 Kg/cm^2) air puffs applied to the ipsilateral eye, both starting in advance (≤250 ms) to the US.

Results indicated a quantal appearance of conditioned responses (CRs) that built up by a successive increase in the number of eyelid downward sags (≈50 ms in duration) with the repeated presentation of paired CS-US stimuli. The Fourier analysis of the data indicated a dominant frequency of ≈20 Hz when measured in the acceleration profiles of lid displacements or in EMG recordings. The power spectra of the dominant frequency increased with the number of sags and/or with the amplitude of individual quantum of lid downward displacement. Modifications in the CS-US interval changed the amplitude but not the frequency of the sags, when compared for lid downward movements of the same final amplitude. The present data suggest the presence of a fast oscillation (≈20 Hz) that underlies the acquisition of conditioned eyelid responses. (Supported by DGICYT PB93-1175).

SINGLE NEURON ACTIVITY IN CA1 HIPPOCAMPUS DURING THE ACQUISITION OF TRACE EYEBLINK CONDITIONED RESPONSES. M.D. McEchron* and J.F. Disterhoft. Cell and Molec. Biology, Northwestern University Med. Sch., 303 E. Chicago Ave., Chicago, IL 60611 USA.

The hippocampus is involved in the learning of a number of behaviors, including those that require temporal processing of information. Eyeblink conditioning has been shown to be hippocampally dependent when a trace interval (500 ms duration) separates tone conditioned stimuli (CS; 100 ms duration) paired with corneal airpuff unconditioned stimuli (US; 150 ms duration) (Solomon et al., 1986; Moyer et al., 1990). We and others have provided *in vivo* and *in vitro* electrophysiological evidence that learning-related neuronal changes occur in CA1 after trace eyeblink conditioning. In the present study we examined the activity of CA1 single neurons during the acquisition of trace eyeblink conditioned responses. New Zealand albino rabbits received 12 days of either trace eyeblink conditioning (80 CS-US trials/day) or pseudoconditioning (80 CS and 80 US trials/day). Over 400 CA1 neurons with pyramidal cell firing characteristics were recorded extracellularly and separated with DataWave software. These cells were held for at least 1 or 2 days of training. Changes in activity were measured with standard scores which compared the amount of activity during the trial to pretrial activity. Neurons from both trace and pseudoconditioned animals exhibited heterogeneous response profiles in all phases of training. These responses included: significant increases and decreases in unit firing to the CS and US, no change to the CS or US, and silent cells which rarely fired (<0.5 Hz). Analyses revealed that early in training (Days 1-5) as eyeblink conditioning rates showed the greatest increases, conditioned animals exhibited increases in unit activity during the CS, trace period, US, and period following the US compared to pseudoconditioned animals. Later in training (Days 8-12) after conditioning was maximal, conditioned animals showed decreases in unit activity during the trace, US, and period after the US compared to pseudoconditioned animals. Cells from conditioned animals also showed increased background firing rates later in training, suggesting that these cells may have a higher baseline level of excitability following conditioning. NEURONAL ACTIVITY IN THE MEDIAL PREFRONTAL CORTEX DURING CLASSICAL EYEBLINK AND NICTITATING MEMBRANE CONDITIONING IN THE RABBIT. D.A. Powell*, Brian Maxwell, and James Penney. VA Medical Center and Unversity of South Carolina, Columbia, SC 29209.

In two experiments, rabbits received classical eyeblink or nictitating membrane conditioning in which either periorbital shock or a 3 psi airpuff was the unconditional stimulus (US). Tones served as conditional stimuli (CSs) in both cases. Multiple unit activity in the medial prefrontal cortex and CS-evoked heart rate changes were also recorded. Nonassociative control groups received explicitly unpaired presentations of either the eyeshock or airpuff US, and the tone CS. Although both eyeblink and nictitating membrane conditioning occurred over 4 days of acquisition, CS-evoked increases in neuronal activity occurred only in the paired group that received the eyeshock US. CS-evoked decelerations in heart rate were also found only in the group that received the periorbital shock US. These findings reinforce the idea that the neuronal activity associated with medial prefrontal function underlies an emotional component of associative learning, which may be essential for the attentional aspects of learning and memory.

SINGLE UNIT ACTIVITY IN THE MEDIODORSAL NUCLEUS OF THE THALAMUS DURING CLASSICAL HEART RATE CONDITIONING IN THE RABBIT. Mark Chachich*, Shirley Buchanan & D.A. Powell. VA Medical Center and University of South Carolina, Columbia, SC 29209.

Rabbits received two sessions of differential heart rate conditioning in which tones served as CS+ and CS-. On subsequent test days neuronal activity was recorded from single units in the mediodoral nucleus of the thalamus (MD) during unreinforced presentations of CS+ and CS-. Approximately a third of the cells in MD showed significant increases in discharge in response to either the presentation of the CS+ or the CS-. Two general patterns of discharge were observed. Approximately half the reactive cells showed immediate increases at tone onset, which declined gradually during CS presentation. The remaining cells showed increases in discharge that changed gradually during the CS, reaching their greatest discharge at tone offset, when the US would be expected to occur. Approximately half these cells showed significantly greater discharge to CS+, and half significantly greater discharge to CS-. Thus, some MD cells appear to signal aversive contingencies, while others signal relative "safety". Many reactive cells were significantly correlated with the magnitude of the decelerative HR CR, but the unreactive cells were not.

PAVLOVIAN CONDITIONING OF THE MAUTHNER NEURON REFLEX IN THE UNRESTRAINED GOLDFISH, *CARASSIUS AURATUS*. M. M. Nikoletseas[1], E. G. Antzoulatos[1], A. D. Konstantinidou*[2] and A. C. Kalyva[1]. [1]Dept. of Psychol., Deree, The American College of Greece, A. Paraskevi, GR-15342; [2]Dept. of Experimental Physiol., Sch. of Medicine, Aristotelian Univ., Thessaloniki, GR- 54006, Greece.

The giant Mauthner neuron mediates the fast startle reflex in the goldfish. This is a stereotypic, co-ordinated response that is initiated by novel or noxious stimulation and results in rapidly displacing the fish from the vicinity of the stimulus. Unrestrained goldfish were individually trained for eleven days, twenty trials per day. There were four conditions: delay 800 ms interstimulus interval (ISI, D800), delay 300 ms ISI (D300), trace 800 ms ISI (T800), and trace 300 ms ISI (T300) at an intertrial interval of 100 s. The conditional stimulus (CS) was a light (approx. 5×10^6 lumens) flashing at 90 Hz. The unconditional stimulus (US) was a constant current shock of 50 mA, 5 ms duration. The reflex was recorded by the use of a force transducer placed in the tank. Signals were fed into a computerscope for storage and analysis. A US alone (USa) group was also employed as control for temporal conditioning. Gradually developing conditioned responses (CRs) were observed in the D800, and T800 groups and reached peak frequency in seven to nine days. No conditioning was observed in the D300, T300 or USa groups. Better conditioning was obtained in the D800 group ($p < .01$). Most CR latencies ranged from 300 to 600 ms. Most UCR latencies were 5-8 ms. The failure to obtain conditioning of a skeletal response with an ISI in the known optimal range of 200-500 ms (300 ms groups) may be related to our finding that CR latency is longer than 300 ms. INHIBITORY LONG-TERM POTENTIATION UNDERLYING LONG-LASTING HABITUATION OF GOLDFISH ESCAPE RESPONSE. Y. ODA*, K. KAWASAKI, M. MORITA, H. MATSUI, and T. MAEJIMA. Dept. Biophys. Engin., Fac. Engineering Science, Osaka Univ., Osaka 560, Japan.

Previously we demonstrated that long-term potentiation (LTP) of the glycinergic inhibitory synapses on the goldfish Mauthner (M-) cell is induced *in vivo* by tetanization of the auditory (VIII) nerve (PNAS, 89:440-443, 1992; J. Neurophysiol., 74:1056 -1074, 1995). The M-cell initiates a fast startle reflex in response to sound stimulus. The reflex is produced by excitatory transmission from the VIII nerve to the spinal motoneuron via the M-cell, which is concurrently modulated by feedforward inhibition on the M-cell. Therefore, if such LTP occurs in free swimming fish, it should result in depression of M-cell triggered behavior. In the present study, we examined first whether applying a repeated sound stimulus (300 to 800 Hz) instead of the VIII nerve tetanization gives rise to an LTP of synaptic connections onto the M-cell. The test synaptic responses were evoked in the M-cell on both sides by electrical stimulation of posterior branch of VIII nerve. The inhibitory synaptic conductance in the test response exhibited LTP (lasting >40 min) with an increase of $76 \pm 18\%$ contralaterally (14 cells) and $79 \pm 11\%$ ipsilaterally (12 cells). In contrast, electrotonic coupling potential recorded in the lateral dendrite of the ipsilateral M-cell did not show any significant potentiation ($4.4 \pm 3.7\%$, n=8). Secondly, we examined whether the goldfish startle response can be modified by the conditioning sound. Probability of escape response evoked by a ball falling onto the water was stable in control (for >70 min). After applying subthreshold sound stimulus with an underwater loudspeaker, it decreased to $26 \pm 10\%$ (9 fish) of control and the habituation was maintained for more than 40 min. These findings suggest that natural sensory input induces an inhibitory LTP of the identified pathway, and that the enhanced feedforward inhibition causes a long-lasting habituation of the M-cell initiated startle response. This study thus relates LTP to behavioral modification. Supported by Japanese grants-in-aid for Higher-Order Brain Processes.

DIRECTION OF CHANGE IN SYNAPTIC EFFICACY FOLLOWING PAIRING DEPENDS ON THE TEMPORAL RELATION OF PRESYNAPTIC INPUT AND POSTSYNAPTIC SPIKE DURING PAIRING. C. Bell*, V.Han, K. Grant and Y. Sugawara. R.S.Dow Neurological Sciences Institute, Portland, OR 97209.

This study extends previous *in vivo* studies of plasticity in the cerebellum-like electrosensory lobe (ELL) of mormyrid fish to an *in vitro* slice preparation. Previous studies showed that the responses of ELL cells to central inputs depends on prior pairing with electrosensory stimuli or intracellular current pulses. A large broad spike of presumed dendritic origin, appeared to be critical for this plasticity.

Transverse slices of ELL were maintained in an interface chamber. Two stimulating electrodes, S1 and S2, were placed at different levels of the molecular layer to stimulate separate sets of parallel fibers. The Purkinje-like cells of ELL were recorded with sharp microelectrodes. Parallel fiber stimuli that evoked short latency epsps or epsp-ipsp sequences were paired at various delays with a brief (25 ms) intracellular current pulse that evoked a broad spike. Both S1 and S2 were usually given during the same pairing but at different delays. Pairing was usually at 1 Hz. Epsp amplitudes were measured at 0.1 Hz before and after pairing.

Significant depression (10 - 60%) and potentiation (10 - 100%) were obtained as a result of pairing. Both depression and potentiation (10 - 100%) were seen to last at least 25 minutes. Epsp depression was seen after pairings in which the broad spike was evoked at delays of 0 to 60 msec following the epsp. Epsp facilitation was seen after pairings at all other delays including those in which the broad spike was evoked only 10 ms before the epsp. The ipsp also appeared to be affected by pairing, decreasing when the epsp increased and vice versa.

Thus, the plastic change for synaptic inputs that arrive just before a postsynaptic response is opposite to the plastic change for inputs that arrive after the response or too early to affect it. This may reflect a different treatment of inputs which could cause or affect a postsynaptic response from inputs which could not do so. (Supported by NIMH grant MH-49792)

SYNAPTIC PLASTICITY IN AN AMYGDALA-CORTICAL SYSTEM STUDIED *IN VITRO*. J.M.Beggs* and E.W.Kairiss. Department of Psychology and Neuroengineering and Neuroscience Center, Yale University, New Haven, CT 06511.

Converging empirical and theoretical evidence suggests that cortical and limbic areas are engaged interactively in mammalian memory. We have been using the *in vitro* amygdala-cortical slice as a model system to gain insight into the synaptic interactions that might underlie mnemonic processing in these areas. We have previously identified synaptic plasticity in both the intracortical (Kairiss & Beggs, *Soc. Neurosci. Abstr. 19:1445*) and amygdala-cortical (Beggs & Kairiss, *Soc. Neurosci. Abstr. 20:1415*) pathways. Here we extend these observations to the determine whether stimulation of the amygdala input can facilitate plasticity, in the cortex, of a coactivated cortical input.

Coronal slices 400μm thick were taken from rat brain (-2.2 to -3.8 bregma) and contained the lateral nucleus of the amygdala (LA) and adjacent perirhinal and agranular parietal insular cortices (Prh-aPI). Baseline stimulation was applied to LA and adjacent temporal cortex areas with, low-frequency (.033 Hz) pulses. High-frequency (HF) stimulation (100 Hz) could be delivered to one or both inputs. Extracellular recordings were performed in Prh-aPI at a location corresponding to Layers II/III.

As in our previous work, a long-lasting increase of the response recorded in Prh-aPI could be induced by HF stimulation of either the LA or cortical input. Associative interactions were studied by pairing HF cortical stimulation (whose strength was adjusted to be below threshold for the induction of plasticity) with HF LA stimulation. In 9/32 cases, this resulted in a long-lasting increase (at least 20% for longer than 15 min) of the extracellularly-recorded Prh-aPI response to the cortical stimulus.

These results suggest that, under the appropriate conditions, the input from LA might serve as a "reinforcement signal" to consolidate intracortical plasticity. Future studies will will attempt to identify the specific neural circuits that are involved in amygdala-cortical interactions and their neuropharmacological properties. CENTRAL (BRAIN) MECHANISMS INVOLVED IN LEARNED CARDIOVASCULAR ADJUSTMENTS TO EXERCISE (LCVAE). S.I. Chefer, M.I. Talan* and B.T. Engel. Lab.of Behavioral Sciences, National Institute on Aging, Baltimore,MD 21224.

Four monkeys were operantly conditioned to slow heart rate (HR), to exercise (lift weights), and to attenuate the tachycardia of exercise (LCVAE) by combining these two skills. During counterbalanced, 17-min sessions of exercise (E) or exercise and attenuation of HR (C), electrical brain stimulation (EBS) was delivered to one of several brain regions involved in cardiovascular control. The magnitude of HR change was compared between the E and C sessions with and without EBS using ANOVA. Four groups of effects have been established. EBS of ventral anterior and mediodorsal thalamic nn. and cingulate cortex resulted in the first group of effects - EBS interacted with learned cardiovascular adjustment to exercise (LCVAE) by exacerbating the differences between HR changes in E and C. During stimulation of n. hypothalami dorsomedialis, ventromedial group of thalamic nn. and pedunculus cerebri the second group of effects was shown: EBS-induced change in HR was superimposed on the tachycardia of exercise without interfering with LCVAE. Stimulation of intralaminar group of thalamic nn., n. caudatus or c. callosum, which constitute the group 3 of the effects, exacerbated the tachycardia in both E and C, but eliminated the LCVAE. The effects of EBS in the sites of the fourth group (ventrolateral thalamic n., and anterior group of thalamic nn.) were suppressed by exercise and did not affect LCVAE. The data suggest that there are several different mechanisms involved in central command and mediating conditioning behavior. Most of the limbic thalamus nuclei participate in learned cardiovascular adjustments to exercise.

THE SYNCHRONY OF FAST (25-50 Hz) CORTICOTHALAMIC OSCILLATIONS AND THE INCREASE OF ITS SPATIAL COHERENCE AFTER CONDITIONAL REINFORCEMENT. D. Neckelmann*, F. Amzica and M. Steriade. Lab. Neurophysiology, Sch. Medicine, Laval University, Quebec, Canada G1K 7P4.

Multisite, local field potential and unit-discharge recordings from cortical areas 4, 5, 7 and 17, as well as from the intralaminar central lateral (CL) and lateral geniculate (LG) thalamic nuclei, were made in chronically implanted behaving cats. Under control condition, the synchrony of fast oscillations between different recording sites was studied. Fast activities were correlated between functionally linked cortical foci or cortical and thalamic sites (Steriade et al., J. Neurosci. 1996,16:392; *ibid.*, 16:2788). The correlations were a function of distance.

Subsequently, in a conditional reinforcement paradigm, a LED flash (duration 20 ms) was presented to the animal every 10 sec and, contingent upon the presence of a burst of fast EEG activity within two seconds after the LED presentation, a squirt of water was delivered into the oral cavity. [The animal had not access to water the last 12 hours before the experimental session.] The burst detection (automated, at least 5 cycles of fast waves with a suprathreshold amplitude) was performed on the cortical EEG from motor area 4. A progressive increase in the number of bursts fulfilling the criteria was observed over the seven recording sessions ($p<0.0001$). *The peak of the mean correlations between related cortical and thalamic foci (e.g. cortical area 4 and 5, or area 4 and CL) increased up to 60 percent in these sessions relative to control condition.* A three-day extinction procedure with LED presentations without water reward, reduced the peak of the mean correlation of fast activity back to the levels of control condition. After the extinction, a second similar conditional reinforcement procedure was performed over seven more recording sessions, but this time water delivery was contingent upon bursts of fast activity in the visual cortex. Similar increases in the number of bursts fulfilling the criteria and in the peak of the mean correlations were again observed.

GLUTAMATE RECEPTORS CONTRIBUTE TO SYNAPTIC TRANSMISSION BETWEEN THE BRACHIUM OF THE INFERIOR COLLICULUS AND THE MEDIAL GENICULATE NUCLEUS. T.J. Webber, E.J. Green, N. Schneiderman and P.M. McCabe*. Dept. of Psychology, University of Miami, Coral Gables, FL 33124

Previous work from this laboratory (McEchron et al., J. Neurosci., 16, 1273-83, 1996) has demonstrated that monosynaptic inputs from brachium of the inferior colliculus (BIC) to the medial subdivision of the medial geniculate nucleus (mMG) strengthen as a result of associative conditioning with an acoustic conditioned stimulus (i.e., fear conditioning). The purpose of the present study is to determine whether this pathway is glutamatergic.

In New Zealand albino rabbits, bipolar stimulating electrodes were stereotaxically implanted in BIC and recording stereotrodes (attached to 30g cannulae for delivery of drug) were positioned in mMG. Single pulses (150 μs, 100-350μA) delivered to BIC resulted in short latency (<5ms) responses in mMG. BIC-evoked single unit activity was recorded from mMG before, during, and at several intervals after injection of the non-NMDA antagonist, CNQX (10μM, 20 - 200nl).

Injection of CNQX into mMG significantly attenuated the short latency BIC-evoked responses in the vast majority of cells tested. CNQX also attenuated the spontaneous activity in many of these cells. These findings suggest that the monosynaptic pathway from BIC to mMG is glutamatergic. Current work involves the use of the NMDA antagonist, AP5, to assess the role of NMDA receptors in the synaptic transmission of the BIC-mMG pathway. The results will have implications for the mechanisms of synaptic plasticity observed during associative learning.

POSTTRAINING ELECTRICAL STIMULATION OF VAGAL AFFERENTS WITH CONCOMITANT EFFERENT INACTIVATION ENHANCES MEMORY STORAGE PROCESSES IN THE RAT. K.B. Clark*[1], D.C. Smith[1], D.L. Hassert[1], R.B. Browning[2], D.K. Naritoku[3], and R.A. Jensen[1]. Departments of Psychology[1] and Physiology[2], Southern Illinois University, Carbondale, IL 62901; Departments of Pharmacology and Neurology[3], SIU School of Medicine, Springfield, IL 62794.

Recently our laboratory (Williams & Jensen, 1991, 1993) demonstrated that subdiaphragmatic vagotomy attenuates the memory-enhancing and -impairing effects of peripherally acting 4-OH amphetamine and Leu-enkephalin respectively. Additionally, posttraining vagus nerve stimulation (VNS) enhances retention in an intensity-dependent fashion (Clark, Krahl, Smith, & Jensen, 1995). Together these findings suggest that substances which do not freely pass the blood-brain barrier may influence memory storage processes by activating peripheral receptors that in turn send neural messages to the brain via the vagus. However, since VNS activates both afferent and efferent pathways, it is possible that the observed effects may be due to stimulation of peripheral organs that then indirectly modulate memory storage. To evaluate this hypothesis male Long-Evans rats were implanted with cuff-electrode/catheter systems along the left cervical vagus. Forty-eight hours after surgery, animals received an infusion of lidocaine hydrochloride (75.0 mM, 3.0 μl, 1.0 μl/min) below the point of VNS to block descending action potentials. Each rat was then trained 10-min later in an inhibitory avoidance task (0.75 mA; 1.0 s footshock). Immediately after training each rat received either sham VNS or VNS (0.5 ms biphasic pulses; 20.0 Hz; 30 s; 0.2, 0.4, or 0.8 mA). Inactivation of efferent pathways was verified during VNS by recording from a probe placed caudal to the catheter. Memory, tested 24 h later, was enhanced by VNS ($H = 9.8$, $p < .05$). An inverted U-shaped function was seen (Control = 32 s; 0.2 mA = 266 s; 0.4 mA = 620 s; 0.8 mA = 293 s). These findings suggest that ascending vagus fibers carry messages that lead to the enhancement of memory storage and that activation of peripheral organs by vagal efferents do not contribute to this effect. (This research was supported by a grant from Cyberonics, Inc.)

NEURAL PLASTICITY IV

736.1

SELECTIVE LIPID BINDING BY SYNELFIN, A PRESYNAPTIC PROTEIN IMPLICATED IN NEURAL PLASTICITY AND ALZHEIMER'S DISEASE J.M. George*, W.S. Davidson, M.K. Urban, R.J. Perrin, W.S. Woods & D.F. Clayton. Depts. of Cell & Struc. Biol., and Biochemistry, Univ. of Illinois, Urbana, IL, 61801.

We previously identified a soluble presynaptic protein, synelfin, which is regulated in the zebra finch song circuit during the critical period for song learning, suggesting that it might serve to modulate neural plasticity (Neuron 15:361). The human form (NACP) is the precursor to an intrinsic component of Alzheimer's amyloid (PNAS 90:11282). Related sequences have been identified in both rat (synuclein) and bovine (PNP-14), although the function of this intriguing protein remains unknown.

Analysis of synelfin's secondary structure reveals the presence of a repeating 11-mer motif which closely resembles the class A_2 lipid-binding α-helices of the apolipoproteins, leading us to hypothesize that synelfin might bind lipids. Here we show binding of recombinant synelfin to synthetic lipid vesicles as assayed by gel filtration chromatography. Synelfin binds vesicles made either from a crude brain extract enriched in phosphatidylserine (PS) or from 10% PS in phosphatidylcholine (PC), but not from PC alone. Experiments are underway to determine whether this represents specificity for PS or a more general preference for negatively charged phospholipids. Additionally, we have produced recombinant synelfin protein with mutations at specific sites to address the structural requirements for lipid binding. An understanding of synelfin's molecular interactions should help illuminate its normal physiological function [Supported by NIH: NS 25742].

736.2

EXPERIENCE-DEPENDENT ALTERATION OF SYNELFIN EXPRESSION IN THE RAT CEREBELLUM. R.A. Swain*, A.D. Birnbaum, J.D. Lambert, S.A. Irwin, J.M. George, D.F. Clayton, & W.T. Greenough. Neurosc. Prog., Depts. of Psych., Biology, Cell and Struct. Bio., & Beckman Inst., Univ. of Illinois, Urbana, IL 61801.

The morphological sequelae of skilled motor acquisition (synaptogenesis) can be discriminated from those structural alterations occurring as a result of repetitious motor activity (angiogenesis) (Black et al., 1990). Experience-dependent morphological modifications of the brain such as these must involve alterations of protein expression. A novel presynaptic protein has been identified independently in several laboratories (synuclein, PNP-14, NACP, synelfin), and has been found to increase during periods of developmental synaptogenesis in rats (Shibayama-Imazu et al., 1993). Studies in songbirds showed the protein's expression is dynamically regulated during the critical period for song learning, suggesting an involvement with the synaptic modifications that occur at this time (George et al., 1995). In the present study, we used a cross-reactive antibody originally raised against canary synelfin to examine whether synelfin levels are altered in the adult rat cerebellum following motor skill acquisition or repetitive motor activity. Male and female Long-Evans hooded rats were trained for 5 days on either an elevated 10-task obstacle course (skill acquisition), an elevated alleyway (minimal exercise), a running wheel (extensive exercise) or maintained individually in standard laboratory cages. Synelfin expression, as measured immunocytochemically, was significantly down-regulated by extensive motor activity. Synelfin levels were decreased in the molecular but not granular layers of the cerebellar paramedian lobule in the running wheel group. This effect was even more pronounced in the deep cerebellar nuclei.

736.3

MODULATION OF VISUAL CORTEX SYNELFIN IMMUNO-REACTIVITY IN RATS REARED IN A COMPLEX ENVIRONMENT. C.X. Stamoudis, T.A. Comery, K.E. Armstrong*, J.M. George, D.F. Clayton and W.T. Greenough. Neurosc. Prog., Depts. of Psych., Biology, Cell and Struct. Bio., and Beckman Inst., Univ. Illinois, Urbana, IL 61801.

Rearing in a complex environment results in increased synapse number, spine density and dendritic branching in various brain regions. The morphological plasticity observed in this paradigm requires plasticity on the molecular level, including increased mRNA transcription and protein synthesis. Synelfin, a newly discovered brain specific protein, may play a role in the observed neuronal plasticity. Synelfin is down regulated following the period of song acquisition in zebra finches, and is also homologous to a protein component of Alzheimer's senile plaques (George et al, 1995). In an attempt to investigate synelfin's possible role in synaptic plasticity rats (aged 28-32 days) were housed either individually or in a toy and object filled environment for 5, 15 or 30 days. Densitometric analysis was used to measure the level of synelfin immunoreactivity in the visual cortex. Animals housed in enriched environments for 30 days showed significantly decreased synelfin immunoreactivity relative to both isolated animals and animals housed in a complex environment for either 5 or 15 days. This decrease in immunoreactivity may represent either an actual decrease in synelfin levels or an alteration in protein conformation. Although the function of synelfin is not known, these results indicate that expression or modification of the protein is sensitive to behavioral experience. Supported by MH 35321 and NS25742.

736.4

NEURONAL STIMULATION TRIGGERS SEQUENTIAL BINDING OF EGR FAMILY MEMBERS TO THEIR RESPONSE ELEMENT K. J. O'Donovan* and J. M. Baraban. Dept. of Neuroscience, Johns Hopkins University School of Med., Baltimore, MD 21205

The Zif268 transcription factor and its closely related family members (Egr-2 and Egr-3) are rapidly induced in brain neurons following synaptic stimulation. Accordingly, these immediate early genes may orchestrate changes in gene expression underlying stimulus-induced neuronal plasticity. As these factors bind to the same consensus sequence, we have used gel shift assays to monitor changes in their binding to their common response element. We have shown previously that seizure activity induces a rapid (1 HR) and transient increase in a band that corresponds to the Zif268 DNA binding complex and that it returns to basal levels by 4 hours. In addition, we have noted a delayed increase in two additional bands that begins at 4 hours. These delayed bands appear to represent Egr-3 isoforms since they co-migrate with recombinant Egr-3 in gel shift assays and on SDS-PAGE following UV-crosslinking. *In situ* hybridization studies of the hippocampus indicate that Zif268 and Egr-3 mRNAs are induced in parallel post seizure in dentate granule cells. However, Zif268 mRNA levels return to baseline by 2 hours while the increase in Egr-3 mRNA persists for up to 8 hours. These findings appear to indicate that Zif268 and Egr-3 exhibit sequential binding to their common response element and presumably confer different transcription regulatory properties to this *cis* element. Supported by NIMH and NIDA.

736.5

A NOVEL, BRAIN SPECIFIC FACTOR THAT BINDS TO THE EGR RESPONSE ELEMENT. E. Taira and J. M. Baraban* Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med. Baltimore, MD 21205

Egr-1/NGFI-A/zif268 is a transcription regulatory factor thought to mediate changes in gene expression underlying stimulus-induced neuronal plasticity. Egr-1 and several closely related Egr family members bind to the same double-stranded DNA consensus sequence, referred to as the Egr response element. Recent studies suggest that protein complexes that bind preferentially to single-stranded versions of other response elements may also function as transcription regulatory factors. Accordingly, we have examined this possibility for the Egr response element.

Using single-stranded probes containing the Egr consensus sequence in gel mobility assays, we have detected a novel factor that binds to the Egr response element in a strand-specific manner. Among brain regions, this binding activity is most abundant in cerebellum and brain stem with lower levels present in forebrain regions, but is undetectable in a variety of peripheral tissues assayed, including liver, muscle and kidney. Thus, this novel factor may modulate the interaction of the previously identified Egr family members with their cognate cis element in brain. Supported by NIDA and NIMH.

736.6

CLONING OF TWO HOMEOBOX GENES IN *APLYSIA* L.R. Olson*[1] R. Marois [2], F. Ruddle,[3] and T.J. Carew[1,3]. Dept. of Psychology,[1] Interdepart. Neurosci. Prog.,[2] and Dept. of Biology,[3] Yale Univ., New Haven, CT 06520.

Homeobox genes are known to be important in developmental functions such as cell differentiation and neurogenesis. Several lines of evidence suggest that some homeobox genes may also have a role in the molecular basis of long-term synaptic plasticity: (1) they are expressed in the *adult* nervous system; (2) they are regulated by intra- and extra-cellular signals (e.g. cAMP, NMDA) already implicated in long-term plasticity; and (3) they regulate and coordinate the expression of numerous effector genes, including some involved in transmitter synthesis. We have begun to explore the possible role of homeobox genes in adult neuronal function by asking whether they are involved in the formation and maintenance of long-term memory in the marine mollusc *Aplysia*.

As a first step, the present work describes the cloning of two homeobox genes in *Aplysia*. We have previously examined the expression pattern of an engrailed-like protein (Marois et al., 1994) and of a POU-like protein (Olson et al., in prep) in developing and adult *Aplysia*. To isolate the corresponding genes, we have used genomic DNA and degenerate primers for both engrailed and POU domain (class III) genes. A 220 bp fragment, a size that is similar to the homeodomain found in other molluscs, was amplified using PCR with engrailed-specific primers; sequencing is presently underway. PCR with POU-specific primers yielded a 350 bp product that has 85% sequence homology to *Drosophila cfla* and mouse *scip*. This represents the first POU gene cloned in the molluscan phylum.

Having identified these two classes of homeobox genes in *Aplysia*, it will now be of interest to examine their expression during both development and long-term memory.

736.7

REGULATION OF *C-FOS* EXPRESSION BY NEURAL IMPULSES: RELATION BETWEEN STIMULUS PATTERN, INTRACELLULAR CALCIUM, AND CREB PHOSPHORYLATION. R.D. Fields*, K. Itoh, B. Stevens, and F. Eshete. LDN, NICHD, NIH, Bethesda, MD 20892.

CREB is an important transcription factor regulating gene expression in response to neural impulse activity during development and synaptic plasticity. Our previous research shows that neuronal gene expression can be regulated by specific patterns of impulse activity. To determine the physiological basis for this pattern-specific signal transduction, we have monitored the relation between neural impulse pattern, intracellular calcium transients, phosphorylation of CREB at serine 133, and *c-fos* expression in primary cultures of mouse dorsal root ganglion neurons. The results show that transcription of *c-fos* is largely independent of the number of action potentials in the stimulus, but well correlated with the interval between successive bursts of action potentials. The interval between calcium transients correlated with *c-fos* expression better than the amplitude of the calcium transient. Phosphorylation of CREB paralleled the rapid rate of increase in $[Ca^{++}]_i$, but $[Ca^{++}]_i$ recovered to basal levels much faster than CREB dephosphorylation. As a result of this non-linearity, phosphorylation of CREB was not well correlated with *c-fos* expression for some temporal patterns of stimulation. The results suggest the best relation between *c-fos* transcription and action potential stimulation is the interval between bursts in trains of action potentials, and that CREB phosphorylation at serine 133 need not be the limiting factor in *c-fos* transcription.

Funded by the NICHD.

736.8

THE ACTIVATION OF CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE II AFTER GLUTAMATE STIMULATION IN HIPPOCAMPAL SLICES. S.E. Tan* and S.S. Chen*. *Dept. Psychology, *Dept. Neurology, Kaohsiung Med. Coll., Taiwan, R.O.C.

Two forms of long-term potentiation (LTP), N-methyl-D-aspartate receptor (NMDAR)-dependent and non-NMDAR-dependent, have been reported in hippocampal CA1 and CA3, respectively. The present study examined the activation of CaM-kinase II (calcium/calmodulin-dependent protein kinase II) in CA1 and CA3 areas after glutamate stimulation.

Rat hippocampal slices were incubated in a balance salt medium and maintained at 34°C, under a humidified 95% O_2/5% CO_2 atmosphere. After 1 hr of recovery period, one of the drugs (EGTA, DL-APV, CNQX, AP3, nitrendipine, KN-62, staurosporin, and H-89) was injected into the insert where the slices were present. After 15 min of drug pre-incubation, the slices were stimulated with glutamate/glycine (100 μM/1 μM) for 15 min. The slices were then removed. CA1 and CA3 areas were cut apart and saved at -70°C until *in-vitro* CaM-kinase II assays. Glutamate stimulation enhanced the percentage of calcium-independent CaM-kinase II activity in CA1 area. This enhancement was suppressed by KN-62. The elevation in the Ca^{2+}-independent kinase activity in CA1 area was also depressed with EGTA and DL-APV, suggesting that the glutamate stimulation effect was mediated through NMDA receptors. Overall, there were no significant changes in the CaM-kinase II activity in CA3 area with or without inhibitor's pre-incubation. Our results indicate that the activation of CaM-kinase II by glutamate stimulation occurs only in CA1 area, the stimulation effect in CA3 area is not correlated with CaM-kinase II activation.

PKC IS SWITCH TO LATENT NMDA RECEPTOR-MEDIATED COUPLING BETWEEN HIPPOCAMPAL CA1 NEURONS. Tsintsadze* T., Lozovaya N., Krishtal O. Bogomoletz Institute of Physiology, Bogomoletz str.4, 252024, Kyiv, Ukraine

NMDA and non-NMDA receptor-mediated component of excitatory post-synaptic currents (EPSC) evoked by the stimulation of Schaffer collateral/commissural pathway were studied by *in situ* whole-cell voltage-clamp in CA1 area of rat hippocampus. We have found that the activation of PKC by phorbol 12,13-diacetate (PDAc) leads to a dramatic change in the EPSC. Application of PDAc (1-4 μM) increased the amplitude of EPSC and its duration acquired stimulus-dependence, increasing with the increase in the stimulus strength. The latter effect demonstrated calcium-dependence: it could be elicited only when the Ca^{2+} concentration in the external medium was increased to 2-2.5mM. The effects of PDAc were markedly attenuated by the extracellular application of the PKC inhibitor H-7 (300μM). The late stimulus-dependent component of EPSC disappeared under either the NMDA antagonists 2-amini-5-phosphonovaleric acid (APV) or the non-NMDA antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). This findings indicate that the late components of the SCC-evoked EPSC becomes polysynaptic: reccurent NMDA receptors-mediated connections between CA1 neurons become operational in addition to the monosynaptic predominantly non-NMDA receptors-mediated SCC input. This reccurent connections are normally latent and become active upon the activation of PKC.

736.10

TRANSIENT NCAM POLYSIALYLATION DURING MEMORY CONSOLIDATION IS A UNIVERSAL FEATURE OF SPATIAL AND NON-SPATIAL LEARNING. C.M. Regan*, G.B. Fox, K.J. Murphy and A.W. O'Connell, Department of Pharmacology, University College, Belfield, Dublin 4, Ireland.

Neural cell adhesion molecule (NCAM) members of the immunoglobulin superfamily regulate cell-cell interactions in development, and in discrete regions of the adult, by prevalence modulations and by the addition of α2,8 linked polysialic acid homopolymers. This plasticity is now demonstrated to be associated with learning. Animals trained in a passive avoidance task exhibited a transient, time-dependent increase in hippocampal NCAM polysialylation in a distinct population of granule-like cells at the border of the dentate granule cell layer and hilus in the adult rat hippocampus at 10-12h following the initial learning trial. These changes were paradigm-specific as they failed to occur in animals rendered amnesic with scopolamine. Further, they are not *de novo* granule cell precursors as bromodeoxyuridine incorporation revealed no significant difference between trained and passive animals in the small number of labelled cells which were heterogenously distributed. These changes appear to be a universal response to learning as precisely the same transient and temporal changes in dentate NCAM polysialylated neurons was observed in animals trained in the Morris water maze but not in those required to locate a visible platform. In the water maze task a rapid reactivation of NCAM polysialylation state followed each training session in a manner which was independent of inherent circadian rhythms. These repetitive increases did not change in magnitude despite improved maze performance, suggesting their activation to be associated with information processing rather than consolidation.*This work was supported by the Health Research Board of Ireland and EU Biotechnology Programme.*

736.11

THE CATALYTIC ACTIVITY OF THE LIMBIC-SPECIFIC SERINE PROTEASE, NEUROPSIN. S. Yoshida, C. Shimizu, Y. Momota, Z-L. Chen and S. Shiosaka*. Department of Structural Cellular Biology, Nara Institute of Science and Technology (NAIST) Ikoma 630-01 Japan

Serine proteases are thought to play important roles in plastic events in the brain. We cloned a novel cDNA for a putative serine protease, named neuropsin, whose mRNA is expressed exclusively in the limbic systems of the adult mouse brain and showed that the level of the mRNA expression is activity dependent (Chen et al. J. Neurosci. 15:5088, 1995). To see the enzymatic activity of neuropsin, we produced recombinant neuropsin in the insect cell protein expression system with baculovirus. The whole open reading frame was inserted into a transfer vector and transfected into SF9 cells with baculovirus. The expressed protein was purified from the culture medium, which indicated that this protein was processed by a signal peptidase and secreted. This "secreted" form of recombinant neuropsin showed low proteolytic activity to three synthetic peptide, Val-Pro-Arg-MCA, Asp-Pro-Arg-MCA and Pro-Phe-Arg-MCA but not to other substrates tested. Further treatment of the protein with trypsin or lysylendopeptidase dramatically increased the enzymatic activity to the same substrates. The results suggested that neuropsin is an enzymatically active protease with a relatively narrow range of the substrate spectrum and needed be processed by other proteases to have proteolytic activity.

Ca^{2+} stimulation of CRE-mediated gene expression in neurons involves crosstalk between the cAMP and MAPK pathways.

S. D. Impey*, S. T. Wong, M. D. Mark, S. W. Poser, and D. R. Storm
Dept. of Pharmacology, Univ. of Washington, Seattle, WA 98195

The cAMP response element is involved in the cAMP and Ca^{2+} inducibility of numerous immediate early and late response genes. Because the CRE is synergistically transactivated by cAMP and Ca^{2+} signals in neuronal cells, it has been proposed to couple coincident signals to long-term adaptive change. In agreement with this hypothesis several studies suggest that the CRE transcriptional pathway may play a role in the formation of long-term memory. Furthermore, in a recent study we provide evidence that long-lasting LTP-associated increases in CRE mediated gene expression depends on both the cAMP and Ca^{2+} signalling pathways.

In agreement with earlier work, we provide evidence that Ca^{2+} regulation of CRE transactivation and fos expression depends on PKA and CREB/ATF function. We provide evidence that the MAP kinase and cAMP/PKA pathways converge to synergistically activate CRE-mediated and fos gene expression in neuronal cell lines and in primary neuron culture. Moreover, we find that activation of the MAP kinase cascade by Ca^{2+} or growth factors is synergisitcally enhanced by cAMP signaling. This observation and further experiments using dominant interfering inhibtors of the MAP kinase cascade leads us to conclude that the regulation of CRE-mediated gene expression by Ca^{2+} depends on coincident MAP kinase and cAMP signaling.

CHARACTERIZATION OF IONIC CURRENTS IN PRESYNAPTIC HAIR CELLS OF *HERMISSENDA*. Ebenezer N. Yamoah*. Dept. of Physiology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205 and Marine Biological Laboratory, Woods Hole, MA 02543.

Hermissenda hair cells are the presynaptic neurons involved in Ca^{2+}-dependent neuronal plasticity associated with classical conditioning. To begin to understand presynaptic mechanisms of plasticity in the vestibulo-visual system, a locus for conditioning-induced neuronal plasticity, ionic currents that may govern the excitability of the hair cells were recorded by means of whole-cell patch electrodes. Three K^+ currents were characterized: a 4-AP-sensitive transient outward current (I_A), a TEA-sensitive delayed rectifier current ($I_{K,V}$) and a Ca^{2+} and voltage-activated current ($I_{K,Ca}$). I_A activates and decays rapidly; the steady-state activation and inactivation curves of the current reveal a window current close to the apparent resting voltage of the hair cells suggesting that the current is partially activated at rest. By modulating firing frequency and perhaps damping membrane oscillations, I_A may regulate synaptic release at baseline. In contrast, $I_{K,V}$ and $I_{K,Ca}$ have slow onsets and exhibit little or no inactivation. These two K^+ currents may determine the duration of the repolarization phase of hair-cell action potentials and hence synaptic release *via* Ca^{2+} influx through voltage-gated Ca^{2+} channels. Two distinct Ca^{2+} currents, transient and sustained currents were expressed in hair cells. While the transient current was sensitive to block by Ni^{2+}, the sustained current was blocked by Cd^{2+} and nitrendipine. The distinct properties of these ionic currents determine the nature of synaptic release and alteration of these properties following conditioning may contribute towards plasticity in *Hermissenda*.

Neuron Models With Activity-Dependent Conductances Reproduce Effects of Activity on Cultured STG Neurons. Z. Liu*, E. Marder and L.F. Abbott. Volen Center, Brandeis University, Waltham, MA 02254.

Changing patterns of electrical activity can modify the membrane conductances of neurons, an effect seen, for example, in crustacean stomatogastric ganglion (STG) neurons grown in culture (Turrigiano et al. (1994) Science 264:974-977). Activity-dependent mechanisms of conductance modification can resolve two key problems with conductance-based neuron models. Such models depend on a large number of free parameters and are hypersensitive to small changes in parameter values. Previous models (LeMasson et al. (1993) Science 259:1915-1917) in which membrane conductances depended on activity through the level of intracellular calcium solved the second of these problems by exhibiting robust behavior over a wide range of conditions. However, these models still depended on a large number of free parameters and setting their values severely restricted the way that activity could affect membrane conductances. We have now developed models the eliminate these restrictions and develop complex and robustly stable patterns of activity without involving large numbers of parameters. A model of this sort based on measured membrane conductances of cultured STG neurons (Turrigiano et al. (1995) J. Neurosci. 15:3640-3652) accurately reproduces both the sequence of modifications that occur when these cells are isolated in culture, and the changes that take place when they are chronically stimulated. In isolation, this model can develop bursting behavior from any starting set of conductances and in model circuits, the neurons can generate different sets of conductances even though they are described by identical equations. For stability, the model requires three separate sensors of intracellular calcium that operate on significantly different time scales. These may correspond to separate calcium feedback pathways. Supported by MH46742.

A Robust Pattern Generating Network Of Model Neurons With Activity-Regulated Conductances M.Casey*, E.Marder and L.F.Abbott
Volen Center, Brandeis Univ., Waltham, MA 02254

The growth and maintenance of neural circuits requires the coordinated development and regulation of both intrinsic membrane conductances and synaptic connections. To study the interplay of dynamically regulated membrane conductances with synaptic connectivity, we have built model circuits from individual neurons with membrane conductances that are modulated by activity (LeMasson et al. (1993) Science 259:1915-1917). The neuron models we use have membrane conductances of the standard Hodgkin-Huxley form but the maximal conductance parameters are not held fixed, as in conventional models, but are allowed to vary as a function of the electrical activity of the cell as reflected by its intracellular calcium concentration. We show that neurons of this type, when coupled with appropriate synaptic connections, can spontaneously develop into pattern generating circuits. In these circuits, the individual neurons play different roles in the generation of rhythmic activity; some neurons act as pacemakers while others are followers.

As a specific example, we have studied a simplified version of the pyloric circuit of the stomatogastric ganglion (STG). The reduced pyloric circuit we study consists of three neurons that are coupled by inhibitory synapse and that fire in a three-phase rhythm. In addition to exhibiting spontaneous self-assembly, the model circuit is extremely robust to perturbations that would disrupt the rhythm of a circuit of cells with fixed membrane conductances. In the model circuit, as in the STG, one neuron acts as a pacemaker while the others are followers. However, if the model neurons are isolated from each other for an extended period of time, they all revert to bursting behavior. This resembles the behavior of STG cells isolated in culture (Turrigiano et al. (1994) Science 264:974-977).

A COMPUTER MODEL OF THE ALIGNMENT OF AUDITORY AND VISUAL MAPS OF SPACE IN THE OPTIC TECTUM OF THE BARN OWL M. Rucci, G. Tononi and G. M. Edelman*, The Neurosciences Institute, 10640 John Jay Hopkins Drive, San Diego, CA 92121.

In the optic tectum of the barn owl, visual and auditory maps of space are found in precise alignment with each other. Experiments in which such alignment has been disrupted have shown a significant degree of plasticity in the auditory map. The external nucleus of the inferior colliculus, an auditory center which projects massively to the tectum, is the main site of plasticity. However, it is unclear by what mechanisms the alignment between the auditory map in the inferior colliculus and the visual map in the tectum is established and maintained. We propose that such map alignment occurs through a process of value-dependent learning. According to this paradigm, value systems, identifiable with neuromodulatory systems having diffuse projections, respond to innate or acquired salient cues, and release substances that can modulate changes in synaptic efficacy in many brain regions. In order to test the self-consistency of this proposal, we have developed a computer model of the principal neural structures involved in the process of auditory localization in the barn owl. This is complemented by simulations of owl's phenotype and of the experimental environment. In the model, a value system is activated whenever the owl carries out a foveation towards an auditory stimulus. A term representing the diffuse release of a neuromodulator interacts with local pre- and post-synaptic events to determine synaptic changes in the inferior colliculus. Through large-scale simulations, we have replicated a number of experimental observations about the development of a spatial alignment between the auditory and visual maps during normal visual experience, after the retinal image was shifted through prismatic goggles, and after the reestablishment of normal visual input. The results suggest that value-dependent learning is sufficient to account for the registration of auditory and visual maps of space in the tectum of barn owl, and lead to a number of experimental predictions (*Supported by Neurosciences Research Foundation*).

MODULATION OF EFFECTIVE CONNECTIVITY BY STOCHASTIC BACKGROUND ACTIVITY IN NEURAL ASSEMBLIES. M. A. Kisley* & G. L. Gerstein, Dept. of Neuroscience, Univ. of Pennsylvania, Philadelphia, PA 19104.

Effective connectivity (synaptic connectivity as measured by cross-correlation) can be rapidly modulated by "background" activity. For example, Boven & Aertsen (1990, *Parallel Processing in Neural Systems and Computers*, Eckmiller *et al.* (eds.), Elsevier: 53-56) demonstrated that efficacy of connection between two modeled neurons is a function of the rate of stochastic EPSP-bombardment onto the post-synaptic cell. The objective of the present study is to replicate and then extend the findings of these authors with a conductance-based point-neuron model.

Each neuron contains channels for synaptic connections and action-potential generation. All connections are of equal strength and relatively weak. The results of the simulations (Genesis) are compared to an analytical model based on membrane potential variations as "shot-noise" due to stochastic background activity.

Effective connectivity between directly connected cells is found to vary as a function of the rate of stochastic EPSP-bombardment of *both* the pre- and post-synaptic cells. The observed decrease in efficacy of connection with increased rate of input onto the pre-synaptic cell is likely due to non-linearities in spike-generation and refractoriness. Simpler models, such as the probabalistic "copy" model of Aertsen & Gerstein (1985, *Brain Res.*, 340: 341-54), often fail to account for such non-linearities.

Effective connectivity between cells not directly connected, but receiving shared input from a third cell, is predicted to be extremely weak by the analytical model, and found to be undetectable in the simulation results. However, increased correlation between the background inputs to the two cells greatly strengthens this effective connectivity. This suggests that significant shared input correlations seen in cortical recordings are due to synchronous input from *many* cells.

COMPUTATIONAL MODELS OF cAMP-DEPENDANT ACTIVATION AND REPRESSION OF GENE TRANSCRIPTION INVOLVED IN LONG-TERM MEMORY FORMATION. P. Smolen*, J. H. Byrne, and D. A. Baxter, Dept. of Neurobiology and Anatomy, The University of Texas Medical School, Houston, TX 77225.

Long-term memory (LTM) is generally produced more effectively by massed training (training sessions following one after the other) than by spaced (separated by intervals) training sessions. This can sometimes be the case even for the same total training time. The dynamics of recently characterized transcriptional activators and repressors may provide a molecular explanation. Elevated cAMP leads to phosphorylation of transcriptional activators such as CREB. Repressor proteins for this transcription may be phosphorylated and activated as well. Whether repressors interact primarily with the CRE region or with the activator proteins may be system-dependent. We have formulated, as sets of ordinary differential equations, alternative versions of a biochemical model for activation and repression that incorporate these observations. We postulate that training sessions cause transient increases in the rates of phosphorylation of both activator (CREB) and repressor, and that phosphorylated repressor can form inactive heterodimers with CREB. The rate of LTM formation is taken as proportional to the concentration of phosphorylated CREB homodimers. Confirming a suggestion of Yin et. al (Cell 81: 107-115, 1995), we find that if both CREB and repressor are rapidly phosphorylated upon training, but the dephosphorylation of CREB is slower than that of repressor, then spaced training more effective produces LTM because during longer rest intervals the net difference of phosphorylated (CREB - repressor) increases. However, in *Aplysia* repressor appears to be phosphorylated more slowly (Bartsch et. al., Cell 83: 979-992, 1995). This suggests another mechanism where individual training sessions produce little phosphorylated repressor, and significant temporal summation of phosphorylated repressor occurs for massed, but not spaced, training. We find that with such a mechanism the greater efficacy of spaced training is also predicted by our model. Supported by NIH grant RR11626-01.

RETROGRADE AXONAL REGULATORY MECHANISMS MIGHT MEDIATE SIGNIFICANT NETWORK ADAPTIVE BEHAVIOR
R.D. Brandt and F. Lin* Department of ECE, Wayne State University, Detroit, MI 48202

It is reasonable to believe that the amout of any presynaptic adaptation be ultimately reflected in some form of transcriptional activity in the nucleus. Such adaptation-dependent nuclear activity would be evidence of a retrograte transmission of information measuring synaptic adaptation. Depending on the time constants associated with such coupling, the information conveyed could enable significant cooperative adaptation at the network level that would otherwise be impossible. A simple mathematical model which is a subtle variant of the Hebbian models sometimes considered in the context of LTP, can exploit the information conveyed by the transcriptional activity. This has been verified with computer simulations of the model, which demonstrate that networks consisting of such neurons solve pattern recognition problems that are not linearly separable. Indeed, as the accuracy of axonic feedback is increased, the network behavior becomes identical to well-studied optimized artificial neural networks, which have until now not been regarded as biologically plausible.

DRUGS OF ABUSE: COCAINE V

737.1

COCAINE ALTERS mRNA LEVELS FOR THE Na/K ATPase PUMP IN VIVO AND IN VITRO. X-Y Cha[1], C Pierce[2], JB Zuckerman[1], TR Kleyman[1], PW Kalivas[2]& SA Mackler[1]*. [1]Department of Medicine, Univ. of PA & Phila VAMC, Phila PA 19104 &[2]Wash. State Univ., Pullman WA 99164-6530.

Cocaine-regulated gene expression may contribute to drug self-administration and sensitization. Experiments to identify mRNAs that have their levels altered by cocaine were performed. Rats administered i.v. cocaine for 15 of 21 days (x=40 mg/kg/3 hr session/day) and then kept drug-free for 21 days. cDNAs were made from the nucleus accumbens (NAcc) by in situ transcription. An oligothymidine primer with the T7 promoter sequence at its five prime end initiated cDNA synthesis. mRNAs for the β1 subunit of the Na/K ATPase and an ankyrin isoform were shown to be increased among rats that self-administered cocaine relative to yoked saline controls, using antisense RNA for differential hybridization of a rat brain library and slot-blot analysis. A PC12-derived cell line was next exposed to 10 uM cocaine intermittently for 3 days. Northern blots demonstrated a decrease in β1 subunit mRNA in cocaine-exposed cells. Cocaine (10uM, 100uM, 1mM) added to nonneuronal A6 cells did not acutely alter transepithelial Na transport, suggesting that cocaine does not directly affect Na/K ATPase function. Increased mRNAs may regulate insertion and activity of the Na/K pump, leading to long term changes in neurotransmitter levels in the NAcc. A novel cocaine-regulated cDNA has also been isolated in these studies, and its function will be studied in vitro.

737.2

REPEATED COCAINE ADMINISTRATION DECREASES WHOLE-CELL SODIUM CURRENT IN ACUTELY DISSOCIATED NUCLEUS ACCUMBENS NEURONS. F.J. White* and X.-F. Zhang Dept. Neuroscience, FUHS/Chicago Medical School, North Chicago, IL 60064-3095.

Neuroadaptations responsible for the behavioral effects of repeated cocaine administration include changes in both presynaptic and postsynaptic activity within the mesoaccumbens dopamine (DA) system. We have previously reported that repeated cocaine treatment decreases the excitability of NAc neurons, in part, by increasing threshold for spike discharge and decreasing spike amplitudes. Such results may be indicative of alterations in whole-cell Na^+ current which, in striatal neurons, is modulated by DA D_1 receptors. In this study, whole-cell voltage clamp recordings were used to investigate possible changes of whole-cell sodium current (I_{Na}) after 5 daily injections of cocaine (15 mg/kg, i.p.) and a 3 day withdrawal period. NAc neurons from saline-pretreated, cocaine-pretreated, and lidocaine-pretreated adult rats were acutely dissociated. Only medium-sized neurons (diameter < 14 μm), were used. D_1R stimulation reduced I_{Na} in NAc neurons via a cAMP-PKA pathway. Repeated administration of cocaine, but not lidocaine, significantly decreased I_{Na} (nA/pF) and shifted the voltage-dependence of activation in the depolarizing direction with a reduced slope factor. These findings are, in part, consistent with results obtained upon PKA and PKC phosphorylation of brain Na^+ channels expressed in various cells. Thus, we propose that during repeated cocaine administration, enhanced stimulation by DA of $DA D_1Rs$ increases the steady-state level of Na^+ channel phosphorylation, leading to a reduction of I_{Na}. In addition, because phosphorylation of brain Na^+ channels by PKA requires concomitant PKC phosphorylation, we propose that additional actions of cocaine on as yet unidentified signaling systems may act in concert with enhanced PKA activity to increase phosphorylation of NAc Na^+ channels. Thus, in addition to synaptic changes, cocaine addiction may involve "non-synaptic" (whole-cell) plasticity which diminishes the responsiveness of NAc neurons (Support:DA 04093 and 00207 to FJW).

MESOLIMBIC DOPAMINE D1, D2, AND D3 RECEPTOR mRNA LEVELS FOLLOWING COCAINE ADMINISTRATION. S.L.Vrana*, T.L. Moore, and K.E. Vrana. Dept of Physiology and Pharmacology and Center for the Neurobiological Investigation of Drug Abuse, The Bowman Gray School of Medicine, Medical Center Blvd, Winston-Salem, NC 27157-1083.

Cocaine exerts its actions by blocking dopamine reuptake through the dopamine (DA) transporter. Previous studies have reported that cocaine administration upregulates tyrosine hydroxylase (the rate-limiting enzyme in DA biosynthesis) mRNA, protein, and enzyme activity. While results are ambiguous, cocaine also appears to alter DA binding activity. The present study sought to characterize DA receptor (DAR; subtypes 1, 2 and 3) mRNA levels in the ventral tegmental area (VTA) and nucleus accumbens (NAcc). F344 rats received response-independent *i.v.* infusions of cocaine (0.33 mg/0.2 µl every 8 min for 6h/day, 7 days). Animals were then sacrificed, the VTA and NAcc dissected, and total RNA isolated. DAR subtype mRNAs were assessed using sequence-specific RT-PCR, normalized as recently described (Vrana *et al.*, Mol. Brain Res. 34:127-34, 1995). Briefly, subtype-specific first strand cDNAs were synthesized in a tube that contained total RNA and an internal standard, followed by PCR amplification (26 cycles; annealing step performed above the primer T_m). Amplification products were analyzed *via* PAGE, followed by direct radioactivity measurement using a blot analyzer. Robust levels of RNA were detected for the D2 and D3 subtypes in both regions. However, D1 RNA was only detected under these conditions in the NAcc, not the VTA. While cocaine treatment appeared to increase DAR expression, normalized values for VTA and NAcc D1, D2 and D3 mRNAs from cocaine-treated animals were not significantly different from saline controls. Previously reported changes in DAR binding may be occurring at the level of translation control or protein stability. *Supported by GM-38931 (KEV) and DA-00230 (SLV).*

EFFECT OF CHRONIC COCAINE EXPOSURE ON THE DENSITIES OF DOPAMINE D_1- AND D_2-LIKE RECEPTOR BINDING IN FETAL RHESUS MONKEY BRAIN. Y. Fang*, A. Janowsky, O. K. Ronnekleiv, Dept. of Physiology and Pharmacology, Oregon Regional Primate Research Center, VA Medical Center, Oregon Health Sciences University, Portland, OR 97201

The present study was performed to elucidate the effect of cocaine exposure on the development of dopamine receptors in the fetal monkey. Pregnant monkeys were treated with cocaine (3 mg/kg; i.m.) or saline (n=3, each), four times per day from day 18 of pregnancy until day 70. Quantitative dopamine receptor autoradiography was performed on day 70 fetal brain sections using [^{3}H]SCH23390 (2 nM, 71.3 Ci/mmol, NEN) for D_1-like, and [^{3}H]spiperone (0.6 nM, 96 Ci/mmol, Amersham) for D_2-like binding. High density of dopamine D_1 receptor binding was found mainly in the striatum and the substantia nigra, whereas dopamine D_2 receptor binding was found in the striatum, but was not detectable in the substantia nigra or other brain areas. Such a distribution pattern for D_1 and D_2 receptors was the same in control and cocaine-treated animals. However, the binding densities of D_1 receptors in the striatum and substantia nigra, and D_2 receptors in the striatum were significantly increased in day 70 cocaine-treated fetuses vs. control ($P< 0.05$, 0.01, 0.01, respectively). Maternal cocaine treatment did not significantly affect the body weight, crown-rump length or head circumference of day 70 fetuses. These findings together with our previous studies support the hypothesis that chronic cocaine exposure results in reduced synthesis and release of dopamine which causes dopamine receptor up-regulation in the dopamine terminal fields of the developing monkey brain. 737.5

IN VIVO COCAINE EFFECTS ON MESOLIMBIC DYNOROPHIN LEVELS. Yasmin L. Hurd* and Ingrid Nylander. Karolinska Institutet, Dept. of Clinical Neuroscience, Psychiatry Section, S-171 76 Stockholm, and Uppsala University, Dept. Pharmaceutical Biosciences, Division of Pharmacology, Sweden.

The primary action of cocaine is to potentiate dopamine (DA) levels which in turn modulates post-synaptic neuronal circuits to induce its neurobiological effects. One neuronal system that is post-synaptic to DA terminals and has potent effects on motor behavior and mood is the opioid peptide system. Of the endogenous opioid peptides, recent attention has focused on the role of dynorphin (DYN) in the neurobiological actions of cocaine based on consistent post-mortem findings of elevated DYN-immunoreactivity and mRNA expression in the striatum following cocaine administration to animals and similar DYN mRNA changes in human cocaine users. In the current work, we have begun to explore whether the post-mortem DYN alterations are matched by functional *in vivo* changes in the release of the opioid peptide in limbic-related brain areas associated with reinforcement. To this end, extracellular levels of DYN B were measured in the nucleus accumbens during repeated administration of cocaine in awake freely moving rats using *in vivo* microdialysis. Both passive cocaine administration (30 mg/kg, i.p.) as well as direct cocaine self-administration (3hr session; 1.75 mg/injection, iv) elevated DYN B levels (200%) compared to predrug concentrations or rats receiving saline. DA levels measured in the same animals were also found to be increased (300-400%). The slope of DA increase was, however, steeper than for the DYN B elevation implying a faster DA than DYN B response to cocaine. DA-opioid interactions may play a role in the actions of cocaine. *This work was supported by the Swedish Medical Research Council.*

737.6

COCAINE AND AMPHETAMINE REGULATED TRANSCRIPT (CART) LOCALIZATION IN SOME NEURONS AND NEUROENDOCRINE CELLS. E. Koylu, P. Couceyro and M.J. Kuhar*. Division of Neuroscience. Yerkes Regional Primate Research Center, Emory University, Atlanta, GA 30322

CART is a novel transcript regulated by cocaine and amphetamine administration which lacks homology to other cDNAs. It exhibits moderate to abundant levels within selective nuclei of the rat brain, such as the nucleus accumbens and amygdala, as well as in circuitry associated with sexual function and autonomic function. The putative CART peptide is about 125 amino acids, has a leader sequence, several pairs of basic amino acids and is found in locus coeruleus and paraventricular nucleus of the hypothalamus. All of these findings suggest that CART is a novel peptide transmitter/cotransmitter.

In this investigation we have further studied the distribution of CART by *in situ* hybridization. We have identified regions of the brain and neuroendocrine organs containing CART that have not yet been reported. In the pituitary, CART is found only in the anterior lobe, in few cells that stain lightly with thionin. Its distribution within the adrenal glands is under study. Outside these neuroendocrine tissues, CART has been localized: in the spinal cord, where it is found in neurons near the central canal, possibly in lamina X; in the olfactory bulb, where CART is found in mitral cells; in the retina, where it is found in ganglion cells; and in whisker barrels of the sensory cortex. Thus CART may function in part in processing primary sensory information.

These findings support the notion that CART peptide is a peptide neurotransmitter and also a possible peptide hormone as well. Supported by the Intramural Research Program of NIDA and Yerkes Primate Center.

737.7

CHRONIC COCAINE TREATMENT. ALTERS [^{35}S]*t*-BUTYL-BICYCLOPHOSPHOROTHIONATE (TBPS) BINDING: INFLUENCE OF COCAINE ON $GABA_A$ RECEPTOR-ASSOCIATED CHLORIDE CHANNELS. T. Suzuki[1]*, T. Ito[2], I.K. Ho[2], H. Shiraishi[1]. [1]Dept. of Psychiatry, University of Tsukuba, Tsukuba, 305, Japan, [2]Dept. of Pharmacology and Toxicology, University of Mississippi Med. Ctr., Jackson, MS 39216-4505.

The dysfunctions of dopaminergic system in the mesostriatal and mesolimbic systems have been the main focus of neurochemical studies on the mechanism of behavioral sensitization after repeated cocaine treatment, and possible involvement of GABAergic system has had less attention in spite of clinical relevance. Therefore, we have investigated effects of chronic cocaine treatment on [^{35}S]TBPS binding (specific ligand for the $GABA_A$ receptor-associated chloride channel) in the rat brain using *in vitro* quantitative autoradiography. Treatment group received 20 mg/kg (i.p.) of cocaine hydrochloride once a day for 14 days. Behaviors were scored during this period. Following an abstinence period of one week, rats were killed by decapitation 2 h after challenge dose of cocaine. Control animals underwent the same procedure except vehicle solution was injected. [^{35}S]TBPS binding autoradiography was performed according to our previously reported method (Ito et al. J. Neurosci. Methods 59: 265-271, 1995). Repeated cocaine treatment resulted in an increase in rating of both stereotyped behaviors and locomotor activities. Significant increases in [^{35}S]TBPS binding were observed in layers II-III and IV of the cerebral cortex, and the field CA1 and dentate gyrus of the hippocampus, in the treatment group ($p<0.05$). These results suggest that $GABA_A$ receptors were involved in the behavioral sensitization after repeated cocaine treatment, which might be associated with changes in dopaminergic system in these regions. (supported by NIDA04480)

737.8

EFFECTS OF REPEATED COCAINE INJECTIONS ON PROTEIN KINASE C ACTIVITY IN DOPAMINERGIC BRAIN REGIONS. J.D. Steketee* and L.A. Rowe. Department of Pharmacology and Therapeutics, Louisiana State University Medical Center, Shreveport, LA 71130-3932.

Behavioral sensitization is the augmented motor-stimulant response which ocurrs with repeated intermittent cocaine administration. Much work has been conducted in an attempt to determine the role the ventral tegmental area (VTA) plays in the development of cocaine-induced sensitization. Previous studies have suggested that cocaine may alter receptor-mediated signal transduction systems in the VTA. We have recently reported that intra-VTA injection of the nonspecific protein kinase inhibitor H7 blocked the acute response and delayed development of the sensitized response to cocaine. In the studies outlined below the effects of acute and repeated cocaine administration on PKC activity and on concentrations of PKCγ was determined in the mesocorticolimbic and nigrostriatal dopamine systems. Male Spraque-Dawley rats received injections of saline or cocaine (15 mg/kg) and motor activity was monitored. Animals then received injections of saline or cocaine (15 or 30 mg/kg) in their home cages for 3 consective days. Twenty-four hours later animals received a challenge injection of saline or cocaine (15 mg/kg) and motor activity was monitored. Two hours, 1 day or 4 days after receiving their last injection, animals were sacrificed and brains were removed and dissected. Tissue samples were prepared for analysis of PKC acitivity by a histone phosphorylation assay or for determination of concentrations of PKCγ by western blot analysis. Preliminary data suggest that in animals sensitized to cocaine, there is a significant enhancement of PKC activity in the VTA, but not in the substantia nigra, nucleus accumbens, striatum or medial prefrontal cortex, 2 hr after the last injection of cocaine. These data suggest that enhanced PKC activity in the VTA may play a critical role in the development of sensitization. This work was supported by grants from the Louisiana Educational Quality Support Fund (RD-A-18) and the National Institute on Drug Abuse (DA08079).

COCAINE SELF-ADMINISTRATION ALTERS BRAIN GENE EXPRESSION: CHARACTERIZATION OF DIFFERENTIALLY REGULATED cDNAs. P. Couceyro*, M. Shoaibt, M. McCoyt, S. Goldbergt & M. J. Kuhar Division of Neuroscience, Yerkes Regional Primate Center, Emory Univ., Atlanta, GA. and Natl. Inst. of Drug Abuse/NIHt, Baltimore, MD.

Passive administration of drugs of abuse produce altered patterns of gene expression in the brain that may result in long lasting behavioral changes. However, passive drug administration only addresses some of the issues of drug reinforcement and reward. The rat cocaine self-administration (SA) model was used to examine changes in brain gene expression with differential display PCR (DD-PCR).

Male Sprague Dawley rats were trained to intravenously self-administer cocaine (0.66 mg/kg/infusion) in daily, limited sessions. Only after exhibiting greater than 90 accuracy in nose-pokes and a stable intake for 5 consecutive days on an FR3 schedule were animals considered for this study.

DD-PCR was performed on mRNA from various brain regions of yoked and cocaine SA rats. Over 20 differential regulated bands were identified. One of these regulated cDNAs shows homology with a mitochondrial gene. By Northern blot analysis, this mRNA is up-regulated in the caudate putamen and ventral midbrain, but reduced in the nucleus accumbens; changes in other brain regions are not seen. These results suggest that contingent drug intake affects metabolic enzymes in reward pathways. We are in the processing of characterizing this and other cDNAs. These studies further strengthen the role of gene regulation in drug reward and reinforcement. This work is supported by NIDA/IRP.

737.10

LONG-TERM COCAINE SELF-ADMINISTRATION ALTERS CEREBRAL METABOLISM IN THE AMYGDALA OF MONKEYS D. Lyons*, M.A. Nader, D.P. Friedman & L.J. Porrino Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, N.C. 27157.

Previous work from this laboratory found that following the acute intravenous administration of cocaine to drug-naive monkeys, cerebral metabolism was diminished in the striatum but not the amygdala (Lyons et al., J Neurosci, 16:1230, 1996). We hypothesized that the failure of cocaine to alter functional activity in the amygdala was due to the absence of a conditioned context of drug exposure that would be present following repeated administration of the drug. To test this hypothesis, the functional consequences of long-term cocaine self-administration were assessed in two rhesus monkeys that had self-administered cocaine daily for 18 or 20 months. On the day of the experiment, the tracer was injected immediately following the first lever press, which produced an intravenous infusion of one mg/kg cocaine. Rates of local cerebral glucose utilization were measured in the amygdala, striatum and related structures and compared with rates from cocaine-naive controls (n=4). Cocaine self-administration significantly decreased cerebral metabolism in the basolateral, lateral and medial nuclei of the amygdala by as much as 40%, as well as in the related bed nucleus of the stria terminalis (-39%). Within the striatum, cerebral metabolism was significantly altered only in the shell of the accumbens (-31%) and olfactory tubercle (-29%). Thus, changes in functional activity following cocaine self-administration were focussed within anatomically related portions of the amygdala, extended amygdala and ventral striatum. This is in contrast to the pattern of changes in cerebral metabolism following a first exposure to one mg/kg cocaine in which the amygdala itself was unaffected and undifferentiated changes were present throughout the striatum (Lyons et al., 1996). Cocaine self-administration produced, therefore, a clear shift in the topography of the functional response to cocaine. Furthermore, it appears the amygdala and extended amygdala may be critically involved in the development of the conditioned significance of long-term cocaine exposure.

EFFECTS OF ACUTE AND CHRONIC INFUSIONS OF CREB ANTISENSE OLIGONUCLEOTIDES IN THE NUCLEUS ACCUMBENS ON COCAINE SELF-ADMINISTRATION. D.W. Self*, J.J. Spencer and E.J. Nestler. Div. of Mol. Psychiatry, Yale Univ. Sch. of Med., New Haven, CT, 06513.

In a recent report (Widnell et al., JPET 276:306, 1996), we found that acute and chronic nucleus accumbens (NAc) infusions of antisense oligonucleotides directed against the mRNA for the transcription factor CREB (cAMP-Response Element Binding protein) produce a sustained decrease in the levels of CREB immunoreactivity, and the immunoreactivity for the catalytic subunit of PKA (cAMP-dependent protein kinase), without detectable toxicity. In the present study, we tested the effects of similar acute and chronic infusions of CREB antisense oligonucleotides on cocaine self-administration in rats. A single bilateral NAc infusion of fully phosphorothioated CREB antisense (10 µg/1.0 µl/side), administered 18 hours prior to testing, produced a 30% reduction in cocaine self-administration (0.5 mg/kg/injection), which recovered gradually to pre-infusion rates over 5 days Similar infusions of the complementary CREB sense oligonucleotide produced a 7% reduction in cocaine self-administration that recovered fully after 2 days. Chronic infusion of partially phosphorothioated CREB antisense (20 µg/12 µl x 10 days) also reduced cocaine self-administration for the 10 day period, without causing weight loss or obvious behavioral deficits. Decreases in cocaine self-administration rate were characterized by prolonged and regular interinjection intervals, an effect that resembles increasing the self-administered dose of cocaine. Possible neurotoxic effects are unlikely because of 1) full recovery of behavioral and biochemical parameters, 2) a lack of significant behavioral or biochemical with sense oligonucleotides, and 3) only specific proteins in the NAc were reduced. These results support a role for the NAc-cAMP system in drug reinforcement and addiction. Supported by NIDA grants DA08227 and DA00203.

737.12

COCAINE SELF-ADMINISTRATION ALTERS STRIATAL GENE EXPRESSION IN RHESUS MONKEYS. J.B. Daunais*, M.A. Nader and L.J. Porrino. Physiology and Pharmacology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, N.C. 27157.

Our knowledge of cocaine's effects on the opioid system largely comes from rodent and human studies which report conflicting results. For example, cocaine reduces the expression of preproenkephalin (PPE) mRNA in the striatum of human addicts (Hurd and Herkenham, 1993), but generally does not alter PPE mRNA levels in rats. The complexity of human brain, however, makes it difficult to relate findings across species. Furthermore, variable drug histories, co-morbid psychiatric diseases, post-mortem artifacts, etc., can confound the human data. Therefore, the present study of the genomic effects of cocaine in adult, nonhuman primates was undertaken in an attempt to bridge across species, as well as to avoid these confounds. Using *in situ* hybridization histochemistry, striatal PPE mRNA was assessed in rhesus monkeys that had self- administered cocaine for 1.5-2 years. Twenty micron sections collected through the anterior caudate and putamen at the level of the nucleus accumbens were hybridized with a 48 base pair oligodeoxynucleotide complementary to bases 130-145 of human PPE (Comb et al., 1982). Autoradiograms revealed high levels of PPE hybridization signal in the caudate, putamen, and nucleus accumbens core and shell regions of drug-naive monkeys. A general medial to lateral gradient, as well as dorsal to ventral, gradient of hybridization signal was observed in normal control animals. Chronic cocaine self-administration produced significant reductions in PPE mRNA in widespread portions of both the dorsal and ventral striatal regions when compared to control levels. These data suggest that long-term abuse of cocaine can result in significant alterations in opioid regulation of striatal output systems. Brains from monkeys allowed short-term access to cocaine self-administration are currently being processed. Data comparing the effects of short- and long-term cocaine self-administration on PPE mRNA will be presented. Supported by DA 09085 (LJP) and DA 07246 (JBD).

COCAINE SELF-ADMINISTRATION INDUCES LONG TERM CHANGES IN THE EXPRESSION OF CONNEXIN 26 AND 32: AN IMMUNOHISTOCHEMICAL STUDY. J.L. Stenger[1]*, J.M. Arnold[1], S.A.L. Bennett[1], D.L. Paul[2], and D.C.S. Roberts[1]. [1]Life Sciences, Carleton University, Ottawa, Ont., Canada, K1S 5B6; [2]Dept. of Neurobiology, Harvard Medical School, Boston, Mass 02115-6092.

Our working hypothesis is that cocaine-induced reinforcement and neural plasticity involves modification of gap junction communication. Gap junctions are channels composed of six proteins (connexins) that permit direct cytoplasmic connections between apposing cells. It is well established that the site of action for the the reinforcing effects of cocaine is the dopamine (DA) receptor. Furthermore, DA is involved in the regulation of gap junctions in the retina and brain. To determine the effect of cocaine on the expression of Cx26 and Cx32, rats were permitted to self-administer cocaine (1.5 mg/kg) on a FR1 schedule in daily three hour sessions for two weeks. The expression of Cx26 and Cx32 was examined in several brain regions at 0, 24, 48 hrs and 1 week following the last cocaine injection. Immunohistochemical data show that cocaine self-administration produces time-dependent changes in the expression of Cx26 and Cx32 throughout the brain. These differences were not always sequential; the expression of Cx26 is down regulated at 0 hr and one week following chronic cocaine self-administration, and there is a recovery in expression at intermediate time points. These findings are consistent with the notion that gap junctions are important in the neurobiology of cocaine reinforcement. Supported by NIDA contract NOIDA-3-7302.

737.14

COCAINE SELF-ADMINISTRATION INDUCES LONG TERM CHANGES IN CONNEXIN 32 EXPRESSION: WESTERN ANALYSIS. J.M. Arnold*[1], J.L. Stenger[1], S.A.L. Bennett[1], D.L. Paul[2] and D.C.S. Roberts[1]. [1]Dept. of Psychology, Carleton University, Ottawa, Ont K1S 5B6. [2]Dept. of Neurobiology, Harvard Medical School, Boston, Mass 02115-6092.

The reinforcing effects of cocaine are directly linked to stimulation of the mesolimbic dopamine system. However, dopamine has also been shown to regulate gap junction expression in central nervous system tissue. Gap junctions are hemi-channels composed of six proteins called connexins that allow cytosolic connections between cells. To assess the effect of cocaine on gap junction connexin expression, rats self-administered cocaine (1mg/kg) on an FR 1 schedule of reinforcement in daily 3 hour sessions over a 14 day period. They were decapitated at various time points after final drug exposure (0, 24, 48 hr, 7 and 21 days) and the expression of connexin 32 (Cx32) was examined in several brain regions by Western analysis. Results show consistent changes in Cx32 expression across all brain regions after cocaine self-administration. Furthermore, changes in expression depend on the time lapse since last exposure to cocaine with maximal increases obtained 24-48 hours after last drug exposure. These data indicate that chronic cocaine self-administration can induce long term changes in gap junction expression. Supported by FCAR to JMA and NIDA contract No. N0lDA-3-7302.

737.15

WITHDRAWAL FROM LONG-TERM CONTINGENT COCAINE ADMINISTRATION REDUCES D2 DENSITY IN CAUDATE AND ACCUMBENS NUCLEI IN RATS.
A.González(#),J.A.Crespo,R.Ferrado,C.García-Lecumberri,S.Martín, N.Díez and E.Ambrosio*. Dept.Psicobiología.UNED.28040 Madrid.(#)Dept. Farmacología.Fac.Medicina.Univ.Cantabria.39011 Santander.Spain.

The neurochemical changes underlying the withdrawal process of long-term cocaine exposure are not well known. Although repeated noncontingent cocaine administration has been reported to alter the density of dopaminergic receptor binding sites, the reports are inconsistent.The purpose of this study was to determine the effect of withdrawal from long-term cocaine self-administration on D2 receptors using the yoked-box procedure.Fifteen littermate male Lewis rats were randomly assigned in triads to one of three conditions:a)contingent self-administration of 1mg/kg/injection of cocaine(CONT) and b)noncontingent injections of either 1mg/kg of cocaine(NONCONT) or c)saline yoked(SALINE) to the intake of the self-administering subject.The self-administering rats were trained to self-administer cocaine under a FR3 schedule of reinforcement during daily 2 hr sessions for a long period(between 4 and 6 weeks). After stable baseline levels of drug intake had reached, saline was substituted for drug during 5 days at least. Following this first extinction period, cocaine self-administration was reinstated for an additional minimum period of 2 weeks and until stable baseline of cocaine self-administration behavior was again obtained (less than 10% of variation in the number of injections during three consecutives days).20 days after the last injection of the third day that reached the stable baseline self-administration criterion, animal brains in each triad were removed and processed for 3H-Spiperone autoradiography.D2 receptor binding in CONT rats showed a significative reduction in caudate and accumbes nuclei compared to NONCONT and SALINE yoked subjects($p<0.01$). Densities of D2receptors increased in a significative manner in the olfactory tubercle of NONCONT rats compared to CONT($P<0.01$) and SALINE rats($P<0.05$).D2 binding was not changed in substantia nigra,hippocampus(CA lac.mol.) and frontal cortex. These results suggest that reductions in D2 receptor expression may be relevant in the long-term stages of withdrawal from contingent cocaine administration and confirm the importance of controlling the behavioral factors to an adequate understanding of neurobiological processes underlying cocaine withdrawal. USE OF DIFFERENTIAL DISPLAY TO IDENTIFY A ZINC-FINGER PROTEIN WHICH IS DOWN-REGULATED FOLLOWING WITHDRAWAL FROM COCAINE.
D.J. Ennulat* and B.M. Cohen. McLean Hospital and Harvard Medical School, 115 Mill Street, Belmont, MA 02178.

We have used differential display reverse transcriptase PCR (DDRT-PCR) to identify candidate genes whose expression is modulated in the caudate putamen (CPu) of rats following cocaine treatment. Either 0.9% saline or 6 mg/kg cocaine-HCl was given to male, Sprague Dawley rats by IV injection three times daily (10:00, 13:00, 16:00), with a challenge injection the following day (10:00). The animals were allowed to recover for 1 hr., 1 day and 2 days following the challenge injection. The CPu was removed and total RNA was isolated from each individual. DDRT-PCR anaylsis revealed a candidate gene (8G226) whose expression is repressed at 1 hr. and 1 day, following withdrawal from cocaine. The DNA sequence of 8G226 was found to have near identity with a zinc-finger protein (MMPZFI, accession no. U05343) that was originally identified in mouse testis (Saotome et al., Gene 152:233-8, 1995). By analogy with the mouse sequence, the cDNA 8G226 represents a coding region encompassing the first of five C_2H_2 zinc-finger domains. Northern blot hybridization with this cDNA revealed hybridization to a 5.0 kbp mRNA whose expression is repressed at 1 hr. and 1 day, but not at 2 days following withdrawal from cocaine. Further characterization of the functional significance of the repression of 8G226 during withdrawal from cocaine is under investigation and the temporal and anatomical expression pattern of 8G226 is being documented by *in situ* hybridization, This work is supported by a grant from NIMH.

RESPONSE OF CNS NEUROTENSIN AND SUBSTANCE P SYSTEMS FOLLOWING IBOGAINE TREATMENT.
M.E. Alburges* and G.R. Hanson. Department of Pharmacology and Toxicology, Univ. of Utah, Salt Lake City, UT 84112.

Ibogaine (Endabuse™), is a psychoactive indole alkaloid found in the West Africa shrub, *Tabernanthe iboga* . It has been reported to interrupt cocaine and amphetamine abuse and has been proposed for treatment of addiction to these stimulants. In previous studies we have demonstrated differential effects of psychotomimetic drugs (cocaine and methamphetamine) on neuropeptide systems (neurotensin and substance P). In the present study, we examined the effect of multiple doses of ibogaine (40 mg/kg, i.p., daily, for 4 consecutive days) on striatal, nigral, cortical, and accumbens neurotensin (NT) and substance P (SP) systems. Ibogaine treatment had profound effects on NT- and SP-systems causing 177% to 279% increases in striatal, nigral, and accumbens contents of NT-like immunoreactivity, and 143% to 198% increases in striatal and nigral contents of SP-like immunoreactivity 12-hours after the last ibogaine administration. In addition, significant decreases in SP-like immunoreactivity were observed in the frontal cortex tissues from animals treated with ibogaine. The NT- and SP-system in the striatal-nigral pathway appeared to be more sensitive to the ibogaine effects. We will compare these changes in neuropeptide systems to those caused by cocaine and methamphetamine (Supported by a minority supplement to NIDA grant 09407).

DRUGS OF ABUSE: COCAINE VI

EFFECTS OF NEONATAL COCAINE EXPOSURE ON BEHAVIORAL RESPONSE TO CLONIDINE IN RATS.
L.S. Trench*, C.M. Staton, and S.Barron. Department of Psychology, University of Kentucky, Lexington, KY 40506-0044.

The effects of neonatal cocaine exposure on behavioral response to a NE agonist, clonidine, was examined in rat pups. Cocaine was administered during the early neonatal period, or "brain growth spurt". On postnatal day (PND) 4, one male and one female subject per litter were assigned to one of four treatment groups: 1) artificially reared (AR) receiving 40 mg/kg cocaine, 2) AR receiving 20 mg/kg cocaine, 3) an AR control, and 4) a sham surgery control reared normally by a dam. AR groups were fed via a surgically implanted intragastric feeding tube from PND 4-10. On PND 11, subjects were randomly assigned to 1 of 3 doses of clonidine: saline, 0.25 mg/kg clonidine, or 1 mg/kg clonidine. Wall climbing and locomotor response to an i.p. injection were assessed. Clonidine administration produced wall climbing in all treatment groups. A sex difference in latency to initiate wall climbing was specific to the 20 mg/kg cocaine pups. In addition, clonidine produced a dose-dependent increase in locomotor activity in all treatment groups except the 40 mg/kg cocaine dose. Therefore, neonatal cocaine exposure may alter the behavioral response to clonidine by affecting the developing NE system. This research was supported, in part, by NIDA DA06049 to SB and a Howard Hughes undergraduate award to MS.

PRENATAL COCAINE ALTERS PHOSPHOLIPASE C ACTIVITY AND 5-HT RECEPTOR-MEDIATED RESPONSES IN RAT PROGENY
G. Battaglia,* T.M. Cabrera , L.D. Van de Kar and W.A. Wolf. Dept. of Pharmacology, Loyola Univ. Chicago, Stritch Sch. of Med., Maywood, IL 60153.

We previously reported that prenatal cocaine potentiates 5-$HT_{2A/2C}$ serotonin receptor-mediated hormone responses in prepubescent progeny (NIDA Research Monogr. 162:313,1996). The present study investigates the effects of prenatal cocaine exposure on phospholipase C (PLC) activity and 5-$HT_{2A/2C}$ mediated PLC activity in various brain regions of progeny. Pregnant rats were administered saline or (-)cocaine (15mg/kg,sc, bid) from gestational day 13 through 20. Phospholipase C activity (PLC) was measured in membrane homogenates by modification of the method of Wallace & Claro (JPET, 255:1296,1990). Briefly, tissues (50ug protein) were incubated (37°C for 20min) in a total volume of 100 ul containing 50 mM Hepes-Tris, pH 7.4, 6 mM $MgCl_2$, 1 mM sodium deoxycholate, and specified concentrations of Ca^{+2} using an EGTA-Ca^{+2} buffering system and exogenously added ^{3}H-phosphatidylinositol (PI). The production of ^{3}H-Inositol phosphate (^{3}H-IP), following extraction, provided an index of PLC activity (pmol/mg protein/min). Initial studies in hypothalamus of prepubescent male progeny indicated that, in cocaine-exposed progeny, PLC activity in response to an Emax concentration of mCPP (1uM) was increased 5.4-fold over basal (i.e. activity in the presence of 150nM Ca^{+2}). PLC activity was increased only 3.8-fold over basal in saline offspring. Serotonin (1uM) did not significantly alter PLC activity in hypothalamus. In contrast, serotonin (1uM) markedly increased PLC activity (+205 ± 20 pmol/min/mg protein) in cortex of saline-exposed progeny. However, prenatal cocaine did not alter the serotonin stimulated PLC activity. These data suggest that prenatal exposure to cocaine may alter the sensitivity of PLC to 5-HT_2 receptor agonists in a region-specific manner. (Supported by NIDA Grant DA 07741)

PRENATAL METHAMPHETAMINE EXPOSURE IN SPRAGUE-DAWLEY RATS: MATERNAL AND OFFSPRING OUTCOMES. S. Bucher-Yiannoutsos*, S. Kilroy, A. Smith, J. Spodnick, W. Michaud and J.D. Salamone. Department of Psychology, University of Connecticut, Storrs, CT 06269.

Recently, the number of human methamphetamine abusers has risen sharply; about 11% of this group are women of childbearing age. Despite this, there are few reports concerning the effects of prenatal methamphetamine (METH) administration on later offspring behavior, and little characterization of its effects on pregnant dams. We investigated the effects of moderate doses of METH (5 mg/kg and 3 mg/kg SC; gestation day 7-20) on the general heath, induction of stereotypy, and nestbuilding activity of pregnant dams, as well as the characteristics of their litters at birth, and subsequent physical, reflexive, and social development of METH exposed versus pair-fed saline injected (PFS) control dam offspring. Preliminary results concerning general health and nestbuilding during pregnancy indicate that METH has dose-dependent detrimental effects; METH-treated dams at both doses exhibited significantly less weight gain throughout the latter part of pregnancy, compared to PFS controls, and the integrity of their nests was compromised. All METH-treated dams exhibited stereotypic behavior at 30 minutes, 1 hour, and 3 hours post-injection. Prenatal METH administration (5.0 mg/kg) also resulted in an increased rate of dam mortality, litter reabsorption, offspring malformation, and decreased litter size. Although the overall number of pups in litters born to METH exposed dams was lower as compared to PFS dams, there was no difference observed in average pup weight on postnatal days 5, 10, 15, or 21. Postnatal maternal health and nestbuilding behavior was unaffected by previous METH exposure. No significant differences were observed between METH and PFS litters in physical or reflexive development. Future research should also examine the effects of prenatal METH exposure on juvenile social activity.

COCAINE KILLS DOPAMINE NEURONS *IN VITRO* BY EITHER APOPTOSIS AND/OR NECROSIS: A POSSIBLE UTERINE POSITION PHENOMENON IN FETAL RATS. J.W. Lipton*[1,2], E.D. Potter[1], D.E. Weese-Mayer[2], and P.M. Carvey[1]. [1]Neurological Sciences and Pediatrics[2], Rush Presbyterian-St. Luke's Med. Ctr.., Rush Children's Hospital, Chicago IL 60612

Using our established rat model for *in utero* cocaine exposure (30 mg/kg b.i.d., s.c., E7-E21 of gestation), we have previously shown that fetuses so exposed have reduced numbers of cultured DA neurons (Buhrfiend et al., 1996), and that as neonates exhibit DA deficits in the carotid body (Lipton et al., 1996a) and abnormal ventilatory responses to hypoxia (Lipton et al., 1996b). Using this dosage, fetal brain cocaine levels can reach levels exceeding 10^{-9}M. In addition, brain cocaine levels vary significantly in relation to a fetus' position in the uterine horn. At peak brain levels (60 min post-injection) cocaine levels at proximal uterine positions are over 400% of those in distal positions. In order to examine the mechanisms whereby cocaine induces alterations in the normal neurodevelopmental sequelae of the fetal rat, we investigated the possibility that cocaine is inducing programmed cell death or apoptosis in the rostral mesencephalic tegmentum (fetal substantia nigra). Examination of the cultures using the TdT enzyme -catalyzed labeling of DNA fragments, confirmed with DAPI nuclear stain and DNA laddering revealed that physiologically relevant concentrations of cocaine (10^{-10}M) killed DA neurons through apoptosis while higher concentrations killed through necrosis. Taken together, these data suggest that fetal position may impact the type of neuron toxicity observed and that such differences may produce variable findings in subsequent neurochemical and behavioral investigation of rats so exposed. (Supported by NIDA--DA05730 (JWL), and the Justin Suth Foundation(DWM)).

PERIADOLESCENT COCAINE AND STRESS EFFECTS ON REPRODUCTIVE MATURATION AND ESTROUS CYCLICITY IN THE FEMALE RAT. D.K. Sheppard, R.F. Smith*, B. Morin, C.N. Medici. Dept. of Psychology, George Mason University, Fairfax, VA 22030.

Research on the short- and long-term effects of chronic periadolescent cocaine exposure is minimal. Only recently have we become aware of the extent to which adolescents are exposed to cocaine. During the pubertal period, one of the most dynamic systems in the central nervous system (CNS) is the hypothalamic-pituitary-gonadal axis. Puberty marks the final and crucial stage in the development of a system that forms the basis for reproductive competence in adulthood. Since elements of the CNS exhibit plasticity through adolescence, and early exposure to cocaine has been shown to have long lasting effects, selected indicators of reproductive maturation and estrous cyclicity in the female rat were examined. Sixty female Long-Evans hooded rats were randomly assigned to one of three dosing conditions (20mg cocaine/kg body weight/day, saline injected, and uninjected). The subcutaneous injections extended from weaning-through-puberty (P21-P60). Each female was evaluated for date of onset of puberty (date of vaginal opening), date of first ovulation (first non-leukocytic vaginal smear), regularity of the estrous cycle (proportion of regular 4 and 5 day cycles) during (P41-60) and after (P61-80) exposure, and rate of ovulation (number of proestrus-estrus transitions) during and after exposure. There were no differences among the three groups in onset of puberty or date of first ovulation. The cocaine exposed females had a significantly lower number of proestrus-estrus transitions, *both* during exposure *and* after exposure. The *saline* injected females had a significantly lower proportion of regular 4 and 5 day cycles, an effect which was consistently (yet insignificantly) attenuated by cocaine. The findings suggest (1) immediate *and* long lasting alterations in the control of ovulation by chronic cocaine exposure throughout adolescence, and (2) stress-induced irregularity of the estrous cycle, possibly attenuated by cocaine and recoverable after exposure, in female rats. (Funded by NIDA Grant 1 R15 DA09686-01)

CHRONIC COCAINE TREATMENT ALTERS MATERNAL BEHAVIOR IN A DOSE RESPONSE MANNER IN SPRAGUE DAWLEY RATS. **C.J.Nelson*, A.Ayers, K.E.Meter C.H.Walker and J.M.Johns. Depts. of Psychology, Psychiatry and UNCNC, Univ. of North Carolina, Chapel Hill, N.C. 27599.**

The effects of chronic cocaine administration on maternal behaviors in Sprague-Dawley rats were examined. Gravid dams were injected sc, BID on GD1-20 with approximately 6.3, 13 or 25mg/kg cocaine HCL or an equivalent volume of saline. Maternal behavior was tested on postpartum days 1 and 3. Results indicate that cocaine affects the onset (PPD1) of maternal behavior in a dose dependent manner for retrieval, crouching, nestbuilding and rest off/lay on pups. High dose animals were slower to retrieve, less likely to crouch or nest and more likely to lay off to the side of the pups. Differences could not be attributed to general increases in locomotion or stereotypies. There were no significant differences between groups on oxytocin levels assessed on PPD 11 in the amygdala, ventral tegmental area or hippocampus. Data will also be presented for cocaine's effects on established maternal behavior (PPD3). It appears that cocaine disrupts at least some aspects of maternal behavior in a dose-dependent manner.

(NIDA grant DA 08456-02).

738.7

ACUTE COCAINE TREATMENT DECREASES MATERNAL AGGRESSION IN A DOSE RESPONSE MANNER IN SPRAGUE DAWLEY RATS. **J.M.Johns*, A.Ayers, C.D.Couch C. J.Nelson, K.E.Meter, and C.H. Walker. Depts. of Psychiatry, Psychology and UNCNC, Univ. of North Carolina, Chapel Hill, N.C. 27599.**

Gravid Sprague-Dawley rats (250-275g) received one of four treatments throughout gestation; s.c. injections b.i.d. of saline or 30, 15 or 7.5 mg/kg of cocaine HCL. A non-treated control group was also tested. Females were tested on postpartum day 6 for maternal aggression towards a male or female intruder during a 10 min. period. Cocaine treated dams in the 30 and 15 mg/kg dose groups attacked an intruder less frequently than did saline controls (p<.02). There was no effect of sex of the intruder on number of attacks. The 15 mg/kg dose females pinned the intruder less and spent less time fighting than saline controls (p<.05). For all groups, male intruders were pushed or boxed more than female intruders (p<.05) and female intruders were rough groomed and nipped more than male intruders (p<.01). Most aggressive behaviors were altered in a dose response manner with the highest cocaine dose associated with the least aggression. **(Supported by NIDA grant DA 08456-02).**

738.8

ACUTE COCAINE DISRUPTS ALL COMPONENTS OF ESTABLISHED POSTPARTUM MATERNAL BEHAVIOR IN THE RAT. E.M. Vernotica*[1], J.S. Rosenblatt[2], & J.I. Morrell[1], Ctr. for Molec. & Behav. Neurosc.[1] & the Inst. of Anim. Behav.[2]., Rutgers Univ. Newark, N.J. 07102

Previously we demonstrated that repeated exposure to cocaine disrupts maternal behavior only when cocaine is present in the dam's circulation. However, we did not know whether the impairment in maternal behavior depends upon sensitization caused by previous cocaine treatment or if one dose of cocaine in the postpartum period could produce the same impairment. This study examines whether a single injection of cocaine will disrupt established maternal behavior. Dams received either 0, 10, 20, or 40 mg/kg of cocaine (sc), on postpartum days 4 and 5. All cocaine-treated dams showed deficits in most aspects of maternal behavior, pup retrieval, nestbuilding, crouching over pups, and maternal aggression. Dams with cocaine in their blood had retrieval latencies 3-fold greater than when the same females were drug-free or compared to controls; maternal nestbuilding was rare or poor; maternal crouching over pups was reduced 3-fold; maternal aggression decreased 2-fold. Hoarding behavior was not affected in dams receiving either the lower or moderate cocaine doses. Locomotor activity & stereotypy increased 7-10 fold. This pattern of impaired maternal behavior following only one or two cocaine injections is similar in magnitude and direction of the impairments after chronic treatment. Thus, drug sensitization is not necessary for the cocaine-induced impairment of maternal behavior. Dams displayed both retrieval and hoarding behaviors suggesting that motor skills and patterns of activity other than locomotor and steretotypy are still available to the female while cocaine is in the circulation. These results provide evidence that the impairment of maternal behavior is not simply a derivative of increased motor activity or stereotypy. Supported by NIDA grant DA-07513 to JIM & JSR.

738.9

GONADAL INFLUENCE ON COCAINE METABOLISM IN THE RAT. B. P. Bowman*, S. L. Davis, P. J. Little, N. M. Rehder, B. F. Thomas and C. M. Kuhn. Dept. of Pharmacology, Duke Univ. Medical Center, Durham, NC 27710 and Research Triangle Institute, Research Triangle Park, NC 27709.

Behavioral work has indicated that female rats are more sensitive to the acute and chronic stimulatory effects of cocaine (coc) and amphetamine. For amphetamine, gender differences in metabolism play at least a partial role in this effect. Previous work in our labs has shown that no gender differences in coc levels exist after acute administration of 15 mg/kg coc i.p. There was however a difference in the major metabolites produced in males and females. The purpose of the current study was to determine the effects of gonadal steroids on coc metabolism in male and female rats. One week after sham surgery or gonadectomy, adult males and females were given 15 mg/kg coc i.p. Thirty minutes after injection brain and plasma were collected and analyzed for coc, Benzoylecgonine (BE) and Ecgonine Methyl Ester (EME) by GC/MS. As previously reported, no gender differences in plasma coc levels were found, but there were gender differences in metabolites as males showed higher BE and females higher EME (ANOVA $p < .01$ for gender). Gonadectomy significantly decreased BE levels ($p < .02$), but did not change EME levels, indicating that gonadal steroids play a partial role in regulating coc metabolism. These gender differences in coc metabolism patterns but not tissue coc levels suggest that gender differences in behavior reflect differential sensitivity to cocaine. (Supported by DA-9079)

BEHAVIORAL EFFECTS OF IRON DEFICIENCY IN C57BL/6 AND DBA/2 MICE. A.C. Morse*, J.L. Beard, B.C. Jones, Departments of Biobehavioral Health and Nutrition, The Pennsylvania State University, University Park, PA 16802-6508 USA.

It has been proposed that iron deficiency mediates changes in behavior by causing a decrease in the functional activity of dopamine D_2 receptors. This study was designed to evaluate the influence of iron deficiency in C57 and DBA mice on open field behaviors under three conditions; unmolested, saline injection and 15mg/kg cocaine injection. Open field behaviors included horizontal activity/total distance traveled, nosepokes (anemic infants are said to demonstrate a lack of interest in their surroundings), stereotypy, and margin time (fear response - infants with low ferritin are reported to be more fearful). We hypothesized that iron deficient mice would show decreased iron stores and locomotion under all conditions compared to control subjects due to iron induced changes in the dopamine system. The results support out hypotheses, showing significant effects of strain, sex and iron status on hepatic and brain iron stores, and on multiple measures of open field behavior. The strain differences observed in our mouse model of iron deficiency suggest that particular aspects of iron deficiency may be genetically mediated.

This research was supported in part by USPH grants DA07171, DA07277 and a grant from Hershey Foods.

IDENTIFICATION OF AN ANIMAL MODEL FOR ASSESSING MAJOR GENE EFFECTS ON COCAINE SENSITIVITY. K.K. Henricks', B.C. Dudek & R.J. Marley. Dept. Psych., SUNY, Albany, NY 12222.

While there is evidence that individual differences in response to cocaine are mediated, in part, by genetic factors, no single gene has been identified that can account for differential responsivity to cocaine. Recent studies in our laboratory may have moved us closer to identification of the gene(s) underlying cocaine sensitivity. We have identified several cocaine-related phenotypes on which 2 closely-related substrains of C57BL mice (6J and 6ByJ) differ. The genealogy of these 2 substrains leads to the expectation that they should be genetically very similar, differing at only a few genetic loci. The large differences between the 2 substrains in cocaine sensitivity may be influenced by allelic differences at a major gene which mediates cocaine's effects. Naive ByJ mice are more resistant to cocaine-induced seizures than are 6J mice. Furthermore, among 6J mice repeated exposure to cocaine results in a decreased susceptibility to cocaine-induced seizure, while among ByJ mice, the same treatment gives rise to an increased susceptibility to seizures. In contrast to their lesser sensitivity to cocaine-induced seizures, ByJ mice show a greater sensitivity to the locomotor stimulant effect of an acute dose of cocaine. However, repeated pairing of cocaine and the test environment results in the development of conditioned locomotion during subsequent exposure to that environment among 6J, but not ByJ, mice. Similarly, conditioned sensitization to the locomotor stimulant effects of cocaine develops in 6J, but not ByJ mice. An analysis of cocaine-induced locomotion in the F1 generation from a 6J x ByJ cross indicates dominance in the direction of the more highly activated ByJ mice. Supported by the Univ. at Albany Res. Found (320 9724) and NIH (AAK0200170 & AAR0109038).

PSYCHOSTIMULANT RESPONSE IN C57BL/6J AND 129/SvJ INBRED MICE AND THEIR F1 CROSS. L. L. Miner *. Molecular Neurobiology, NIDA, IRP, Box 5180, Baltimore, MD 21224

Individual differences in mouse behavioral responses to drugs of abuse can have substantial genetic bases. Transgenic mice provide new genetic tools for assessing the roles of specific candidate genes in drug responses in studies that also provide opportunities for confounding effects of genetic backgrounds. We have thus characterized cocaine and amphetamine activation and reward in the two most commonly used strains for production of transgenic mice, C57BL/6J and 129/SvJ, and their outcrossed F1 offspring. There are large strain differences in spontaneous locomotor activity and cocaine's rewarding effects using conditioned place preference. The 129/SvJ strain is hypoactive, very sensitive to the locomotor activating effects of cocaine, but does not develop cocaine conditioned place preference under conditions that yield significant place preference in C57BL/6J mice. Large strain differences also exist in amphetamine's locomotor activating effects; animals of the 129/SvJ strain displaying blunted amphetamine responses. Many of these phenotypes may not be inherited in simple additive fashions providing evidence for significant dominance effects. The F1 generation resembles the C57BL/6J progenitor strain for a number of behaviors examined. These results suggest the need for careful attention to genetic backgrounds in studies of transgenic mice.

DRUGS OF ABUSE: COCAINE—FETAL AND NEONATAL EFFECTS

739.1

PRENATAL IV COCAINE PRODUCES PERSISTENT ALTERATIONS IN HIPPOCAMPAL α_2-ADRENERGIC RECEPTOR DENSITY AND FUNCTION. D. R. Wallace*, C. F. Mactutus, and R. M. Booze. Univ. of Kentucky, Dept. of Pharmacology, Colleges of Medicine and Pharmacy & THRI, Lexington, KY 40536-0084.

The present studies examined α_2-adrenergic receptor (α_2-AR) density and [^{3}H]NE release in the hippocampus of adult rats (10 month-old) prenatally exposed to IV cocaine. Beginning at 135 days of age the offspring were challenged with 0, 10, or 20 mg/kg (i.p.) cocaine. Altered sensitivity to cocaine was seen with female and male rats prenatally exposed to cocaine significantly more and less responsive, respectively, to the locomotor stimulatory effects of cocaine on centrally directed activity. Determination of hippocampal α_2-AR density was then performed as previously described (Eur. J. Pharmacol., 258:67, 1994). The binding of [^{3}H]RX821002 (5 nM) displayed gender-specific alterations in the cocaine group with the density of [^{3}H]RX821002 labeled sites being decreased 18% in male rats, yet increased 11% in female rats. Potassium-stimulated (30 mM) fractional release of [^{3}H]NE in 300 µm hippocampal slices was reduced in cocaine-exposed male rats as indicated by a 18% reduction in both S1 release and S2/S1 (release in the presence of 1 µM RX82001/absence of drug) release ratio. Release of [^{3}H]NE was slightly reduced in cocaine-exposed female rats, but the S2/S1 ratio was elevated 26% in cocaine-exposed females compared to saline rats. These data suggest that the hypoinnervation previously reported (Soc. Neurosci. 20:597, 1994) results in a persistent hypofunction of the noradrenergic system in the hippocampus as indicated by alterations in; 1) response to cocaine challenge, 2) receptor density and 3) [^{3}H]NE release. These changes may underlie the long-term alterations observed in offspring behavior following prenatal exposure to cocaine. (Supported by DA06638, DA09160 & ES06259).

EFFECT OF PRENATAL COCAINE ON FOOT SHOCK-INDUCED CRF mRNA AND hnRNA IN THE PARAVENTRICULAR NUCLEUS OF HYPOTHALAMUS (PVN). Cleopatra S. Planeta, Bruce T. Hope*, and Barry E. Kosofsky. Laboratory of Molecular and Developmental Neuroscience, Massachusetts General Hospital, Harvard Medical School, Boston, MA 02114.

We have previously shown a decrease in foot shock-induced freezing behavior in mice exposed to cocaine *in utero*. Foot shock is a stressful stimulus that activates the hypothalamic-pituitary-adrenal (HPA) axis, and increase the expression of CRF mRNA in the PVN. In the present study we used in situ hybridization (ISHH) to analyze the expression of CRF mRNA and heteronuclear RNA (hnRNA) after foot shock in mice exposed to cocaine *in utero*. Pregnant dams (SW) were assigned to one of three groups: a cocaine group injected with cocaine 20 mg/kg, sc. twice daily from E8 to E17 (COC); a saline-injected group pair-fed with the cocaine animals (SPF); and a saline-injected group with food available *ad libitum* (SAL). On P75 twelve mice received foot shock (N = 4 offspring per treatment group). Each animal was placed in a shock box and received 5 foot shocks (0.5 mA, 1 sec duration) at 30-sec intervals. Mice were sacrificed 10 or 60 minutes after the last shock. Controls (N = 2 offspring from each group) were sacrificed immediately after removal from their home-cages. Brain sections were processed for ISHH detection of CRF mRNA and hnRNA. Prenatal cocaine did not change basal expression of CRF mRNA in the PVN. Foot shock induced CRF mRNA and hnRNA in both COC and SAL animals, but we observed differences in the time course of hnCRF induction between the groups. In SAL offspring CRF hnRNA (and CRF mRNA) peaked 10 minutes after foot shock. Sixty minutes after foot shock CRF hnRNA expression returned to basal levels, while CRF mRNA remained elevated. In the cocaine-exposed animals the increase in CRF hnRNA (and CRF mRNA) was observed only 1 hour after foot shock. The results suggest that prenatal exposure to cocaine may produce permanent changes in HPA axis function and compromise the response to stress. (CSP - FAPESP # 9411711-5; BK-DA00175 and DA08648).

739.3

PRENATAL COCAINE EXPOSURE ALTERS SEXUAL MOTIVATION IN ADULT MALE RATS. Robert C. Eaton* and Ilona Vathy. Dept. of Psychiatry, Albert Einstein College of Medicine, Bronx, NY 10461.

Previous work of Vathy and colleagues (1993) demonstrated that prenatal cocaine (COC) exposure increases mounting and intromitting behaviors, and decreases post-ejaculatory intervals in adult-exposed male rats. This work suggests that gestational cocaine alters either mechanical and/or motivational components of male sexual behavior.

Eaton and colleagues (1994) demonstrated that prenatal cocaine exposure reduces spontaneous erections in restrained males rat by about 36%—suggesting alterations in neural mechanisms regulating erections. To determine whether motivational aspects of sexual behavior are affected this study investigated the effects of prenatal cocaine on sexual motivation in adult male rats in the X-maze.

Pregnant rats were administered either COC 10 mg/kg or saline (SAL) twice a day on gestational days 11-18. The volume of the subcutaneous injections were 0.1cc for both treatments. Beginning on postnatal day 80, males were given three weekly 30-minute tests with sexually receptive females. Males that copulated on all tests were included in the study, and were trained to run to goal box 1 containing an estrus female. Goal boxes 2 & 4 were empty and goal box 3 contained a confederate male. Once 70% choice to goal box 1 was achieved, both SAL- and COC-exposed males received either a SAL or a 10 mg/kg COC injection in a counter-balanced fashion, 15 minutes prior to each trial.

Prenatal COC exposure decreased percent choice to an estrus female compared to their SAL counterparts. Moreover, COC-exposed males also took longer to initiate copulation (e.g., increased mount latency).

These results suggest that prenatal COC exposure alters sexual motivation in adult male rats. Supported by an Aaron Diamond Foundation Fellowship to RCE and NIDA Grant DA 05833 to IV.

EFFECTS OF PRENATAL COCAINE ON DOPAMINERGIC MODULATION OF ACETYLCHOLINE RELEASE FROM STRIATAL SLICES OF JUVENILE RAT OFFSPRING. D. Jackson*, S. L. Abel, and C. A. Bolanos, Psychology Dept., Northeastern University, Boston, MA 02115.

Rats exposed to cocaine *in utero* sustain neurological and behavioral alterations that are prolific at juvenile periods of development. These effects appear to involve the actions of cocaine on nigrostriatal dopamine (DA) neurons. Previous research has shown that cocaine treatments (30 mg/kg/day, bid) to pregnant rats has apparent degenerative effects on nigral DA fiber projecting to the striatal matrix of adult female but not male offspring. Decreased tyrosine hydroxylase (TH) immunoreactivity was discernable at postnatal day (PD20) and persisted into adulthood. In contrast, a greater area of darkly-stained TH patches was revealed in striatum of prenatally-cocaine-exposed offspring of both sexes. In this study, the functional integrity of nigrostriatal DA neurons after prenatal cocaine exposure has been examined by measuring DA inhibition of striatal acetylcholine (ACh) release in offspring (PD20 and adult rats). From ED15-21, pregnant rats received saline or cocaine hydrochloride in saline (15 mg/kg, b.i.d.,sc.). Striatal slices (350 μM) were prelabelled with ^{3}[H] choline then superfused with Krebs buffer. Electrically-evoked (1 Hz/2-min, 10 mA) tritium efflux served as a measure of ACh release. The % inhibition of ACh release by nomifensine is listed below:

	Females		Males		(S)= saline; (C)= cocaine
PD20	(S) -72±15	(C) -69±13	(S) -63±15	(C) -55±11*	*=p<.05 from PD20 females
Adult	(S) -56±10*	(C) -12±4*	(S) -56 ±19	(C) -56±10	*= p<.05 from C females

This experiment indicates a greater inhibition of Ach release by reuptake blockade in PD20 female rats. This finding may be due to decreases in electrically-stimulated DA release relative to that observed in slices from other rats such that DA potentiation by nomifensine yields greater inhibition of Ach release. Selective nomifensine-induced increases in DA inhibition of cholinergic neurons in PD20 female offspring may involve sex differences in the DA transporter as evidenced by similarities in the effects of nomifensine in male offspring. Between PD20 and adulthood, prenatal cocaine exposure severely reduces responsiveness of the DA transporter to nomifensine in female rats. Future investigations will examine the developmental nature of reductions in transporter efficacy.

PRENATAL COCAINE EXPOSURE AND ALTERED NEURONAL EXCITABILITY IN THE NEONATAL RAT. P.A. Schwartzkroin* and S.C. Baraban. Dept. of Neurol. Surg., Univ. of Washington, Seattle WA 98195

A variety of neurological complications have been reported in infants exposed to cocaine during gestation. In the present study, intrinsic neuronal properties from CA1, CA3 and dentate gyrus regions were measured and compared in tissue from neonatal rats exposed to saline or cocaine *in utero* (60 mg/kg/day, s.c.; admin. daily from E8 to term). Synaptic properties of the CA1 pyramidal cell region were also examined at P20. *In vitro* intracellular recordings (n = 223) in tissue from cocaine- or saline-exposed animals revealed no differences in standard cell properties such as resting membrane potential, input resistance, time constant, and action potential duration or amplitude. However in slices from cocaine-exposed animals, spike frequency adaptation (SFA) measured during a long depolarizing current pulse (500 ms, 0.5-0.6 nA) was markedly reduced in CA1, CA3 and granule cells. SFA time constants determined at P20 for CA1 neurons were 79.4 ± 9.1 ms for controls (n = 19) and 148.9 ± 15.3 ms for cocaine animals (n = 17; $p < 0.05$). The amplitudes of afterhyperpolarizations following a spike train (100 ms, 0.5 nA; at least 4 APs) were also decreased in CA1 and CA3 neurons (P20 CA1 neurons from controls: 17.3 ± 1.4 mV, n = 14; P20 CA1 neurons from cocaine-exposed animals: 9.1 ± 1.1 mV, n = 23; $p < 0.05$). In slices from cocaine-exposed animals, synaptic responses in the CA1 region were characterized by multiple spike activity and reduced inhibitory postsynaptic potentials. These results suggest that gestational cocaine exposure induces significant changes in the electrophysiological properties of hippocampal neurons. The cell and synaptic changes are consistent with a general increase in excitability and may contribute to the neurobehavioral and epileptogenic deficits reported in this at-risk infant population. PERINATAL COCAINE EXPOSURE RESULTS IN IMMUNE DYSFUNCTION. T.C. Pellegrino*[1], K.L. Dunn [1], C.M. Ferrari[2], A.L. Riley [2], and B.M. Bayer [1]. [1]Georgetown University, Washington D.C. 20007, [2]American University, Washington D.C. 20016.

In utero cocaine exposure produces a number of behavioral and neurochemical changes in offspring of exposed mothers. Although these effects are well documented, little is known about the effects of such exposure on immune function. Sobrian and colleagues (Sobrian et al. Pharmacol. Biochem. Behav. 35: 617-629, 1990) found a change in the size of primary and secondary lymphoid tissues in young adult rats following prenatal cocaine exposure, suggesting that these changes may be a result of the prenatal drug history. The present study examined the effect of prenatal cocaine exposure on cell-mediated immunity. Specifically, adult female breeders were administered 40 mg/kg cocaine sc during gestation days 7-19. A second group was also administered cocaine daily for 30 days prior to pregnancy. Pups from both groups were compared with those born of pair-fed and vehicle-injected controls. Daily cocaine exposure 30 days prior to and on days 7-19 during pregnancy resulted in a significant decrease in mitogen-induced lymphocyte proliferation in whole blood in both male and female pups. This effect was not accompanied by changes in circulating white blood cell number or plasma corticosterone levels. The decrease in lymphocyte proliferation was not evident in control pups or pups born of mothers exposed to cocaine only during pregnancy, suggesting that maternal cocaine history may increase sensitivity to cocaine following in utero exposure.

NEONATAL COCAINE EXPOSURE EFFECTS ON THE VOLUME OF THE SEXUALLY DIMORPHIC NUCLEUS OF THE PREOPTIC AREA. T. M. Segar[1]*, K. F. Hauser[2], S. Barron[1]. [1]Department of Psychology, [2]Department of Anatomy, Univ of Kentucky, Lexington, KY 40506-0044.

A neonatal rodent model of cocaine exposure was used to study cocaine's effect on the sexually dimorphic nucleus of the preoptic area (SDN-POA) of the hypothalamus. This nucleus is larger in males than females and its development is mainly dependent on the early hormonal milieu. However, a recent study has reported that perinatal cocaine exposure alters the development of this sex difference. Rat pups were injected s.c. with either 60 mg/kg, 40 mg/kg cocaine HCL, saline or left untreated from postnatal day (PND) 1-10. The volumes of the SDN-POA and the nucleus of the anterior commissure (NAC) were examined in 80-90 day-old offspring. The NAC was examined as a reference nucleus because it is not sexually dimorphic. Neonatal cocaine exposure did not alter the volumes of the SDN-POA or the NAC, nor did it affect the normal sex difference in the SDN-POA; male volumes were larger than female volumes. Although male brain weights were larger than female brain weights, the NAC did not show a sex difference, suggesting that the sex difference in the SDN-POA is not due to brain size. This experiment suggests that neonatal cocaine exposure does not affect the development of the SDN-POA. This research was supported, in part, by NIDA DA06049 to SB.

DEVELOPMENT OF GLUTAMATE RECEPTOR SUBTYPES IN LATERAL AMYGDALA AFTER PERINATAL COCAINE EXPOSURE. A. Snyder-Keller* and Judy Jean, Wadsworth Center for Laboratories and Research, New York State Dept. of Health, Albany, NY, 12201.

Perinatal cocaine exposure increases susceptibility to cocaine-induced seizures later in life (Snyder-Keller and Keller, Neurosci. Lett. 1995). Because cocaine-induced seizures involve limbic structures, we are investigating whether perinatal cocaine exposure affects the development of glutamate receptor subtypes in the lateral amygdala, as assessed by immunocytochemical localization of the AMPA and NMDA subtypes of glutamate receptors. The brains of Sprague-Dawley rats exposed to cocaine prenatally (40 mg/kg E10-20) or postnatally (15 mg/kg P1-10) were compared at postnatal ages 1, 10 or 30 to perinatally saline-treated or untreated rats. In control rats, the apparent density of all glutamate receptor subtypes decreased with age, although cellular localization became more distinctive. Perinatal cocaine exposure resulted in age-, sex- and subtype-specific increases in GluR but not NMDAR immunostaining: prenatally cocaine-treated males had small increases in GluR2/3 at P1 that returned to normal, and a delayed increase in GluR1 at 1 month. Postnatally cocaine-treated rats exhibited more robust increases in both GluR1 and GluR2/3 immunostaining density at P10 which returned to normal by 1 month. This increased density of AMPA glutamate receptors may alter the excitatory tone of the amygdala, thus contributing to the increased seizure susceptibility of perinatally cocaine-treated rats. Supported by DA 08694.

DEVELOPMENT OF SEROTONERGIC AND DOPAMINERGIC INNERVATION OF LIMBIC REGIONS: EFFECTS OF PRENATAL COCAINE. N. Liao* and A. Snyder-Keller, Wadsworth Center for Laboratories and Research, New York State Dept. of Health, Albany, NY, 12201.

Prenatal cocaine exposure has been shown to alter brain monoaminergic systems. We examined the time course of serotonergic and dopaminergic innervation in several limbic regions in order to determine whether any alterations could contribute to the increased seizure susceptibility seen in prenatally cocaine-treated rats (Snyder-Keller and Keller, Neurosci. Lett. 1995). At postnatal day 1 (P1), immunocytochemical staining for serotonin (5-HT) in untreated rats revealed dotted fibers more dense in lateral amygdala than surrounding nuclei or piriform cortex. By P10 the basolateral amygdala received a dense 5-HT innervation, whereas the dorsal portion was less densely innervated, and the central nucleus was nearly devoid of 5-HT-immunoreactive fibers. In contrast, tyrosine hydroxylase (TH)-immunoreactive fibers were very sparse in basolateral amygdala and almost absent in more dorsal lateral amygdala. A dense dopamine innervation was present from birth to one month in the central nucleus, as well as TH-immunoreactive cell bodies located more medially. No differences were observed between prenatally cocaine-treated (40 mg/kg E10-20) and prenatally saline-treated rats in the serotonergic or TH-immunoreactive innervation of amygdala, hippocampus or piriform cortex at any age. Supported by DA 08694.

739.10

EFFECTS OF EARLY PSYCHOMOTOR STIMULANT EXPOSURE ON DOPAMINE RECEPTOR FUNCTION IN THE RAT. B.S. Neal-Beliveau*, A. Mason and A. Boyd. Department of Psychology, Indiana University - Purdue University Indianapolis, Indianapolis, IN 46202.

Dopamine (DA) receptor development occurs in distinct stages during the first weeks of life. Critical windows of vulnerability to drug exposure may occur during this period of rapid receptor proliferation. There has been some suggestion of permanent alterations in DAergic function after early psychomotor stimulant (PMS) exposure. To test the hypothesis that timing is a critical determinant of the consequences of developmental PMS exposure, rat pups were injected (sc) once daily with saline, cocaine (32 mg/kg), or methamphetamine (3.2 mg/kg) on either: (1) P0-P2, when D1 receptors within the striatal patch compartment are undergoing a rapid rate of development; (2) P3- P5, when D2 receptors are undergoing a rapid rate of development; or (3) P0-P5 to expose pups through both stages. A cohort of rats was utilized for behavioral studies, whereas another was killed on P90 for receptor autoradiography studies. DA agonists were administered on P21 and in adulthood (≥P90) to test the sensitivity of DA receptors. Responses to a challenge dose of the D1-like agonist SKF38393 (30 mg/kg) or the D2-like agonist quinpirole (0.1 mg/kg) on P21 were not significantly altered due to early PMS exposure. The incidence of certain behaviors (*e.g.*, stereotypic licking) was altered in PMS-exposed rats following DA agonist treatment in adulthood. In many cases, there were also significant treatment by injection days interactions, which suggests that timing does play a role in the consequences of PMS exposure. Thus, brief exposure to drugs which alter synaptic levels of DA during development is sufficient to cause long-term alterations in DAergic functioning. (Supported in part by DA09362)

EFFECTS OF PRENATAL COCAINE EXPOSURE ON SERIAL REVERSAL LEARNING. H. Garavan, R.E. Morgan, C.F. Mactutus, R.M. Booze, & B.J. Strupp*. Dept. of Psychology & Div. of Nutritional Sciences, Cornell Univ., Ithaca, NY 14853, & Department of Pharm., Coll. Medicine, College Pharmacy, THRI, University of Kentucky, Lexington, KY 40546.

The present study was designed to examine the long-term effects of prenatal cocaine exposure, using a regimen that avoids both prenatal undernutrition and skin lesions, confounding factors in many previous studies. Long-Evans dams were administered cocaine from gestational day (GD) 8-20 (3mg/kg, 1x/day, GD8-14, 2x/day, GD15-20) using the IV route of administration. Controls received IV saline injections. In adulthood, the offspring were tested on a serial reversal task involving a 2-choice olfactory discrimination followed by a similar 3-choice olfactory serial reversal task. No differences in learning rate were observed between the COC (n = 31) and control (n = 29) rats in the 2-choice serial reversal task. In the 3-choice task, the COC and control rats did not differ in the rate at which they mastered the original discrimination, but the COC animals required significantly more trials to reach the learning criterion on each of the four reversals. The 3-choice reversal task places a greater demand on both working memory and susceptiblity to proactive interference, processes which may therefore be affected by prenatal COC exposure. An in-depth analysis of treatment differences on the patterns of responses will also be presented to illuminate the basis of the COC effect. These findings provide evidence for enduring cognitive effects of prenatal cocaine exposure and shed light on the nature of the effects.

Supported by NIDA grants DA 07559 & DA 09160.

739.12

LONG-TERM EFFECTS OF PRENATAL COCAINE EXPOSURE ON SUSTAINED AND SELECTIVE ATTENTION, AND INHIBITORY CONTROL. R.E. Morgan*, J. Lorber, H. Garavan, C.F. Mactutus, R.M. Booze, & B.J. Strupp. Div. of Nut. Sci & Dept. of Psychology, Cornell Univ., Ithaca, NY 14853, & Dept. Pharm., Coll. Med., Coll Pharm., THRI, Univ. of Kentucky, Lexington, KY 40546.

The present study was designed to further investigate the enduring cognitive effects of prenatal cocaine exposure, using a regimen that avoids both prenatal undernutrition and skin lesions, confounding factors in many previous studies. Long-Evans dams were administered cocaine or saline injections (IV) during gestation (3mg/kg: 1x/day GD8-14, 2x/day GD15-20). In adulthood, 1 male and 1 female offspring from each litter were first trained on an automated visual discrimination task. Following mastery of the initial discrimination, saline (n = 29) and COC (n = 30) S's were tested on a series of increasingly difficult vigilance tasks in which they were required to respond to a brief visual cue presented at variable intervals following trial onset. S's then progressed to a more demanding attention task in which both cue duration and pre-stimulus delay were varied across trials within a testing session. Subsequently, the animals were tested on a distraction task, a modified version of the vigilance task in which olfactory distractors were presented on some trials, during the interval prior to illumination of the light cue. The following dependent measures were analyzed: percent correct, premature responses (a measure of response inhibition), omission errors (a measure of attentional lapses), and speed of information processing. No treatment or sex differences were found on the initial visual discrimination. Preliminary analyses of the vigilance tasks revealed a gender effect but no treatment effect. The analyses of the distraction task are still ongoing, but will be presented. Preliminary analyses do not support the hypothesis that prenatal cocaine exposure impairs sustained attention or response inhibition; effects on selective attention remain to be determined.

EFFECTS OF NEONATAL COCAINE EXPOSURE ON BEHAVIORAL RESPONSE TO A NOVEL ODOR IN AN OPEN FIELD. J.A. Willford, A. Withers and S. Barron*. Department of Psychology, University of Kentucky, Lexington, KY 40506-0044.

Using a rodent model, this study examined the effects of neonatal cocaine exposure on the behavioral response towards a novel odor in an open field. After implantation with an intragastric cannula, subjects were artificially reared (AR) from postnatal days (PN) 4-11 with drug added to the milk solution. This model represented a binge model with drug exposure occurring between the hours of 1000 and 1600 each day. There were four treatment groups: high dose cocaine (40mg/kg/day), low dose cocaine (20 mg/kg/day), stock (an AR control) and sham (a suckled control). Subjects were habituated to four familiar odors for five days in an open field. On the sixth day, subjects were tested with a novel odor. Grooming behavior, activity and time spent with the familiar and novel odors was assessed. There were no treatment group differences in the number of grooming bouts, grooming duration, activity or time spent investigating the novel odor. However, the low dose cocaine group spent more time with familiar odors than did the high dose cocaine, stock or sham groups. This may indicate an increased neophobic response in the low dose cocaine group. These findings suggest that neonatal cocaine exposure may differentially alter the behavioral response to a novel odor in an open field. This research was supported, in part, by NIDA DA06049 to SB.

Early Olfactory Learning: Cocaine-Induced Odor Preference. R.M. Philpot*, T. Dark, E. Guion, C.L. Kirstein Cognitive and Neuroscience Department, University of South Florida, Tampa Fl, 33620.

In Experiment one, postnatal day 6 (PND 6) pups received an IP injection followed by immediate vs. delayed (10 min) peppermint odor exposure. Behavior preference for the odor was tested on PND 7. Animals were received an IP injection of either cocaine (20.0 mg/kg) or saline on PND 6. Animals were either immediately exposed to peppermint odor or exposed to the odor following a ten minute delay. In both conditions odor exposure continued for a period of 30 min. Behavioral odor preference was measured as time spent on the odor side of testing chamber. An odor preference was established in both the immediate and delayed conditions (p= .0021) A trend was observed with pups in the delayed exposure condition demonstrating increased temporal differences compared to the immediate condition. To establish the dose response of these effects in Experiment two, six-day-old rat pups received an IP injection of either cocaine (2.0, 5.0, 10.0, 20.0 mg/kg) or saline followed by peppermint odor exposure on PND 6. Behavioral odor preference testing occured on PND 7. Preliminary data suggest a direct relationship between increasing dose and subsequent increased preference for the odor. These data demonstrate cocaine-induced odor preferences in young rat pups. We are currently examining the neurochemical substrates which underly this type of learning.

739.15

PRENATAL IV COCAINE: ACCURACY OF SPATIAL NAVIGATION AND TASK DIFFICULTY. C.F. Mactutus*, B.J. Strupp, and R.M. Booze. Div. Pharmacol. Exp. Therap., Col. Pharmacy; Dept. Pharmacology, Col. Medicine; Graduate Ctr. Toxicol., and THRI, Univ. of Kentucky, Lexington, KY 40546, and Div. Nutritional Sci. and Dept. Psychology, Cornell Univ., Ithaca, NY 14853.

Using the IV route of administration and doses that mimic the peak arterial levels of cocaine in human volunteers (NIDA Res. Monog. 153:318, 1995), the present studies sought to re-examine the effects of prenatal cocaine on offspring cognitive development, and to assess the generality of these effects with a pigmented strain of rat. Long-Evans female rats, implanted with an IV access port prior to breeding, were administered saline or 3 mg/kg cocaine HCl from GD8-20 (1x/day-GD8-14, 2x/day-GD15-20). Litters were culled to 8 at birth and fostered to surrogate dams. Cocaine treatment did not affect maternal, litter, offspring birth weight or growth parameters. Acquisition of spatial learning in the Morris water maze (180 cm tank, 26°C water, 10x10 cm platform, ~10 lux) began at ~30 days of age with 8, 8, and 4 training trials given over 3 days followed by a probe test on the last day. An additional set of 8 trials followed by a probe trial on day 4 was given to a male/female pair of each litter randomly assigned to each of two training conditions which differed 4-fold in hidden platform size. Prenatal cocaine treated pups displayed faster escape latencies (15%-20%), but small platform training removed the treatment effect. Spatial accuracy as defined by platform crossings and platform proximity, but not necessarily spatial preference (quadrant dwell), was significantly improved by reduced size platform training as well as by prenatal cocaine. In sum, the present data further support the hypothesis of an underlying alteration in attentional processes due to prenatal intravenous cocaine and, moreover, suggest highly specific neurobehavioral consequences of the structural (TH/DBH innervation patterns) and functional (α_2-adrenergic receptors) changes in the central noradrenergic system recently reported.

***IN-UTERO* EXPOSURE TO COCAINE AND CINGULOTHALAMIC NEURONAL ACTIVITY DURING LEARNING.** **C. Taylor*, J. H. Freeman, Jr., W. Holt, and M.Gabriel. Dept. of Psych. and Beckman Institute, Univ. of Illinois, Urbana, IL 61801.**

Twice daily injections of cocaine (4 mg/kg) administered to pregnant Dutch-belted rabbits from gestational days 8 - 29 alter the morphology and biochemistry of neurons in the anterior cingulate cortex (AC) of the offspring (Murphy et al., Lab Animal Sci, 45:163-168, 1995). A preliminary study of the functional consequences of these effects showed significant attenuation of average AC learning-related neuronal activity (N=9) in cocaine-exposed adult rabbits during discriminative avoidance training. The rabbits learned to step in a large activity wheel in response to a footshock-predictive tone (CS+) and they learned to ignore a different tone (CS-), not predictive of shock (Freeman et al., Soc Neuroci Abstr, 2:708, 1995). Here we examine the activity of an increased sample of AC neuronal records (N=23) and activity in related limbic (MD and AV) thalamic nuclei during training to criterion and ten days of reversal training (with CS+ and CS- interchanged). AC training-induced neuronal excitation and neuronal discrimination between CS+ and CS- in cocaine exposed rabbits were significantly attenuated during original learning ($P < .05$), and during reversal training ($P < .02$). AV and MD thalamic neuronal activity in exposed rabbits did not differ from that of saline exposed controls during acquisition. However, control rabbits showed discriminative neuronal activity appropriate only to original training during reversal learning, whereas the cocaine-exposed rabbits showed significant reversal of the original discriminative activity (AV: $P < .03$; MD: $P < .02$). It is suggested that compensatory cingulothalamic circuit changes during development in exposed rabbits maintain normative behavior despite cocaine-related alterations in AC (Support: NIH NS26736, NIDA PO1DA06871).

739.17

PRENATAL AND EARLY POSTNATAL COCAINE EXPOSURE: LONG-TERM EFFECTS ON COCAINE SENSITIVITY IN THE ADULT RAT. C. N. Medici*, R. F. Smith and D. K. Sheppard. Dept. of Psychology, George Mason Univ., Fairfax, VA 22030.

Prior studies in our laboratory and others have shown that prenatal cocaine has long term effects on several behaviors. These behaviors affected by cocaine seem to be mediated by dopaminergic (DA) systems which, in the rat, mature during the first three weeks of postnatal life. The present study was an investigation of the effects of cocaine during development and maturation of DA systems on spontaneous activity and cocaine sensitivity in the adult rat. Pregnant Long-Evans hooded rats were dosed with 5 or 20 mg/kg/d cocaine HCl from gestation day (GD) 7 to GD 20 and their offspring through postnatal day (PND) 10. Saline and uninjected dams and pups were used as controls. Male and female rats were tested on spontaneous activity in the open field (OF) from PND 21 to PND 53 and cumulative cocaine dosing in the OF on PND 60. Activity in the OF was different between groups with the 20 mg/kg/d animals being more active across days than 5 mg/kg/d, saline and uninjected rats. With a cumulative cocaine challenge (0, 5, 10 and 20 mg/kg), there were significant interactions with cocaine challenge and prenatal/postnatal groups, as well as gender. After the final 20 mg/kg cocaine challenge, 20 mg/kg/d rats were hyperactive in the OF, while the 5 mg/kg/d rats were hypoactive compared to saline and uninjected controls. In addition, females were more active than males after the 20 mg/kg cocaine challenge. These behavioral measures extend findings that developmental cocaine exposure alters activity and sensitivity to cocaine in the adult rat.

PRENATAL COCAINE AND CALCIUM-BINDING PROTEINS IN THE ANTERIOR CINGULATE CORTEX: A COMPARISON OF PARVALBUMIN AND CALBINDIN-D28K IMMUNOREACTIVITY. C.A. Murphy*, I. Fischer, H-Y. Wang, G. Baker, L. Terry and E.H. Murphy. Dept. Neurobiol. & Anat., Med. Coll. of PA and Hahnemann Univ., 3200 Henry Ave., Phila., PA 19129.

The anterior cingulate cortex (ACC) in rabbits exposed to cocaine in utero contains an increased number of GABA-immunoreactive neurons. The calcium-binding proteins parvalbumin and calbindin-D28K are expressed by distinct populations of GABAergic neurons, modulate the effects of calcium on neuronal firing patterns and are expressed during periods of excessive neuronal activation. We previously reported increased dendritic parvalbumin immunoreactivity in ACC of cocaine progeny. The aim of this study was to determine if calbindin-D28K would be similarly upregulated after prenatal cocaine. Pregnant female Dutch-belted rabbits were given twice-daily intravenous injections of either cocaine (2, 3 or 4 mg/kg) or saline from gestational day 8-day 29. Sections containing ACC from two groups of postnatal day 20 (P20) rabbits (saline or 3 mg/kg cocaine) were processed for calbindin immunocytochemistry. Homogenized samples of ACC from additional groups of P20 rabbits (saline, 2, 3 or 4 mg/kg cocaine) were used in Western blot analyses of calbindin. We found no significant difference in counts of calbindin-IR cells in ACC between cocaine and saline-treated animals. Western blot analyses were consistent with this observation at the 3 mg dose, and indicated an absence of prenatal cocaine effects on calbindin at the 2 and 4 mg doses as well. These results contrast with previous data demonstrating a dose-dependent increase in parvalbumin immunoreactivity. We conclude that the effects of prenatal cocaine on calcium-binding proteins in the ACC may reflect influences which are selective for certain subpopulations (parvalbumin- but not calbindin-immunoreactive) of GABAergic neurons, and that calbindin-D28K is not involved in the effects of in utero exposure to cocaine in altering CNS development in the ACC. Funded by NIDA - PO1DA06871.

PRENATAL COCAINE EXPOSURE PRODUCES MINIMAL CHANGES IN TISSUE LEVELS OF DOPAMINE, SEROTONIN, AND THEIR METABOLITES IN ADULT RATS.

R.W. Keller, Jr.*, M.T. Chen, A. Snyder-Keller#, J.N. Carlson, and S.D. Glick. Dept. of Pharmacology and Neuroscience, Albany Medical College, Albany, NY and #Wadsworth Ctr., NYS Dept. Health, Albany, NY

Pregnant Long-Evans rats were given injections of saline or cocaine (20 mg/kg twice daily, SC) between gestational days 7-21. Previous studies from this laboratory have indicated that prenatal cocaine exposure increases extracellular levels of dopamine (DA) and its metabolites (DOPAC and HVA) in striatum (STR) and N. accumbens (NA) as measured by microdialysis. This effect was observed in rat pups, but the levels returned to normal in adults. Altered tissue levels of these neurochemicals have been observed in 12-day old pups [Soc. Neurosci. Abstr. 21, 704 (1995)]. Additionally, we have observed increased levels of the serotonin (5-HT) metabolite, 5-HIAA, in the extracellular fluid of adult frontal cortex (FC) and increased 5-HT immuno-reactive fibers in the striatum of adult rats.

In the present study we examined the tissue levels of DA, 5-HT, and their metabolites in adult rats prenatally exposed to saline or cocaine. STR, rostral STR, NA, FC and hippocampus were examined. The only difference-observed was in the STR of male rats where DA levels were higher in controls than in prenatally cocaine-treated rats (71% of control levels). Levels in all other regions were similar.

PRENATAL COCAINE EXPOSURE ALTERS μ OPIOID RECEPTOR LEVELS IN BRAIN REGIONS OF NEWBORNS. A. Tempel * and R. Basheer. Department of Anesthesiology, Long Island Jewish Medical Center, New Hyde Park, New York 11040.

Clinical and animal studies show that maternal cocaine exposure results in a variety of adverse pharmacological and behavioral effects in their offspring. Adult animal studies show increased μ opioid receptor levels following cocaine treatment in brain regions where the major dopaminergic pathways terminate (i.e. striatum). Gestational cocaine exposure shows increased (^{3}H) naloxone binding in a number of brain regions in newborns. The present study was designed to determine the alterations in specific opioid receptor types in brain regions of newborns prenatally exposed to cocaine. Pregnant rats were injected daily with cocaine HCL (30mg/kg/3c.c.; S.C.) or saline, one week prior to the birth of pups. Pups from each treatment group were sacrificed on the day of birth (PD0). Quantitative in vitro receptor autoradiography was carried out on brain sections from each group. μ receptors were labeled with (^{3}H)D-Ala^2-N-Me-Phe^4, Gly-ol^5-enkephalin (DAMGE), δ receptors with (^{3}H)D-pen^2-D-pen^5-enkephalin (DPDPE) and κ receptors with (^{3}H) ethylketocylazocine (EKC) in the presence of μ and δ receptor blockers. Brain sections were placed against film for 6 months. Quantitative determinations were made using the MCID system (Imaging Research Inc.) equipped with the receptor autoradiography program. Prenatal cocaine resulted in increased μ opioid receptor levels in striatum of newborns relative to controls. Since cocaine binds to the dopamine (DA) transporter resulting in increased DA concentrations in the synapse, our data suggest that a DA-opioid interaction may be involved in the long-lasting behavioral effects observed with gestational cocaine exposure.

LONGITUDINAL INCREASE IN CORTISOL DURING HUMAN AGING PREDICTS HIPPOCAMPAL ATROPHY AND MEMORY DEFICITS.

S. Lupien[4], M. DeLeon[3], S. DeSanti[3], A. Convit[3], B.M. Tannenbaum[1], N.P.V. Nair[1], B.S. McEwen[4], R.L. Hauger[2] and M.J. Meaney[1]*. [1]Douglas Hosp Res Ctr, McGill University, Montréal, Canada H4H 1R3; VA Med Ctr, [2]UCSD, San Diego CA 92093; [3]NY Univ Med Ctr, New York NY 10016; [4]The Rockefeller Univ, New York NY 10021.

In previous studies we reported a relationship between cortisol levels over years and memory impairments. In the present study we examined the possibility that this glucocorticoid effect on cognition was mediated by an effect on hippocampal integrity. Eleven subjects (73.9±6.2 years of age) were selected from our population on the basis of cortisol history (high cortisol, n=6; stable, low cortisol, n= 5). Twenty-four hour diurnal plasma cortisol rhythms were available for all subjects for at least the past four years, as well as measures of delayed and immediate recall for the most recent year. High resolution magnetic resonance imaging was performed on all subjects and measure of the left and right hippocampal volume were derived. The results showed a significant 22% reduction ($p<.01$) in the hippocampal volume of the High Cortisol subjects. The groups differed significantly on delayed ($p<.005$), but not immediate recall. Moreover, over all subjects there was a significant correlation between the slope of the increase in basal cortisol levels over years and hippocampal volume ($r=0.78$; $p<.005$) suggesting a relationship between exposure to elevated glucocorticoid levels and hippocampal atrophy. These data provide support for the importance of increased HPA activity for hippocampal function and cognitive performance in later life. 740.2

DAILY SALIVARY CORTISOL LEVELS IN HEALTHY ELDERLIES: RELATIONSHIP TO DIETARY LIFESTYLE.

B.M. TANNENBAUM *[1], S. LUPIEN[2], E. OHASHI[1], AND M.J. MEANEY[1]. [1]McGill Univ-Douglas Hospi. Res. Ctr., Montreal, Canada, H4H 1R3. [2]Neuroendocrinol. Lab, Rockefeller Univ., NY, NY, 10021-6399.

There is considerable variability in hypothalamic-pituitary-adrenal (HPA) functioning and cognitive function both in aged humans and rats. Lupien et al. (1994, J Neurosci 14) found that individual differences in basal cortisol levels were correlated with cognitive impairments and hippocampal volume (see Lupien Soc Neurosci Abst 1996). Thus, elevated glucocorticoid levels are associated with cognitive impairments and decreased hippocampal volume. The question, then, concerns the source of the elevated HPA activity. Considering the prevalence of metabolic disorders in elderly humans, we examined the relationship between basal HPA activity and diet in the same population of elderly subjects. As part of a longitudinal study, subjects (men and women, aged 65-80 years) were asked to provide daily saliva samples for one month, four times across the day (08:00, 12:00, 16:00 and 20:00) and to record the contents of their meals. Saliva was assayed for cortisol and dietary contents were broken down into cereals, fruits and vegetables, fat/sugar, dairy items and meats. Salivary cortisol levels closely matched plasma levels obtained in earlier studies, confirming the variation in subjects. Correlational analysis revealed that salivary cortisol levels obtained at 8:00 am were highly correlated ($r=0.7$) with the ingestion of fats and sugar. This correlation was also seen at 12:00 ($r=0.67$), 16:00 ($r=0.7$) and 20:00 ($r=0.68$). The correlation with fats and sugar were the highest of any of the food groups analyzed. These preliminary data suggests that differences in diet may be relevant predictors for individual variation in cortisol and are consistent with our previous studies showing that high fat consumption can elevate basal HPA activity. (Supported by NIH AG09488).

740.3

SEROTONIN 5-HT_{1A} RECEPTORS ARE DIFFERENTIALLY REGULATED BY CORTICOSTERONE ACROSS BRAIN REGIONS IN AN AGE-DEPENDENT MANNER.

L.W. Maines* B.J. Keck and J.M. Lakoski. Departments of Pharmacology and Anesthesia, The Penn State University College of Medicine, Hershey, PA 17033.

As animals age, they become less adaptive to stressors and have prolonged elevation of stress hormone levels following an insult. Glucocorticoids and 5-HT_{1A} receptors are associated with the stress response; an increase in the density of hippocampal 5-HT_{1A} receptors occurs following acute adrenalectomy (ADX). The interaction between corticosterone (CORTS) and 5-HT_{1A} receptors across aging will be examined using radioligand binding and quantitative autoradiographic analysis to identify synaptic changes that underlie the reduced effectiveness of the stress response in the elderly.

Virgin female Fischer 344 rats (2, 12 and 17 mo) were bilaterally ADX under Nembutal anesthesia (40mg/kg, i.p.) and implanted with 21 day release CORTS pellets (placebo, 200, or 600 mgs CORTS; s.c.). At 21 days, the brain was harvested and the hippocampus, frontal cortex and hypothalamus dissected for Scatchard analysis using [^{3}H]8-OH-DPAT (0.4-13.4 nM) and results correlated with plasma CORTS levels and age. Findings revealed differential regulation of 5-HT_{1A} receptor density and affinity between the age groups by varied CORTS. In comparison to groups with 200 mgs CORTS, there was a significant increase in hippocampal 5-HT_{1A} receptor B_{max} values in the 2 and 12 mo placebo groups (35 and 32%, respectively); this response did not occur in the 17 mo group. Significant declines in B_{max} values were observed with 600 mgs CORTS in 2 mo and 12 mo groups (16 and 22%, respectively) but again this response did not occur in the 17 mo group. In the frontal cortex the affinity of 5-HT_{1A} receptors was found to be significantly dependent on CORTS across age. In contrast, the hypothalamus maintained the ability to regulate 5-HT_{1A} receptor density in the 17 mo group. Discrete changes in the regional localization of 5-HT_{1A} receptors with aging is now under current investigation using autoradiographic techniques.

740.4

PLASMA CORTICOSTERONE LEVELS IN YOUNG AND AGED RATS DURING EXTINCTION OF OPERANT BEHAVIOR.

R.L. Port*[1], M.E. Sisak[2], R.W. Brown[1] and K.S. Seybold[1]. Dept of Psychology[1] and Chemistry[2], Slippery Rock University, Slippery Rock, PA 16057.

Glucocorticoids have been implicated in age-related cognitive and neurological dysfunction. However, basal levels and responses evoked by robust stressors, such as restraint, are not markedly different in aged animals. The present study examined levels evoked by a moderate stressor: the extinction of an appetitive operant response.

Six young (3 mos) and six aged (18 mos) rats were trained to criterion (>100 responses on 2 consecutive days) using appetitive reinforcement of a barpress response. Immediately after a 20 min extinction session, blood samples were drawn and corticosterone (CORT) levels determined fluorometrically. Results indicated no significant difference between young (28.5 ug/100 ml) and aged (27.2) groups. Thus, moderate stressors do not appear to differentially affect aged subjects. However, CORT levels were found to be negatively correlated with extinction response rates. Supported by SRU.

SPECIFIC AGE-RELATED IMPAIRMENT IN THE INDUCTION OF ADRENAL NPY mRNA BY STRESS.

J.H. Silverstein*, T.M. Mizuno, J. Beasley, E. London, C.V. Mobbs Anesthesia Research and Neurobiology of Aging, Bronx VAMC, Bronx, NY 10468 and Mount Sinai School of Medicine, NY

Stress has been described as eliciting a stereotypical response to a wide variety of stimuli. Age-related alteration of some aspects of the stress response have been reported. To assess if molecular responses to stress in the adrenal gland change with age, we studied 6, 15, and 22 month old Fischer 344 rats subjected to a 2 hour restraint stress paradigm (controls has no stress), followed immediately by decapitation. Baseline glucose and corticosterone levels were not altered by age. Glucose levels following stress were significantly increased with no difference between ages. Corticosterone increased significantly after stress in all groups with the largest increase in the 22 month old rats. Corticosterone was significantly higher in 22 month vs. 6 month old rats. Neuropeptide Y mRNA levels in the adrenal glands were assessed by Northern Blot. Baseline levels of NPY mRNA were similar for all age groups. For the 6 and 15 month old animals there was a statistically significant increase in NPY mRNA following stress while there was not a statistically significant increase following stress in the 22 month old animals. In contrast, induction of proenkephalin mRNA by stress was significant at all ages, and, as with NPY mRNA non-stress levels were similar at all ages. Therefore, induction of adrenal NPY mRNA by stress is impaired during aging, although other responses to stress (glucose, corticosterone, and adrenal proenkephalin mRNA) are not.

CHANGES IN LEVELS OF GALANIN AND PROOPIOMELANOCORTIN mRNA WITH AGING AND LIFELONG MODERATE CALORIC RESTRICTION.

T.M. McShane* and P.M. Wise. ***Department of Physiology, University of Kentucky, College of Medicine, Lexington, KY 40536-0084.***

We are interested in how neuropeptides that regulate both food intake and reproductive function change with age and life-prolonging moderate caloric restriction. We have previously shown that neuropeptide-Y (NPY) mRNA in the arcuate nucleus (ARC) does not change between 4 and 18 months of age, whereas, moderate caloric restriction results in elevated levels at all ages. In the present study, we measured proopiomelanocortin (POMC) mRNA in the ARC, and galanin (GAL) mRNA in the ARC and medial septum-diagonal band (MSDB). Female Sprague-Dawley rats (7 wk) were placed on caloric restriction (CR; n=70) which was 60% of ad libitum (AL) intake measured in control rats (n=70). Rats were rapidly decapitated 2.5 weeks following ovariectomy, when rats were 4, 12, or 18 mo old. Brains were frozen and coronal section (12 microns) were cut at -20°C using a cryostat. Relative levels of POMC and GAL mRNA were measured using in situ hybridization histochemistry (ISH). cDNA clones complementary to rat POMC and GAL were used to synthesize cRNA probes labeled with [^{35}S]UTP. Slides were dipped in photographic emulsion, exposed for 2 weeks before developed, and silver grains were quantified using computer-assisted image analysis. Data were statistically analyzed using analysis of variance for a factorial design including main effects of age and diet, and the interaction between age and diet. Concerning relative level of mRNA/cell: POMC in the ARC was lower in CR vs. AL rats ($P<.02$) overall, but there was no effect of age or an interaction between age and diet, whereas GAL was not affected by age, diet or an interaction. Concerning the number of cells detected using ISH: POMC and GAL cells in the ARC, and GAL cells in the MSDB did not differ as a result of age, diet, or an interaction between age and diet. In summary, CR differentially affects levels of NPY, POMC and GAL mRNA in the ARC. However, in this animal model, we did not detect age-related changes in gene expression of these neuropeptides. Supported by NIH AG02224 to PMW and AG05648 to TMM.

DIET RESTRICTION REDUCES AGE-RELATED IMPAIRMENTS IN MEMORY AND IN MOTOR SKILLS IN FISCHER-344 X BROWN NORWAY HYBRID (F1) MALE RATS. A.L.Markowska*, M.Barra and M.Mooney
Department of Psychology, Johns Hopkins University, Baltimore, MD 21218.

A decrease in caloric intake by 40% (DR) in laboratory strains of mice and rats, in comparison to those fed ad libitum (AL), has been shown to extend their life span and to postpone the onset of some age-associated diseases as well as lowering their incidence. In the present study we have addressed the question of whether the beneficial effects of diet restriction on longevity extend to cognition and motor skills. Previously we have reported only modest beneficial effects or a lack of effects from DR on certain cognitive processes in aged Fischer-344 male rats. In order to determine the generality of DR effects and the genetic predisposition toward sensitivity to this treatment, a different strain of male rats was employed in the present study: Fischer-344 x Brown Norway hybrid (F1). Two ages of rats: 9 months old (9MO) and 33 months old (33MO), maintained on AL diet or DR diet were tested in cognitive tasks such as spatial navigation, repeated acquisition, delayed match-to-position, visual discrimination, and in a series of motor tests. Aging impaired performance in the majority of the above tasks in AL rats. DR rats showed age-related impairment but the magnitude of this effect was much milder than that in AL rats. These data indicate that the beneficial effects of diet restriction on cognition and motor skills may be, in part, genetically determined.

SEX DIFFERENCES IN MEMORY AND MOTOR SKILLS AS A FUNCTION OF AGING: INTERACTION WITH DIET RESTRICTION. M.Barra, M. Mooney, P. Cooney* and A.L. Markowska. Dept. of Psychology, Johns Hopkins University, Baltimore, MD 21218 and Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157

Gender differences in spatial abilities have been reported in both humans and rodents. While there is consensus that these gender differences exist, little is known about their development across life span. To address this question, two ages of Fischer-344 x Brown Norway hybrid rats (F1) - 4 months old (9MO) and 33 months old (33MO) - were behaviorally tested in spatial and non-spatial cognitive tasks and several motoric tasks. All rats were tested under one of two conditions: life-long, ad libitum diet (AL) , or restricted diet (DR; 40% less caloric intake) introduced at the age of 14 weeks - the later condition being the only treatment which can alter the rate of aging. Aging impaired performance in place discrimination, repeated acquisition, delayed match-to-position and sensorimotor tasks, but not in visual discrimination. Young females fed an ad libitum diet performed worse on spatial tasks than young ad libitum males. With age, differences in performance of spatial tasks disappeared, suggesting a different rate of aging in both genders. Females showed superior performance in sensorimotor tasks in both ages tested. DR produced several interactions, mainly attenuating age-related changes and to a greater extent in males rats than in females.

AGE-RELATED IMPAIRMENTS IN COGNITIVE AND MOTOR PERFORMANCE OF MICE ARE CORRELATED WITH OXIDATIVE PROTEIN DAMAGE IN BRAIN. M.J. Forster,* A. Dubey, W.A. Stutts, K.M. Dawson, H. Lal and R.S. Sohal.
Department of Pharmacology, University of North Texas Health Science Center at Fort Worth, Fort Worth, TX 76107 and Department of Biological Sciences, Southern Methodist University, Dallas TX 75275.

The current studies addressed the hypothesis that age-related declines in brain function are related to oxidative molecular damage. Protein carbonyl, an indicator of protein oxidative damage, was measured in various brain regions of aged C57BL/6JNia mice (23 mo.) which had been tested for cognitive and motor skills. When compared with young mice (5 mo.), the aged mice were impaired in learning of spatial water maze and shock-motivated discrimination tasks. The aged mice also showed impairments in a battery of tests requiring locomotor and motor coordination capacities. Individual differences in carbonyl content of cerebral cortex showed a significant relationship with degree of learning impairment in the water maze, and carbonyl content of the cerebellum showed correlation with individual differences in motor coordination performance of the aged mice. These results support the hypothesis that oxidative damage plays a significant role in age-associated declines in brain functions responsible for impaired cognitive and motor capacities.

THE VASOTOCIN SYSTEM IN THE QUAIL BRAIN: CHANGES WITH AGE.

C.Viglietti-Panzica*°, E.Garcia-Ojeda°, N.Aste°, G.C.Panzica°, N.Thompson°°, M.A.Ottinger°°. °Dept. Anatomy, Pharmacology & Forensic Med., Univ. Torino, I-10126 Torino, Italy, and °°Dept. Poultry Sc., UMD, College Park, MD, USA.

Immunocytochemical techniques were used to investigate morphological changes in vasotocin (VT) positive cells and fibers in hypothalamic and extrahypothalamic regions of male Japanese quail of different age and reproductive status. Four groups of male quail were studied: young, sexually active (6-months; YA), middle-aged, sexually active (18 months; MA), middle-aged, sexually inactive (18 months; MI), old, sexually inactive (senescent, 36 months; OI). The anatomical distribution of VT cell clusters at diencephalic level was similar in all considered groups. Specific morphological parameter, including cell size, dendritic size and staining, number of somatodendritic spines, and VT innervation in the neuropil appeared to vary during aging. In particular, magnocellular neurons showed an increase of one or more of the above-mentioned parameters in aging. These results indicate that some groups of magnocellular VT-positive neurons are activated in aging, whereas others remain unaltered. Small VT-positive neurons were observed in several locations,decrease with aging was, however, detected only in the medial preoptic nucleus (POM) and in nucleus of the stria terminalis (nST). VT neurons project to a large number of brain areas, among them a strong reduction of the innervation as well as of the immunostaining intensity was observed in nST, POM, lateral septum, dorsomedial posterior thalamus, nucleus intercollicularis, central gray, and optic tectum.
These data give evidence for specific changes in the VT system, rather than a generalized age-related decline during aging. Some magnocellular elements are activated, whereas testosterone sensitive regions show a decrease in immunoreactivity for both cell bodies and fibers. *Work supported by grants from CNR, MURST, EU (GCP), NRI 92-37023-7742 (MAO) and NATO.*

BIPHASIC AND REGION-SPECIFIC MAO B RESPONSE TO AGING IN CONTROL HUMAN BRAIN. J. Saura, N. Andrés, C. Andrade, J. Ojuel[1], K. Eriksson, and N. Mahy*. Biochemistry Unit, Statistics Department[1], School of Medicine, University of Barcelona, Barcelona 08028 Spain.

Variations of monoamine oxidases (MAO) A and B were studied during aging in 27 human subjects (age range 17-93 years) in 18 brain structures of temporal cortex, precentral gyrus, hippocampal formation, striatum, cerebellum and brainstem. [^{3}H]Ro41-1049 and [^{3}H]lazabemide were used as selective radioligands to image and quantify MAO-A and MAO-B respectively by enzyme autoradiography. Post-mortem delay or time of tissue storage did not affect MAO-A or MAO-B levels. There was, moreover, no evidence of sexual dimorphism.

A marked age-related increase in MAO-B was observed in most structures. This increase started at the age of 50-60 years. Before this age, MAO-B levels were constant in all structures studied. MAO-B-rich senile plaques were observed in some cortical areas but they did not significantly influence the age-related MAO-B increase. Surprisingly, no age-related MAO-B changes were observed in the substantia nigra. In contrast to MAO-B, no clear age-related changes in MAO-A were observed, indicating an independent regulation of the two isoenzymes, also suggested by the cross-correlation analysis of these data. (Supported by FISss 94/1461 and Biomed PL93 1359)

BRAIN CHOLINE UPTAKE AND ITS RELATION TO COGNITIVE FUNCTION IN MIDDLE AGED SUBJECTS B.M. Cohen,* D. Yurgelun-Todd, S.M. Babb, P.F. Renshaw, McLean Hospital and Harvard Medical School, 115 Mill Street, Belmont, MA 02178

Using proton magnetic resonance spectroscopy, we have observed that while brain choline uptake following ingestion of choline is substantial in young adults, it is reduced to low levels in healthy adults aged 60 and over. An inability to transport choline efficiently into brain may be a factor underlying loss of neurons, and cholinergic neurons in particular, commonly seen with age. To determine the course of changes in brain choline uptake during life and its association with cognitive function, brain choline uptake and tests of learning and recall are being studied in healthy middle aged subjects. Thus far, a wide range of values for brain choline uptake (BCU=.230 ± .244) have been observed in six middle aged subjects (45-55 yrs old). These values fall, on average, between those of younger adults, aged 20-40, (BCU=.340 ± .153) and older adults, aged 60-85, (BCU=.105 ± .026). In the middle aged subjects, there was an association between performance on the California Verbal Learning Test, total score, and brain choline uptake, r=.599, p=.209. On the short delay recall condition (CVLT-SDFR) a stronger association was found (r=.66, p=.154). Correlations are in the direction predicted; that is, poorer cognitive performance is found in subjects with lower brain choline uptake. Additional subjects are being studied, and results will be presented for a larger cohort. This work is supported by a generous gift from Mr. and Mrs. Irving Brudnick.

740.13

CHOLINERGIC CELL NUMBER IN THE NUCLEUS BASALIS OF YOUNG AND AGED BEHAVIORALLY CHARACTERIZED MONKEYS. H.M. Vercesi*, C.A. Buckmaster, and P.R. Rapp. Cntr. for Behav. Neurosci., SUNY Stony Brook, Stony Brook, NY 11794-2575.

The present study examined cholinergic cell number in the nucleus basalis of Meynert (NBM) in a nonhuman primate model of normal cognitive aging. Prior to sacrifice and histological evaluation, mature adult (10-12 years, n=4) and aged (23-25 years, n=4) rhesus monkeys were tested on a standardized battery of learning and memory tasks. Two aged subjects exhibited a profile of impairment similar to the effects of medial temporal lobe damage; the other aged animals performed as accurately as controls. Neurons immunoreactive for choline acetyltransferase (ChAT) were quantified in an evenly spaced series of histological sections from each brain, covering a 4.8 mm rostro-caudal extent of the NBM. The total number of ChAT-positive cells across all rostro-caudal levels was significantly lower in the aged group ($p=0.05$). This effect was anatomically selective and entirely accounted for by a 17% age-related reduction in ChAT cell number in the anterior half of the region examined ($p<0.05$). The topography and magnitude of ChAT cell loss was comparable in the subgroups of behaviorally-impaired and unimpaired aged monkeys. Taken together with earlier evidence (Stroessner-Johnson et al. (1992) *J. Neurosci., 12*, 1936; Voytko et al. (1995) *Dementia, 6*, 131), the findings demonstrate that different components of the basal forebrain cholinergic system are differentially susceptible to aging, and that cholinergic cell loss alone fails to account for the learning and memory deficits observed in a proportion of aged monkeys. It remains to be determined whether cell loss in non-cholinergic components of this system are more tightly coupled to age-related cognitive decline. Supported by NIH Grant AG09973.

REDUCTION OF PRESYNAPTIC CHOLINERGIC FUNCTION AS A CONSEQUENCE OF AGING: POSITRON EMISSION TOMOGRAPHY STUDIES IN RHESUS MONKEYS. RH Mach*, ML Voytko, RL Ehrenkaufer, JR Tobin, MA Nader, TE Morton and SMN Efange#. Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC and #University of Minnesota, Minneapolis, MN.

The vesamicol receptor (VR), an allosteric binding site on the vesicular transporter system for acetylcholine, has been shown to be a useful marker for studying presynaptic cholinergic function in vivo (Ann Rep Med Chem 28: 247, 1993). The goal of the current studies was to determine if there is a reduction in VR function as a consequence of aging using the novel radiotracer [F-18](+)-4-fluorobenzyltrozamicol ([F-18]FBT) in conjunction with Positron Emission Tomography (PET).

A series of PET studies (bolus injection; 180 min dynamic acquisition) were conducted in both young adult (age: 8-12 years; N=5) and aged (age: 25-35 years; N=6) rhesus monkeys. There was a high accumulation of radiotracer in the basal ganglia (BG) and lower accumulation in the cerebellum (Cb) and all regions of the cortex, a result that is consistent with the labeling of terminals of striatal cholinergic interneurons. There was a linear increase in the BG:Cb ratio as a function of time, reaching a maximum value of 1.95 ± 0.11 in the young adults. The BG:Cb ratios were markedly lower in four aged rhesus monkeys (maximum BG:Cb = 1.44 ± 0.16), whereas two aged monkeys had values within the range of the young adults (maximum BG:Cb = 2.04 and 1.88, respectively). These data suggest that there may be a reduction in presynaptic cholinergic function as a consequence of aging, that this reduction may not uniformly occur among all aged monkeys, and that PET studies with [F-18]FBT are useful in identifying age-related cholinergic deficits.

UNBIASED CELL COUNTING TECHNIQUES: LACK OF HIPPOCAMPAL PYRAMIDAL CELL LOSS IN AGED F-344 OR F-344xBN RATS. R.M. Booze*, C.L. Colson and C.F. Mactutus. Dept. of Pharmacology and College of Pharmacy, University of Kentucky Medical Center, Lexington, KY 40536.

Loss of hippocampal pyramidal neurons may occur with aging; however, recent studies using modern morphometric techniques have challenged the occurrence of cell loss in hippocampal aging (Rasmussen *et al.*, 1996; Rapp and Gallagher, 1996). In these experiments we have used traditional morphometric techniques and more recently developed unbiased estimators of cell loss (Smith and Booze, *Neurosci.* **67**:1995) to study age-related alterations in the hippocampus. Additionally, we examined two strains of rats to assess the generality of any cell loss. Adult male rats of the F-344 (N=35; 6, 18 or 24 M) or F-344xBrown Norway (N=15; 6, 20, or 32 M) strains were sacrificed and the hippocampal formation sectioned (40 µm). Serial sections through the hippocampus were processed for Nissl staining. Computer-assisted morphometry was used to assess hippocampal parameters (volume, area, length of cell fields and pyramidal cell density). Unbiased estimates of total pyramidal cell number within these regions were produced using a three-dimensional optical probe, the optical disector, in combination with a systematic random sampling scheme. The F-344 results indicate 1) that hippocampal area and volume significantly increases across the lifespan, 2) pyramidal cell density shows a slight decrease with age, but 3) no change in total cell number occurs in the pyramidal cell fields of the hippocampus with age. Similar results, but no significant volume change, were observed in the F-344xBN strain. Collectively, these data indicate that observations of age-related cell loss in studies using density measures may reflect increased hippocampal volume, rather than actual cell loss. A COMPUTATIONAL INVESTIGATION OF DENTRITIC GROWTH AS A COMPENSATORY MECHANISM FOR NEURONAL LOSS IN THE AGING BRAIN. I. E. Dror* and C. C. Morgret. Cognitive Neuroscience Lab., Dept. of Psych., Miami Uni., Oxford, OH 45056.

Cognitive abilities may be preserved with aging through a host of changes that accompany the general degradation of the aging brain. Such compensatory mechanisms are relatively well understood biologically, however, their computational significance has yet to be investigated. In the research reported here we used an artificial neural network to computationally examine one such compensatory mechanism. Namely, the incremental dentritic connections found in older people as a possible compensatory mechanism for neuronal death (Flood et al., 1985; Buell & Colemand, 1979).

We trained three-layered feed-forward neural networks to perform a variety of tasks. Any unutilized connections and neurons were pruned to eliminate any reserve computational power within the network. Then we simulated neuronal loss by randomly eliminating neurons. As a result of the lesions, the networks were not able to fully perform the tasks on which they were initially trained. Additional connections were then added to the network using a reverse-pruning algorithm. The network was able to utilize the additional computational power provided by the new connections and to counter the degradation that occurred by the loss of the lesioned neurons. Hence, the addition of dentritic connections can computationally compensate for neuronal loss that occurs with age, allowing the aging brain to continue to compute cognitive operations.

SYNAPTIC LOSSES IN CEREBELLAR PARALLEL FIBERS OF THE AGING RAT. N. Brown, R. Huang, C. Huang*. Sch. of Biol. Sci., Univ. Missouri-Kansas City[1], KC, MO 64110

To compare synaptic loss with cellular loss in the aging cerebellum, varicosities along parallel fibers were examined in Golgi sections in 3-, 9-, and 23-month-old rats (NIA Fischer 344). The density of these axonal varicosities reflects the density of synapses between the parallel fibers and the Purkinje cells whereas the size of varicosities represents the size of the synaptic mitochondria.

In the cerebellar hemisphere, rats lose 30% of the thickness of the molecular layer, 60% of the length of parallel fibers, and 80% of the synapses along parallel fibers between 3 and 23 months. Nearly 60% of the synapses is lost between 3 and 9 months. Data in the posterior vermis revealed similar but less dramatic changes. However, various literature data indicated only a 30-40% decrease of Purkinje cells during approximately the same age span and no loss in granule cells.

Because the axons of granule cells traverse both the granule cell layer and the molecular layer, regions that may differ in oxidative stress in excitotoxicity, three segments of parallel fibers were studied in the hemisphere and in the vermis: 1) ascending axon in the granule cell layer; 2) ascending axon in the molecular layer; and 3) horizontal segment in the molecular layer. Major findings are: a) the same significant age-related changes in the density of varicosities exist in all segments; b) within an age group, no significant differences exist in the size of varicosities among segments except in segment 1 which has smaller varicosities.

Thus the loss of varicosities along the axons of granule cells occurs early and may trigger losses in the Purkinje cells. This age-dependent decrease of axonal varicosities, however, appears to be the same in the granule cell layer and in the molecular layer.

ASTROCYTE MORPHOLOGY IN THE HIPPOCAMPAL DENTATE GYRUS OF BEHAVIORALLY CHARACTERIZED YOUNG AND AGED RATS. P.R. Rapp*, T.L. Aiello and M. Gallagher[†]. Cntr. for Behav. Neurosci., Univ. at Stony Brook, Stony Brook, NY 11794-2575, [†]Dept. of Psychol., UNC Chapel Hill, Chapel Hill, NC 27599-3270

Aged rats with spatial learning deficits exhibit pronounced increases in glial fibrillary acidic protein (GFAP) mRNA expression. The present study examined the morphological consequences of this effect, focusing on the hippocampal dentate gyrus as a model system. Young (6 mo) and aged (27-28 mo) male Long-Evans rats were tested on a standardized behavioral protocol in the Morris water maze prior to morphological assessment. Half of the aged subjects displayed significant deficits on the hippocampal-dependent, "place" version of the task; the other half learned as quickly as young subjects. One hippocampus from each brain was used for stereological estimation of neuron number. This analysis revealed that the total number of principal hippocampal neurons is preserved during aging, and that cell loss fails to account for age-related spatial learning impairment. GFAP-positive astrocytes were visualized immunohistochemically in closely spaced sections through the contralateral hippocampus of the same brains. The overall density of GFAP-positive cells in the dentate gyrus molecular layer was comparable across age groups. The length and complexity of GFAP labeled processes, however, appeared greater in the aged brains. This effect was most evident in outer portions of the molecular layer that receive perforant path input, and was not observed among the morphologically distinct astrocytes occupying the inner molecular layer. Notably, the magnitude of regionally selective astrocyte hypertrophy appeared comparable in cognitively-impaired and intact aged rats. Quantitative studies of astrocyte number and morphology, using modern stereological methods, are currently in progress. Our initial survey, however, suggests that astrocyte hypertrophy in the aged hippocampus occurs independent of neuron death, and that this response in the dentate gyrus is unrelated to the status of hippocampal-dependent learning. AGE-RELATED CHANGES IN NMDA RECEPTOR SUBUNITS, NR1, NR2A, AND NR2B IN RAT STRIATUM AND HIPPOCAMPUS.
YH Wang, JH Luo, RP Yasuda, M Gallagher, KJ Kellar*, and BB Wolfe. Dept. Pharmacol., Georgetown University, Washington, D.C.

Prior studies using quantitative receptor autoradiography have shown that the number of NMDA receptor binding sites in the striatum, but not hippocampus, of aged (27 month-old) Long-Evans rats is decreased relative to that found in young (6 month-old) rats. To investigate these observations more thoroughly, we have utilized selective antibodies that recognize subunits of the NMDA receptor to determine, *via* quantitative western blot analysis, the levels of each of the common subunits (NR1, NR2A, NR2B) found in the adult striatum and hippocampus. Furthermore, we examined the possibility that the levels of any of the subunits might correlate with the ability of aged rats to learn on a Morris Water Maze. Levels of NR1, NR2A, and NR2B are all significantly ($p<.05$; 2-way ANOVA) decreased in striatum and hippocampus of aged rats (n=16) compared to young rats (n=8). Correlational analysis of the aged rats alone examining the relationship of each subunit with learning index on the Morris Water Maze failed to produce any significant correlations. The age-related changes were more modest in the hippocampus (11-13%) than in the striatum (16-22%). The loss of NMDA receptor subunits may reflect reduced synaptic connectivity, or a specific down-regulation of the proteins in these tissues.

LEVELS OF NMDA RECEPTOR PROTEINS NR2A AND NR2B ARE DECREASED IN THE HIPPOCAMPUS OF AGED RATS.
K.E.Eckles* and M.D. Browning. Dept. of Pharmacology, UCHSC, Denver CO 80262

We have shown that aged animals have deficits in LTP produced by physiologically patterned stimulation paradigms, while they are still able to produce LTP induced by traditional high frequency stimulation (Moore et al. Hippocampus 3:57, 1993). A similar deficit has also been show by Deupree et al. using a minimal stimulation paradigm (10 pulses at 100Hz; Neurobiol.Aging 14:249, 1993). One possible cause of this deficit could lie within the threshold for LTP induction. As activation of the NMDA receptor (NMDAR) is critical for induction of LTP, we hypothesized that deficits in the NMDAR could be responsible for age-related deficits in LTP. The NMDAR is composed of subunits derived from two related gene families, NMDAR1 (NR1 and splice variants), and NMDAR2 (NR2A-D). The physiological current is thought to be produced by a combination of NR1 and one or more of the NR2 subunits. Changes in the subunit composition of the receptor could have profound effects on the channel function, thus altering the threshold for LTP induction. We have previously shown that NR2A and NR2B proteins are highly expressed in the hippocampus of young rats. In the present study we examined the levels of expression of these NMDAR proteins in the hippocampus of aged (24 mos) rats. Using quantitative western blot analyses with antibodies specific for NR2A and NR2B, we show that the levels of NR2A are reduced ~50% compared to young rats. An even greater reduction (~75%) was seen in the expression of NR2B. These decreases in the specific activity of NR2A and NR2B may provide a basis for explaining, at least in part, the deficits in LTP seen in aged rats.

ALZHEIMER'S DISEASE: CELL BIOLOGY

741.1

ABNORMAL CALCIUM REGULATION IN FIBROBLASTS FROM ALZHEIMER PATIENTS WITH THE APP$^{670/671}$ MUTATION
G. Gibson*[1], M. Vestling[2], H. Zhang[1], S. Szolosi[1], D. Alkon[3], L. Lannfelt[2], S. Gandy[4], R. Cowburn[2]
[1]Cornell Univ. Med. Coll. at Burke Medical Res. Inst., White Plains, NY 10605, [2]Karolinska Institute, Huddinge, Sweden, [3]NINDS, Bethesda 20892 MD. [4]Cornell Univ. Med. Coll., NY, NY 10021

Abnormalities in cultured fibroblasts from Alzheimer (AD) patients uniquely enable the determination of how gene deficits alter cell biology in native tissue from affected individuals. Calcium and oxidative metabolism are closely linked. Previous studies documented the existence of abnormalities in calcium regulation and a key enzyme of oxidative metabolism (α-ketoglutarate dehydrogenase; KGDHC) in fibroblasts from sporadic AD subjects and from patients with presenilin-1 abnormalities. The pathogenesis of AD in these cases is unknown. The current studies examined these variables in fibroblast lines from six controls and 4 demented (AD) and 2 non-demented (preAD) subjects with the Swedish familial AD (FAD) APP$^{670/671}$ mutation that causes AD via exaggerated production of Aβ. Bombesin- induced elevations in calcium were reduced from control values by 40% ($p<0.05$) in AD + pre-AD cells as compared to a 100% increase in sporadic and presenilin-1 AD cells in published studies. The peak of the bradykinin-insensitive-A23187-sensitive store was increased 14% over controls ($p<0.05$) compared to a 20% increase in previous results. KGDHC activity was not changed compared to a 44% decrease in published studies. Thus, altered regulation of internal calcium stores is common to all FAD lines tested so far, but the precise change varies with different gene mutations. Comparison of signal transduction in cell lines from different FAD families will allow testing of the hypothesis that the various FAD gene abnormalities converge at the level of abnormal signal transduction.

Differentiation-Regulated Sialylation of the Alzheimer ßA4 Amyloid Protein Precursor in Primary Cerebellar Neurons
U. Mönning*, R. Sandbrink[1], J. Turner and K. Beyreuther[1]
Research Laboratories of Schering AG, Department of CNS Research, 13342 Berlin, Germany
[1]Center for Molecular Biology, University of Heidelberg, Im Neuenheimer Feld 282, 69120 Heidelberg, Germany

Since Alzheimer's disease is defined as a neurodegenerative disorder, neuronal cells occupy a critical position in Alzheimer research. It is suggested that neuronal APP and APP degradation products are major components of amyloid plaques.
To gain insight into possible neuronal-driven amyloidogenesis, we have chosen cerebellar neurons as a model because the postnatal development of cerebellum in rodents has already allowed numerous and extensive studies of their properties in tissue culture. We cultured mouse cerebellar neurons at postnatal day (P) 6, to explore how neuronal APP biogenesis changes during in vitro maturation.
Three distinct isoforms of transmembrane APP 695 and two secreted APP 695 isoforms were identified in cerebellar granule cells. We have shown that transmembrane and secreted isoforms of APP 695 differ in their sialylated state. Prolonged cultivation of granule cells leads to a change in the ratio of sialylated and non-sialylated APP isoforms. A drastic increase in the production of sialylated APP isoforms was observed. These changes in sialylated state of APP695 are associated with changes in proteolytic processing of APP. We were able to demonstrate that prolonged cultivation of granule cells leads to enhanced amounts of amyloidogenic C-terminal fragments. These findings support the hypothesis that sialylation of neuronal APP favours the generation of potentially amyloidogenic fragments which cause the neuropathological features of Alzheimer's disease and related disorders.

RATS TRANSGENIC FOR HUMAN APP^{770} HAVE IMPAIRED PLACE MEMORY AND HIPPOCAMPAL LONG-TERM POTENTIATION.
D.P. Binsack[1,*], H.K. Lee[2], C.M. Leonard[3], M. Montoya-Zayala[3], and C.A. Marotta[1,2], Departments of Psychiatry and Human Behavior[1] and Neuroscience[2], Brown University, Providence, RI 02912; and, Alteon, Inc.[3], Ramsey, N.J. 07446.

Causal factors related to memory loss in Alzheimer's Disease (AD) are unclear, however, evidence has accumulated to support the view that cellular functioning and/or viability may be compromised by amyloid-related pathology. Previously we reported the preparation of transgenic rats that overexpress the amyloid precursor protein and which have a memory deficit. This animal system was used to test the hypothesis that APP^{770} rats have altered synaptic plasticity in certain neuronal populations. Hippocampal slices were obtained from APP^{770} [N=15] and matched control [N=13] and were given 0-burst stimulation and monitored for 1 hour. Field-potential recordings from the CA1 region displayed a reduction in EPSP's and in LTP. The data support the view that expression of the APP^{770} gene was related to decreased synaptic plasticity in rats. The mechanistic basis for these observations is currently being addressed.

741.4

DISTRIBUTION OF INTRACELLULAR AND CELL-SURFACE AMYLOID PRECURSOR PROTEIN IN CORTICAL ASTROCYTES.
M.J. Young*, R.K.K. Lee, R.J. Wurtman, and S. Jhaveri, Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Amyloid (Aß) peptides that form plaques in Alzheimer's disease are derived from a large transmembrane protein, the amyloid precursor protein (APP), that is ubiquitously expressed in mammalian cells. In polarized cells (e.g., hippocampal neurons), compartmentalization of APP to the trans-Golgi network or the cell surface may be prerequisite to secretory cleavage. During this process, APP is cleaved within the Aß domain to release non-amyloidogenic, soluble APP (APPs). We have shown that APPs secretion in astrocytes is accelerated by neurotransmitters and second messengers that activate PKC; also APP synthesis (mRNA and protein) is increased by receptors coupled to cAMP formation. However, the distribution of APP in these unpolarized cells is not known. We now provide immunocytochemical data on the distribution of APP in process- and non-process-bearing astrocytes.

Cortical astrocytes were cultured from P1 rats for 7-10 days. Some cultures were treated with 8-Bromo-cAMP for 24h. Cultures were fixed with aldehydes and incubated with mAb22C11, followed by FITC-secondary antibody. Some cultures were permeabilized with 0.1% Triton after fixation.

In astrocytes without processes, patchy and punctate APP immunoreactivity (APP-IR) was observed on the cell soma. Regions close to the nucleus had the highest levels of APP-IR. In process-bearing astrocytes, intense but discontinuous APP-IR was seen along the processes. When the membrane was permeabilized with Triton, diffuse and filamentous APP-IR was seen in the cell soma and processes. These data suggest that cell-surface APP is localized principally to the perikaryon, with limited amounts in the processes, while intracellular APP is uniformly distributed in the cytoplasm. Preliminary results show that increased APP expression caused by 8-Bromo-cAMP increases APP-IR. Our data are consistent with neuronal studies showing that the distribution of APP at the cell-surface is discrete, whereas intracellular APP is uniformly distributed in the cytoplasm.

BAITING THE YEAST INTERACTION TRAP WITH THE MINIMAL NEUROPROTECTIVE DOMAIN OF SECRETED βPP: A TWO-HYBRID HUNT FOR βPP'S RECEPTOR. B. L. Sopher, D. G. Pham, M. P. Mattson, and G. M. Martin*. Dept. of Pathology, Univ. of Washington, Seattle, WA 98195. Sanders-Brown Research Center on Aging, Univ. Kentucky, Lexington KY 40536.

Proteolytic cleavage of the amyloid precursor protein (βPP) by α- and β-secretase yields soluble α- and β-cleaved products (sβPPα and sβPPβ respectively) which have been shown to suppress neuronal activity and protect neurons from a variety of insults (e.g. amyloid β toxicity and glucose deprivation) by activating K^+ channels and stabilizing cellular calcium homeostasis (Nature 379:74-78). These effects appear to be mediated by a receptor-cGMP dependent pathway. Recent studies have localized the neuroprotective domain to amino acids 591-612 of βPP695 and have demonstrated that sβPPα is approximately 100 fold more potent than sβPPβ as regards the stimulation of this signal transduction pathway (see Furukawa et al., this meeting). We are currently trying to clone the sβPPα receptor using the yeast interaction trap (Cell 75: 791-803). A bait consisting of LexA fused to βPP(591-612) has been used to screen a human fetal brain cDNA fusion library. Several positive clones have been identified and are currently being screened against a negative bait (LexA fused to amino acids 597-624 of βPP695). Clones which interact strongly with amino acids 591-612 and weakly or not at all with amino acids 597-624 of APP695 will be considered the best candidate(s) (supported by the Alzheimer's Association and the NIH).

741.6

CHARACTERIZATION OF THE MOUSE APLP1 GENE PROMOTER REGION. S. Zhong*, K. Wu, D. G. Schaar and I. B. Black Dept. Neurosci. and Cell Biol., UMDNJ/Robert-Wood Johnson Med. Sch., Piscataway, NJ 08854

Amyloid Precursor Proteins (APPs) give rise to amyloid beta protein (βA4), the major component of amyloid deposits in Alzheimer's disease. The gene encoding APPs is a member of an evolutionarily conserved gene family, of which the mammalian Amyloid Precursor-Like Protein (APLP1) is expressed primarily in the nervous system. Western blot analysis suggests that APLP1 is specifically localized to the postsynaptic density (PSD) and may thus play a role in brain synaptic function. Our previous studies indicated that the promoter region of the mouse *APLP1* gene is devoid of apparent "TATA" and "CAAT" boxes and contains putative binding sites for AP-1, heat-shock protein and Sp1 (Zhong et al., 1996, *Genomics* 32, 159-162). We now report further characterization of the promoter in mouse neuro-2A cells. Transient transfection analysis reveals that a 180-base pair 5' upstream promoter region containing the possible Sp1 binding site is sufficient to drive expression of a CAT reporter gene. The Sp1 site appears to be required for *APLP1* promoter activity, as deletion of this site diminishes the CAT expression to background levels. Moreover, *APLP1* promoter activity is enhanced 4 folds by including the AP-1 site. Finally, a 3K-base pair 5' upstream fragment linked to the CAT reporter gene results in promoter activity equivalent to the level of 180-base pair fragment alone, suggesting that a negative-regulating element maybe present in this region. We propose that the transcription of the mouse *APLP1* gene is a concerted action of Sp1, Heat-shock protein, AP-1 factors, and transcription factors that act on the 5' silencer.

741.7

NACP IS A GENETIC RISK FOR VERY OLD PATIENTS WITH ALZHEIMER'S DISEASE Y. Xia, D. Kang, E. Masliah, L. Hansen, L. Thal, R. Katzman*, and T. Saitoh. Dept of Neurosci, School of Medicine, UCSD, La Jolla, CA 92093-0624

Alzheimer's disease (AD) is an age dependent disorder characterized by the presence of senile plaques and neurofibrillary tangles. Previous studies showed that the NAC peptide was present in amyloid preparations from AD patients. Here we report a polymorphism found in the NACP gene and its association with AD. The polymorphism is located in the fifth intron of the gene, 0.9kbp away from the end of exon 5. PCR amplification of this region detected an insertion of 100bp (B allele). We have found that the frequency of the B allele in normal and AD, is age dependent. In the normal group, the B allele frequency decreased with age, whereas in the AD group, it increased with age. For those individuals older than 80 years, the B allele frequency is significantly higher in AD (n=122) than in normal (n=48) after controlling for APOE (p=0.0159, OR=2.821, with 95%CI: 1.212-6.563 by Fisher's exact test). This result suggests that individuals with the B allele might have a higher risk for AD after 80 years old than those without this allele. The biological role of this polymorphism in AD pathogenesis needs to be further investigated. The current study was supported by NIH and American Health Assistance Foundation.

741.8

NACP, THE NON-Aβ COMPONENT PRECURSOR PROTEIN OF ALZHEIMER'S DISEASE AMYLOID IS ABUNDANTLY EXPRESSED IN PLATELETS A. Kittel, M. Hashimoto, M. Sundsmo, M. Yoshimoto*, and T. Saitoh. Dept of Cell Biology, Institute Expermental Medicine, Hungary Academy of Science, Budapest, POB 67, 1450, Hungary, and Dept of Neurosciences, School of Medicine, UCSD, La Jolla, CA 92093-0624

NACP, a member of the synuclein/synelfin/NACP family of peptides, has been identified in nerve terminals and neural plaques in AD brain. NACP has an amyloidgenic domain, NAC, which binds to Aβ with high affinity, suggesting that NACP may be involved in the amyloidogenic process in AD. Since physiological roles of NACP are still unclear, we tried to establish a simple cellular system to investigate NACP functions. Using RT-PCR and Western blotting analysis, we screened a variety of cell lines and found that both NACP (α-synuclein) and β-synuclein are expressed in K562, a human myelogenic cell line, under undifferentiated conditions. When cells were induced to differentiate into megakaryocytes by TPA treatment, expression of NACP was up-regulated, whereas that of β-synuclein was down-regulated within 24 hrs. Consistent with these findings, we observed that NACP, but not β-synuclein, was abundantly expressed in platelets, a terminal differentiation product of megakaryocytes. The immuno-electron microscopy study revealed that NACP is localized to secretory granules. Furthermore, the activation of platelets by thrombin stimulated NACP release. Our results suggest that NACP may play a critical role in megakaryocyte and platelet differentiation, and that platelets may be used as a model system to investigate the biological function of NACP. AMYLOID P COMPONENT AND COMPLEMENT PROTEINS IN THE PROGRESSION OF ALZHEIMER'S DISEASE. T. Duong* and P. J. Acton. Terre Haute Center, Indiana Univ. Sch. of Med., Terre Haute, IN 47809.

Chronic inflammatory reactions in brains afflicted with Alzheimer's disease (AD) have been previously shown. The evidence includes the abnormal localization of the amyloid P component (AP) and complement proteins to AD brain lesions. In this study, the distribution of AP and the complements in AD lesions were compared in brains staged for AD severity according to the method of Braak in order to estimate when these proteins become localized to the AD lesions. Autopsied brains from normal and AD patients (age range 74-92) were staged histopathologically into the AD subclinical stage II and the AD clinical stages III, IV and V. Cryostat sections were obtained from the striate, parastriate and peristriate cortices and immunolabeled for AP or the complement proteins (C1q, C3d, C4c, C5). These cortical areas were chosen because the number of AD lesions progressively decreases from the peristriate cortex to the striate cortex and these areas are thus useful for comparisons on the severity of AD changes. The results showed that AP and complement immunolabeling was present as early as stage II where AD clinical symptoms were not seen. The labeling intensity was increased with increasing AD severity and was seen mainly in senile plaques. The immunolabeling intensity in senile plaques was densest with the AP antibody and this distribution pattern was closest to that of C3d. The degree of intensity and the distribution pattern of AP immunoreactivity in senile plaques were also more similar to that of C1q than those of C4c and C5. **These data suggest that AP and the complement may be incorporated into senile plaques at an early stage of AD brain changes.** This work was supported by NIH NINDS grant NS31524.

741.10

EXPRESSION OF VOLTAGE-DEPENDENT CALCIUM CHANNEL (VDCC) SUBUNITS IN NEURITIC AMYLOID PLAQUES IN ALZHEIMER'S DISEASE. P.G. Ince[1], N.M. Thatcher[1], N.C. Day[1*], P.J Shaw[2], A.L. McCormack[3], P.J. Craig[3], R.E. Beattie[3], W. Smith[3], M. Williams[4], M.M. Harpold[4], S.G. Volsen[3]. [1]MRC Neurochemical Pathology Unit and [2]Dept. of Neurology, University of Newcastle upon Tyne NE4 6BE UK; [3]Lilly Research Centre, Erl Wood Manor, Windlesham UK; [4]SIBIA Neurosciences Inc., La Jolla, Ca.

Current understanding of VDCCs suggests that N, P and Q channels are implicated in neurotransmitter release. These channels are thought to comprise complexes of pore-forming α_{1B} (N channels) and α_{1A} (P and/or Q channels) subunits in combination with structural/regulatory α_2/δ and β subunits.

Immunocytochemistry of the normal human hippocampus, and in Alzheimer's disease, with affinity purified polyclonal antisera raised against recombinant $\alpha_{1A,B,E}$ and $\beta_{1,2,3,4}$ subunit proteins was performed.

Complementary patterns of staining indicate that the subunit combination α_{1B}/β_3 probably represents the most common presynaptic complex, whereas α_{1A}/β_4 in some hippocampal subfields colocalise in a pattern suggesting a dendritic distribution (possibly post-synaptic or related to dendrodendritic synapses). Within senile plaques there are strongly immunoreactive profiles for α_{1B} and β_3 but not the other α_1 or β subunits.

The expression of VDCC-subunit complexes associated with presynaptic function (ie α_{1B}/β_3) on senile plaque neurites would favour a regenerative rather than degenerative origin for these structures.

This work was funded by an MRC ROPA Award.

REVERSIBLE INACTIVATION OF CALPAIN I BY OXIDATION. R.P Guttmann*[1], P.D. Bell[2] and G.V.W. Johnson[1]. Depts. of [1]Psychiatry, [2]Physiology, and [2]Medicine, Univ. of Alabama at Birmingham, Birmingham, AL 35294-0017.

Oxidative stress has been postulated to play a role in several neurodegenerative disorders, including Alzheimer's disease (AD). Oxidative stress results from the inability of the cell to compensate for increased free radicals or other reactive oxygen species (ROS) including hydrogen peroxide, which cause damage to proteins, lipids and DNA. It has also been suggested that increased proteolytic processing by calpain, a calcium-dependent thiol protease, may contribute to the neurodegeneration observed in AD. However, if these neurons are under oxidative stress it could be postulated that calpain activity should decrease because the cysteine residue of the active site of calpain requires a reduced environment. In the present study, calpain I was incubated in the presence or absence of oxidant, either hydrogen peroxide or hypochlorite, and the activity measured using the fluorescent compound Suc-Leu-Leu-Val-Tyr-AMC or the microtubule-associated protein tau as substrates. Calpain I activity was strongly inhibited by oxidation with either oxidant, decreasing tau proteolysis by nearly 70 percent. This is of interest because the paired-helical filaments (PHFs) of AD are abnormal aggregates of tau. Although the initial rate of hydrolysis for the fluorescent compound was unchanged in the presence of oxidant compared to control, the amount of substrate cleaved was reduced significantly such that calpain activity was completely inhibited. Interestingly, calpain I activity was immediately recoverable to control levels upon addition of the reducing agent dithiothreitol (DTT), indicating that oxidation results in disulfide bond formation within calpain I. These data demonstrate that calpain I activity is inhibited under oxidizing conditions, in vitro, and may suggest a role for calpain inactivity under conditions of oxidative stress as observed in AD brain.

PROTEIN-PROTEIN INTERACTIONS OF HUNTINGTIN INVOLVE CALMODULIN. J. Bao* [1,2], A. H. Sharp[3], F. Persichetti[5], G. Shilling[3], M. V. Wagster[4], M. Becher[4], J. Gusella[5], M. MacDonald[5], C. A. Ross[4], V. L. Dawson[1,2], and T. M. Dawson[1,2].

Departments of [1]Neurology, [2]Neuroscience, [3]Psychiatry, and [4]Pathology, Johns Hopkins University, School of Medicine, Baltimore, MD 21287; [5]Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown, MA 02129.

Huntington's disease (HD) is an autosomal dominant progressive neurodegenerative disorder. It is believed that the expansion of polyglutamine (polyGln) in huntingtin causes HD. Abnormal protein-protein interactions involving the HD protein may account for the neuronal death in HD. Previously, we reported that huntingtin is retained on a calmodulin-Sepharose column in a calcium-dependent fashion, while mutant huntingtin with an expansion of polyGln alters the calcium-dependency. Thus, huntingtin may form a complex including calmodulin and some putative calmodulin-binding proteins. To identify these putative calmodulin-binding proteins, we applied co-immunoprecipitation of huntingtin using antibodies against huntingtin and ^{125}I-calmodulin overlay assays. We have found several calmodulin-binding proteins that associate with huntingtin from rat brain extract. Their identities are presently under study. [Supported by AFAR]

THE EFFECT OF DISRUPTING CALCINEURIN ON NEURONAL CYTOSKELETAL PROTEINS. U.S. Kayyali*†, W. Zhang¶, A.G. Yee†, J.G. Seidman¶§, and H. Potter†. Departments of Neurobiology†, Genetics¶, and Howard Hughes Medical Institute§, Harvard Medical School, Boston, MA 02115.

Mice in which the expression of the alpha isoform of the catalytic subunit of calcineurin was disrupted (CNA$\alpha^{-/-}$), exhibited significant biochemical and histological changes in their brains. The hippocampal mossy fibers of the CNA$\alpha^{-/-}$ mice were stained weakly with Bielschowsky silver stain compared to wild type. These fibers in the CNA$\alpha^{-/-}$ mice were strongly labeled with an antibody against hyperphosphorylated tau from Alzheimer's brain (PHF-1). The increased PHF-1 staining was confirmed by Western blotting. The specificity of the increase in tau phosphorylation was demonstrated by lack of increase in tau staining in the CNA$\alpha^{-/-}$ brain samples with tau-1, an antibody against dephosphorylated tau Furthermore, the CNA$\alpha^{-/-}$ mossy fibers exhibited a much weaker staining with an antibody against neurofilament protein than the wild type controls, consistent with the lack of silver staining in the CNA$\alpha^{-/-}$ mossy fibers. The changes in neurofilaments were confirmed by elctron microscopic examination of the mossy fibers. We observed that there is a reduction in the neurofilament to microtubule ratio in the CNA$\alpha^{-/-}$ mice when compared to wild type controls. The changes in tau are likely due to absence of direct activity of calcineurin on hyperphosphorylated tau. Experiments are under way to try to induce the mice to form paired helical filaments and neurofibrilary tangles.

741.14

NEURONAL EXPRESSION OF STM2 mRNA IN THE HUMAN BRAIN IS REDUCED IN ALZHEIMER'S DISEASE P.J. McMillan*, J.B. Leverenz, P. Poorkaj, G.D. Schellenberg and D.M. Dorsa. Depts. of Pharmacology, Psychiatry and Behavioral Sciences, Neurology, and Medicine, University of WA, Seattle WA 98195 and Geriatric Research, Education and Clinical Center, VA Medical Center, Seattle, WA 98108.

Mutations in the STM2 gene located on chromosome 1 have been shown to be involved in the development of familial Alzheimer's Disease in Volga German families. The function of this recently identified protein is currently unknown. To understand the function of this protein and how mutations lead to Alzheimer's Disease (AD), it is important to determine which cell types in the brain express this gene, especially in regions that are know to be affected in AD. In situ hybridization histochemistry indicates that STM2 expression in the human brain is widespread and is primarily neuronal. In addition, STM2 mRNA is expressed in a cell line with neuronal origins. Quantification of the level of expression of the STM2 message in the basal forebrain, frontal cortex and hippocampus reveals a significant decrease in AD affected subjects compared to normal age-matched controls. These data suggest that down-regulation of neuronal STM2 gene expression may be involved in the progression of AD. Supported by USPHS Grant AG05136 and NIH Grant NS20311 (DMD) and RBT Grant HD07453-01 (PJM).

REDUCED mRNA CONTENT OF SPARC IN FIBROBLASTS FROM ALZHEIMER'S DISEASE PATIENTS. S.Govoni, B.Arosio#, M.Racchi^@, A.Bianchetti^, L.Gasperini^, M.Trabucchi*^C.Vergani#, G.Annoni#. Inst. Pharmacol., Univ. of Pavia, #Chair of Gerontol., Univ. of Milano, @Inst. Pharmacol. Sci., Univ. of Milano; Alzheimer's Dept. FBF Hospital, Brescia, Italy.

Several studies have been focused on detecting biochemical and physiological alterations present in AD fibroblasts in order either to study putative pathogenetic mechanisms or to obtain biological markers potentially useful for the diagnosis of the disease. Within this context we investigated the expression of a series of acute phase and matrix proteins in cultured fibroblasts from control and AD patients. The rationale resided in the observation that cellular stress may alter the expression of such proteins and that these conditions may also be associated with altered amyloid precursor protein (APP) synthesis and secretion. For the experiments human fibroblasts derived from shoulder skin biopsy from AD donors and age-matched controls were used. Resting as well as heat shock (HS) induced mRNA levels for HSC 73 and HSP 70 were similar in controls and in AD. HS induced a modest increase of sAPP secretion which, again, was comparable in controls and in AD fibroblasts. Among the other mRNA evaluated those for procollagen type I (COL-I), COL-III and fibronectin were equal in the two groups. In contrast with the above results we found a highly significant 50% decrease of basal leves of the mRNA for SPARC, an extracelllular matrix protein. SPARC has been associated with neuronal development. Notably, substantial amounts of SPARC mRNA have been detected also in the adult brain. It has been proposed that this protein may stabilize synaptic structures. The detected deficiency of SPARC may contribute to the observed changes of fibroblast adhesiveness and, if present in the brain, may contribute to the loss of synapses characterizing AD brain.

EVIDENCE FOR *IN SITU* DNA FRAGMENTATION AND EXPRESSION OF CELL DEATH GENES IN ALZHEIMER'S DISEASE BRAIN CORTEX. S. Ledoux* and P. Desjardins, Neuroscience Research Unit, Hôpital Saint-Luc (University of Montreal), Montreal, Quebec H2X 3J4 Canada

In order to characterize cell death mechanisms involved in Alzheimer's Disease (AD), we quantitated the expression of *ced-3* and *ced-9* homologs in AD frontal cortex. Positive (*ICE*, *ICE$_{rel}$-II*, *ICE$_{rel}$-III*, *ICH-1$_L$*, *CPP32*, *Mch2*, *Mch3*, *Bcl-x$_S$*, *bax* and *bak*) and negative (*bcl-2*, *Bcl-x$_L$*, *MCL1* and *Ich-1$_S$*) regulators of apoptosis were successively examined using a semi-quantitative technique of reverse transcription-polymerase chain reaction. Total RNA was extracted from postmortem frontal, temporal and cerebellar cortex of AD patients (n=7) and elderly controls (n=7) matched for age and autolysis time. *GAPDH* was used as an internal standard to monitor loading variations. Baseline level of messages were detected for 3 *ced-3* homologs (*CPP32*, *Ich-1* and *ICE*) and 4 *ced-9* homologs (*Bcl-2*, *Bcl-x*, *MCL1* and *Bax*) in the frontal cortex. The relative abundance of these *ced-3* and *ced-9* family members was similar in other brain regions and no specific regional splicing pattern was documented. There was an overexpression of the ICEα cDNA in AD patients as compared with age-matched controls (P=0.03 by unpaired t test). In addition, marked *in situ* DNA fragmentation was observed in the same AD specimens using the TdT-mediated dUTP nick end-labeling technique. Our results indicate that several *ced-3* and *ced-9* homologs are expressed in the adult human brain, and suggest that *in situ* DNA fragmentation in AD might involve an aberrant expression of ICEα. GENE ANALYSIS OF NEURODEGENERATIVE DISEASES USING DIFFERENTIAL DISPLAY. J.M.Wells*. Bedford VAMC,Bedford MA 01730. Department of Neurology, Boston University School of Medicine.

Differential display is a powerful technique that allows one to detect changes in gene expression using small quantities of RNA. This system is ideal for detecting genes that are differentially regulated in neurodegenerative diseases. It has been suggested by some that Alzheimer disease (AD) and Lewy Body disease (LBD) are part of a spectrum of one neurodegenerative disease.

Using differential display, I have compared gene expression using RNA isolated from the frontal lobes of either AD patients or LBD patients. Several differences were detected using differential display. Two gene fragments were subsequentially reamplified and used to probe northern blots. Northern blot analysis confirmed that the two clones are preferentially expressed in LBD vs AD. This system should be ideal for examining the similarities and differences among various neurodegenerative diseases.

Supported by a grant from the Department of Veterans Affairs.

ANALYSIS OF TRANSCRIPTION FACTORS AFTER INJECTION OF N-METHYL-D-ASPARTATE (NMDA) INTO THE NUCLEUS BASALIS MAGNOCELLULARUS (nBM) IN RATS S.T. Ahlers*, A.V. Prasad, C.M. Cortes, and C.A. Auker Div. Environ. Physiol. Dept., Naval Medical Research Institute, Bethesda, MD 20889-5607.

We have previously demonstrated that administration of NMDA into the nBM produces a substantial reduction in acetylcholine in the ipsilateral frontal cortex and a subsequent increase in ß-amyloid precursor protein (ß-APP) mRNA. In order to further characterize the consequences of lesions to the nBM, 2 µl of 50mM NMDA was infused into the nBM at a rate of 0.5 µl/min in anesthetized rats. Controls were similarly injected with the saline vehicle. Rats were euthanized from 1-24 hours after injection into the nBM, the brains removed, and analyzed for various transcription factors. Brain slices were analyzed for Fos protein using immunocytochemistry. Analysis of the transcription factors NF-κB, AP1, and Sp1 was performed using electromobility shift assays on frontal cortex ipsilateral and contralateral to the injection site using elements that have been shown to bind to the APP promoter. Fos protein labeled specific cortical projection areas of the nBM between 1-3 hours post injection, but only ipsilateral to the injection. Analysis of the transcription factors in the frontal cortex homogenates indicated that Sp1 increased progressively from 1-24 hours contralaterally. AP1 was increased ipsilaterally at 1 and 6, but not 24 hours. NF-κB was increased at 1 and 6 hours on both sides. (Supported by DOD/VA grant JA432)

STUDY OF THE AD3 AND AD4 FAMILIAL ALZHEIMER'S DISEASE GENES. J. Li*, J. Ma , H. Zhou, M. Xu, P. Nilsson and H. Potter. Department of Neurobiology, Harvard Medical School, 220 Longwood Avenue, Boston, MA 02115, U.S.A.

Familial AD genes have been a particular focus of research because the characterization of their gene products should provide insights into of the molecular mechanism underlying the disease. Recently, we and others have identified a AD gene on chromosome 1 (termed AD4, STM-2 or PS-2) encoding a seven-transmembrane domain protein very similar to that encoded by AD3 (on chromosome 14, also termed S182 or PS-2) in structure and sequence. Both of these genes harbor mutations that cause inherited Alzheimer's disease at an early age. They are expressed in a variety of tissues, including brain, with different distribution and in differently spliced forms. The presence of the seven transmembrane domains and several DNA binding and/or cdc2 kinase target motifs of the form S/TPXX in the AD3 and AD4 proteins suggested to us that they may reside in the nuclear membrane and be involved in gene expression and/or in linking chromatin to the nuclear membrane. The potential chromatin-binding function for the two new AD gene products is of interest in the light of growing evidence from this lab that chromosome nondisjunction and trisomy 21 may play a role in AD. To test this hypothesis, the wild type and mutant (by site-directed mutagenesis) AD3 and AD4 cDNAs are being introduced into a yeast strain which has a phenotype (color) marker that reveals chromosome non disjunction. The two genes are also being analyzed for their affect on nondisjunction in mammalian cells. The ability of the AD3 and AD4 proteins to bind DNA and become phosphorylated by cdc2 and other mitotic kinases is being analyzed. The localization of AD3 and AD4 proteins in cells is being determined in cells transfected with a chimeric cDNA tagged with the FLAG epitope, and in untranslated cells using anti-AD3- and AD4-specific antibodies.

ISCHEMIA: ENZYMES AND METABOLISM

742.1

CLONING AND EXPRESSION OF HUMAN BRAIN µ-CALPAIN AND INHIBITION BY MDL 28,170. Matthew D. Linnik*, Pamela J. Mason, Michael R Angelastro, Shujaath Mehdi. CNS Research, Hoechst Marion Roussel, Inc., Cincinnati, OH

The calpains are a family of calcium-activated neutral cysteine proteinases that have been implicated in acute and chronic neurodegenerative diseases. The family is divided into 3 subtypes (µ-, m/µ-, and m-) based on concentration of calcium required for activation. In addition, tissue specific isozymes have been identified. Here we report the cloning, sequencing, and expression of the large subunit of human brain µ-calpain in a baculovirus expression system. The enzyme was PCR cloned from a human brain cDNA library into pFastBac1 and transposed into a bacmid expression vector. Sequencing in both directions comfirmed the presence of the active site residues Cys-115 and His-272 and near complete fidelity relative to the human skeletal muscle µ-calpain isoform. The resulting baculovirus was used to infect Sf9 insect cells and the cell lysates were evaluated. Western blot analysis of the lysates revealed a prominent band that co-migrated with authentic porcine µ-calpain. Baculovirus infected lysates readily cleaved the calpain substrate t-Boc-Val-Leu-Lys-amino methyl coumarin and this activity was completely abolished by the addition of MDL 28,170 (Cbz-Val-Phe-H). The specificity of MDL 28,170 was also established against several additional classes of proteases, including serine, aspartyl and other cysteine proteinases. The results indicate that the large subunit of µ-calpain does not require co-expression of the small subunit for activity and that MDL 28,170 is a potent and specific inhibitor of calpain, including recombinant human brain µ-calpain.

742.2

PROTECTIVE EFFECTS OF MDL 28,170, A CNS-PENETRATING CALPAIN INHIBITOR, IN THREE MODELS OF CEREBRAL ISCHEMIA. N.L. Velayo, C.G. Markgraf, J.R. Koehl, S. Mehdi, P.A. Chmielewski, M.R. Angelastro, R.J. Dinerstein* and M.D. Linnik. Hoechst Marion Roussel Inc., CNS Research, Cincinnati, OH 45215.

MDL 28,170 (Cbz-Val-Phe-H) is a potent, selective calpain inhibitor that readily penetrates cell membranes. We investigated the ability of MDL 28,170 to penetrate the blood-brain-barrier in non-ischemic rats and examined efficacy of MDL 28,170 in three different models of cerebral ischemia. Blood-brain-barrier penetration was investigated in rats using an *ex vivo* enzyme activity assay 30 min. after i.v. vehicle or MDL 28,170. MDL 28,170 penetrated the blood-brain-barrier in a dose-dependent manner, showing inhibition of cysteine proteinases between 3 and 30 mg/kg. Global ischemia was produced in gerbils by 5 min. of bilateral common carotid artery occlusion. MDL 28,170 (60 mg/kg i.p) or vehicle was administered 30 min prior to ischemia and activity was scored 24 h later. Permanent focal ischemia was produced in Wistar rats by the monofilament method. MDL 28,170 (90 mg/kg i.v) or vehicle was administered starting 5 min after ischemia; infarct volumes were measured after 24 h survival. Ischemia / reperfusion was produced in a separate groups of rats in which 180 min of ischemia, followed by reperfusion, was accomplished by the monofilament method. MDL 28,170 (40 mg/kg i.v.) or vehicle was given 30 min. after ischemia. Infarct volume and a behavioral reflex score were compared between groups. We found that MDL 28,170 decreased hyperactivity after global ischemia by 40%. It reduced infarct volume after permanent focal ischemia by 21% and after ischemia / reperfusion by 64 %. MDL 28,170 is a calpain inhibitor that demonstrates efficacy across a diversity of therapeutic models, due in part to its ability to rapidly penetrate the blood-brain-barrier.

742.3

BEHAVIORAL DEFICITS AFTER FOCAL CEREBRAL ISCHEMIA IN RATS ARE IMPROVED BY MDL 28,170 TREATMENT. C.G. Markgraf,* N.L. Velayo, P.A. Chmielewski and M.D. Linnik Hoechst Marion Roussel Inc., CNS Research, Cincinnati, OH 45215.

MDL 28,170 (Cbz-Val-Phe-H) is a potent CNS-penetrating calpain inhibitor that has shown acute efficacy in three diverse animal models of cerebral ischemia. Here, we investigate the effects of acute MDL 28,170 treatment on chronic behavioral and histological outcome measures in the rat following ischemia / reperfusion. We assessed the ability of MDL 28,170 to provide *functional* neuroprotection as measured by a series of behavioral tests over 8 days and also measured infarct volume on day 8. Wistar rats were subjected to 180 min middle cerebral artery (MCA) occlusion by the monofilament method. MDL 28,170 (40 mg/kg; MDL group) or vehicle (1.8 ml; VEH group) was administered i.v starting 30 min after MCA occlusion. Acute behavioral deficits were evaluated 48 h after occlusion using a battery of 4 tests that measured postural reflex, elicited limb placing, muscle strength and grooming sequences. Behavioral deficits were measured again after infarct maturation on day 8 and brains were processed for infarct determination. Acutely, the MDL group showed improved function in elicited limb placing, By day 8, each animal in the MDL group had improved on the limb placing, posture reflex and grooming tests, while each VEH rat showed no change in performance or got worse. MDL 28,170 reduced infarct volume on day 8 by 73%, similar to the reduction seen at 24 h after ischemia (Velayo et al., 1996). Thus, treatment with the calpain inhibitor MDL 28,170 produced acute histological neuroprotection accompanied by moderate sparing of behavioral function; the histological neuroprotection persisted over 8 days during which time the MDL group showed dramatic improvements across a variety of behavioral functions.

742.4

EXPRESSION OF m-CALPAIN mRNA AND IMMUNOHISTOCHEMICAL STAINING OF m-CALPAIN AND CALPASTATIN IN NEONATAL RAT HYPOXIC-ISCHEMIA. K. Blomgren*[1], A. McRae[1], T. Ono[2], S. Kawashima[2], T. C. Saido[2], C. Hall[1] and H. Hagberg[1,3]. [1]Institute of Anatomy and Cell Biology, Medicinaregatan 3-5, S-413 90 Göteborg, Sweden. [2]Tokyo Metropolitan Institute of Medical Science, 3-18-22 Honkomagome, Bunkyo-ku, Tokyo 113, Japan. [3]Dept. of Obstetrics and Gynecology, Sahlgrenska University Hospital, 413 45 Göteborg.

Seven-day old rats were subjected to transient cerebral hypoxic-ischemia (unilateral occlusion of the common carotid artery plus hypoxia, 7.7 % O_2 for 1.5 h). Total RNA was prepared from the ipsilateral, hypoxic-ischemic (HI) and the contralateral, hypoxic (H) hemisphere, respectively, and subjected to Northern blotting, using an RNA probe homologous to a non-coding sequence of rat m-calpain. The ratio of m-calpain mRNA between the hemispheres (HI/H) increased after the insult, and had nearly doubled after 48 h (179%, p=0.02). As shown earlier, areas with brain injury, such as the CA1 and CA2 of the hippocampus and cortical regions in the HI hemisphere, were characterized by loss of MAP 2 staining. In damaged areas, the loss of MAP 2 was preceded by loss of calpastatin staining, 2 h after the insult, and accompanied by intensified m-calpain staining, obvious after 48 h. In summary, calpastatin staining decreased early after HI, followed by an increased expression of m-calpain and loss of MAP 2. The m-calpain mRNA increased at a time-course similar to that of the protein.

742.5

EFFICACY OF CILAZAPRIL ON NERVE BLOOD FLOW IN EXPERIMENTAL DIABETIC NEUROPATHY. M. Kihara*, Y. Mitsui, M. K. Mitsui, K. Okuda and M. Takahashi. Department of Neurology, Kinki Univ. Sch. of Med., Osaka, Japan, 589.

NBF is decreased in experimental diabetic neuropathy. Angiotensin-1 converting enzyme (ACE) inhibitors may improve peripheral circulation. We decided to undertake the following experiments evaluate the efficacy of cilazapril (ACE inhibitor) on NBF in EDN. Control and streptozotocin induced diabetic neuropathy rats were fed a cilazapril supplemented diet to see if there was an improvement in NBF. We also evaluated whether epineurially applied cilazapril could act as vasodilator in peripheral nerve of normal and diabetic rats. In the diet study, diabetes caused a reduction in NBF and abnormal nerve conduction velocities and amplitudes of CMAP. NBF was significantly increased in diabetic rats supplemented with cilazapril (10mg/kg/day) at four weeks on diet and nerve conduction velocity and amplitudes of the CMAP were also improved by four weeks on this diet. Direct application (10^{-3}M) of cilazapril on sciatic nerve did not increase NBF in normal or diabetic rats. These results suggest that angiotensin-2 may be one of vasoconstrictor factor in diabetic neuropathy and that cilazapril dose not act as a direct vasodilator. Cilazapril may have potential in the treatment of diabetic nuropathy.

742.6

IMMUNOGOLD LABELING OF CALCIUM CALMODULIN-DEPENDENT KINASE II IN HIPPOCAMPAL NEURONS DURING GLOBAL ISCHEMIA. R.W. Neumar*[1,2], S.S. Alousi[1,3], B.C. White[1,2], and J.A. Rafols[3]. Depts. of Emerg. Med.[1], Physiology[2] and Anatomy[3], Wayne State Univ. School of Med., Detroit, MI 48201.

Immunohistochemical labeling of calcium/calmodulin-dependent protein kinase II (CaMKII) decreases in hippocampal neurons following transient ischemia (Onodera, et al, *Neurosci Let* 1990;113:134). Several investigators have reported translocation of CaMKII from cytosolic to subcellular fractions in ischemic brain homogenates without changes in overall enzyme levels. To further characterize subcellular redistribution of CaMKII in ischemic neurons, we performed electron microscopic examination of ischemic hippocampal neurons after immunogold labeling for CaMKII.

Adult male Long Evans rats underwent either 0 (control) or 10 minutes of complete global cerebral ischemia by cardiac arrest. Brains were transcardially perfusion fixed with 0.1% gluteraldehyde and 4.0% paraformaldehyde. Subcellular distribution of CaMKII was analyzed by immunoelectron microscopy using primary antibody to the α and β/β_1 subunits of CamKII (Upstate Biotechnology) and secondary antibody conjugated to immunogold (Sigma).

Immunogold labeling of CamKII was seen in both the soma and nuclei of hippocampal neurons. Pre-synaptic vesicles, post-synaptic densities, microtubules and organelle membranes were preferentially labeled. Ischemia resulted in an overall decrease in immunogold labeling. However, in the nuclei of many ischemic neurons, a greater number of gold particles were seen in association with the nuclear chromatin. These results suggest translocation of CaMKII within neuronal nuclei during ischemia where it is known to phosphorylate transcription factors. Work is currently underway to further characterize the regional an subcellular redistribution of CamKII during cerebral ischemia.

Inhibitors of Protein Kinase C Exacerbates Neuronal Cell Death Caused by Ionomycin in Rat Cultured Cortical Neurons . **T. Tanaka[1], I. Tatsuno[1,3], I. Moroo[2], D. Uchida[1], A. Hirai[1], and Y. Saito[1]. Depts. of [1]Internal Medicine 2 , and [2]Neurology, Chiba Univ. Sch. of Med.; [3]Health Science Center, Chiba Univ., Chiba, Japan.**

Calcium has been widely believed to play an critical role in the glutamate-induced neuronal cell death, however, its intracellular mechanism has been still under investigation. In order to clarify the roles of protein kinase C (PKC) on calcium-dependent neuronal cell death, we focused the neuronal cell death induced by ionomycin. The rat cultured neurons were obtained from E17 embryos and the purity of neurons was more than 95% after the culture for 10 days. The number of viable neurons was determined by MTT method. Ionomycin induced the neuronal cell death at as small a concentration as 0.5 μM, which was dependent on the extracellular calcium, in a dose-dependent manner. The pattern of this neuronal cell death showed delayed and apoptotic based on the observations of electron microscopy and molecular biology. Ionomycin also stimulated the translocation of PKC from cytosol to membrane from 0.4 μM in a dose-dependent manner. Although H-89 ,which is known as an inhibitor of protein kinase A, had no effect in the number of live neurons, inhibitors of PKC (staurosporin and calphostin C) exacerbated the ionomycin-induced neuronal cell death in a dose-dependent manner. These results indicate that ionomycin induce apoptotic type of cell death, which is dependent on the calcium, in rat cultured cortical neuron and that ionomycin activates PKC pathway which protects the neurons from the cell death.

742.8

THE RESPONSE OF PROTEIN KINASE C TO AN ANOXIC INSULT IS ISOFORM-SPECIFIC. J. M. Libien*, T. C. Sacktor, and J. S. Kass. Dept. of Pharmacology, State University of New York at Brooklyn, Brooklyn, NY 11203

Protein kinase C (PKC) has been suggested to play a significant role in the mechanisms of neuronal cell death initiated by cerebral anoxia. There are 10 isoforms of PKC, differing in method of activation, substrate specificity, and cellular and subcellular localization. We have therefore hypothesized that the isoforms subserve unique roles during anoxic brain damage.

The response of the PKC isoforms to anoxia was studied using hippocampal slice preparations from 25-35 day old Sprague-Dawley rats. Subjecting hippocampal slices to an anoxic gas mixture consisting of 95% N_2 and 5% CO_2 for 15 min resulted in 7 ± 6% (mean ± SEM, n = 7) recovery of the population spike in CA1 pyramidal cells. For biochemical assays, slices were frozen in liquid nitrogen immediately following anoxia. Controls consisted of adjacent slices from the same hippocampus, treated for equivalent periods of time. The CA1 regions were dissected, separated into cytosolic and membrane-particulate fractions by centrifugation, and loaded onto adjacent lanes of SDS-polyacrylamide gels. PKC isozymes were assayed by Western blots, with optimized concentrations of affinity-purified antisera to the full cohort of PKC isoforms in brain. PKCs α, βI, βII, γ, δ, and η were translocated from cytosol to membrane. PKC ε was downregulated, while the level of PKMζ, the persistently active catalytic domain of PKCζ that has been implicated in the maintenance of LTP and LTD, was unchanged. These results suggest that the PKC isoforms are differentially regulated during anoxia. Studying the differential activation of PKC isozymes may lead to a better understanding of the mechanisms leading to anoxic damage of neurons.

TRANSLOCATION OF PROTEIN KINASE C DURING HYPOXIA

Hsueh-Meei Huang* and Chyong-Hwa Weng Department of Education and Medical Research, Taichung Veterans General Hospital, Taichung, Taiwan , R.O.C.

Hypoxia increases neurotransmitter release, and protein kinase C activation has been associated with neurotransmitter release and survival of neurons. Thus, translocations of protein kinase C during hypoxia were examined. PC 12 cells were treated with KCN for various time, and protein kinase C isozymes in subcellular fractions were determined by Western blot analysis. The level of PKC γ was elevated in both nuclei and membrane fractions following 0.5 mM KCN treatment for 15, 30 or 60 min. Moreover, phorbol ester increased PKC γ in both nuclei and membrane fractions, and KCN further enhanced the phorbol ester effect. On the other hand, the level of PKC α was elevated in both nuclei and membrane fractions by phorbol ester, but not by chemical hypoxia. Surprisingly, pretreatment of cells with phorbol ester significantly enhanced PKC α in both nuclei and membrane after hypoxia treatment. (supported by TVGH 857312 and NSC 85-2331-B-075A-004)

TAU PROTEINS PHOSPHORYLATION AND PROTEOLYSIS IN A CANINE MODEL OF CEREBRAL ISCHEMIA/REPERFUSION. L. Buée*[1], P.R. Hof[2], R.E. Rosenthal[3], A. Delacourte[1], G. Fiskum[3]. [1]INSERM U422, 59045 Lille France. [2]Dept of Neurobiology, Mount Sinai Sch. Med., New York, NY 10029. [3]Dept of Biochem. and Mol. Biol., George Washington Univ., Washington, DC 20037.

The effects of cerebral ischemia and reperfusion on microtubule-associated tau proteins metabolism were assessed in a canine model of cardiac arrest. By immunoblotting, both proteolysis and phosphorylation were analyzed using phosphorylation-dependent monoclonal antibodies (AD2 and Tau-1). AD2 recognizes phosphorylated Ser396 and 404 in human tau proteins (Buée-Scherrer et al., 1996) and Tau-1 recognizes dephosphorylated tau proteins (Binder et al., 1985). Polyclonal antibodies against amino- and carboxy-terminal region of tau proteins were also used to investigate proteolysis. AD2 recognized a 70 and 74 kDa tau doublet in cerebral cortex of control dogs indicating that tau proteins are highly phosphorylated. After ischemia, tau proteins were not labeled by AD2. There was a molecular weight (MW) shift and tau proteins were recognized as a broad 65 kDa band by Tau-1 antibody indicating complete dephosphorylation. Polyclonal antibodies also labeled lower MW products suggesting that a limited proteolysis had occurred. After 2 hours of reperfusion, tau proteins had a higher MW ranging from 65 to 70 kDa. They were recognized by both AD2 and Tau-1 antibodies indicating a partial restoration of phosphorylation. However, proteolytic products were numerous suggesting that Ca^{2+}-dependent proteases may be activated. After 24 hours of reperfusion, these proteolytic products were not detected any longer, and tau proteins migrated as a 70 and 74 kDa tau doublet recognized by AD2 suggesting that normal brain metabolism had been restored. Such restoration of tau proteins phosphorylation indicates that the balance of kinases/phosphatase is still functional after global brain ischemia. Kinases involved in tau phosphorylation are MAP kinases, GSK3 and other Proline-directed protein kinases. Clearly, the integrity of this system is crucial for the recovery of neuronal function.

Supported by APHP BV940005, CNRS, INSERM and NIH grant NS34152. AD2 was developed through a collaboration between CNRS UMR 9921 (C. Mourton-Gilles & B. Pau) and INSERM.

REMODELING OF PSDs FOLLOWING TRANSIENT CEREBRAL ISCHEMIA IN RAT. B.R. Hu*, T. Wieloch[1], T. Saitoh, J. Zivin. Dept of Neurosci, UCSD, La Jolla, CA 92093, [1]Lab for Exp. Brain Res, Lund University, S 22185, Lund, Sweden.

Using a two vessel occlusion global ischemia model in the rats, we prepared postsynaptic densities (PSDs) and light membranes (LMs) from sham-operated rats and postischemic subjects. They were subjected to 15 min ischemia followed by 4 hr of reperfusion. We found the following changes: 1). The yield of PSDs was 111.68 µg per gram tissue in control brains and 278.06 µg per gram tissue in postischemic brains. Although the postischemic PSDs were increased two and a half times, NMDA and AMPA receptors were not significantly altered in the equal amounts of the PSD-proteins from the postischemic and control brains. 2). Protein composition of postischemic PSDs changed. In comparison with the controls, there were increases of six protein bands and decrease of one protein band in the postischemic PSDs. The PSD immunoblots were highly labeled with antibodies against p38-kinase and gp145trkB in postischemic PSDs, but not in control PSDs. 3). There were substantial increases in phosphotyrosine proteins in postischemic PSDs. The pattern of phosphotyrosine proteins is unique in postischemic PSDs. These phosphotyrosine proteins include NMDA receptor 2, gp145trkB and MAP-kinases. We conclude that synapses are remodeled after transient cerebral ischemia. This study was partially supported by NIH grant, NS 28121.

IN VITRO ISCHEMIA AND PHOSPHATASE 1/2A INHIBITION CAUSE SELECTIVE NEURONAL DEATH IN HIPPOCAMPAL SLICE CULTURES. J.H. Laake, E. Rundén, P. Brodal* and O.P. Ottersen. Dept. of Anatomy, Inst. of Basic Medical Sciences, University of Oslo, POBox 1105 Blindern, 0317 OSLO, NORWAY.

In an attempt to elucidate the mechanisms of selective neuronal death in ischemia and other neurodegenerative disorders, hippocampal slice cultures were subjected to metabolic and chemical insults. Slice cultures were prepared according to the roller drum technique (Gähwiler, B.H., 1988, Trends Neurosci., 11, 484-489) and were at 14 days in vitro subjected to 30-40 min. exposure to 95% N_2 / 5% CO_2 and a HEPES buffer without glucose. This caused swelling of the tissue, notably in subfield CA1, where massive cell death in the pyramidal cell layer was demonstrated with propidium iodide labelling 24 h later. This loss of neurons could be prevented if cultures were incubated with 10 mM Mg^{++} or the NMDA receptor antagonists MK-801, CPP and D-AP5, but not with the AMPA receptor antagonist CNQX nor with the metabotropic receptor antagonists MCPG, 4CPG or 4C3HPG (all drugs at 100 mmol/L). In another set of experiments cultures were exposed to the protein phosphatase 1/2a inhibitor okadaic acid (10-100 nmol/L). This treatment caused strong labelling with propidium iodide in subfield CA3 at 24 h. Only with higher doses and prolonged incubation time (48 h), was labelling also observed in CA1. The okadaic acid induced cell death could not be prevented with the protein kinase inhibitors staurosporine (100 nmol/L) or K-252a (100 nmol/L - 10 mmol/L) which themselves caused widespread and unselective cell death. The two patterns of cell death in ischemia and after protein phosphatase inhibition highlights the different susceptibilities to noxious stimuli of pyramidal cells in subfields CA1 and CA3.

EFFECT OF PHOSPHOLIPASE A_2 (PLA_2) INHIBITOR, CDP-CHOLINE ON REGIONAL ACTIVITIES OF ORNITHINE DECARBOXYLASE (ODC) AND BLOOD-BRAIN BARRIER (BBB) BREAKDOWN AFTER TRANSIENT ISCHEMIA. A. M. Rao*, M. K. Baskaya, A. Dogan, and R. J. Dempsey: Department of Neurological Surgery, University of Wisconsin, Madison, WI 53792.

Phospholipase inhibitors could limit arachidonic acid generation and decrease ODC gene expression and activity and alter the physiologic outcome after transient cerebral ischemia. In this study, we examined the effect of the PLA_2 inhibitor, CDP-choline, on regional activities of ODC and BBB breakdown in cortices and hippocampi after transient cerebral ischemia. **Methods:** The brains of control and ischemic gerbils were frozen *in situ* to measure the activity of ODC by determining the release of CO_2 from L-[1-^{14}C]- ornithine at 6 h reperfusion after 10 min transient ischemia in pentobarbital anesthetized gerbils. Fluorometric measurements quantified the blood-brain permeability tracer, Evans blue (EB). **Results:** Ischemia induced a significant increase in ODC activity in the cortex and hippocampus after 6 h reperfusion. CDP-Choline (20 mg/kg i.p.) significantly inhibited the ODC (Cortex: Control, 7.3 ± 1.9 pmol/mg protein/h, Expt., 59.4 ± 3.9, Expt.+CDP-choline, 32.6 ± 3.2; Hippocampus: Control, 8.3 ± 0.9 pmol/mg protein/h, Expt., 46.3 ± 6.1, Expt.+CDP-choline, 20.5 ± 3.9). A significant amount of EB was present after 6 h reperfusion and CDP-choline significantly attenuated the BBB (Hippocampus: Control, 9.8 ± 0.7 µg EB/g tissue, Expt., 61.6 ± 9.2, Expt.+CDP-choline, 29.6 ± 4.6). **Conclusions:** These findings suggest 1) phospholipase activity after transient ischemia increases ODC activity and alters physiologic outcome, 2) polyamines play a role in BBB breakdown, and 3) phospholipases and ODC are inter related in transient cerebral ischemia.

DELAYED NEURONAL DEATH FOLLOWING GLOBAL ISCHEMIA IN DOGS IS ACCOMPANIED BY ALTERED PHOSPHOLIPASE Cβ (PLC) EXPRESSION, F.E. Sieber, R.J. Traystman, L.J. Martin, D.F. Hanley* Johns Hopkins Hospital, Baltimore, MD

We hypothesized that PLCβ expression is altered in brain regions that undergo neurodegeneration following global incomplete ischemia in dogs. Beagles (n=12) were subjected to 20 minutes of global incomplete ischemia followed by either 1 (n=5) or 7 days (n=7) recovery. Non-ischemic dogs (n=6) were controls. H&E staining was used to determine the % ischemic neurons and % remaining neurons in cerebellum, caudate and CA1. Immunocytochemistry (ICC) was used to localize $PLC\beta_1$, in control (n=3), 1 day (n=3), and 7 days postischemia brain (n=5). Western blotting of cell membranes (P2 fractions) was used to analyze regional brain PLCβ expression in control (n=3), 24 hour (n=2), and 7 day postischemia brain (n=2). The % ischemic neurons increased from 13±10 to 40±35% in CA1, 24±25 to 59±16% in cerebellum, and 4±2 to 18±12% in caudate, from 1 day to 7 days postischemia, respectively (M±SD). The % remaining neurons was unchanged from non-ischemic control in all 3 regions at 1 day, but decreased at 7 days to 56±15% and 75±17% of control in CA1 and caudate, respectively. By ICC increased PLCβ immunoreactivity occurred in Purkinje cell bodies and in their dendrites in molecular layer at 1 and 7 days postischemia. In caudate, more neurons and neuropil were expressing PLCβ at 1 day postischemia, but at 7 days, decreases occurred in the neuropil. In CA1, the pyramidal cell bodies, their proximal dendrites, and distal dendrites were heavily immunoreactive at 1 day postischemia. Yet at 7 days, the neuropil was only modestly immunoreactive. This loss of immunostaining was related to the % remaining neurons. By western blotting PLCβ expression in cerebellum was 266 and 227% control at 1 and 7 days postischemia, respectively. In hippocampus, PLC expression was 97 and 84% control at 1 and 7 days, respectively. These results show that cerebral ischemia alters PLCβ expression. PLCβ increases acutely postischemia in the somadendritic compartments of selectively vulnerable neurons. Delayed decreases in PLCβ occur in conjunction with neuronal dropout postischemia. Early postischemic elevations in PLC may represent an aberrant signal transduction mechanism resulting in delayed neuronal death, whereas decreased PLC levels at 7 days postischemia may reflect ongoing neurodegeneration. HYPOXIA-ISCHEMIA DECREASES BRAIN PHOSPHOLIPASE D ACTIVITY IN EXPERIMENTAL NEONATAL PIG BRAINS. J. H. F. Peng*, M. H. LeBlanc, X. B. Quian, N. N. Zhu and P. G. Rhodes. Dept. of Pediatrics/Newborn Med., Univ. of Mississippi Med. Ctr., Jackson, MS 39216.

Phospholipase D (PLD), reported to be involved in signaling pathways, membrane traffic, and growth control, is currently under intense investigation. Our goals are to study the effect of hypoxia-ischemia on PLD activity and to finally elucidate the possible role of PLD in fetal and neonatal brain development, since little is known about this subject. The in vitro assays measure the formation of ^{14}C-phosphatidylethanol through a transphosphatidylation reaction catalyzed by PLD in the presence of ethanol and ^{14}C-labeled phosphatidylcholine. Maximal PLD activity was observed at 4 mM oleate concentration in our initial study using experimental neonatal, piglet brain membrane fractions. Therefore, oleate-dependent PLD activity was determined at this concentration in the presence of various activators, including cytosolic factors, guanosine 5'-(gamma-thio)-triphosphate, ammonium sulfate, ATP and Triton X-100. There is low but consistent measurable PLD activity in the absence of oleate and PIP_2. At 1 mM, Ca^{2+} ions tend to stimulate, while Mg^{2+} reduces oleate-dependent PLD activity. Our results demonstrated that under hypoxic-ischemic conditions, oleate-dependent PLD activity was significantly decreased by >20% compared with sham controls. There were no measurable differences in PLD activity between groups of piglets treated with either low or high dose of 21-aminosteroid. However, PLD activity in control piglets treated with the same steroid was also slightly decreased. This study indicated that global ischemia may affect PLD, which in turn may be related to disorders of intracellular signal transduction and acetylcholine synthesis.

BRAIN ACYL-CoA IN ISCHEMIA AND ISCHEMIA-REPERFUSION. O. Rabin, E. Grange, J. Deutsch, M.C. Chang, K. Drieu◊, S.I Rapoport J. Stoll* and AD Purdon. LNS, NIA, NIH, Bethesda, MD 20892.◊ IHB-IPSEN, Paris, France.

Cerebral ischemia, followed or not by reperfusion, results in a massive release of free fatty acids from phospholipids. We investigated the status of acyl-CoA, the precursor pool for acylation of fatty acids into lysophospholipids, in both ischemia and reperfusion. Fatty acids were isolated by extraction and thin layer chromatography and analyzed as methyl esters by gas chromatography. Acyl-CoA molecular species were isolated by solubilization, solid phase extraction and analyzed by RP- HPLC. After 3 and 15 min of ischemia in rats, and after 5 min of ischemia followed by 5 min reperfusion in gerbil, all fatty acids were elevated in brain with the relative increase in arachidonate being the greatest (~ 30 fold). In both preparations, the total acyl-CoA concentration remained similar to the control concentration (30.0±2.0 nmol/g). However, there was a redistribution of molecular species, with a significant increase in arachidonoyl-CoA and decrease in docosahexaenoyl-CoA. In ischemia-reperfusion, there was also a significant elevation of stearoyl-CoA and decrease in palmitoyl-CoA. High arachidonoyl-CoA is probably due to the elevated levels of arachidonic acid whereas competition for the same acyl-CoA synthetase decreased the docosahexaenoyl-CoA level. The levels of other acyl-CoAs were less affected. Maintenance of acyl-CoA during ischemia or the early phase of reperfusion indicates that the potential for reacylation in brain is retained in both cases. However, increased concentrations of arachidonoyl-CoA and stearoyl-CoA suggest that re-incorporation of these fatty acids is prioritized during ischemia and reperfusion.

EXTRACELLULAR GLYCEROL AS A MARKER OF MEMBRANE LIPID DEGRADATION IN THE ACUTELY INJURED HUMAN BRAIN. L. Hillered, L. Valtysson, P. Enblad and L. Persson*. Depts. of Neurosurgery and Clinical Chemistry, Uppsala Univ. Hospital, S-751 85 Uppsala, Sweden.

Glycerol is an end product of membrane phospholipid degradation, a prominent feature of acute brain injury, that may lead to membrane dysfunction. Glycerol measured in brain homogenate has been implicated as an indicator of phospholipid degradation in experimental cerebral ischemia[1,2], presumably reflecting Ca^{2+}-induced phospholipase activation. This study tested the possibility of using extracellular (EC) glycerol for monitoring of lipolytic activation in human cerebral ischemia.

We used microdialysis[3] to harvest glycerol, lactate and pyruvate in the frontal cortex of neurointensive care patients after aneurysmal subarachnoid hemorrhage. Dialysate samples were collected 24h/d during 7-8 days and analyzed for glycerol (enzymatically), lactate and pyruvate (by HPLC).

Clinical events involving secondary ischemia, evidenced by e.g. increased lactate/pyruvate ratios[3-5], were associated with marked elevations of the dialysate level of glycerol, amounting to 10-15 times the pre-ischemic level. In patients without signs of secondary ischemia glycerol levels remained low.

In conclusion, EC glycerol is a promising marker for monitoring of membrane lipid degradation in acute human brain injury.

INCREASING REGIONAL ENERGY DEBT CONTRIBUTES TO IRREVERSIBLE BRAIN DAMAGE IN PERMANENT FOCAL ISCHEMIA. T. S. Whittingham*, W. D. Lust, W. R. Selman, Y. Zhou, S. Pundik, and R. A. Ratcheson. Lab. of Neurol. Surgery, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106

The ischemic core and penumbra become infarcted by 1 day after middle cerebral artery (MCA) occlusion in the rat, although the rate of deterioration differs in the two regions. The energy state in the dorsolateral striatum (DS), dorsolateral (DC), lateral (LC) and ventrolateral (VC) cortex was examined following permanent focal ischemia in normotensive rats. The MCA was occluded with a monofilament in male Wistar rats and the brains were frozen in situ at 1, 2,4 and 6 hr. Brains were sectioned, lyophilized and tissue samples weighing 1 μg were dissected from the four areas described above. The levels of P-creatine, ATP, ADP, glucose, and glycogen were assayed in each region, and the high-energy phosphate equivalents (HEPE) were calculated to be 163.7 $\pm$ 27.2 and 114.3 $\pm$ 13.9 nmol/mg dry wt (mean $\pm$ SD, n=6 rats/group) in the control cortex and striatum, respectively. The rate of HEPE loss in the DS, VC, LC and DLC was 40.5, 64.5, 45.5 and 13.8 nmol/mg dry wt/hr, respectively. The estimated time to energy depletion in each of these tissues was calculated to be 2.6, 2.5, 3.6, and 11.7 hr after MCA occlusion, respectively. The results indicate that the time for metabolic failure takes 4-times longer in the penumbral region (DC) than in the other tissues examined. Nevertheless, it remains clear that preventing energy failure by reducing the metabolic debt is a necessary first step to prevent infarction in each of these regions. SPATIAL RESPONSE OF CYCLIC AMP AND ATP TO SPREADING DEPRESSION INDUCED BY FOCAL ISCHEMIA. W. D. Lust, S.P. Kiefer, W.R. Selman, T.S. Whittingham, S. Pundik, and R.A. Ratcheson*. Lab. of Neurol. Surgery, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106

Spreading depression (SD) is evident in the cortex following focal ischemia and the increased energy demands imposed on the cortex by the SD have been implicated in the demise of the penumbra. Cyclic AMP and ATP levels have been shown to change both during and after SD in the dorsolateral cortex (DC). In this study, the metabolites were measured in the lateral cortex (LC), ventrolateral cortex (VC) and the striatum (S) during a spontaneous SD about 1 h after middle cerebral artery occlusion to determine if the response of cyclic AMP and ATP to SD is altered in areas exhibiting a greater reduction in blood flow than that observed in the DC. The cortical potential was monitored at a depth of 0.3 mm in the cortex with a glass microelectrode filled with isotonic saline. At the first spontaneous deflection after 45 min of MCA occlusion, the rats were frozen in situ when the amplitude of the shift was maximal. Brains were removed, sectioned coronally at 10 representative levels from 4 mm anterior to 4 mm posterior to the electrode site, and lyophilized. While the ATP levels were significantly less than control in the LC, VC and S in advance of the SD, an additional decrease occurred at the wavefront which did not recover in its aftermath. While only the cyclic AMP levels in the VC were significantly elevated in advance of the SD, the levels were significantly elevated in all the cortical areas after the passage of the SD. The metabolic data indicate that the spontaneous SD after focal ischemia spreads across the entire ipsilateral cortex, even in regions (VC and LC) with lower blood flows than that in the DC. Study supported by USPHS #NS22571.

MENTAL EFFORT AND MENTAL FATIGUE AFTER MILD HEAD INJURY: A ROLE FOR BRAIN MAST CELLS AND NITRIC OXIDE? F.F. LeFever. Helen Hayes Hospital, West Haverstraw, NY 10993.

Mast cells (MC) are found in normal brain, especially in thalamus and hippocampus, are activated and proliferate after nerve damage (agents include Nerve Growth Factor and myelin protein), but are ignored in brain trauma studies. They respond to and secrete cytokines in a selective and graded manner. Building on an argument that MC and cytokines (e.g. IL-1) upregulated after trauma or infection may cause lethargy and poor memory in mild head trauma and other disorders (LeFever JINS 1995), this paper focuses on mental effort, mental fatigue, variability, and lapses. Nitric oxide (NO) mediates local blood flow increases after increased activity, and can enhance or inhibit NMDA modulation of neural activity or induction of LTP and memory formation. Performance decrements with sustained effort may reflect phasic, cumulative NO over-production by MC responsive to IL-1 or by preferentially-surviving NO-producing neurons, briefly blocking NMDA: interrupting intense activity in midline thalamus could cause attention lapses and, in hippocampus, memory gaps. MC and NO are implicated in headache, a common outcome of mental effort after mild head injury. Priming of NGF production by prior trauma may enhance second-trauma effects. Piroxicam may induce IL-1 antagonists; it blocks IL-1 behavioral effects, corrects blood flow dysregulation in migraine, and improves self-reported concentration, suggesting treatment options.

ASSESSMENT OF OLFACTORY FUNCTION FOLLOWING TRAUMATIC BRAIN INJURY. R. M. Costanzo[1]*, J. M. Andelin[1], and N. D. Zasler[2], [1]Virginia Commonwealth University - Medical College of VA, Richmond, VA 23298-0551 and [2]National NeuroRehabilitation Consortium, Glen Allen, VA 23060.

Olfactory impairment is a common occurrence following traumatic brain injury. Although comprehensive olfactory function tests have proven to be effective in assessing the degree and location of olfactory impairment following brain injury, the availability of such tests has been limited to specialized smell and taste centers. In this study we employed a simple screening test to evaluate olfactory function in a population of 62 patients undergoing rehabilitation following closed head injury. Patients included 47 males and 15 females ranging in age from 19 to 73. A control group of subjects was also tested. The screening test consisted of three odor stimuli (baby powder, chocolate and coffee) presented to each nostril separately using small plastic squeeze bottles. Scores were based on detection (1 point) and identification (1 point) for each of the three odors. Scores from the screening test (maximum of 6 pts. for each nostril) were compared to those obtained using a comprehensive olfactory function test. Results indicate that the screening test is effective in identifying olfactory impairment in patients with closed head injury and may provide a practical alternative to comprehensive olfactory function. This research was supported by NIH grant DC 00165.

ENLARGEMENT OF THE VISUAL FIELD IN PATIENTS WITH HOMONYMOUS HEMIANOPIA BY COMPUTER TRAINING: A DOUBLE-BLIND, RANDOMIZED PLACEBO-CONTROLLED TRIAL. E. Kasten[1]*, S. Wüst[1], W. Behrens-Baumann[2] and B. A. Sabel[1]. Inst. of Med. Psychology[1] & Dept. of Ophthalmology[2], Medical Faculty, Otto-von-Guericke University, Leipziger Str. 44, 39120 Magdeburg, Germany.

Brain damage is often accompanied by homonymous hemianopia and only few therapeutic approaches exist for the treatment of visual field deficits. We have recently conducted an open pilot-study using a computerized training of eleven patients with homonymous visual field deficits. This training resulted in a significant visual field enlargement (Kasten & Sabel, Rest. Neurol. Neurosci., 1995), but the power of this study is limited by a number of methodological shortcomings. We have therefore initiated a double-blind, randomized olacebo-controlled trial with 24 carefully selected patients which had visual field defects. The patients were randomly assigned to a treatment (restitution-training) or a placebo group (fixation-training). The treatment consisted of daily home-training on a computer for 1 hr. over a period of 6 months in which small visual stimuli were presented on the computer monitor in a subsection of the visual field extending 15° vertical and 25° horizontal eccentricity. While the placebo-group experienced a slight decrease in the visual field size, the treatment group displayed a reliable enlargement of visual field size as revealed by a significant improvement in the detection of small light stimuli (t-test: $p<0.05$). Thus, daily home-training of the "blind" visual field with computer-controlled stimuli leads to improvement of vision.

PARTIAL RESTITUTION OF LOST VISUAL FUNCTION IN PATIENTS WITH OPTIC NERVE LESION USING COMPUTER TRAINING. S. Wüst, E. Kasten and B.A. Sabel. Inst. of Med. Psych., Otto-von-Guericke University, 39120 Magdeburg, Germany. (SPON: European Neuroscience Association)

We recently found preliminary evidence that visual functions after brain damage can be improved by using computer-based training programs in patients with post-chiasmatic lesions (Kasten & Sabel, Rest. Neurol. Neurosci., 1995).

The present study was conducted to study the following questions: (1) Do computer-based visual training methods improve the visual field size in patients with prechiasmatic lesions (i.e. after optic nerve injury)? (2) Does this training, which focusses on simple light perception, also improve other aspects of vision such as acuity, form or color perception?

Fourteen patients with partial optic nerve lesions were assigned to an experimental (n=9) or control group (n=5) (patients are currently still being entered into the study). The patients practised for a six-month period with PC-based visual training daily at home for one hour. While the experimental group was trained with a stimulus detection task in the border region located between „blind" and intact areas of the central subsection of the visual field, the age-matched control group received just a fixation-training.

Eight patients from the experimental group showed a pronounced increase in light sensitivity. On average, the size of the tested region in which light stimuli could be detected was increased by twenty percent ($p<.05$). Furthermore, acuity values were also significantly ($p<.05$) and contrast sensitivity was slightly increased; form and color recognition did not significantly change. In the control group, in contrast, none of the patients showed a noticable improvement in any of the visual tests. These preliminary data indicate, for the first time, that computer based training can be effective in partially restoring the defective visual field of patients with optic nerve lesions. THE BIONIC GLOVE: CLINICAL TRIALS OF A NEW ELECTRICAL DEVICE THAT AUGMENTS GRASP AND HAND OPENING IN PEOPLE WITH QUADRIPLEGIA AND STROKE, Arthur Prochazka* and Marguerite Wieler. Div. of Neuroscience, Univ. of Alberta, Edmonton, Alta, Canada T6G 2S2

The Bionic Glove is a new functional electrical stimulation device that stimulates paralyzed muscles of the fingers and thumb in people who have had a spinal cord injury (SCI) or stroke. Conductive areas on the internal surface of the glove automatically make contact with self-adhesive electrodes placed on the skin over selected muscles. Voluntary wrist movement is monitored by an in-built sensor whose signals are used to control electrical stimulation of muscles either to produce a pinch-grip or to open the hand. Some control parameters are pre-set using a Notebook computer and others may be adjusted by the user. A multicentre clinical trial in 5 countries involving 37 SCI users is nearing completion. The peak force of tenodesis grip was typically increased from a passive value of 2N to 10-15N when the glove was active. Several standardized manual tasks improved with the use of the Bionic Glove. Feedback from the users has been crucial in understanding the practical problems encountered in daily use of the device and in improving the design to optimize its efficacy and convenience. A final version of the Bionic Glove will be subjected to a brief clinical trial in the Fall of 1996, prior to commercialization in 1997.

ASSESSMENT OF CHANGES IN ANKLE PLANTARFLEXOR SPASTICITY FOLLOWING INTRAMUSCULAR BOTOX INJECTIONS. L. Abraham*, N. Childs, H. McWilliams, R. Chitre, S.-W. Chou, D. Gobert, & D. Waddell. Healthcare Rehabilitation Center, Austin, TX 78745 and Kinesiology & Health Education, Biomedical Engineering, and Institute for Neuroscience, University of Texas, Austin, TX 78712.

In an attempt to characterize quantitatively the nature and duration of changes in lower extremity spasticity following intramuscular injection of Botulinum toxin, we have begun testing range of motion and both reflex and voluntary movement following treatment. We report here preliminary results on ankle plantarflexor spasticity from two traumatic head injury patients tested for up to six months. Both subjects received unilateral injections to the gastrocnemius; one also received bilateral injections of the iliopsoas, while the other received unilateral injection of the tibialis posterior. Bilateral tests included resting ankle angles, passive and active ranges of ankle motion (ROM), peak plantarflexion torque, and reflex threshold angle (RTA).

Most measures showed little change from pre-injection scores on the day after the injection, although some measures appeared to indicate short-lasting hyperreactivity. Several measures (e.g. dorsiflexion ROM, resting knee angle) revealed changes representing improvements after injection. For up to 4 months, the subject with the more severe spasticity initially showed an increase in RTA as well as an increased ability to actively dorsiflex. Some measures (e.g. calf girth, peak plantarflexor torque) revealed no changes as a result of the injections. These results suggest that both ipsilateral and contralateral changes occur following intramuscular injection of Botulinum toxin. In addition, the intensity and duration of these effects are highly dependent upon the patient's unique neuromotor deficits, the amount and location of the injections, concurrent treatments (casting, bracing, and physical therapy), and possibly the patient's initial level of functional mobility.

743.7

FRONTAL INFLUENCES ON STARTLE IN PTSD

K.A. Young*, T.L. Rawls, M.N. Smith, C. Poche, D.B. Elliott, A.A. Freeman, D.N. Root and P.B. Hicks. Department of Psychiatry and Behavioral Science, Texas A&M University Health Science Center, Scott & White Clinic and the VA Central Texas Health Care System Neuroscience Laboratory, Waco, Texas 76711.

A multi-dimensional information processing battery, the Continuous Performance Task (CPT), and the Wisconsin Card Sorting Test (WCST) were administered to eleven subjects diagnosed with DSM-IV Post-traumatic Stress Disorder (PTSD) to examine relationships between psychophysiological and neuropsychological performance. WCST perseverative and CPT commission errors were positively correlated with blink rate and auditory startle amplitudes. In addition, startle amplitudes were inversely correlated with smooth pursuit eye movement (SPEM) accuracy, and positively correlated to SPEM saccade counts. Startle, SPEM, CPT and WCST performance were not correlated with dual pip-generated auditory cz evoked potential amplitudes, latency or gating. The relationships between elevated startle amplitude on one hand, and on the other hand, of elevated blink rates and indices of poor performance on SPEM, CPT and WCST tasks suggests that elevated startle responding may be yoked to disturbances in frontal cortical function in PTSD. This is inferred because disruption of SPEM, WCST and blinking are classically associated with dysfunctions in frontal cortical circuits. In the broadest sense, the findings support the concept of cortical inhibitory control over behaviors such as startle which have prominant subcortical components. Since similar relationships between startle and frontal dysfunction are not present in controls or schizophrenics, the present findings suggest that the frontal cortex may play a crucial role in modulating symptoms of PTSD.

LIGHT AND ELECTRON MICROSCOPE STUDY OF NERVE CELLS IN TRAUMATIC EDEMATOUS HUMAN CEREBRAL CORTEX.

O.J. Castejón*, C. Valero and M. Díaz**. Instituto de Investigaciones Biológicas. Fac. Medicina. LUZ. **Policlínica Maracaibo. Apartado Postal 526. Maracaibo. Venezuela.

The cerebral cortex of 8 patients with complicated head and brain traumatic injuries has been examined with the light and transmission electron microscopes. The neuronal and neuroglial cell bodies and their processes have been examined to study the changes induced by the brain injury and the associated vasogenic and citotoxic, moderate or severe, brain edema. Light microscopy study showed edematous and ischemic neurons and neuroglial cells, in both moderate and severe edema, and breakdown of blood brain barrier with perivascular and parenchimatous hemorrhagic foci. Astrocytes and oligodendrocytes exhibited edematous and reactive changes. At the electron microscope level edematous changes of intraneuronal and glial somatic compartments were found. Myelinated axons showed clear and dark degenerative features. Beaded dendrites and clear and dense synaptic degeneration were also found. The extracellular space appeared distended with the presence of clear and electron dense hematogenous edema fluid and fibrinous organization. Phagocytosis of degenerated myelinated axons and synaptic endings by neuroglial cells and non-nervous invadings cells was observed. The clinical evolution time of traumatic brain injuries was considered in relation with nerve cell degenerative features. (Subventional by CONDES-LUZ).

CHOLINE ACETYLTRANSFERASE ACTIVITY FOLLOWING HEAD INJURY : HUMAN POSTMORTEM AND EXPERIMENTAL STUDIES.

D Dewar*, D Dawson, M Fitzpatrick & D I Graham. Wellcome Surgical Institute, University of Glasgow, Garscube Estate, Glasgow G61 1QH, U.K.

It has been hypothesised that abnormalities of cholinergic transmission underlie the memory impairment which occurs following head injury. In support of this we have reported deficits of choline acetyltransferase (ChAT) activity in the temporal cortex of postmortem brain from human patients who died following head injury (1). However, in our initial study of 7 cases, not all head-injured patients had reduced ChAT activity. In the present study we examined ChAT activity in the cingulate cortex of a larger group of head-injured patients. In order to investigate which acute pathophysiological events might lead to reduced ChAT activity after head injury we used animal models of permanent focal ischaemia (MCAO) and subdural haematoma (SDH). In the human study ChAT activity was reduced compared to control cases in approximately half of the head-injured patients. Those with reduced ChAT activity tended to have longer survival periods following the injury. In animals subjected to 2h of MCAO, where there is no mechanical deformation of the brain, ChAT activity was not reduced. Similarly in animals subjected to 4h SDH, ChAT activity was not reduced in the hippocampus where there is mechanical deformation and pronounced hypermetabolism but no significant ischaemia. The results suggest that reduction in ChAT activity following head injury matures over a time period within which the process may be amenable to therapeutic intervention. (1) J Neurotrauma, 13 : 181. THE EVOLUTION OF CAVITIES WITHIN HUMAN SPINAL CORDS AFTER CLOSED CONTUSIVE INJURIES.

WR Puckett, JD Guest, RP Bunge*. The Miami Project to Cure Paralysis, Univ. of Miami Sch. of Med. Miami, Fl. 33136

Studies performed on 54 human spinal cords obtained at autopsy between 8 days and 22 years following spinal cord injury indicate that approximately one-third are closed contusive injuries which result in the formation of intraparenchymal cavities which may remain stable for years. Whereas cavities may form after lacerating injuries, they form most frequently following a closed contusive injury. Spinal cords were immersion fixed in 10% buffered formalin, embedded in paraffin, and stained for general tissue assessment, myelin evaluation, axon evaluation, and connective tissue components. From this material, we were able to evaluate the cellular responses at various times after injury. We have found that, while hemorrhage may be a substantial early component in some cords, others exhibit very small amounts of intraparenchymal hemorrhage, despite considerable parenchymal tissue disruption. Tissue damage is most severe in the central portions of the cord, with a high frequency of spared tissue at the rim of the cord. Cleared, fluid-filled cavities were seen within four months after injury. Macrophages enter the damaged regions of the cord within 16 days and begin clearing debris. Debris-laden macrophages persisted for years, clustered around blood vessels. Axons without myelin sheaths were seen in the walls of the cavities between four months and two years after injury. Schwann cells were seen within the walls of the cavities and in bundles within the cavities in all cases examined after four months. Some of these Schwann cells were forming myelin around axons; others were found in association with small diameter axons, but were not forming myelin. We have elsewhere emphasized the modest response of astrocytes at the margins of these cavities. Connective tissue was not found to be invading these cavities at any time. We ascribe this lack of connective tissue invasion to the absence of disruption in the glia limitans/pial border in these cases.

TOPOGRAPHY OF BREAKDOWN OF BLOOD BRAIN BARRIER AFTER CORTICAL COLD INJURY IN THE RAT.

H. Laurer, A. Mautes, H. Ludt, M. Fuchs, M. Weinzierl, A.C. Nacimiento and W. Nacimiento*, Neurosurgical Research Laboratory, Saarland University, Medical School, 66421 Homburg/ Saar,Germany.

To study the contribution of the breakdown of the blood brain barrier to regional posttraumatic changes in energy metabolism, it was found necessary to analyse its distribution and volume. We approached this question by using the well-defined cold-injury edema paradigm. In pentobarbital anaesthetized rats a freezing probe was placed on the exposed right parietal cortex. Evans blue in saline was given intravenously after the injury. 4h, 12h and 24h later rats were reanaesthetized and perfused. Stained extravasation areas were determined morphometrically in 20µm serial brain tissue slices. Topographical distribution was achieved by a 3-dimensional reconstruction of the whole brain. Volume was calculated from the ratio of stained to unstained areas. Results: i) Staining was confined to the ipsilateral cortex. ii) Extravasation volume increased steadily over time. Conclusions: i) The topographic extension of the breakdown of blood brain barrier corresponded closely with the degree of energy loss in the ipsilateral cortex, thus demonstrating a regional correlation between morphological and functional changes in this injury model. Supported by BMBF Grant 01KO9405/4.

743.12

REGIONAL SUBCORTICAL ENERGY METABOLISM FOLLOWING CORTICAL COLD INJURY IN THE RAT.

M. Weinzierl, A.Mautes, M. Fuchs, H. Laurer, L. Ludt and A.C. Nacimiento*, Neurosurgical Research Laboratory, Saarland University, Medical School, 66421 Homburg/ Saar , Germany.

Many secondary posttraumatic events are observed in regions distant from the lesion site. In order to analyse the possible mechanisms underlying this phenomenon, we evaluated energy metabolism as a reliable predictor of posttraumatic secondary injury. A freezing probe was placed on the exposed right parietal cortex of the anaesthetized rat. 4h, 12h and 24h after the lesion, bioluminescent imaging of ATP, glucose and lactate contents were measured in serial tissue sections by computer-assisted densitometry bilaterally in the thalamus and the caudate nucleus. Results: i) ATP and glucose content decreased bilaterally at all time points in these structures; no side differences could be discerned. ii) there were no changes regarding lactate. Conclusions: i) focal cortical damage leads to energy loss in subcortical regions as signaled by glucose and ATP decrease. ii) This altered metabolic profile cannot be solely attributed to blood brain barrier breakdown, since in a parallel investigation we found no evidence of such a change in these subcortical structures. iii) the bilateral appearance and persistence of the abnormal metabolic profile, however, suggests an implication of a steadily increasing spread over time of blood brain barrier breakdown as a possible contributing factor to secondary tissue damage. Supported by BMBF Grant 01KO9405/4.

743.13

REGIONAL ENERGY METABOLISM IN THE COLD-INJURED CORTEX OF THE RAT.

M. Fuchs, A. Mautes*, H. Laurer, M. Weinzierl, H. Ludt and A.C. Nacimiento, Neurosurgical Research Laboratory, Saarland University, Medical School, 66421 Homburg/ Saar, Germany.

After determining by 3-D reconstruction the extent of the breakdown of the blood brain barrier following cortical cold-induced injury, we studied its possible contribution to the accompanying changes of cortical energy metabolism profile. In pentobarbital anaesthetized rats a freezing probe was placed on the exposed right parietal cortex. 4h, 12h and 24h after the lesion bioluminescent imaging of ATP, glucose and lactate was performed on 20µm serial tissue sections. Quantification was achieved by computer-assisted densitometry. Results: i) ATP and glucose content decreased bilaterally at all time points postlesion, with predominance in the lesion side. ii) there were no significant changes in lactate content on either side. Conclusions: i) The ipsilateral ATP and glucose decrease occured in areas affected by the breakdown of the blood brain barrier. ii) Contralaterally, where the blood brain barrier remained intact, energy metabolism profile was also altered, but to a lesser extent. iii)Localized breakdown of the blood brain barrier may enhance derangements of energy metabolism profile in these areas, and additionally, trigger similar metabolic changes in the uninjured contralateral cortex. Supported by BMBF Grant 01KO9405/4.

743.14

REGIONAL BLOOD FLOW RESPONSE TO SPINAL CORD STRESS-RELAXATION AND DECOMPRESSION.

G.C. Carlson, K.E. Warden, J.M. Barbeau, E. Bahniuk, K.L. Kutina-Nelson, C.L. Biro, J.C. LaManna*. Case Western Reserve University, School of Medicine, Cleveland, OH 44106.

To determine the response of regional spinal cord blood flow (rSCBF) to constant velocity SC loading, static compression and decompression, 12 beagles underwent T-13 laminectomy and rigid implantation of a hydraulic piston loading device configured with subminiature pressure transducer. SSEP's from the upper and lower extremities were recorded at regular intervals. Constant displacement loading was initiated at 0.16 mm/min until SSEP amplitudes had been reduced by 50% of baseline (defined as "critical cord displacement"=CCD), at which point piston displacement was stopped. Six animals underwent early decompression within 5 min of maximum compression while 6 animals had the piston maintained at CCD. Regional SCBF measurements were made at baseline, max. compression, 30 and 180 min after max. compression, using a fluorescent microsphere technique .

At max. compression, rSCBF at T-13 fell from 22.0±2.9 to 15.6±3.2 ml/100gm/min, while SC pressure was 4.5 ± 0.3 psi (mean±se) with a CCD of 1.4 ± 0.3mm. Within 4 min, 53% of SC pressure had dissipated while SSEP amplitudes continued to decrease to 16% of baseline. In the static compression animals, max. cord relaxation of 0.51±0.06 psi occurred 90 min post max. compression, however this did not lead to recovery of SSEP function or rSCBF. In the SC decompression animals, SSEP function recovered to baseline at 90 min and was associated with a transient hyperemia. Regional SCBF at 180 min was significantly lower than baseline, 16.4 ml/100gm/min, in both static compression and decompression groups.

Despite rapid cord relaxation within less than 5 min post CCD, neurologic function only recovered with early decompression. Spinal cord decompression was associated with a early transient hyperemia and neurologic recovery. Whether or not neurologic function returned significant hypoperfusion persisted at 180 min recovery.

OPTICAL INTRINSIC IMAGING OF THE BARREL FIELD CORTEX VASCULAR RESPONSE AFTER LATERAL FLUID PERCUSSION BRAIN INJURY.

G. K. Wong*, and D. A. Hovda A. W. Toga. Laboratory of Neuroimaging, Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Methods: Using Optical Intrinsic Signaling (OIS) to monitor regional cortical blood volume changes due to activation of the PBMSF, rats were monitored before and after lateral fluid percussion injury.

Pre-injury and control rats were imaged using OIS at a wavelength of 850 nm. The bone of the right parietal hemisphere was thinned until the cortical vessels of the brain were visible. Image acquisition time for each frame was 200 msec with an interframe time of 750 msec. Stimulation of the PBMSF commenced after the first frame and was elicited by deflection of the whiskers on the left cheek by a motorized nudger moving at 4 Hz for 3 sec. Activation maps were made by using standard image analysis procedures.

12 hours after pre-injury OIS imaging, the rats received a lateral fluid percussion. Injury severity was measured by atmospheric pressure (ATM), apnea, and unconsciousness time. Unconsciousness time is based on the time during which the rat fails to respond to a hind limb toe pinch.

24 hours after the injury, the rats were re-imaged using OIS. Activation maps were then compared to the pre-injury, or control activation maps.

Results: 24 hours after lateral fluid percussion injury, a physiological response to whisker deflection was detected in the right cortical PMBSF area using OIS imaging techniques. A 70-45 and 22-18 percent average decrease was seen in the maximum and minimum pixel intensities for post injury vs pre-injury activation maps ($p's < 0.05$) in severely and moderately injured rats respectively.

Conclusion: The CBF response to stimulation is markedly reduced 24 hours after lateral fluid percussion injury, and injury severity (mild, moderate and severe), directly effects the magnitude of the response as measured using OIS. (Funding sources MH 52083, NS 30308)

L-ARGININE INCREASES CEREBRAL BLOOD FLOW FOLLOWING CORTICAL CONTUSION INJURY: IMPLICATIONS REGARDING VULNERABILITY.

S.L. von Stück*, S.M. Lee, D.A. Hovda and D.P. Becker. Division of Neurosurgery, UCLA Sch. of Med., Los Angeles, CA 90024.

Following a cortical contiusion injury (CCI), there is an immediate decrease in cerebral blood flow with a simultaneous increase in glucose utilization. This injury-induced mismatch is responsible in part for the well described state of cellular vulnerability following traumatic brain injury. The following study determined the effectiveness of L-arginine to increase CBF during the vulnerable period utilizing [^{14}C] iodoantipyrine autoradiography. Rats were divided into three groups: CCI only, CCI with L-arginine (300 mg/kg, i.p.) injections 5 min and 2 h post-injury, and CCI with L-arginine injections 16 h and 3 h pre- and 5 min and 2 h post-injury. The injury was induced under general anesthesia (2.0-2.5 ml/min enflurane; 100% O_2) using a 5 mm diameter flat tip (centered at -3,4 mm from bregma) driven to a depth of 2 mm beneath the cortical surface at a velocity of 1.6 m/s. CBF studies were conducted 2.5 hours after the injury. CBF rates (ml/100g/min) were calculated from coronal sections through the center of impact. CBF rates in control animals were 28.6±13.1 for the impacted site, 58.3±12.3 for ipsilateral cortex, and 141.8±25.3 for contralateral cortex. Animals that received L-arginine after the injury revealed no increase under the impact exhbited rates of 20% of control. However, ipsilateral cortical areas distant from the injury site (265%) as well as contralateral cortical regions (138%) did increase. Animals that received injections prior to the injury, however, showed an increase in the impacted zone (212%) as well as in both ipsilateral (216%) and contralateral (183%) regions. These results indicate that blood flow may be increased in the injured zone when L-arginine is administered pre- and post-trauma. Higher levels of blood flow following the injury may reduce the mismatch between blood flow and glucose metabolism which may attenuate the degree and extent of injury, including vulnerability.

THE EXTENT OF CEREBRAL GLUCOSE METABOLISM DEPRESSION FOLLOWING HUMAN TRAUMATIC BRAIN INJURY IS NOT RELATED TO FUNCTIONAL STATE.

M. Bergsneider, D.F. Kelly, E. Shalmon, P. Vespa, B. Yang, S.Y. Bookheimer, J.C. Mazziotta, M.E. Phelps, D.A. Hovda and D.P. Becker*. UCLA Brain Injury Research Center, Los Angeles, CA 90095

During the days that follow experimental and clinical traumatic brain injury (TBI), local cerebral metabolic rate of glucose (lCMRglc) is depressed. The purpose of this study was to investigate whether the degree or anatomical location of metabolic depression, measured by [^{18}F]fluorodeoxyglucose positron emission tomography (fdg-PET), correlated with the neurological (functional) state of head-injured patients.

The fdg-PET images of 32 patients were analyzed: 11 initial Glasgow Coma Score (GCS) 9-15, median 14; and 21 initial GCS 3-8, median 6. A single fdg-PET study was obtained in each patient within 3-34 days post injury (mean 10 days). Regions of interest were drawn and lCMRglc calculated corresponding to the following functional regions: sensorimotor, supplemental motor, primary visual, visual association, anterior language, posterior language, thalamus, corpus striatum, and cerebellar hemisphere. A global cortical lCMRglc value was calculated, and qualitative metabolic scores determined for each functional region by normalizing to the global lCMRglc. On the day of PET, GCS scores, including individual eye, verbal, and motor scores, were documented. GCS scores were correlated to global and functional region lCMRglc values. Separate analyses were made based on injury severity.

The mean (±standard deviation) global lCMRglc was 4.2±1.1 mg/100g/min (normal 6.6). Poor R^2 correlation coefficients were found in all comparisons, including initial GCS and PET-GCS to global lCMRglc, as well as functional region lCMRglc (both absolute and qualitative) to individual GCS scores (best R^2=0.5, mean 0.11).

This study suggests that the period of lCMRglc depression following human TBI represents a pathophysiologic state rather than a functional state occurring to the same degree regardless of injury severity. The mechanism and significance of this metabolic depression are yet to be determined. Supported by NS30308.

LONG TERM EFFECTS OF CORTICAL TRAUMA ON ACETYLCHOLINE METABOLISM AND CHOLINE ACETYLTRANSFERASE ACTIVITY.

D.J. Jenden*, O.U. Scremin, M.G. Li, M. Roch and N. Prieto. West L.A. V.A. Medical Center and UCLA School of Medicine, Depts of Physiology and Pharmacology. Los Angeles CA 90073.

We have previously shown in rats that cognitive function is severely impaired 4 days after cortical trauma (TR4) with a spontaneous recovery 14 days after (TR14). In the present experiments, tissue contents of deuterated ACh (D4ACh) and Ch (D4Ch), total (endogenous + D4) ACh (TACh) and free Ch (TCh) and ACh synthesis (AChTr), were measured in cortex by gas chromatography-mass spectrometry 1 min after i.v. injection of D4Ch (20 µmoles/kg) in adult rats at 4 (n=7) and 14 (n=10) days after trauma, and in 7 intact controls (CON). Trauma was produced under halothane-N_2O anesthesia by weight drop (20 g, 30 cm) over the motor-sensory cortex. Choline acetyltransferase (CHAT) activity (Fonnum's method) was measured in 4 additional groups of 7 animals each, under the same experimental conditions. The average results of regions in the traumatized cortex showed enhanced TCh (Mean±SE, nmoles/g) in TR4 with little recovery in TR14 (CON= 35.5±2.18, TR4= 71.8±8.11, TR14= 55.4±3.3), decreased TACh (nmoles/g) at both times (CON= 40.4±3.22, TR4= 23.1±3.79, TR14= 30.5±3.26), and decreased AChTr (nmoles/g/min) in TR4 with complete recovery at TR14 (CON= 4.36±0.36, TR4= 1.56±0.7, TR14= 4.27±0.76). CHAT (µmoles/g/hr) activity was depressed in the traumatized cortex relative to craniotomy (CRA) controls at both times (CRA4= 6.09±0.29, TR4= 2.81±0.49, CRA14= 5.81±0.28, TRA14= 3.36±0.55). In conclusion, cortical trauma induced decreased CHAT activity, AChTr and TACh with increase in TCh at 4 days. Recovery of cognitive function at 14 days was associated with normalization of AChTr. CORRELATIONS BETWEEN BLOOD FLOW AND ACETYLCHOLINE METABOLISM IN THE TRAUMATIZED CEREBRAL CORTEX.

O.U. Scremin*, D.J. Jenden, M.G. Li and M. Roch. West L.A. V.A. Medical Center and UCLA School of Medicine, Depts of Physiology and Pharmacology. Los Angeles CA 90073.

We have previously shown abnormal acetylcholine (ACh) metabolism after direct trauma to the cerebral cortex. In this study, tissue contents of deuterated ACh (D4ACh) and free Ch (D4Ch), total (endogenous + D4) ACh (TACh) and free Ch (TCh) and ACh synthesis (AChTr) were measured in cortex by gas chromatography-mass spectrometry 1 min after i.v. injection of D4Ch in 7 adult rats. These results were correlated with blood flow (CBF) measured by Iodo-^{14}C-antipyrine autoradiography of the same regions and under identical experimental conditions in 7 additional animals. Trauma was induced under halothane-N_2O anesthesia by weight drop (20 g, 30 cm) through a trephine craniotomy over the motor-sensory cortex, and variables were measured 2 hr later, after discontinuation of anesthesia. The results showed that TCh and D4Ch in cortex increased progressively as CBF decreased. Regression analysis was performed for the model TCh (D4Ch) = $B \cdot (1/(CBF\text{-}C)^2) + A$. For Ch, A = 29.0, B = 26.7, C = 0.02, r = 0.81, P<0.001. For D4CH, A = 2.16, B = 20.1, C = -1.85, r = 0.68, P<0.001. The function is asymptotic to a line parallel to the x axis at high CBF and rises steeply at low CBF for both variables. TACh showed no dependence on CBF. AChTr was increased at very low CBF. It is hypothesized that the increases in Ch and D4Ch observed at low CBF represent decreased incorporation of Ch into phospholipids and could be used as markers of the rate of degradation of membrane phospholipids in direct trauma or ischemia. The stability of ACh at low CBF may be due to a sustained synthesis rate favored by the enhanced availability of free choline. Supported by the US Dept. of Veterans Affairs and USAMRDAC-MM4587JLM BASIC.

PRAZOSIN BLOCKADE OF α1-ADRENOCEPTORS DURING TRAUMATIC BRAIN INJURY INCREASES BEHAVIORAL DEFICITS.

A.A. Dunn-Meynell*, Y. Yarlagadda and B.E. Levin. Neurol.Svc., VA Med. Ctr., E.Orange, NJ 07018 and Dept.Neurosci, NJ Med.Schl., Newark NJ 07103.

Experimental enhancement of noradrenergic activity following traumatic brain injury (TBI) accelerates behavioral recovery if performed at a time when brain norepinephrine (NE) turnover is decreased. But, since NE turnover is markedly increased immediately after TBI, the present study was undertaken to evaluate the effect of modulating these early changes in NE metabolism on recovery of function. Rats were pre-trained on a modified beam walking task. Thirty min prior to TBI, rats received a single dose of NE re-uptake blocker (desmethylimipramine [DMI]; 10 mg/kg, i.p.) or an α1-adrenoceptor antagonist (prazosin [PRZ]; 3 mg/kg, i.p.). They were then anesthetized, and a pneumatic piston was used to produce an open cranium rigid indentation TBI (3.0 mm depth) centered over the left somatosensory cortex.

PRZ pre-treatment markedly worsened beam walking performance throughout the three weeks following injury, whilst DMI pretreatment did not affect performance compared to injured controls. Despite the behavioral deficits, all 3 groups showed similar lesion sizes and similar histological damage in the hippocampus, striatum and thalamus. In separate experiments, PRZ lowered basal blood pressure and prevented the rise in pressure immediately following TBI. However, blood pressures in the three groups came to the same level within 20 sec following TBI. This suggests that the action of PRZ was not simply due to hypotension-induced ischemia. Rather, the results suggest that enhancement of excitatory neurotransmission during the peri-injury period may be responsible for the exacerbated behavioral deficits.

NEUROPROTECTIVE EFFECT OF RILUZOLE IN TRAUMATIC BRAIN INJURY IN RATS.

F. Wahl, E. Renou, V. Mary and JM Stutzmann*. Rhône-Poulenc Rorer, Neurodegenerative Diseases Dept, 94403 Vitry-sur Seine, France.

Traumatic brain injury (TBI) is one of the main causes of morbidity and mortality in young adults. If various experimental studies demonstrated protective effects with different drugs, no therapy is at present available. We investigated the effect of riluzole, a neuroprotective drug, on the brain damage and neurological deficit induced by a TBI in rats.

Anesthetized rats (chloral hydrate, 300 mg/kg ip) were submitted to a TBI induced by a fluid percussion of moderate severity (1.6-1.8 bars) on the right parietal cortex. In study I, riluzole at 4 and 8 mg/kg or vehicle for control groups, was administered 15 min iv, 6h and 24h sc post TBI. One week after TBI, brain damage was quantified histologically. In study II, riluzole or vehicle for control groups, was administered at 2x8 mg/kg/d for 7 days (first injection iv at 15 min post TBI, then by ip route 6h after TBI, and then *bid* ip for the 6 following days). One, 2 and 3 weeks after TBI, the neurological deficit was evaluated.

In study I, riluzole at 3x4 and 3x8 mg/kg significanlty reduced by 43% (P<0.05) the TBI-induced cerebral lesions. In addition (study II) at 2x8 mg/kg/d for 7 days, riluzole significantly reduced the TBI-induced neurological deficit 3 weeks after the TBI (P<0.05), whereas no significant effect was observed 1 and 2 weeks after the TBI.

In a model of TBI in rats, we have demonstrated that riluzole (i) reduced by nearly 50% the brain lesions and (ii) improved the neurological function in rats (which confirmed previous results, McIntosh et al., 1995). Our data thus indicate that riluzole may be useful in the clinical treatment of TBI.

Quantitative assessment of respiratory function following contusion injury of the cervical spinal cord. A. El-Bohy[1], G.W. Shrimsher[*2], P.J. Reier[2] and H.G. Goshgarian[1]. Dept. Of Anatomy&Cell Biology[1], Wayne State University, Detroit, MI 48201 and Depts of Neuroscience and Neurosurgery[2], University of Florida Brain Institute, Gainesville, Fl 32610.

In this study, we describe a new method for quantitative assessment of phrenic motor activity following cervical spinal cord contusion injury. Anesthetized rats received contusion injury either to the descending bulbospinal respiratory pathway alone (C2 contusion) or to both the descending pathway as well as phrenic motoneurons (C4/C5 contusion). Following injury, respiratory associated phrenic nerve motor activity was recorded under standardized and then hypoxic conditions. Signals were electronically rectified, integrated, and quantitated by determining the mean area under the integrated waveforms. The mean integrated area of the 4 respiratory bursts recorded just before turning off the ventilator (to induce hypoxia) was determined and divided by the integrated area under the single largest respiratory burst recorded during hypoxia. This latter value was taken as the maximal respiratory response that the rat is capable of generating during respiratory stress. Thus a percentage of the maximal respiratory capability was established for breathing in control and injured rats under standardized conditions. Correlations of the physiological results also were made with morphological data. The results indicate that non-injured rats use 51±1.8% of maximal respiratory capability. In C2 contused rats the lesion was intentionally lateralized to the right side and the results indicate that while the percentage on left side was similar to the control (55±4%), it was increased on the right (78±2.6%). In C4/5 lesions the injury was made in the midline and the results indicate that the percentage was increased on both sides (Lt=83±5.4% and Rt.=72±6.9%). The results show that respiratory dysfunction may be reliably quantitated following cervical contusion injury. These studies form the basis for future investigation of neuroplasticity and/or therapeutic interventions directed at ameliorating respiratory compromise following spinal cord trauma. (Sup. EXPERIMENTAL SPINAL CORD CONTUSION: COMPARISON BETWEEN MOUSE AND RAT, P.L. Kuhn*, J.R. Wrathall. Program in Neuroscience, and Dept. of Cell Biology, Georgetown University, Washington, D.C. 20057

Animal models of experimental spinal cord injury (SCI) are used to investigate pathophysiologic mechanisms of injury and recovery after CNS trauma. Recently, we reported a new mouse model of contusive SCI that was adapted from methods used to produce and evaluate graded experimental injury in the rat. Briefly, C57Bl6 mice were anesthetized and a laminectomy was performed at the T8 vertebral level. After the spinal column was stabilized, a 1.5 mm diameter impounder was lowered onto the exposed dura and a 1.0, 2.0, or 3.0 g weight was dropped from a height of 2.5 cm onto the impounder. Behavioral testing of animals and lesion histopathology were performed at regular intervals up to 56 days after injury. SCI in the mouse shares several features characteristic of contusive SCI in the rat. The weight-drop technique initially produced profound functional impairment, followed by partial recovery that correlated to impact force at injury. At chronic injury time points, there was significant correlation between functional deficit and residual white matter at the lesion epicenter. However, histopathology was strikingly different. Instead of central cavitation characteristic of the injury epicenter in rat and other animal models—and after human SCI—the mouse epicenter lacked a central cavity. Instead, the epicenter was filled with non-neuronal cells and connective tissue. Clearly, the results indicate a different cellular response to SCI in the mouse, providing a unique opportunity to investigate the cellular mechanisms that contribute to chronic histopathology, and are likely to affect functional recovery after SCI. (Supported by NIH-P01-NS-28130)

TIME-RELATED CALPAIN I ACTIVITY ANALYSIS FOLLOWING TRAUMATIC BRAIN INJURY IN RAT USING CASEIN ZYMOGRAPHY, X. Zhao, R.M. Posmantur, J.S. Liu, J.K. Newcomb, G. Clifton, and R.L. Hayes*. Dept. of Neurosurgery, University of Texas Medical School, Houston, TX 77030.

Analyses using casein zymography were performed to identify changes in calpain I activity in naive, sham-injured, and injured rat cortex at 15 minutes, 3 hours, 6 hours and 24 hours following traumatic brain injury (TBI). Ipsilateral and contralateral cortical samples were separated into cytosolic and membrane fractions. Calpain activity levels obtained from the ipsilateral and contralateral cortices revealed similar temporal profiles, although, overall calpain activity was higher in the ipsilateral cortex. Important differences were noted between the cytosol and membrane fractions. Supernatant fractions from both the ipsilateral and contralateral cortices did not contain any staining in naive samples and only very lightly stained bands (low activity) in sham-injured samples. Significant increases in calpain activity in the supernatant fraction occured as early as 15 minutes, became maximal at 6 hours, and decreased at later time points to levels observed at 15 minutes post-TBI. The detection of a shift in calpain activity levels between the two sample fractions, first occurred at 3 hours post-TBI when a significant increase in calpain activity was first noted in the membrane fractions. Increases in calpain activity in the membrane fraction became maximal at 24 hours post TBI. In contrast, the cytosol fraction showed maximal activation at 6 hours. This shift in calpain activity between the two fractions could be due to the translocation of calpain I from the cytosol to the membrane fraction following TBI. In addition, the evolutionary temporal profiles of calpain activity in both the ipsilateral and contralateral cortex suggest that calpain activity is not exclusively a function of localized contusion and cell death, but may present a more global response to injury. Supported by NIH grants P 01 NS 31998- 01 and NS 21458.

A ONE AND TWO-DIMENSIONAL IMMUNOBLOT ANALYSES OF PUTATIVE CALPAIN MEDIATED NEUROFILAMENT BDPs FOLLOWING TRAUMATIC BRAIN INJURY IN RATS. R.M. Posmantur*, X. Zhao, A. Kampfl, J.S. Liu, G. Clifton, and R.L. Hayes. Dept. of Neurosurgery, University of Texas Medical School, Houston, TX 77030.

Analyses using one and two-dimensional gel electrophoresis were performed to identify the contribution of calpain proteolysis to lower molecular weight (MW) NF68 break down products (BDPs) detected in cortical homogenates following unilateral cortical impact injury in rats. One and two-dimensional immunoblot "maps" of BDPs obtained from *in vitro* cleavage of enriched neurofilaments by purified calpain 2 (mM calpain) were compared to *in vivo* TBI samples. Comparison of these "maps" provided information on the relative contribution of calpain 2 proteolysis in neurofilament loss following mechanical brain injury. Fifteen minutes following traumatic brainrijury (TBI) neither a significant decrease of NF68 immunoreactivity nor the appearance lower MW NF68 BDPs was detected in homogenates from cortex ipsilateral to the injury site using 1 dimensional SDS-PAGE and Western blotting. By 3hrs post -injury, cortical impact resulted in the presence of lower MW NF68immunopositive bands at 57 kD and 53 kD, a pattern almost identical to those previously reported to be produced by calpainmediated proteolysis of neurofilaments. Immunostains of these lower MW NF68 BDPs significantly increased for 24 hrs post-TBI, suggesting that calpain proteolysis may be ongoing during that time. Further, 1 and 2 dimensional peptide maps containing a 1:1 ratio of *in vivo* and *in vitro* tissue samples showed complete comigration of lower MW immunopositive spots at 24 hrs post-TBI, thus providing the first confirmation of the role of calpain 2 mediated proteolysis in the production of NF68 BDPs following TBI. Specifically, the contribution of a 57 kD band was most evident after calpain 2 digestion of neurofilaments. In addition, immunopositive NF68 spots shifted to the basic pole (+) suggesting a dephosphorylation of the remaining NF68 subunit pool, an observation not previously noted in studies of TBI. EXAMINATION OF CALPAIN I SPECIFIC BREAKDOWN PRODUCTS TO α-SPECTRIN IN A CONTROLLED CORTICAL IMPACT MODEL AT BOTH EARLY AND LATE TIMEPOINTS, J.K. Newcomb*, S.J. Liu, A. Kampfl, X. Zhao, R.M. Posmantur, G.L. Clifton, and R.L. Hayes. Dept. of Neurosurgery, University Of Texas Medical School, Houston, TX 77030.

We examined the effect of unilateral controlled cortical impact on appearance of calpain I specific α-spectrin breakdown products in cortex and hippocampus at both early and late timepoints following injury. Coronal sections, approximately 40 μM, were taken from animals at 15 minutes, 1 hour, 3 hours, 6 hours, 24 hours, 7 days, and 14 days after injury and stained with an antibody specific for calpain I cleaved α-spectrin (Roberts-Lewis et al., 1994). Sections from separate rats were also taken at the same timepoints and stained with hematoxylin and eosin for comparison. Analyses of early timepoints (15 minutes, 1 hour, 3 hours, and 6 hours) showed clear and evident staining in structurally intact neurons in cortex ipsilateral to site of injury that was not present in tissue from sham injured control rats. Later timepoints (24 hours, 7 days, and 14 days) showed no clearly defined neuronal structures in ipsilateral cortex, although there was an increased extent of diffuse labelling not restricted to cell bodies. These breakdown products coincided with detectable hematoxylin and eosin morphopathology. Spectrin breakdown products were also observed in the hippocampus and in regions rostral and contralateral to the injury in the absence of overt cell death. These data confirm that activated calpain I is present after controlled cortical impact and could be responsible for necrosis at the site of injury. The appearance of calpain I mediated breakdown products at sites distal to the contusion site also suggest that calpain activation may precede or occur in the absence of overt necrosis. Supported by NIH grants PO1 31998 and RO1 NS21458.

CHANGES OF INTRACELLULAR FREE CALCIUM FOLLOWING SINGLE CELL INJURY IN A GLIAL CELL CULTURE. L. Leybaert* and M.J. Sanderson. Laboratory of Physiology University Ghent, B-9000 Ghent, Belgium and Department of Physiology, University of Massachusetts, Worcester, MA 01655, USA.

Mechanical destruction of a single cell in a confluent glial cell culture was used as a model to study injury related changes of intracellular free calcium ($[Ca^{2+}]_i$). Mixed glial cell cultures were prepared from neonatal rat cortex and were grown to confluency over 7-14 days. Single cells were injured by the impact of a glass micro-needle. $[Ca^{2+}]_i$ was measured using fura-2 and epifluorescence video microscopy.

Single cell injury initiated a wave of transient $[Ca^{2+}]_i$ increase that propagated radially over the tissue culture, with a velocity of 20.1±5.8 μm/s (mean±SEM; 5 experiments [exp]) at 21 °C and 27.4±5.4 μm/s (13 exp) at 35 °C. This corresponds to a Q_{10} of 1.25±0.09. The wave was propagated up to a distance of 131±6 μm (13 exp) away from the injury. In the cells just adjacent to the injured cell, the $[Ca^{2+}]_i$ increase reached a peak that was above fura-2 saturation in one third of the cells and that averaged 1400±266 nM (11 exp) in the other two thirds. The peak $[Ca^{2+}]_i$ change decreased further away from the injury, with a slope of 6.25±0.68 % per 10 μm (16 exp). In some cells the wave was followed by $[Ca^{2+}]_i$ oscillations; most of these cells were located some distance away from the injury, 90.0±5.6 μm (34 cells in 7 exp) on the average. Long-term monitoring over a 4 h period showed changes of $[Ca^{2+}]_i$ in individual cells or groups of cells. Some cells clearly migrated during this period; their movement vector was slightly but not significantly directed towards the injury site (5 exp). There was no obvious relation between migratory activity and $[Ca^{2+}]_i$.

We conclude that glial cell injury is associated with a propagating calcium wave that is mediated by a passive diffusion process. These waves are similar to the waves induced by non-destructive mechanical stimulation of glial cells although their amplitude is larger. Within 4 h, a correlation of calcium signaling and cell migration was not observed. (Small Grants Program UMMC and grant from NFWO, Belgium).

EXPRESSION OF IL-1β AND NEUROTROPHIN mRNAs FOLLOWING SPINAL CORD INJURY AND EFFECTS OF METHYLPREDNISOLONE TREATMENT

M.Hayashi[1,2], T.Ueyama[2], Y.Tamai[3*], T.Tamaki[1], K.Nemoto[4], E.Senba[2]
[1]Dept.of Orthopedic Surgery, [2]Dept.of Anat.and Neurobiol., [3]Dept.of Physiol., Wakayama Medical Coll., 640 Wakayama, [4]Lab.of Health Sci., Univ.of Shizuoka, 422 Shizuoka, Japan.

The purpose of this study is to investigate the temporal and spatial expression patterns of IL-1β and neurotrophins(NGF,BDNF,NT-3) mRNAs in the spinal cord lesion. Furthermore,effects of methylprednisolone(MP) on the expression of these genes were analysed. Male adult Sprague-Dawley rats were laminectomized at T10. Spinal cord was crushed by clipping (holding force 60gms) and dissected from 1 h to 72 h after the injury. Another group of rats were treated with MP (165 mg/kg) just after the injury and sacrificed at 6 h. These mRNA levels were elevated at the lesion site after the injury. IL-1β mRNA level was already increased at 1 h and peaked at 6h. The increased levels of neurotrophin mRNAs were first detected at 6 h and lasted for several days. Upregulation of these mRNAs was attenuated by MP treatment. Our data show that MP suppresses the reactive increase of neurotrophin mRNAs, which might be disadvantageous to the survival of spinal neurons.

HYPOXIA POTENTIATES TRAUMATIC BRAIN INJURY-INDUCED ACTIVATION OF *c-fos* GENE IN VARIOUS REGIONS OF RAT BRAIN. J.R. Dave*, R.A. Bauman and J.B. Long. Division of Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

Hypoxia commonly accompanies severe traumatic brain injury (TBI) in clinical settings and may be responsible for appreciable additional damage to the brain tissue. Among the events triggered by TBI, changes in gene expression have been recognized as an important component of the neuronal response to injury. The objectives of the present study were to establish whether the *c-fos* gene is activated differentially in various brain regions following traumatic injury and to determine if hypoxia following TBI potentiates *c-fos* activation. One day following surgical preparation, spontaneously-breathing halothane-anesthetized male Sprague-Dawley rats (300-350 g) were subjected to either parasagittal fluid percussion-induced TBI (4.5±0.1 atm, 16 m sec duration) or sham injury. For 30 min immediately after injury, hypoxia was induced in half the rats from each group by substituting a 13% O_2 source to deliver halothane for continued anesthesia. Thirty min after completion of hypoxic or normoxic treatment, brains were removed and dissected to isolate the frontal cortex, cerebellum and hippocampus. Levels of *c-fos* mRNA were determined by Northern blot analysis. Arterial blood gases, which did not differ among injured and sham-injured rats, revealed significant hypoxemia following exposure to 13% O_2 (PaO_2 of 35 mm Hg). Hypoxia in sham-injured rats had no significant effect on *c-fos* mRNA levels in any of the three brain regions studied. TBI produced significant increases in *c-fos* mRNA levels in the three regions. A maximal activation of approximately 100% above sham controls was observed in the hippocampus and a minimal activation of 60% was observed in the cortex. Hypoxia following TBI dramatically potentiated these changes in *c-fos* mRNA levels in all the three brain regions. These findings support the hypothesis that hypoxia is an important factor influencing pathophysiological responses to TBI.

DOSE-DEPENDENT NEURONAL LOSS PRODUCED BY THE INTRASPINAL INJECTION OF NMDA: BLOCKADE BY MK-801 BUT NOT NBQX OR A METABOTROPIC ANTAGONIST S. Liu*, G.L. Ruenes, R.P. Yezierski, The Miami Project, Univ. of Miami, Miami, FL 33136.

The involvement of glutamate in excitotoxic cell death of spinal neurons is well documented. There is, however, controversy over the involvement of different receptor subtypes in this process. In the present study the technique of intraspinal microinjection was used to evaluate the excitotoxic effects of NMDA receptor activation in the rat. Varying concentrations of NMDA (125-500mM) or NMDA combined with NBQX (AMPA antagonist), MCPG (metabotropic antagonist) or MK-801 (NMDA antagonist) were evaluated 48 hours following injection. Drugs were injected intraspinally (total volume 0.3-0.6μl) between spinal segments T13-L4. Spinal segments with injection sites were cut (75μm) on a freezing microtome. Serial cross-sections were collected and stained with cresyl violet. The extent of cell loss and gray matter damage at the epicenter of injection sites were evaluated quantitatively with light microscopy and/or image analysis. The results have shown a positive dose response relationship between tissue damage and increasing concentrations of NMDA. Furthermore, the extent of cell loss and area of gray matter damage with NMDA+MK-801 was significantly less than with NMDA+NBQX or NMDA+MCPG. In conclusion, the results support the involvement of NMDA receptors in glutamate induced excitotoxic injury of neurons in the rat spinal cord. Furthermore, the results support the use of intraspinal microinjection as a technique to study the pathological consequences of specific neurochemical changes associated with traumatic or ischemic spinal cord injury. The results will be discussed in relation to the role of spinal EAA receptors, including AMPA and metabotropic, in excitotoxicity of spinal neurons. Supported by NS28058, The Miami Project, and U.S. Army (DAAH04-94-G-0425).

EFFECTS OF HYPOTENSION AND HYPOXIA ON TRAUMATIC BRAIN INJURY. D.A. Chorney-Lane*, J.S. Soblosky, L.L. Colgin, J.F. Davidson, and M.E. Carey. Dept. of Neurosurgery, LSU Medical Center, New Orleans, LA 70112.

We quantified the effects of secondary insults upon traumatic brain injury on rodent sensory/motor behavior. Isoflurane-anesthetized rats were injured in the right sensory/motor cortex followed by 20-minutes of either hypotension (MABP 50mm Hg) or hypoxia (PaO_2 40mm Hg). Injury was produced using a piston with a 4X8mm elliptical tip that depressed the dura 1mm. Impact speed was 5M/sec. Hypotension was produced by removing 5ml of blood via a jugular cannula. The blood was reinfused after the 20-min. period. Hypoxia was produced by using a reduced oxygen tank (75% O_2) for the 20-min. period. We evaluated motor deficits using four tests: performance traversing a flat narrow beam, the number of footslips on a pegged narrow beam, the number of foot-faults on a grid platform, and a forepaw preference test. The results indicated that hypotension was more detrimental on brain injury than hypoxia. Injured rats made hypotensive performed poorer than rats receiving injury alone. However, there were no significant differences in scores between injured rats made hypoxic and rats receiving injury alone. This research was supported by a grant from the Joe W. and Dorothy Dorsett Brown Foundation, New Orleans, Louisiana.

REGIONAL GENERATION OF LEUKOTRIENE C_4 AFTER LATERAL FLUID PERCUSSION BRAIN INJURY IN THE RAT. H.S. Dhillon, J.M. Dose and M.R. Prasad.* Department of Surgery, University of Kentucky Medical Center, Lexington, Ky-40536.

Our previous studies have demonstrated the accumulation of arachidonic acid, the substrate for leukotriene C_4 (LTC_4) biosynthesis, in the brain regions that undergo neuronal cell loss after lateral fluid percussion (FP) brain injury in the rat. LTC_4 is implicated in the blood brain barrier breakdown (BBB) and in the development of edema formation after central nervous system injury. The present study examined regional levels of LTC_4 after FP brain injury. Male Sprague Dawley rats (325-350 g, N=30) were anesthetized with sodium pentobarbital (60 mg/kg, IP) and subjected to either sham operation (N=6) or lateral FP brain injury (N=24) of moderate severity (2.0 atm.). After brain in situ freezing at 10 min, 30 min, 1 h and 2 h (n=6 each time point) after injury, the ipsilateral left cortex (LC) and, left hippocampus (LH), and the contralateral right cortex (RC) were dissected out. The levels of LTC_4 were significantly elevated in the LC and LH at 10 min after injury and those elevations persisted as long as 2 h. The levels of LTC_4 were not significantly elevated in the RC at any time after injury. These results suggest that LTC_4 may play a role in the BBB, edema formation and in neuronal cell loss associated with brain injury. (Supported by NIH Grant NS 31816).

EVIDENCE OF TRANSIENT INCREASES IN GLUTAMATE ASSOCIATED WITH DECREASES IN CPP BELOW 60 TORR AFTER HUMAN HEAD INJURY P. Vespa, M.L. Prins, S.M. Lee*, D.A. Hovda, E. Shalmon, N. Martin, T. Glenn, M. Bergsneider, D. Kelly, and D.P. Becker
Division of Neurosurgery, UCLA Sch. Med., Los Angeles, California 90024

The release of excitatory amino acids (EAA) in response to traumatic and/or ischemic brain injury is a well accepted component of the post-injury neurochemical cascade. Following traumatic brain injury (TBI), cells not irreversibly damaged are very vulnerable to reduction of cerebral blood flow. Given that, we utilized chronic cerebral microdialysis in human brain injured patients to determine if reduction in cerebral perfusion pressure (CPP) was associated with increases in the extracellular concentration of glutamate.

Cerebral microdialysis was conducted beginning as early as post-injury day 2 in five patients (ages: 28-55 ; initial glascow coma score: 3-6) all with elevated intracranial pressure. The microdialysis probe was positioned in the frontal grey-white matter junction and perfused with Ringer's lactate (1-2μl/min). Hourly dialysate concentrations of glutamate were determined by HPLC analysis using a non-isocratic method with fluorescence detection.

When CPP was compared to the changes in EAA the following observations were made (1) when the CPP dropped below 60 torr there was a transient increase in glutamate (1-2 hrs duration; 70-120μM increases), (2) when CPP returned to 70-80 torr the glutamate concentrations were low (below 20μM), (3) there were multiple spikes of glutamate levels in each patient, each corresponding to period of low CPP (average : 3.2 glutamate spikes per patient). This data suggest that during this post-injury period decreases in CPP below 60 torr generate secondary injuries as evidenced by increases in EAA, which could lead to excitotoxicity.

HYPOTHERMIA REDUCES ACUTE INFLAMMATION AFTER TRAUMATIC BRAIN INJURY IN RATS M. Whalen, T. Carlos, P. Kochanek*, R. Clark, S. Heineman, J. Schiding, S. DeKosky, S. Graham, C. Dixon, D. Marion, Safar Center for Resuscitation Research, Univ. of Pittsburgh, PA.

Mild hypothermia reduces secondary damage after traumatic brain injury (TBI) in rats. Recent studies suggest that the beneficial effects of hypothermia after TBI may not be completely mediated by reduced excitotoxicity or energy demands. We reported that TBI induces an acute inflammatory response (adhesion molecule upregulation and neutrophil [PMN] accumulation) in rat brain. Since PMN accumulation may be associated with blood-brain barrier injury and hyperemia, we hypothesized that hypothermia would reduce acute inflammation after TBI. Sprague Dawley rats were anesthetized with isoflurane and subjected to controlled cortical impact to the left parietal cortex. Brain temperature was controlled at 32°C, 37°C, or 39°C, (n=8/group) for 4 h after TBI, then rats were decapitated. Immunohistochemistries were performed on brain sections using MoAbs recognizing PMN (RP-3), ICAM-1 (TM-8, Athena Neurosciences), or polyclonal Ab that reacts with E-selectin (La-Roche), and quantitated in 100x fields. PMN accumulation was also quantified with myeloperoxidase assay (MPO). Absolute neutrophil count (ANC) was measured in blood samples before, 1 h, and 4 h after TBI. PMN accumulation in injured brain was decreased in rats maintained at 32°C vs 39°C (4-fold by immunohistochemistry, $p < 0.05$; 8-fold by MPO, $p < 0.05$). E-selectin was induced after TBI ($p < 0.05$), but only modestly decreased at 32°C vs 39°C ($p = 0.11$). ICAM-1 was not upregulated at this early time after TBI. ANC was not affected by temperature. Hypothermia reduces early PMN accumulation after TBI, without affecting E-selectin or ICAM-1 expression, or ANC. The direct relationship between brain temperature and PMN accumulation after TBI suggests that beneficial effects of hypothermia may be mediated, in part, by effects on inflammation. Support: 2P50 NS30318-04A21 from NINDS, and SCCM.

ALTERATIONS IN THE AXOLEMMA FOLLOWING TRAUMATIC BRAIN INJURY: COMPARISON OF TWO EXTRACELLULAR TRACERS OF DIFFERENT MOLECULAR WEIGHTS. M.O. Fitzpatrick*[1,2] M.L.Giebel[2] and J.T.Povlishock[2,1]Institute of Neurological Sciences, Glasgow, Scotland, and [2]Dept. of Anatomy, Med. Col. of VA, VA Commonwealth University, Richmond, VA 23298.

Recent studies have demonstrated that focal alteration of the axolemma occurs following traumatic brain injury (TBI). The extracellular tracer, horseradish peroxidase(HRP), which is excluded by the intact axolemma in non-injured axons, is detected in the axoplasm as early as 5 mins postinjury. The present study extends these observations by employing the extracellular tracer microperoxidase (MP) to determine if there is a spectrum of axolemmal failure in TBI which can be detected by tracers of different molecular weight. Mechanically ventilated, halothane anaesthetized rats received intrathecal infusions of HRP (MW 40,000) or MP (MW 1900). Thirty minutes following tracer infusion, the animals were subjected to an impact acceleration closed head injury. At 5, 15 and 60 mins postinjury, the brains were perfusion fixed and processed for LM and EM. For both HRP and MP appropriate sham controls were used. In all material prepared for LM, homologous 50,000 μm^2 regions from the pontomedullary and cervicomedullary areas were subjected to quantitative analysis to determine the number of tracer-containing axons per unit area. In the controls, no evidence of intra-axonal tracer uptake was found. In the injured animals receiving HRP, HRP- containing axons were detected in the ventral brain stem where they were most numerous in the pontomedullary and cervicomedullary regions. Those injured rats receiving MP also demonstrated axonal flooding; however, statistically fewer axons were detected. These observations were consistent at all postinjury time points. This study suggests that, following TBI, alterations in the axolemma do not involve a spectrum of membrane perturbation. Rather, it appears that a non-specific passage of macromolecules occurs in an " all or none" fashion. Further, in this protocol, HRP appears to be a better marker of altered axolemmal permeability than MP. The reason for this is unclear and may be related to differences in the intra-axonal binding properties of the tracers.(Supported by NS20193)

BEHAVIORALLY-INDUCED CONTUSIONS FOLLOWING TRAUMATIC BRAIN INJURY: USE-DEPENDENT SECONDARY INSULTS .

D.A. Kozlowski*, S.L. von Stück, S.M. Lee, D.A. Hovda, & D.P. Becker.
Division of Neurosurgery, UCLA Sch. of Med., Los Angeles, CA 90095.

Previous studies have shown that immobilization of the non-impaired limb following a unilateral electrolytic lesion of the forelimb-representation area of the sensorimotor cortex (FL-SMC) in adult rats, results in an exaggeration of neuronal injury and significantly larger and longer lasting behavioral deficits presumably due to forced overuse of the impaired limb. (Kozlowski, James & Schallert, 1996). The present study attempted to determine whether a similar overuse phenomenon occurs following a biomechanical traumatic brain (TBI) induced by a unilateral fluid percussion (FPI) or controlled cortical impact (CCI) injury. After induction of general anesthesia (~2.0 ml/min enflurane; 100% O_2) a craniotomy was performed, unilaterally, either over the FL-SMC or over the parietal cortex and either a FPI or a CCI was administered. Following TBI, the forelimb contralateral to the injury was immobilized with a one-sleeved cast for 15 days post-injury in injured and sham-injured control groups. Animals were sacrificed 15 days post-cast removal, their brains were removed, sectioned and Nissl stained. Quantitative analyses of cortical contusion volume was conducted along with a general inspection of contused areas in subcortical structures. Results indicated that forced use of the impaired forelimb resulted in an enlargement of the contusion cavity following CCI (CCI+forced use=15.94 mm^3; CCI+no forced use= 10.78 mm^3). Following FPI, forced use resulted in an induction of neural degeneration and additional contusions in both cortical (FPI+forced use=14.83 mm^3; FPI+no forced use=0.34 mm^3) and subcortical structures (thalamus and amygdala) following FPI. No contusions were seen in sham-injured controls forced to use one forelimb. These results suggest that behavioral pressures may produce additional physiological demands on injured brain tissue, thereby acting as secondary insults following traumatic brain injury.

LACK OF COGNITIVE DEFICITS FOLLOWING TRAUMATIC BRAIN INJURY IN THE DEVELOPING RAT

M.L. Prins*, S. Payrovi, D.A. Hovda
Division of Neurosurgery, UCLA Sch. Med., Los Angeles, California 90024

Previous work has demonstrated that perinatal and adult rats show different physiological responses to fluid-percussion (FP) brain injury. Unlike adult animals, the younger rats showed sustained hypotension and higher mortality following traumatic brain injury (TBI). This age-dependent physiological response to TBI suggests that the resulting behavior may also show an age effect. The Morris water maze was used to compare the degree of cognitive impairments between sham operated and moderately injured rats at postnatal day 17 (P17) (n=18; 9 sham,9 injured), P28 (n=8; 4 sham, 4 injured), and adulthood (n=10; 5 sham, 5 injured). Under enflurane anesthesia rats sustained a moderate (2.75 atm) FP injury over the left parietal cortex or sham surgery and were trained to locate a hidden platform ($15cm^2$) in the Morris water maze tank (1.5m, diameter) for the next 10 days. All animals showed consistent weight gain with no significant difference between injured and sham animals. Adult and P28 injured rats showed learning deficits compared to controls across several parameters : (sham, injured respectively) # days to reach average latency <5s (adult: 4 ±2 days, >10 ±1.5 days; P28: 6±1.5days, 9±2 days), total number of direct paths to the platform (adult: 61, 34, $p \leq 0.05$; P28: 35, 24, $p \leq 1.0$), and days to criterion performance (adult: 5±1days, 8±2days; P28: 8±2days, 8±2days). P17 injured rats did not show significant differences in either the average escape latency, or days to criterion. There was, however, a 7% decrease in the total number of direct paths made to the platform (sham: 24; injured:18, $p \leq 0.15$), which suggests that while they are able to locate the platform they may be utilizing a less direct or inefficient search strategy.

MODELS OF PERIPHERAL NERVE INJURY.

A. Dailey, J. Silver, A. Avellino, K. Andrus, T. Bosch, and M. Kliot*, Department of Neurological Surgery, Univ. of WA. & Seattle VAMC, Seattle, WA. 98108 / Department of Neuroscience, CWRU, Cleveland, Ohio 44106

Nerve trauma of sufficient magnitude and duration can result in the loss of sensory-motor function as well as produce painful dysesthesias. Most animal models of peripheral nerve injury have applied either acute or chronic compressive forces (MacKinnon and Dellon 1992). However tension, produced either by an acute stretch injury or intermittently through extraneural tethering adhesions, is a frequent component of both acute and chronic nerve trauma. In addition, intraneural scarring is thought to contribute to the loss of nerve function and impede recovery (Sunderland 1978). We have developed animal models to investigate the biological and behavioral responses of peripheral nerves subjected to acute and chronic stretch/compression forces. In addition, the effects of inducing intraneural fibrosis were also investigated.

The sciatic nerves of adult Lewis rats exposed at thigh level underwent three types of experimental manipulation. Group I rats (n=6) underwent acute stretch/compression of their sciatic nerves. Although these rats did not develop significant and sustained behavioral deficits, immunostaining with the ED1 macrophage marker showed an increasing number of macrophages in nerves subjected to increasing forces of stretch. Group 2 rats (n=12) were subjected to chronic stretch/compression by deviating the course of their sciatic nerves by means of a sling fashioned from adjacent muscle and fascia. These animals developed a behavioral deficit which slowly recovered over a 7 week period as determined by computer gait track analysis. Immunostaining of these nerves demonstrated very high numbers of macrophages. Surgical release of the sling (n=5) resulted in a more rapid normalization of their gait. Group 3 (n=11) rats underwent internal neurolysis of their sciatic nerve into 6 components. These animals demonstrated intraneural scarring and an acute deterioration in their gait followed by significant recovery within 3 weeks.

These experiments suggest that chronic trauma of a peripheral nerve produces more severe and longer lasting behavioral deficits than does acute trauma of a similar magnitude.

DYNAMIC BIAXIAL NEURONAL STRETCH *IN VITRO*

DH Smith*[1], JA Wolf[1], D Sun[2], and DF Meaney[2]. [1]Div. of Neurosurgery and [2]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA 19104.

While dynamic deformation of neurons plays an integral role in traumatic CNS injury, most *in vitro* models utilize either non-neuronal cells, non-deformation injury, or quasistatic injury. We have developed an *in vitro* injury system using human neuronal-like cells (differentiated N-Tera2 [NT2] cells) grown on a deformable substrate that can be dynamically stretched in a controlled fashion. The substrate is a silicon gloss/gloss .005 inch membrane attached via an O ring to the bottom of a milled steel well. Mature NT2 cells are subjected to dynamic deformation by applying a rapid vacuum to a sealed cell chamber mounted on an inverted microscope. This force results in the dynamic biaxial application of a high strain field to the cells. Prior to injury, the cells are loaded with Fura-2 allowing for observation of post-traumatic changes in intracellular calcium concentration. The cells are visualized through fluorescence microscopy integrated with an image analysis system. At 60-100% strain, we observe an acute and very marked increase in intracellular free calcium. Despite the large deformation, almost all cells stay attached for several hours following injury. However, by 24 hrs following injury, many cells, approximately 40%, become dysmorphic or detached. These results suggest that dynamic deformation of neurons may be produced *in vitro* resulting in calcium dysregulation and damage.

MECHANISMS OF CELL DEATH INDUCED BY MITOCHONDRIAL TOXIN 3-NITROPROPIONIC ACID: CONCURRENT EXCITOTOXICITY AND APOPTOSIS.

Z. Pang and J.W. Geddes*. Sanders-Brown Center on Aging and Dept. Anatomy & Neurobiology, Univ. Kentucky, Lexington, KY 40536.

Energy metabolism impairment may play an important role in neuronal cell death under ischemic conditions and in age-related neurodegenerative diseases. Both excitotoxicity and apoptosis have been implicated in the cell death induced by mitochondrial toxins. In the present study, we test the hypothesis that the mechanisms of neuronal cell death induced by 3-nitropropionic acid (3NPA), an irreversible inhibitor of succinate dehydrogenase, are determined by the level of extracellular glutamate. Treatment of cultured rat hippocampal neurons with 3NPA resulted in two types of cell death with distinct pharmacological, morphological, and biochemical features. A rapid cell death, characterized by cell swelling and nuclear pyknosis, could be completely blocked by NMDA receptor antagonist MK801 (10μM) and potentiated by subtoxic levels of glutamate. A slowly-evolving cell death, characterized by nuclear fragmentation, a hallmark of apoptosis, was insensitive to MK801, but was blockable by cycloheximide (1μg/ml). A combination of MK801 and cycloheximide resulted in an almost complete protection. TUNEL staining decorated all the apoptotic nuclei whereas only a subpopulation of pyknotic nuclei were stained. Increased c-Jun immunoreactivity was associated with fragmented nuclei, but not pyknotic nuclei. Quantitative analysis demonstrated that increased levels of extracellular glutamate shifted the cell death mechanism from apoptosis to necrosis. We conclude that 3NPA induced-cell death occurs via two seperate pathways: an excitotoxic necrosis as a result of NMDA receptor activation, and apoptosis which is NMDA receptor-independent.

METABOLIC EFFECTS OF 3-NITROPROPIONIC ACID (3-NPA) IN THE ADULT RAT BRAIN.

R.D. Prapurna*, R.L. Rountree, A.C. Scallet, W. Slikker, Jr., and Z. Binienda. Division of Neurotoxicology, NCTR/FDA, Jefferson, AR 72079.

The metabolic effects of acute 3-NPA exposure on male Sprague-Dawley rats were investigated in this study. Adult rats were dosed either with vehicle or 3-NPA at 30 mg/kg s.c. Animals were sacrificed at 1,2,3, and 6 hrs following 3-NPA administration. Brains were immediately dissected into frontal cortex (FC), corpus striatum (CS), hippocampus (HIP), cerebellum (CB), and brain stem (BS). Rectal core temperature was measured at the time of injection and sacrifice. The activities of succinate dehydrogenase (SDH) and superoxide dismutase (Cu-Zn SOD and Mn-SOD) were determined spectrophotometrically in tissue homogenates. The activity of SDH was inhibited significantly in CS in a time dependent manner: 75% (1 hr), 80.2% (2 hr), 81.7% (3 hr), and 78.4% (6 hr). There was a significant drop of the core body temperature from 38.9°C ± 0.1 to 36.0°C ± 0.3 (mean ± SEM, $p<0.05$). The activity of both types of SOD increased in the HIP at 1 hr. There was a gradual decrease of SOD by 3 hr to 25-30% of the control values. At 6 hr, SOD activity returned to the baseline level. However in the FC, no marked changes in SOD were observed. The results indicate that the generation of reactive oxygen species is associated with the response to acute 3-NPA exposure.

THE EFFECT OF 3-NITROPROPIONIC ACID (3-NPA) ON FREE FATTY ACID (FFA) LEVELS IN THE RAT BRAIN. Z. Binienda*, R.D. Prapurna, T. Flynn, I.A. Ross, and C.S. Kim. NCTR/FDA, Jefferson, AR 72079 and CFSAN/FDA, Washington, DC 20204.

The ability of the fungal and plant toxin 3-NPA, a mitochondrial succinate dehydrogenase inhibitor, to produce lipid peroxidation in brain and liver tissues was recently reported (Fu et al., Toxicon. 33:327-331, 1995). In our study, we investigated the effect of acute 3-NPA exposure on the cerebral concentrations of free fatty acids (FFA) used as a marker of oxidative stress. Adult male Sprague-Dawley rats were dosed with either vehicle or 3-NPA at 30mg/kg s.c. Animals were sacrificed at 1,2,3, and 6 hrs following 3-NPA administration. Brains were then dissected into frontal cortex (FC), corpus striatum (CS), hippocampus (HIP), cerebellum (CB), and brain stem (BS). The concentrations of FFA after conversion to methyl esters were determined in tissue homogenates by gas chromatography. Tissue adenosine triphosphate (ATP) level was measured by HPLC. A significant increase in individual FFA, e.g., arachidonic acid and total FFA concentrations was observed in all regions as early as 1-2 hrs after the treatment. ATP levels decreased by 37% in CS and 30% in FC by 1 hr. Data suggest a role of oxidative stress in the mechanism of 3-NPA toxicity. (Supported by NCTR/FDA).

DISTRIBUTION OF 3-NITROPROPIONIC ACID (3-NPA) INDUCED DEGENERATION OF MYELINATED AXONS AND TERMINALS: A COMBINED FLUORO-JADE AND $AuCl_3$ STUDY. L. Schmued*, A. Scallet, W. Slikker Jr., and Z. Binienda. NCTR/FDA. Jefferson, AR 72079

3-nitropropionic acid (3-NPA) is a bacterially produced contaminant of sugar cane. Brain lesions are thought to result from disruption of metabolic respiration via mitochondrial succinate dehydrogenase inhibition. Primary lesions of myelinated axons were localized with a reduced $AuCl_3$ method. All effected rats exhibited large lesions of the striatum, globus pallidus, and deep nuclei of the cerebellum characterized by an absence of fine myelinated fibers and disrupted, pale and varicose appearing fascicles. Isolated animals also exhibited lesions within the vestibular nuclei, cochlear nuclei, medial geniculate, posterior thalamus, perirhinal cortex, and endopiriform nucleus. Fluoro-Jade, a recently developed simple and reliable fluorescent marker of neuronal degeneration revealed conspicuous labeling of axons which originate or pass through the lesioned areas. Degenerating axons were found in the internal capsule, pyramidal tract, central tegmental tract, and superior cerebellar peduncle. Degenerating terminals were seen in the entopeduncular nucleus, ventral thalamus, subthalamic nucleus, substantia nigra pars reticulatta, pedunculopontine region, red nucleus and cingulate and frontal cortex. These findings are consistent with the idea that 3-NPA produces relatively large hypoxic lesions of the basal ganglia and deep cerebellum which in turn results in secondary degeneration of axons which originate or pass through the primary lesion. Thus, terminal degeneration could be found in the efferent projection targets of the globus pallidus and deep cerebellar nuclei.

CHARACTERIZATION OF THE INHIBITION OF BRAIN SUCCINATE DEHYDROGENASE AFTER SYSTEMIC ADMINISTRATION OF 3-NITROPROPIONIC ACID. S. Palfi, M. C. Guyot, P. Hantraye, S. Altairac, E.Brouillet*. URA CEA-CNRS 2210, SHFJ, DRIPP, DSV, Orsay, FRANCE.

An alteration of succinate dehydrogenase (SDH) may be involved in the selective striatal degeneration observed in Huntington's disease (HD). Consistent with this, chronic intoxication with the selective SDH inhibitor 3-nitropropionic acid (3NP) in rats and non-human primates leads to selective striatal lesions and abnormal motor behavior reminiscent of HD. In the present study, we determined in rats receiving systemic 3NP the regional pattern of SDH inhibition in the brain and the degree of inhibition required to produce *in vivo* striatal neuronal death and motor symptoms. Brain SDH activity was assessed *in situ* by semi-quantitative histochemistry, 24h after intraperitoneal injection of 3NP. We found that administration of increasing doses of 3NP (10-40 mg/kg) produced a dose-dependent and irreversible SDH inhibition. The level of inhibition in the striatum was similar to that obtained in brain regions more resistant to 3NP toxicity. Behavioral observations combined with determination of SDH activity showed that obvious motor symptoms and early signs of striatal degeneration occured for 40-50% inhibition of SDH activity. The present results demonstrate that the selective striatal toxicity of 3NP is not related to a preferential inhibition of the toxin on striatal SDH.

ENERGETIC AND MORPHOLOGICAL CHANGES IN STRIATAL CULTURES EXPOSED TO THE MITOCHONDRIAL TOXIN METHYLMALONATE. B.A. McLaughlin*[1] D. Nelson[2] I. Silver[3] M. Erecinska[2] and M-F Chesselet[1,2] [1]Institute of Neurological Science and [2]Dept. of Pharmacology, U. Penn., Philadelphia, PA 19104 [3] Dept. of Anatomy, School of Veterinary Science, Bristol BS2 8EJ, UK

In vivo administration of mitochondrial toxins such as 3-NPA and malonic acid produce selective striatal cell death similar to Huntington's Disease. However, the mechanisms of cell death induced by these toxins have not been elucidated. To address this question, primary striatal and cortical cultures were exposed to methylmalonate, which is hydrolysed to malonate intracellularly, and energetic and morphological changes were assessed. As previously reported (McLaughlin and Chesselet, 1995), methylmalonate induced neuronal death in a dose dependent manner, and both 1 and 10 mM methylmalonate caused > 80% cortical and striatal cell death at 24 hours. Cell death induced by 1 mM methylmalonate was attenuated by addition of medium containing free radical scavengers. Time lapse video microscopy revealed asynchronous apoptotic blebbing and chromatin condensation as well as necrosis during 24 hour exposure to 1 mM toxin. Following 3 hour exposure to 1 mM methylmalonate, the ADP and ATP levels decreased in cortical, but not striatal, cells. After 20 minutes of exposure to 10 mM methylmalonate, neuronal $[Na^+]_i$ increased while $[K^+]_i$ and membrane potential decreased. At 2 hours, there was also significant Ca^{++} influx. After 3 hours, there was a decrease in ATP/ADP as well as in the absolute levels of ADP and ATP in both cortical and striatal cultures. Coincubation with free radical scavengers did not improve nucleotide ratios or levels, suggesting that these agents do not induce their protective effects by interfering with the effect of methylmalonate on mitochondrial function. The data suggest that methylmalonate induces neuronal death through both apoptotic and necrotic mechanisms triggered by inhibition of ATP-dependent Na/K pump, calcium influx and free radical generation. THE EFFECT OF 6-AMINONICOTINAMIDE ON METABOLISM OF ASTROCYTES AND C6-GLIOMA CELLS IN VITRO. N. Haghighat* and D.W. McCandless. Department of Cell Biology and Anatomy, Chicago Medical School, 3333 Green Bay Road, North Chicago, IL, 60064.

Brain tissue has been shown to use two predominant methods for production of ATP. The first of these is the pentose phosphate shunt, and the second pathway is glycolysis, followed by the TCA cycle. Inhibition of these pathways can result in reduction of ATP, and changes in the concentration of various metabolites. In this study, the acute and chronic effect of 6-aminonicotinamide (6-AN) (0.01, 0.02., and 0.03 mg/ml) was tested on astrocytes and C6-glioma cells. Following treatment, glucose, lactate, glutamate, ATP, and PCr were assayed according to the procedures of Lowry and Passonneau. Our data indicate that following 15 minutes treatment of astrocytes and C6-glioma with 6-AN there was no significant difference in the concentration of metabolites measured. However, following 24 hours treatment there was significant increase in glucose concentration and statistically significant reduction in the concentration of ATP, PCr, lactate and glutamate in both cell types. Morphological changes showed up later following 48 hours treatment with 6-AN in both cell types. Glucose accumulation can easily be explained by the fact that it is the precursor to both glycolysis and the pentose phosphate shunt. If these processes are inhibited, glucose will obviously accumulate and products like ATP, PCr, lactate and glutamate will decrease. Additionally, there was significant differences in concentration of glucose and lactate between astrocytes and C6-glioma cells.

GOLD-THIO-GLUCOSE-INDUCED LESIONS IN VENTROMEDIAL HYPOTHALAMUS ARE ASSOCIATED WITH ELEVATED TGF-β AND TGF-α IMMUNOREACTIVITY AND GFAP mRNA. C.V. Mobbs*, H.-S. Choi, P. Hytiroglou, F. Paronetto, and T. M. Mizuno. Fishberg Center for Neurobiology, Mt. Sinai School of Medicine, and Bronx VAMC, New York, 10029

A single i.p. injection of gold-thio-glucose (GTG) in mice produces a specific lesion in the ventromedial hypothalamus, associated with obesity, which can be attenuated by glucocorticoids. To assess if markers of glial activation are expressed after GTG injection, CBA mice were injected i.p. with GTG (0.8 mg/gm b.w.) or saline, and sacrificed 48 hours later. Brains were sectioned and stained with antibodies which recognized TGF-β (all subtypes) or TGF-α. TGF-β and TGF-α immunoreactivity were elevated in cells near the hypothalamic lesion produced by GTG. TGF-β immunoreactivity appeared to be induced primarily in neurons, whereas TGF-α immunoreactivity appeared to be induced in glial cells. GFAP mRNA, as assessed by both Northern blot and in situ hybridization, was also induced about 3-fold in ventromedial hypothalamus 48 hours after injection of GTG. These studies suggest that molecular responses are activated in both neurons and glia near the GTG-induced hypothalamic lesion.

Induction of Serine Proteases in the Adult Rat Spinal Cord Following Kainic Acid Administration

I.A. Scarisbrick, M.D. Towner and P.J. Isackson*
Department of Biochemistry and Molecular Biology, Mayo Clinic, Jacksonville, FL 32224

Using a PCR cloning strategy with degenerate primers, we have isolated cDNA clones of tissue plasminogen activator (tPA) and a previously unidentified serine protease, M44, in adult rat spinal cord. Sequence analysis of a full-length cDNA clone of M44 predicts an amino acid sequence that is most similar to that of trypsin and neuropsin and suggests trypsin-like specificity. Expression of tPA, M44 and a glandular kallikrein, mGK22, were examined in the lumbosacral spinal cord of control and kainic acid treated adult male rats by in situ hybridization and Northern blot analysis. In control rats, tPA mRNA and, to a lesser extent, mGK22 mRNA are predominantly expressed in the gray matter of the spinal cord. In contrast, M44 mRNA is most robustly expressed in white matter glia, with significant but lower levels of expression in the spinal cord gray matter. Each is expressed by alpha motoneurons of the ventral horn. Increased expression of each of these serine proteases was observed from 1 to 7 days following intraperitoneal injection of kainic acid (10 mg/kg). The induction of these serine proteases suggests that they play functional roles in glutamate receptor mediated excitotoxic events in the spinal cord following injury.

METABOTROPIC GLUTAMATE RECEPTOR MEDIATED NEUROPROTECTION IN RAT HIPPOCCAMPUS. M. Pizzi*, F. Boroni, M. Benarese, O. Consolandi, M. Memo, P.F. Spano. Div. Pharmacol., Dept. Biomed. Sci. & Biotechnol., Brescia University Scholl of Medicine, 25123 Brescia, Italy.

Metabotropic glutamate receptors (mGluRs) belong to a relative large receptor family consisting of multiple members with important roles in a number of brain functions.

We report here that activation of mGluRs prevents the neurotoxic effect induced by N-methyl-D-aspartate (NMDA) in slices from rat hippocampus.

Neuroprotection was elicited when slices were simultaneously exposed to both the selective mGluR agonist, (±)-1-aminocyclopentane-trans-1,3-dicarboxylic acid (tACPD), and NMDA. Persisting stimulation of mGluRs after the toxic exposure did not improve survival of pyramidal or granular cells.

The neuroprotection elicited by tACPD was also evoked by its active isomer, (1S,3R)-ACPD, and was prevented by the selective mGluR antagonist (+)-α-methyl-4-carboxyphenyl-glycine (MCPG, 500 μM), confirming that mGluR activation is involved in the mechanism of action of tACPD.

The effect of 100 μM tACPD was reproduced by 100 μM quisqualate, and by (RS)-3,5-dihydroxyphenylglycine, an agonist for mGluR1 and mGluR5, as well as by 1 μM of (2S,1'S,2'S)-2-carboxycyclopropyl-glycine (L-CCG-I) a preferential agonist at mGluR2 and mGluR3 subtypes. No neuroprotection was induced by the selective agonist for mGluR4, mGluR6, mGluR7 and mGluR8, L-2-amino-4-phosphonobutyrate (L-AP4) at 500 μM concentration.

Since the NMDA-mediated cell death in hippocampal slices is considered relevant to ischemia-induced brain injury, these results indicate that mGluRs may be important safety devices used by neurons to decrease their sensitivity to excitotoxic stimuli and increase their chance of survival.

MEDIAL SEPTAL CELLS ARE VULNERABLE TO KAINIC ACID (KA), QUINOLINIC ACID (QA), COLCHICINE (COL), and 2,5-HEXANEDIONE (2,5-HX): THE REVERSAL ROLE OF NIMODIPINE ON KA- AND QA-INDUCED NEUROTOXICITY

Justin D. Oh* and Thomas N. Chase. Clinical Pharmacology, NINDS-ETB, NIH, Bethesda, MD 20892.

Various known neurotoxins have been shown to affect medial septal cells in the basal forebrain of rats. However, the mechanism by which these cells undergo cell death remains unclear. To explore these, we challenged the medial septal cells with the following neurotoxins: i) excitotoxins such as QA and KA, ii) microtubule disrupting agent (COL), and iii) neurofilament disrupting agent (2,5-HX). The type of cell death and the reversal role of calcium channel blockers were then characterized. Male Sprague-Dawley rats weighting 250-300 g were used in these experiments. Aforementioned agents were continuously infused into the medial septum (0.3 AP; 0.4 L; 5.5 V) in these animals by use of the microinfusion pump (0.2 ml/min.). Following the infusion, the subjects were either sacrificed or perfused for either biochemical detection of DNA fragmentation or histological detections for cell death, respectively. Nissl staining revealed that all neurotoxins examined caused a significant cell loss 3 to 5 days after the surgery. Furthermore, both the TUNEL labeling and gel electrophoresis analysis for DNA fragmentation showed evidence for internucleosomal DNA fragmentation 24 hrs. after the surgery in all experimental groups. Finally, nimodipine (0.5 to 4.0 mg/kg, i.p.) injected 30 minutes before and after excitotoxin infusion (QA, KA) were effective in preventing medial septal cell death. {Support: NINDS, NIH}

NMDA-RECEPTOR AGONIST INDUCED NEURODEGENERATION IN THE RAT BRAIN AND RELATION TO OXIDATIVE AND NITRERGIC STRESS. G. Wolf*, H. Noack, J. Lindenau, and F. Rothe. Inst. for Med. Neurobiol., University of Magdeburg, Leipziger Str. 44, D-39120 Magdeburg, Germany.

Glutamate-induced excitotoxic processes are accompanied by an elevated formation of reactive oxygen and nitrogen species which can combine to peroxynitrite, a strong oxidant and radical precursor, thought to be involved in the degeneration of neurons. Superoxide dismutases (SOD) protect cells against elevated concentrations of reactive oxygen species as well as peroxynitrite formation, but, as for Cu/Zn-SOD described, participate also in the formation of peroxynitrite derived reactive radicals. Neurodegeneration was induced by intrastriatal injection of the NMDA-receptor agonist quinolinic acid (Quin). Immunohistochemistry and Western blotting analysis revealed a rapid increase in the level of the Mn-SOD (2 fold) that declined slowly over the time period considered (7 days). Cu/Zn-SOD levels increased only moderately (1.3 fold). Prominent staining intensities for both isofoms SOD were seen in macrophages and microglia in the lesioned area. Cell type specific marker proteins provided evidence for a loss of neurons, whereas astroglial cells seemed to be less influenced. Ascorbic acid showed a considerably diminished degree in reduction at the beginning of the degeneration followed by a general decline in ascorbic acid content during the first 2 days (loss by 40 %). Over the whole time period studied an increased peroxynitrite formation was observed by means of Western blotting analysis of nitrated proteins being most likely a consequence of an activation and/or induction of nitric oxide synthases. The nitration of proteins was particularly prominent for proteins of a 30 kD fraction. Preliminary immunohistochemical observations indicate that nitrated proteins are confined to single neurons at the early stage of the degeneration (sparing SOD rich macrophages) and, at later stages, to a microglia like cell type occurring in a more or less homogeneously grainy stained area of cell debris. - The data demonstrate the early occurance of radical-mediated processes which are accompanied by an induction of Mn-SOD that might be indicative for a protective response.

SELECTIVE CALPAIN INHIBITORS REDUCE RESIDUAL SPECTRIN PROTEOLYSIS AND THE DELAYED LOSS OF PRE- AND POSTSYNAPTIC MARKERS WHEN APPLIED AFTER SEVERE NMDA EXPOSURE IN CULTURED HIPPOCAMPAL SLICES. Brian T. Kawasaki & Ben A. Bahr*. Cortex Pharmaceuticals, 15241 Barranca, Irvine, CA 92718.

Calpain activation is associated with many pathogenic conditions that can lead to functional brain damage. Excitotoxic calpain responses in long-term hippocampal slices are not unlike those expected *in vivo* (Bahr et al., *J. Pharmacol. Exp. Ther.* 273:902, 1995), and the slices have been used to study calpain's role in NMDA-induced pathophysiology (Bednarski et al., *Brain Res.* 694:147, 1995). In the present study, compounds that selectively inhibit the calcium-dependent protease calpain were tested for neuroprotective action. Cbz-Leu-aminobuturate-CONH$(CH_2)_3$-morpholine (CX295; 100 μM) and related α-keto amides blocked >80% of the calpain-mediated spectrin breakdown induced in the slice model with NMDA (100 μM; 40 min). Interestingly, CX295 applied immediately after a 20-min NMDA exposure reduced the residual breakdown present 2-7 h post-insult by the same degree as when the drug was pre-incubated for 60 min (-70±5%, p<0.001, ±sem; Mann-Whitney test, n=8). Post-insult CX295 also appeared to attenuate delayed synaptic deterioration. Studies with Cbz-Leu-aminobuturate-CONH$(CH_2)_8CH_3$) (CX370) and the α-keto acid Cbz-Leu-Phe-COOH (CX270) indeed showed that synaptic markers were spared from decay by pre- and post-application of the inhibitors. Antibodies to the GluR1 subunit were used to show that processing of AMPA-type glutamate receptors is rapidly induced by NMDA in slice cultures; this is likely via calpain proteolysis (Vanderklish et al., *Soc. Neurosci. Abstr.* 17:1536, 1991) that targets the carboxy-terminal domain(s) (Bahr et al., *Neuroscience* in press, 1996). Immediately after the insult, GluR1 C-terminal immunostaining was decreased by 45±13% without drug but by only 7±8% or 18±13% when either 1 μM CX270 or 10 μM CX370 was present (n=4 each). The stable 80±3% loss of GluR1 between 4 and 21 h post-insult was reduced to 38±6% when 300 nM CX270 was pre-applied, and to 46±8% when the drug was applied post-insult; the 2-3 fold increase in GluR1 was significant in both cases (p<0.01; n=6-10). Similarly, the post-insult decline in the presynaptic marker synaptophysin was reduced from 47±7% to 14±9% by CX270 (p<0.01). Post-applied CX370 also caused significant synaptic sparing. Thus, selective calpain inhibitors exhibit substantial protection in an *in vitro* model of neurotoxicity (supported by Cortex Pharmaceuticals., Inc.).

KETAMINE INHIBITS NITRIC OXIDE PRODUCTION BY GLUTAMATE IN CULTURED CORTICAL NEURONS.

1)Masanori YAMAUCHI, 1)Akiyoshi NAMIKI, 2)Takafumi NINOMIYA, 3)Hiroshi ABE* Dept. of Anesthesiology[1], Dept. of Anatomy[2], Sapporo Medical University, and Dept. of Physiology, Faculty of Med. Hokkaido University[3], Sapporo, JAPAN, 060

We recently reported that a non-competitive NMDA-receptor antagonist, ketamine, can antagonize glutamate (Glu)-induced neuronal death; however, it is not clear whether this anesthetic could antagonize nitric oxide (NO) production induced by Glu or L-arginine (Arg). We studied the effect of ketamine on Glu- or Arg-induced neuronal death and NO production in rat cultured cortical neurons. After 7 days in culture, cells were incubated with ketamine, MK-801, or L-NMMA in addition to the exposure to 1mM of Glu or 0.3mM of Arg. NO production from the cells to the medium was measured for 1hr using NO-selective electrode. Similarly to this protocol, the number of surviving neurons was counted using anti-MAP2 antibody as a neural marker after 24-hr. exposure. The effect of glial cells was measured by glial culture. By exposure to Glu or Arg, NO concentration in the medium was significantly increased and the number of surviving neurons was decreased. Ketamine or MK-801 could inhibit this Glu-induced neurotoxicity. The effect of L-Arg on the cultured neurons was inhibited only by L-NMMA. Ketamine prevents Glu-induced neuronal death by inhibiting NO production, however, it dose not have inhibitory effect to the direct activation of NO synthase by Arg.

746.7

PROTECTIVE EFFECT OF THE α_2-ADRENOCEPTOR ANTAGONISTS (+)-EFAROXAN AND (±)-IDAZOXAN ON QUINOLINIC ACID-INDUCED LESIONS OF THE RAT STRIATUM. J.-C. Martel*, P. Chopin, F. Colpaert and M. Marien, Centre de Recherche Pierre Fabre, Castres 81100, France.

A deficiency in the locus coeruleus-noradrenergic system is proposed to be an important factor in the pathogenesis and progression of central neurodegenerative disorders. α_2-Adrenoceptor antagonists, by increasing central noradrenergic neurotransmission, may have a therapeutic potential in these diseases (Colpaert, 1994, *Noradrenergic Mechanisms in Parkinson's Disease*, CRC Press, p. 225). Using a rat model thought to be relevant to Huntington's disease, the quinolinic acid (QUIN)-lesioned striatum, we have examined the neuroprotective potential of the selective α_2-adrenoceptor antagonists, (+)-efaroxan (EFX) and (±)-idazoxan (IDZX). At 12 days following the unilateral infusion of QUIN (150 nmoles/1 µl) into the left striatum of adult male SD rats, animals exhibited ipsilateral rotation (256 ± 31 turns in 60 min) in response to a single dose of apomorphine (APO, 0.63 mg/kg s.c.). In these same rats, choline acetyltrans-ferase (ChAT) activity (measured after sacrifice on day 14) in the lesioned striatum was reduced by 73% compared to the intact contralateral striatum. Thrice-daily i.p. injections of EFX (0.63 mg/kg) or IDZX (2.5 mg/kg), beginning 30 min before the intrastriatal QUIN infusion and continuing thereafter for 7 days, resulted in a partial (55-56%) and significant ($p < 0.05$) reduction in the QUIN-induced deficit in striatal ChAT activity. In these same animals, the APO-induced rotations were also reduced, by 43% ($p < 0.05$) in the EFX-treated group, and by 28% (not significant) in the IDZX-treated group. In sham-operated rats, the EFX and IDZX treatments had no significant effect on APO-induced turning, or on striatal levels of ChAT activity. These findings suggest a neuroprotective potential of the systemically-administered α_2-adrenoceptor antagonists EFX and IDZX against excitotoxin-induced neurodegeneration *in vivo*, and a therapeutic potential in CNS disorders where excitotoxic mechanisms have been implicated.

Intrastriatal quinolinic acid injection in rat: effects on metabolism. Y.Bordelon*, D. Nelson, F. Welsh, M. Erecinska and M.-F. Chesselet Depts. of Pharmacology and Neurosurgery, University of Pennsylvania, Philadelphia, PA 19104.

Quinolinic acid (QA), an NMDA agonist, produces striatal lesions similar to those found in Huntington's disease (HD), suggesting that excitotoxic mechanisms may contribute to HD pathology (Schwarz, 1983). Evidence also support the involvement of energy impairment in HD pathogenesis (Beal et al., 1993, Jenkins et al., 1993). Whether the cascade of events initiated by QA and resulting in neuronal death includes energy impairment is unknown. We have investigated the occurrence of metabolic alterations in the striatum following QA administration. Male Sprague-Dawley rats (250-300 g) received a unilateral QA injection (60 nmols in 0.5 µl) over 5 min in the striatum. Controls received saline (Sal) injections. Rats were sacrificed 6 or 12hr post-injection by freezing the brain in situ and striatal samples taken for nucleotide and amino acid analysis. No significant differences were observed in striatum from rats sacrificed 6hr post-QA and Sal controls. In contrast, 12hr post-QA injection, NAD(-36%), ATP (-31%), Asp (-59%) and Glu (-38%) were decreased when compared to Sal controls. Oxygen consumption was measured in striatal homogenates polarographically using an oxygen electrode. The respiratory control ratio, an indicator of coupling of electron transfer to ADP phosphorylation (Chance and Williams, 1956), was decreased by 26% and 40% 6hr and12hr after QA injection, respectively. The data show that excitotoxic injury alters cellular energetics and induces a perturbation of mitochondrial function as early as 6 hr after the insult. These alterations are more profound by 12 hr post-surgery, a time when DNA damage is evident in the striatum (Bordelon et al., 1995).Supp. by F-30-MH-10890 and MH-44894.

ALTERATION OF BRAIN GLUTATHIONE LEVELS IN RESPONSE TO INTRACEREBRAL INJECTION OF QUINOLINIC ACID. C. C. Kwon, G. Capone*, W. Trescher, J. Vertifuille, C. Randazzo, M.V. Johnston, Neuroscience Labs, Kennedy Krieger Institute, Baltimore MD 21205.

Glutathione (GSH) exists in the reduced form throughout the brain and serves as an important endogenous antioxidant, protecting the brain from oxidative stress. Oxygen free radical formation has been shown to increase in cerebellar granule cells following NMDA receptor activation [LeFon-Cazel, 1993]. Quinolinate, which mimics the effects of NMDA, induces a similar pattern of neuronal injury as NMDA when injected intrastriatally [Trescher, 1994]. Our aim was to determine the response in GSH levels to neuronal excitation induced by a 50nmol/.5ul injection of quinolinate into the anterior striatum of adult C57Bl/6J mice. [GSH] was measured by determining the levels of non-protein sulfhydryl groups in tissue homogenates from the striatum and cerebellum at various intervals up to 24 hours post injection. At 4 hrs there is an apparent overall elevation of [GSH] in the striatum (injected =. 346 U/mg, control =. 142 U/mg, p = .032) compared to controls. Slightly increased levels were observed in the ipsilateral side compared to the contralateral side (ipsilateral = . 375 U/mg, contralateral = .316 U/mg, NS) . At 12 hrs and 24 hrs, [GSH] in striatum approaches control values with no significant difference between injected and non-injected hemispheres. We observed similar trends in the cerebellum, where there was an overall increase in [GSH] compared to controls by 4 hrs, with an apparent increased [GSH] in the ipsilateral (injected) side versus the contralateral side. By 12 and 24 hrs, [GSH] is comparable to uninjected controls.

These findings suggest an early adaptive increase in GSH synthesis in response to quinolinate injections prior to normalizing to control values by 12 hrs.

DETERMINATION OF QUINOLINIC ACID SYNTHESIS IN HUMAN ASTROCYTES AND MICROGLIA IN VITRO. M.G. Espey*, J.F. Reinhard, Jr., O.N. Chernyshev, C. Colton and M.A.A. Namboodiri, Georgetown University , Washington DC 20057.

Quin has been extensively studied for its potential role as an excitotoxin affecting N-methyl-D-aspartate receptor-bearing neurons. Substantial increases in the concentration of Quin in plasma and cerebrospinal fluid occur in a variety of diseases with neuropathological components. However, the intracerebral source(s) of Quin under these conditions is not clear. The objective of this study was to determine the level of Quin synthesis and release from cultured human microglia and astrocytes during immune stimulation. The basal level of Quin was 44 ± 6 nM, which increased 61% and 168% in response to treatment with lipopolysaccharide or interferon-γ, respectively, as determined by mass spectrometric analysis of the culture supernatants. Immunocytochemical staining indicated that Quin production between individual cells in the microglia culture was heterogenous. In contrast, Quin synthesis and staining was not detectable in astrocyte cultures under all conditions studied. These data suggest that, in addition to systemic immune cells, microglia are a source of Quin during brain injury or disease.

746.11

DOMOIC ACID: TIME COURSE OF NEURONAL ACTIVATION AND DEGENERATION , J. N. Johannessen*, †A. C. Scallet, S. A. Long, S. Hall, and T.J. Sobotka, CFSAN and †NCTR, FDA, Laurel, MD 20708

Domoic acid (DOM) is an excitotoxin that causes seizures and neuronal damage. Several potential histological biomarkers for degenerating neurons were visualized in brains from rats treated with DOM (2 mg/kg, ip) or vehicle and sacrificed 0.5, 2, 6, 12, 24, or 72 hr later . After fixation, brains from rats that seized were cut coronally and sets of sections were Nissl stained (cresyl violet); immunostained for Fos, Jun, HSP-72, and GFAP; and silver stained.

Nuclei were Fos+ in olfactory and limbic cortex 0.5 h after DOM; clumps of extravascular red blood cells were widely distributed. Two h after DOM endothelial cells had Fos+ nuclei and were ensheathed by GFAP+ processes. Fos+ nuclei appeared in olfactory cortex, limbic cortex and dentate gyrus at 2 h, then throughout the brain, including CA1-CA4, at 6 h. Limited silver staining first appeared after 2 h in CA1 and dentate gyrus. Bands of degenerating fibers in the fimbria and CA1 appeared at 6 h. Nuclei in olfactory cortex and in hippocampal pyramidal cells near the amygdala were Jun+. By 12 h, focal areas devoid of GFAP+ glia, but with Nissl+ neurons, were evident in piriform cortex and thalamus. At 12 h pyramidal cells of hippocampus and piriform cortex had Fos+ and Jun+ nuclei . Few cells had cytoplasmic Fos. Silver+ cells and fibers were seen in CA1, CA3 and CA4, but not CA2. By 72 h, piriform cortex, amygdala, CA1, and thalamus had large necrotic areas lacking Nissl and GFAP staining. Elsewhere, intense gliosis was widespread. Degenerating silver+, HSP-72+, and Jun+ neurons dominated CA1 and CA3, and were widely scattered throughout the cortex.

The temporal changes in staining pattern induced by DOM suggest that damage resulted from seizure-induced activation of olfactory and limbic areas and diffuse vascular damage. The focal degeneration of glia that preceeds neuronal loss suggests the possibility that glial loss, which may result from vascular damage, may contribute to subsequent neuronal loss.

DOMOIC ACID (DOM) : HEMI-HIPPOCAMPAL NEUROPATHOLOGY WITHOUT BEHAVIORAL DEFICITS A.C. Scallet*, P. Morris, L.C. Schmued, R.L. Rountree, C.M. Fogel, M.G. Paule, J. Sandberg, W. Slikker, Jr., S .Hall[1], J.N. Johannessen[1], and T.J. Sobotka[1].
NCTR/FDA, Jefferson, AR and [1]CFSAN/FDA, Laurel, MD.

DOM (1.33 or 1.66 mg/kg, IP) caused extensive, bilateral neurodegeneration of the hippocampus in a subset of treated rats. Such rats could be identified non-invasively: they lost the most weight after treatment, were poor at passive avoidance, and had exaggerated startle responses compared to controls. Low-dose animals, despite normal water intakes, consumed significantly less food than controls during the first 24 hrs after dosing. High-dose rats reduced both their food and water intakes. Several rats, despite normal startle and passive avoidance performance, had a small area of argyrophilic, degenerating axons and terminals in CA3, but restricted to one side of the brain: a hemi-hippocampal lesion. Our results indicate that decreased food intake explains the acute weight loss from DOM exposure, and that "silent" histological lesions (damage in the absence of an obvious functional deficit) may sometimes be a feature of DOM exposure.

REGULATION OF THE KYNURENINE ENZYMES EXPRESSION IN INTERFERON-γ-PRIMED MURINE MACROPHAGES AND MICROGLIAL CELLS. D. Alberati-Giani, P. Malherbe, C. Köhler* and A.M. Cesura. Pharma Div. Preclinical Res. F. Hoffmann La Roche Ltd., CH-4070 Basel, Switzerland.

Several pieces of evidence suggest a major role for brain macrophages in the overproduction of neuroactive kynurenines, including quinolinic acid, in brain inflammation. To investigate the specific role of activated macrophages and brain microglia, we studied the regulation of the expression of indoleamine 2,3-dioxygenase (IDO) and of other kynurenine pathway enzymes by interferon-γ (IFN-γ) in cloned murine macrophages (MT2) and microglial (N11) cells. Both cell lines expressed IDO activity after IFN-γ-stimulation. The enzyme levels in IFN-γ-primed MT2 cells were ~4-fold higher than in N11 cells. The induction of the enzyme activity appeared to be differently regulated in the two cell lines. Thus, it was found that endogenous nitric oxide acted as a negative modulator of IDO expression only in MT2, but not in N11 cells. This suggests the existence of a cross-talk between the IFN-γ-activated kynurenine and nitridergic pathways of relevance for the fine-tuning of functional response of murine macrophage. Kynurenine amino-transferase, kynurenine 3-hydroxylase (KH) and 3-hydroxyanthranilate dioxygenase were constitutively expressed in both cell lines to a similar extent and, among them, only KH activity appeared to be up-regulated by IFN-γ in both cells. Kynureninase activity was much higher in MT2 macrophages than in N11 microglial cells. In addition, IFN-γ markedly stimulated the activity of this enzyme only in MT2 cells.

AMPA RECEPTOR ANTAGONIST YM90K BLOCKS INDUCTION OF HEAT SHOCK PROTEIN HSP-70 IN RAT CORTICAL NEURONS BY PHENCYCLIDINE. N.Narita*, K.Hashimoto, S.Tomitaka, Y.Minabe and K.Yamazaki. Natl. Inst. Neurosci., NCNP, Tokyo 187 and Dept. of Psychiatry, Tokai Univ. Sch. of Med., Kanagawa 259-11, Japan.

It is known that NMDA receptor antagonists such as phencyclidine (PCP), ketamine and dizocilpine cause neuronal injury in the posterior cingulate and retrosplenial (PC/RS) cortex of rat brain, and the induction of heat shock protein (HSP-70), a marker for neuronal injury, has been shown in the same regions by these drugs. Recently, it has been reported that AMPA receptor antagonist DNQX inhibits the expression of HSP-70 by PCP or ketamine (Sharp et al., 1995), suggesting the role of AMPA receptors in the neurotoxicity of NMDA receptor antagonists. YM90K is a more selective and potent AMPA receptor antagonist than DNQX. Therefore, we studied the effects of YM90K on the expression of HSP-70 protein and hsp-70 mRNA in the PC/RS cortical neurons by PCP. PCP (50 mg/kg, i.p.) was injected into female SD rats. The HSP-70 immunocytochemistry and in situ hybridization for hsp-70 mRNA were studied 24 hrs and 6 hrs after administration of PCP, respectively. YM90K (1, 3 and 10 mg/kg, i.p.) were administered 15 min before injection of PCP. A single administration of PCP produced the induction of heat shock protein HSP-70 and hsp-70 mRNA in the PC/RS cortex of rat brain. The pretreatment with YM90K could attenuate the induction of HSP-70 protein and hsp-70 mRNA by treatment with PCP, in a dose dependent manner. Thus, these results suggest that AMPA receptors may play a role in the induction of heat shock protein HSP-70 by NMDA receptor antagonists such as PCP. (Supported by the grant from the Ministry of Health and Welfare, Japan).

ROLIPRAM, A SELECTIVE PHOSPHODIESTERASE TYPE-IV INHIBITOR, BLOCKS THE INDUCTION OF HEAT SHOCK PROTEIN HSP-70 IN RAT CORTICAL NEURONS BY DIZOCILPINE. K.Hashimoto*, S.Tomitaka, Y.Bi, N.Narita, Y.Minabe and M.Iyo. Natl. Inst. Neurosci., NCNP, Tokyo 187 and NIMH, NCNP, Chiba 272, Japan.

The non-competitive NMDA receptor antagonists such as MK-801 (dizocilpine) and phencyclidine injure a discrete populations neurons in the posterior cingulate and retrosplenial (PC/RS) cortex of rat brain. It is shown that these drugs produce vacuolization and necrosis in PC/RS cortical neurons, and that these drugs cause expression of heat shock protein HSP-70 and hsp-70 mRNA in these neurons. It has been suggested that phosphodiesterase (PDE) type-IV, a diverse family of proteins that are important regulators of intracellular signaling, may play a significant role in the CNS. The present study was undertaken to examine the role of PDE type-IV in the induction of HSP-70 protein and hsp-70 mRNA by dizocilpine. Dizocilpine (1 mg/kg, i.p.) was injected into female SD rats. The HSP-70 immunocytochemistry and in situ hybridization for hsp-70 mRNA were studied 24 hrs and 6 hrs after administration of dizocilpine, respectively. The PDE inhibitors such as rolipram, Ro 20-1724 and IBMX were administered 15 min before injection of dizocilpine. The pretreatment with rolipram (2.5, 5 and 10 mg/kg) blocked the induction of heat shock protein HSP-70 and hsp-70 mRNA by dizocilpine, in a dose dependent manner. Furthermore, other PDE inhibitors such as Ro 20-1724 and IBMX blocked partially the induction of HSP-70 protein and hsp-70 mRNA by dizocilpine. Moreover, abnormal behaviors caused by dizocilpine could be inhibited by pretreatment with rolipram, in a dose dependent manner. These results suggest that PDE type-IV may play a role in the neurotoxicity of NMDA receptor antagonists such as dizocilpine. (Supported by the grant from the Ministry of Health and Welfare, Japan).

746.16

GFAP PROTEIN IS INDUCED IN THE HIPPOCAMPUS OF RATS FOLLOWING MK-801 ADMINISTRATION, C. Gonzales*, T. L. Miller, D. R. Bramlett and M. M. Zaleska. CNS Disorders, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

Mechanically and chemically-induced brain injury results in reactive gliosis. Hypertrophic astrocytes are identified by the immunohistochemical detection of glial fibrillary acidic protein (GFAP), the major protein of astrocyte intermediate filaments. Therefore, enhanced expression of GFAP has been used as a sensitive biomarker of neuronal injury. Exposure to pharmacological agents at therapeutic doses is not expected to affect GFAP levels. However, the non-competitive NMDA antagonist MK-801, shown to be neuroprotective in models of ischemia, has been reported to increase GFAP in the posterior cingulate/retrosplenial cortex (Fix, et al. 1995), an area susceptible to vacuolization and necrosis following administration of NMDA antagonists (Olney, et al. 1989). In the present study, several neuroprotective agents that act via inhibition of glutamate receptors or sodium channel blockade were evaluated for their ability to elicit an astrocytic response in the absence of injury. Immunocytochemistry was used to localize the induction of GFAP in rats treated with either 3mg/kg MK-801, 30mg/kg CGS 19755, 30mg/kg GYKI 52466, 3mg/kg ifenprodil, 24mg/kg lamotrigine, 28mg/kg cerestat, or saline (control). Brains from these animals were processed for GFAP immunocytochemistry using a monoclonal antibody. In addition to an increased number of GFAP-positive astrocytes in the posterior cingulate/retrosplenial cortex, an increased number of GFAP-positive astrocytes were found in the hippocampus of the rats treated with MK-801. No obvious evidence of neuropathology, as determined by a Nissl stain, was observed in this brain region. Degeneration studies using a silver stain are being conducted to determine whether neuronal damage can be detected. In animals treated with either CGS 19755, GYKI 52644, ifenprodil, lamotrigine or cerestat, no increase in GFAP-positive cell number was found.

MK-801-EVOKED RETROSPLENIAL NEURODEGENERATION: MOLECULAR PROFILE AND BEHAVIORAL CONSEQUENCES. M. Hetman, E. Nikolacv, W. Danysz¶, and L. Kaczmarek*. Nencki Institute, Pasteura 3, PL-02-093 Warsaw, Poland ¶Merz&Co., Eckenheimerlandstr. 100-104, D-60318 Frankfurt/Main, FRG.

Antagonists of NMDA receptor are potential drugs for treatment of neurodegenerative disorders. However, their administration at high doses was shown to evoke neurodegeneration in retrosplenial cortex in rodents. Dizocilpine maleate (MK-801) is a blocker of the opened ion channel of NMDA receptor, and exerts profound neurodegenerative effect on rat retrosplenial neurons. In order to characterize the neuronal cell death evoked by a single intraperitoneal administration of MK-801 at a dose 5 mg/kg, we used in situ TUNEL assay for detection of DNA fragmentation, considered as a typical feature of programmed cell death. Cells with DNA fragmentation were rarely seen in layer III of retrosplenial cortex 24 hours after the treatment but were not detected 72 hours after the drug administration. Cathepsin D is a major lysosomal aspartic protease, which is postulated to be an important element of cell death machinery. Using northern blot and immunohistochemistry, elevated expression of Cathepsin D was found in degenerating neurons 24-72 hours after the treatment. Northern blot and immunohistochemistry for glial fibrillary acidic protein (GFAP) revealed astroglia reactivation 24-72 hours after the treatment. To study behavioral consequences of MK-801-evoked neurodegeneration, 3 different paradigms based on learning of two-way active avoidance reaction were used. There was no statistically significant effect of single administration of 5 mg/kg of MK-801 ten-forty days after the treatment. Supported by the grant 4-P-05-A-085-08 from KBN (State Comitee for Scientific Reasearch, Poland).

MEASUREMENT OF THE TIME-COURSE AND DEGREE OF CELL DEATH IN CULTURED CORTICAL NEURONS USING A MULTIWELL FLUORESCENCE SCANNER. Rita Sattler*[a,b], Milton P. Charlton[a], Mathias Hafner[b] and Michael Tymianski[a]. [a]Playfair Neuroscience Unit, University of Toronto, Toronto, Canada. [b]Dept. of Applied Cell Biology, Technical University Mannheim, Mannheim, Germany.

We validated the use of sequential measurements of propidium idodide (PI) fluorescence in a multiwell fluorescence scanner (MFS) for studies of the time-course of cell death in cultured cortical neurons following excitotoxicity. Results were compared with manual counts of PI-stained cells in the same cultures as well as with lactate dehydrogenase (LDH) release. Experiments were performed in a HEPES-buffered salt solution containing 50μg/ml PI. Neurotoxicity was induced by exposing the cultures to varying concentrations of L-glutamate for defined times (5-60min). Changes in PI fluorescence were monitored by the MFS at constant time intervals (1h) over a period of 24h at room temperature. Then, propidium iodide stained nuclei were counted in 3 high power fields chosen at random from each well (4 wells per glutamate concentration). The quantity of LDH released into the extracellular fluid was determined by standard methods. PI fluorescence measurements taken with the MFS increased with time after the insult, and with the glutamate concentration used, revealing a distinct time-course of cell death for each concentration group. Comparison of the PI fluorescence signal from each well as measured with the MFS with the number of manually counted PI labelled cells from the same culture showed a tight linear relationship between the two methods ($R=0.958$, $p<0.0001$). Similarly, a strong linear relationship was found between PI fluorescence measured with the MFS and LDH measurements ($R=0.964$, $p<0.0001$). The results indicate that PI fluorescence measurements with a MFS accurately reflect the time-course and extent of cell death. (Supported by The National Centers of Excellence of Canada and an Ontario Technology Fund grant with Allelix Biopharmaceuticals).

EXPOSURE TO ORGANOCHLORINE INSECTICIDES AND PARKINSONISM. M. L. Kirby and J. R. Bloomquist *. Department of Entomology, Virginia Polytechnic Institute and State University, Blacksburg, VA, 24061.

Behavioral and neurochemical changes in C57BL6 mice were investigated following subchronic intraperitoneal doses of the organochlorine insecticide heptachlor (25-100 mg/kg). The major behavioral effects of heptachlor include increased rearing frequency and open field ambulation at all doses tested. Heptachlor altered [^{3}H]dopamine uptake in striatal synaptosomes prepared from treated mice, which may reflect changes in dopamine transporter expression in response to changes in synaptic levels of dopamine. Neurotoxicity of heptachlor *in vivo* was also expressed by a reduction of striatal synaptosome respiration *in vitro*. Neurotransmitter release studies with striatal synaptosome preparations revealed that heptachlor epoxide, the metabolic activation product of heptachlor, stimulated release of dopamine, serotonin, glutamate and GABA. The lack of effect by picrotoxinin and bicuculline suggests a mechanism that is unrelated to GABAa receptor effects. These studies demonstrate that exposure to subconvulsive doses of heptachlor have significant effects on motor behaviors and striatal neurochemistry. These findings suggest that heptachlor has significant effects on the nigro-striatal pathway and a possible role for exposure to organochlorine insecticides in neurodegenerative disorders, such as idiopathic Parkinson's Disease. This work was supported by the Hawaii Heptachlor Research and Education Foundation.

REPRODUCABLE DECREASES IN THALAMIC GFAP IN THE RAT AFTER TOLUENE INHALATION: A ROLE FOR CORTICOSTERONE? AR Little*, ZL Gong, U. Singh, HL Evans. Nelson Institute of Environmental Medicine, New York University Medical Center, Long Meadow Rd., Tuxedo, New York, 10987.

Increased Glial Fibrillary Acidic Protein (GFAP) indicates reactive gliosis following neuronal injury from toxic chemicals. Thus, the assay was included in the EPA neurotoxicity screening battery. Toxicant-induced decreases in GFAP reported here, are a novel finding. Decreases in GFAP are now replicated in two studies of rats following toluene inhalation at concentrations relevant to occupational health concerns. In the first study young male F-344 rats were exposed to air, 100 or 1000ppm inhaled toluene 6hr/day for 28 days (n=8). A notable finding was a decrease of GFAP in the Thalamus at days 3 and 7. The second experiment exposed rats to either air or 1000ppm toluene for 3 and 7 days (n=6). The second study replicated the decreased of GFAP and showed increased corticosterone (CORT) in the serum. CORT is known to be a strong negative regulator of GFAP, so we examined serum CORT levels, GFAP concentration, body weight, adrenal and thymus weights during toluene exposure. There were no differences between air or toluene-exposed rats for body weight, thymus or adrenal weights (adjusted for body weight).There were no differences in GFAP concentration in the cortex, hippocampus, or cerebellum between air and toluene groups however there was a large decrease of GFAP in the thalamus. There was a large increase in serum CORT on days 3 and 7 in toluene-exposed rats compared to air controls. These results suggest that 1) toluene-induced decreases in GFAP seem to be specific to the thalamus and are associated with toluene-induced increases in serum cort 2) some toxic exposures cause GFAP concentration to decrease which may be due to an indirect effect 3) disregulation of the hypothalamic-pituitary-adrenal-axis is an early effect of toluene inhalation, which may be an important parameter to control when interpreting results of GFAP assays. Approved by the NYUMC Animal Care and Use Committee in accordance with current N.I.H. guidelines. Supported by grants from the NIH (ES00260) and from the American Petroleum Institute.

747.3

CONGENER-SPECIFIC ANALYSIS OF POLYCHLORINATED BIPHENYLS IN BRAIN REGIONS OF ADULT RATS FOLLOWING REPEATED EXPOSURE TO AROCLOR 1254. T.R. Ward*, E.C. Derr-Yellin, W.R. Mundy, H.A. Tilson and P.R.S. Kodavanti, Neurotoxicology Division, NHEERL, U.S. E.P.A, RTP, NC 27711.

Our previous *in vitro* studies indicate that some of the PCBs (non-coplanar in nature) at concentrations of 5-50 μM perturb intracellular signal transduction mechanisms in neuronal cultures. It is not clear whether such concentrations are achievable in brain *in vivo*. In the present study, we have conducted PCB congener-specific analysis in different brain regions of male Long-Evans rats, dosed orally with Aroclor 1254 (0 or 30 mg/kg/day; 5 days/week for 4 weeks) in corn oil. Twenty four hours after the last dose, rats were sacrificed, brains removed and dissected into regions. Congener-specific analysis of PCBs was performed using a graphitized carbon and high-resolution gas chromatography with electron capture detection. While PCB concentration in control rat brain regions were less than 0.02 ppm, total PCB congeners in treated animals accumulated to ppm levels. Total PCB congeners were greater in frontal cortex (15.9 $\pm$ 0.3 ppm) and cerebellum (13.1 $\pm$ 1.7 ppm) compared to striatum (0.64 $\pm$ 0.19 ppm) suggesting differential accumulation of PCBs in brain regions. The levels of PCBs in the fat were high (555 $\pm$ 41 ppm). The circulating levels of PCBs in the blood were 1.55 $\pm$ 0.01 ppm. Among 99 different PCB congeners analyzed, hexachlorinated biphenyls constituted about 50% of the total congeners. Predominant congeners detected in different brain regions are: 2,2',4,4',5- (PCB 99) and 2,3',4,4',5- (PCB 118) pentachlorobiphenyls; 2,2',4,4',5,5'- (PCB 153), 2,2',3,3',4,6'- (PCB 132), 2,2',3,4,4',5'- (PCB 138), 2,3,3',4,4',5- (PCB 156) and 2,3,3',4',5,6- (PCB 163) hexachlorobiphenyls; 2,2',3,3',4,4',6- (PCB 171) heptachlorobiphenyl. PCB concentrations observed in brain are equivalent to approximately 2 to 50 μM, which are similar to those used in earlier *in vitro* studies.

747.4

REPEATED EXPOSURE OF ADULT RATS TO AROCLOR 1254 ALTERS MOTOR ACTIVITY AND CAUSES BRAIN REGION SPECIFIC CHANGES IN INTRACELLULAR Ca^{2+} BUFFERING AND PROTEIN KINASE C ACTIVITY. P.R.S. Kodavanti, E.C. Derr-Yellin, W.R. Mundy, T.J. Shafer, J.D. Farmer, R.C. MacPhail and H.A. Tilson*, Neurotox. Div., NHEERL, US EPA, RTP, NC 27711.

Polychlorinated biphenyls (PCBs) are ubiquitous environmental contaminants, some of which have been reported to be neurotoxic. Our *in vitro* studies indicated that non-coplanar PCBs perturbed intracellular signal transduction mechanisms including Ca^{2+} homeostasis, inositol phosphate production, and translocation of protein kinase C (PKC). In the present study, we examined the effects of PCBs *in vivo* by dosing male Long-Evans rats orally with Aroclor 1254 (0, 10 or 30 mg/kg/day; 5 days/week for 4 weeks) in corn oil. At 24 hr after the last dose, rats were tested for motor activity in a photocell device for 30 min, then immediately sacrificed for neurochemistry. Freshly isolated cerebellum, frontal cortex and striatum were fractionated to obtain different subcellular fractions. Intracellular Ca^{2+} buffering was determined by measuring $^{45}Ca^{2+}$-uptake by microsomes and mitochondria. Total and membrane-bound PKC were determined by measuring the incorporation of ^{32}P from γ-[^{32}P]ATP into neurogranin. Following Aroclor 1254 treatment, body weight gain in the high-dose group was significantly lower than the control and low-dose groups. Motor activity (horizontal but not vertical) was significantly lower in rats dosed with 30 mg/kg Aroclor 1254. Ca^{2+} buffering by microsomes was significantly lower in all three brain regions from the 30-mg/kg group. In the same dose group, mitochondrial Ca^{2+} buffering was affected in cerebellum but not in cortex or striatum. Similarly, total PKC was decreased significantly while membrane bound PKC was elevated significantly in cerebellum at 10 and 30 mg/kg. PKC was not altered in cortex or striatum. These results suggest that *in vivo* treatment with a PCB mixture produces neurochemical changes similar to those observed after *in vitro* exposure of neuronal cell cultures.

747.5

DISTRIBUTIONS OF ARYLHYDROCARBON AND ESTROGEN RECEPTOR mRNAS OVERLAP IN SPECIFIC REGIONS OF THE RAT BRAIN THAT CONTROL REPRODUCTION. S.R. Marconi, S.L. Petersen and J.D. Blaustein*. Biology Department, Neuroscience and Behavior Program, Univ. of Massachusetts, Amherst, MA 01003

Dioxins are ubiquitous polychlorinated biphenyls that produce a variety of toxic responses in humans and laboratory animals. The most potent dioxin congener, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), is known to reduce female fertility, but neither the site nor the mechanism of its reproductive toxicity is known. To determine whether dioxins may exert these effects in the brain, we hybridized 12-μm frozen sections from the preoptic area (POA) and hypothalamus of female rats to ^{33}P-labeled cRNA probes for arylhydrocarbon receptor (AhR) mRNA and for the mRNA of its chaperon, arylhydrocarbon nuclear translocator (Arnt). Because resulting autoradiograms showed that the distribution of these mRNAs was similar to that previously reported for estrogen receptor (ER) mRNA, we subsequently hybridized adjacent sections to probes for ER, AhR and Arnt mRNAs. The distributions of these mRNAs overlapped in the cortex, hippocampus and other regions, but the most striking overlap was in the medial preoptic area and arcuate nucleus, regions in which estrogen action is critical for ovulation. Studies of nonneural tissue indicate that TCDD (through the AhR) interferes with intracellular actions of estrogen. We are currently testing the hypothesis that TCDD interferes with female reproduction by altering ER regulation and/or estrogen metabolism in the brain. LOCALISATION OF CYSTEINE CONJUGATE β-LYASE/KYNEURENINE AMINO TRANSFERASE mRNA IN ADULT RAT BRAIN. I. Kitchen*, N.J Plant, P.S. Goldfarb & G.G. Gibson, School of Biological Sciences, University of Surrey, Guildford, Surrey, GU2 5XH, UK.

Many halogenated xenobiotics such as the industrial degreaser trichloroethylene are detoxified to cysteine conjugates. These may then serve as substrates for enzymes with cysteine conjugate β-lyase activity. In rats and humans, this activity is present in glutamine transaminase K (GTK), a multifunctional enzyme present in kidney and brain. Cysteine conjugate β-lyase/GTK in the brain has been demonstrated to possess kyneurenine amino transferase (KAT) activity, implicating it in transmission via modulation of NMDA receptors. Exposure of humans to halogenated xenobiotics results in neurotoxicity and neurodegeneration. Effects include facial cold sores, trigeminal analgesia, facial paresis, ptosis, dysarthria, vocal chord paralysis, visual loss and dysphagia. We have investigated the localisation of cysteine conjugate β-lyase mRNA in rat brain using *in situ* hybridisation to examine possible roles of this enzyme in the brain, and to investigate the underlying mechanisms of neurotoxicity caused by halogenated xenobiotics. Coronal and saggital sections (20μm) were cut through adult rat brain at an interval of 500μm. [^{35}S] cRNA probes were prepared, in both sense and antisense orientations, to a 243bp sequence of the 5' region of the rat cysteine conjugate β-lyase cDNA. *In situ* hybridisation was carried out for 16 hours at 60°C, serial sections being used for antisense and sense probes. Washed and dried sections were apposed to β-max hyperfilm for 7 days and autoradiograms quantified by video-based computer densitometry. Preliminary results (n=3) demonstrate localisation of cysteine conjugate β-lyase mRNA to specific regions in rat brain, including commissural fibres, visual system, thalamus and several cortical regions. Structure-function relationships suggest a role for cysteine conjugate β-lyase in sensory transmission in the brain, and such a function may underlie the response of humans to halogenated xenobiotics. CHLORPYRIFOS: LACK OF COGNITIVE EFFECTS IN ADULT LONG-EVANS RATS. J. P. J. Maurissen*, M. R. Shankar and J. L. Mattsson. The Dow Chemical Co., Midland, MI 48674.

No short-term memory effects (as evidenced by the retention rate) and no attention/encoding deficits were found in female Long-Evans rats gavaged 5 days a week for 4 weeks with chlorpyrifos. The test was a delayed matching-to-position task and the main dependent variable was the percent correct accuracy on several time delays. Slope over delay and intercept at time zero were calculated from these data for each rat and represented the "forgetting" curve. The rats were first trained and then divided into four groups of ten of similar overall cognitive performance. They were randomly assigned to treatment groups of 0, 1, 3, and 10 mg/kg/day of chlorpyrifos in oil. They were observed for cholinergic signs and tested for cognitive dysfunctions during the four weeks of dosing and for another four weeks after dosing termination. The study was run blind to treatment, and the effectiveness of the blind was tested and found satisfactory. Some noncognitive performance changes and miosis began to occur at ~70-80% and at ~60% inhibition of brain cholinesterase, respectively. The intercept at time zero (i.e. a measure of encoding/attention/motivation) was statistically significant overall and was attributed to deviations from controls in the high-dose group on dosing weeks 2 and 3 (in opposite directions). Because of the lack of a temporal pattern and of the low strength of association with chlorpyrifos, this difference was not considered treatment related. The slope of the retention gradient (i.e. a measure of retention rate) did not show any statistically significant difference between groups at doses that inhibited brain cholinesterase by up to ~85%, i.e. chlorpyrifos had no effects on retention in this study. (Funded by the DowElanco Company).

EFFECTS OF THE ANTICHOLINESTERASE SOMAN ON POTASSIUM-STIMULATED *EX VIVO* RELEASE OF [^{3}H]-ACETYLCHOLINE AND ENDOGENOUS AMINO ACIDS IN GUINEA PIG BRAIN SLICES.

T.J. Townend, J.R. Wetherell, I. Kitchen[§] and J. Tattersall*. Medical Countermeasures, Protection & Life Sciences Division, CBD Porton Down, Salisbury, Wiltshire, SP4 0JQ, U.K. [§]School of Biological Sciences, University of Surrey, Guildford, Surrey, GU2 5XH, U.K.

The superfused brain slice technique was used to study the effects of soman on the *ex vivo* uptake and release of acetylcholine (ACh) and on the release of the endogenous amino acids glutamate, aspartate and GABA in the guinea-pig hippocampus and striatum. Animals were killed at various time-points (1hr, 4hrs, 24hrs, 7 days and 14 days) after dosing with soman (27μg/kg, s/c) or with saline. Endogenous amino acid release was quantified by HPLC with fluorimetric detection. ACh release was quantified by tritium release after pre-incubating with [^{3}H]-choline. Soman had no effect on [^{3}H]-choline uptake at any time-point in the hippocampus, but at 7 days, striatal uptake was significantly less ($p<0.01$) than control levels. Preliminary results indicated that in soman-treated animals there were no effects upon the basal or potassium-stimulated [^{3}H]-ACh release, but potassium-stimulated striatal amino acid release appeared to be decreased at some time-points. In control animals *in vitro* application of the cholinergic agonist oxotremorine decreased [^{3}H]-ACh release, whereas at 1 hour after soman there appeared to be an increase in release. These results suggest that there may be a change in cholinergic receptor function. Therefore, further investigations are under way using ligand-binding techniques to examine any changes in receptor binding and distribution that may be associated with changes in neurotransmitter release.

ABNORMAL DEVELOPMENT OF CRANIAL NERVES IN MICE INDUCED BY IN VIVO EXPOSURE TO TRIADIMEFON. P.M. Martin[*1], J. Andrews[2], J.P. O'Callaghan[3], and C.Y. Kawanishi[2]. Curriculum in Toxicology[1], Univ. of North Carolina, Chapel Hill, NC 27599, Reproductive Toxicology Division[2], and Neurotoxicology Division[3], U. S. Environmental Protection Agency, RTP, NC 27711.

The triazole fungicides, such as triadimefon (TDF), are known to induce branchial arch defects as well as craniofacial malformation in cultured rat embryos. The mechanism by which this occurs is unknown, although it has been suggested that these defects may be mediated by alterations in the expression of *Hox* or *Krox* genes. Alternatively, TDF may act by altering other growth-related proteins, such as the receptor tyrosine kinases, or in some non-specific manner. The purpose of this study was to establish dose-response and time-course data for embryos treated with TDF *in vivo*, prior to testing specific hypotheses about the mechanisms of action of TDF. Dose-response data were generated from timed-pregnant Swiss-Webster CD-1 dams dosed orally with vehicle (corn oil), 100, 250 or 500 mg/kg TDF on gestational day 8 (about the 3-6 somite stage). Embryos were recovered on gestational day 10, and immunostained using a monoclonal antineurofilament antibody (2H3; Johns Hopkins University School of Medicine) to visualize defects in the central nervous system. To establish a time-course, timed-pregnant dams were dosed orally with 400 mg/kg of TDF on gestational day 7, 8, or 9. The embryos were collected on gestational day 10 and stained as described above. Cranial nerves of TDF-treated embryos had a disorganized, ragged appearance, and there was a dose-related increase in fusions between the glossopharyngeal and vagus nerves. At the highest doses, embryos showed multiple, fused, cranial nerves, with increased abnormal branching, merging, or fusion between fibers of the trigeminal, facial, glossopharyngeal, and vagus nerves. The most sensitive time for the occurrence of these effects appeared to be between gestational days 7 and 8. These data suggest an impairment of axonal guidance following exposure to TDF. (Supported by U.S. EPA Training Agreement T901915.)

POST INDOMETHACIN REBOUND HYPERTHERMIA FOLLOWING CENTRAL T-2 TOXIN ADMINISTRATION. T.R. Harrigan, J. R. Wilson*, and D.W. Fitzpatrick. University of Manitoba, Winnipeg, Manitoba, Canada, R3T-2N2.

T-2 toxin is a trichothecene produced by *Fusarium* molds that when ingested or administered systemically in large amounts causes hyperthermia and aphagia. The site of action of T-2 toxin is unclear, but a central mechanism is suggested since ICV delivery of other organic toxins, namely bacterial endotoxins cause hyperthermia, and pithed rats show blunted responses to T-2 toxin. Thus, T-2 toxin-induced hyperthermia, like bacterial endotoxins, may be mediated by central prostaglandins. Accordingly, two studies were conducted to determine 1) the effects of central T-2 toxin on body temperature and food intake, and 2) whether prostaglandins participate in these effects. In Experiment 1, 18 rats received chronically indwelling minimitters, for monitoring body temperature, and ICV cannuli for drug administration. Following recovery and adaptation, the rats received an ICV injection of 1 of 3 doses (vehicle, 17 μg/μl, 35 μg/μl) of T-2 toxin, delivered over 45-60 s in 3 μl of dimethyl sulfoxide (DMSO). The rats were returned to their home cage and their core temperature recorded every 20 min for 4 h. The results showed that T-2 toxin produced a prolonged hyperthermia which developed after 2.5 h, and significant weight loss was observed in the high T-2 toxin group. In Experiment 2, 24 animals received minimitters and ICV cannuli. After recovery and adaptation, rats were pretreated with either DMSO or indomethacin (150 μg/μl), a prostaglandin inhibitor. Twenty minutes later, half of the rats in each pretreatment group were administered either T-2 toxin (35 μg/μl) or DMSO. The results revealed that T-2 toxin produced a biphasic thermal response in indomethacin pretreated rats. Indomethacin initially dampened the thermal response to T-2 toxin, but after 2.5 h, the approximate half-life of indomethacin, a thermogenic rebound developed. Indomethacin pretreatment reduced T-2 induced weight loss. Collectively, these results suggest that the hyperthermia and aphagia associated with T-2 toxin may be linked to central prostaglandins.

QUALITATIVE ESTIMATION OF THE WAVELENGTH DEPENDENT CARCINOGENESIS DUE TO ULTRAVIOLET (UV) SECONDARY EMISSION INDUCED BY A ND:YAG LASER DURING PHOTOABLATION OF CEREBELLAR TISSUE K. Sentrayan,[1,2] A. Thrope Jr.,[1] and C.O. Trouth* Depts. of 1. Physics, and 2. Physiology and Biophysics, Howard University, Washington, D.C. 20059.

The wavelength dependence of carcinogenesis due to UV exposure is critically important in assessing risk factors for skin cancer. We have observed UV secondary emission due to Mg II (279.4 nm and 280.1 nm); Mg I (285.0 nm); IV (306.3 nm and 306.7 nm); O III (326.2 um; Fe III (327.2 nm); ca IV (335.9 nm and 336.9 nm) ; Fe I (358.1 nm, 358.3 nm, and 385.3 nm) when the fundamental of a ND:YAG laser at 1064 nm was focused on the cerebellar tissues derived from brain slices of rats. We have qualitatively estimated the wavelengths dependent carcinogenesis using skin cancer Utrecht-Philadelphia (SCUP) action spectrum for human obtained from that of mice by correcting for the differences epidermal UV transmission between mice and humans. We have also included the change in epidermal transmission due to UV induced hyperplasia. The most carcinogenic radiation observed is due to Mg II (279.4 nm and 280.1 nm); Mg I (285.0 nm); O IV (306.3 nm and 306.7 nm).

RADIATION-INDUCED NEURONAL TOXICITY AND PROTECTION BY THE ANTIOXIDANT N-ACETYL-L-CYSTEINE. F.Noel*, J.J.Chen, G.J.Gumin, P.J.Tofilon, Department of Experimental Radiotherapy, University of Texas M.D. Anderson Cancer Center, 1515 Holcombe, Houston, TX 77030.

A major treatment modality for adult brain tumors is radiotherapy, which can result in significant damage to the normal tissue of the CNS. Although the mechanisms responsible for radiation-induced CNS injury have not been defined, the cellular targets are generally considered to be glial and/or endothelial cells. Neurons in the adult brain, being terminally differentiated, have been assumed to be radioresistant and have received little attention with respect to radiation-induced CNS injury. To more thoroughly investigate the effects of radiation on neuronal function and survival, we have begun to employ in vitro neuronal cultures generated from rat embryos (E18). Dissociated hippocampal and cortical tissue were plated in 96-well plates in serum-free medium using standard techniques. After 6 days cultures consisted almost entirely of neurons and were irradiated with increasing doses of X-ray (5-20 Gy). Cell survival was determined using the MTT cytotoxicity assay. The clinically relevant dose of 5 Gy reduced neuronal survival by 25, 40 and 40% in hippocampal cultures at post-irradiation days 1, 2 and 3, respectively. Similar results were obtained from cortical neuron cultures. Larger doses (10 and 20 Gy) did not significantly increase the amount of cell death. The antioxidant N-Acetyl-L-Cysteine (NAC) is a free radical scavenger and has previously been shown to protect against radiation-induced DNA damage and subsequent cell death when applied before irradiation. Addition of NAC to neuronal cultures 5 min after irradiation, i.e. after DNA damage induction, completely prevented radiation-induced neuronal toxicity in both hippocampal and cortical cultures. These results indicate that neurons are not resistant to ionizing radiation and, furthermore, suggest that irradiation induces an oxidative process (independent of DNA damage) that leads to neuronal death. EFFECTS OF AZT AND DDC ON LEARNING AND MEMORY IN MALE AND FEMALE RATS. C. Skvorc[1], H.D. Davis[2]*, D.E. Morse[2], and N.E. Grunberg[1]. [1]Uniformed Services University of the Health Sciences, Bethesda, MD 20814. [2]Antiviral Research Laboratory, Food and Drug Administration, Rockville, MD 20857.

AZT and ddC slow the progression of HIV infection and AIDS, but may have adverse behavioral and neurotoxic effects. We have recently reported decrements in spontaneous activity and the acoustic startle response in rats treated with ddC or AZT. In this experiment we used active and passive avoidance paradigms to examine effects of AZT and ddC on learning and memory in male and female rats. It was hypothesized that AZT and ddC administration would impair learning and memory. A total of 120 Sprague-Dawley rats (60/sex) were tested. Half of each gender was tested in an active avoidance paradigm, and the other half was tested in a passive avoidance paradigm. Active avoidance consisted of a single session of 15 trials, with a retention test either 1 or 8 days after the training trial. Passive avoidance consisted of a single training trial, with retention testing 1 day later. Animals were dosed IG with water, ddC (500mg/kg), or AZT (250 mg/kg), one hour before the first training trial. The dosages were based on previous reports. There was an increased latency to respond in the active avoidance paradigm among male animals dosed with AZT or ddC. The decrement in performance was maintained after a 24 hour interval and extinguished with continued learning in the active avoidance paradigm. Females dosed with AZT or DDC did not display an increased latency compared to water controls in the active avoidance paradigm. There were no drug effects in either gender in passive avoidance learning. The antiviral nucleosides tested had a detrimental effect on learning and performance that was gender and situation specific.

THE EFFECTS OF CAPSAICIN ON THE VASOPRESSIN & OXYTOCIN NEURONS OF HYPOTHALAMUS IN THE ADULT RAT. K. A. Park*, J. E. Lee, H. Yoon, W. T. Lee. *Dept. of Anatomy, Yonsei University College of Medicine, Seoul 120-752 Korea.*

Capsaicin, the pungent substance of the red pepper is known to be a neurotoxic substance, interrupting the pain conducting pathway. To investigate the effects on the hypothalamus in adult animals, immunohistochemical and immunoelectron microscopical studies have been done after capsaicin treatment. Capsaicin 50mg/kg was injected subcutaneously into adult Sprague-Dawley rats and after 1week, 1 month and 2 months later, vasopressin and oxytocin in supraoptic and paraventricular nuclei of the hypothalamic area were investigated. The results obtained are as follows;

1. The count of vasopressin- and oxytocin-immunoreactive cells in supraoptic and paraventricular nuclei were decreased from 1 month after capsaicin treatment and these decrement was continued.
2. The cross sectional area of neurons in the supraoptic and paraventricular nuclei were measured by image analyzer and average cross sectional area were decreased in 2 months 34.4% and 28.9% respectively.
3. In immunoelectronmicroscopical findings, vasopressin- and oxytocin-immunoreactive cells showed high density immunopositive materials in the axoplasm of unmyelinated nerve fibers and of small diameter myelinated nerve fibers. In the capsaicin treated group, immunopositive findings were hardly observed and some axons showed swelling and destruction of cell organelles and microtubules.

The conclusions from the above results showed that capsaicin treatment in adult rats had effect on the certain parts of the hypothalamus.

SEXUAL BEHAVIOR OF ADULT MALE RATS AFTER POSTNATAL TREATMENT WITH CAPSAICIN. Manzo, J.*, Vázquez, M., Camacho, M., García, L., Carrillo, P., Hernández, M.E., Pacheco, P. Inst. Neuroetología. Univ. Veracruzana, Xalapa, Ver. Inst. Inv. Biomédicas, UNAM. México.

Alterations produced by the neonatal treatment with the neurotoxic Capsaicin (Cap) include more effects than just changes in thermal and nociceptive perception. Thus, several lines of evidence show effects in skin vascular processes, in content of peptides in several reproductive organs, and in micturition reflex, all of them as a consequence of Cap-sensitive fibers destruction. In this study, we analyzed the effect that the neonatal administration of Cap has on the copulatory performance of males when they reach sexual maturity. In the second day of life, experimental (CAP) rat pups were subcutaneously injected with Cap (50 mg/kg bw) and controls (CTRL) just with vehicle. Pups were raised in mixed gender litters and weaned at 22 day of life. Afterwards they were separated by gender and tested after they reached 90 days. CAP (n=8) and CTRL (n=9) males were trained to get sexual experience. Then they were tested twice a week for two weeks and copulatory parameters were recorded. Results show that CAP animals had a reliably decrement in the latency to the first mount and a highly significative increment in the number of mounts before ejaculation. Also, in CAP males the intromission rate value was significatively decremented. Other parameters were similar in both groups. Data suggest that the neonatal Cap treatment has effects that influence some specific copulatory processes. One of them is penile erection, which is a process reflected in the number of attempts to reach intromission and ejaculation, therefore influencing the intromission rate value. Thus, the neonatal neurotoxic effect of Cap on C and Aδ fibers is seen in adulthood in the expression of penile erection. As pelvic nerve transection alters micturition and penile erection in intact adult male rats, it could be argued that Cap treatment is destroying pelvic nerve fibers dealing with micturition as well as with penile erection. DOPAMINERGIC CELLS CONTAINING CALRETININ ARE RESISTANT TO L-DOPA TOXICITY. M. E. Wolpoe, K. R. Isaacs, and D.M. Jacobowitz*. NIMH, IRP, LCS, Bethesda, MD 20892

Calretinin (CR), is a calcium-binding protein which has been suggested to serve a neuroprotective function based on its potential calcium buffering capacity and the resistance of cultured CR-containing cells to excitotoxins (Lukas et al., Neuroscience, 61:307, 1994; Isaacs et al., Mol Brain Res, 36:114, 1996) . In addition, the number of CR-containing substantia nigra cells remained unchanged in patients with Parkinson's disease (Mouatt-Prigent et al., Brain Res., 668:62, 1994). Recent reports demonstrated that an incubation L-ß-3,4-dihydroxyphenylalanine (l-DOPA) caused significant dopaminergic cell loss in mesencephalic cultures, while a subpopulation of neurons were unaffected. CR was found to colocalize with tyrosine hydroxylase (TH) in embryonic rat mesencephalic cells both in vivo and in vitro. In order to determine whether the cells resistant to the l-DOPA toxicity contained CR, E14 rat embryo mesencephalic neurons were plated on coated plastic 4-well slides and were incubated for 5 days in varying concentrations of l-DOPA (10^{-5} to 10^{-7} M). The cells were subsequently fixed and incubated simultaneously in antibodies to CR and TH and visualized with either Texas Red- or FITC-conjugated secondary antibodies. The number of CR-only, TH-only and CR+TH cells was counted directly from the fluorescent microscope using 10 fields/slide well, 7-8 wells/condition. The number of TH-only cells dropped significantly with increasing concentrations of the drug, while the number of CR-only and CR+TH cells remained constant across all concentrations. As such, it appears that the presence of CR in dopaminergic cells either confers protection against a disruption in calcium homeostasis which could accompany l-DOPA incubation or identifies a subset of neurons impervious to the drug.

MPTP-INDUCED OXIDATIVE STRESS AND THE ANTIOXIDANT SYSTEM IN THE NIGROSTRIATAL AND MESOLIMBIC DOPAMINERGIC PATHWAYS IN MICE. H.C. Hung* and E.H.Y. Lee. Graduate Institute of Life Sciences, National Defense Medical Center and Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, R.O.C.

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is known to produce a differential toxicity in the nigrostriatal and mesolimbic dopaminergic pathways. To determine whether oxidative stress plays a role in this phenomenon, levels of malondialdehyde (MDA) and glutathione (GSH) as well as superoxide dismutase (SOD) activity were measured in different dopamine (DA) neurons. Results indicated that MDA level, an index of lipid peroxidation, was significantly increased in the striatum, but not in the nucleus accumbens, after chronic MPTP treatment. In the antioxidant system,MPTP decreased GSH level and increased MnSOD activity in the substantia nigra, while it produced a more significant increase of both MnSOD and CuZnSOD activities in the ventral tegmental area. These results together suggest that supplies of the antioxidant system, especially the GSH level and the CuZnSOD activity, is more sufficient in the mesolimbic dopaminergic pathway than the nigrostriatal dopaminergic pathway. This may partially explain the differential toxicity of MPTP in these two DA systems. (This work was supported by a Grant from the National Science Council of Taiwan, NSC85-2331-B-001-034M10)

DIFFERENTIAL MPTP AND MPP^+ KINETICS IN THE RAT STRIATUM AND ACCUMBENS: IN VIVO VOLTAMMETRIC MEASUREMENT OF MPTP AND MPP^+. T. NAKAZATO*[1] and A. AKIYAMA[2]. [1]Dept. of Physiol., Juntendo Univ. Sch. of Med., 2-1-1 Hongo, Tokyo 113, [2]Dept. of Electrochem., Graduate Sch. at Nagatsuta, Tokyo Inst. of Tech., Yokohama 227, Japan.

The dopaminergic neurotoxin MPTP, has been shown to affect dopamine neurons that project to the striatum to a greater extent than those project to the nucleus accumbens. To investigate the difference in vulnerability between these regions, the intracerebral kinetics of exogenous MPTP and MPP^+ was examined using in vivo voltammetry. A carbon fiber measuring electrode was implanted in the rat striatum or accumbens, and a cannula was inserted ipsilaterally into these areas. MPTP (5 mM, 6 μ l) was injected over 24 min. In the striatum, MPTP concentration reached a maximum 27.6 ± 1.2 min after the start of injection, while in the accumbens, maximum was reached 33.6 ± 2.2 min ($p<0.01$). Levels of endogenously produced MPP^+ were elevated in the accumbens for a more extended time than in the striatum ($p<0.01$). Similarly, exgenously applied MPP^+ reached maximum levels later in the accumbens than in the striatum. MPTP was also administered intrastriatally following pretreatment with pargyline. The time course of changes in MPTP concentration was similar to that in cases without pargyline pretreatment. MPTP and nomifensine co-administration following pretreatment with pargyline resulted in a significantly delay in peak levels of MPTP. These results suggest that not only is MPP^+ taken up faster in striatal dopamine neurons than in accumbens dopamine neurons, but that MPTP may also be taken up.The difference in vulnerability between striatal and accumbens dopamine neurons may be related to a difference in uptake rates of MPTP and MPP^+ between the striatum and accumbens.

HEAT SHOCK PROTEINS PROTECT CULTURED FIBROBLASTS FROM THE CYTOTOXIC EFFECTS OF MPP^+. T.E. Freyaldenhoven* and S.F. Ali. Neurochemistry Laboratory, Division of Neurotoxicology, National Center for Toxicological Research/FDA, Jefferson, AR, 72079.

We showed previously that a single injection of MPTP (50 mg/kg) caused hyperthermia with consequent induction of heat shock protein 70 in the brains of CD-1 mice. The present study was designed to determine whether HSP synthesis is protective toward the cytotoxicity of 1-methyl-4-phenylpyridinium (MPP^+), the cytotoxic metabolite of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), in a simplified *in vitro* model. The addition of media containing 1 mM MPP^+ to cultures of Chinese hamster ovary (CHO) fibroblasts led to the gradual depletion of cellular ATP stores and subsequent cell death. A 12 minute heat shock of the cells at 45°C, three hours prior to the addition of MPP^+-containing media, significantly attenuated cell death. Heat shock pretreatment led to an increased synthesis of all the major heat shock proteins (HSPs) in CHO cells. Further, the addition of the protein synthesis inhibitor, cycloheximide, prevented the protective effect of heat shock pretreatment, indicating that this protection was dependent upon new protein synthesis. In additional experiments, a rat fibroblast cell line which has been stably transfected with, and constitutively expresses a cloned human HSP-70 gene, was found to be more resistant to the cytotoxic effects of MPP^+ than the parental fibroblast cell line. These results indicate that HSPs are protective toward the deleterious effects of MPP^+ and that their synthesis represents an important parameter in the neurotoxicity of MPTP.

748.5

ROLE OF METALLOTHIONEIN IN MPP^+-INDUCED TOXICITY IN CHO CELLS THAT OVER-EXPRESS METALLOTHIONEIN. S. Hussain*, B. Hass+, W. Slikker Jr and S.F. Ali. Neurochemistry Laboratory, Division of Neurotoxicology, and +Division of Nutritional Toxicology, National Center for Toxicological Research/FDA, Jefferson, AR 72079.

Metallothioneins (MTs) are low molecular weight (6-7 Kd) metal binding proteins known to detoxify and sequester toxic heavy metals. Recently, they have been shown to protect from the toxicity of various chemicals and drugs. The protective mechanisms of these proteins is still unknown. Evidence supports the hypothesis that MT acts as an oxygen free radical scavenger. MPP^+ is an active metabolite of 1-methyl-4-phenyl-1,2,3,6 tetrahydro-pyridine (MPTP), a potent neurotoxicant known to cause selective degeneration of the nigrostriatal dopamine system by producing reactive oxygen species. In an effort to elucidate the function of MT against the neurotoxicant, MPP^+, a simple in vitro model was applied by using a CHO cell line that over-expressed amplified MT genes. In the present experiments we evaluated if MT protects against MPP^+-induced toxicity. The normal wild-type cells and MT over-expressed cells were exposed to MPP^+ for 24 or 48 hours in culture. The results show that 1 mM MPP^+ reduced the viability about 95% in 24 hours. The survival of the cells was a dose-dependent. There was no difference in the viability of MT over-expressed cells compared to normal cells. As a positive control, the cells were treated with 5 uM $CdCl_2$ for 24 or 48 hours. The viability of normal cells was 40% whereas 95% of the MT-cells were viable. MT-cells were 5 times more viable than normal cells in the presence of 5 uM $CdCl_2$. The activity of the antioxidant enzyme, catalase, was also measured in these cells lines. There was a slight increase in catalase activity in MPP^+-treated cells at 250 and 500 uM. However, there was no difference in the activity of catalase in wild type cells compared to MT-cells. The data suggest that MT is not protecting against the toxicity of MPP^+ in CHO cells and may not be involved in MPP^+-induced neurodegeneration.

MICROGLIA IN THE STRIATUM HYPERTROPHY AND PROLIFERATE AFTER A SINGLE DOSE OF MPTP. W.G. McAuliffe* and R.S. Nowakowski. Dept. of Neuroscience and Cell Biology, R.W. Johnson Medical School, Piscataway, NJ 08854.

The dopaminergic neurotoxicant MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) is known to produce a reactive gliosis in the striatum, presumably as a result of the destruction of dopaminergic terminals. We administered a single intraperitoneal dose of MPTP, 40 mg/kg, to male C57Bl6/J mice. Twenty-four hours to 14 days later we administered a single dose of bromodeoxyuridine (BUdR) to mark cells in DNA synthesis. Frozen or paraffin sections were immunostained with antibodies to Mac-1 to demonstrate microglia, GFAP to demonstrate astrocytes and BUdR to identify proliferating cells. Both microglia and astrocytes showed pronounced hypertrophy after MPTP, as early as 18 hours for microglia and at 36 hours for astrocytes. Thirty-six hours after MPTP there was a ten-fold increase in the number of BUdR-labeled nuclei in each side of the striatum, from 29.1 ± 4.6 in control animals to 309.8 ± 31. Forty-eight hours after MPTP the number of labeled nuclei in one side of the striatum was 106.7 ± 22.9. The number of labeled nuclei 24 or 72 hours or longer after MPTP was not significantly different from control values. Mice given Deprenyl before MPTP showed no increase in BUdR incorporation and glial hypertrophy was absent. When GFAP or Mac-1 immunostaining preceded BUdR staining it was clear that many of the labeled nuclei belonged to microglia but virtually none belonged to astrocytes. We conclude that while both microglia and astrocytes hypertrophy after MPTP, only microglia proliferate. (Supported by UMDNJ/RWJMS.)

SEVERE LONG-TERM MPTP-INDUCED PARKINSONISM IN THE VERVET MONKEY *(CERCOPITHECUS AETHIOPS SABAEUS).* J.R. Taylor*, J.D. Elsworth, R.H. Roth, J.R. Sladek, Jr.[1], and D.E. Redmond, Jr. Dept. Psychiat. and Pharm. Yale Univ, Sch. of Med., New Haven CT 06520 and [1]Dept. of Neurosci., Finch Univ. Hlth Sci., Chicago Med. Sch., Chicago IL 60064

The utility of MPTP-induced parkinsonism in monkeys as an model of Parkinson's disease depends on a stable syndrome so that the effects of novel graft or therapeutic treatments can be assessed. This study focused on long-term (5-6 months) stability and persistence of behavioral deficits in parkinsonian monkeys. Adult male vervet monkeys were treated with MPTP (cum. dose 2.5 mg/kg i.m.), and 6 were saline treated. MPTP-treated subjects were examined in two previously defined groups: 'severe' (N=11) and 'moderate' (N=5). It is difficult to maintain severe subjects for these extended time periods without neural grafts and thus it has taken years to accumulate sufficient data to allow rigorous statistical analyses. Observers recorded spontaneous behaviors twice daily for 5 mins during the study. Scored behaviors were recorded if they occurred any time during a 5 sec period or lasted for a full 5 sec. Other behaviors were rated (scale of 0-5) during the session and also after subsequent 'challenges' with food or threats. Monthly summary scores of behaviors, previously derived from a factor analysis, were analyzed; these reflected normal 'healthy' behavior or 'parkinsonian' behavior. Severely parkinsonian subjects showed a stable deficit. In contrast, those that initially were moderately parkinsonian showed a less stable deficit. These data suggest that the initial severity of the deficit is a reliable predictor of outcome. Striatal dopamine levels paralleled the degree of parkinsonian disability. Some less parkinsonian subjects have survived for several years, and interestingly, one mildly affected subject has developed dyskinesias and dystonia. MPTP-treatment in the vervet monkey can result in persistent deficits and provides an excellent model of Parkinson's disease, as long as adequate behavioral assessments are conducted.

DIETHYLDITHIOCARBAMATE (DDC): A PROMOTER OF DOPAMINERGIC TOXICITY, I. Irwin*, M. Thiruchelvam, M. Verma and J.W. Langston. The Parkinson's Institute, Sunnyvale, CA 94089

DDC is the prototypic member of a family of widely used agricultural, industrial and pharmaceutical chemicals (dithiocarbamates, DTCs). Exposure of humans to DTCs has been associated with the development L-DOPA responsive extrapyramidal movement disorders, strongly suggestive of disturbances in nigrostriatal dopamine (DA). Although experimental studies with DDC have not demonstrated any direct dopaminergic toxicity for this compound, DDC has been shown to enhance neurotransmitter depleting and other effects of the dopaminergic neurotoxin MPTP. The purpose of the present study was to investigate the interaction of DDC with other known and suspected DA toxins. DDC (400 mg/kg) or saline was administered to groups of 8 week old male C57BL/6 mice. One half hour later animals were given either MPTP, methamphetamine of L-DOPA (administered as the methyl ester in combination with benserazide). Animals were sacrificed 5-21 days later and striatal DA was measured by HPLC/EC. DDC alone had no effect on striatal DA, but combined treatment significantly enhanced the effects of MPTP and methamphetamine. More remarkably, DDC appeared to confer DA-depleting ability on L-DOPA, a compound which is without such effects when administered alone. The ability of DDC to act in combination with L-DOPA provides a new and potentially interesting model to investigate mechanisms of nigrostriatal damage in conditions such as Parkinson's disease. These findings also lend credence to the possibility that one or more environmental compounds may be involved in the etiology of this disorder. Work supported by the Parkinson's Institute.

DOPAMINERGIC NEURONS ARE MORE RESISTANT TO DEPLETION OF GLUTATHIONE THAN OTHER MESENCEPHALIC NEURONS. K. Nakamura*, W. Wang and U.J. Kang. Department of Neurology, University of Chicago, Chicago, IL 60637

Parkinson's Disease (PD) is characterized by the selective degeneration of nigral dopaminergic neurons. While the etiology of this cell death remains unknown, a combination of autopsy data, genetic analysis and research into the mechanism of MPTP toxicity has focused attention on an oxidant stress hypothesis. Glutathione (GSH) levels are decreased to the same extent in incidental Lewy body disease (pre symptomatic PD) as in advanced Parkinson's Disease, and hence represents an early index of oxidative stress. We examined the selective effect of GSH depletion or supplementation on the survival of primary dopaminergic neurons at a tissue culture level. Glutathione was depleted by L-buthionine-[S,R]-sulfoximine (BSO), while the GSH precursors, glutathione ethyl ester and L-2-oxo-4-thiazolidine-carboxylate, were administered in an attempt to increase GSH levels. The addition of increasing concentrations of BSO was toxic to both the mesencephalic neurons as a whole, as well as TH+ neurons. Nevertheless, compared to total mesencephalic neurons, TH+ neurons proved to be comparatively resistant to BSO toxicity at increasing concentrations. The addition of GSH precursors did not increase survival of either TH or total neurons. Taken together, these data suggest that reduced GSH levels alone, will not selectively kill dopaminergic neurons. In fact, primary dopaminergic neurons are more resistant to reduced GSH levels than other mesencephalic neurons, and supplying exogenous GSH does not enhance their survival. However, reduced GSH may still be required in combination with other etiologic agents to develop PD. Supported by Natl Park Fdn, Park Dis Fdn, United Park Fdn, and USPHS grants NS07113 and NS32080.

MOLECULAR MECHANISMS OF NOVEL SIGMA LIGANDS AS POTENTIAL NEUROTOXICANTS. B.L. Blake, S.D. Wyrick, and R.G. Booth*. Div. of Med. Chem., School of Pharmacy, Univ. of North Carolina, Chapel Hill, NC, 27599.

The intracellular generation of reactive oxygen species (ROS) (e.g. free radicals, peroxides and quinones) is proposed to be involved in the cytotoxic mechanism of many neurotoxicants. ROS are produced from the oxidative metabolism of endogenous catecholamines. Catecholamine-derived free radicals and quinones are hypothesized to be involved in neurotoxic insults that may have a role in the pathogenesis of neurodegenerative diseases, such as Parkinson's disease [*Pharmacol. Rev.* (1994) 46: 467]. We have synthesized a series of phenylaminotetralins (PATs) that act through a proposed novel σ_3 receptor to stimulate tyrosine hydroxylase (TH) and catecholamine (DA) synthesis in rat brain *in vitro* [*Mol Pharmacol.* (1993) 44: 1232] and *in vivo* [*Soc. Neurosci Abstr.* (1994) 20: 748]. DA synthesis stimulated by PATs *in vivo* is 300-fold in excess of basal levels. We hypothesize that certain PATs may increase levels of catecholamine-derived metabolites to produce neurotoxicity through the formation of ROS. The neurotoxic effects of PAT administration, as well as the formation of catecholamine-derived oxidative metabolites and the moderation of these effects by scavenging agents are being evaluated. We administered doses (0.4-40 nmole/kg) of (1*R*,3*S*)-(+)-*trans*-1-phenyl-3-(*N*,*N*-dimethylamino)-tetralin (H_2-PAT) to rats to stimulate brain TH and catecholamine synthesis *in vivo*. Quinone-type DA metabolites are measured in catecholamine-containing brain areas using UV-Vis spectrophotometry. Neurotoxicity is assessed as a decrease in nerve terminal function as measured by TH activity, catecholamine release, and by quantitation of nerve terminal catecholamine uptake sites using autoradiography. In addition, functional "neuro"toxicity is examined in cultures of TH-containing PC 12 cells. These studies may suggest biochemical mechanisms to support hypotheses of endogenously-formed neurotoxicants. BENZAMIDE PROTECTS AGAINST METHAMPHETAMINE-INDUCED DOPAMINE DEPLETION IN C57Bl/6 MICE. M. Marien, P. Chopin and C. Cosi*, Centre de Recherche Pierre Fabre, Castres 81100, France.

Poly(ADP-ribose)polymerase (PARP), when fully activated by DNA strand breaks, can deplete NAD+/ATP energy stores to an extent which could severely compromise cell survival. PARP inhibitors (Banasik, 1992, *J. Biol. Chem.* 267, 1569) including benzamide (BNZ), prevent glutamate-induced neurotoxicity in primary cell culture (Zhang, 1994, *Science* 263, 687; Cosi, 1994, *J. Neurosci. Res.* 39, 38); BNZ partially prevents methamphetamine (METH)-induced neuronal death in mesencephalic cell cultures (Sheng, 1994, *Pharmacol. Lett.* 55, PL51). We investigated whether BNZ was protective against METH-induced striatal dopamine (DA) depletion in C57Bl/6 mice, a model of DA neurotoxicity where excitatory amino acids, free radicals and energy impairment are implicated as causative factors. At 7 days following METH injections (protocol A, 10 mg/kg i.p. at 0, 2, 4 and 6 h; protocol B, 20 mg/kg i.p. at 0 and 2 h), striatal DA content was 46.6% (protocol A) and 47.2% (protocol B) of that measured in vehicle-treated control mice. In mice treated with BNZ (160 mg/kg i.p.) at 30 min before and 3.5 h after the first METH injection, striatal DA content was 64.6% (protocol A) and 78.4% (protocol B) of vehicle controls ($P < 0.01$ vs. METH alone). BNZ alone did not alter striatal DA or metabolite (DOPAC, HVA) levels, neither acutely (at 1 h) nor after 7 days. BNZ (160 mg/kg i.p.) did not alter body temperature at 30, 60 or 120 min after injection. Measurement of BNZ in the striatum after a single i.p. injection (160 mg/kg) gave estimated concentrations of 0.60-0.64 mM at 15, 30 and 60 min, 0.29 mM at 2 h, and 0.05 mM at 4 h. Although the underlying mechanism(s) remains uncertain at present, BNZ appears to have neuroprotective activity in this *in vivo* model.

METHAMPHETAMINE CAUSES SUPEROXIDE GENERATION AND APOPTOSIS IN NEURAL CELLS. J.L. Cadet, S. Ordonez, and J. Ordonez. Molecular Neuropsychiatry Section, DIR, NIH/NIDA IRP, Baltimore, MD 21224.

Methamphetamine (METH) is a drug of abuse that cause degeneration of monoaminergic systems in vivo. Other studies have shown that METH is toxic to dopaminergic neurons in vitro. Mechanistic studies have suggested that nitric oxide and superoxide radicals are involved in the neurotoxicity of this drug both in vitro and in vivo. The present study was under-taken to assess the possible production of superoxide radicals by METH in vitro. An immortalized cell line obtained from fetal rat mesencephalon was used. Superoxide radical production was evaluated by using the dye hydroethidine which can be oxidized to ethidium bromide by superoxide anions. METH caused very early production of superoxide in punctate regions of the cytoplasm and in the nucleus. Confocal microscopic analysis revealed chromatin condensation and nuclear fragmentation within three hours of exposure to the drug. Studies are underway to better define the time course of the production of superoxide radicals and of apoptotic changes after treatment of the cells with METH.

748.13

METHAMPHETAMINE-INDUCED NEUROTOXICITY IS ASSOCIATED WITH PROLONGED INCREASE IN STRIATAL AP-1 DNA-BINDING IN MICE.

Peilin Sheng*, Bruce Ladenheim,#T.H. Moran, X.-B Wang, and J.L. Cadet
Molecular Neuropsychiatry and Molecular Neurobiology Sections, NIH/NIDA IRP, Baltimore, MD 21224 & Dept. of Psychiatry & Behavioral Sciences, #The Johns Hopkins University School of Medicine, Baltimore, MD 21205

Multiple injections of methamphetamine (METH) produce long-lasting neurotoxic effects on the nigrostriatal dopamine (DA) system. The drug also causes increase in AP-1 DNA-binding activity in mice. In the present study, we tested the idea that toxic doses of METH might cause long-term increases in AP-1 DNA-binding. Mice were given 10 mg/kg of METH twice, three or four times at 2- hr interval in one day. Striatal DA levels were markedly decreased at 3 hr and 24 hr in all injection groups. After one week, striatal DA level recovered to near control's in the METH x2 group, but were still significantly decreased in the METH x3 and x4 groups. Similar drug administration schedules caused increases in AP-1 DNA-binding activity. The AP-1 binding activity almost returned back to control level in the 2 and 3 times injection groups at the 24hr and 1-week time point, but there were still increased levels of AP-1 biding activity in the METHx4 group. These findings raise the possibility that METH-induced neurotoxicity might involve prolonged activation of AP-1 transcription factor. This might be related to the report that c-fos activation may be important in some models of neurodegeneration.

LACK OF GENDER DIFFERENCES IN METHAMPHETAMINE-INDUCED REDUCTIONS IN STRIATAL NEUROTRANSMITTER CONTENT IN RATS. M. Fukumura, G.D. Cappon, H.W. Broening, and C.V. Vorhees*. Division of Developmental Biology, Children's Hospital Research Foundation and Department of Pediatrics, University of Cincinnati, Cincinnati, OH 45229.

In mice, it has been reported that the methamphetamine (MA)-induced neostriatal DA reduction is greater in males than in females. We examined MA-induced neurotransmitter alterations in male and female Sprague-Dawley CD rats (treatment groups were assigned to each gender: saline, MA 5, and MA 10 mg/kg, N=8/group; MA expressed as free base). The treatments were administered s.c. four times at 2 hr intervals. Body temperatures were measured rectally every 30 min beginning from the first MA administration and continuing until 3 hr after the final MA administration. If rectal temperatures reached or exceeded 41.5°C the subjects were immediately placed on ice. Animals were sacrificed 3 days post-treatment for the determination of DA, 5-HT, and metabolites. MA induced significant DA and 5-HT reductions in striatum but the magnitude of these reductions were not significantly different between the sexes. In the MA 5 mg/kg groups, striatal DA content was reduced by 44.8% and 51.2%, and striatal 5-HT content was reduced by 23.9% and 30.5% of controls for females and males, respectively. In the MA 10 mg/kg groups, striatal DA content was reduced by 65.8% and 72.9%, and striatal 5-HT content was reduced by 73.6% and 77.4% of controls for females and males, respectively. Maximum rectal temperatures are as follows: 39.3°C and 38.9°C for saline treated females and males; 40.4°C and 40.5°C in MA 5 mg/kg treated females and males; 41.5°C and 41.5°C in MA 10 mg/kg treated females and males. No significant differences in the thermal response to MA was observed between the genders. Our data demonstrate no gender difference in MA-induced DA and 5-HT reductions in rats under conditions in which the magnitude of MA-induced hyperthermia was matched across sexes. (Supported by NIH Grant DA06733)

748.15

DOPAMINERGIC INNERVATION TO THE NUCLEUS ACCUMBENS CORE AND SHELL IS DIFFERENTIALLY VULNERABLE TO METHAMPHETAMINE-INDUCED NEUROTOXICITY. H.W. Broening*, C. Pu, and C.V. Vorhees. Div. Developmental Biology, Children's Hospital Research Foundation, and Dept. Pediatrics, Univ. Cincinnati, Cincinnati, OH 45229.

Dopaminergic innervation to the nucleus accumbens was investigated following a neurotoxic regimen of methamphetamine (MA) treatment. Four 10 mg/kg doses of MA or saline were administered subcutaneously to male Sprague Dawley CD rats with a 2 hr interval between doses. Rectal temperatures were monitored at 30 min intervals for the induction of MA-induced hyperthermia. Three days or two weeks after MA treatment the animals were sacrificed by transcardial perfusion and processed for tyrosine hydroxylase (TH-IR) and glial fibrillary acidic protein immunoreactivity (GFAP-IR). MA treatment produced a severe loss of TH-IR throughout the striatal regions including the nucleus accumbens. However, within the nucleus accumbens, there was substantial sparing of TH-IR in the shell region while in the core region immunoreactivity was almost entirely lost. Furthermore, astrogliosis, as demonstrated by GFAP-IR, was observed in the core but not the shell region. Thus, dopaminergic innervation to the nucleus accumbens core undergoes degeneration following MA treatment while innervation to the shell is resistant to the neurodegenerative effects of MA. (Supported by NIH Grant DA06733)

748.16

ONTOGENY OF METHAMPHETAMINE-INDUCED NEUROTOXICITY AND ASSOCIATED HYPERTHERMIC RESPONSE. G.D. Cappon*, L. Morford and C.V. Vorhees. Div. of Developmental Biology., Children's Hosp. Res. Foundation, Neuroscience Program and Dept. of Pediatrics, Univ. of Cincinnati, Cincinnati, OH 45229.

Methamphetamine (MA) administration to adult rats results in neurotoxicity characterized by persistent depletion of caudate-putamen (CP) dopamine (DA). Acute thermoregulatory responses following MA treatment correlate with long-term DA depletion. In the following study, the thermoregulatory and neurotoxic effects of MA administration (4 x 10 mg/kg) were investigated in developing rats at postnatal days (PND) 20, 40 and 60. MA was administered at ambient temperatures of 22°C and 30°C (PND 60 rats were administered MA at 22°C only). Rectal temperatures were measured and thermal responses were compared using the maximum rectal temperature (Tmax) achieved. MA administration to PND 60 rats at 22°C resulted in a Tmax of 40.8°C (Sal Tmax = 38.6°C) and reduced CP DA by 43%. Administration of MA to PND 40 rats at 22°C failed to induce a hyperthermic response or alter DA content. Administration of MA to PND 40 rats at 30°C resulted in a Tmax of 41.1°C and reduced CP DA by 54%. MA administration to PND 20 rats at 30°C induced hyperthermia (Tmax = 40.7°C) but did not result in DA depletion, while administration of MA to PND 20 rats at 22°C resulted in neither hyperthermia or DA depletion. These results demonstrate that the induction of hyperthermia is necessary to elicit MA-induced neurotoxicity at PND 40. However, PND 20 rats are resistant to the DA depleting effects of MA despite the induction of hyperthermia. (Supported by NIH Grant DA06733)

748.17

METHAMPHETAMINE-INDUCED DAMAGE TO CORTICAL NEURONS IS INDICATED BY A NEWLY-DEVELOPED FLUORESCENT TAG. A.J. Eisch[1], J.F. Marshall[1], W. Slikker Jr.[2] and L.C. Schmued[2] (1) Psychobiology Dept., Univ. of California, Irvine, CA 92717-4550 and (2) Div. Neurotox., Natl. Ctr. for Toxicol. Res., 3900 NCTR Rd., Jefferson, AR 72079-9502.

Methamphetamine (m-AMPH) damages both striatal dopaminergic terminals and non-monoaminergic cortical neurons. Clarification of the relationship between the subcortical and cortical damage is warranted in light of research implicating dopamine (DA) and glutamate (GLU) in the resulting toxicity to DA terminals. One barrier to exploring this relationship is that the light microscopic techniques used to demonstrate m-AMPH-induced cortical cell damage are either mercurial (e.g. silver stain) or indirect (e.g. loss of GLU immunoreactivity or [^{3}H]GLU binding to NMDA receptors). In this study we used Fluoro-Jade, a new *ex vivo* fluorescent marker that labels degenerating neurons, to identify populations of neurons that are damaged after repeated injections with m-AMPH. Rats were given four s.c. injections of saline (SAL; 1 ml/kg) or m-AMPH (4 mg/kg) two hours apart. After survival times of one, three or seven days post-treatment, separate sections were examined for tyrosine hydroxlyase immunoreactivity (TH-IR) and Fluoro-Jade-positive neurons (FPN). SAL-treated rats showed normal striatal TH-IR and no FPN neurons in any region examined. In contrast, m-AMPH-treated rats showed loss of striatal TH-IR and the presence of FPN in the parietal cortex. The soma and the proximal processes of the cortical FPN were evident at both one and three days post-treatment, but the number of FPN was greatest at three days post-treatment. By seven days post-treatment, FPN were noticeably fewer in number, and those FPN that were evident were shrunken and dystrophic. The present data support the hypothesis that neocortical neurons degenerate after repeated exposure to m-AMPH. Future studies will use pharmacological agents during m-AMPH administration to determine the consequences for cortical cell damage and the striatal DA terminal loss. *Funding provided by NIDA DA05647 (AJE), PHS DA08052 and DA10249 (JFM), and FDA/NCTR (WS, LCS).*

EFFECT OF LOW DOSE OF Nω-NITRO-L-ARGININE METYL ESTER (LNAME), A NITRIC OXIDE SYNTHASE INHIBITOR ON METHAMPHETAMINE-INDUCED DOPAMINERGIC AND SEROTONERGIC NEUROTOXICITY IN THE RAT BRAIN. T. Abekawa*, T. Ohmori and T.Koyama. Department of Psychiatry, Hokkaido University School of Medicine, Sapporo, Japan.

The toxic dose of MA(5mg/kg,sc,x4) significantly decreased the contents of dopamine(DA), dihydroxyphenylacetic acid(DOPAC) and homovanillic acid(HVA) in the striatum(ST), and the contents of serotonin(5-HT) in both the ST and nucleus accumbens(NA). In contrast to high dose of Nω-nitro-L-arginine(LNAME),a nitric oxide synthase inhibitor,coadministration with low doses of LNAME(5 and 10mg/kg,ip,x1)significantly enhanced the MA-induced decreases in the contents of DA, DOPAC and HVA in the ST.It did not changed the MA-induced decreases in the contents of 5-HT in the ST or NA. These findings suggest that nitric oxide(NO) may play a role in the MA-induced dopaminergic, but not serotonergic neurotoxicity.

The work was supported in part by Grant-inAid No 05670796,No o761042 and No 07457206 for Scientific Research from the Ministry of Education,Science and Culture,Japan.

NEUROTOXIC AND PHARMACOLOGIC STUDIES OF (-) EPHEDRINE. J.Yuan*, G.Hatzidimitriou, B. Callahan, G. Ricaurte. Department of Neurology, Johns Hopkins Medical Institutions, Baltimore, MD 21224.

(1R, 2S)-2-(methylamino)-1-phenylpropan-1-ol or (-) ephedrine is one of the principal active ingredients in non-prescription weight loss aids that are being touted as "natural" or "organic" appetite suppressants (e.g., *Ma Huang*), and are sometimes recreationally abused. Since (-) ephedrine is structurally related to several amphetamines known to damage brain monoaminergic neurons, the present studies were undertaken to determine whether (-)ephedrine also has neurotoxic potential. Male Swiss-Webster mice were given (-) ephedrine, s.c., at doses of 40, 80, and 120 mg/kg, either twice daily for 4 days or every 2 hours x 4. These doses were selected after determing that 80 mg/kg of (-) ephedrine reduced food intake in mice by approximately 50%. Control animals received saline. One, two, and four weeks after drug treatment, mice were sacrificed and brains were evaluated for evidence of brain dopamine neurotoxicity. (-) Ephedrine produced dose-related decreases in DA, DOPAC, and [^{3}H]mazindol-labeled DA uptake sites in the corpus striatum at all time points evaluated. Further, silver degeneration studies revealed evidence of terminal degeneration in the corpus striatum of mice treated with 80 mg/kg (-) ephedrine. These studies indicate that (-) ephedrine, like several structurally related amphetamines, has potential to damage brain dopamine neurons. Since doses found to damage brain dopamine neurons in mice produced little or no weight loss, these data suggest that the margin between therapeutic (anorectic) and neurotoxic doses of (-) ephedrine may be quite narrow. [Support: DA00206 and DA06275]

REDUCTIONS IN BRAIN DOPAMINE AND SEROTONIN TRANSPORTERS DETECTED IN HUMANS PREVIOUSLY EXPOSED TO REPEATED HIGH DOSES OF METHCATHINONE USING PET. G. Ricaurte, D. F. Wong, Z. Szabo, F. Yokoi, U. Scheffel, W. Mathews, H. Ravert, R. Dannals, S. Naidu*. Departments of Neurology and Radiology, Johns Hopkins Medical Institutions, Baltimore, MD. 21205.

In recent years, the synthetic amphetamine analog methcathinone (2-methylamino-1-phenylpropanone, ephedrone, "Cat") has emerged as a recreational drug of abuse. In animals, methcathinone, like methamphetamine, produces toxic effects on brain dopamine (DA) and serotonin (5-HT) neurons. The purpose of the present studies was to determine if human subjects with a history of exposure to repeated high doses of methcathinone showed evidence of DA or 5-HT neurotoxicity.

Positron emission tomography (PET) with ligands that selectively label the DA and 5-HT transporters ([^{11}C]WIN 35,428 and [^{11}C](+)McN5652, respectively) was used to assess the status of brain DA and 5-HT neurons. Studies of the DA transporter were carried out in 11 healthy controls and 3 subjects with a history of methcathinone abuse; studies of the 5-HT transporter were carried out in 5 healthy controls and two of the methcathinone subjects. All subjects were drug-free for at least 2 weeks prior to study. No subject had a neuropsychiatric disease in which either DA or 5-HT dysfunction has been implicated.

Compared to controls, subjects previously exposed to methcathinone had reductions in both DA and 5-HT transporter density. Reductions were evident in multiple brain regions, including the caudate and putamen and neocortex (5-HT only). To the extent that lasting reductions DA and 5-HT transporter density reflect DA and 5-HT neurotoxicity, respectively, these preliminary findings suggest that methcathinone and related drugs may produce neurotoxic effects in the human brain [Supported by: DA19487, DA10217, DA09482 and DA06275]

749.1

NEUROHISTOLOGICAL STUDIES OF IBOGAINE IN MICE AND RATS. R.L. Rountree*, S.F. Ali, L.C. Schmued, X. Ye and A.C. Scallet. Division of Neurotoxicology, National Center for Toxicological Research/FDA, Jefferson, AR 72079.

Ibogaine is a psychoactive indole alkaloid, derived from the roots of the rain forest shrub *Tabernanthe iboga*, which has been considered as a treatment for drug addiction. A single dose of ibogaine (30-100 mg/kg ip) in rats caused tremors and necrosis of cerebellar Purkinje cells (O'Hearn and Molliver, 1993). In the present study, we administered ibogaine (100 mg/kg ip) or saline to adult rats and mice and perfused them one hr, 24 hrs, or 6 days later. Cerebellar degeneration was detected with a degeneration specific silver staining and a novel fluorescence method. Patches of necrotic Purkinje neurons were present in the cerebellar vermis of dosed rats, but not mice. Intense c-fos immunoreactivity was evident in neocortical cells only at one hr after ibogaine, in both rats and mice. These results confirm the previously reported neurotoxicity of ibogaine in rats and extend the study in mice. In rats, ibogaine induced c-fos activation throughout the cortex, whereas in mice cortical c-fos activation was selective for layer 2 of the neocortex. Based on these data, we hypothesize that neuroanatomical differences in cortical projections to the cerebellum may underlie the sparing of Purkinje cells in the mouse.

749.2

ATTENUATION OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA)-INDUCED NEUROTOXICITY BY PHENYL-t-BUTYLNITRONE (PBN) IN RATS. S.Y. Yeh* Molecular Neuropsychiatry Section, NIH/NIDA, IRP, P.O. Box 5180, Baltimore, MD 21224

MDMA-induced neurotoxicity is hypothesized to be due to free radicals. Rats were treated with two concurrent PBN (50 to 400 mg/kg dissolved in 25% of ethanol, 50 mg/ml, i.p.) and MDMA injections (20 mg/kg, s.c.) 6 h apart. Control rats received saline and or 25% ethanol as vehicle. Rats were sacrificed 5 days after the last injection. Brain tissues were dissected and frozen until used for measurement of monamines by HPLC and of 5-HT receptor density by binding of [^{3}H]paroxetine with citalorpram as nonspecific binding. MDMA caused an increase (NS Abstract, pp.973, 1995), whereas PBN caused a decrease in rectal temperature. MDMA caused marked decreases in levels of 5-HT, and 5-HIAA in the frontal cortex, hippocampus, stratum, and brain stems. PBN prevented the effects of MDMA on these parameters. MDMA caused a decrease in 5-HT uptake sites in the frontal cortex and hippocampus whereas PBN prevented the effects of MDMA on 5-HT uptake sites. These results suggest that MDMA induced-neurotoxicity might be related to production of free radicals during metabolism of MDMA.

749.3

3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) 5HT NEUROTOXICITY IS A FUNCTION OF AMBIENT TEMPERATURE (AMB TEMP) AND CORE BODY TEMPERATURE (CORE TEMP) IN RATS J.E. Malberg* and L.S. Seiden. Dept. of Pharmacol. and Physiological Sci., University of Chicago, Chicago IL 60637

This study sought to quantify the relationship between CORE TEMP, AMB TEMP and MDMA-induced 5HT neurotoxicity. We use a chamber which can 1) regulate AMB TEMP ± .5° and 2) record CORE TEMP once per minute from unrestrained rats. Male Holtzmann rats (250-300g) were given a single injection of MDMA (20 or 40 mg/kg,s.c.) or saline and exposed to one of 6 AMB TEMPs (20, 22, 24, 26, 28 and 30°C) for 24 hours. Two weeks after the MDMA treatment, rats were sacrificed and 5HT and 5HIAA concentrations in the frontal cortex and somatosensory cortex were determined. CORE TEMP data was analyzed by using the area-under-the-curve for the first 11 hours after the MDMA injection. At an AMB TEMP of 20° and 22°C, MDMA (20 or 40 mg/kg) produced a hypothermia compared to control. At 24°C and 26°C, there was no change in CORE TEMP relative to control. At 28°C and 30°C, a hyperthermia was observed. Analysis of the frontal and somatosensory cortex indicates that rats treated with MDMA (20 or 40 mg) in an AMB TEMP of 20°, 22° or 24° showed no change in 5HT or 5HIAA levels compared to control. At 26°C, there was a significant decrease in 5HT levels with 40 mg/kg MDMA in the somatosensory cortex and with both 20 and 40 mg/kg MDMA in the frontal cortex. At 28° and 30°, there was a significant decrease in 5HT and 5HIAA levels in the frontal and somatosensory cortex at both doses of MDMA. In addition to the neurotoxicity being dependent on CORE TEMP, this study shows that there is a very small range of AMB TEMPs that have a large effect on CORE TEMP and MDMA-induced neurotoxicity (Supported by NIDA Training Grant DA-07255-01, L.S.S.: RSA MH-10562).

MORPHOLOGICAL CHANGES IN NEURONS AND GLIA AFTER CHRONIC INHIBITION OF SEROTONIN SYNTHESIS. P. Tagliaferro, J. Ramos, E.M. López, O. Canessa , J. Pecci Saavedra and A. Brusco * Instituto de Biologia Celular y Neurociencias "Prof. Eduardo De Robertis". Facultad de Medicina. UBA. Paraguay 2155. (1121) Buenos Aires. Argentina

Despite of the great number of studies based on the model of acute serotonin (5-HT) depletion, there are few data on the effects produced by a long-term 5-HT depletion in adult mammals. Using parachlorophenilalanine (PCPA), a well-known inhibitor of 5-HT synthesis, we developed an animal model with 5-HT chronic depletion in order to study the morphological changes induced by such treatment on serotoninergic and glial cells. PCPA saline solution was injected daily i.p. to adult rats for 14 days . The first dosis was 300 mg/kg followed by 13 dosis of 100 mg/kg. The control group was injected with the same volume of saline solution. Both groups of rats were anaesthetised one day after the last administration and were perfused intracardiacally with 4 % paraformaldehyde and 0.25 % glutaraldehyde in 0.1 M phosphate buffer pH 7.5. Sagital sections of cerebral hemispheres and transverse sections of the mesencephalon, medulla and pons were obtained with vibratome and stored at -20°C until immunocytochemical procedure. Sections were processed by the peroxidase-anti-peroxidase method using anti-5-HT, anti-gliofibrillary acidic protein (GFAP) or anti-S-100 protein. We observed in treated rats: i) absence of 5-HT fibers in caudate-putamen; ii) reduced immunostaining for 5-HT in the central areas of Raphe Dorsalis and Raphe Medialis Nuclei, but not in the other 5-HT nuclei, compatible with other reports indicating lowest turnover of Triptophan hidroxylase in the central area of the Nucleus Raphe Dorsalis; iii) similar immunostaining for S-100 protein compared with control group; iv) increased immunostaining for GFAP was observed. The astrocytes immunolabelled for GFAP showed a large soma with a great number of processes, resembling an astroglial reaction. This work was supported by grants of CONICET and UBACYT, Argentina.

T-588, A NOVEL COGNITION ENHANCER, PROTECTS RAT PRIMARY CEREBELLAR GRANULE CELL CULTURES AND PC 12 CELLS AGAINST β-AMYLOID NEUROTOXICITY. S. Ono*, N. Iwakami, H. Yamaguchi, and H. Narita. Research Laboratories, Toyama Chemical Co. Ltd., Toyama 930, Japan.

T-588 is under development for Alzheimer's disease (AD). Previous studies demonstrated that T-588 exhibited protective effects against cerebral anoxia in mice, ameliorated the memory and learning impairment in embolized and ischemic rats, and enhanced the neuronal transmitter system not only by increasing acetylcholine and noradrenaline, but also by facilitating phosphoinositide hydrolysis and cyclic AMP formation. Deposition of the β-amyloid protein (Aβ) is a characteristic of patients with AD. We investigated the effects of T-588 on *in vitro* models of neuronal cell death. Using primary rat cerebellar granule cells and PC 12 cells, we examined the protective effects of T-588 against neuronal degeneration caused by $A\beta_{25-35}$. The cell viability was quantitated by the LDH or MTT method. T-588 (0.1 - 10 μM) significantly protected neurons against $A\beta_{25-35}$ -induced neurotoxicity. Apoptosis can also be induced in rat hippocampal neurons by deprivation of serum in culture media. T-588 (1 - 10 μM) prevented serum deprivation induced cell death in a concentration dependent manner. Rat hippocampal neurons and cerebellar granule cells undergo necrosis when they are exposed to glutamate (50 μM, 15 min). T-588 (30 - 100 μM) markedly reduced the neuronal cell death. These results indicate that T-588 can interrupt the neurodegeneration associated with AD.

749.6

THE CHOLINERGIC CHANNEL ACTIVATOR (ChCA) ABT-418 PROTECTS AGAINST gp120 AND Aβ(1-42)-INDUCED NEUROTOXICITY D. Donnelly-Roberts*, L.Xue, O. Delbono, S. P. Arneric and J.P. Sullivan Neuroscience Research, D-47W, Abbott Laboratories, 100 Abbott Park, IL 60064-3500 & Bowman Gray School of Medicine of the Wake Forest University, Winston-Salem, NC 27157

ABT-418 is a novel ChCA with cognitive enhancing and anxiolytic-like effects in a number of species. Previously, we have shown ABT-418 to be neuroprotective against glutamate (GLU)-induced excitoxicity in vitro. Herein, we have extended the studies to two additional models of neurotoxicty; gp120- and Aβ(1-42)-induced toxicity. Accumulating evidence links gp120 and Aβ(1-42)-induced toxicity to the neuropathology associated with AIDS dementia complex and Alzheimer's disease. Exposure of primary rat cortical cells to either gp120 (pm-nm) or Aβ(1-42) for 5 days resulted in a significanct increase in the level of lactate dehydrogenase released into the extracellular media. Both gp120- and Aβ(1-42) induced toxicity was prevented in a concentration-dependent manner by ABT-418 (EC50 = 3.5 ± 0.5 and 3.2 ± 0.3 μM, respectively). Effects of ABT-418 are mediated via an interaction with the nicotinic acetylcholine receptors (nAChRs) since mecamylamine, α-bungaratoxin and methyllycaconitine (selective antagonists of the α7 subtype) attenuated the protection. GLU-, Aβ(1-42) and gp120-induced toxicity are associated with a disruption of intracellular calcium (Ca^{2+}) homeostasis. The finding that α7 nAChRs may be mediating the protective effects of ABT-418 raised the possibility that this compound may be altering intracellular Ca^{2+} dynamics. Indeed, ABT-418 can increase intracellular Ca^{2+} to a subtoxic/ neurotrophic level in cell lines expressing human α7 nAChRs. This modulation of Ca^{2+} may participate in a common cascade of intracellular events which result in neuroprotection. This work was supported by Abbott Laboratories.

THE GP120-INDUCED RISE IN $[Ca^{2+}]_i$ IN RAT HIPPOCAMPAL NEURONES IN CULTURE DEPENDS ON THE TIME OF CULTURE DEVELOPMENT. S. Ghose, I. Medina, Y. Ben-Ari and G. Mandl* INSERM, Unité 29, 123 bd Port-Royal, 75014 Paris; *Physiology Dept., McGill University, Montréal, PQ H3G 1Y6, Canada.

The HIV-1 envelope glycoprotein gp-120 is known to induce cell death in cultures of postnatal rat ganglion neurones (Dreyer et al., 1990). One of the earliest effects of gp-120 is an increase of intracellular calcium concentration ($[Ca^{2+}]_i$) in these neurones. We have studied the effect of gp-120 on $[Ca^{2+}]_i$ in rat hippocampal neurones in culture using confocal scanning microscopy with Fluo-3AM.

In neurones from neonatal (P0) rats, gp-120 (200-1000 pM) did not modulate $[Ca^{2+}]_i$ even after 28 days of development in culture (n=17). In neurones from P2 rats cultivated during 5-8 days, gp-120 also did not modulate $[Ca^{2+}]_i$ (n=8). After 9-11 days in culture, gp-120 (200 pM) increased $[Ca^{2+}]_i$ in 7 out of 13 neurones. Maintenance of neurones in culture during more than 13 days resulted in an increase of $[Ca^{2+}]_i$ induced by gp-120 (200 pM) in 45 out of 51 experiments. Therefore our first conclusion is that the effect of gp-120 depends on the postnatal age and the maturation in vitro of neurones.

To study the role of glia, we plated neurones on 7 days-old glial cultures. A rise of $[Ca^{2+}]_i$ was induced by gp-120 in neurones from P0 or P2 rats when these were plated during 5 days (or more) on glia from P2 but not from P0 rats. Thus glia at P2 but not at P0 have properties which are determinant for gp-120's action on neurones. Applications of a conditioning medium from cultures incubated with gp-120 (14 days-old cultures of P2 neurones responding to gp-120) to 7 days-old cultures of P2 or P0 neurones did not induce a rise of $[Ca^{2+}]_i$. This suggests that the determinant glial factor is not diffusible.

NEUROTOXICITY OF THE HIV-1 PROTEIN TAT IN PERINATAL RAT BRAIN. P. Wang, J. D. E. Barks*, F. S. Silverstein, Depts. of Pediatrics and Neurology, Univ. Michigan, Ann Arbor, MI

Two HIV-1 derived proteins, the transactivator protein Tat and the envelope protein gp120, are secreted by HIV-1 infected cells and can exert biological effects on adjacent uninfected cells. Both accelerate T-cell apoptosis and have been implicated as mediators of HIV neurotoxicity; the molecular mechanism(s) that underlie these shared effects are unknown. Deleterious effects of these proteins in the brain may include induction of cytokines, microglial activation, and indirect over-activation of excitatory amino acid (EAA) receptors; the immature nervous system may be particularly vulnerable. The goals of this study were to determine if Tat is neurotoxic *in vivo*, and if Tat increases susceptibility to neuronal damage resulting from over-activation of NMDA-type EAA receptors in neonatal rat brain. Experiments were performed in 7 day old rats; Tat, alone, or in combination with NMDA (5 nmol, threshold neurotoxic dose), was administered by stereotaxic intra-hippocampal (HIP) injection; HIP damage (quantitated morphometrically) was compared with outcome in controls that received equal amounts of heat-treated(ht)-Tat. Tat (250-500 ng) caused no overt tissue damage; 1 µg Tat was lethal. Co-injection of Tat (20, 100, or 500 ng) with NMDA resulted in dose-dependent increases in the severity of HIP damage (maximum > 2-fold increase)($p<0.005$, ANOVA). Treatment with the NMDA antagonist CPP (20 mg/kg) blocked HIP injury elicited by co-injection of Tat (100 ng) with NMDA ($p<0.001$). To test the hypothesis that Tat increased NMDA-induced apoptosis, TUNEL staining was used to identify apoptotic cells; numbers of reactive cells were compared in animals that were killed 6 h after administration of NMDA+Tat or NMDA+ht-Tat; the number of reactive cells was 30% higher in brain regions adjacent to the lesion core in the NMDA/Tat group. These data demonstrate that Tat increases susceptibility to NMDA-mediated neurotoxicity *in vivo* in mammalian brain, and suggest that Tat neurotoxicity may involve pro-apoptotic mechanisms. Whether these mechanisms contribute to neurodegeneration in children with CNS HIV infection remains to be determined. Supported by grant NS31054 (to FSS and JDEB)

PX-52 AND PX-18, NOVEL INHIBITORS OF PHOSPHOLIPASE A_2 (PLA_2), ARE NEUROPROTECTIVE *IN VITRO* AND IMPROVE SURVIVAL *IN VIVO* IN RATS. L. Clapp[1], R. Franson[2], E. Bernton, K. Klette, J. Dave, M. Laskosky and F. Tortella*. [1]Dept. Neurol., Walter Reed Army Med. Ctr. and Div. Neurosci., Walter Reed Army Inst. Res., Washington, DC 20307 and [2]Dept. Biochem., Virginia Comm. Univ., Richmond, VA 23298.

We have previously described the potent neurotoxic potential of a PLA_2 in *in vitro* (primary neuronal cultures) and *in vivo* (EEG/lethality) rat models of CNS injury (Brain Res. 693:1995). *In vitro*, PLA_2 is highly neurotoxic causing injury at a level comparable to water cell lysis. *In vivo*, i.c.v. injections of PLA_2 cause a delayed neurotoxic syndrome consisting of seizures progressing to death associated with extensive neuronal and axonal forebrain damage. In the present study, we confirmed that the active site of the PLA_2 enzyme appears to be essential for neurotoxicity since alkylation of the enzyme active site with *para*-bromophenacyl bromide eradicated *in vitro* PLA_2 neurotoxicity in primary neuronal cultures, and eliminated *the in vivo* lethality of PLA_2. Also, the degree of PLA_2 mediated neurotoxicity correlated directly with the neuronal release of arachidonic acid (AA). Further experiments identified the neuroprotective capability of PX52 and PX18, two novel unsaturated fatty acyl moiety containing PLA_2 enzyme inhibitors. *In vitro*, maximal neuroprotective concentrations (10 nM) of PX52 and PX18 resulted in complete (100%) neuroprotection and inhibited PLA_2-induced AA release by 62% and 46%, respectively. *In vivo*, pretreatment of rats with PX52 or PX18 (200 µg, i.c.v.) improved survival in PLA_2 treated rats (PLA_2 LD_{50} increased from 0.6 µg to 1.47 µg and 2.58 µg, respectively). These results confirm the role of a PLA_2 enzyme active site and AA release in PLA_2 neurotoxicity and describe the neuroprotective effects of a novel class of PLA_2 antagonists. (Research funded by the U.S. Army Medical Res. & Materiel Command)

749.10

Protease-Activated Receptor-2 (PAR-2) Is Present in the Rat Hippocampus and Is Associated With Neurodegeneration. **V.L. Smith-Swintosky *, R.J. Santulli, A.L. Darrow, C.T. Cheo-Issacs and P. Andrade-Gordon. The R.W. Johnson Pharmaceutical Research Institute, Spring House, PA 19477-0776.**

Protease activated receptor-2 (PAR-2) is a proteolytically activated seven transmembrane G-protein coupled receptor which possesses a similar structure and activation mechanism to the thrombin receptor. It is activated by low concentrations of trypsin (300 pM) and a synthetic hexapeptide (SLIGRL) representing the first 6 amino acids following the putative PAR-2 cleavage site. The active physiological protease for PAR-2 is unknown. In addition, relatively little is known about PAR-2 expression and function.

Previous studies have demonstrated that α-thrombin and SFLLRN (the thrombin receptor "tethered ligand") induce neurite retraction and neurotoxicity. In the present study, we demonstrate that PAR-2 is present in the rat hippocampus and that the PAR-2 "tethered ligand", SLIGRL, is toxic to hippocampal neurons in a concentration-dependent manner. RT-PCR was used to detect the presence of PAR-2 mRNA in 7 day old rat hippocampal cultures. Primers were designed to the rat thrombin receptor and murine PAR-2. Rat aortic smooth muscle cDNA served as a positive control. Products of the appropriate size were detected with each primer pair in cDNA from both rat aortic smooth muscle and hippocampus.

To determine the physiological role of PAR-2 in the brain, rat hippocampal cultures were treated with various concentrations of SLIGRL or SFLLRN. Cell survival was assessed at 48 h post-treatment by visual inspection. Neurons with a rounded soma and intact neurites were counted as viable. Neuronal survival was calculated as the percent of initial number of neurons. SLIGRL treatment caused a concentration-dependent decrease in neuron survival (>500 nM; $p<0.01$), which appeared more cytotoxic than SFLLRN (>30 µM; $p<0.001$). These results suggest that PAR-2 may play an important role in neurodegeneration and synaptic plasticity.

PROTEIN TYROSINE KINASES AND RHO A IMPLICATED IN THROMBIN-INDUCED TOXICITY. Frances M. Donovan, Christian J. Pike, Alan L. Goldin*, and Dennis D. Cunningham. Dept. of Microbiology and Molecular Genetics, and Irvine Research Unit in Brain Aging, University of California, Irvine, California 92717.

Thrombin is a multifunctional serine protease rapidly produced from prothrombin at sites of injury and implicated in many stages of inflammation and wound healing. Thrombin has numerous effects on neurons and astrocytes in vitro. Recently we reported that low nanomolar doses of thrombin protect neurons and astrocytes from toxic insults whereas higher doses are directly toxic. In the current study, we sought to characterize the cellular pathways that contribute to thrombin-induced cell loss. We exposed cultures of rat cortical astrocytes and rat hippocampal neurons to a panel of pharmacological agents predicted to either attenuate or promote thrombin-induced signal transduction cascades potentially underlying thrombin-induced toxicity. In astrocytes, thrombin caused DNA fragmentation suggesting an apoptotic form of cell death. In these cells, thrombin increased activity of Rho A, a regulator of actin cytoskelleton; exoenzyme C3, which inactivates Rho A, blocked toxicity in astrocytes. In addition, cytochalasins (agents that disrupt actin cytoskelleton) also blocked thrombin's modulation of viability in astrocytes. Further, thrombin -induced cell loss was significantly reduced by tyrosine kinase inhibitors and potentiated by tyrosine kinase activators. In cultured neurons, preliminary data show that thrombin-induced cell loss exhibits characteristics of both apoptosis and necrosis. Consistent with observations in astrocyte cultures, initial findings suggest that tyrosine kinase activators potentiate thrombin neurotoxicity. Further studies are required to determine the level of mechanistic similarity between the actions of thrombin on astrocytes and neurons. These data are consistent with recent reports form our group and others that thrombin is a significant modulator of cellular responses to central nervous system injury. TUMOR NECROSIS FACTOR AND CERAMIDE ACTIVATE PLATELET ACTIVATING FACTOR RECEPTORS TO INDUCE NEURONAL APOPTOSIS. K.A. Dzenko, S.W. Perry, H.J. James, R.A. Angel, S. Dewhurst[§], L.G. Epstein*, and H.A. Gelbard Depts. of Neurology, Pediatrics, Pharmacology and [§]Microbiology and Immunology, University of Rochester, Rochester, N.Y. 14642

We have previously demonstrated that the neurotoxins tumor necrosis factor alpha (TNFα) and platelet activating factor (PAF) are produced by antigenically activated monocytes infected with human immunodeficiency virus type 1 (HIV-1) and can induce dose-dependent neuronal apoptosis (Gelbard et al., 1994. J. Virology. 68:4628-4635; Talley et al., 1995. Mol. Cell Biol. 15:2359-2366). It remains unclear whether TNFα binds to receptors on neurons to induce neuronal apoptosis, or works through other mechanisms to induce neurotoxicity. We have demonstrated that TNFα (1-10 ng/ml)-mediated neuronal apoptosis can be significantly ameliorated by co-application of the PAF receptor antagonist WEB 2086 (10 µM). Similarly, C2 ceramide (10 µM)-mediated neuronal apoptosis can be ameliorated to the same degree by co-application of WEB 2086 (10 µM). However, PAF-mediated neurotoxicity is not abrogated by co-incubation with TNFα antibodies. We further demonstrate that application of TNFα at a dose of 1 ng/ml (within the range measured in conditioned media from activated HIV-1-infected monocytes) induces the formation of reactive oxygen species (ROS) in human fetal neurons. Here ROS are measured by oxidation of dichlorofluorescin using fluorescence microscopy. Neuronal ROS are present by 10 minutes after application of TNFα to primary human cerebral cortical neuronal cultures. ROS in neurons further increase up to 40 minutes after application of TNFα. In contrast, ROS are evident in neurons beginning 40 minutes after application of carbamyl PAF (125 ng/ml, resistant to catabolism by brain acetylhydrolases). Taken together, these results suggest that TNFα and ceramide induce PAF receptor activation, which in turn increases neuronal ROS as an early event in neuronal apoptosis. INHIBITION OF PROTEIN PHOSPHATASES INDUCES INSULIN-LIKE GROWTH FACTOR- DEPENDENT NEURONAL APOPTOSIS. M. T. Fernández-Sánchez*, A. García-Rodríguez, R. Díaz-Trelles and A. Novelli. Dept. Biochemistry and Molecular Biology and Dept. Psychology, University of Oviedo, 33006 Oviedo, Spain.

Abnormalities in protein phosphorylation are characteristic of some neurodegenerative disorders. However, the relation between abnormal protein phosphorylation and neuronal degeneration and death has not been established. We have previously described that exposure of neurons to the protein phosphatase (PP) 1 and 2A inhibitor okadaic acid (OKA) results in extensive neurotoxicity (Life Sciences 49, PL157, 1991). We now show that death induced by OKA involves the DNA fragmentation characteristic of apoptosis. Apoptotic neurotoxicity was abrogated by the transcriptional inhibitor actinomycin D indicating that protein synthesis is necessary. DNA fragmentation and cell death was observed for PP inhibitors with high affinity for PP2A such as OKA or calyculin A, but not for PP inhibitors with higher affinity for PP1, suggesting a major contribution for PP2A inhibition in the induction of neuronal apoptosis. Pretreatment of neurons with insulin growth factor-1 totally prevented OKA-induced DNA fragmentation and neurotoxicity. Neurotrophin-3 and brain-derived neurotrophic factor showed no effect, although they did protect neurons against degeneration following exposure to calcium channel antagonists. The L-type calcium channels agonist Bay K8644 significantly enhanced the survival of OKA-treated neurons, suggesting a dependence of OKA neurotoxicity upon calcium influx via voltage sensitive calcium channels. Accordingly, reduction of free extracellular calcium by the calcium quelator BAPTA significantly potentiated the neurotoxic effects of OKA, reducing both the number of surviving neurons and the time of exposure to OKA required to induce neurotoxicity. Neither activation of adenylate cyclase nor modulation of protein kinase C activity affected neurotoxicity by OKA, suggesting that protein kinases other than protein kinase A and protein kinase C may be involved in the phosphorylation of substrates affected by OKA and leading to apoptotic death. CALPAIN ACTIVATION AND CALPASTATIN PROCESSING IN CULTURED HUMAN RETINOBLASTOMA (Y-79) CELLS. Panaiyur S. Mohan* and Ralph A. Nixon Laboratories for Molecular Neuroscience, McLean Hospital; Harvard Medical School, 115 Mill Street. Belmont, MA 02178.

Activation of calpain I following a rise in intracellular concentration of calcium is considered to be important in the initiation of various physiological transduction pathways. Upon exposure to calcium the enzyme autolyzes from a 80 kDa precursor form to a 78 kDa intermediate form and a 76 kDa activated form. Autolysis can be prevented by its specific inhibitor calpastatin. Hence we studied calpain I activation in cultured human retinoblastoma (Y-79) cells in suspension. After incubation with 2-4 mM calcium, Y-79 cells showed substantial activation of calpain I as examined by antibodies that recognize precursor and activated calpain I isoforms and calpain-specific breakdown of spectrin (240 kDa) into 150 kDa and other small molecular forms. Concomitantly the 110 kDa native form of calpastatin was processed into 70 kDa, 41 kDa and 31 kDa forms that retained full calpain inhibitory activity. These effects were blocked by a membrane permeable calpain inhibitor calpeptin and could be reversed by removing excess calcium. This is the only cell line currently known to achieve reversible calpain activation without using calcium ionophores. Although treatment with excess calcium for 2-12 hours did not kill cells, prior attachment to poly D-lysine coated dishes greatly increased their vulnerability to cell death after calcium exposure. The ability of calpastatin to act as a suicide substrate by generating low molecular weight fragments with preserved inhibitory activity was confirmed in vitro with purified enzyme and inhibitor. While the native 110 kDa form of calpastatin was identified in Y-79 and human neuroblastoma (SH-SY5Y) cells, that purified from human brain, liver and spleen was composed of 110 kDa, 70 kDa and 41 kDa forms indicating proteolytic processing. On the other hand calpastatins partially purified from bovine, monkey, rabbit, rat and mouse brains and other tissues migrated as 110-130 kDa forms with minimal degradation. The proteolytic processing of calpastatin observed in human brain and other tissues was similar to that generated by activated calpain I in retinoblastoma cells. Therefore these cells may serve as a useful model system for studying calpain-calpastatin interaction and function. (AG-10916 to RAN)

LESIONING OF MEDULLARY NORADRENERGIC AND ADRENERGIC NEURONS USING THE IMMUNOTOXIN ANTI-DBH-SAPORIN. C.C. Wrenn*, M.J. Picklo, D.A. Lappi, D. Robertson, and R.G. Wiley. Department of Pharmacology, Vanderbilt University, Nashville, TN 37232.

Anti-DBH-saporin (α-DBH-sap) is an anti-neuronal immunotoxin comprised of an antibody against the noradrenaline synthesizing enzyme dopamine β-hydroxylase (DBH) coupled by a disulfide bond to the ribosome inactivating toxin saporin. This immunotoxin was injected into the left lateral ventricle of rats at doses of 5, 10, and 20 μg. After a two week survival time, the rats were sacrificed and the ability of the immunotoxin to lesion noradrenergic and adrenergic neurons was assessed by immunohistochemical staining for tyrosine hydroxylase (TH), DBH, and phenylethanolamine n-methyl transferase (PNMT). The locus coeruleus was completely lesioned at all three doses. The A5 and A7 cell groups were completely lesioned at the two higher doses. In the medulla, lesioning of the ventrolateral A1/C1 cell group and the dorsomedial A2/C2/C3 cell group was qualitatively observed to be incomplete at all three doses. Cell counts of TH+, DBH+, and PNMT+ neurons revealed that the number of neurons staining for each enzyme was reduced by the immunotoxin dose dependently. The ventrolateral population was lesioned more closely to completeness than the dorsomedial population. These data show that α-DBH-sap can be used to produce lesions of brainstem noradrenergic and adrenergic neurons. Supported by the Department of Veterans Affairs.

INDUCTION OF APOPTOSIS AND SECONDARY NECROSIS IN RAT DORSAL ROOT GANGLION CELL CULTURES BY OXIDIZED LOW DENSITY LIPOPROTEIN. A. Papassotiropoulos, M. Ludwig, W. Naib-Majani, M. L. Rao* and G. S. Rao. Inst. of Clin. Biochemistry, Inst. of Exptl. Ophthalmology, Lab. of Neurochemistry, University of Bonn, Sigmund-Freud-Strasse 25, 53105 Bonn, Germany

INTRODUCTION: Neural cell degeneration underlies central and peripheral nervous system disorders. Accumulating evidence suggests that neural cell loss, in many cases, occurs due to increased apoptosis. Oxidized low density lipoprotein (Ox-LDL) is an atherogen which exerts cytotoxic effects. Endothelial cells, smooth muscle cells and monocytes oxidatively modify the low density lipoprotein (LDL) molecule in the presence of transition metal ions. WORKING HYPOTHESIS: Since there is evidence for the occurrence of LDL in the CSF and of metal ions in the brain, it is highly probable that in the nervous system, LDL could be subjected to oxidative modification. In this study we examined the influence of Ox-LDL on rat dorsal root ganglion (DRG) cells in culture. MATERIALS AND METHODS: Cultures were established from adult rat (male Sprague Dawley) DRGs. Methods used to assess neurotoxicity were cell morphology, LDH release, the TUNEL-reaction and DNA fragmentation. RESULTS: Exposure of DRG cells to Ox-LDL (100 μg/mL) for 24 h led to elevation of LDH in the culture medium; short term exposure (4 h) induced apoptosis, evidenced by DNA fragmentation and a positive TUNEL-reaction. DRG cells modified LDL in the presence of Cu^{2+} to mildly oxidized and to a small extent to fully oxidized forms; these in situ generated LDL oxidation products were strongly toxic. CONCLUSION: Ox-LDL is a neurotoxin; it initiates apoptotic cell injury which progresses to necrosis and cell death.

INDUCTION OF C-FOS AND HSP 70 PROTEIN IN THE RAT BRAIN FOLLOWING HYPERBARIC OXYGEN-INDUCED CONVULSION.

A. Ishikawa, Y. Takeda*, M. Hirakawa. Dept. Anesthesiology & Resuscitology, Okayama Univ. Medical School, Okayama, 700 Japan

Acute oxygen toxicity of the central nervous system occurs at the onset of a grand-mal convulsion. The purpose of our study was to examine the effect of hyperbaric oxygen (HBO) on c-fos and HSP 70 protein induction in the rat brain by an immunohistochemical method. Rats were exposed to oxygen at 3.4 atmospheres absolute. HBO was terminated with the appearance of the first general tonic convulsion (GTC), or continued for up to 3 hours after the onset of compression if no GTC was noted. The animals were sacrificed at 2 hours or 1 day after exposure. C-fos protein was detected only in the brains of animals that had experienced a GTC. HSP 70 protein was not induced by HBO regardless of whether or not a seizure had occurred. C-fos protein was assayed in neurons (confirmed by double staining) in the dentate gyrus of the hippocampus, cerebral cortex, and piriform cortex.

OXIDANT-INDUCED NEUROTOXICITY WAS BLOCKED BY ANTI-OXIDANTS AND METAL CHELATORS IN MOUSE CEREBRAL NEURON CULTURES. S.T. Park,* Y.J. Mun, M.K. Choi, S.U. Kim, Y.T. Chung. Dept. of Anatomy, School of Medicine, Wonkwang University, Iksan, Korea, *Div. of Neurology, Dept. of Medicine, Univ. of British Columbia, Vancouver, Canada

It is well known that oxygen radicals induce neuronal cell damage by initiation of lipid peroxidation chain reaction. Recent work has been also demonstrated that enzymatically generated free radicals cause the release of glutamate and aspartate from cultured rat hippocampal slices. In order to characterize the mechanism of oxidant-mediated neurotoxicity in mouse cerebral neuron cultures, cultured cells were exposed to 20mU/ml glucose oxidase as H_2O_2 generating system after 2 hours of preincubation with oxygen radical scanvengers and metal chelators. Cell viability was determined by MTT assay and neurofilament ELISA assay. Glucose oxidase-induced neurotoxicity resulted in significant cell death in a time-dependent manner on cerebral neuron cultures. The neurotoxicity induced by oxygen radicals was blocked by superoxide dismutase(SOD)(1-60μg/ml), catalase(1-100μg/ml) and allopurmol (10-150μM) in a dose-dependent manner. Tetrakis(2-pyridymethyl) ethylene-diamine(TPEN), a metal chelator(5-30μM) also showed positive effect against oxidant-induced neurotoxicity in mouse cerebral neuron cultures. These results indicate that selective antioxidants and metal chelators such as catalase and TPEN are effective in protecting oxidant-induced neurotoxicity in CNS.

NEUROSTEROIDS AND GINKGO BILOBA EXTRACT PREVENT CELL DEATH INDUCED BY HYDROGEN PEROXYDE IN HIPPOCAMPAL NEURONAL CELL CULTURES: S. Bastianetto*, C. Ramassamy, S. Doré, J. Poirier and R. Quirion. Douglas Hospital Research Centre, Department of Psychiatry, Mc Gill University, Montreal, Quebec, Canada, H4H1R3.

There is some evidence that oxygen radical reactions play a role in the physiopathology of Alzheimer's disease (AD). Furthermore, oxydative stress induced by hydrogen peroxide (H_2O_2) is known to induce neuronal death in different types of mixed or primary neuronal cultured cells. The aim of the present study was to investigate the effect of the pro-oxydant H_2O_2 on cultured hippocampal neurons.

Primary cultures of hippocampal neurons were prepared under serum-free conditions (N2 supplement, Gibco BRL) according to the method previously described (Alonso et al, Mol. Cell. Neurosci., 5, 530-539, 1994). Cell viability assessed by the MTT (an indicator of mitochondrial activity) colorimetric assay is dose-dependently decreased after a 3h exposure of H_2O_2 (10^{-5}-10^{-4}M). The neurotoxic effect of H_2O_2 is attenuated in the presence of dehydroepiandrosterone sulfate (DHEA-S) (10^{-7}M), a neurosteroid with possible neuroprotective and beneficial effects in brain disorders such as AD. This protective effect was also observed in the presence of Ginkgo biloba extract (EGb 761, 10ug/ml), a free radical scavenger (Ramassamy et al., Biochem. Pharmacol., 44, 2395-2401, 1992).

In parallel, daily treatment of EGb761 (1-10ug/ml) or neurosteroids including DHEA-S (10^{-9}-10^{-7}M) increased the number of surviving neurons (assessed by MTT and acid phosphatase colorimetric assays) under serum-free conditions (N2 supplement). Taken together, these data suggest that EGb 761 and neurosteroids such as DHEA-S may prevent neuronal death induced by oxydative stress. Supported by MRCC.

IMAGING OF HYDROGEN PEROXIDE PRODUCTION IN CELLS AND MODEL SYSTEMS. P.E. Hockberger*, T.A. Skimina, S.S. Dadras, R. Chu, A.V. Yeldandi and J. K. Reddy. Depts. of Physiology and Pathology, Northwestern Univ. Medical School, Chicago, IL 60611.

Hydrogen peroxide (H_2O_2) is a normal by-product of oxygen metabolism. It is produced in peroxisomes by either superoxide dismutase or flavin-containing oxidases, and it is immediately reduced to water and oxygen by catalase or peroxidase. Excessive production of H_2O_2 has been implicated as a causal agent in several neuropathologies and cancers, although direct evidence has been lacking. We are using imaging techniques to evaluate the effectiveness of chemical probes for detecting H_2O_2 in cells and model systems (saline droplets & microcapillary wells). In model systems, carboxy-dichloro-dihydro-fluorescein-diacetate (C-DCDHF-DA) was a poor indicator of H_2O_2, because it was susceptible to photo-oxidation, whereas carboxy-dichloro-fluorescein-diacetate (C-DCF-DA) was more stable and fluorescent in the presence of H_2O_2. Fibroblasts, loaded with the acetoxymethyl ester form of C-DCDHF-DA, fluoresced when exposed to either H_2O_2 or light. The light-induced response was altered in cells with mutations in oxidase activity, and video analysis indicated that light-induced responses originated in subcellular organelles, most likely peroxisomes. These results, combined with the wavelength dependence of the response, suggest that H_2O_2 was generated in cells, possibly from light-induced activation of flavin-containing oxidases. Such a mechanism could be responsible for the phototoxic effect of visible light on cells.

This research was sponsored in part by The Whitaker Foundation (PEH) and the NIH (JR).

PROTECTION OF HYDROGEN PEROXIDE DAMAGE IN PC12 CELLS BY QUERCETIN. H. Wang*, J. Strain and J. A. Joseph. USDA-ARS, Jean Mayer Human Nutrition Research Center on Aging at Tufts University, Boston, MA 02111.

Oxidative stress has been implicated in various neurodegenerative diseases in aging. These neurotoxic insults from oxidative stress involve large increases in intracellular calcium (Ca^{2+}). Failure to maintain calcium homeostasis will eventually lead to cell death. However the exact role of oxidative stress on various parameters in Ca^{2+} increase has not been specified. We investigated possible antioxidants to combat the reactive oxygen species generated by oxidative stress involving Ca^{2+} flux. The protective effects of quercetin, a flavonoid compound commonly present in fruits and vegetables, against transient H_2O_2 damage in PC12 cells were examined by measuring Ca^{2+} flux prior to and following depolarization with KCl. Cystosolic free Ca^{2+} level was measured by analyzing fluorescent images using fluorescent indicator fura-2 with dual wavelength excitation in a computerized image analysis system. Exposure to H_2O_2 induced a rise in baseline Ca^{2+} in cells and inhibited the cells' ability to restore the Ca^{2+} levels to 20% of the total Ca^{2+} increase within 300 seconds after depolarization (Ca^{2+} RT). Preincubating the cells with quercetin for 60 minutes prior to H_2O_2 exposure prevented the rise of baseline Ca^{2+} and decreased the Ca^{2+} RT. Cells treated with quercetin alone exhibited greater Ca^{2+} flux into the cells upon depolarization than that seen in control cells, but the Ca^{2+} recovery was unaffected. Collectively, these data indicated quercetin could protect the cells from transient H_2O_2 damage and may act to modulate the function of voltage-gated calcium channels.

NGF PROTECTS DRG NEURONS FROM HYDROGEN PEROXIDE TOXICITY, IN VITRO. J. L. Podratz, S. W. Carmichael*, and A. J. Windebank. Molecular Neuroscience Program, Mayo Clinic, Rochester, MN 55905 USA

Hydrogen peroxide exposure increases the production of oxygen radicals leading to lipid peroxidation, protein oxidation and DNA damage of the cell. NGF has been shown to protect PC12 cells from hydrogen peroxide toxicity by upregulating catalase, superoxide dismutase (SOD) and glutathione peroxidase (GPx). Catalase, SOD and GPx protect the cell from oxygen radicals by converting superoxide anions, hydrogen peroxide and organic peroxides into water and oxygen. We studied the protective effects of NGF against hydrogen peroxide toxicity on intact and dissociated Dorsal Root Ganglion (DRG) neurons. The intact DRG contained both neurons and supporting cells while the dissociated cultures were treated with fluorodeoxyuridine (10 μM) to eliminate the support cells. Hydrogen peroxide (1 mM) in medium containing 3.5 ng/ml NGF produced beading of DRG neurites in intact neurons and induced cell death in dissociated DRG neurons. Neurite beading of intact DRG neurites was inhibited partially by increasing the concentration of NGF to 5 ng/ml NGF and completely inhibited by increasing NGF to 10 ng/ml. Cell survival of dissociated DRG neurons was increased when cultured in medium containing 10 ng/ml NGF These results indicate that NGF rescues DRG neurons from hydrogen peroxide toxicity by acting on the neurons themselves. It is most likely that this protection is achieved by upregulation of catalase or glutathione peroxidase (NIH, NS 14304).

CHLOROADENOSINE- AND NITRIC OXIDE-MEDIATED HIPPOCAMPAL NEUROTOXICITY *IN VITRO*. R. Wender, A. Barth*, H. R. Winn, D. W. Newell and D. Janigro. Dept. of Neurosurgery, Univ. of Washington, Seattle, WA 98104

Adenosine (ADO) and nitric oxide (NO) have been implicated in a variety of neurophysiological actions, including induction of long-term potentiation, regulation of cerebral blood flow, and neurotoxicity/neuroprotection. ADO has been shown to promote NO release from astrocytes by a direct effect adenosine receptors, thus providing a link between actions of NO and adenosine in the brain (Janigro *et al.*, Neuroreport, in press). We have investigated the effects of adenosine and NO on neuronal viability in cultured organotypic hippocampal slices exposed to sub-lethal (20') *in vitro* ischemia. Up to a concentration of 500 μM ADO did not cause toxicity while exposures to 100 μM of the stable ADO analogue chloroadenosine (CADO) caused widespread neuronal damage. CADO effects were significantly prevented by the ADO receptor antagonist theophylline and blockade of NO production by L-NA (100 μM). Moreover, CADO effects were mimicked by the NO donor SIN1 (100 μM). Application of 100 μM ADO following blockade of adenosine deaminase (with 10 μM EHNA) replicated the effects of CADO. CADO, ADO+EHNA but not ADO alone caused a prolonged and sustained release of nitric oxide as measured by direct amperometric detection. We conclude that at high concentrations and/or following blockade of its enzymatic catabolism, ADO may cause neurotoxicity by triggering NO release from astrocytes. These results demonstrate for the first time that activation of pathways other than those involving neuronal glutamate receptors can trigger NO-mediated neuronal cell death in the hippocampus. NITRIC OXIDE AND DOPAMINERGIC NEURONAL DEGENERATION. M. B. Mattammal*, H. Macarthur, J.E. Morley and T. C. Westfall. Geriatric Research Education and Clinical Center, VA Medical Center, Jefferson Barracks St. Louis , MO, 63125 and Department of Pharmacological and Physiological Sciences, St. Louis University Heath Science Center, Saint Louis University School of Medicine, St. Louis, Missouri, 63104.

There is evidence to show that in parkinsonian substantia nigra there is a marked increase of reactive macrophages-microglia. Macrophages can cause the death of mesencephalic dopaminergic neurons. Activated macrophages synthesize nitric oxide (NO) and reactive nitrogen oxides from L-arginine. NO and its derivatives $ONOO^-$, NO_2^-, NO_2^- are powerful oxidants, cause lipid peroxidation and inhibition of mitochondrial iron-sulfur enzymes. Recently we have shown the NO donor sodium nitroprusside or authentic NO treatment caused an apparent inhibition of dopamine or norepinephrine release from PC12 cells. Absorption spectroscopic studies revealed that dopamine and norepinephrine are oxidized by NO. Dopamine and norepinephrine gave nitrated-indole derivatives as the major isolable product. The studies reveal that in CNS, NO generated from activated macrophages can interact with dopamine or norepinephrine resulting in the inhibition of the biological activities of these neurotransmitters.

THE NITRIC OXIDE SYNTHASE INHIBITOR, AMINOGUANIDINE, BLOCKS PERMEABILITY INCREASES IN THE BLOOD-BRAIN BARRIER DURING EXPERIMENTAL MENINGITIS. K.M.K. Boje*. Dept. of Pharmaceutics, School of Pharmacy, University of Buffalo, Buffalo, New York, 14260 USA

Increased permeability of the blood-brain barrier (BBB) occurs subsequent to an inflammatory process during meningitis. It was hypothesized that pathological production of nitric oxide (NO) contributes to BBB breakdown during experimentally - induced meningitis in the rat. Experimental meningitis was initiated with the intracisternal administration of lipopolysaccharides (LPS) or vehicle. Groups of rats were concomitantly infused with saline or aminoguanidine (AG). BBB alterations were pharmacokinetically quantitated using ^{14}C-sucrose 8h after LPS dosing. Serum and regional brain tissues were obtained 0-30 min after tracer dosing. Sucrose influx transfer coefficients ($K_{in(app)}$) were calculated from the regional brain tissue data. Increased BBB barrier penetration of ^{14}C-sucrose was observed in LPS/saline infused rats, as $K_{in(app)}$ increased 1.6-2.1 fold from control. Remarkably, $K_{in(app)}$ data for the LPS/AG infused rats were similar to the observed control saline/AG and saline/saline groups. A separate experiment showed that the AG dosing regimen was effective in blocking NO production from meningeal tissues obtained from rats with meningitis. In conclusion, these data suggest that NO production during meningitis may contribute to alterations in BBB permeability. (NIH NS31939.)

BALANCE BETWEEN THIOL AND S-NITROSOTHIOL DETERMINES NEUROTOXICITY IN CORTICAL CULTURES. Danielle M. D'Emilia, Nikolaus J. Sucher*, Jonathan S. Stamler†, and Stuart A. Lipton. Department of Neurology, Children's Hospital; Program in Neuroscience, Harvard Medical School, Boston, MA 02115; and †Dept. of Medicine, Duke University Medical Center, Durham, NC 27710.

S-nitrosocysteine (SNOC) and S-nitroso-homocysteine (SNHC) may be formed under physiological conditions (Stamler et al., *J Clin Invest* 1993; Scharfsteine et al., *ibid.* 1994;). Such nitrosothiols may be neurotoxic to cerebrocortical cultures via formation of peroxynitrite from NO• and $O_2^{\bullet-}$ (Lipton et al., *Nature* 1993). Additionally, cysteine or homocysteine themselves may be neurotoxic by acting directly as agonists of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor (Olney et al. *Science* 1990; Kim et al., *Soc Neurosci Abstr* 1995). Paradoxically, however, we show here that approximately millimolar concentrations of cysteine or homocysteine can protect from acute exposures to relatively low concentrations of SNHC (50 μM) that are normally neurotoxic. Other thiols can substitute equally well for cysteine and homocysteine in this regard (e.g., N-acetylcysteine and glutathione; *n* = 11 experiments). Nitrosothiol undergoes homolytic cleavage to produce NO• and subsequent neurotoxicity. By adding thiol, one can stabilize nitrosothiol (Feelisch and Stamler, Methods in Nitric Oxide Research 1996). Thus, the balance between thiol and nitrosothiol merits consideration in determining the outcome in studies of neuronal degeneration. While these are in vitro observations, our data highlight the importance of equilibria that exist between thiols and nitrosothiols.

BUTHIONINE SULFOXIMINE COMBINED WITH DOPAMINE DECREASES BRAIN GLUTATHIONE LEVELS AND PRODUCES DEFICITS IN SPATIAL LEARNING AND MEMORY. B. Shukitt-Hale* and J.A. Joseph. USDA, Human Nutrition Research Center on Aging at Tufts Univ., Boston, MA 02111.

It has been shown that administration of buthionine sulfoximine (BSO) selectively inhibits glutathione (GSH) biosynthesis and induces a GSH deficiency. Since GSH plays a critical role in intracellular antioxidant defense, decreased GSH levels in the brain result in less oxidative stress (OS) protection. Thus, the pro-oxidant effects of dopamine (DA), which rapidly auto-oxidizes to form reactive oxygen species, may increase. To test the cognitive behavioral consequences of this reduced OS protection, BSO (3.2 mg in 30μl Ringer's solution) was administered (i.c.v.) to male Fischer 344 rats every other day for 4 days. In addition, DA (15μl of 500μM) was administered every day [either 1h after BSO (BSO + DA group) or 1h before BSO (DA + BSO group)] and spatial learning assessed (Morris Water Maze, six trials/day). BSO + DA rats demonstrated cognitive impairment compared to both Vehicle and DA + BSO groups in three important measures: 1) increased escape latencies to find the hidden platform, particularly on the first trial each day; 2) non-spatial strategies during the probe trials (60 sec swim with no platform) (e.g., fewer crossings and longer latencies to the previous platform location, as well as more time spent around the edge of the pool rather than in the zone that had contained the platform); and 3) longer escape latencies to learn a new platform location during reversal training. No differences were seen between the groups with respect to swim speed. Therefore, the cognitive behavioral consequences of reducing GSH brain levels with BSO in conjunction with DA administration depends on the order of administration. These findings are similar to those seen previously on rod walking and beam walking performance, as well as to those seen in aged rats, suggesting that the auto-oxidation of DA coupled with a reduced capacity to respond to oxidative stress may be responsible for the induction of age-related cognitive deficits. ROLE OF GLUTATHIONE PEROXIDASE IN THE PROTECTION OF NEURONS AND GLIA FROM OXIDATIVE STRESS. O. Ben-Yoseph[1], J.A. Dykens[2], P.A. Boxer*[2], J. Levy[1] and B.D. Ross[1]. [1]Dept. of Radiology, University of Michigan, Ann Arbor, MI 48109 and [2]Parke-Davis Pharmaceutical Research, Div. Warner-Lambert Co., Ann Arbor, MI 48105.

Oxidative stress has been implicated in the etiology of various neurodegenerative disorders as well as aging. Hydrogen peroxide (H_2O_2), a pro-oxidant generated as a product of normal metabolism, is detoxified by glutathione peroxidase (GPx) or converted to cytotoxic hydroxyl radicals via the Fenton reaction. We have previously reported (Ben-Yoseph et al., 1996, *J. Neurochem.* 66) that the glutathione pathway is activated by H_2O_2 in primary mixed and glial purified cerebrocortical cultures, as evidenced by stimulation of the enzymatically linked pentose phosphate pathway (PPP). The present experiments sought to assess the differential role of neuronal and glial GPx in detoxifying endogenously produced H_2O_2. The GPx inhibitor mercaptosuccinate (MS, 3 mM) was toxic to cultured cerebellar granule neurons and caused an inhibition of H_2O_2-induced stimulation of the PPP. Electron paramagnetic resonance (EPR) studies using the spin trap α-pyridyl 1-oxide N-tert- butyl nitron (POBN) revealed a low intensity radical signal with hyperfine splitting values consistent with lipid peroxyl and hydroxyl radicals. In contrast, a similar paradigm with glial cultures resulted in neither toxicity nor EPR signal. These results indicate the pivotal role of GPx in protecting cells from endogenously produced H_2O_2. Furthermore, they suggest that the reserve capacity of the PPP and/or GPx may be the determining factor in the cell's susceptibility to oxidative stress, thus conferring higher resistance in glia compared to neurons.

NOVEL FIXED SIDE CHAIN CATECHOLAMINES as NEUROTOXINS. Russell J. Lewis, Robert Johnson, Charles Francis, Roland E. Lehr, C. LeRoy Blank*, Department of Chemistry & Biochemistry, University of Oklahoma, Norman, OK, USA, 73019.

Investigation of fixed side chain catecholamines (tri-substituted quinolines) showed substantially more serotonergic depletion in mouse brain than the generally accepted neurotoxin 5,7-DHT, but with only moderate selectivity. The extent of neuronal destruction afforded by these toxins was measured as their ability to elicit long-term depletion of endogenous transmitters, i.e., NE, DA, 5-HT, using LCEC. The uptake blockade interaction of these toxic agents with NE, DA, and 5-HT uptake sites appears to be competitive; however, the affinities for these sites are only modest, with Ki's ranging from 14 to 280 μM and an apparent facilitation of uptake for DA and NE with a 6,8-dihydroxy analog. Investigation of autoxidation showed that oxidation rates of 6,7-dihyroxy analogs increased in the presence of metal ions, while the 6,8-dihydroxy analog showed an overall slower rate and no significant rate change upon addition of metal ions. Examination of reactive O_2 species produced during autoxidation showed the majority of O_2 consumed leads to prodution of H_2O_2, which generally decreased with an increase in metal ion concentration. Pathways leading to the production of $O_2^{-\bullet}$ appeared to be negligible. We are currently investigating OH• production during autoxidation. Mitochondrial oxidative phosphorylation effects of these toxins has been investigated; preliminary results indicate oxidative phosphorylation inhibition of 20-30% for ca. 200 μM toxin concentrations. While this class of compounds is neurotoxic, there is a lack of correlation between an individual toxin's uptake blockade and/or ease of oxidation and its neurotoxic potency.

STRESS MAY AFFECT ANTIOXIDANT ENZYME ACTIVITY AND OXIDATIVE DAMAGE AFTER KAINIC ACID-INDUCED SEIZURES L J McIntosh*, K M Cortopassi, J Liu, B N Ames, R M Sapolsky Department of Biological Sciences, Stanford University, Stanford, CA 94305.

Glucocorticoid stress hormones (GCs) are known to exacerbate neuron death during a variety of metabolic crises such as ischemia, shock, and seizure. The increased pathology may be due to GC interference in pathways protective against oxidative damage. Preliminary experiments in this laboratory suggest that GCs decrease the activity of antioxidant enzymes in the brain and liver in a tissue-specific and enzyme-specific pattern. Cu/Zn superoxide dismutase was significantly decreased in hippocampus, cortex, and cerebellum ($p=0.01$), catalase was lower in cerebellum and liver ($p< 0.01$), and glutathione peroxidase decreased in hippocampus and cortex ($p<0.02$). Since cells would normally upregulate the amount of protective cellular compounds in response to an insult such as a seizure, we are testing whether GCs not only drive down the basal activity of these enzymes, but also blunt the expected compensatory increase in enzyme activity. Enzyme activities are being analysed at 0, 2, 4, 8, 12, and 24 hours post kainic acid injection (10 mg/kg). Each tissue cytosol is then being tested for lipid and protein oxidative damage to determine if enzyme activity and damage correlate. The results will indicate the importance of oxidative damage after seizure, and whether the neurotoxicity of GCs can be partially attributed to influencing the antioxidant protection system. MEASUREMENT OF SUPEROXIDE, NITRIC OXIDE, MALONDIALDEHYDE, AND PROTEIN CARBONYL CONTENT FOLLOWING IMPACT INJURY TO RAT SPINAL CORD. D. Liu*, M. L. Leski, H. Qian and T. Sybert. Departments of Human Biological Chemistry & Genetics and Neurosurgery, and Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77555-1143.

To provide *in vivo* evidence for the hypothesis that free radical-triggered oxidative damage is the final common pathway for neuronal death in central nervous system injury, we measured free radicals and oxidative products following impact (75g.cm) injury to the rat spinal cord. An unique method established in our lab was used to measure superoxide ($O_2^{\cdot-}$) levels. Cytochrome *c* was infused into rat spinal cord through a cannula and reduced cytochrome *c* from perfusates was quantitated colorometrically. We found that levels of $O_2^{\cdot-}$ increased 3-fold upon impact injury ($N=5$) and that co-infusion of superoxide dismutase reduced this increase ($p<0.05$; $N=5$). Using a nitric oxide ($NO^{\cdot}$)-sensitive electrode, we found that $NO^{\cdot}$ levels rose immediately and returned to basal levels in two hours. Nitro-L-arginine (1mg/kg, ip) - an inhibitor of nitric oxide synthase - reduced $NO^{\cdot}$ to basal levels in one hour. Protein carbonyl content - a marker for oxidative damage to protein - was measured spectrophotometrically after treatment of the tissue extracts with 2,4-dinitrophenylhydrazine. The carbonyl content in protein samples from the injury site (3.7 ± 1.2, $N=6$) was significantly higher than those 1.5 cm away from the injury center (2.5 ± 1.1, $N=6$, $P<0.05$). Malondialdehyde (MDA) - an end product of membrane lipid peroxidation - levels were measured using HPLC after treatment of microdialysates with thiobarbituric acid. MDA levels gradually increased following injury. The increased levels of free radicals and products of oxidative damage to protein and membrane lipids observed following spinal cord injury support the hypothesis that free radical-triggered oxidative damage plays an important role in secondary injury. MEASUREMENT OF DITYROSINE AFTER EXPOSURE TO HYPERBARIC OXYGEN (HBO) AND CHRONIC ADMINISTRATION OF CORTICOTROPIN RELEASING FACTOR (CRF) C.M. Cortes, P.A. Shea, S.T. Ahlers, C.A. Auker, A. Verma[2], I. Elayan, and J. Schrot Diving and Environ. Physiol. Dept., Naval Med. Res. Inst.;[2]Dept. Neurol., Uniform. Serv. Univ. Hlth. Sci., Bethesda, MD

The amino acid tyrosine has been shown to dimerize to form dityrosine under conditions where the formation of reactive oxygen species (ROS) is increased. Several studies have suggested that the presence of dityrosine could be a useful biological marker for oxidative stress. In the present study we measured levels of dityrosine in cerebral spinal fluid (CSF) in rats exposed to acute HBO stress or a chronic stress regimen in which CRF is administered repeatedly. Groups of rats were exposed to 4 ATA HBO from 0-20 minutes. Immediately after the exposure they were euthanized and CSF removed from the cisterna magna. In the CRF study rats were fitted with a chronic guide cannula in to the lateral ventricle, allowed to recover, and then administered 3.0 µg CRF or saline once a day for 6 days. 48 hours after the last injection rats were euthanized and the CSF sampled as previously described. Dityrosine was measured using high performance liquid chromatography with electrochemical detection. Analysis indicated that a 1 minute exposure to HBO doubled CSF dityrosine; exposure to 4 ATA HBO for 10 or 20 minutes produced a 3-fold increase in CSF dityrosine. Administration of CRF chronically doubled the levels of dityrosine relative to saline injected controls. The results demonstrate that acute HBO exposure or chronic stress induced by CRF can increase the production of ROS in brain. DEVELOPMENT OF A MICRODIALYSIS PROCEDURE TO MEASURE NEUROTRANSMITTERS DURING EXPOSURE TO HYPERBARIC OXYGEN (HBO) P.A. Shea[1], T.M. Kerr[1], C.M. Cortes, S.T. Ahlers, N.S. Nadi, and C.R. Auker. Div. Exp. Physiol. Dept., Naval Medical Res. Inst., Bethesda, MD; [2]Dept. Neuropharm., Scripps Res. Inst., La Jolla, CA

Exposure to 100% hyperbaric oxygen (HBO) has neurotoxic effects (including seizures). These effects are thought to directly or indirectly result from changes in endogenous excitatory amino acid neurotransmitters. HBO-induced changes in endogenous catecholamines have also been suggested. Elucidation of neurotransmitter dynamics would be greatly aided by measurement of neurotransmitter changes using in vivo microdialysis during exposure to HBO. However, performing microdialysis experiments in hyperbaric oxygen environments is a unique challenge, as the equipment used to collect dialysate samples presents a significant electrical fire hazard. We have configured a hyperbaric chamber that allows the use of in vivo microdialysis measurement of neurotransmitters during HBO. CMA\Microdialysis equipment was modified to perform in a nitrogen-rich hyperbaric chamber. This equipment was connected to tubing in and out of a sealed box residing inside the hyperbaric chamber through which pure oxygen constantly flowed. The chamber, including the box with an awake, freely moving rat, was pressurized to depths of 33-99 feet of seawater. Analysis indicates that exposure to HBO increases extracellular norepinephrine in striatum and hippocampus. Increases in excitatory amino acids and GABA were observed in these regions but only after exposure to HBO produced a running bouncing seizure. (Supported by NMRDC work unit #62233MM33P30.005-1519)

OXYPURINE METABOLISM AS AN INDEX OF OXIDATIVE STRESS IN THE NERVOUS SYSTEM OF RATS EXPOSED TO NORMOBARIC HYPEROXIA, D. B. Holmes* and P.C. Bickford , Veterans Administration Medical Center, Research Service, and the Dept. of Pharmacology, Univ. of Colo. Health Science Center, Box C-236, Denver, CO 80262

Free radical mediated damage to neurons has been implicated in aging, trauma, and many neurodegenerative diseases. However, the study of reactive oxygen species (ROS) is often hindered by difficulties in quantifying the degree of *in vivo* tissue stress. Alterations in oxypurine metabolism, characterized by inhibition of xanthine dehydrogenase (XDH) and stimulation of xanthine oxidase (XO) and uricase, has become a standard biochemical marker of oxidative stress in animals subjected to ischemia reperfusion injury (IRI) models. In this study we provide data on the time-course and role of purine metabolism as a biochemical index of oxidative stress in the brains of rats subjected to prolonged exposure to normobaric hyperoxia.

Male Fischer F344 rats were placed into oxygen chambers and subjected to normobaric (760 mmHg) hyperoxia (90-100% O2 tension) for varying time periods of 0, 12, 24, 36, and 48 hours of O2 exposure. Various brain regions were then assayed for concentrations of xanthine oxidase and uricase metabolites utilizing high performance liquid chromatography (HPLC) with UV detection. Our data demonstrates a clear parallel between IRI induced oxidative stress as compared to normobaric hyperoxia exposure and the resultant alterations in oxypurine metabolism in the nervous system.

EFFECT OF ANTIOXIDANT TREATMENT ON THE VCM SYNDROME. D.A. Klugewicz*[1], K. Tracy[1], T. Lafargue[1], J.L. Goldman[1], M.P. Sanfilipo[1], M.F. Egan[2] and J. Rotrosen[1]. [1]Departments of Psychiatry, NYDVAMC, New York, NY & NYU Medical Center, New York, NY and [2]NIMH at St. Elizabeth's, Washington, DC.

It has been hypothesized that neuroleptic treatment increases free radical formation causing oxidative damage to neuronal membranes, in turn resulting in the dyskinetic movements which characterize tardive dyskinesia (TD). Since oxidative damage may be preventable and reversible in its early stages, antioxidants such as vitamin E (vit E) may be used for prophylaxis and/or treatment. The goal of these studies was to assess the effect of vit E on the development of the vacuous chewing movement (VCM) syndrome which has been proposed as an animal model of TD.

Male Sprague-Dawley rats were randomly assigned to one of 4 groups: +H/+E (haloperidol decanoate, 28.5 mg/kg, IM, every 21-30 days and vit E supplemented diet, 1000 mg/kg food), +H/-E, -H/+E, -H/-E. Three weeks prior to haloperidol treatment, animals were placed on their appropriate diets and maintained on these throughout the entire study. Animals were injected with haloperidol or vehicle every 21-30 days through day 228. Throughout the haloperidol treatment phase of the study, animals were observed for VCMs on the day before each injection. Following day 228, animals were observed for VCMs every 10-14 days.

A group x treatment repeated measures ANOVA revealed significant group differences, significant treatment differences, and a significant group x treatment interaction. VCM scores were higher for +H rats than -H rats (independent of vit E treatment) during treatment and withdrawal, and +H/+E rats had lower VCM scores than +H/-E rats for all except two observations. Furthermore, a greater number of rats met criteria for the VCM syndrome in the +H/-E group than in the +H/+E group. Overall, these results indicate that vit E may provide partial protection against the development of the VCM syndrome. The variability and magnitude of the vit E effect is consistent with its minimal to moderate efficacy in treatment of TD in humans. Neurochemical studies will be conducted to address pathophysiology and mechanism of action.

BRAIN ALUMINUM CONCENTRATION: NEW LOW ESTIMATE AND INFLUENCE OF CONTAMINATION. E.G. Chikhale[1], D.R. Brady[1], C.R. Swyt[2], G. Gillen[2], N.M. Appel*[1,3] and Q.R. Smith[1]. [1]Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892, [2]National Institute of Standards and Technology, Gaithersburg, MD 20899 and [3]FDA, Laurel, MD 20708.

Literature values for normal brain aluminum (Al) concentration vary over several orders of magnitude, with most values in the range of 0.2 - 1 μg Al/g wet weight. However, Al is abundant in the environment which may cause problems with regard to contamination. We examined this issue using graphite furnace atomic absorption spectrometry and extreme methods to avoid or limit Al contamination. Rat brain samples were dissected in a clean HEPA-filtered biosafety hood using powder-free gloves. Plastic ware was decontaminated by an extensive washing procedure with acid, EDTA and MilliQ water. Samples were digested in Ultrex II nitric acid (J.T. Baker, Phillisburg, NJ) and analyzed in triplicate. All chemicals and solutions were monitored and verified to be Al-free. Contaminated chemicals (10 - 100 μg Al/L) were replaced by freshly prepared or ultra pure equivalents. Using these procedures, rat brain Al concentration was found to be $\leq$ 0.02 μg Al/g wet brain (n = 13), which is more than an order of magnitude lower than most standard literature estimates. In our assay the limit of detection was $\leq$ 0.01 μg Al/g wet brain weight. Despite our precautions to prevent Al contamination, 10% of the samples did exhibit 3 - 10 fold higher Al concentrations than the corresponding triplicate values. Al recovery from Al doped rat brain samples (1 - 2 μg Al/g wet brain weight) was 68 - 92%. In conclusion, these results demonstrate that rat brain Al is much lower than previously thought and that contamination is a major factor in brain Al assays.

EMERGENCE AND PROGRESSION OF ALUMINUM EFFECTS ON MOUSE NEUROBEHAVIORAL INDICES DURING CHRONIC DIETARY EXPOSURE. M. S. Golub*, S. L. Germann, C. L. Keen, Dept. of Internal Medicine, Univ. California, Davis, CA 95616.

Previous studies have shown that excess dietary aluminum (Al) alters grip strength and auditory startle in mice. This experiment examined the time of onset and progressive nature of these changes. Swiss Webster mice (n=24/group) were fed purified diet with control (7 μg Al/g diet) or high (1000 μg Al/g diet) Al lactate from puberty (35 days of age) through middle age (215 days of age). They were evaluated every 2 wks for grip strength with an online strain gauge, and auditory startle (50 trials, 120 db buzzer) with an automated apparatus. Body weight, determined at 2 wk intervals, and brain and liver weights at 215 days of age, were not influenced by Al. Spinal cords were significantly heavier and had greater Al concentrations in the high Al group. Depression in startle response amplitude began 4 wk after diet initiation and continued throughout the exposure period. Hindlimb grip strength was lower from 2 to 6 wks after diet initiation but was similar to controls on subsequent tests. Forelimb grip strength declined in the high Al group, but not in controls, after 18 wks. Both tests showed an early pattern of change suggesting a practice effect. These data suggest that manifestations of CNS response to chronic Al exposure differ in time of onset and progressive nature. In general, progressive degenerative effects were not observed. Duration of exposure, the time of testing during chronic treatment and number of repeated tests are important factors in characterizing CNS toxicity at the neurobehavioral level. Supported by ES04190.

ALUMINIUM ACCUMULATION AND TOXICITY IN CULTURED NEURONS AND ASTROCYTES. A. Novelli*, M. B. Suárez-Fernández, M.T. Fernández-Sánchez, A. Torreblanca-Pacios, J. A. Vega, A. B. Soldado, A. Sanz-Medel. Dept. Biochem. and Mol. Biol., Dept. Psychol., Dept. Physical and Anal. Chem., Dept. Morphol. and Cell. Biol., Univ. Oviedo, 33006 Oviedo, Spain.

Molecular mechanisms of Al^{3+} neurotoxicity are poorly defined. We have studied the effects of prolonged exposure to Al^{3+} on cultured cerebellar neurons and astrocytes. Following exposure of neurons at 10-12 days in culture to $AlCl_3$ (1 mM) in the neuronal growth medium for 8 days, in the presence of citric acid (1mM) as a chelating agent, up to 60 nmoles of Al^{3+} were found to be associated to 10^6 neurons, as measured by atomic absorption in a grafite oven. In the event that Al^{3+} may be accumulated in the neurons, the intracellular concentration should be approx. 30 mM Al^{3+}, assuming an approximate diameter of 8.6 μm for the neuronal cell body, and a total volume for the cell body and the neurites of approx. 2 pl/neuron. Al^{3+} treatment produced only a small although significant reduction in neuronal survival (- 20%, p=0.016). A longer exposure to Al^{3+} did not further reduce neuronal survival. Glutamate neurotoxicity was not significantly enhanced by Al^{3+} treatment. Because neuronal survival in culture is dependent upon trophic Ca^{2+} influx via voltage sensitive calcium channels (VSCC), we measured Ca^{2+} influx via VSCC in Al^{3+}-treated neurons by using confocal laser microscopy. Intracellular Ca^{2+} concentration increase following KCl (50 mM)-mediated VSCC opening, was unaffected either by the acute presence of Al^{3+} or by a prolonged Al^{3+} treatment. Accordingly, neuronal exposure to Al^{3+} from 4 days in culture, a crucial moment for calcium-dependent neuronal survival, did not produce neuronal loss nor morphological differences compared to untreated cultures. Exposures to Al^{3+} of neurons co-cultured with astrocytes produced neuronal clustering, a reduction in neurite-astrocyte adhesion, and a significant reduction of neuronal survival that was associated to an extensive DNA fragmentation characteristic of apoptosis. We suggest that Al^{3+} effects on the interaction between neurons and astrocytes may be relevant to understand Al^{3+} encephalopathy. Supported by CICYT, Grant SAF94-0394.

THE VALENCE STATE OF MANGANESE AND IRON QUANTITATIVELY INFLUENCES THEIR NEUROTOXIC EFFECTS AS MEASURED BY LIPID PEROXIDATION AND HISTOLOGICAL EVALUATION. H.M. Duhart, L. Schmued, W. Slikker, Jr., D. B. Miller* and S.F. Ali. Neurochemistry Laboratory, Division of Neurotoxicology, National Center for Toxicological Research/FDA, Jefferson, AR 72079 and *Neurotoxicology Division, USEPA, Research Triangle Park, NC 27711.

Manganese (Mn) and Iron (Fe) are essential elements, however, deficiencies or excesses of either are known to cause neurotoxicity in animals and humans. The present study was designed to evaluate whether the valence state of Mn and Fe differentially influences the oxidative stress caused by these compounds as measured by malonaldehyde (MDA) and 4-hydroxyalkenals [4-hydroxy-2(E)-nonenal (4-HNE)] levels as indices of lipid peroxidation. *In vitro* exposure to MnOAc (Mn^{+3}) produced dose-dependent increases in MDA and 4-HNE levels in several regions of rat brain whereas $MnCl_2$ (Mn^{+2}) showed an increasing trend only in hippocampus, cerebellum and brainstem. Mn^{+3} was threefold more potent than Mn^{+2}. *In vitro* exposure to iron (Fe^{+2} or Fe^{+3}) produced dose-dependent increases of lipid peroxidation in different regions of the rat brain. Fe^{+2} was tenfold more potent than Fe^{+3}. Lipid peroxidation and histological evaluation after intrastriatal injection of these ions also demonstrated that Mn^{+3} and Fe^{+2} produced degeneration at lower doses than Mn^{+2} and Fe^{+3}. These data suggest that the various valence states of Mn and Fe have different potencies in producing oxidative stress as measured by lipid peroxidation and histological evaluation. INVESTIGATION OF HUMAN SERUM TRANSFERRIN INTERACTING WITH FE, MN AND PB USING CIRCULAR DICHROISM SPECTROSCOPY. R. Rosal and L. Claudio*. Departments of Community Medicine and Pathology, Mount Sinai Medical Center, New York, NY 10029.

Analyzing the role of serum proteins in modulating the transport of metals through the Blood-Brain Barrier (BBB) will help elucidate the mechanism by which environmental metals exert neurotoxic effects on human health. Within the BBB exists an Fe transport mechanism consisting of a transferrin receptor-mediated endocytotic system, that may also transport other metals besides Fe. In order to establish whether this Fe transport mechanism can also carry other environmental metals such as Mn and Pb we analyzed the interaction of purified human serum transferrin, with these metals through the use of Circular Dichroism Spectroscopy (CD). It was observed that Fe had the greatest effect on CD spectral change, followed by Mn. Lead, even at very high concentrations did not change the CD spectrum significantly. Based on an accepted method for obtaining binding characteristics from CD data, we obtained the binding characteristics of these metals to Tf. The binding curve obtained from the CD data for Tf exhibited a sigmoidal shape when Fe was added to the protein, suggesting a cooperative binding mechanism. Transferrin was also observed to bind Mn with negative cooperativity, while showing little binding to Pb. Our data suggest that human serum transferrin has the highest affinity for Fe, followed by Mn, while exhibiting no affinity for Pb. The analysis of Tf binding to Mn is important in the understanding human environmental exposure to Mn by way of MMT, a manganese containing fuel additive. More importantly, the similarities in the neurological effect of overexposure to Mn and Parkinson's Disease gives relevance to the study of Tf binding to metals and its possible role in transport through the blood-brain barrier.

THE INVOLVEMENT OF IRON IN TERT-BUTYL HYDROPEROXIDE INDUCED OXIDATIVE DEATH IN PRIMARY MOUSE ASTROCYTES. S. J. Robb-Gaspers and J. Connor*. Dept. of Neuroscience and Anatomy, M. S. Hershey Med Center, Penn State University, Hershey, PA 17033.

The purpose of this research is to determine the role of iron in oxidative cell death in astrocytes. Astrocytes have low concentrations of ferritin, the iron storage protein, yet take up iron. Astrocytes may be particularly susceptible to oxidative damage because they are rich in monoamine oxidase B (MAO-B), and contain nitric oxide synthase (NOS). MAO-B produces H_2O_2, further increasing the amount of peroxide in the system. NOS produces nitric oxide (·NO), which can increase cellular iron and change mitochondrial respiration. This inability to store iron in combination with H_2O_2 production is hypothesized to make astrocytes more suceptable to iron induced oxidative damage. To examine the role of iron in astrocyte oxidative death, enriched astrocytes cultures were generated from C57/Bl6 mouse pups. All cell cultures were maintained in serum free media for two days prior to the beginning and throughout the duration of all experiments. Tert-butyl hydroperoxide (tOOH) was added to the media as an exogenous source of peroxide. Cells were treated for a duration of four hours and lactate dehydrogenase (LDH) release used as a measure of loss of viability. Astrocyte cell death following four hours of tOOH exposure was between 80 and 90%. To determine the role of iron, the chelator Desferal (DF; 20mM) was added to the media for one hour and then removed at the time of the addition of tOOH. DF pretreatment provided complete protection, bringing the level of LDH release down to the level of control at all time points examined. Furthermore, the antioxidant N,N'-diphenyl-1,4-phenylenediamine (DPPD; 1μM) was added to the culture as a radical scavenger at the time of tOOH addition. DPPD provided moderate protection, indicated by decreased amount of LDH release relative to the tOOH condition. When DF pretreatment and subsequent removal preceded the addition of DPPP and tOOH, the level of LDH release fell to the level of control. In conclusion, removing iron from this system completely protected astrocytes from tOOH induced oxidative death and scavenging radicals provided moderate protection, demonstrating the involvement of iron in oxidative toxicity in astrocytes. ORGANOTIN TOXICITY IN PRIMARY GLIAL CELL CULTURE. VC Hardy*, R Sobolik, and CL Ever. Department of Pharmaceutical Sciences, University of Montana, Missoula, MT 59812-1075.

Primary astrocyte cell cultures were used to assess the time and concentration dependence of the gliotoxic actions of a series of organotin compounds. Cultures of purified type 1 astrocytes were prepared from cortices of 3-4 day old rat pups. The astrocyte cultures were exposed to a range of concentrations of triphenyltin (TPT), tributyltin (TBT), triethyltin (TET), dimethyltin (DMT), and trimethyltin (TMT) for periods of time up to 72 hours. Cytotoxicity was assessed by determining the degree of lactate dehydrogenase (LDH) release into the culture medium.

Following 24 hr exposure, 2.5 μM TPT produced a fourfold increase in extracellular LDH. Similar levels of cell lysis were seen with 10 μM TBT and TET. 100 μM DMT approximately doubled extracellular LDH and 100 μM TMT showed no gliotoxicity at this time point. Astrocytes chronically exposed to each of the organotins for 72 hours exhibited significant cytotoxicity. TMT concentrations of 5 μM and above produced significant increases in cell lysis, while, 2.5 μM TET, 2.5 μM TBT, and 100 μM TMT exposure elevated extracellular LDH approximately threefold. Concentration-response curves for TMT and DMT were comparable at this time. Cytotoxic concentrations of TPT, TBT, and TET all produced similar morphological changes including prominent nuclear abnormalities. These changes were clearly distinguishable from the cell swelling and process extension produced by TMT and DMT prior to cell lysis. It appears that gliotoxicity produced by TMT and its dimethyl analog may occur by a distinct mechanism from that observed with TPT, TBT, and TET. (Research supported by NIH-ESO7440A.)

TRIMETHYLTIN INTOXICATION IN MALE AND FEMALE SPRAGUE-DAWLEY RATS: A COMPARISON OF LEARNING AND MEMORY DEFICITS WITH SENSORY EFFECTS. D.S. Chapin*, W.P. Weisenburger, L.A. Medeiros, C.L. Kozak, and M.A. Engwall, Pfizer Inc., Central Research Division, Department of Drug Safety Evaluation, Groton, CT 06340.

Trimethyltin (TMT) is a neurotoxicant when administered systemically in rats. Among the CNS effects is neuronal damage to the hippocampus. In addition to learning and memory deficits in rats following exposure to TMT, there is evidence that TMT produces pathological changes in sensory system organs such as the retina and inner ear. The extent of changes in cognitive function and the differential effects between sexes were compared to sensory changes with the administration of TMT. TMT (or vehicle, arachis oil) was administered once by oral gavage at doses of 3, 6, and 9 mg/kg to groups of 10 male and 10 female young adult Sprague-Dawley rats. Animals were tested at the following time points post dose: for motor activity (MA) at 16-18 days, Cincinnati Water Maze (CWM) for learning at 3-4 weeks, passive avoidance (PA) for memory at 5 weeks, auditory startle (ASR) and auditory thresholds (AT, 10 & 20 kHz) at 5 weeks, and electroretinograms (ERG) and flicker potentials (FP) at six weeks. The CWM test showed learning deficits at 6 mg/kg in the females and 9 mg/kg for both sexes. The PA test showed memory deficit trends similar to the results in the CWM. MA was increased at the 9 mg/kg dose for both sexes. The ASR was reduced for both the 6 and 9 mg/kg dose groups for both sexes and AT shifts were seen at the 9 mg/kg dose only for both sexes. The ERG and FP tests showed effects of treatment only in the 9 mg/kg dose group for both sexes. The results from this study show that the changes in sensory function are similar in both males and females, and that females may be more sensitive to the learning and memory effects of TMT intoxication.

INCREASED INTRACELLULAR Ca^{2+} CONCENTRATIONS ($[Ca^{2+}]_i$) CONTRIBUTE TO RAT CEREBELLAR GRANULE CELL MORTALITY FOLLOWING *IN VITRO* METHYLMERCURY (MeHg) EXPOSURE. M. S. Marty* and W. D. Atchison, Dept. of Pharm. & Tox. and Neurosci. Prgm., Michigan State University, East Lansing, MI 48824.

MeHg is a neurotoxicant which causes preferential degeneration of cerebellar granule cells. Previous work in our laboratory has shown that *in vitro* MeHg exposure results in a biphasic increase in $[Ca^{2+}]_i$ in these cells. The objectives of this study were to determine if: 1) MeHg-induced elevations in $[Ca^{2+}]_i$ corresponded with altered granule cell survival; and 2) whether these alterations in cell viability could be attributed to the $[Ca^{2+}]_i$ rise. Granule cells were exposed *in vitro* to 0.5 or 1 μM MeHg for 45 or 38 min, respectively, periods shown to produce alterations in $[Ca^{2+}]_i$. Viability was measured immediately after exposure, as well as 3 and 24 hr later. MeHg did not induce an immediate decline in viability, because cell survival was similar to control levels immediately post-exposure. By 3 hr, granule cell survival had declined from 83.0% in control cells to 63.8% in 0.5 μM MeHg-exposed cells and 41.8% in 1 μM MeHg-exposed cells. By 24 hr post-exposure, viability had decreased dramatically to 16.8% and 18.4% for 0.5 and 1 μM MeHg exposures, respectively (control cell survival was 74.2%). To test whether elevations in $[Ca^{2+}]_i$ contributed to the decline in granule cell survival, cells were incubated with 10 μM BAPTA AM, a Ca^{2+} chelator, prior to and during MeHg exposure. BAPTA exposure improved cell survival at 3 hr post-exposure; viability improved from 37.8% in 1 μM MeHg-exposed cells to 72.2% in cells exposed to MeHg with BAPTA. The improvement in cell survival was only slight with 0.5 μM MeHg, where BAPTA increased viability from 67.8% to 74.6%. These results show that elevations in $[Ca^{2+}]_i$ play a role in granule cell death following acute *in vitro* MeHg exposure. (Supported by NIH grant ES03299 and NINDS training grant NS07279).

CHRONIC LEAD (Pb) EXPOSURE IN RATS ALTERS THE FUNCTIONS OF THE CHOROID PLEXUS. W. Zheng*, Q. Zhao, S. Ren, J. H. Graziano. Depts. of Environmental Health Sciences and Pharmacology, Columbia University, New York, NY.

The choroid plexus (CP), which serves as the blood-cerebrospinal fluid (CSF) barrier, sequesters Pb. This study was undertaken to test the hypothesis that Pb accumulation in the CP may alter CP functions, as reflected by CSF concentrations of TTR (a major CSF protein manufactured by the CP), CSF essential metal ions (Ca, Mg, K, and Na), and CP protein kinase C (PKC) activity. Weanling Sprague-Dawley rats were exposed to Pb in drinking water at doses of 0, 50 or 250 μg Pb/ml (as Pb acetate) for 30, 60 or 90 days. Two-way ANOVA of CSF TTR concentrations revealed that Pb exposure significantly decreased CSF TTR ($p<0.09$). The % of reduction of CSF TTR was inversely associated with CP Pb concentrations. In-vitro studies of a primary CP cell culture grown in a two-chamber system suggested that Pb exposure hindered the transport of ^{125}I-T4 across the monolayer of choroidal epithelial cells, an effect possibly attributable to the inhibition by Pb of TTR production and/or secretion in the CP. Our previous work indicated that rat CP expressed α, β, γ, and ε subtypes of PKC. While chronic Pb exposure did not significantly alter CP PKC activity in vivo, the primary cell culture treated with Pb showed that Pb promoted a dose-dependent translocation of PKC from the cytosol to membrane ($p<0.05$). In addition, we found that Pb exposure did not seem to markedly alter CSF concentrations of essential metal ions. Our results indicated that the sequestration of Pb in the CP resulted in CP dysfunction. The physiological/toxicological significance of this damage is currently under the investigation. ROLE OF METAL-BINDING PROTEINS IN Pb^{2+}-INDUCED NEUROTOXICITY IN MESENCEPHALIC PRIMARY CULTURES. M. Scortegagna and I. Hanbauer*, Laboratory of Molecular Immunology, NHLBI, Bethesda, MD 20892.

To understand how Pb^{2+} exerts its toxic effects on the developing brain, we studied metallothionein (MT) and glutathione (GSH) expression, two metal binding proteins expressed by astrocytes present in mesencephalic primary cultures (MPC) prepared from 14 day rat embryos. When MPC are exposed in presence of serum to 3 - 200 μ M Pb^{2+}, neurotoxicity failed to occur during 48 h of exposure. A 24 h exposure to 25 μM Pb^{2+} caused a 2-fold increase of GSH (sum of reduced and oxidized) content. A similar increase was also obtained with 50 or100 μM Pb^{2+}. Immunoblots showed that after a 24 h exposure to 25 μM Pb^{2+} in presence of serum, also MT expression was maximally increased (3-fold). Appropriate controls (1 h incubation in presence of Pb^{2+}) failed to show a change in GSH and MT levels. In serum-free medium, however, a 6 h exposure to 6 μM Pb^{2+} decreased the GSH content and the MT expression by 95 % after a 6 h exposure to 25 μ M Pb^{2+}. A 6h exposure of MPC to 3 μM Pb^{2+} in serum-free medium decreased ^3H-dopamine uptake by 50 % and 12.5 μM Pb^{2+} obliterated it. Since Pb^{2+} failed to cause neurotoxicity in serum-containing media, it is inferred that the increase of GSH and MT levels may have a neuroprotective effect. Whereas, Pb^{2+} exposure in serum-deprived media decreases GSH and MT levels and Pb^{2+}-induced neurotoxicity ensues.

751.12

LEAD-INDUCED CHANGES IN BRAIN GFAP AND mRNA LEVELS OF GFAP, VIMENTIN AND SYNAPTOTAGMIN IN RATS. Z.L. Gong*, A.R. Little, G.J. Harry#, H.A.N. El-Fawal, A. Petrenko, and H.L. Evans. Nelson Inst. of Environ. Med., New York Univ. Med. Ctr., Tuxedo, NY 10987. #NIEHS, RTP, NC, 27709.

Lead exposure may cause behavioral disorders in humans and animals. The role of astrocytes in the early stages of neurobehavioral toxicity was investigated by determining the concentration of glial fibrillary acidic protein (GFAP) and the mRNA levels of GFAP, vimentin and synaptotagmin in the brain of rats during continuous exposure to Pb which resulted in locomotor behavioral changes. Male F344 rats (42 days old) received lead acetate at 150 or 2000 ppm as Pb in their drinking water for up to 21 days, producing blood Pb concentrations of 34 and 80 μg/dl for 150 and 2000 ppm respectively. Brain samples from cerebral cortex, hippocampus and cerebellum were examined at days 1, 3, 7 and 21 of exposure to Pb, while other rats were tested repeatedly for behavior. GFAP was determined by ELISA and mRNA by northern analysis. The GFAP concentration and GFAP mRNA in all three brain regions were positively correlated with the concentration of Pb in whole blood. The earliest changes were in GFAP and vimentin mRNAs, as early as day 1 and more substantially on day 3 of Pb exposure, with synaptotagmin mRNA increasing as early as day 3 and more substantially on day 7. GFAP concentration was first changed on day 3. Thus, there may be a 1 - 2 day interval between change in GFAP mRNA and change in GFAP. The hippocampus was the region most sensitive to Pb. Locomotor behavior was first changed on day 7. These results indicate that (1) Pb-induced changes in GFAP and GFAP mRNA indicate an early role for astrocytes before behavioral signs appear; (2) Pb exposure can increase or decrease GFAP mRNA; these changes were followed by qualitatively similar changes in GFAP levels; (3) Increased vimentin mRNA might indicate astrocyte hyperplasia; (4) Increased synaptotagmin mRNA indicated that there may be axonal damage and that the neuron was undergoing repair processes. Supported by grants from NIH (ES-00260) and from the Amer. Petroleum Inst.

LEAD-INDUCED IMPAIRMENT OF LTP AND PPP IN HIPPOCAMPAL DG AND ANTAGONISTIC ROLE OF ZINC. D.Y.RUAN*, Y.M.ZHAO, Y.WU, J.T.CHEN, Y.Z.XU
Dept.of biology, Univ. of Sci.& Tech. of China, 230027, P.R.China

Two groups of neonatal Wistar rats were exposed to lead and lead plus zinc separately from parturition to weaning via the milk of dams drinking 0.2% lead acetate solution and 0.2% lead acetate plus 500ppm zinc gluconate solution. The alterations of LTP and PPP in hippocampal dentate gyrus (DG) in adult rats following developmental lead and lead plus zinc exposure were studied in vivo. Excitatory postsynaptic potentials (EPSPs) and population spikes (PSs) were recorded in the dentate in response to stimulation applied to the perforant path. The results showed that the LTP was induced in Pb+Zn-exposed rats with average PS potentiation of 264.3±41.4% (n=12), which was significantly smaller than the increase in PS potentiations in control rats (321.1±50.0%, n=17, $P<0.05$) and larger than that in Pb-exposed rats (173.5±30.0%, n=18) after tetanizing stimulation. The mean EPSPs amplitudes increased to 138.8±21.4% (n=17) for Pb-exposed rats, 148.1±21.3% (n=12) for Pb+Zn-exposed rats and 172.4±27.0% (n=18) for the controls after tetanizing stimulation. The lead-induced impairment of LTP of PS potentiations was greater than that of EPSP potentiations. Paired-pulse potentiation (PPP) across a range of interpulse intervals is also depressed in Pb-exposed rats. Following pairs stimulation of perforant fiber at 250μA and an interpulse interval of 60ms, the PPP was 157.0±42.0% for Pb-exposed rats (n=11), 191.2±45.0% for Pb+Zn-exposed rats (n=11) and 213.0±54.0% for control rats (n=13). The results suggest that the lead exposure in neonatal rats caused impairments in LTP and PPP of hippocampal dentate gyrus and zinc might play an important role in preventing lead-induced damages. Supported by NNSFC (DYR)

751.14

LOW LEVEL Pb AND MAZE EXPLORATION: DOSE-DEPENDENT EFFECTS DEPEND UPON DEGREE OF PHYSICAL MATURATION WHEN Pb IS FIRST ADMINISTERED. P.W. Stewart*, R.G. Burright & P.J. Donovick. Environmental Neuropsychology Laboratory, SUNY Binghamton, Binghamton, NY 13902.

We investigated the effect of low-level Pb exposure on exploratory-based learning behavior in Binghamton Heterogeneous Stock mice. Mice in these experiments were either nontreated or given sodium acetate, 10 or 25 mg/kg Pb acetate intragastrically every three days beginning between postnatal day 5-7 and ending between postnatal days 17-19. On postnatal days 38-42, all mice were individually tested in a complex runways maze under non-deprived conditions. Locomotor activity, exploration, and experience-dependent changes in cul-de-sac entries were recorded. Although Pb did not affect bodyweight and blood-Pb levels were below 10 ug/dl at the time of behavioral testing, a history of low-level preweaning Pb exposure caused a dose-dependent increase in cul-de-sac entries. This behavioral change was dissociable from changes in bodyweight, degree of exploration or an *a priori* bias to enter cul-de-sacs. Later experiments showed that this effect was remarkably dependent upon the physical size/maturation attained by the mouse at the time Pb was first administered. Specifically, Pb caused dose-dependent increases in cul-de-sac entries in mice who weighed approximately 4.4g or more at the time of first intubation. However, Pb caused a *decrease* in cul-de-sac entries in mice who weighed approximately 3.8g or less at the time of the first intubation. Pb caused no net change in the behavior of mice who weighed between 3.8 and 4.4g at the time of the first intubation. These striking interactive effects were extensively replicated across 4 experiments. It is hypothesized that the effects of Pb in larger (>4.4g) mice are related to changes in the cholinergic and/or noradrenergic system. However, the role of early handling must be considered as a potentially interactive variable when interpreting the effects of Pb in physically smaller (<3.8g) mice. Future work should focus not only on Pb's effects on transmitters involved in exploratory-based learning (Ach, NE), but also on the development of the HPA axis and how the latter might be altered by both early handling and Pb. *Internally funded.*

ACUTE AND CHRONIC EFFECTS OF LEAD ON LONG-TERM POTENTIATION AT MOSSY FIBER-CA3 (MF-CA3) AND SCHAFFER COLLATERAL-CA1 (SC-CA1) SYNAPSES IN RAT HIPPOCAMPAL SLICES. R. Hussain, R. J. Brady* and D. O. Carpenter. School of Public Health, University at Albany and Wadsworth Labs, Albany, NY 12201 .

Exposure of children to lead remains one of the most significant environmental public health problems. This pollutant affects intellectual functioning and neuronal plasticity, particularly during development. Hippocampal long-term potentiation (LTP) of synaptic transmission represents a cellular phenomenon which is thought to be a substrate for learning and memory in mammals. In the rat hippocampus, LTP at the SC-CA1 and MF-CA3 synapses are different. Protein kinase C (PKC) has a role in the LTP at both synapses, presynaptically in MF-CA3 and postsynaptically in SC-CA1. It is known that lead can interfere with PKC activity. Lead blocks LTP in SC-CA1, but the mechanism is not known. In contrast, we find that in adult rats lead applied acutely to brain slices or administered chronically to animals causes a potentiation of LTP in MF-CA3. Phorbol ester (0.5 μM) causes a potentiation of synaptic responses in CA3, and this is enhanced in the presence of 20 μM lead. Enhancement of LTP and phorbol potentiation by acutely applied lead suggests that lead stimulates PKC activity. In contrast, lead exposure during gestation and lactation (0.2% in drinking water) caused significant inhibition of LTP at both the MF-CA3 and SC-CA1 synapses when studied in slices of young (26-30 day) animals. These observations suggest that lead has more than one site of action, one of which is a stimulation of PKC, and indicate that the mechanisms of LTP at the MF-CA3 and SC-CA1 sites are different, consistent with previous data. It is also possible that sensitivity to lead varies with development. Supported by ES05203 and NS23807.

751.16

DISTRIBUTION OF HIPPOCAMPAL PROTEIN KINASE C ACTIVITY IS ALTERED BY LEAD EXPOSURE AND ACTIVE AVOIDANCE TRAINING H.-H. Chen, I. A. Paul, and I. K. Ho* Department of Pharmacology and Toxicology, University of Mississippi Medical Center, Jackson, MS 39216

Long-term exposure to a low level of lead (Pb)(<80 mg/dl) is associated with learning and other behavioral deficits in human and experimental animals. Several types of learning have been correlated to hippocampal PKC activation. This study was designed to correlate the effects of Pb on hippocampal PKC activation with learning performance. Male S.D. rats (N=48) were divided into 4 experimental groups: a control group; a maternally exposed group which exposed to 0.2 % Pb acetate *in utero*, via maternal milk ended at postnatal day (PN) 21; a postweaningly exposed group which exposed to Pb from drinking water started at PN21 and continued until PN56; a permanently Pb exposed group which comprised maternal and postweaning Pb exposure. Half of the rats in each group were trained in a 2-way active avoidance learning task (20 sec/trial for 150 trials) at PN53 to PN55. All the rats were killed at PN56 for tissue preparations to measure the hippocampal PKC activity. Maternal, postweaning and permanent Pb exposure all decreased membrane/cytosolic PKC activity in the hippocampus. Membrane/cytosolic PKC activity increased after 2-way active avoidance learning task. In active avoidance paradigm, the permanently exposed group displayed a higher number of no responses and lower number of escapes. These data indicate that a change in the distribution of hippocampal PKC activity is involved in the Pb-induced deficit in learning. (Supported by research funds of the University of Mississippi Medical Center).

NMDA RECEPTOR SUBUNIT COMPOSITION DEPENDENCY OF LEAD ACTION IS A COMMON PHENOMENA. I.A. Omelchenko, C.S. Nelson and C.N. Allen* Center for Research on Occupational and Environmental Toxicology and Department of Physiology and Pharmacology, Oregon Health Sciences University, Portland, OR 97201.

Developmental changes of the subunit composition of NMDA receptors may lead to differential vulnerability to Pb^{2+} toxicity. Previously, we have shown that the actions of Pb^{2+} on NMDA receptors consisting of $\zeta 1\varepsilon 1$, $\zeta 1\varepsilon 2$, and $\zeta 1\varepsilon 1\varepsilon 2$ subunits were dependent on the receptor subunit composition. To determine if this was a common phenomena we investigated the actions of Pb^{2+} on additional NMDA receptor subunit compositions. Concentration-response curves for glutamate were generated in the presence and absence of Pb^{2+} using the two electrode voltage-clamp technique and NMDA receptors consisting of NR1b, NR2A and NR2C subunits expressed in *Xenopus laevis* oocytes. Pb^{2+} inhibited NR1b2A receptors with an IC_{50} of 1.52 ± 0.66 μM (mean ± S.E.) and NR1b2C receptors with an IC_{50} of 3.71 ± 0.46 μM. The lead inhibition of both NR1b2A and NR1b2C receptors was by a noncompetitive mechanism. NMDA receptors consisting of NR1b2A2C subunits had a significantly higher IC_{50} of 8.19 ± 1.85 μM. The inhibition of NR1b2A2C receptors by Pb^{2+} appeared to be noncompetitive at low agonist concentrations and competitive at high agonist concentrations. These data indicate that the composition of the NMDA receptor may play a role in the selective vulnerability of NMDA receptors to Pb^{2+}. (Supported by grant NS19611)

SYMPOSIUM. CAUGHT IN THE ACT: STRUCTURAL CHANGES ASSOCIATED WITH CHANNEL GATING. S.A. Siegelbaum, HHMI, Columbia U. (Chairperson); A. Finkelstein, Albert Einstein Col. of Medicine; R.J. Horn, Jefferson Medical College; E.Y. Isacoff, Univ. of California, Berkeley.

Recent studies on a variety of ion channels address the nature of dynamic structural rearrangements that may underlie channel gating. Alan Finkelstein will provide evidence that a large 70 amino acid domain of the bacteriocidal channel protein colicin Ia undergoes a translocation across the membrane during voltage-dependent channel gating. Richard Horn will present studies on voltage-gated sodium channels using cysteine mutagenesis and sulfhydryl modifying reagents which suggest the outward movement of the S4 voltage sensor through a hydrophilic pore-like region of the channel in response to membrane depolarization. Ehud Isacoff will report studies that lead to a similar picture during activation of the voltage-gated Shaker K channels, using cysteine mutagenesis and fluorescence probes that allow real time measurements of structural gating changes. Steven Siegelbaum will present data on regions of the cyclic nucleotide-gated channels that underlie the allosteric conformational changes associated with their ligand-dependent activation. The above experimental studies suggest new structural models for channel activation gating.

753

SYMPOSIUM. GENES IN ISCHEMIA. R. P. Simon, Univ. of Pittsburgh (Chairperson); R. S. Zukin, Albert Einstein Coll. Med. (Co-Chairperson); S.H. Graham, Univ. of Pittsburgh; D. Pellegrini-Giampietro, University of Florence; C.R. Wahlestedt, Astra Research Center; D.J. Fink, Univ. of Pittsburgh.

Cerebral ischemia alters the expression of genes that determine if ischemic neurons live or die. Blocking the expression of cell-death genes or inducing cell-survival genes could lead to new treatments for stroke. This symposium highlights the search for genes induced in ischemic brain and the manipulation of their expression by antisense and gene transfer techniques. R.P. Simon will provide a brief introduction. S.H. Graham will discuss the role of death-promoter and death-suppresser genes in neuronal responses to ischemia. D. Pellegrini-Giampietro will review the regulation of glutamate receptor gene expression in global ischemia. C.R. Wahlestedt will consider the use of antisense oligodeoxynucleotide techniques in the study of ischemia. D.J. Fink will describe approaches to experimental ischemia based on gene transfer, focusing on the use of replication-defective herpes virus vectors. Finally, R.S. Zukin will provide a summary overview.

PEPTIDES: BIOSYNTHESIS, METABOLISM, AND BIOCHEMICAL CHARACTERIZATION II

754.1

THE NEUROENDOCRINE POLYPEPTIDE 7B2 IS ESSENTIAL FOR THE ACTIVATION OF PC2 *IN VIVO*. B. Seidel[1], J.E. Pintar[2], N.G. Seidah[1] and R. Day[1]*, [1]Clinical Research Institute of Montreal, Montreal, Quebec H2W 1R7 & [2]Univ. of Medecine & Dentistry of New Jersey, Piscataway, NJ 08854.

The neuroendocrine polypeptide 7B2 is widely distributed in neural and endocrine tissues. Its biological function was found to be related to the activity of the enzyme PC2 which belongs to the growing family of precursor activating convertases acting via carboxyl-terminal cleavage at specific single or pairs of basic amino acid residues. In order to examine the proposed chaperone-like action concerning PC2 for *in vivo* models, we investigated the distribution of both 7B2 and PC2 in the rat brain by means of *in situ* hybridization with adjacent sections. 7B2 expression was found to be almost pan-neuronal, but additionally we observed 7B2 mRNA in the ependyma and in the subcommissural organ. PC2 expression was much more restricted, sparing some regions which are rich in 7B2. This may suggest that 7B2 could have an additional function in non-PC2 expressing cells. No evidence for cells which are PC2- positive but 7B2-negative could be achieved in the adult rat brain. However, in the developing rat brain (E17), such regions exist, resulting in the generation of more inactive PC2-forms. Similarly, in the animal model of insulin-induced hypoglycemia shock, which decreases the 7B2 expression, the ratio of inactive pro-PC2 to active PC2 also increased. Finally, the cell line SK-N-MCIXC does not express 7B2 but PC2. Accordingly, only pro-PC2 forms could be found in the cells and media. After permanent transfection with 7B2, active PC2 was produced and secreted into the medium. Our data suggests a critical role for 7B2 for the activation of PC2 *in vivo*.

SPECIFIC REPRESSION OF THE PREPROENDOTHELIN-1 GENE IN INTRACRANIAL ARTERIOVENOUS MALFORMATIONS R.L.P. Rhoten, Y.G. Comair*, M.S. Simonson, Dept. of Neurosurgery, Cleveland Clinic Foundation, Cleveland, OH, 44195.

Cerebrovascular arteriovenous malformations (AVM) display abnormal vascular development and dys-autoregulation of blood flow. Genetic mechanisms that contribute to the pathogenesis and phenotype of cerebral AVMs are unknown. As a first step in understanding the pathophysiology of AVMs, we investigated the hypothesis that endothelial dys-function, specifically deregulation of endothelin 1 (ET-1) secretion, contributes to the abnormal vascular phenotype and lack of hemodynamic auto-regulation elaborated by these lesions. ET-1 peptide and preproET-1 mRNA were not detected in the vascuature of 17/17 AVM patients but was prominently expressed in normal human cerebro-vascular controls ($P<0.01$). Although AVM vessels lacked ET-1, ET-1 expression was prominent in vessels away from the AVMs, suggesting local ET-1 repression. Repression of the ET-1 gene was maintained in AVM EC cultures. Taken together these results demonstrate that the preproET-1 gene is locally repressed in AVM lesions and suggest a role for abnormal gene regulation in the pathogenesis and clinical sequelae of AVMs.

ANALYSIS OF THE BOVINE AND RAT NEUROPEPTIDE FF AND AF GENE. F.S. Vilim* and E. Ziff. Dept. of Biochem. HHMI NYU Med. Ctr. NY, NY 10016.

Last year we described the cloning of the precursor for the neuropeptides NPFF and NPAF. Now we have defined the complete structures of both the mRNA and the genomic RNA, including about 1 Kb of rat promoter region. The gene is composed of 3 exons (E1, E2, and E3) and 2 short introns (I1 and I2). 5' RACE was used to identify transcription start site which is ~30 bp downstream from a conserved TATA box. The mRNA contains 10-13 bp of 5' untranslated sequence, ~345 bp open reading frame, and ~85 bp of 5' untranslated sequence. Northern analysis indicates that the size of the message is ~700bp in the hypothalamus and ~600bp in the brainstem. RNase protection confirms the presence of the mRNA in these brain regions. This size difference could reflect use of different transcription start sites, polyadenylation signals, diffences in the length of the polyA tail, or alternative splicing of the message. Thus far, use of PCR and RNase protection has failed to detect any alternitively spliced variants of this message and only one polyadenylation signal has been seen. We are in the process of studying the effect of morphine on mRNA levels in the rat and generating a knockout of the gene in the mouse.

A PROPOSED MECHANISM FOR THE THIOL ACTIVATION OF ENDOPEPTIDASE 24.15. C.N. Shrimpton[1], R.A. Lew[1], M.J. Glucksman[2], E.H. Margulies[2], J.L. Roberts[2] and A.J. Smith[1]*. [1]Baker Med. Res. Inst., Prahran, Vic., Australia 3181 and [2]Fishberg Ctr., Mt Sinai School of Med., New York, USA 10029

Endopeptidase E.C.3.4.24.15 (EP24.15) is a 75kDa neutral metalloendopeptidase implicated in the regulated metabolism of several neuropeptides. One feature of the enzyme is its dependence on thiols for activation. Under reducing conditions EP24.15 elutes as a 75kDa protein, as judged by size exclusion chromatography (SEC). However in the absence of thiol based reagents EP24.15 elutes predominantly as aggregates of 150, 240 and greater than 300kDa, suggesting that disruption of multimer formation may be the mechanism of thiol activation. To determine the catalytic site availability in the multimeric form, recEP24.15 was incubated with a radiolabelled EP24.15-specific transition state inhibitor in the presence and absence of dithiothreitol (DTT, 1mM) and fractionated by SEC. Radioactivity which co-eluted with EP24.15 immunoreactivity was 1000-fold higher under reducing conditions, indicating that access to the catalytic site may only occur in the monomeric form. These data suggest that the thiol activation of EP24.15 may reflect the conversion of an inactive multimeric form to an active monomeric form. To determine which cysteine (Cys) residues may be involved in intermolecular disulphide bridges, we generated a series of Cys mutants via site directed mutagenesis. Activity assays were performed in the presence and absence of 1mM DTT. The mutated enzymes at Cys residues 6,7 and 8 exhibited activity up to 8 fold greater than wild type in the absence of DTT, whilst the remaining mutant activities were similar to, or lower than the wild-type activity. All enzymes showed similar levels of activity in the presence of DTT. The activities of the Cys mutants 6,7 and 8 were not further activated in the presence of DTT and did not form multimers to the same extent of the wild-type or to the other mutants. We speculate that these 3 Cys residues play a role in EP24.15 multimer formation, thus providing a mechanism by which thiol agents may activate the enzyme.

A specific CCK-8 serine peptidase in rat cortical membranes. Purification, localisation and synthesis of highly potent specific inhibitors.
Froylan Vargas*, C. Rose**, P.Facchinetti, P.Bourgeat, R.B.Bambal, P.B .Bishop, S.M.T. Chan, A.N.J. Moore, C.R.Ganellin and J.C. Schwartz. Laboratoire de Neurobiologie, Unité 109 INSERM, France.

CCK-8 membrane-bound SP was purified using succesive DEAE 5 PW, Hydroxyapatite, Protein Pak 300 SW and Phenyl 5 PW columns. The purified enzyme has a molecular weight of 135 kD on SDS-PAGE. The enzyme is labeled specifically by [^{3}H]diisopropylfluorophosphate (DFP). Inhibition of the CCK-8 SP by DFP was prevented by the presence of the peptide substrate CCK-8. A inhibition constant of 0.119 min^{-1} was observed at 100 uM DFP concentration, using Ala-Ala-Phe-Amc as the peptide substrate. CCK-8 prevented the inhibition. A histidine residue for the catalysis to occur was evidenced by the inhibition of the enzyme by $(CH_3CH_2OCO)_2O$. this inhibition was prevented by acetylimidazole. CCK-8 SP showed a marked resemblance with the erythrocyte enzyme tripeptidylaminopeptidase II (TPP II). CCK-8 sulphated form was the best natural substrate as compard to CCK-5, CCK-8 non-sulphated, Neurokinin A, Somatostatin(1-14), Somatostatin(15-28) and Dynorphin. Dynorphin B, Bradykinin, Boc-CCK-8 were poorly active as substrates or not hydrolyzed by this CCK-8 serine peptidase. Natural or commercial available small peptides with a decreasing affinity to inhibit the CCK-8 serine peptidase were: Ala-Ala-Phe-chloromethylketone, Ala-Pro-NH2, CCK-8, Diprotin, Ala-Pro-Ala and Gly-Trp-Met. These observations lead us to synthetize three highly potent non-toxic inhibitors Ala-Pro-boro-Val, Abu-Pro-NH(Butyl), and Abu-Indolynil-NH(Butyl) with Ki=1, 7 and 80 nM, respectively.

A COMPARISON OF ACUTE AND CHRONIC ADMINISTRATION OF ANTIPSYCHOTICS ON THE IN VIVO RELEASE OF NEUROTENSIN IN THE RAT
James M. Radke, Micheal J. Owens and Charles B. Nemeroff* Dept. Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta GA.

Neurotensin is an endogenous CNS tridecapeptide which has been implicated in the mechanism of action of antipsychotic drugs. Administration of the typical antipsychotic haloperidol has repeatedly been shown to increase both the tissue concentrations and the mRNA expression of neurotensin in the rat striatum and nucleus accumbens. The purpose of these experiments was to determine how haloperidol may influence the release of neurotensin using in vivo microdialysis. The method of in vivo microdialysis has been used extensively to examine the release of various neurotransimitters and we have shown that in combination with a solid phase radioimmunoassay, we can measure the release of neurotensin in the awake freely moving rat. Neurotensin release is increased by depolarizing concentrations of KCl and is Ca^{++} dependent. The acute administration of haloperidol (2.0 mg/kg) did not significantly alter the release of neurotensin over a 30 hour period. In contrast, chronic administration of haloperidol (2.0 mg/kg/day x 21 days) resulted in a significant increase in neurotensin release in both the striatum and the nucleus accumbens. The differences in neurotensin release found between acute and chronic administration of haloperidol may help to explain both the extrapyramidal side effects as well as the latent clinical efficacy often observed with typical antipsychotics. Current studies examining the effects of the atypical antipsychotic, clozapine, on neurotensin release are in progress.

754.7

GENDER BASED DIFFERENCES IN THE EFFECTS OF ANTIPSYCHOTIC DRUG TREATMENT ON NEUROTENSIN CONCENTRATIONS IN THE RAT BRAIN.
B. Kinkead*, S. Lorch, M.J. Owens and C.B. Nemeroff, Lab. of Neuropsychopharmacology, Dept. Psychiatry and Behavioral Sciences, Emory Univ. Sch. of Med., Atlanta, GA 30322.

Neurotensin (NT), an endogenous tridecapeptide, has been implicated in the pathophysiology of schizophrenia. While numerous studies have demonstrated that treatment with typical antipsychotic drugs specifically increases NT concentrations in the caudate nucleus and nucleus accumbens of the rat, all of these studies have been conducted using male rats. An increasing literature indicates the presence of gender influences in schizophrenia and recent biochemical studies in the rat indicate that estrogen may have an effect on NT-containing neurons. To further explore this possibility, sexually mature male and female rats in different stages of the estrous cycle received a single subcutaneous injection of either haloperidol (2.0 mg/kg) or vehicle (1.0 ml/kg). Rats were killed 18 hours after the single injection, the brains removed and regional brain NT concentrations were examined using a highly specific and sensitive radioimmunoassay. Haloperidol significantly increased NT concentrations in the caudate nucleus and nucleus accumbens in both male and female rats. In female rats, however, the estrous cycle significantly influenced the effect of haloperidol on NT concentrations in the posterior caudate and the nucleus accumbens. In the posterior caudate, the increase in NT concentrations was significantly greater in females during proestrus (P) and estrous (E) compared to females in diestrous 1 (D1), diestrous 2 (D2) and males. In the nucleus accumbens, haloperidol had no effect on NT concentrations in females in P, while the effect of haloperidol on NT concentrations in females in D1 and D2 was significantly greater than males or females in P or E. There were no significant differences between NT concentrations in male or female controls in any brain region examined. These results further indicate an effect of estrogen on the NT system. EFFECT OF DOPAMINERGIC DRUGS ON REGIONAL NEUROPEPTIDASE ACTIVITY AND MRNA LEVELS.
S.M. Waters*, M.P. Rounseville and T.P. Davis. Dept. Pharmacology, Univ. Arizona, Tucson, AZ 85724.

Drugs which act upon dopamine receptors affect the peptide level and mRNA of neuropeptides associated with the modulation of dopaminergic neurons. Two neuropeptides affected by these drugs are substance P and Met-enkephalin. Our laboratory has previously determined that the *in vitro* degradation of these peptides is affected by the administration of dopaminergic drugs. In the present study, the effects of acute and subchronic administration of the antipsychotic haloperidol (1 mg/kg) or dopamine agonist apomorphine (5 mg/kg, bid) on the activity of specific neuropeptidases were determined in rat frontal cortex (FC) and caudate putamen (CP). Additionally, the effect of these drugs on neuropeptidase mRNA levels was studied.

The activity of neutral endopeptidase 24.11 (NEP), aminopeptidase N (APN) and angiotensin converting enzyme (ACE), peptidases known to degrade substance P and/or Met-enkephalin, was determined in regional, plasma membranes after administration of haloperidol or apomorphine. After subchronic administration, haloperidol decreased NEP (25% in FC, 15% in CP) and APN (25% in FC, in 20% CP) activity whereas apomorphine differentially affected the activity of NEP (15% decrease in FC, 10% increase in CP) and APN (25% increase in FC, 60% increase in CP). ACE activity was not affected by any drug treatment in any region studied. The mechanism of drug-induced changes on neuropeptidase activity was examined by RNase protection analysis of mRNA levels. Our data suggest (n=5 rats) that changes in mRNA levels are involved in alterations of neuropeptidase activity observed after identical dopaminergic drug treatments. DIFFERENTIAL EFFECTS OF CHRONIC ETHANOL CONSUMPTION ON $GABA_A$ RECEPTOR SUBUNITS FROM CORTEX OF ETHANOL DEPENDENT VERSUS ETHANOL WITHDRAWING RATS.
L. L. Devaud*[1], J.-M. Fritschy[2] and A. L. Morrow[1], [1]UNC School. of Med., Chapel Hill, NC and [2]Inst. of Pharmacol., Univ. of Zurich, CH-8057, Zurich, Switz.

Chronic exposure to ethanol (Et) alters $GABA_A$ receptor function. Et removal after chronic exposure results in a withdrawal syndrome, with symptoms of rebound CNS hyperexcitability. Chronic Et consumption elicits selective effects on $GABA_A$ receptor subunit gene expression. However, different effects on $GABA_A$ receptor subunits were observed during Et withdrawal (6-8 hrs after removal of the Et diet) than during Et exposure. $GABA_A$ α1 subunit mRNA levels decreased by 43 ± 7% and α4 levels increased by 89 ± 25% during Et exposure compared to pair-fed control values ($P<0.05$). These effects partially reversed during withdrawal (α1, -20 ± 3% and α4, +34 ± 3%) compared to pair-fed controls. In contrast, while β2 and β3 subunit mRNA levels were not altered in dependent rats during Et exposure, these subunit mRNA levels were increased, by 37 ± 3 and 82 ± 16%, respectively, during withdrawal ($P<0.05$). Relative changes in mRNA and polypeptide levels for $GABA_A$ receptor α1 and β2/3 subunits showed a good correlation in Et dependent but not Et withdrawing rat cortex. Polypeptide levels for the α1 subunit decreased by 39 ± 7% in dependent rats and by 27 ± 7% during withdrawal, compared to controls. β2/3 subunit peptides increased by 36 ± 10% in dependent rats and by 5 ± 4% during withdrawal. These findings show that adaptations in $GABA_A$ receptor subunit gene expression vary between ethanol dependent and withdrawal states. (Supported by AA00191 and AA09013).

MODULATION OF THE EXPRESSION OF PHOSPHOLIPASE C ISOZYMES IN THE RAT BRAIN BY CHRONIC NICOTINE OR ETHANOL TREATMENT.
S.C. Pandey.* Psychiatric Institute, Department of Psychiatry, College of Medicine, University of Illinois at Chicago, Chicago IL 60612

During the past decade, many lines of evidence have indicated that consumption of alcohol and tobacco are correlated. The molecular mechanism of the interaction of these two drugs is unknown. Inositol phospholipid-specific phospholipase C (PLC) catalyzes the hydrolysis of phosphoinositide to generate two second messengers, inositol trisphosphate and diacylglycerol, which control several important cellular functions. PLC enzymes exist mainly as three families, i.e., PLC-β, -γ, and -δ isozymes. To examine the possible involvement of PLC isozymes in the interaction of nicotine and ethanol, we studied the expression of PLC isozymes in the brain during chronic nicotine or ethanol exposure. Male Sprague-Dawley rats received the Lieber-DeCarli control or ethanol (9% v/v) diet for 15 days. The ethanol-withdrawn (24 hrs) group received the control liquid diet on the 15th night instead of the ethanol diet. Another group of rats were injected subcutaneously with nicotine bitartrate (2.0 mg/kg) or vehicle for 10 days. The expression (immunolabeling) of PLC-β_1, -γ_1, and -δ_1 isozymes in the rat cortex was determined by Western blotting using specific monoclonal antibodies. Chronic ethanol treatment (15 days) resulted in a significant decrease in the expression of PLC-β_1, whereas the expression of PLC-γ_1 and -δ_1 isozymes in the rat cortex was not altered. The decreased protein expression of PLC-β_1 was not altered by withdrawal (24 hrs) after 15 days of ethanol consumption. On the other hand, chronic nicotine treatment (10 days) significantly increased the immunolabeling of PLC-β_1, whereas the expression of PLC-γ_1 and -δ_1 isozymes in the rat cortex was not altered. These results suggest that chronic ethanol or nicotine treatments have a selective effect on the PLC-β_1 isozyme in the brain. It is possible that changes in the phosphoinositide signaling system via the PLC-β_1 isozyme represent a possible molecular locus in the brain for the interaction of ethanol and nicotine.

Chronic Ethanol Exposure and Withdrawal Delay Kindling at Hippocampal Area CA3 L.M.Veatch* & L.P. Gonzalez. Univ of Oklahoma HSC, Dept. of Psychiatry & Behavioral Sci., P.O. Box 26901, OKC, OK 73190

Seizures during withdrawal after chronic alcohol exposure are potentially life-threatening problems seen in clinical treatment. In order to understand the neural mechanisms responsible for seizure activity and to develop effective pharmaceuticals to aid in treatment, researchers have used a variety methods to model the seizure activity seen in the alcohol withdrawal syndrome. This study reports the effect of chronic ethanol exposure and withdrawal on the development of kindling, a laboratory manipulation wherein sub-threshold electrical stimulation of a specific brain site eventually results in generalized tonic-clonic seizures. In this study, adult male Sprague-Dawley rats were surgically prepared with electrodes in hippocampal area CA3. After recovery from surgery, the after discharge threshold (ADT) of each animal was assessed beginning at 10μA and increasing in 10μA steps every five minutes until afterdischarge was elicited. Half of the animals were then continuously exposed to ethanol in vapor inhalation chambers for forty-two days. These animals were removed from the chamber and allowed a fourteen-day recovery period. The remaining animals served as ethanol-naive controls. Each animal then received a daily electrical stimulation (2sec duration, 60Hz, 1msec pulse width, amperage 120% of ADT) to criterion of three consecutive generalized tonic-clonic seizures. Stimulation amperages did not differ significantly between the ethanol-exposed (40±4μA) and ethanol-naive (43±3μA) groups. However, ethanol exposed animals required a mean of 45±7 stimulations to attain criterion in contrast to the control animals which required only 23±1 stimulations. The results demonstrate that chronic ethanol exposure and withdrawal result in a persistent change in the neural processes associated with electrical kindling.

MEDIAL PREFRONTAL SEROTONIN LESIONS ALTER VOLUNTARY ALCOHOL CONSUMPTION IN THE RAT. A.W. Deckel*, W.J. Shoemaker, & L. Arky. Alcohol Research Center, Dept. Psychiatry, UCONN Medical School, Farmington, CT 06030.

This experiment examined both the relationship between prefrontal serotonin lesions and voluntary etoh consumption, and the ability of CNS monoamines to predict etoh consumption. Thirty adult male Wistar rats received 8 ug bilaterally of 5,7 dihydroxytryptamine (dht) into the medial prefrontal cortex (mPFC). Rats were then trained, via a sucrose fading paradigm, to consume increasing concentrations of etoh. Following sacrifice, dopamine (DA), norepinephrine (NE), serotonin (5-HT) and their metabolites were measured in the mPFC, nucleus accumbens (NA), and raphe nucleus. The lesioned group demonstrated a reduction in 5-HIAA, DA and NE in the mPFC ($p<.05$), and a trend towards reduction of 5-HT in the NA. In comparison to controls, lesioned animals consumed less of all solutions containing sucrose and etoh. On regression analyses, monoamines in the mPFC (i.e., 5-HIAA, DOPAC, and NE) but not the other brain regions predicted consumption of the 5% etoh solution ($p=.009$), 10% etoh solution ($p=.0006$), and the 5% sucrose solutions ($p=.0006$), but not the 20% sucrose solutions. In each case, monoamine levels were positively correlated with consumption.

OPIOIDERGIC MODULATION OF THE ETOH DISCRIMINATIVE STIMULUS IN LEWIS RATS. T.A. Kosten* and C. N. Haile. Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508.

Recent research suggests that the opioid antagonist naltrexone (NTX) has clinical utility for treating alcoholism. Preclinical data show that NTX reduces, and the opioid agonist, morphine (MOR), enhances EtOH preference in rats. This study examined whether NTX or MOR alters the discriminative stimulus properties of EtOH. Five Lewis rats were trained to discriminate EtOH (1.5 g/kg, i.g.) from water in a two-lever, food-reinforced (FR15) discrimination procedure. Once EtOH demonstrated control over behavior (six consecutive days of ≥90% drug-appropriate responding), dose-effect curves for EtOH (0.25-2.0 g/kg) and substitution tests with MOR (0.32-5.6 mg/kg, s.c.) and pentobarbital (3-18 mg/kg, i.p.) were run. Results showed dose-related responding to EtOH and that pentobarbital, but not MOR, substituted for EtOH. Next, we tested whether NTX antagonized EtOH discrimination in combination tests of NTX (1-30 mg/kg, s.c.) plus EtOH (1.5 g/kg) and NTX (10 mg/kg) with EtOH (0.25-2.0 g/kg). NTX partially antagonized EtOH-appropriate responding to the training dose of EtOH and lead to a small, but significant disruption of response rates. The EtOH dose response curve was flattened after pretreatment with 10 mg/kg NTX, with EtOH-appropriate responding not exceeding 40-50% across EtOH doses. Finally, tests of whether MOR (0.32-5.6 mg/kg, s.c.) would potentiate the discrimination of low EtOH doses (0.25, 0.5 g/kg) were run but the data did not support such an effect. These data suggest that opioid actions may be involved in the discriminative stimulus properties of EtOH. Support: VA-Yale Alcoholism Research Center and NIDA DA-08227.

755.6

EFFECT OF CLOZAPINE, BMY 14802 AND TIOSPIRONE ON THE VOLITIONAL CONSUMPTION OF ETHANOL BY RATS. B. A. McMillen*, H. L. Williams and R. D. Myers, Dept. of Pharmacol., School of Medicine, East Carolina University, Greenville, NC 27858.

Atypical antipsychotic drugs do not produce a strong inhibition of the dopaminergic system and offer an alternative treatment strategy for the reduction of ethanol (EtOH) drinking. Unlike classical neuroleptics, such drugs do not produce dysphoria or extrapyramidal side-effects. Three such antipsychotic drugs were tested on cyanamid-treated rats. The rats received a 10 day step-up procedure with free access to tap water and 3% to 30% EtOH (v/v). The concentration of EtOH which produced maximal consumption with a proportion nearest to 50% was selected as the preferred concentration. Food, fluids and body weight were measured each day and the position of the bottles rotated. Injections were made s.c. 2 hr. before and 3 hr. after lights out on 3 consecutive days. Up to 12 mg/kg of clozapine was without effect on the consumption of EtOH. The sigma antagonist and $5HT_{1a}$ partial agonist, BMY 14802, caused a 64.3% reduction of drinking at a dose of 20 mg/kg, which also decreased food intake by 23.5%. The DA/$5HT_{1a}$ drug, tiospirone at 1.5 mg/kg, potently reduced the consumption of EtOH from 4.59 g/day to 1.95 g/day (57.5%) and caused a 12.8% increase in consumption of food. The proportion declined by 37.4%. Thus, only tiospirone had an effect that was specific for the consumption of EtOH and allowed a compensatory increase of food intake to offset the loss of calories. These data suggest tiospirone may have potential as an adjunct to the psychotherapy of alcoholism. (Supp. by AA-04200-13)

755.7

THE EFFECTS OF ISOLATION-REARING ON ETHANOL CONSUMPTION IN WISTAR AND FAWN HOODED RATS. F. S. Hall*, S. Huang, G. Fong, A. Pert, M. Linnoila Laboratory of Clinical Studies/DICBR, NIAAA and Biological Psychiatry Branch, NIMH, Bethesda, MD 20892

Fawn Hooded rats have been reported to be an ethanol-preferring strain (Overstreet et al, 1992). Social isolation has also been reported to increase voluntary ethanol consumption (Wolfgramm, 1990). The present experiment examined the interaction between these genetic and experiential effects on voluntary ethanol consumption. Fawn Hooded and Wistar rats were received at day 21 postnatal and either single housed (isolation) or paired housed (social. After at least 8 weeks of housing voluntary consumption of ethanol was monitored in home cages using a 2 bottle test (ethanol versus water). The initial concentration of ethanol was 2% and following establishment of stable consumption (1-2 weeks at each concentration) was increased to 4%, 8%, and 16%. At low concentrations (2% and 4%), but not higher concentrations, Fawn Hooded rats consumed more ethanol than Wistar rats, independent of rearing condition. To determine whether this was due to delayed acquisition the two lowest concentrations were repeated and, once again, Fawn Hooded rats consumed more ethanol. A different pattern was found at the highest concentration: Isolation-reared rats consumed more 16% ethanol than socially reared rats independent of strain. These Fawn Hooded rats (from NCI, Frederick) had enhanced consumption of low concentrations of ethanol, which is different from the reportedly enhanced consumption of higher concentrations in other Fawn Hooded rats (from UNC, Chapel Hill). The effects of genetic background and isolation-rearing on ethanol consumption were independent. These effects may be related to increased sensitivity to either the rewarding or anxiolytic effects of ethanol. Isolation-reared rats exhibit enhanced responses to a variety of reinforcers, and also exhibit enhanced anxiety, relative to social controls. Fawn-hooded rats also exhibit enhanced anxiety relative to Wistar rats. (Funding: NIAAA/DICBR, NIMH/BPB)

SENSITIVITY TO NICOTINE CO-SEGREGATES WITH SENSITIVITY TO ETHANOL: STUDIES IN THE SELECTIVELY-BRED HIGH AND LOW ALCOHOL SENSITIVITY (HAS/LAS) RAT LINES. C.M. de Fiebre*, C. Stokes and E.M. Meyer. Dept. of Pharmacology & Therapeutics, Univ. of Florida Col. of Med. Gainesville, FL 32610.

Although the positive correlation between alcoholism and smoking has often been noted, little is known about the factors which influence the development of this most common form of polydrug abuse. The current study is a follow-up of a previous study (*Alc Clin Exp Res*, 15: 270-6, 1991) in which the nicotine sensitivity of the High Alcohol Sensitivity (HAS) and Low Alcohol Sensitivity (LAS) rats was examined at an early stage of selective breeding (generations 11 and 13). In the earlier study, minor differences in nicotine sensitivity were seen. In the present study, the sensitivity of the replicate lines to nicotine-induced depression of locomotor activity and body temperature as well as to nicotine-induced seizures was examined. At all doses examined, both replicate alcohol sensitive lines (HAS1 and HAS2) were more sensitive to nicotine-induced depression of locomotor activity than were the alcohol insensitive lines (LAS1 and LAS2). There was a trend for the HAS lines to also be more sensitive to nicotine-induced hypothermia; however, statistical significance was not attained with the number of animals tested to date. No line differences were seen on the seizure test; however, females were more sensitive to nicotine-induced seizures than were males. These data support the hypothesis that on some, but not all measures of drug sensitivity, sensitivity to ethanol and nicotine are genetically correlated,

This project was supported by a grant from the NIAAA (AA-09585). HAS/LAS rats were generously supplied by Drs. Richard Deitrich and Laura Draski of the University of Colorado Health Sciences Center.

EFFECTS OF ETHANOL ON TEMPORAL RECOVERY OF AUDITORY EVOKED POTENTIALS IN HIGH RISK INDIVIDUALS H.L. Cohen*, B. Porjesz and H. Begleiter Neurodynamics Lab, SUNY Hlth. Sci. Ctr., Bklyn Bklyn, N.Y. 11203

The effects of placebo (P), low dose (LD) and high dose (HD) ethanol on auditory (AEP) recovery functions were examined in young adult males at high risk (HR) for alcoholism, and matched, low risk (LR) controls. Condition order was randomized, with one condition per day and at least one day between conditions. Blood alcohol level(s)(BAL) and ERPs (entire 10/20 International System), were assessed prior to and at 20, 60, 90 and 130 min after drink ingestion. N100 and P200 components of the AEP were elicited with a series of binaural auditory stimuli with randomly interposed interstimulus intervals(ISIs) of 0.5, 1.0 and 10.0 sec., and were evaluated at Fz, Cz Pz, F3, F4, C3, C4, P3 and P4. Baseline measures revealed no within group differences across test days and no between group differences on the same test day. In both groups, ethanol ingestion produced amplitude decrements without latency changes during the ascending BAL (acute sensitization); the magnitude of the decrease was greater in the HR group, particularly in P200 under HD ethanol and 1.0 and 10.0 sec ISIs. During the descending BAL both groups demonstrated returns to baseline levels (acute tolerance); the magnitude of the return was greater in the HR group, again under HD ethanol and 1.0 and 10.0 sec ISIs. Neither group manifested dose-related differences. Our findings support Newlin and Thomson's (1990) Differentiator Model indicating that LR and HR individuals are differentially sensitive to the rising and falling phases of the blood alcohol curve.

AGGRESSIVE AND SOCIAL BEHAVIOR AFTER SELF-ADMINISTERED ETHANOL IN SQUIRREL MONKEYS. K.A. Miczek,* K. Titchen, J. Cole, S. Mandillo, Dept. Psychology, Psychiatry, Pharmacology, Tufts Univ., Medford MA 02155.

The current objective was to establish ethanol self-administration in socially living squirrel monkeys and to study how the self-administered ethanol affected aggressive and social behavior. Three studies were conducted, using a specially designed experimental chamber that was inserted into the large colony room housing 6-10 member troops of squirrel monkeys. Individual monkeys entered the chamber for specific periods of access to ethanol solutions. In the first experiment, monkeys were induced to consume ethanol in a 20% sucrose solution, while food and water were continuously available. The consumption of increasing concentrations of ethanol (1-4% w/v) during a daily 10 min access period produced BACs ranging from 15-55 mg/dl. After consuming these low non-sedative doses of ethanol, dominant monkeys increased their aggressive displays toward other group members. When drinking the higher ethanol concentrations, lower ranking monkeys became the target of aggressive displays by other non-drinking monkeys. When given unlimited access to 3% ethanol for 48 h, 6 out of 8 monkeys consumed ethanol in preference to an isocaloric sucrose solution, up to intoxicating levels (ca.1-5 g/kg/24h) during at least one of four ethanol "binge" episodes. The concentration- and time-dependent ethanol intake point to the feasability of studying self-administration in a social context. Sending and receiving more aggressive acts after alcohol consumption points to distorted social communication. (Supported by U.S.P.H.S. R37 AA05122)

CEREBRAL SIGNS OF IMPAIRED ADAPTATION TO AUDITORY STIMULI IN IMPULSIVE VIOLENT ALCOHOLICS J. Karhu*, J. Kuikka, A. Pääkkönen, K. Bergström, J. Partanen, and J. Tiihonen Kuopio University Hospital, and Niuvanniemi Hospital, Kuopio, Finland.

Impulsive violence and alcoholism encompass impaired adaptation to surroundings and frequent misjudgement of external cues. Decrease in the size of cortical event-related potentials (ERPs) to repeated stimuli reflects diminishing arousal (or orienting) elicited by a novel stimulus and subsequent building of a neuronal model of external input. These neural representations of immediate events are required for recurring correct detection of novelty in the surroundings.

We studied the processing of auditory stimuli in ten habitually violent alcoholics with poor impulse control (mean age 30.3 years; all males), in ten age-matched normal subjects (mean age 31.3 years; all males), and in six alcoholics with no history of impulsive behaviour (mean age 46.7 years; all males). Identical tones (frequency 800 Hz; duration 85 ms) were presented in trains of four (interstimulus interval, ISI, of 1s). The trains were separated by 12s silences to evaluate the orienting reaction and adaptation to stimuli. Similar tones were delivered also with a continuous ISI of 1s and randomly interspersed "oddballs" (15 %; frequency 560 Hz). Subjects were told to ignore the sounds and they watched an attention-capturing silent video while evoked electric signals were monitored continuously from 21 scalp electrodes.

Impulsive alcoholic offenders with antisocial personality traits showed markedly impaired adaptation of auditory ERPs and delayed responses to deviant tones, whereas alcoholics with no history of violent assaults showed signs of diminished arousal. This difference in automatic information processing supports the concept of two types of alcoholism, one connected with genetic loading, early onset, and antisocial behaviour, and another without these signs. Moreover, the alterations in involuntary adaptive functions of neuronal networks may reflect the basic pathophysiological mechanisms associated with impulsive behaviour and substance abuse.

CHRONIC USE OF COMMERCIAL BENZODIAZEPINES IN ANXIOUS SUBJECTS AND PROTRACTED EXPOSURE TO ENDOGENOUS BENZODIAZEPINES IN HEPATIC ENCEPHALOPATHY REDUCE THE LEVELS OF CIRCULATING DIAZEPAM BINDING INHIBITOR (DBI). M. Baraldi[a], R. Avallone, L. Corsi, I. Venturini[a], F. Farina[a], M.L. Zeneroli[a], N. Pecora[b], M. Frigo[b] and C. Ferrarese[b]. Depts. of Pharmaceutical Sciences and of Internal Medicine[a], Modena University and Dept. of Neurology[b], Milan University (Monza), Italy.

It is well established that protracted assumption of benzodiazepines (Bzs) yields tolerance to the acute effects of these compounds, induces physical dependence and withdrawal reactions after abrupt treatment discontinuation. It has been suggested that the tolerance phenomenon to Bzs could result from a desensitization process of GABA receptors in the brain. The molecular mechanism, however, is still unclear. The chronic exposure to Bzs, in fact, is not associated with changes in the chracteristics of benzodiazepine recognition sites. While these phenomena have been correlated in men with an increased level of circulating Bzs after drug medication, little is known on the level of the polypeptide termed DBI which is a negative allosteric modulator of GABA receptors. Moreover there are pathological conditions such as hepatic encephalopathy (HE) due to liver cirrhosis where there is an increased sensitivity of the GABA receptor system. In this pathological condition it has been demonstrated an increased presence of Bzs-like substances which seems to be represented by Diazepam and Desmethyldiazepam but mainly by unknown compounds. The present experiments were designed in order to further characterize the nature of the Bzs endogenous ligands in HE and to test whether a change in the level of DBI may undergo to compensatory phenomenon as described in the CNS. The total amount of circulating Bz-like material was estimated by a radioreceptor binding assay using ^{3}H-Flunitrazepam as radioligand in the plasma of 19 controls, 17 liver cirrhosis without HE, 12 liver cirrhosis with HE, and 8 anxious subjects chronically assuming Bzs. In parallel the plasma level DBI was tested by RIA using a specific antibody. Bz-like compounds were found significantly increased in cirrotic patients with HE in comparison with controls and with liver cirrhosis without HE. The maximum values were recorded however in anxious patients addicted to Bzs. By the contrary the levels of DBI were normal in liver cirrhosis without HE while they were significantly decreased in both HE and Bz consumers. This seems to indicate a direct influence by plasma Bzs on the levels of DBI in the periphery. (Grant N. 7240/93 MIRAF-Rome-Italy)

THE K-OPIOID RECEPTOR AGONIST, U-69593, MODIFIES COCAINE- BUT NOT QUINPIROLE-INDUCED ALTERATIONS IN STRIATAL DOPAMINE
J.B. Acri *, Ch. A. Heidbreder, A.C. Thompson, A.K. Pani, and T.S. Shippenberg, Neuroimaging/Drug Action Section, NIDA-ARC, NIH, Baltimore., MD 21224

The locomotor stimulant effects of an acute cocaine challenge can be blocked by repeated prior administration of the selective K-opioid receptor agonist, U-69593. Likewise, the same treatment regimen in combination with cocaine can block the sensitized locomotor response to cocaine. While the mechanism by which these effects are mediated are unclear, it is known that acute administration of K-agonists decreases dopamine concentration in the striatum, and there is evidence that daily treatment regimens with U-69593 can acutely downregulate dopamine D2 receptors in the striatum. The present studies were undertaken to evaluate the influence of repeated administration of U-69593 on cocaine- and quinpirole-induced changes in extracellular dopamine in the dorsal striatum as measured by in-vivo microdialysis. Male Sprague-Dawley rats implanted with microdialysis cannulae in the caudate putamen were treated with once-daily SC injections of 0.32 mg/kg U-69593 on days 1-3. On day 5, basal dialysate samples were taken for 1.5 hr, followed by acute challenge with either 20 mg/kg cocaine or 0.05 mg/kg of the dopamine D2/D3 receptor agonist, quinpirole. Dialysate samples were then taken for 3.5 hrs. Two additional groups of rats were challenged via infusion of 10 µM quinpirole through the microdialysis probe. Administration of cocaine resulted in a mean peak increase of ~300% in extracellular dopamine that was potentiated to ~500% in animals pre-treated with U-69593. In contrast, data reveal a ~40% decrease in striatal dopamine concentration following systemic or intra-striatal infusion of quinpirole, and pre-treatment with U-69593 had no effect on this decrease. Taken as a whole, these data suggest that the mechanism by which U-69593 affects behavioral responses to cocaine does not involve dopamine D2/D3 autoreceptors in the striatum.

EFFECTS OF CAFFEINE ON COCAINE-INDUCED DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS (NAc). C. E. Chen, N. D. Volkow*, J.S. Fowler, and S.L. Dewey, Chem and Med Dep'ts, BNL, Upton, NY 11973; College of Pharm & Allied Health Prof, St. Johns Univ, Queens, NY.

Using positron emission tomography (PET) we previously imaged neurotransmitter interactions (dopamine, 5-HT, ACh, GABA, and the opiates) in the living primate and human brain and utilized *in vivo* microdialysis techniques to support our PET findings. In an ongoing effort to develop new treatment strategies for cocaine abuse, we recently applied our PET findings to an examination of the effects of neurotransmitter-specific drugs on the ability of cocaine to increase extracellular dopamine. Gamma vinyl-GABA (GVG, GABAergic) and caffeine (adenosine) are examples of two such drugs. Budney, et al., (1993) demonstrated that the prevalence of caffeine use is significantly less in cocaine-dependent individuals. We measured the effects of caffeine (30 mg/kg) on cocaine-induced (20 mg/kg) extracellular dopamine release in the NAc of freely moving rats (n=6). While both caffeine and cocaine significantly increased locomotor activity, there was no effect of caffeine on extracellular dopamine concentrations. However, caffeine pretreatment significantly attenuated cocaine-induced dopamine release relative to saline matched controls (270% vs. 480% for caffeine and saline, respectively) and significanlty increased the time it took for dopamine to return to baseline values. Dopamine metabolites were unaffected by either drug. These data may explain, in part, the findings that cocaine-dependent individuals tend to consume less caffeine than their control counterparts. DOE/OHER.

TRAINING DOSE HISTORY INFLUENCES THE D1 AND D2 RECEPTOR MECHANISMS MEDIATING THE DISCRIMINATIVE STIMULUS EFFECTS OF COCAINE. A.K. Singha* and L.L. Hernández. Dorn VA Medical Center & University of South Carolina, Columbia, SC 29209.

We examined the role of training dose on the dopamine receptor mechanisms mediating the discriminative stimulus (DS) effects of cocaine in rats trained to discriminate either 5.0, 10.0, or 20.0 mg/kg cocaine from saline (i.p.), using the two-lever drug discrimination procedure. The ED50 values for cocaine increased with training dose (i.e., 1.4, 2.8 and 3.7 mg/kg, respectively). Moreover, cocaine alone was twice as potent in the 5.0 mg/kg group than when combined with the D2 antagonist eticlopride (0.03 mg/kg), and 7.5 times more potent than when combined with the D1 blocker SCH 39166 (0.20 mg/kg). However, in the 10 mg/kg group, cocaine alone was approximately 1.8 times more potent than when combined with either the D1 or the D2 antagonist. Finally, in animals trained on 20 mg/kg cocaine, eticlopride and SCH 39166 reduced the ED50 of cocaine by about 1.7 and 2.3 times. These data show that both D1 and D2 receptor subtypes mediate the cocaine DS, but the contribution of each receptor subtype depends on the animals' training dose history.

THE CLINICALLY AVAILABLE DOPAMINE RELEASER, PHENTERMINE, REDUCES COCAINE-INDUCED INCREASES IN MESOLIMBIC DOPAMINE AND COCAINE SELF-ADMINISTRATION. R.B. Rothman*1, M. Ayestas1, F.H.E. Wojnicki2, J.R. Glowa2 and M.H. Baumann1. 1CPS, DIR, NIDA and 2LMC, DIR, NIDDK, NIH, Baltimore and Bethesda, MD.

Combined dopamine (DA) and 5-HT releasers such as phentermine (PHEN) and fenfluramine (FEN) are reported, in open label studies, to reduce craving for alcohol and cocaine and to prevent relapse (J. Subst. Ab. Res. 11:273-275, 1994; 11:489-490, 1994; 12:449-453, 1995). In vivo microdialysis experiments demonstrate that these agents preferentially release mesolimbic DA (PHEN) and 5-HT (FEN) (see Baumann et al., this meeting). Patients who relapse and use cocaine while taking these medications report diminished cocaine-like subjective effects. The experiments reported here examined the effect of phentermine alone in two animal models of cocaine addiction. Study 1. Microdialysis experiments were performed in awake rats, and dialysate samples were analyzed for DA and 5-HT. PHEN (1 mg/kg iv) elevated DA (2-3 fold) for over 1.5 hr. Administration of cocaine (1 mg/kg iv) increased DA 6-fold in saline-treated rats, but only 3-fold in phentermine-treated rats. Study 2. Lever-pressing was maintained under multiple FR 30-response schedules of food and intravenous cocaine delivery to 8-9 kg male rhesus monkeys. Intermediate unit doses of cocaine (10-30 µg/kg/inj) maintained high levels of responding in the drug delivery components, comparable to those maintained by food presentation. The effect of phentermine determined as a single dose (0.3 - 3.0 mg/kg, i.v. slow infusion) selectively decreased cocaine self-administration. These effects were sustained with repeated daily dosing. Conclusion. These results demonstrate that a clinically available DA releaser with low abuse liability can suppress cocaine self-administration in an animal model of cocaine-seeking behavior and also reduce the ability of cocaine to increase mesolimbic DA. Viewed collectively, these results provide a strong preclinical rationale for clinical trials of DA releasers as substitution-type medications for cocaine addiction.

FURTHER EVIDENCE FOR DIFFERENCES BETWEEN THE DOPAMINE REUPTAKE INHIBITORS BTCP AND COCAINE AFTER REPEATED TREATMENT

E.P.M. Prinssen*[1], M.S. Kleven[1], J. Vignon[2], J. Kamenka[3] and W. Koek[1], [1]Institut de Recherche Pierre Fabre, Castres, France; [2]INSERM U336, and [3]CNRS UPR 9008, INSERM U429, Montpellier, France

The dopamine reuptake inhibitors BTCP and cocaine produce similar effects on locomotion after acute treatment, but different effects after repeated treatment (Prinssen et al., JPET 276, 904, 1996). In order to further examine differences in cocaine-induced locomotion after repeated cocaine or BTCP treatment, male C57BL/6 mice were treated IP with cocaine (20 mg/kg) or BTCP (20 mg/kg) during one 3-day period (days 1-3) and, 3 days later, repeatedly treated with BTCP (20 mg/kg) or cocaine (20 mg/kg; days 7-9), and then tested with cocaine (0-40 mg/kg, IP) on day 10. During daily sessions, mice were placed in an observation cage for a 50 min habituation period, injected, and locomotion was recorded for 30 min using an automated activity monitor.

Cocaine during period 1, followed by saline, cocaine or BTCP during period 2, induced leftward shifts of the cocaine dose-response function on day 10 that were similar for the three conditions. Treatment with BTCP, followed by saline, produced effects similar to those found previously (i.e., left- and downward shifts of the cocaine dose-response curve). Administration of cocaine during period 2 partially attenuated the effects of BTCP, although they were still significantly less than those produced by repeated cocaine alone. These data suggest that the initial effects produced by either repeated cocaine (i.e., a leftward shift of the cocaine dose-response function) or repeated BTCP (i.e., left- and downward shifts of the cocaine dose-response) are not markedly altered by subsequent repeated treatment with cocaine and/or BTCP, thus further demonstrating the existence of differences between BTCP and cocaine that become apparent after chronic administration. A CONTINUUM MODEL OF CENTRAL DOPAMINE-SEROTONIN INTERACTIONS: STUDIES WITH AMPHETAMINE DERIVATIVES. M.H.Baumann*, M.A. Ayestas, C.M. Dersch and R.B. Rothman. CPS, DIR, NIDA, NIH, Baltimore, MD 21224.

Dopamine (DA) neuronal activity is modulated by serotonin (5-HT) in a complex manner. In the present work, we examined the relationship between DA and 5-HT function by testing a series of amphetamine analogs in neurochemical and behavioral assays. In vivo microdialysis was performed in the nucleus accumbens of awake rats. Phentermine, chlorphentermine, fenfluramine, or a mixture of phentermine plus fenfluramine (PHEN/FEN), was administered locally through the probe and by ip injection. Phentermine preferentially elevated extracellular DA whereas fenfluramine elevated 5-HT. Chlorphentermine and PHEN/FEN produced concurrent increases in DA and 5-HT. These agents were tested for their ability to release preloaded [^{3}H]DA and [^{3}H]5-HT from rat brain synaptosomes; the relative potencies and DA/5-HT selectivity ratios determined in vitro were similar to in vivo findings. Phentermine produced robust locomotor activation in mice, but fenfluramine and chlorphentermine did not. Interestingly, coadministration of fenfluramine antagonized the stimulant effects of phentermine. Our data support historical literature that suggests DA and 5-HT neuronal systems can be viewed as opposing forces along a continuum, with net behavioral state being defined by the sum total of these forces. Shifting the balance in favor of DA is expressed as behavioral activation whereas shifting the balance in favor of 5-HT results in behavioral inhibition.

PRECLINICAL SCREENING OF AN IBOGAINE METABOLITE (NORIBOGAINE) ON COCAINE-INDUCED HYPERLOCOMOTION AND COCAINE SELF-ADMINISTRATION. D.C. Mash*[1] & S. Schenk [2], [1] Depts. Neurology & Mol. Cell. Pharmacol., Univ. Miami Med Sch., Miami, FL 33101; [2] Dept. Psychol., Texas A & M Univ., College Station, TX 77843.

The potential for deriving new psychotherapeutic medications from natural sources has led to an interest in rain forest plants for the development of anti-addiction medications. Recent studies have suggested that some of the neurobehavioral and physiological effects of ibogaine may be mediated by an active metabolite. Ibogaine undergoes first pass metabolism and is O-demethylated to 12-hydroxyibogamine (noribogaine). We report here the effects of noribogaine on cocaine-induced hyperlocomotion and self-administration of cocaine. For the activity tests, male Sprague-Dawley rats (4-6 per group) were pretreated with noribogaine (0.0, 20.0, or 40.0 mg/kg, IP) 45 min prior to being placed in Digiscan Activity monitors. The first 15 min of this test comprised a habituation period. Cocaine (0.0, 20.0 or 40 mg/kg, I.P.) was then administered and activity was monitored for an additional 30 min. Cocaine produced a dose-dependent increase in horizontal activity. Although the 20 mg/kg dose of noribogaine was ineffective, 40.0 mg/kg shifted the dose-effect curve for cocaine to the right. For self-administration tests (N = 4), dose-effect curves were generated using a within-session multi-dose procedure. The rising phase of the dose-effect curve was obtained as the dose of cocaine was increased from 0.03 to 0.06 mg/kg infusion. Higher doses defined the falling phase of the curve. Noribogaine (40.0 mg/kg) administered one hour prior to the test, also shifted the dose-effect curve to the right. Higher doses of noribogaine completely abolished responding for cocaine. Futher studies are underway to relate the pharmacokinetic profile of noribogaine to its potential anti-addictive properties. Supported by NO1 DA38201 and the Addiction Research Fund.

QUANTIFICATION OF HABITUATION-SENSITIZATION DURING DRUG SELF-ADMINISTRATION SESSIONS. John M. Roll* and Frances K. McSweeney. University of Vermont and Washington State University, Burlington VT 05401 and Pullman, WA 99164.

When organisms respond for drug reinforcers, during operant conditioning procedures, their rate of responding frequently changes during the course of individual experimental sessions. Behavioral pharmacologists have espoused a number of putative explanations for these changes in response rate such as dopamine-loading and stereotypy. Recent research has shown, however, that similar changes in responding occur during operant sessions in which non-drug reinforcers are used (e.g., food, water, light onset). These changes in responding, when they occur with non-drug reinforcers, are generally attributed to sensitization-habituation which occurs to both the experimental context and the delivery of reinforcers. Recently, McSweeney, Hinson, & Cannon, (1996) presented a quantitative model describing these changes in response rate (Equation 1). This model describes a variety of operant data, commonly accounting for over 90% of the variance in a given data set. The current study assess the utility of this model for describing data obtained when organisms self-administer drugs. Results indicate that the model describes responding for ethanol and cocaine reinforcers quite well. This suggests that factors (i.e., habituation-sensitization) which control the form of within-session response patterns in traditional operant preparations (e.g., food- or water-reinforced) may control within-session response patterns in drug-reinforced preparations. This challenges some explanations for these within-session response patterns commonly held by behavioral pharmacologists such as dopamine-loading and stereotypy. Supported by the National Science Foundation under grant number IBN-9207346.

(Equation 1) {(P= b/e^{at} - (c*t)/(c+t) * 1/t) P= proportion of total-session responses emitted during a specified interval; t= ordinal number of interval (P); a, b and c = free parameters}

A MULTI-COMPONENT LEARNING MODEL OF DRUG ABUSE: DRUG-TAKING, CRAVING, AND PHYSIOLOGICAL CHANGES MAY INVOLVE DIFFERENT BRAIN CIRCUITS. J.L. Haraczy*, R. Sircar. Dept. Psychiatry, Albert Einstein Coll. of Med., Bronx, NY 10461.

Exposure of cocaine abusers to cues previously associated with cocaine elicits what appears to be conditioned responses, which include craving and physiological signs of arousal. This and other evidence supports the conclusion that "drug-taking is learned behavior and is controlled by the normal principles of learning" (Bigelow, NIDA Res. Monograph 152, 1995, p. 1). Studies of animals and humans suggest that, rather than being a unitary phenomenon, learning may involve behavioral, emotional, and physiological changes mediated by different brain circuits. For example, different brain pathways mediate the behavioral and physiological conditioned-fear responses in rats as well as the conditioned motor and physiological (e.g., heart-rate) responses in rabbit classical conditioning. Analogously, a multi-component learning model (MLM) of drug abuse predicts that drug-taking behavior, feelings of craving, and physiological arousal depend to some extent on different brain substrates. Accordingly, drugs targeted at suppressing craving have not had widespread success in achieving long-term reductions in drug abuse. For example, desipramine decreased craving for cocaine without affecting cocaine self-administration by addicts (Fischman et al., JPET 253:760, 1990). Furthermore, craving and relapse showed little correlation in 1626 cocaine or alcohol abusers (Miller and Gold, Annals Clin. Psychiatry 6:99, 1994). The MLM suggests that research on mechanisms of craving can be usefully complemented by studies of the neural plasticity underlying learned drug self-administration behavior. Elucidating this neural plasticity could provide a new target for drug development because the pharmacotherapeutic reversal of these neural adaptations may yield an enduring extinction-like effect on learned drug-seeking behavior. Such drug development may achieve a more sustained treatment for addiction than drugs that merely suppress symptoms of craving or withdrawal. Recidivism associated with symptomatic treatments may reflect the failure of these drugs to reverse long-lasting neural plasticity underlying drug-seeking behavior. INFLUENCE OF BUTYRYLCHOLINESTERASE (BChE) ON COCAINE-INDUCED MOTOR ACTIVITY IN RATS, C.W. Schindler, G.N. Carmona, S.R. Goldberg, N.H. Greig#, E.J. Cone, M. Shoaib, K. Preston,* and D.A. Gorelick. NIH/NIDA Div. of Intramural Research, Balt., MD 21224 and #NIH/NIA Gerontology Research Center, Drug Design & Development.

BChE (EC 3.1.1.8) is an important cocaine-metabolizing enzyme; thus, changes in its activity may alter effects of cocaine. We evaluated this by administering exogenous horse serum-derived BChE (5,000 U iv), the BChE inhibitor cymserine (10 mg/kg ip), or saline (iv) to separate groups of 10 male Sprague-Dawley rats 30 minutes before cocaine (1 mg/kg iv) or saline. Cocaine produced the expected substantial increases in distance traveled and stereotypy time over the 120-minute monitoring period, which were significantly reduced by BChE pretreatment and enhanced (during the 2nd 30 minutes only) by cymserine pretreatment. BChE by itself had no significant effect during the 30-minute pre-cocaine habituation period, while cymserine significantly reduced motor activity during the first 15 minutes only. In a separate group of rats, this dose of iv BChE increased brain BChE activity three-fold. These findings suggest that enhancement of cocaine metabolism with exogenous BChE can significantly reduce acute effects of cocaine administration.

DIFFERENTIAL EFFECTS OF DOPAMINE UPTAKE INHIBITORS ON DOPAMINE TRANSPORTERS AND BLOOD PRESSURE IN RATS. S.R.Tella*, Bruce Ladenheim, Steven R.Goldberg, J.L. Cadet. Department of Pharmacology, Georgetown University School of Medicine, 3900 Reservoir Road, Washington, DC 20007. and Behavioral Pharmacology & Genetics and Molecular Neuropsychiatry Sections, NIH/NIDA, Division of Intramural Research, P.O. Box 5180, Baltimore, MD 21224

We have recently shown that cocaine produces a norepinephrine transporter-independent rapid, short lasting initial increase in blood pressure which is followed by a more moderate longer lasting pressure elevation. Also, cocaine self-administration causes upregulation of dopamine (DA) transporters. In contrast, GBR-12909, a DA-selective uptake inhibitor, produces neither this rapid pressor response nor upregulation of DA transporters and it has limited reinforcing effects. In the present study, we tested the reinforcing, neuroadaptive and blood pressure effects of two other DA uptake inhibitors, bupropion and nomifensine in Sprague-Dawley rats. Rats were trained to lever press for food on a fixed-ratio 10 schedule. Following lever press training, the iv infusions of bupropion (0.75-3 mg/kg/infusion), nomifensine (0.1-1 mg/kg/infusion) or sterile water replaced food reinforcement. Bupropion (3 mg/kg/infusion) and nomifensine (1 mg/kg/infusion), unlike water, reliably maintained high rates of responding for the entire testing period (8 to 10 weeks, 2 hr/day). Bupropion self-administration caused upregulation of DA transporters in several dopaminergic regions, while nomifensine did not alter these transporters as assessed by quantitative in vitro autoradiography using [^{125}I]RTI-121. Similar to cocaine, bupropion, but not nomifensine, produced a rapid pressor response in rats following pretreatment with DA antagonist, SCH23390. These data indicate that though both drugs are self-administered by rats, bupropion, but not nomifensine, is cocaine-like in causing upregulation of DA transporters and in producing rapid pressor responses. These results suggest that there may be two pharmacological subclasses of dopamine uptake inhibitors; one is cocaine-like causing upregulation of DA transporters and rapid pressor responses, while the other is noncocaine-like and lacks these effects. *Supported in part by USPHS, NIDA grant # DA08830.*

COCAINE DELIRIUM AND SUDDEN DEATH: IMBALANCED DOPAMINERGIC AND CHOLINERGIC SIGNALING MAY MEDIATE THE PATHOGENIC CONSEQUENCES. E. M. Garland*[1], J. K. Staley[1], R. E. Mittleman[2], E. J. Mufson[3], W. J. Weiner[1], and D.C. Mash[1], [1]Dept. Neurology, Univ. Miami Med Sch., [2]Metro-Dade County Med. Exam. Dept., Miami, FL 33101, and [3]Rush Presbyterian Med. Ctr., Chicago, IL 60612.

The cocaine delirium (CD) and sudden death syndrome was first described in 1985 at the beginning of the crack cocaine epidemic in Dade County, FL. The syndrome is characterized by marked agitation, psychotic behaviors, hyperthermia, and a sudden onset of rigidity prior to death. We report here neurochemical autopsy findings on the status of the dopamine transporter (DAT), D1 and D2 receptors and choline acetyltransferase (ChAT) activity. Ligand binding, autoradiographic mapping and enzyme assays were conducted in the striatum and hypothalamus. A significant decrease in ChAT activity was observed in the CD subgroup of cocaine overdose victims ($n = 13$) when compared to drug-free, age-matched control subjects ($n = 11$; $p < .005$). Cocaine overdose (CO) victims without preterminal psychosis ($n = 11$) had ChAT values that were in the normal range. DAT densities were decreased significantly in the CD subgroup ($p < .05$), while striatal D2 receptors were unchanged. In contrast, DA transporter densities were markedly elevated in the CO victims as compared to age-matched and drug-free control subjects ($p < .001$). D2 receptors were decreased ($p < .05$) also in the CD subgroup over hypothalamic thermoregulatory centers. Autopsy findings provide neurochemical evidence for a dysregulation in the balance of striatal dopamine and acetylcholine signaling. Altered striatal DAergic signaling that is exacerbated by a cholinergic deficit may precipitate the acute onset of cocaine delirium. Funded by DA 06227.

EXTRACELLULAR REGIONS OF RECEPTOR PROTEIN TYROSINE PHOSPHATASE (RPTP)β BIND TO NEURONAL CELL ADHESION MOLECULES AND INDUCE NEURITE OUTGROWTH M. Lustig*, T. Sakurai, J. Schlessinger, E. Peles, and M. Grumet. Dept. of Pharmacology, NYU Medical Center, 550 First Avenue, New York, NY 10016 and SUGEN, Redwood City, CA 94063.

Receptor protein tyrosine phosphatase β (RPTPβ) is expressed as short and long receptor forms and as a soluble form called phosphacan that are regulated during neural development. To analyze the function of receptor forms, we used recombinant Fc fusion proteins with the extracellular region of the short form of RPTPβ, consisting of domains homologous to carbonic anhydrase (C), the fibronectin type III repeat (F), and a unique region called S. We showed previously that the C domain of RPTPβ (βC) can bind to the lipid-anchored cell adhesion molecule contactin, and thereby promotes neuronal adhesion and neurite extension (Peles, et al, Cell 82:1-20,1995). As a substrate, the βCFS fusion protein was less effective in supporting cell adhesion, but it was a more effective promoter of neurite outgrowth from primary chick tectal neurons than βC and βCF. Although the βS fusion protein did not support neuronal adhesion, it bound to Ng-CAM and Nr-CAM but not to contactin. These results suggest that C and S regions of glial RPTPβ bind to different CAMs on neurons and that their combined action is important for neurite growth. To evaluate the ligands for RPTPβ and potential functions in vivo, we have begun to analyze binding of recombinant Fc fusion proteins with the extracellular region of RPTPβ to whole mounts and vibratome sections of chick embryos. Detection of βCF with fluorescent antibodies against the Fc region revealed staining of ventral and lateral fiber tracts in the spinal cord of developing embryos. Comparison of staining patterns of the various Fc fusion proteins with the distribution patterns of known CAM ligands suggests that RPTPβ may interact with certain neural CAMs in vivo. A NEW METHOD TO DELIVER ANTIBODIES INTO LIVING CELLS: INTRACELLULAR ANTIBODIES AGAINST PHOSPHOTAU INTERRUPT NEURITOGENESIS W.L. Klein[1], K.L. Barber[1]*, M.P. Lambert[1], B.A. Chromy[1], R. Kurtz[1], E. Donnelly[1], and R.C. MacDonald[2]. [1]Dept. of Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60208; [2]Dept. of Biochemistry, Molecular Biology, and Cell Biology, Northwestern Univ., Evanston, IL 60208

Delivery of antibodies into live cells is potentially of great use for identifying the function of specific antigens. Typical delivery protocols, however, are either extremely difficult (microinjection) or are intrinsically cytodisruptive (permeabilization). We have developed ***"lipotransfer"*** as a new and simple method to circumvent the cell permeability barrier and rapidly deliver active antibody to the cytoplasm of living cells. By lipotransfer, antibodies are transferred within minutes to essentially all cells in a culture population. Lipotransfer vehicle by itself is non-disruptive, making this method ideal for acute analyses.

In initial studies, lipotransfer was used to deliver PHF-1 into living B103 CNS nerve cells. PHF-1 is a monoclonal selective for a tau phosphoepitope found in immature and in Alzheimer's-afflicted neurons. Antibody introduced into live cells by lipotransfer binds to its antigen within 20 minutes. Localization is to cytoskeletal filaments (putatively microtubules). This distribution is identical to that in cells first fixed and then given PHF-1. The lipotransfer vehicle does not permeabilize cells to antibody added directly to culture medium. Time-lapse studies of cell behavior showed that intracellular PHF-1 eliminates the ability of B103 cells to maintain neurites. Lipotransfer of heat-treated PHF-1 has no effect. The results establish the functional importance of phosphorylated forms of tau to neuritogenesis. Lipotransfer also has been found effective at delivering other antibodies and impermeant drugs and probes. In conclusion, lipotransfer is a simple, strikingly effective, non-disruptive technique for functional knockout of antigen in living cells. Its ability to selectively neutralize post-translationally modified protein forms make it an excellent complement to antisense procedures. Lipotransfer promises to be of widespread usefulness for cell biological studies.

MOLECULAR ANALYSIS OF GROWTH-ASSOCIATED PROTEIN-(GAP)-43 FUNCTION L. Baizer*[a], M.C. Waage[a], R.G. Allen[b], and C. Gamby[c] [a]R.S. Dow Neurological Sciences Institute of Good Samaritan Hospital and Medical Center, and [b]CROET and [c]Department of Cell and Developmental Biology, OHSU Portland, Oregon 97209.

We reported previously that forced expression of GAP-43 in mouse anterior pituitary AtT-20 cells facilitates high potassium-evoked peptide hormone secretion and alters cellular morphology (Gamby et al, J. Biol. Chem.271:10023). We have proceeded to analyze the role that GAP-43-mediated sequestration of calmodulin (CaM) at the inner face of the plasma membrane plays in these responses.

Using chemical cross-linking in combination with co-immunoprecipitation and protein blot analyses, we show that in AtT-20 cells expressing wild-type GAP-43 and in cultured hippocampal neurons GAP-43 and CaM form a membrane-associated complex that is sensitive to intracellular calcium and phosphorylation. Transfection of several mutant forms of GAP-43 into AtT-20 cells shows that the effects on secretion depend on both membrane association and CaM binding. In contrast, the morphological changes depend only on membrane association. Thus the multiple effects of GAP-43 noted in previous studies may result from divergent properties of this protein.

GAP-43 AND CAP-23 PROMOTE NERVE SPROUTING AND SYNAPTIC GROWTH IN ADULT TRANSGENIC MICE. P. Caroni*, L.Aigner, and C. Schneider. Friedrich Miescher Institute, Basel, Switzerland.

We have analysed neurite outgrowth and structural plasticity in transgenic mice overexpressing the growth-associated proteins GAP-43 and CAP-23 specifically in adult neurons. GAP-43 overexpressing mice showed striking spontaneous nerve sprouting at the neuromuscular junction and in the hippocampus. Sprouting induced by a variety of stimuli was greatly potentiated. The enhanced sensitivity allowed us to establish that one such stimulus is reduced transmitter release. Analysis of neuromuscular junctions in the transgenic mice revealed greatly elevated levels of α-bungarotoxin-labeled synaptic branches and overall synaptic area. CAP-23 had a sprout-promoting activity comparable to that of GAP-43. Closer examination revealed that in the presence of CAP-23 sprouts were less frequent, longer, and with much less prominent growth cones. Lesion of adult motor nerves induces both GAP-43 and CAP-23. Double-transgenic mice overexpressing GAP-43 and CAP-23 displayed dramatically potentiated nerve sprouting, suggesting that the two proteins synergize. The experiments establish GAP-43 and CAP-23 as intrinsic determinants potentiating structural plasticity. (FMI Foundation)

INCREASED LEVELS OF GAP-43 IN THALAMIC NUCLEI CONTRALATERAL TO INJURED CORTEX: POTENTIAL BASIS FOR FUNCTIONAL COMPENSATION P.E. Stieg*, J. Torron, C.A. Irwin, J. Levine, and L.I. Benowitz. Department of Neurosurgery, Children's Hospital and Brigham and Women's Hospital, Harvard Medical School, Boston, MA 02115.

In a number of model systems, neurons of the mammalian CNS have been found to undergo considerable synaptic reorganization after injury. In most of these instances, synaptic reorganization is accompanied by an increased expression of the growth associated protein, GAP-43. In humans, the most prevalent form of CNS injury is cortical infarction after stroke, yet the extent to which compensatory sprouting might contribute to functional recovery after this type of injury is unknown. To address this question, we utilized immunohistochemistry to visualize GAP-43 levels after inducing stroke in rat cortex by occlusion of the middle cerebral artery (MCA). Between 4 and 14 days after stroke, we observed a striking increase in GAP-43 levels in the posterior complex of the thalamus contralateral to the infarct. This increase could be a result of several alternative mechanisms, e.g., a de-repression of GAP-43 synthesis in layer 6 neurons of the intact hemisphere after loss of the commissural afferents, leading to increased levels of the protein in corticothalamic terminals. Changes in thalamic organization could in turn provide a basis for limited functional recovery. In light of the potential clinical relevance of these observations, further studies are needed to elucidate the anatomical pathways involved and to identify treatments that might enhance sprouting. *(Support: Brigham Surgical Group and The Boston Neurosurgical Foundation.)*

OVEREXPRESSION OF ACEYTYLCHOLINESTERASE INCREASES NERVE GROWTH RATE INDEPENDENT OF ITS HYDROLYTIC ACTIVITY. G-l. Ming[1], H-j. Song[1], M. Sternfeld[2], M-m. Poo[1]* and H. E. Soreq[2]. [1]Dept. Biol., UCSD, La Jolla, CA. 92093, [2]Dept. Biol. Chem., Life Sci. Inst., Hebrew Univ. of Jerusalem, 91904, Israel.

Acetylcholinesterase (AChE) is well known for its function in the hydrolysis of acetylcholine (ACh) at neuromuscular junctions. Sequence homology between AChE and several neurexin ligands and the early appearance of AChE in developing embryos suggest developmental roles of AChE unrelated to its enzymatic function. In this study, different forms of human AChE were expressed in *Xenopus* spinal neurons by injection of cDNA constructs into one of the early blastomeres of *Xenopus* embryos. Overexpression of AChE in cultured neurons was confirmed by immunostaining. We found that neurons expressing human AChE-E6 (bearing exon 6), which is the brain and muscle form of AChE, showed markedly increased rate of nerve growth (37.9±5.2 μm/hr, SEM, n=32) than that of control neurons (12.9±2.7 μm/hr, SEM, n=33) not injected with the cDNA. In contrast, expression of an alternative spliced AChE mRNA, which terminates with pseudointron 4 and exon 5 at the 3' end and encodes secreted AChE, resulted no effect on nerve growth. The effect of AChE-E6 was not due to its hydrolytic activity, since a mutant form of AChE-E6 incapable of hydrolyzing ACh showed similar effect on nerve growth as the native form of AChE-E6. These results clearly demonstrated a non-classical role of AChE in neural development. (Supported by NIH grant NS 31923 and USARMED 17-94-C-4031)

TOPOLOGY OF EXOCYTOTIC EVENTS IN GROWING AXONS. L. Antonov and S. Popov*. Dept. of Physiology and Biophysics, University of Illinois at Chicago, Chicago, IL 60612.

Attempts to detect sites of addition of plasma membrane proteins and lipids to the growing neurite were previously made using various microscopy techniques. Because of the low fluorescent signal associated with a single vesicle, these experiments were not able to resolve single vesicle fusion events in neurons. In the present study we investigated the topology of exocytotic events in growing *Xenopus* spinal cord neurites by detecting individual exocytotic events with a patch clamp technique.

Isolated *Xenopus* myocytes were manipulated into contact with the distal (growth cone) or middle segment of the growing neurites in culture. Whole-cell voltage clamp recordings from myocytes were used in the detection of secretion events at the different segments of neurite. In 1 day old neuronal cultures secretion events were observed both at the middle segment of neurite and near the growth cone. The frequency of secretion events at the middle segment (5.2 + 2.3 events/min; mean + s.d., n = 9) was not statistically different from that at the distal segment of neurite (6.6 + 4.0; n = 10). In 3 day old neuronal cultures secretion events were observed in 1 out of 25 experiments in the middle segment of neurite and in 15 out of 25 experiments at the distal segments of neurite, indicating that at the later stages of axonal growth the insertion of new membrane material occurs primarily at the distal neuronal segments. Taken together, the results of these experiments suggest that at the initial stages of axonal growth, new membrane is added not at the growth cone but along the neurite. Axonal stabilization at the later stages of growth leads to preferential insertion of membrane components into the growth cone region.

INTEGRINS AND CD9 SIGNALING IN NEURAL CELLS. S. A. Banerjee*, M. Hadjiargyrou, Z. Kaprielian and P. H. Patterson. Division of Biology, Caltech, Pasadena, CA 91125.

CD9, a member of the tetraspan family of cell surface proteins, has been implicated in intercellular signaling in hematopoietic cells. CD9 is also expressed in Schwann cells and peripheral neurons. Here we demonstrate the effects of an anti-CD9 antibody (mAb), B2C11, on sympathetic neurons and glia and report an association of CD9 with specific integrins on the Schwann cell surface.

When dissociated sympathetic ganglia are plated on collagen along with immobilized mAbs to CD9 or other cell surface proteins, B2C11 promotes neurite outgrowth that is comparable to outgrowth on a collagen substratum, and greater than that on other mAb-coated surfaces. An anti-α3β1 integrin mAb attenuates the extent of neurite outgrowth on B2C11. B2C11 also induces dramatic morphological changes in both neurons and glia, causing flattening to the substrate.

We have previously demonstrated that B2C11 causes proliferation, adhesion and migration of Schwann cells in culture, suggesting a signaling role for CD9. *In vivo* expression patterns of CD9 during development and following injury also support such a role. These data and an earlier demonstration of a CD9-integrin association in non-neural cells led us to investigate the interaction of CD9 with integrins in the S-16 Schwann cell line. We show that CD9 is co-precipitated by mAbs against the α3, α6 and β1 integrins in cell extracts. Double immunofluorescence labeling and co-capping experiments further confirm that CD9 and these integrins are co-localized on the membrane of Schwann cells. Thus, CD9-integrin association in neural cells may be involved in the signaling function of CD9.

PROTEIN F1/GAP-43 PROMOTER/INTRON ACTIVATION AND GENE EXPRESSION PRECEDE DEVELOPMENTAL AXONAL OUTGROWTH IN HIPPOCAMPAL GRANULE CELLS IN VIVO. I. Cantallops, and A. Routtenberg*. Cresap Neuroscience Laboratory, Northwestern University Institute for Neuroscience (NUIN), Evanston, IL 60208.

Nerve cells both extend and guide their processes during development in a precisely timed manner. Gene products essential for extension and guidance are developmentally regulated to orchestrate this temporal organization. Protein F1/GAP-43, in agreement with its association with axonal growth, is highly expressed in neurons during development and axonal regeneration. In adult animals, F1/GAP-43 expression is down-regulated. Certain areas in the adult nervous system related to synaptic plasticity continue to express it. To study the gene regulatory mechanisms underlying this differential cellular regulation, we have analyzed the postnatal development of hippocampal granule cells of transgenic mice bearing a lacZ reporter gene under the control of 6 kb of the rat F1/GAP-43 5' flanking promoter and 11 kb of the first intron.

We discovered an "outside-in" pattern of development in the granule cell layer (GCL). From P4-P9, transgene expression is detected only in cells located in the external part of the GCL. From P12-P30, transgene expression is restricted to a band in progressively more internal levels of the GCL. This "band-shift" pattern of transgene expression faithfully parallels F1/GAP-43 mRNA expression and precedes the development of granule cell axon extension (J.Comp.Neurol. 241:154, 1985). Since induction of F1/GAP-43 precedes excess axonal sprouting (J.Comp.Neurol. 366:303, 1996) and mouse mutants overexpressing F1/GAP-43 demonstrate exuberant axonal sprouting (Cell 83:269, 1995), we propose that **guided axonal outgrowth in developing brain is regulated by the F1/GAP-43 promoter**. It will be of value to determine the relative contribution of endogenous developmental programs and input-dependent activity to F1/GAP-43 transcription. AN *IN VITRO* MODEL OF MOSSY FIBER SPROUTING IN ORGANOTYPIC EXPLANT CULTURES. M. J. Routbort* and J. O. McNamara. Epilepsy Research Laboratory, Departments of Medicine (Neurology), and Neurobiology, and Pharmacology, Duke University Medical Center, Durham, NC 27710.

Pathologic recurrent excitatory synapses formed by sprouted mossy fibers likely contribute to hyperexcitability in the epileptic hippocampus. Elucidating the molecular determinants of mossy fiber sprouting could provide novel pharmacologic approaches to limit sprouting, but identifying these factors has been hampered by lack of an accessible preparation. We now report that application of kainic acid (KA) to slice cultures of rat hippocampus induces mossy fiber sprouting.

We cultured slices from the hippocampal formation of P12 rats. After ten days *in vitro*, explants were treated with varying concentrations of KA for anywhere from 4 to 48 hours. KA caused a dose- and time-dependent regionally selective toxicity, with concentrations between 3 and 9 μM leading to nearly complete destruction of CA3 with relative sparing of the granule cell layer. Over the course of several weeks, a dramatic sprouting of mossy fibers ensued as evidenced by an increase in Timm stained granules in the supragranular region in KA treated cultures as compared to controls.

To verify that the Timm granules reflected mossy fiber sprouting, a morphological analysis of individually labelled dentate granule cells was performed. Whole-cell patch clamping was used to fill individual granule cells in slice cultures with Neurobiotin and reveal their axonal arborizations. Granule cells in KA treated cultures demonstrated a dramatic increase in overall intra- and supragranular sprouting. The number of axonal branch points in the granule cell or molecular layer increased from 1.3±0.5 in control cultures (n=15) to 10.1±1.6 in KA treated cultures (n=24, $p<0.0001$). This relatively simple and accessible system should prove useful for investigating the mechanisms and consequences of seizure and degeneration-induced reactive synaptogenesis.

PLATELET-DERIVED GROWTH FACTOR ALTERS ACTIN-BINDING PROTEINS OF CORTICAL NEURONS *IN VITRO*. J.B. Hutchins* and F.X. Zhang. Depts. of Anatomy and Neurology (Research), University of Mississippi Medical Center, Jackson, MS 39216.

Our laboratory has studied the effects of platelet-derived growth factor (PDGF) on the metabolism and cytoskeleton of cultured neurons. Previous work by our lab and others has shown that neurons express PDGF receptors both *in vivo* and *in vitro*. We have used PDGF-BB stimulation of cultured cortical neurons to demonstrate the direct and indirect effects of PDGF on phosphorylation. In other cell types, PDGF triggers phenomena such as membrane ruffling and lamellopodial extension through pathways mediated by the G proteins *rac* and *rho*. As a first step towards studying whether similar signal transduction pathways operate in neurons, this study reports the effect of PDGF on the expression and post-translational modification of cytoskeletal proteins.

Cortical neurons were isolated from embryonic day 14 (E14) mouse and E9 chick. A preplating step was used to remove adherent cells, and the remaining cells (more than 95% neurons, by previous studies) were cultured in serum-containing medium for 2 days. At the end of the second day *in vitro*, neurons were fed serum-free G5/N3 medium for 16-24 hours. On the third day, "PDGF-stimulated" neurons were given 30-50 ng/ml PDGF and ^{32}P-P_i while "control" neurons were labeled with ^{32}P only. PDGF greatly increased the overall levels of protein phosphorylation in cultured neurons. An actin-binding overlay assay revealed which of the proteins were both phosphorylated *de novo* and capable of actin binding. Using this method, two groups of actin-binding proteins have been identified. One is similar to the ezrin/radixin/moesin family, while the other appears to be vinculin. Supported by Univ Mississippi Medical Center.

NEURITE RETRACTION OF RAT DORSAL ROOT GANGLION NEURONS INDUCED BY THROMBIN. J. S. Gill[1]*, K. Pitts[2], F. M. Rusnak[2], W. G. Owen[2], and A. J. Windebank[3]. Mayo Cancer Center[1], Department of Biochemistry and Molecular Biology[2], Molecular Neuroscience Program[3], Mayo Clinic, Rochester, MN 55905 USA

Thrombin is a multifunctional protease. Recent studies on cultured neuronal cells have suggested an important function of thrombin in the development and maintenance of the nervous system. Thrombin has been found to induce neurite retraction and reverse stellation in neuroblastoma cell lines and rat astrocytes, respectively. The major focus of our study was to investigate the role of thrombin on neurite outgrowth from rat dorsal root ganglion (DRG). Our findings indicate a dose dependent retraction of DRG neurites exposed to 0.1 - 10 μM thrombin. This effect was completely reversible when cultures were co-treated with the specific thrombin inhibitor, hirudin. Thrombin's effect is mediated through a receptor which is a member of the superfamily of seven-transmembrane-domain receptors typical of those coupled to G proteins. A synthetic peptide that imitates the fully active receptor (thrombin receptor-activating peptide/TRAP) was also found to induce neurite retraction. DRG cultures exposed to thrombin or TRAP for 4-24 hrs did not show cell death as evidenced by bis-benzimide staining. Immunohistochemical studies revealed specific staining of the thrombin receptor on the neuronal cell population, with intense label along the course of neurites. Furthermore, positive thrombin receptor staining co-localized to the small diameter neuron population.

Conclusion: These findings are the first to describe the localization of the thrombin receptor to DRG neurons. Thrombin or TRAP induces neurite retraction from DRG. Studies are underway to investigate the contribution of thrombin receptor activation to neurite retraction (Mayo Foundation).

DRUGS OF ABUSE: COCAINE VIII

758.1

INHIBITION OF BRAIN NITRIC OXIDE SYNTHASE MODULATES THE BEHAVIORAL SENSITIZATION TO COCAINE AND METHAMPHETAMINE. Y. Itzhak* and M.D. Norenberg, Depts. of Biochemistry & Mol. Biology and Pathology, University of Miami, School of Medicine, Miami FL 33101.

The present study was undertaken to determine whether blockade of brain nitric oxide synthase (NOS) by 7-nitroindazole (7-NI) attenuates the development of behavioral sensitization to repeated administration of cocaine and methamphetamine (METH), and if environmentally conditioned locomotion is affected. Male Swiss Webster mice were administered (i.p.) either vehicle/saline, vehicle/cocaine (15 mg/kg), 7-NI (25 mg/kg)/cocaine, vehicle/METH (1.0 mg/kg), or 7-NI/METH for 5 days. On day 8 all animals received a single saline injection (conditioning test) in the test cage. On day 12, animals pre-exposed to cocaine received a challenge dose of cocaine (15 mg/kg), and METH pre-exposed animals received a challenge injection of METH (0.5 mg/kg). Control animals received either a single injection of cocaine or METH. Using an activity meter (15 infrared emitter/detector paries) total and ambulatory counts were measured on days 1, 5, 8, and 12. Pretreatment with 7-NI completely blocked the induction and expression of sensitization to the locomotor stimulating effect of cocaine and also the conditioned locomotion produced by pairing cocaine injection with the environmental stimuli. However, 7-NI only partially attenuated METH-induced locomotor sensitization, and it had no effect on METH-induced conditioned locomotion. These findings indicate that inhibition of NOS completely blocks cocaine sensitization, and suggest some differences in the mechanisms underling the development of sensitization to cocaine and methamphetamine. (Supported by R55DA08584 from NIDA).

758.2

COCAINE-INDUCED BEHAVIORAL SENSITIVITY IN LONG-EVANS RATS: INDIVIDUAL DIFFERENCES IN HPA AXIS AND STRIATAL NEUROPEPTIDE ACTIVATION L. R. Lucas*†, M. J. Kreek††, and B. S. McEwen† †Lab of Neuroendocrinology, †† Lab of Biology of Addictive Diseases, Rockefeller University, New York, NY 10021

Outbred strains such as Sprague-Dawley display individual differences in locomotor response to a novel stress stimulus. Behavioral sensitization, defined by incremental locomotor behavior during chronic cocaine administration, is associated with the activation of the hypothalamic-adrenal-pituitary (HPA) axis and the mesocorticolimbic neuropeptidergic system. To determine whether individual behavioral differences are maintained after behavioral sensitization, we placed outbred Long Evans rats in a novel environment, monitored locomotor activity for 2 hours, and divided them evenly into two activity groups: Low- and high-responders (LR: 367 cumul. beam breaks ± 38 s.e.m, HR: 797 ± 43). Rats were randomly assigned to saline or chronic binge pattern (CBP) cocaine (15 mg/kg, i.p., 3X/day, 14 d) treatment groups. At sacrifice, trunk blood was collected for serum corticosterone (B) determination and brains were removed and stored at -70°C. B levels were different between saline and CBP groups (4.9 μg/dL ± 2.4 and 14.7 ± 2.2 resp., $p<0.01$). Furthermore, B levels were 27% lower in LRs than HRs in CBP rats. Neuropeptide-mRNA levels in the striatum were determined by *in situ* hybridization histochemistry. Dynorphin- (DYN) and enkephalin- (ENK) mRNA levels were higher in HRs compared to LRs after CBP treatment ($p=0.05$, $p<0.001$ resp.). Tyrosine hydroxylase radioimmunoreactive (THRIC) levels were also higher in HRs compared to LRs after CBP treatment ($p<0.01$). In summary, differences in striatal DYN- and ENK-mRNA levels between HRs and LRs paralleled differences in B levels. Thus, individual differences in HPA axis activation results in differences in THRIC and DYN- and ENK-mRNA levels ultimately resulting in the execution of the behavioral differences observed. SENSITIZATION OF COCAINE INDUCED GLUTAMATE RELEASE IN THE NUCLEUS ACCUMBENS: INVOLVEMENT OF DOPAMINE Malcolm S. Reid* and S. Paul Berger. UCSF/VAMC, Substance Abuse Treatment Research 116W, 4150 Clement St., San Francisco, CA 94121

Previously, we have shown that acute injections of cocaine or amphetamine stimulate glutamate release in the nucleus accumbens and prefrontal cortex. In the present study, cocaine stimulated glutamate release in the nucleus accumbens was studied following repeated cocaine or saline pretreatment. Rats were pretreated with cocaine (30 mg/kg) or saline for five consecutive days and were tested with cocaine (15 mg/kg) after a ten day withdrawal period. Cocaine induced glutamate release, dopamine release, horizontal locomotor activity and stereotypy were monitored simultaneously in animals undergoing *in vivo* microdialysis while in activity monitors. The basal levels of extracellular glutamate and dopamine, as well as locomotor activity, were not affected by cocaine pretreatment. Following cocaine injection the increases in glutamate release, dopamine release, locomotor activity and stereotypy were greater in the cocaine pretreated animals. Regression analysis revealed that the glutamate and dopamine release responses were closely correlated. In addition, acute cocaine stimulation of glutamate release in the nucleus accumbens and prefrontal cortex was calcium dependent and blocked by pretreatment with D1 and D2 dopamine antagonists: SCH 23390 (0.02 mg/kg), haloperidol (0.2 mg/kg) and raclopride (1 mg/kg). These results demonstrate sensitization of cocaine stimulated nucleus accumbens glutamate release and suggest that its expression might be mediated via dopamine release. Studies on the development of glutamate sensitization, following repeated dopamine agonist treatment, are underway. (NARSAD)

EXTRACELLULAR ASPARTATE (ASP) INCREASES IN RAT NUCLEUS ACCUMBENS (NAcc) FOLLOWING BEHAVIORAL SENSITIZATION TO COCAINE (C). S.E. Robinson,* P.M. KUNKO, M.J. Wallace, J.R. Maher, Q. Mo, AND J.A. SMITH. Department of Pharmacology & Toxicology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0613.

Previous research found that extracellular concentrations of ASP, and to a lesser extent, of glutamate (GLU) increase in rat NAcc after i.p. injection of C. The effect of behavioral sensitization to C was determined on ASP and GLU. Male Sprague-Dawley rats under Equithesin anesthesia were implanted stereotactically with guide cannulas aimed at the core of the NAcc. Seven days later a CMA/12 concentric microdialysis probe was inserted into the NAcc. Rats were videotaped and their behavior scored by an observer blind to treatment. After an equilibration time of 2 hr, samples were collected in 10-min fractions for an additional 2 hr to establish baseline values in the awake rat. C (15 mg/kg) or saline (S) were then injected i.p. and fractions collected for an additional 2 hr. Rats receiving C for the first microdialysis procedure were divided into 2 groups receiving 5 additional daily C or S injections in their home cage; rats receiving S for the first microdialysis procedure were divided into 2 groups receiving 6 additional C injections (the first on the day of microdialysis) or 5 additional daily S injections in their home cage. A second microdialysis procedure was performed in which rats were challenged with C or S 48 hrs after the last injection. Repeated measures ANOVA and means comparisons revealed that rats receiving C for the first microdialysis + 5 more C injections exhibited behavioral sensitization and increased extracellular ASP when challenged with C. Rats receiving S in the test chamber did not exhibit behavioral sensitization or increased extracellular ASP whether or not they received C or S in between the microdialysis sessions. GLU was not significantly increased.[NIDA DA05274, DA07027].

COCAINE INDUCED GLOBAL DECREASE IN CEREBRAL BLOOD FLOW DOES NOT OBSCURE REGIONAL ACTIVATION DETECTED BY fMRI. R. Gollub*, H. Breiter, R. Weisskoff, W. Kennedy, D. Kennedy, H. Kantor, D. Gastfriend, J. Berke, J. Riorden, T. Mathew, N. Makris, A. Guimaraes, S. Hyman, B. Rosen MGH NMR Center & Dept. of Psychiatry, Charlestown, MA 02129

We used functional MRI (fMRI) to determine whether physiological changes produced by acute IV cocaine would correlate with global changes in cerebral blood flow (CBF) and if so, whether this would mask neuronally induced regional changes. During the 20 minutes before and after each double-blind cocaine and saline infusion in cocaine-dependent patients, we utilized a FAIR scan sequence to measure mean CBF, and a BOLD sequence during visual stimulation to determine cerebral blood volume and oxygenation changes. BOLD signal changes were also measured during each infusion. In seven subjects, cocaine (0.6 mg/kg, iv over 30 sec) produced a rapid increase in mean HR from (mean $\pm$ SD) 64 $\pm$ 9 to 86 $\pm$ 19 at 2 min post-infusion (paired t-test =-3.41, $p<0.02$). Mean BP rose from 102 $\pm$ 11 torr to 121 $\pm$ 15 torr at 5 min (paired t-test =-2.93, $p<0.03$). End tidal CO2 dropped slowly from a baseline mean of 43 $\pm$ 3 mmHg to 40 $\pm$ 3 mmHg by 10 min (paired t-test =3.35, $p<0.02$). All measures returned to baseline by 2 hours, the inter-infusion interval. Blood cocaine concentration was maximal between 3-10 min post infusion; mean t1/2, Vd and Cmax for these subjects were within previously reported ranges. By FAIR imaging, global mean CBF was unchanged (-0.90 $\pm$ 6.14%) following saline, but decreased (-13.33 $\pm$ 7.13%) with cocaine (t(unpaired)=3.24, p(2-tailed)=.009). The 3 mmHg decrease in end tidal CO2 would predict a 15% CBF decrease; consistent with this result. BOLD imaging during cocaine infusion demonstrated no global changes. During visual stimulation, BOLD imaging showed specific signal increases in V1 which were not statistically different before and after cocaine. Thus, despite a small global decrease in CBF following cocaine infusion, neuronally mediated specific regional changes in BOLD imaging can still be measured. (see Breiter, et. al. this volume for activation of brain reward circuitry)

ACTIVATION OF HUMAN BRAIN REWARD CIRCUITRY BY COCAINE OBSERVED USING FMRI. H. Breiter, R. Gollub, R. Weisskoff, W. Kennedy, D. Kennedy, H. Kantor, D. Gastfriend, J. Berke, J. Riorden, T. Mathew, N. Makris, A. Guimaraes, B. Rosen*, S. Hyman. MGH NMR Center & Dept. of Psychiatry, & Harvard Program in Neuroscience, Charlestown, MA

We sought to map brain reward circuitry in humans using functional MRI (fMRI) during double-blind cocaine (0.6mg/kg) and saline infusions in cocaine-dependent patients. Subjects rated four analog scales (rush, high, low and craving; range=0-3) every 15 seconds during scanning. They reported profound cocaine effects: peak rush (mean$\pm$SD=2.25$\pm$0.6) occurred 0.5-3 minutes and peak high (2.0$\pm$0.6) occurred 1-4 minutes post-infusion. Whole brain imaging with an asymmetric spin-echo sequence was performed for 5 minutes before, and 13 minutes during and after a 30 second infusion. Seven of nine subjects had interpretable data after motion-correction of fMRI data and neuroradiologic reading of clinical scans. Time-course data were Talairach transformed, averaged, and mapped using Kolmogorov-Smirnov (KS) statistics. Cocaine caused average regional signal increases of 1-4% (KS $p<10exp-7$ with Bonferroni correction) in nucleus accumbens, dorsal striatum, insula, superior temporal gyrus (a22), hippocampus, parahippocampal region (a36, a20), anterior cingulate (a24), orbital gyrus (a11), and lateral frontal cortices (a9/45/46, a44), along with regional decreases in signal in amygdala, temporal pole (a38), and medial frontal cortex (a9/10/32). The positive signal change in nucleus accumbens and negative signal change in amygdala were only seen with cocaine; all other regions active from cocaine were also active during saline, though with lower signal change (0.5-2.0%) excepting orbital cortex. As a control, visual stimulation before and after cocaine showed similar activation in V1, indicating cocaine does not preclude regionally specific fMRI changes. Regions active during the saline condition may reflect the expectancy of cocaine. In contrast, the human experience of reward appears to involve specific changes in the nucleus accumbens and amygdala. (see Gollub, et al this volume for global fMRI and physiology results) Supported by NIDA DA09467-02, DA00265-01 and DA00275-01.

PHENTOLAMINE PRETREATMENT PREVENTS A COMPONENT OF GROWTH RETARDATION AND OF INATTENTION INDUCED BY PRENATAL COCAINE EXPOSURE. Barry E. Kosofsky*, Cleopatra S. Planeta, and Aaron S. Wilkins. Laboratory of Molecular and Developmental Neuroscience, Massachusetts General Hospital, Harvard Medical School, Boston, MA 02114.

To better understand the mechanisms by which cocaine impairs brain and body growth and postnatal behavior we have developed a mouse model of transplacental cocaine exposure. We created four prenatal treatment groups: a Cocaine group (COC 40 or 20 or 10: cocaine HCl administered at 40, 20 or 10 mg/kg, sc, divided evenly across twice daily doses from E8-E17 inclusive), a Phentolamine-Cocaine group (Phent COC 40, 20 or 10: administered phentolamine, 5 mg/kg, sc, 15 minutes prior to each cocaine dose), a Phentolamine group (Phent: administered phentolamine, 5 mg/kg, sc, 15 minutes prior to saline injection, twice daily from E8-E17 inclusive), and a saline-injected group (SAL). ANOVAs on P9 revealed main effects of treatment on pup biparietal diameter (BPD) ($F(7,363) = 15.36$, $p<.0001$) and pup weight ($F(7,381) = 12.21$, $p<.0001$). COC 40 and Phent COC 40 offspring had decreased BPD ($p<.01$ vs. SAL offspring, Dunnett t), but only COC 40 offspring had decreased weight ($p<.01$ vs. SAL offspring, Dunnett t). Mice were tested for selective attention on P50, utilizing a blocking paradigm. Within the blocking group, an ANOVA revealed a main effect of treatment ($F(7,230) = 3.09$, $p<.005$). Only COC 40 and Phent COC 40 animals trained in the blocking paradigm spent less time over lemon than did SAL animals in the blocking paradigm ($p<.01$, $p<.05$ vs. SAL respectively, Dunnett t), indicating that these mice, unable to ignore the irrelevant stimulus, were aversive to lemon. We conclude that high dose cocaine exposure (COC 40) impaired brain and body growth through P9 and permanently impaired blocking. Pretreatment with Phentolamine (Phent COC 40) blunted the effect of cocaine in impairing body (but not brain) growth, and may via its growth-protective effects, attenuate the (malnutrition-induced component of) inattention induced by gestational cocaine exposure. GENDER DIFFERENCES IN THE TOXICITY TO PSYCHOSTIMULANTS MAY REFLECT DIFFERENCES IN THE DOPAMINERGIC SYSTEM. J.W. Boja*, S. M. Meehan, and M. D. Schechter. Dept. Of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272

Several studies have reported that females are more sensitive to the stimulating effects of cocaine and amphetamine, whereas females appear to be more resistant to the toxic effects of these drugs. Previous studies have reported that female mice are more resistant to methamphetamine toxicity than are male mice. More recently, we investigated both the stereotypy and toxicity produced by high doses of the cocaine analog 3β-(4-iodophenyl)tropan-2β-carboxylic acid methyl ester (RTI-55) in both male and female HS mice. Administration of 0.5 - 20 mg/kg RTI-55 produced an array of behaviors progressing from compulsive paw-licking to self-injurious behavior (SIB). Death occurred within 24 hrs following administration of high doses of RTI-55. While there seemed to be no gender difference in the stereotypies observed, there was a striking gender difference in the mortality rate following RTI-55 administration. The calculated LD_{50} (95% confidence limits) for males was 3.47 (2.12 - 5.68) mg/kg whereas the calculated values for female mice was significantly higher, 7.57 (5.20 - 11.03) mg/kg. Ovariectomy of adult females did not reduce the LD_{50} values. The toxicity and SIB produced by RTI-55 in female mice was markedly reduced following administration of the dopamine D1 antagonist SCH 23390 (0.3 mg/kg) 30 min prior to RTI-55 administration. Male mice required twice the dose of SCH 23390 to afford the same degree of protection. In contrast to the striking gender difference observed for SCH 23390, MK-801 offered equal protection to both male and female mice against the RTI-55 induced lethality and SIB. The results of this study suggest there may be an intrinsic difference in the male and female dopaminergic systems as induced by the dopamine reuptake inhibitor RTI-55.

MDMA ('ECSTASY') INDUCES DNA FRAGMENTATION AND APPARENT PROGRAMMED DEATH OF HUMAN SEROTONERGIC CELLS. R.Simantov* and M. Tauber. Dept. of Mol. Genetics, Weizmann Institute, Rehovot 76100, Israel.

The amphetamine analogue MDMA (3,4-methylene-dioxymethamphetamine, also called 'ecstasy') is a recreational abused drug with potent psychostimulant and hallucinogenic activities. Recently it became apparent, however, that MDMA also induces long-term neuropsychiatric abnormal behaviours. Neuroanatomical studies with rodents and monkeys indicate that MDMA is cytotoxic to serotonergic brain cells, but this issue is less clear with humans. MDMA activity was studied in the human cell line JAR, that expresses the serotonin transporter. The drug was toxic to JAR cells, altered the cell cycle profile, increased G2/M phase arrest, and induced DNA fragmentation. These effects were blocked by the protein synthesis inhibitor cycloheximide, and were observed in JAR cells, but not in human neuronal dopaminergic cells. The stereospecificity of amphetamines, the selective involvement of catecholamine neurotransmitters, and the key role of nitric oxide were determined. The study has implications regarding the potential neurotoxic activity of MDMA to drug users.

METABOLIC STATE DETERMINES THE ACUTE AND NEUROTOXIC ACTION OF METHAMPHETAMINE. S.E. Stephans* and B.K. Yamamoto. Departments of Psychiatry and Neuroscience, Case Western Reserve University, Cleveland, Ohio 44106.

High doses of methamphetamine (METH) produce a long-term depletion in striatal tissue dopamine (DA) content. This toxicity has been associated with increased concentrations of glutamate and altered energy metabolism. Altered energy metabolism is evidenced by increased extracellular lactate during METH administration and by the reduction of tissue ATP content after METH. Based on previous findings that metabolic inhibition potentiates glutamate toxicity, local inhibition of metabolism should potentiate METH-induced DA depletions whereas supporting energy metabolism with metabolic substrates should attenuate METH-induced toxicity. *In vivo* microdialysis was used to directly perfuse the striatum with 2-deoxyglucose (2-DG) (10 mM) or nicotinamide (NIC) (1 mM) during or after saline or a neurotoxic dosing regimen of METH (4 doses; each i.p. dose administered at 2 hour intervals over 8 hours). Local perfusion with 2-DG during METH administration attenuated METH-induced DA efflux and the depletion of tissue DA content when measured 7 days later. In separate experiments, 2-DG or NIC was perfused for 6 hrs beginning immediately after the last METH or saline injection. Although the late local perfusion of 2-DG had no effect on METH-induced DA depletions in striatum measured 1 week later, the perfusion of NIC after METH attenuated the long-term striatal DA depletions. These results indicate that the pharmacological action of METH relies on energy substrates. In addition, a compromised metabolic state that occurs during and after METH may predispose DA terminals to the neurotoxic effects produced by METH. Supported by DA 07606.

CHRONIC COCAINE ALTERS PRE- NOT POST-SYNAPTIC $GABA_B$ RECEPTOR FUNCTION IN RAT DORSOLATERAL SEPTAL NUCLEUS (DLSN) NEURONS. J.P. Gallagher*, S. Shoji, and D. Simms. Dept. of Pharmacology & Toxicology, Univ. of Texas Med. Br., Galveston, TX 77555-1031.

When cocaine (15 mg/kg, I.P., BID) is administered chronically in vivo for periods of 14 or 28, but not for 7, days, an increased frequency (IF) of spontaneous inhibitory synaptic potentials (SP-IPSPs) is recorded from the DLSN in vitro of brain slices from these rats. The IF of SP-IPSPs is apparent without the addition of any drugs and persists in the presence of biogenic amine receptor antagonists.

Application of the $GABA_B$ receptor agonist, baclofen, or, GABA diminishes the IF of SP-IPSPs. Passive membrane parameters altered by chronic cocaine are a more negative membrane potential (MP) and a decreased neuronal input resistance. Application of the $GABA_A$ or $GABA_B$ receptor antagonists, bicuculline and CGP55845A, respectively, result in MP depolarization with spiking.

Evoked IPSPs or excitatory postsynaptic potentials (EPSPs) are less effectively depressed by low concentrations of baclofen, while there is no change in the concentration of baclofen required to hyperpolarize the MP by a direct postsynaptic action.

These results demonstrate that chronic cocaine has induced changes in presynaptic, while sparing postsynaptic, $GABA_B$ receptors. A selective $GABA_B$ presynaptic receptor agonist may prove useful to mimic the chronic effects of cocaine and serve as a replacement abstinence therapy for cocaine addiction. (Supported by DA-07190).

TRANSIENT COCAINE-INDUCED UPREGULATION OF MU OPIOID RECEPTOR mRNA IN NUCLEUS ACCUMBENS IS ACCOMPANIED BY AN INCREASE IN MOR DENSITIES. A. V. Azaryan*, B. J. Clock, J. Rosenberger, B. M. Cox. Department of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814

Chronic continuous cocaine administration has been shown to selectively upregulate the level of mu opioid receptor (MOR) mRNA in the nucleus accumbens (n. acc.) of rat brain after 3 days treatment (Azaryan et al., 1996). Expression of MOR mRNA in n. acc. was estimated by quantitative RT-PCR assays. The time course of cocaine-induced alterations in the level of MOR mRNA in n. acc. has been determined. Male Sprague-Dawley rats were treated with saline or cocaine (50 mg/kg/day) for 24, 48, 66, 72, 90, 96 and 168 hr delivered by osmotic minipump. A marked increase in the level of MOR mRNA in n. acc. from 66 to 90 hr cocaine treatment was observed. MOR mRNA returned to baseline levels after 96 and 168 hr exposure to cocaine. Thus, the cocaine-induced upregulation of MOR mRNA is transient, developing after 2 days exposure, and peaking at 3 days with return to baseline levels by 4 days of chronic continuous cocaine treatment. MOR levels, measured by [^{3}H]DAMGO binding in n. acc. membranes, were significantly elevated at 72 and 96 hr of cocaine treatment, indicating that increased mRNA expression is translated into increased levels of functional receptors.

REPEATED APPLICATIONS OF SEROTONIN ACTIVATE MAP-KINASE IN *APLYSIA* SENSORY CELLS. D. Michael*[1], K.C. Martin[1], R. Seger[2], and E.R. Kandel[1]. [1]HHMI, Ctr. Neurobiology & Behavior, Columbia Univ., New York, NY 10032; [2]Membrane Research & Biophys., Weizmann Institute of Science., Rehovot, Israel.

The establishment of long-term facilitation in the connections between the sensory and motor neurons of the *Aplysia* gill-withdrawal reflex requires five repeated pulses of 5-HT. These repeated pulses lead to the formation of new synaptic connections by initiating a cascade of gene transcription. Since MAP-kinases are commonly involved in growth by targeting several transcriptional activators and repressors, we examined the role of MAP-kinases in *Aplysia* sensory and motor neurons. By combining in-gel kinase assays with detailed biochemical characterization, we have obtained evidence for two distinct enzymatic activities in *Aplysia* sensory neurons, ApMAPK-1 and ApMAPK-2, that are highly homologous to mammalian ERKs. These ApMAPKs can phosphorylate ApCREB-2, ApC/EBP as well as peptides derived from the cytoplasmic domain of apCAM. When exposed to five pulses of 5-HT (5 µm for 5 minutes with 20 minute intervals), ApMAPK is activated in sensory cells (62% ± 10.3% n=4). By contrast, one application of 5-HT, which produces only short-term facilitation, did not activate ApMAPK. These results suggest that ApMAPK might be important for the modulation of long-term facilitation in sensory cells at two sites: 1) in the nucleus, where it might modify some of the key elements involved in initiating transcription (Martin et al., 1996) and 2) at the membrane where it might affect new synapse formation (Bailey et al., 1996). Supported by HHMI and Weizmann Inst. Of Science.

MAP KINASE IS ACTIVATED AND TRANSLOCATED TO THE NUCLEUS DURING LONG LASTING FORMS OF SYNAPTIC PLASTICITY IN BOTH *APLYSIA* AND MOUSE. K.C. Martin, D. Michael, J.C. Rose, M. Barad, H. Zhu, and E.R. Kandel*. Ctr. Neurobiol. & Behav., Columbia Univ., HHMI, NY, NY 10032.

The formation of long-lasting increases in the strength of synaptic connections in *Aplysia* sensory-motor neurons and in mouse hippocampus is believed to require activation of the PKA pathway, CREB mediated gene expression and the growth of new synapses, (Bailey and Kandel, 1993). Since MAP kinase often is involved in growth and differentiation, we have asked: does PKA produce its long-term effects by acting in conjunction with MAPK? Immunocytochemical analysis of *Aplysia* sensory-motor cultures revealed that one pulse of 5-HT, which produces short-term facilitation, caused no changes in MAP kinase localization in either sensory or motor cell. By contrast, five pulses of serotonin or prolonged application of foskolin, which produce long lasting facilitation, lead to nuclear translocation of MAP kinase in the presynaptic sensory cell but not in the postsynaptic motor cell. This nuclear translocation of MAP kinase is required for the consolidation of long-term facilitation. Microinjection of specific anti-MAP kinase antibodies into the sensory cell, but not of preimmune serum, blocked long-term facilitation without affecting basal transmission or short-term facilitation. Similarly coordinated activity between PKA and MAP kinase may also be required in hippocampal LTP where forskolin treatment, which produces the late phase of LTP, causes rapid phosphorylation of MAP kinase.

This work has been supported by HHMI & NARSAD.

THE B-ZIP NETWORK OF PROTEINS INVOLVED IN TRANSCRIPTIONAL SWITCH FROM SHORT-TERM TO LONG-TERM FACILITATION IN *APLYSIA* HAS COUNTERPARTS IN MAMMALIAN NEURONS. D. Bartsch, M. Ghirardi, P. Skehel, A. Chen, Chen, M.*, A. Casadio and E.R. Kandel. HHMI, Ctr. Neurobiology & Behavior, Columbia Univ., New York, NY 10032.

The transition from short- to long-term memory in *Aplysia*, *Drosophila* and mice requires CRE-binding proteins (CREBs). None of these earlier studies could specify which isoforms of CREB are critical in cells relevant for memory storage. Specifically the earlier studies could not distinguish whether the repressors and activators are isoforms of a single gene or whether they represent different genes. In *Aplysia* sensory neurons we find that only one activator isoform of ApCREB-1 is expressed, indicating that it is this form which transactivates the cAMP-regulated downstream genes. The functional repressor ApCREB-2 is transcribed from a different gene. In addition to ApCREB-1 and the immediate early gene ApC/EBP we have isolated a third activator necessary for long-term facilitation ApAF-1. ApAF-1 is expressed in the basal state and interacts with both ApC/EBP and ApCREB-2. Interestingly, the repressor ApCREB-2 inhibits both ApCREB-1 and ApC/EBP in F-9 cells. Thus, the switch from short- to long-term facilitation is mediated by a network of interacting b-ZIP proteins, each transcribed by a different gene. Different forms of learning might recruit different combinations of these transcription factors.

The activators CREB-1 and C/EBP, and the repressor CREB-2, have homologs in PC12 cells and in the mouse hippocampus. We are now using PC12 cells and the hippocampus to study their role in neuronal differentiation and in memory formation. Supported by HHMI, NIMH & NIH.

TYPE IV-SPECIFIC PHOSPHODIESTERASE INHIBITORS FACILITATE LATE PHASE LTP AND IMPROVE MEMORY. M. Barad, D. Winder*, H. Golan and R. Bourtchouladze. HHMI and Center for Neurobiology and Behavior, Columbia Univ., New York, NY 10032.

Long term potentiation (LTP) in the rodent hippocampus is a likely cellular substrate of behavioral learning, particularly spatial learning. Late phase LTP (L-LTP) in area CA1 of mouse hippocampal slices is a long-lasting form of synaptic plasticity (3h or longer) induced by stimulation of the CA3-CA1 pathway with four tetanic trains. Unlike LTP that follows a single tetanic train and lasts about an hour in mice, L-LTP depends, as do a number of other forms of protein synthesis-dependent plasticity, on the activity of cAMP-dependent protein kinase. We therefore asked whether manipulations that increased the cAMP response to a single tetanus could facilitate L-LTP induction in slice and learning *in vivo*. We hypothesized that low concentrations of phosphodiesterase inhibitors might strengthen signals through the cAMP pathway without affecting basal cAMP, thus avoiding potential side effects or occlusive effects of higher concentrations. We have found that, in hippocampal slices from young adult C57BL6 mice, low concentrations of two Type IV-specific phosphodiesterase inhibitors, rolipram and RO20-1724, increase forskolin-stimulated, but not basal, cAMP concentrations, and allow the induction of L-LTP in CA1 after a single tetanic train. Similarly, *in vivo*, injection of low doses of these inhibitors before training increases freezing to context after 24h, a test of spatial memory, by about 50% ($p < 0.02$), without affecting immediate freezing or freezing after 1h. Our findings indicate that multiple tetanic trains may act to generate L-LTP by increasing or sustaining cAMP responses. Supported by NARSAD, NIH, HHMI and New York State Psychiatric Institute.

DISRUPTION OF THE RAS EXCHANGE FACTOR GENE, RasGRF/CDC25, REVEALS A ROLE FOR RAS SIGNALING IN LEARNING AND MEMORY.
R. Brambilla, N. Gnesutta[1], L. Minichiello, A.J. Roylance[2], C.E. Herron[2], S.G.N. Grant[2], D.P. Wolfer[3], H.-P. Lipp[3], E. Sturani[1] and R. Klein*. European Molecular Biology Lab., 69117 Heidelberg, Germany, [1]Depart. of Biochem. and Gen. Physiol., Univ. of Milano, 20133 Milano, Italy, [2]Center for Genome Res. and Neurosci., Univ. of Edinburgh, Edinburgh, EH9-3JQ, UK, [3]Anatom. Inst., Univ. of Zurich, 8057 Zurich, Switzerland.

RasGRF/CDC25 is a member of the guanine exchange factor family specific for Ras proteins. It is exclusively expressed in the postnatal central nervous system. Cell fractionation studies indicate that RasGRF/CDC25 is localized to post-synaptic structures (Zippel et al., 1996, Soc. Neurosci. abstract). Recently, Ras proteins have been shown to be activated in cortical neurons by calcium influx through voltage-dependent calcium channels. RasGRF/CDC25 has been implicated in the regulation of Ras functions that are influenced by calcium signals. To study the function of RasGRF/CDC25 in the intact nervous system, we have inactivated the RasGRF/CDC25 gene by homologous recombination in embryonic stem cells. Homozygous null mutant mice are viable and fertile. The general architecture of the brain appears normal. In the CA1 region of the hippocampus, expression of parvalbumin and calretinin, specific markers for GABAergic interneurons, appear to be reduced in the mutant mice. Behavioural analysis revealed that RasGRF/CDC25 homozygotes show deficits in the 2-way avoidance test, suggesting an involvement of ras signaling in fear-related conditioning. In addition, mutant mice show reduced flexibility during the reversal phase of the Morris water maze test. Preliminary electrophysiological analysis has shown that RasGRF/CDC25 homozygotes show NMDA receptor-dependent LTP. These results indicate an essential role for RasGRF/CDC25 in the mature central nervous system.

MICRODIALYSIS-COUPLED PLACE CELL DETECTION: A NEW TOOL FOR IDENTIFYING DRUGS THAT MAY FACILITATE LEARNING AND MEMORY PROCESSES. N. Ludvig*. Dept. of Physiology, State University of New York, Health Science Center at Brooklyn, Brooklyn, NY 11203.

Traditionally, behavioral paradigms and neurotransmitter assays have been used as the main methods for identifying drugs that may facilitate learning and memory. This presentation proposes that the new method of microdialysis-coupled place cell detection in freely behaving rats (Ludvig et al., *Hippocampus*, in press) may also be useful in this enterprise. Place cells are apparently parts of a cognitive system in brain which acquires, stores, and recalls spatial information. Microdialysis-coupled place cell detection is able to deliver drugs into the extracellular environment of these neurons during spatial navigation and to determine the drug-induced firing pattern changes. It is possible that those drugs and/or drug combinations which can selectively increase, to an optimal level, the location-specific firing of place cells, may facilitate learning and memory processes.

To initiate this research line and form a reference database, the effects of extracellularly applied potassium on place cells have been studied. The following main conclusions have emerged: (1) Pharmacological excitation of place cells can result in increased out-of-field firing without parallel increase in the in-field firing rate. (2) Increased place cell firing can result in focal epileptiform electrographic events. (3) The pharmacologically induced place cell firing increase can be long-lasting. (4) Activation of neighbouring silent pyramidal cells, albeit not place cells, often accompanies the drug-induced place cell firing increases.

Studies are under way with other drugs to understand the significance of these phenomena and elaborate the neurochemical/molecular machinery that control the firing frequency of hippocampal place cells.

759.7

INTERACTIONS OF NORADRENERGIC AND CHOLINERGIC MODULATION WITHIN THE PIRIFORM CORTEX : BRAIN SLICE PHYSIOLOGY AND COMPUTATIONAL MODELING.
M. Cekic, C. Linster*, D.D.-Y. Ma & M.E. Hasselmo. Dept. Psychology Harvard University, Cambridge MA 02138

Noradrenaline (NA) and acetycholine (ACh) may interact in modulation of cortical plasticity (Bear and Singer, Nature 320:172). NA and ACh show similar post-synaptic effects in cortical structures, and recent data suggests that they both cause differential suppression of excitatory synaptic transmission in layer Ib and Ia of piriform cortex (Hasselmo and Bower, J. Neurophysiol. 67:1222; Vanier and Bower, Soc. Neur. Abstr. 18: 1353). Here we directly compare the separate and combined effects of NA and ACh with sequential perfusion in the same piriform cortex slice. The dose response curve for NA appears to be similar but somewhat steeper than that of ACh in layer Ib (percent suppression at 1μM (n=7), 7.1 ± 1.9% NA, 23.8% ±4.1 ACh; at 5μM (n=6), 55.7 ± 7.0% NA, 45.0 ± 6.9% ACh). NA suppression in layer Ia appears to be stronger than that of ACh (at 10μM (n=5), 24.3 ± 3.7 NA, 4.3 ± 2.3% ACh). The combined effect of equal concentrations of the modulators was comparable to the increase in dose of one modulator alone (combined 5μM NA + 5μM ACh, 64.5% ± 10.3 (n=6); 10μM NA, 63.3 ±3.2 (n=7)). Differences in the anatomical pathways regulating levels of these modulators suggest that they play different roles in the development of odor representations. NA may play a greater role in self-organization of afferent input whereas ACh may play a role in associative memory function within the piriform cortex. In a recently developed biophysical model of the olfactory bulb and the piriform cortex, we have analyzed the modulatory role of NA and ACh on bulbar representations of olfactory stimuli (Linster et al., Soc. Neurosc. *Abstr. 1995; Linster and Gervais, J. Comput. Neuroscience). The combined model allows us to analyze the effects of synaptic transmission in layer 1a and 1b on associative memory function, illustrating how different time scales for modulation by NA and ACh affect the interaction of self-organization and associative memory formation in the model. *Supported by NIMH R29 MH52732-01.*

STRIA TERMINALIS LESIONS MODULATE THE EFFECTS OF GABAERGIC DRUGS ON MEMORY STORAGE. O. Carmi* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory, and Department of Psychobiology, University of California, Irvine, CA 92717-3800.

Extensive evidence indicates that GABAergic drugs modulate memory storage when administered peripherally or directly into the amygdala (AMY). Furthermore, AMY lesions block the mnemonic effects of GABAergic drugs. The stria terminalis (ST) is a major pathway of the AMY. ST lesions, like AMY lesions, block memory modulation produced by various hormonal/neurotransmitters systems. Such findings suggest that ST lesions should also block the effects of GABAergic drugs on memory. The present study examined this implication in male Sprague-Dawley rats using an inhibitory avoidance (IA) and spatial water maze (WM) tasks. A week following bilateral ST lesions and immediately after IA or WM training, rats received injections of saline or the GABAA agonist, muscimol (MUS) or antagonist, picrotoxin (PIC). Retention performance was assessed 48 h after training on each task. In the IA task, MUS impaired and PIC tended to enhance retention performance relative to their respective control groups. ST lesions blocked MUS-induced impairment and potentiated PIC-induced memory enhancement. In the WM task, administration of MUS or PIC had no effect in sham rats. However, PIC enhanced retention in ST-lesioned rats. These data suggest that the ST pathway modulate GABAergic effects on memory processes. The MUS findings are consistent with those of AMY lesions. The potentiation of the mnemonic effects of PIC by ST lesions is surprising and may be attributed to the heterogeneity of the GABAA receptor. We previously reported that ST lesions do not block the benzodiazepine (BZD)-induced anterograde amnesia. This is surprising because GABA and BZDs share the same receptor complex and AMY lesions block the mnemonic effects of both compounds. Therefore, these findings suggest that there is a functional dissociation between the AMY and the ST pathway. It is also hypothesized that GABA and BZDs affect different memory processes, use different AMY pathways and bind different GABAA receptor subtypes.

FRONTAL CORTEX-LOCUS COERULEUS INTERACTIONS DURING SLOW OSCILLATIONS S.J. Sara*, A. Hervé-Minvielle, D. Robinson, R. Lestienne and J-C. Lecas, Institut des Neurosciences, Univ Paris VI, Paris, France.

A small population of neurons in the medial precentral region of Frontal Cortex (FC, region FR2) of the rat can be antidromically driven by stimulation of Locus Coeruleus (LC); suppression of activity in this region results in tonic increase in firing in LC (Sara & Hervé-Minvielle, PNAS, 1995). In an ongoing study of the influence of FC on spontaneous and evoked activity of LC neurons, we recorded single unit or multiunit activity from FC and from LC simultaneously, in urethane or ketamine anesthetized rats. Both FC and LC show periods of oscillatory activity, where some single units fire in a burst mode and multiunit activity is synchronized. The mode of firing in each region appears to be independent of the other. If, however, both regions are engaged in this oscillatory activity at the same time, there is a systematic relationship between their phases, revealed by cross-correlation analyses, with peak LC firing always following FC firing by 200-400 ms. Furthermore, LC cells *never* fire during or within 150ms following a burst of activity in FC. These observations complement our previous findings that FC has an inhibitory influence on LC. This could be involved in the rapid habituation of LC reponses to nonmeaningful stimuli, thus assuring that noradrenaline is selectively released in the forebrain when significant nformation must be processed.

Ritanserin Reduces Activity of Prefrontal Pyramidal Neurons Recorded During Working Memory Tasks. G. V. Williams, S. G. Rao, M. Franowitz, L. Romanski* & P. S. Goldman-Rakic, Section of Neurobiology, Yale Medical School, 333 Cedar St., New Haven, CT 06512.

Previous work in this laboratory has revealed that dopamine influence on prefrontal cortical function appears to be mediated particularly by D1 receptors. In a recent iontophoretic study, we demonstrated a selective enhancement of memory fields of prefrontal cells by SCH39166, a highly specific D1 antagonist. In contrast, we found that less specific compounds such as SCH233390 and A60924 could only accentuate the memory fields indirectly by reducing overall cell activity and thus improving signal-to-noise ratio. As these latter drugs also block 5HT1c/5HT2 receptors, we investigated whether this effect was responsible for the difference in action between the specific and nonspecific D1 compounds. Data was obtained from 2 monkeys performing an oculomotor delayed-response task. Iontophoresis of ritanserin, a 5HT1c/5HT2 antagonist, reduced the overall activity in 8/14 prefrontal pyramidal neurons with task-related activity, including 6 cells with memory fields, but increased activity in 2 cells which showed inhibition during the delay period.

These data support the hypothesis that D1 antagonists may produce non-selective actions via block of 5HT receptors. There is strong evidence that 5HT acts on GABAergic interneurons in cortex. Thus the general decrease in pyramidal neuron activity produced by ritanserin in the present study, and by nonspecific D1 antagonists in the previous study, may be the result of disinhibition of inhibitory interneurons.

VISUAL CORTEX: EXTRASTRIATE—VENTRAL STREAM/MAPPING

760.1

PARALLEL VISUAL STREAMS IN NEAR-EXTRASTRIATE HUMAN VISUAL CORTEX, W. H. Merigan*, A. W. Freeman and R. Patel. Department of Ophthalmology and Center for Visual Science, University of Rochester, Rochester, NY 14642

We have studied the visual field of a patient, who, after suffering a stroke 2 years ago, shows severe loss of color and form perception in one quadrant of his visual field, but sparing of global motion perception. This patient's visual performance is entirely normal over three quarters of his visual field, and the defect described below is present only in his upper left quadrant. The lesion, visualized with magnetic resonance imaging, extends about 5 cm anterior and inferior from the edge of striate cortex, but appears not to invade it.

We tested this patient psychophysically with controlled fixation and forced-choice methods in his upper left quadrant as well as across the vertical and horizontal meridia. Most visual functions, including reading letters, recognizing shapes and identifying colors were virtually absent in this quadrant. These deficits may result from his severe losses of both chromatic and luminance contrast sensitivity tested with low velocity stimuli. On the other hand, there was complete preservation of his global motion perception, measured as a dot coherence threshold with high density (6 dots/deg^2) dynamic random dots at 5 deg/sec. Likewise, his contrast sensitivity for coarse, rapidly drifting gratings was reduced only about two-fold compared to preserved parts of his visual field.

The extreme dissociation shown in this patient for motion versus color and form discriminations is indicative of parallel processing of different stimulus attributes in human visual cortex.

FUNCTIONAL ORGANIZATION FOR ORIENTATION AND SIZE IN PRIMATE V4. D.Y. Ts'o* and G.M. Ghose, The Rockefeller University, NY, NY 10021, and Baylor College of Medicine, Houston, TX 77030.

Using optical imaging methods in combination with single-unit electrophysiology, we have demonstrated an organization in primate visual area V4 for neurons contributing to form and to color processing. In the form domain, we found a discrete patchwork of orientation columns in V4, but surprisingly restricted approximately to the foveal representation of V4. Our single-unit studies as well as those of other groups have previously found oriented cells in other portions of V4. These optical imaging results suggest that although orientation selectivity may be found throughout V4, only in the foveal representation are the oriented cells well organized. This finding may be correlated with our earlier findings in V2, where oriented cells may be found both in regions where orientation is columnar as well in regions of V2 where there is no apparent columnar organization for orientation. Also suggested is a possible special role for the orientation columns in foveal V4. Tracer injections with these patches revealed a pattern of lateral connections connecting orientation columns of like specificity.

Another aspect of form specificity that was organized into patches in V4 was revealed when we manipulated stimulus size. These imaging data uncovered patches (S regions) in V4 that strongly preferred smaller stimuli and were inhibited by larger stimuli. These S regions were present throughout V4, overlapping both orientation and non-oriented regions. In contrast, imaging revealed that surround suppressed regions in V2 were restricted to the unoriented V2 thin stripes. A class of cells outside these S regions of V4 responded optimally to orientation or spatial frequency contrast between center and surround. The properties of cells found in the V4 S regions support the notion suggested by previous lesion and single-unit studies that V4 contributes to the processing of object size and scale invariance.

NEURAL MECHANISM OF LATENCY COMPETITION FOR CORTICAL PROCESSING OF SUBSECOND TIME RANGE. Kiyohiko Nakamura*. Grad. Sch. of Sci. and Eng., Tokyo Institute of Technology, 4259 Nagatsuta, Midoriku, Yokohama 226, Japan.

Evidence supporting hypothesis that neural responses of the subsecond time scale come out of temporal competition among first spikes is presented. Previous study(Nakamura 1995) has built a biologically realistic model of the ventral pathway of temporal lobe and has shown the latency competition performed by the model circuit produces neural activity of the superior temporal sulcus in visual recognition(recorded by Oram & Perrett 1992). This work presents further analysis of the model. MODEL: The model is a sequence of cortical areas V1-V2/V3-V4-PIT-CIT-AIT-STPa. Each area is an array of neuronal populations that laterally inhibit each other. Model neurons are the Hodgkin-Huxley model. PROCEDURE: The experiment done by Oram & Perrett was simulated. Neural activity was predicted with the model and was compared with the empirical data. RESULTS: (1) The hypothesis predicts that latency of neural responses should decrease in strong responses. This prediction was verified both with the model simulation and the empirical data. (2) Mechanisms of real nervous systems should be robust against noise. The simulation showed that the latency competition performed by neuronal populations made stable response under random spontaneous activity. CONCLUSION: From these, the hypothesis of latency competition was verified.

A QUANTITATIVE MODEL FOR NON-CARTESIAN UNITS IN PRIMATE AREA V4 H. R. Wilson & F. Wilkinson* Visual Science Center, University of Chicago, Chicago, IL 60637 & Department of Psychology, McGill University, Montreal, Canada H3A 1B1.

Neurons in cortical area V1 extract edge orientations from the retinal image, while many units in inferior temporal (IT) cortex respond best to complex shapes, including faces. A key issue, is the nature of the neural processing in V2 and V4, which lie between these two extremes of form vision. Gallant, Braun & VanEssen (Science, 259, 100-103, 1993) recently provided a clue to this processing by showing that a subset of V4 units respond better to concentric or hyperbolic gratings than to Cartesian gratings. We have developed a quantitative neural model for these non-Cartesian V4 units that also agrees with psychophysical data on the perception of Glass patterns and discrimination among quasi-circular shapes. The model consists of three stages: (1) filtering by orientation selective V1 simple cells, (2) rectification and pooling operations that are conjectured to occur in V2, and (3) pooling of these responses across orientations in V4. Different pooling rules suffice to construct V4 concentric and hyperbolic units, and the model V4 units agree quantitatively with responses in primate V4. Simulations show that these units extract important shape information from natural images such as faces.

VIEW-INVARIANT REPRESENTATIONS OF OBJECTS IN THE INFERIOR TEMPORAL VISUAL CORTEX. E.T.Rolls*, M.C.A.Booth and A.Treves. Univ Oxford, Dept Exptl Psychol, Oxford OX1 3UD, U.K. and SISSA, Trieste.

To investigate whether view-invariant representations of objects are encoded by some neurons in the inferior temporal cortex of the rhesus macaque, the activity of single neurons was recorded while monkeys were shown very different views of 10 objects. The stimuli were presented for 0.5 s on a colour video monitor while the monkey performed a visual fixation task. The stimuli were images of 10 real plastic objects which had been in the monkey's cage for several weeks, to enable him to build 3D representations of the objects. Control stimuli were views of objects which had never been seen as real objects. The neurons analyzed were in the TE cortex in and close to the ventral lip of the anterior part of the superior temporal sulcus.

So far, many neurons have been found that respond to some views of some objects. In some cases, putative features that account for the responses of these neurons can be identified (e.g. overall shape, texture, or colour). For a smaller number of neurons, the responses occur only to a subset of the objects, irrespective of the view of the objects. These neurons thus convey information about which object has been seen, independently of view, as confirmed by information theoretic analysis of the neuronal responses. Each neuron did not, in general, respond to only one object, but instead responded to a subset of the objects. They thus showed ensemble, sparse-distributed, encoding. The information available about which object was seen increased approximately linearly with the number of neurons in the ensemble. These experiments provide evidence that there is an object-based representation of objects, as well as faces, in the primate temporal cortical visual areas. This may be a representation of 3D objects based on learning about the 2D views of each object (Rolls,E.T., 1995, Learning mechanisms in the temporal lobe visual cortex. Behavioural Brain Research 66: 177-185).

REPRESENTATION OF NATURAL VISUAL CATEGORIES IN ANTERIOR TEMPORAL CORTEX. R. Vogels*. Lab. Neuro- en Psychofysiologie, KULeuven, B-3000 Leuven, Belgium.

Previous behavioral results (Vogels, Soc. Neurosci. Abstr, *20*:1666, 1994) have demonstrated that rhesus monkeys are able to categorize physically dissimilar images of complex visual stimuli into classes. In order to determine the neural representation of these ordinate-level categories, single cell recordings were made in the anterior temporal cortex of 2 rhesus monkeys during categorical discrimination of color images of trees and other objects (non-trees). For each trial, a single stimulus was presented during fixation and the monkeys made a leftward or rightward saccade on presentation of the tree or non-tree image respectively. For each session, 30 images of trees and 30 non-trees were chosen from of a set of 407 images. So far, we have recorded from 182 stimulus selective anterior temporal cortical neurons (histologically verified in one monkey). Most of these neurons were highly stimulus selective: 50% of the neurons responded with at least one third of the maximal net response to 10 (16%) or fewer stimuli, and 12% of the neurons responding to 1 or 2 of the images. Scrambling the image reduced the response in 24 of 40 highly selective neurons tested, paralleling the deterioration of the categorization behavior with increasing levels of image scrambling. Most of 35 neurons tested also showed invariance for size, position and the presence of color. In order to relate stimulus selectivity to categorical discrimination, we computed for each neuron the proportion of tree images (PT) relative to the number of images eliciting at least one third of the maximal net response. 17% of the neurons responded mainly to non-trees only (PT=0). Most other cells responded selectively to images of trees and non-trees, but 9% of the neurons responded mainly or exclusively to tree images (PT>.85). However all of the latter neurons showed no response to at least some of the tree images. These results argue against a prototype representation at the single cell level, but on the other hand favor exemplar-based models of categorization. They suggest that visual, natural categories are represented by units coding for individual or small subsets of the class.

TEMPORAL CORTEX LESIONS IN PRIMATES CAUSE DEFICITS IN TEXTURE SEGMENTATION

K.R. Huxlin*, D. Marchionini, R.C. Saunders and W.H. Merigan
Department of Ophthalmology and Center for Visual Science, University of Rochester, Rochester, NY 14642.

Damage to the temporal lobes of primates has usually been associated with deficits in visual memory and/or learning (see Dean, 1982; Tanaka, 1996 for monkey; see Milner, 1990 for humans). The purpose of this study was to determine if such lesions would result in deficits of visual perception.

Two unilateral temporal lobectomy patients, one monkey with bilateral TEO lesions and two monkeys with bilateral TEO+TE lesions were tested psychophysically on two texture segmentation tasks. The first task required discriminating the orientation (vertical or horizontal) of a group of oblique lines that popout from the background. The second task consisted of identifying a distorted geometric shape relative to its non-distorted controls where the shapes were made up of oblique lines differing from the background only in their orientation.

Both the humans and the monkeys were severely impaired on these tasks. Since they were able to perform the tasks when a luminance cue was added, we concluded that they must be unable to carry out texture segmentation in the absence of simple contrast cues such as luminance. Therefore, it seems that shape from texture discriminations require the integrity of higher cortical areas in the temporal lobes of both human and non-human primates.

FMRI REVEALS DISTINCT EXTRASTRIATE LOCI SELECTIVE FOR FACES AND OBJECTS. N. Kanwisher,* M.M. Chun, J. McDermott, & R. Hamilton. Dept of Psychology, Harvard University, Cambridge. MA, 02138 and MGH-NMR Center, Charlestown, MA 02128.

FMRI was used to find brain areas specialized for the visual recognition of faces and objects. Eleven subjects were scanned while passively viewing alternating 20s epochs of fixation and 30s epochs of stimulus sequences containing rapidly-presented photos (1.5 images/s); alternating stimulus epochs contained either a) 45 different faces or b) 45 different objects. Six of these subjects were also run in scans containing comparisons between these stimuli and c) photos of different houses, d) photos of people in various poses with face occluded, e) 2-tone faces, and f) scrambled 2-tone faces. Subjects were scanned in a 1.5T GE MR scanner equipped with ANMR EPI imaging, using an asymmetric spin echo sequence (TR = 2s, TE = 70ms, flip angle = 90deg). Data were collected with a bilateral enhanced surface coil from 11 near-axial 6mm-thick slices; heads were stabilized with a bite bar. All 11 subjects showed significantly greater signal intensity when viewing objects than faces (b>a) in a bilateral area in the parahippocampal region; Six of the subjects showed significantly greater MR signal in a right fusiform area during face than object viewing (a>b). The regions defined by stronger responses to faces than objects in individual subjects also responded more strongly to i) faces than houses (a>c) ii) faces than people (a>d), and iii) intact than scrambled 2-tone faces (e>f). The regions defined by stronger responses to objects than faces in individual subjects also responded more strongly to houses than faces (c>a). These results suggest a high degree of functional specialization in the occipitotemporal pathway, including i) a right fusiform area selective for faces, and ii) a bilateral parahippocampal area sensitive to some kinds of objects but not faces.

ON THE SPECIFICITY OF NEURAL ACTIVATION EVOKED BY FACES: A FUNCTIONAL MRI STUDY. G. McCarthy*, A. Puce, J.C. Gore and T. Allison. Neuropsychology Lab., VAMC, West Haven CT 06516, and Depts. of Surgery, Neurology and Radiology, Yale University School of Medicine, New Haven CT 06510.

We have previously reported that the presentation of faces evokes activation in the fusiform gyrus as measured by functional MRI (Puce et al. J Neurophysiol 1995). We have also demonstrated that the neural regions activated by faces are distinct from adjacent regions activated by textures and by letterstrings (Puce et al. 2nd Inter. Conf. on Human Brain Mapping, June 1996). However, these studies have not established the specificity of face activations compared to other categories of objects. Here this specificity was tested by periodically presenting faces against a rapidly changing background of either common objects, or unrecognizable scrambled objects with the same spatial frequency and luminance as the objects. We hypothesized that when faces are presented against non-objects, both face-specific and general object recognition systems would be activated. Presenting faces against common objects, however, would saturate the general object recognition system and isolate activation in face-specific regions.

Twelve subjects were tested. In each of 8 runs (4 object and 4 non-object backgrounds), 128 echoplanar gradient-echo MRIs (TR=1.5 s) were acquired from 7 slices. In 4 runs faces were presented with a 6 s on-off period, and in 4 runs the on-off period was 8.7 s. Voxels activated by faces were identified by Fourier analysis and by t-test. As predicted, the extent of activation by faces varied with the background. Faces presented against non-objects evoked an extensive bilateral pattern of activation in the fusiform gyrus. Faces presented against objects evoked a more focal, right-sided fusiform gyrus activation.

COMPARISON OF VISUAL CORTICAL AREA MAPS IN HUMANS AND MACAQUES R.B.H. Tootell*, A.M.Dale, J.B. Reppas, A.Liu, M.I. Sereno. MGH-NMR Center, 149 13-th St., Charlestown, MA 02129

Cortical unfolding and fMRI data were used to create preliminary maps of more than ten functionally distinct areas in human visual cortex. These maps were compared to maps of macaque visual cortex, obtained by other techniques. The maps are quite similar, but a few species differences exist.

Six human areas can be distinguished retinotopically by phase-encoded stimuli (V1, V2, V3, VP, V3A and V4v). The human retinotopy is similar to that in macaque, except perhaps in V4v. The retinotopic "point spread" (related to receptive field size) increases from V1 < V2 < V3A etc., as in macaque.

The topography of macaque areas V3 and VP is very thin (measured along isoeccentric lines) and elongated (perpendicular to isoeccentricity), revealing a highly anisotropic cortical magnification factor (CMF). However, the "width" of human V3 and VP is relatively expanded, allowing a roughly isotropic CMF.

Within-subject comparisons of retinotopy and motion-selectivity consistently indicate that human V3A is motion-selective, whereas V3 is not. Macaque data suggests higher motion selectivity in V3 rather than V3A.

Another human motion-selective area has corresponded well to macaque MT/V5. However, macaque data predicts that small, functionally distinct satellite areas would exist immediately adjacent to human MT/V5. In several fMRI subjects, one such satellite area (presumptive MSTd) can be convergently and consistently distinguished by tests for 1) motion coherence, and 2) the extent of ipsilateral activation.

Another interesting motion-selective human area (MMA) is located at the superior tip of the parieto-occipital sulcus. MMA responds selectively in tests for motion coherence. Unlike other motion-selective areas, MMA also shows evidence for a centrifugal direction bias, a relatively low contrast selectivity, and a high velocity tuning. Macaque VIP is a possible homologue for MMA.

OPTICAL CARTOGRAPHY: SIMULTANEOUS RETINOTOPIC AND FUNCTIONAL MAPPING OF SEVERAL AREAS IN PRIMATE VISUAL CORTEX USING OPTICAL IMAGING.

A. Shmuel, T. D. Schirman, M. Harel, D. Malonek, A. Grinvald* and R. Malach, Dept. of Neurobiology, Weizmann Inst., Rehovot, Israel 76100.

One obstacle in charting the detailed functional organization of primate visual cortex is the difficulty of obtaining retinotopic and functional maps of several visual areas in a single animal. To overcome this difficulty, we mapped the entire expanse of cortex situated between the posterior pole and the sylvian sulcus of individual owl monkeys (Aotus) using optical imaging of intrinsic signals. This stretch of cortex includes a major portion of the visual system in this species. The boundaries and detailed retinotopic organization of visual areas were revealed using Fourier phase analysis of time sequences of cortical activation resulting from stimuli moving across 60° of visual space. The functional selectivity of each area was determined by testing its activation to a wide repertoire of visual stimuli ranging from gratings and random dot arrays to highly complex stimuli. The organization of orientation specific domains in each area was revealed by comparing activity to oriented bars of various orientations. The functional "atlas" obtained in this fashion was related to cyto- and myelo-architectonic features of the tissue revealed in histological processing.

We made the following observations. First, retinotopic mapping: areas V1, V2, and MT showed a well organized retinotopy, area DL showed a coarser and more complex organization. Second, mapping of orientation columns: the orientation domains were best defined in areas V1, V2 and MT. In area V2 orientation domains remained patchy but were clustered in a band-like fashion separated by regions of poor orientation selectivity. Third, functional selectivity: areas V1 and MT were distinguished by strong activation to random dots and short-bar arrays. Anteriorly, the relative response to complex vs. primary visual features appeared to increase. The results indicate that creating a single animal atlas of the layout and columnar architecture of several visual areas is feasible. This approach could nicely complement the data obtained from human visual studies using f-MRI.

760.12

SPREAD OF BOLD SIGNALS IN DRAINING VEINS BEYOND THE REGIONS OF ELECTRICAL ACTIVATION, REVEALED BY HIGH RESOLUTION OPTICAL IMAGING

D. Malonek*, A. Shmuel and A. Grinvald, Dept. of Neurobiol, The Weizmann Inst. Rehovot 76100, ISRAEL

Signals that originate from the microcirculation have been used to obtain functional maps of the brain. Previously we demonstrated the stereotypical spatio-temporal characteristics of various vascular components in capillary regions (Malonek and Grinvald, Science, *272*, 551, 1996). However, the spatio-temporal characteristics of signals originating from other vascular compartments such as draining veins that may be the major source of the BOLD signal for f-MRI, remained to be explored.

Here we present the spatial and temporal characteristics of sensory evoked vascular signals in the different vascular compartments: capillaries and draining veins, in visual cortex of cat and owl monkey. Visual stimuli moving across the visual field activated the corresponding retinotopic regions in various visual areas. Using optical imaging based on intrinsic signals we monitored the spatial extent and temporal characteristics of this "retinotopically" propagating activity wave in capillary regions and along draining veins. We found that along the draining veins, the downstream propagating activity wave differed markedly from that propagating in nearby capillary region. Occasionally, a large signal was detected in draining veins more than 5 mm away from sites of elevated electrical activity. The upstream propagating wave was more similar to that in nearby capillary regions. We also noted activation in medium size draining veins in visual areas which were barely activated by a sensory stimulus optimal for primary visual cortex.

Using optical imaging spectroscopy we found that the propagating wave in the capillary bed had a wavefront of deoxyhemoglobin increased followed by a wavefront of oxyhemoglobin increase, lagging some 1-2 mm behind.

We conclude that detailed knowledge of the spatio-temporal behavior of the BOLD signals and the layout of microcirculation is necessary for reliable interpretation of functional maps based on intrinsic signals.

ISCHEMIA: ANIMAL MODELS

761.1

STRAIN-RELATED DIFFERENCES IN TRANSIENT GLOBAL ISCHEMIA IN MICE. M. Fujii, H. Hara, Z. Huang, W. Meng* and M. A. Moskowitz. Stroke and Neurovascular Regulation Lab. MGH, Harvard Medical School, Charlestown, MA 02129.

We evaluated strain-related differences in SV129 and C57Black/6 mice subjected to bilateral common carotid artery (BCCA) occlusion for 60, 75 or 90 min (SV129) and for 15, 30 or 60 min (C57Black/6), and sacrificed 3 days later. Rectal and temporal muscle temperature, MABP, blood gases, pH and rCBF were measured in parallel groups. Damage depended upon ischemic duration and was most marked in striatum>hippocampus>dentate gyrus. There were several remarkable differences between strains. None of the C57Black/6 mice survived for 72 hr (60 min ischemia), but all SV129 did. Rolling seizures were more common in C57Black/6 (41% vs 15% after 30 and 90 min, respectively. Neuronal damage after 30 min ischemia (C57Black/6) was similar to 90 min ischemia in SV129 mice. Lower MABP and rCBF was noted during ischemia in C57Black/6 mice.

To further validate the model, we also evaluated the effects of NBQX (3 x 30 mg/kg i.p., given immediately, 10 and 25 min after reperfusion) following 30 min BCCA occlusion in C57Black/6 mice. NBQX protected the ischemia-induced neuronal damage in all 3 brain areas.

Mice may be useful animal models to study the consequence of global ischemia. BCCA occlusion appears to be an adequate stimulus. The optimum duration of occlusion in SV129 and C57Black/6 mice is 90 and 30 min, respectively. The strain susceptibility may relate to differences in rCBF during ischemia and possibly to differences in genetic background.

OPTIMAL DURATION OF MILD HYPOTHERMIA IN A FOCAL MODEL OF TRANSIENT CEREBRAL ISCHEMIA C. M. Maier*, M. Adams and G. K. Steinberg. Department of Neurosurgery, Stanford University Medical Center, Stanford, CA 94305.

Previous work in our laboratory demonstrated that whole body mild hypothermia (33°C) is protective against ischemic neuronal damage and improves neurological outcome at 24 h post-ischemia. The present study was undertaken to determine the optimal duration of hypothermia and to evaluate neurological outcome at 72 hours. We studied thirty six rats that underwent a two hour occlusion of the left internal carotid, anterior cerebral, and middle cerebral arteries by an intraluminal suture placed 18-22 mm into the ICA. Animals were randomized into 4 different experimental groups: 1) normothermic ischemic controls (36.5 - 37.5 °C; n=8), 2) mildly hypothermic (32.3 - 33.5 °C) for 30 minutes at the onset of ischemia, 3) mildly hypothermic for one hour, and 4) mildly hypothermic for 2 hours. After suture removal the animals were returned to normothermia and allowed to reperfuse for 72 hours. The animals were closely monitored throughout the recovery period and evaluated for neurological findings at 3 days post-ischemia. The brains were extracted after perfusion fixation, sectioned and stained with hematoxylin and eosin, and infarct volumes measured using a computerized imaging system.

761.3

RAT NEONATAL BRAIN DAMAGE FOLLOWING FETAL HYPOXIA. W.B. Macklin, L. U. Hays, A. Douglas, S. Pundik, M. Buczek, and W.D. Lust*, Dept. Neurosci. Cleveland Clinic Foundation, Cleveland, OH 44195 and Dept. of Neurol. Surgery, Case Western Reserve Univ. Sch. of Med. Cleveland, OH, 44106

Neonatal rat brains were examined at P14 and P21 to assess by histology, immunocytochemistry and Western blots the consequences of graded fetal hypoxia. The uterine artery and the uterine branch of the ovarian artery were occluded for 15, 30 and 45 min on day E18 of gestation. No major gross morphological differences were noted in the cresyl violet or H&E stained sections at P14 and P21, although neonatal brains exposed to hypoxia for 45 min were generally 20-30% smaller than those of control animals. Upon closer examination, however, hyperplasia was evident in the cortex of hypoxic brains at P14 and P21 and the extent of the response in the P14 cortex was greater with longer periods of hypoxia. Disorganization of some cortical layers was also evident at P14, and a population of cells in both the hippocampus and cortex appeared abnormal or damaged. Hippocampal phosphorylated neurofilament (NF) and myelin proteolipid protein (PLP) staining appeared to be increased, and brain stem and cerebellar PLP staining at P21 was increased as assessed by Western blot analysis. In contrast, nonphosphorylated NF immunoreactivity was reduced in several areas postnatally and the effect was striking in the Purkinje cell layer, which also appeared disorganized. No increase in apoptosis or in microglial activation was noted in brains from P14 animals. These data suggest that hypoxia at E18 in the rat does not necessarily cause neonatal dysfunction through cell death but rather by compromising the ability of cells to migrate and to organize appropriately during subsequent development. Study was supported by United Cerebral Palsy R-704-95.

761.4

A NOVEL OUTCOME MODEL OF HYPOXIC/ASPHYXIC CARDIAC ARREST IN NEONATAL PIGS A.M. Brambrink, H.J. Hennes, D.F. Hanley, L.J. Martin, V. Goel, H.D. Shaffner, R.N. Ichord*, N. Thakor, R.C. Koehler, R.J. Traystman Dept. Anesth., J. Gutenberg-Univ., Mainz, Germany, and Depts. Anesth/CCM, Neurol., Path., Biomed. Eng., The Johns Hopkins Medical Institutions, Baltimore, MD 21287

Asphyxia is the primary cause of cardiac arrest in newborns resulting in cerebral injury. We developed a model of hypoxic/asphyxic cardiac arrest in piglets to study mechanisms and longterm outcome after damage in developing brain. One-wk-old piglets (n=16) were randomized to awake controls (n=3), sham operated (n=3) and insulted animals (n=10). The insult consisted of 30min hypoxia (10% O_2), followed by 5min roomair and 7min asphyxia. CPR was performed until return of spontaneous circulation (ROSC, MAP>60mmHg). EEG was recorded during insult and 6hr of recovery. Neurologic Deficit Score (NDS) at 6,12,24,36,48,72and96hr was obtained on a 0(best) to 150(worst) scale. After 96hr neuropathology of perfusion fixed brains was examined. No neurologic injury occurred in controls or shams. Insult consistently caused circulatory arrest after 5-6min of asphyxia. CPR for 1-2 min was necessary to achieve ROSC. EEG vanished within 60sec of asphyxia and reemerged 5-10min of reperfusion with burst suppression pattern. Recovery of EEG power spectra correlated with NDS at 24hr. High NDS (49±29vs11±5,$p<0.01$) at 24hr (before seizures) predicted clinical seizure activity. Non-surviving animals (4/10) died in status epilepticus. Neuropathology was highly topographic. Within cortex somatosensory areas showed the least number of viable neurons (66±20%) and damage appeared along descending corticostriatal motor projections (putamen 46±27%, substantia nigra reticulata <1%). Hippocampus (78±9%) showed less vulnerability. Seizures were associated with worsened neuropathology. This model leads to characteristic neurologic deficits and distinct neuropathology similar to that of human neonates after perinatal insults.(Supported by NS 20020 and NS 24282).

761.5

GENDER-LINKED INJURY AFTER FOCAL CEREBRAL ISCHEMIA. D.A. Woods, N.J. Alkayed, M.J. Williams, K.K. Kibler, R.J. Traystman*, P.D. Hurn. Johns Hopkins Med Inst, Baltimore, MD 21287.

Pre-menopausal women have lower stroke rates than men, suggesting a protective role for female reproductive steroids in brain. We determined if there are gender differences in stroke volume after experimental middle cerebral artery occlusion (MCAO) and if brain injury is increased by early oophorectomy. Halothane-anesthetized male (M,n=6), female (F,n=8), and oophorectomized female (OOPH, at 6-8 weeks, n=5) Wistar rats (250-310g) were instrumented for physiological monitoring, then received 2 hrs MCAO (suture occlusion technique) followed by 22 hrs reperfusion. Behavioral deficits were determined during occlusion and after reperfusion. Cortical (CORT) and caudate-putamen (CP) infarction volumes (2mm coronal slices) were measured by TTC staining and digital image analysis. Endogenous plasma estradiol was reduced from 14±2pg/mL in females to 6±3 pg/mL in OOPH. Temperature, arterial blood gases and blood pressure (MAP) were maintained in a normal physiological range and were equivalent among groups. During MCAO, MAP was 84±3 mm Hg in M, 84±3 in F, and 85±4 in OOPH. CORT infarctions per slice (mean mm^2 ± SEM) are summarized in table. CP infarction was also larger in M relative to F but to a lesser degree. Total infarction volume within ipsilateral hemisphere was 34± 16% in M, 12±7% in F, and 25±11% in OOPH. We conclude that brain injury is less in females after MCAO and mediated in part by estrogen. Supported by NS3368, NS2002.

DEVELOPING A LARGE, SURVIVING ANIMAL MODEL OF PERINATAL HYPOXIC ISCHEMIC ENCEPHALOPATHY (HIE), AND A META-ANALYSIS. Raju TNK*, McCulloch KM, Shankarrao R, Roohey, T. Dept. of Pediatrics, Univ. of Illinois, Chicago, IL, 60612.

In a meta-analysis of 293 animal studies on perinatal HIE, we found that rodents were used in 26%, piglets in 23%, sheep in 22%, and primates and others in 29%. Acute models (<24 hr studies) were 71%, and chronic models 29%. In only 23% were clinical, neurologic, developmental, or behavioral outcomes evaluated. Since human HIE is an acute disease with long-term sequelae, we tried developing a surviving HIE model that mimicked the human diease where CNS insult occurs under no anesthesia. Nine piglets (mean age, 6 days) breathed 10% FiO_2 under minimal anesthesia, during temporary, bilateral common carotid artery occlusion; one other piglet was control. Clinical features, MR spectroscopy and histology (day 4) were tested. **Results:** Even with the mild, <10 min total CNS insult (PO_2 29 mm Hg for 9 min with ischemia for 3.5 min), 2/9 (22%) animals died within 2 hr and 5 (78%) survived untill day 4. All 5 had clinical HIE: unsteady gait (4/5); lethargy (3/5); unilateral weakness (3/5); irritability (1/5); and seizures (1/5), recovering by day 4. MRS showed low PCr and high intensity in the phosphomonoester to phosphodiester regions initally, recovering by day 4. None had histopathology of HIE. **Conclusions:** 1) In newborn animals, even mild cerebral insult under low anesthesia causes death sooner than brain damage; 2) deep anesthesia may be necessary to develop long-term survival models of cerebral palsy, in which the value of behavioral and developmental endpoints can be tested.

COFACTOR ADDITIONS DIFFERENTIALLY ENHANCE VMAX AND DEPRESS KM VALUES FOR CEREBRAL NITRIC OXIDE SYNTHASE IN PUP AND ADULT SHR William J. Pearce, Beatriz Tone, Stephen Ashwal, and Steven M. Yellon*. Dept. of Pediatrics and Center for Perinatal Biology, Loma Linda Univ, Loma Linda, CA 92350.

Because ischemic nitric oxide release is neurotoxic, age-related differences in nitric oxide synthase (NOS) activity may help explain age-related differences in neuronal vulnerability to ischemia. To examine this hypothesis, we measured NOS activity via conversion of 14C-arginine to 14C-citrulline in crude brain homogenates from 14-18 day old and adult SHR. Basal NOS activity (pmol/mg/min) was 37% higher in adult (19.3 ± 1.8; n= 48) than in pup (14.1 ± 0.7; n= 46) brains, tissue Vmax values for NOS were similar in newborn (942±41) and adult (957±31) homogenates, but Km values for L-arginine were markedly higher in neonatal (71±9 μM) than adult (16±2 μM) tissues. Addition of the NOS cofactors calmodulin (264 μM), FAD (3 μM), FMN (μM) and BH_4 (10 μM) increased NOS activity in pups by 9%, 68%, 64% and 72% and in adults by 13%, 64%, 67% and 74% respectively. When all cofactors were combined, the effects of all cofactors were additive. Interestingly, BH4 differentially depressed NOS Km values for L-arginine in the pup (to 4.5 μM) and adult (to 3.4 μM) homogenates, but had no effect on Vmax values. Conversely, FAD and FMN had no effect on Km values, but significantly increased Vmax values in pup but not adult homogenates. These data demonstrate that: 1) cerebral NOS activity is lower in neonates than adults due to a higher Km in neonates; 2) endogenous NOS cofactor levels are not saturating in either age group; and 3) expression of different NOS isozymes and/or post-translational modification must be involved in these observed age-related differences.

NITRIC OXIDE SYNTHASE (NOS) INHIBITION WORSENS ACUTE PLATELET ACCUMULATION AND HEMODYNAMIC DEPRESSION IN A RAT MODEL OF THROMBOEMBOLIC STROKE. N.E. Alexis*, W.D. Dietrich, R. Prado, W. Zhao, M. Dewanjee, M.D. Ginsberg. Cerebral Vascular Disease Research Ctr., Dept. of Neurology, Univ. of Miami, Miami, FL 33101

The role of nitric oxide on blood flow and platelet clearance in an experimental thromboembolic stroke model is unknown. Photochemically-induced non-occlusive common carotid artery thrombosis (CCAT) is a model of carotid artery stenosis and platelet embolization to the brain. The effect of NOS inhibition by nitro-L-arginine methyl ester (L-NAME) on hemodynamic outcome and the pattern of platelet accumulation after CCAT was studied. Right CCAT was produced in 30 male Wistar rats injected with ^{111}In-labeled platelets. Immediately or 15 min. after CCAT, rats were injected intravenously with either 15 mg/kg L-NAME or vehicle. Hemodynamic changes were studied 30 min. after thrombosis using ^{14}C iodoantipyrine autoradiography. Eight coronal levels were analyzed (2.2 and 0.7 mm anterior and 0.3, 1.3, 2.3, 3.3, 5.3 and 6.3 mm posterior to bregma). A higher density of labeled platelet aggregates was seen in the thrombosed hemisphere of L-NAME treated rats (15' post-CCAT) than in CCAT rats or L-NAME shams ($p<0.05$ and $p<0.01$;ANOVA). Mean CBF images revealed mild bilateral global reductions in flow and a distinctive pattern of moderate to severe ischemia encompassing the borderzone areas of the ipsilateral cortex. Frontoparietal regions FR1, 2, and 3, forelimb (FL), hindlimb (HL) and entorhinal (ENT) cortical areas were significantly more ischemic than adjacent areas of cortex ($p<0.05$; ANOVA) in all experimental groups. These data highlight regionally specific flow changes and an increase in platelet capture with NOS inhibition.

AMYLOID PRECURSOR PROTEIN IMMUNOREACTIVITY IN TRANSIENT GLOBAL ISCHEMIC RATS. M.T. Tseng*, S.A. Chan, K.H. Reid, V.G. Iyer. Departments of Anatomical Sciences and Neurobiology; and Neurology, University of Louisville, Louisville, Kentucky 40292.

Immunoreactive amyloid precursor protein (APP) deposits have been reported in brains of head trauma patients and in experimental animals. In this study we examine the APP distribution in rats challenged with a single episode of global ischemia. The latter was mechanically induced by a 7 min chest compression in adult male Long Evans rats. Following cardiopulmonary resuscitation, rats were terminated at days 3, 7 and 21. The perfusion fixed brains were removed, bisected, and vibratome sectioned for immunohistochemical localization of antibody binding sites for APP (A4, 643-695, Boehringer Mannheim). Rectangular blocks of the mid-CA1 regions were dissected and further processed for electron microscopy. It was found that following transient global ischemia, some of the CA1 pyramidal cell and the majority of the cortical neurons were immunoreactive. Occasional strong immunoreactive sites associated with vasculature were observed in the cortical tissues. These findings are compatible with the constitutive nature of APP production and that trauma including cerebral ischemia may alter the APP expression. Supported in part by a grant from the Jewish Hospital Foundation.

THE EFFECTS OF SPATIAL LEARNING AND A PLATELET ACTIVATING FACTOR ANTAGONIST ON NADPH-DIAPHORASE HISTOCHEMISTRY AND SOMATIC EVOKED RESPONSES IN A RAT MODEL OF GLOBAL ISCHEMIA. G. O. Peker*, S. Işlekel, E. Demirtaş, O. Algan, T. Uz, V. Gülmen, L. Kanıt, T. Yurtseven, B. E. Okur, and B. Kulalı. Ege University Center for Brain Research, Bornova 35100 Izmir, TURKEY.

We aimed to simulate middle-old age global ischemia by performing the two-day, four-vessel occlusion procedure (Pulsinelli and Brierly, 1992) on 12-16 months old Wistar male rats for a total occlusion of 10 minutes and compared the preventive effects of chronic treatment with a platelet activating factor (PAF), Egb761 (Tebonin, Schwabe, 100 mg/kg/d, p.o., for 20 days) and the simultaneously introduced intensive learning experience in homing hole maze (HHM; Schenk et al., 1988) both of which were applied prior to ischemia. Somatic evoked potentials (SEP) between sciatic nerve and the corresponding cortical area were recorded before and at the 1-10th minutes of ischemia and at the 1-20th, 40th and 60th minutes of reperfusion. On the treatment-free 6th post-ischemic day, the rats were anaesthetized, transcardially perfused with saline and paraformaldehyde in SPB. 40 um thick alternate frozen sections were cut for NADPH-diaphorase (NADPH-d) histochemistry (Scherer-Singler et al., 1983) and hematoxylene (HE) staining. Representative coronal sections comprising of 1) the entire fronto-parietal cortex, 2) a wide area of striatum including caudate-putamen, and 3) the entire hipocampus were examined by light-microscopy. Regardless of treatment, all SEP recordings revealed 1) a decline and a total loss of P1 wave in the 5th and 10th minutes of occlusion, respectively, and 2) a total recovery within the 50 minutes following reperfusion. HE stained sections from all occlusion operated animals firmly demonstrated that ischemia was profound and reproducible. Basal ganglia, hippocampi and cortices revealed varying population of "red neurons" with pyknotic nuclei and eosinophilic cytoplasm. Multivariate ANOVA showed and Duncan's Multiple Range .Test supported that NADPH-d positive neurons were increased significantly ($p<0.005$) in basal ganglia in all the groups (in the order of Egb761>sham operated>placebo) which had undergone the intensive spatial learning task prior to ischemic insult. An insignificant but similar trend was seen in the fronto-parietal cortices. The Egb761 treated hippocampi expressed an insignificantly increased population of NADPH-d positive neurons. Our results imply that, with regard to neuronal nitric oxide synthase expression, the spatial learning experience, in general, has been more effective than the ischemic insult and the "preventive" PAF antagonist treatment. POSTISCHEMIC CHANGES OF SYNAPTIC TRANSMISSION IN CA1 PYRAMIDAL NEURONS OF RAT HIPPOCAMPUS **IN VIVO**. T. M. Gao and Z. C. Xu* Dept. of Neurology, University of Tennessee Memphis, Memphis, TN 38163, U.S.A.

Neuronal hyperactivity caused by excessive glutamate release during ischemia has been postulated to trigger the process of cell death. To understand the electrophysiological mechanisms associated with postischemic neuronal injury, the present study examined the changes of synaptic transmission of CA1 pyramidal neurons in rat hippocampus after transient forebrain ischemia using *in vivo* intracellular recording and staining techniques.

Male adult Wistar rats were fasted overnight and anesthetized with 1-2% halothane. Four-vessel occlusion was performed to induce ischemic depolarization for about 13 min, which consistently produced selective cell death in CA1 region. Postsynaptic potentials (PSPs) elicited by stimulation of contralateral commissural pathway (CC) were compared between CA1 neurons before and after ischemia.

In animals after reperfusion, CC stimuli elicited EPSPs from CA1 neurons similar to those in control animals. However, the threshold of EPSPs was reduced and the latency of EPSP became longer than that of control ones. In addition to the initial EPSP, CC stimuli elicited a second depolarization from CA1 neurons as early as 6 h after reperfusion. Action potentials occasionally generated from the second depolarization. The second depolarization couldn't be evoked by injection of depolarizing current pulses. This ischemia-induced postsynaptic potential (i-PSP) was voltage dependent. The membrane conductance dramatically increased during i-PSP. Pair-pulse stimulation (50 ms ISI) remarkably enhanced the size of i-PSP. The stimulus/response relationship of initial EPSP and i-PSP suggested that they may be elicited from different fibers.

These results suggest that the efficacy of synaptic transmission in CA1 neurons is increased after ischemia. The i-PSP may be associated with the postischemic neuronal injury.

TRANSIENT SPINAL ISCHEMIA EVOKES A BIPHASIC EXCITATORY AMINO ACID AND TAURINE RELEASE: A POTENTIAL ROLE IN THE DEVELOPMENT OF ISCHEMIA INDUCED PARAPLEGIA. [1]M. Marsala*, [1]Y.Taira, [2]J.Galik, [1]T.L.Yaksh, [1]Anesthesiology Res. Lab., Univ. of California, San Diego, CA 92093-0818, [2]Institute of Neurobiology, Slovakia.

Ischemia induced excitatory amino acid release is believed to play an important role in the development of subsequent neuronal degeneration. In the present study acute and chronic changes in the spinal extracellular concentrations of amino acids were measured by using a previously implanted lumbar intrathecal loop dialysis catheter [1]; samples were assayed using HPLC with UV detection. After a 30 min washout and a 30 min control period, 12 min of reversible spinal cord ischemia in combination with systemic hypotension (40 mmHg) was induced by the inflation of a 2F Fogarty catheter passed through the femoral artery to the descending aorta [2]. 15 min after reperfusion animals were allowed to recover and survived for additional 2 days. During this period, recovery of motor and sensory functions was assessed. Dialysate samples were collected periodically during initial 6 hrs of reperfusion and then at 24 and 48 hrs. Glutamate concentrations showed a biphasic increase in spinal CSF with the first peak (196±43% of baseline) observed immediately after recovery from anesthesia followed by partial normalization during 2-3 hrs. A secondary increase was observed between 4-48 hrs (4hrs-190%; 6hrs-350%; 24hrs-583%; 48hrs-617%). Changes in taurine concentration closely followed the profile of glutamate changes. Serine and glycine showed a progressive decline in extracellular concentration with the lowest values (40-50% of baseline) observed at 48 hrs after ischemia. All animals developed spastic or flaccid paraplegia which remained unchanged for 48 hrs. These data suggest that prolonged activation of glutamate receptors during the period of reperfusion may play an active role in the development of ischema-induced paraplegia. $GABA_A$ RECEPTORS: CELLULAR AND MOLECULAR STUDIES

762.1

DIFFERENTIAL INHIBITORY SYNAPTIC MECHANISMS ON EXPIRATORY NEURONS IN PREBÖTZINGER COMPLEX (PREBÖTC) IN NEONATAL RAT. X.M. Shao & J.L. Feldman*, Depts. of Physiological Science and Neurobiology, UCLA, Los Angeles, CA 90095-1527

Expiratory (E-)neurons in preBötC are actively inhibited during inspiration via a glycinergic synapse (Feldman & Shao, *Soc. Neurosci. Abs*, 21, 925 '95). To further study inhibitory mechanisms in respiratory rhythm generation, we whole-cell patch-clamped E-neurons in spontaneously active medullary slices from P0-P3 rats. In the presence of TTX and when clamped at -45mV: i) local application of THIP (1 mM; $GABA_A$ receptor agonist) induced an outward current antagonized by bath application of bicuculline (BIC, 10 μM); ii) local application of glycine (1mM) induced an outward current antagonized by strychnine (STR, 0.8 μM), &; iii) local application CACA ($GABA_C$ receptor agonist) induced an outward current. We also recorded inspiratory-phase IPSCs (iIPSCs) and spontaneous IPSCs (sIPSCs) during expiration. Bath application of BIC reduced the frequency of sIPSCs but did not affect iIPSCs. We presume that the remaining IPSCs are glycinergic. Bath application of STR abolished all IPSCs. The later result may be due to blockade of glycine receptors by STR and blockade of GABA receptors by cross action of STR (Takahashi et al. *Brain Res 640*, 229,'94). We conclude that there are glycine and $GABA_A$ receptors on E-neurons. These results also indicate that GABA- and glycine-mediated inhibition regulate baseline excitability while glycinergic mechanisms alone provide reciprocal inspiratory inhibition of E-neurons.

CONTRASTING EFFECTS OF LANTHANUM ON DIFFERENT RECOMBINANT $GABA_A$ RECEPTOR ISOFORMS. N.C. Saxena* and R.L. Macdonald. Dept. of Neurology,University of Michigan, Ann Arbor, MI-48104.

Functional studies have indicated that unlike most divalent cations, lanthanum (La^{3+}) increases both native and recombinant $GABA_A$ receptor (GABAR) currents. In the present study we have examined whether La^{3+} shows subunit-dependent selectivity for modification of currents from different GABAR isoforms. The effects of La^{3+} on three different GABAR isoforms, α1β3γ2L, α6β3γ2L and α6β3δ, were determined by transient expression of combinations of α1, α6, β3, γ2L and δ subunit cDNAs in L929 fibroblasts. Whole-cell recording was used to determine the concentration response curves for La^{3+} (0.1μM to 3mM) for the three different isoforms at submaximal concentrations of GABA. La^{3+} (1 mM) potentiated α1β3γ2L GABAR currents to a maximum of 175±12% (n=4, $p<0.01$) of control with an EC_{50} of 178±48 μM and Hill slope of 1.2. In contrast to the potentiation of α1β3γ2L GABAR currents by La^{3+}, α6β3δ GABAR currents were strongly inhibited and α6β3γ2L GABAR currents were weakly inhibited by La^{3+}. The α6β3δ GABAR currents showed a maximal inhibition of 83±4% (n=7;$p<0.000007$) at 600 μM La^{3+} with an IC_{50} of 29±6 μM and Hill slope of -1.3 while α6β3γ2L GABAR currents displayed a maximal inhibition of 32±9% (n=7;$p<0.003$) at 3 mM La^{3+} with an IC_{50} of 117±32 μM and Hill slope of -1.1. Interaction of La^{3+} with GABAR isoforms was competitive with La^{3+} decreasing the EC_{50} for GABA of α1β3γ2L GABARs without changing the maximum current and increasing the EC_{50} for GABA of α6β3δ and α6β3γ2LGABAR currents with no decrease in the maximum GABA-evoked current. Neither potentiation nor inhibition of GABAR currents by La^{3+} showed any voltage-dependence. These results suggest that (1) changing the α subunit subtype from α1 to α6 alters the effect of La^{3+} from potentiation to inhibition, (2) changing the γ2L subunit to the δ subunit changes the level of maximal inhibition of α6-containing GABAR currents by La^{3+}, and (3) the site for interaction with La^{3+} is likely to be on the extracellular surface of GABARs.

762.3

REGULATION OF $GABA_A$ RECEPTOR SINGLE-CHANNEL CURRENTS BY PROTEIN KINASE A IN ACUTELY DISSOCIATED RAT HIPPOCAMPAL DENTATE GRANULE CELLS. Y.-F. Lin*, J. Kapur and R.L. Macdonald. Department of Neurology, University of Michigan, Ann Arbor, MI 48104.

We have demonstrated that activation of cAMP-dependent protein kinase (PKA) in hippocampal dentate granule cells enhanced the $GABA_A$ receptor (GABAR) whole-cell currents by increasing GABA efficacy (Kapur and Macdonald, 1996). The mechanism for this PKA-mediated regulation was further determined using outside-out single-channel recordings on excised membrane patches obtained from acutely dissociated rat dentate granule cells. GABA (0.5 μM) was applied by pressure ejection to evoke GABA-gated channel openings, and the catalytic subunit of PKA (cPKA, 50 μg/ml) was included in the intrapipette solution. Voltage was held at -75 mV during recordings. The kinetic properties of the main conductance level (25 pS) were studied. The opening frequency of GABA-evoked single-channel currents was increased by cPKA treatment. The values are 17.2/sec in control condition (6,721 openings, 3 patches) and 46.8/sec in the presence of cPKA (7,709 openings, 4 patches), respectively. Percent open time was increased from 3.36 to 9.31 by cPKA mainly due to the increase in opening frequency. In addition, inside-out patch recordings were also performed in these cells to enable reversible phosphorylation of the same patch. With GABA (1 μM) included in the intrapipette solution and cPKA applied from a puffer, results were consistent with the outside-out recording findings that PKA increased the opening frequency (8.5/sec in control verses 16.9/sec in PKA-treated condition) and produced a slight increase in mean open time (3 patches). These data suggest that PKA phosphorylation modifies GABAR single-channel open properties in native hippocampal dentate granule cells and thus enhances GABAR function. Supported by NIH grant NS 33300.

α-ALKYL- AND α-BENZYL-SUBSTITUTED FIVE- AND SIX-MEMBERED LACTAM RINGS: A NEW CLASS OF $GABA_A$ MODULATORS AND ANTICONVULSANTS. M.W. Hill[1], P.A. Reddy[1], D.F. Covey[1], J.A. Ferendelli[2], and S.M. Rothman[1]*. [1]Washington University School of Medicine, St. Louis, MO 63110; [2] University of Texas Health Science Center, Houston, TX 77030.

α-Substituted lactam rings act at the $GABA_A$ receptor and modulate GABA-induced currents. These compounds likely act as either inverse agonists at the inhibitory "picrotoxin" site, or as agonists at a distinct positive modulatory "lactam" site near or within the M2 channel-lining region. They compare favorably with previously described picrotoxin inverse agonists, the γ-butyrolactones and γ-thiobutyrolactones, in terms of their in vivo anticonvulsant efficacy. In addition, their protective indices ($PI=TD_{50}/ED_{50}$) compare favorably to those of the clinically used anticonvulsants ethosuximide, phenobarbital, and valproic acid. At concentrations between 0.1 and 1.0 mM, these compounds potentiate currents elicited by exogenously applied GABA (3 μM) in cultured rat hippocampal neurons. This current enhancement is not altered by the benzodiazepine antagonist flumazenil. The lactams also markedly prolong the decay of autaptic inhibitory post synaptic currents (IPSCs) in rat hippocampal micro-island cultures, in some cases doubling the time constant of synaptic decay. The same lactams have no effects on EPSC time courses or amplitudes. The IPSC *peak* amplitudes are not influenced by the lactams. Currents produced by exogenous GABA more rapidly desensitize in the presence of lactams. We believe that the prolongation of IPSCs by the lactams is the most likely explanation for their anticonvulsant effect. The exact mechanism for IPSC prolongation is unclear, but it may be due to their driving more liganded receptors into a desensitized state, which re-opens after the disappearance of GABA from the synaptic cleft.

COMPARISON OF GABA$_A$ RECEPTOR-MEDIATED SYNAPTIC CURRENTS IN RAT VISUAL CORTICAL LAYER V INTERNEURONS AND PYRAMIDAL CELLS. Z. Xiang*, J. R. Huguenard, and D. A. Prince, Dept. of Neurology & Neurological Sciences, Stanford University Medical Center, Stanford, CA94305.

Diversity of GABA$_A$ receptors within mammalian CNS may form the basis for differences in the inhibitory function in subgroups of neurons. We tested the hypothesis that neocortical pyramidal neurons and interneurons, cell groups with different properties and roles in cortical circuits, have differences in GABA$_A$ receptor-mediated inhibitory currents. Kinetics of spontaneous and evoked IPSCs (sIPSCs, eIPSCs) in anatomically identified fast spiking interneurons and regular spiking pyramidal cells of layer V in rat visual cortex were compared.

Whole cell voltage clamp recordings of sIPSCs and eIPSCs were made from visually identified layer V interneurons and pyramidal cells in 350 μm thick coronal visual cortical slices. IPSCs were recorded at V_h=-80 mV in the presence of 18 μM DNQX and 50 μM APV with recording pipettes containing (in mM): 65 KCl, 65 K-Gluconate, 1 $MgCl_2$, 1 $CaCl_2$, 10 HEPES, 10 EGTA and 3 ATP. The access resistance of recordings accepted for analysis ranged from 9-13 MΩ.

The decay phase of sIPSCs in both interneurons and pyramidal cells could be well fit by a double exponential function, and the late phase of sIPSC decay was significantly slower in interneurons than in pyramidal cells (90% width was 21.9± 2.0 ms [n=9] and 16.1±1.1 ms [n=11], respectively, P<0.02). By contrast, no significant differences were found in the mean amplitude (56.7 vs. 55.4 pA), 10-90 % rise time (0.85 vs. 0.88 ms), half width (6.5 vs. 6.0 ms) and frequency (1.9 vs. 1.7 Hz) of sIPSCs between two groups (P> 0.05). The late decay component of eIPSCs was also slower in interneurons than in pyramidal cells (90% width = 122.5±12.9 ms [n=6] and 60.9±5.0 ms [n=9], respectively, P<0.001); whereas the rise time was not significantly different (1.78±0.18 ms vs. 1.83±0.12 ms). Cell-attached recordings with 2 μM GABA in the pipette revealed that GABA activated Cl^- channels had longer open time in interneurons than in pyramidal cells.

These data suggest that GABA$_A$ receptors on interneurons have different functional properties from those on pyramidal cells, leading to differences in the effectiveness (total charge) and time course of IPSCs. It is likely that these variations between cell groups are a consequence of differences in GABA$_A$ receptor subunit compositions. (Supported by a Pimley Postdoctoral Fellowship and a research grant *NS12151* from *NINDS*).

HUMAN TERATOCARCINOMA-DERIVED NEURONAL NT2-N CELLS EXPRESS FUNCTIONAL GABA$_A$ RECEPTORS AND mRNA ENCODING GABA$_A$ RECEPTOR SUBUNITS. L.J. Greenfield, Jr.+*, T. R. Neelands#, J. Zhang+, R. S. Turner+& and R.L. Macdonald+@. Depts. of Neurology+ and Physiology@ and Graduate Program in Neuroscience#, Univ. of Michigan Health Sciences Center, and Dept.of Veterans Affairs Medical Center&, Ann Arbor, MI.

Since mature mammalian neurons are incapable of cell division, electrophysiological studies of neuronal GABARs have relied on non-human primary cultures or acutely isolated neuron preparations. The human NT2 teratocarinoma cell line differentiates into neuron-like NT2-N cells when treated with retinoic acid. We investigated whether these cells express functional GABARs and mRNAs encoding GABAR subunits. NT2-N cells were recorded 1-7 days after replating. NT2-N cells responded to GABA with concentration-dependent inward currents that reversed at the Cl^- reversal potential. The EC_{50} for GABA was 16.6 μM, and the Hill slope was 1.26. GABAR currents were completely blocked by bicuculline, partially blocked by Zn^{++}, and enhanced by diazepam, zolpidem, loreclezole, and pentobarbital. RNA was prepared from plates of NT2-N cells and NT2 stem cells, and reverse transcription polymerase chain reaction (rtPCR) was performed using primers encoding GABAR subunit-specific cDNA fragments. mRNAs encoding some but not all GABAR subunits were detected by rtPCR from NT2-N cells. Human NT2-N neurons express functional GABARs and a limited number of GABAR subunits, and may provide an excellent model system for study of human neuronal GABARs. GABA$_A$ RECEPTOR mRNAS ARE DIFFERENTIALLY ALTERED IN RAT CORTEX FOLLOWING CHRONIC TREATMENT WITH DIAZEPAM OR ABERCARNIL: EVIDENCE FOR COORDINATE GENE REGULATION.

A.N. Bateson[1,2]*, R.A. Holt[1] and I.L. Martin[1]. [1]Department of Pharmacology and [2]Division of Neuroscience, University of Alberta, Edmonton, Alberta, T6G 2H7, Canada.

Diazepam and abercarnil both act at the benzodiazepine site of the GABA$_A$ receptor to produce their anxiolytic and anticonvulsant effects. Long-term treatment with abercarnil, however, does not result in diazepam-like tolerance. We have previously reported (Holt et al. Soc. Neurosci. Abstr. **21**, 624.7) that chronic treatment with diazepam or abercarnil produces drug-specific changes in the steady-state levels of GABA$_A$ receptor α1-, β2- and γ2-subunits mRNAs in rat cortex. We have now determined the effects of 7- and 14-day treatment with either diazepam or abercarnil on the steady-state levels of all rat GABA$_A$ receptor α–, β– and γ–subunit mRNA species. These data confirm and extend our previous findings that diazepam and abercarnil differentially alter the levels of specific GABA$_A$ receptor subunit mRNAs. Further, we have observed a degree of association between a particular drug treatment and the changes in the levels of mRNAs arising from a given cluster of GABA$_A$ receptor genes. Therefore, these results are not only consistent with the notion that diazepam tolerance is associated with specific alterations in GABA$_A$ receptor gene expression, but also that GABA$_A$ receptor genes within a single cluster are, to a degree, coordinately regulated.

GABA$_A$ RECEPTOR CHANGES IN AN ANIMAL MODEL OF HUNTINGTON'S DISEASE. S.C. Trevallyan, L.F.B. Nicholson, R.L.M. Faull*. Department of Anatomy, School of Medicine, University of Auckland, Auckland, New Zealand.

The results of our previous studies in a rat model of Huntington's disease (HD) have shown that quinolinic acid (QA) induced degeneration of the striatopallidal and striatonigral projections results in increased numbers of GABA$_A$ receptors in the globus pallidus (GP), entopeduncular nucleus (EP) and substantia nigra (SN). In this study we have investigated whether striatal lesions using the mitochondrial inhibitor, 3-nitropropionic acid (3-NP), result in similar GABA$_A$ receptor changes to those seen in HD and the QA animal model of HD. In order to investigate the subunit composition of the GABA$_A$ receptor changes we have used immunohistochemistry with subunit specific antibodies, *in situ* hybridisation with subunit specific oligonucleotide probes and ligand binding studies. The animals were anaesthetised using halothane, and stereotaxic 3-NP injections were made into the right striatum. Following survival periods of 1-7 days the animals were sacrificed and processed for immuno-histochemistry, *in situ* hybridisation and autoradiography. The results of the ^{3}H-ligand studies show that 3-NP lesions in the striatum result in topographically related areas of increased GABA$_A$ receptors in the GP, EP and SN. The immunohistochemistry results show that these regions of increased receptors correspond to areas of increased immunoreactivity for the α_1, $\beta_{2,3}$ and γ_2 subunits of the GABA$_A$ receptor. These findings also correlate with the results of the *in situ* hybridisation studies showing the presence of increased mRNA expression for the α_1, β_2 and γ_2 subunits of the GABA$_A$ receptor in the same regions as the receptor increases. These findings show that the pattern of GABA$_A$ receptor changes in the GP, EP and SN in the 3-NP model of HD is similar to that found in HD and in the QA model of the disease.

ALTERATIONS IN GABA$_A$ RECEPTOR ß2 mRNA LEVELS IN THE ANTERIOR CINGULATE CORTEX OF RABBITS EXPOSED PRENATALLY TO COCAINE. Dennis R. Grayson*,[1,2] Yunxing Wu,[1] Adam A. Book,[2] and E. Hazel Murphy,[2] Neurosciences Research Center[1,2], and Department of Psychiatry[1], Medical College of Pennsylvania and Hahnemann University (MCPHU), Allegheny Campus Pittsburgh, PA 15212 and Department of Anatomy and Neurobiology[2], MCPHU, Philadelphia, PA 19129.

We have previously shown that intravenous injection of cocaine (3 mg/kg) twice daily into pregnant rabbits results in a significant increase in GABA immunoreactivity in the anterior cingulate cortex (ACC) of the cocaine-exposed offspring. These effects are significant at postnatal day 5 (P5) and persist through P60. The results suggest that exposure of the developing brain to cocaine results in a modification of inhibitory activity in the dopamine rich ACC. To determine whether these changes were accompanied by changes in the level of GABA$_A$ receptor subunit mRNAs, a portion of the ß2 mRNA encoding the intracellular loop region of the receptor subunit from rabbit was subcloned. The rat and rabbit DNA sequences were 95% identical. Radiolabeled cRNA prepared from this construct was used to analyze ß2 mRNA levels in coronal sections of saline and cocaine-exposed pups (aged P20) by *in situ* hybridization. Sections were emulsion coated, counterstained and analyzed to determine silver grain density within each lamina of the ACC. In saline-treated animals, there was strong labeling for ß2 mRNA in lamina II and a relative absence of labeling in lamina III. In laminae V and VI, where neuronal density is lower than in lamina II, individual labeling of neurons was distinctly visible throughout. The labeling of large pyramidal neurons in lamina V was especially distinct. In sections prepared from the prenatal cocaine-treated group, labeling across laminae II/III was much more homogeneous with no decrease in labeling in lamina III as compared to II. Collectively, the data suggest that *in utero* cocaine exposure modulates GABA$_A$ receptor subunit expression possibly through interactions with the dopamine D1 receptor system. THE PERSISTENCY OF THE DECREASE IN DRUG EFFICACY DURING BENZODIAZEPINE TOLERANCE COINCIDES WITH THAT OF THE MODIFICATION IN GABA$_A$ RECEPTOR mRNA SUBUNIT EXPRESSION. F. Impagnatiello*, P. Longone, C. Pesold, E. Costa and A. Guidotti. The Psychiatric Institute, Department of Psychiatry, University of Illinois at Chicago, Chicago, IL 60612.

Benzodiazepines (BZs) with partial (imidazenil) allosteric modulatory activity (PAM) on GABA$_A$ receptors exhibit full efficacy as anticonvulsants but have a reduced tolerance liability compared to BZs with full (diazepam) or selective (zolpidem) allosteric modulatory activity. We evaluated in the rat the effect of an equipotent, protracted treatment with diazepam, zolpidem, or imidazenil on the duration of the changes in the expression of mRNAs encoding for α, β, and γ GABA$_A$ receptor subunits and that of the decrease of drug efficacy. During diazepam- and zolpidem-induced anticonvulsant tolerance, the content of the mRNA encoding for the α_1 subunit of GABA$_A$ receptors decreased (41% and 20%, respectively) in the frontoparietal motor (FrPaM) cortex but not in the frontoparietal somatosensory (FrPaSS) cortex, whereas equipotent treatment with imidazenil did not produce tolerance, and was not associated with any changes in mRNA subunit density. In the FrPaM cortex, diazepam-tolerant rats also had a concomitant increase in α_5 subunit mRNA. Moreover, the diazepam-induced decrease in α_1 subunit was observed in the hippocampus as well. We also compared the persistency of anticonvulsant tolerance with that of changes in the α_1 and α_5 GABA$_A$ receptor subunit mRNAs after discontinuation of the protracted diazepam treatment. Both anticonvulsant tolerance and GABA$_A$ receptor subunit mRNA expression in the FrPaM cortex of diazepam-tolerant rats returned to normal 72 hours after termination of the longterm treatment with diazepam. These data may represent the first demonstration of a time-dependent relationship between the persistency of behavioral tolerance and that of changes in GABA$_A$ receptor subunit expression. C.P. PHARMACOLOGICAL MODULATION OF GABAERGIC TRANSMISSION AFFECTS NEUROSTEROID CONTENT IN RAT BRAIN.
M.L. Barbaccia*, G. Roscetti, M.Trabucchi, R.H.Purdy#,M.C.Mostallino§, A. Concas§ and G.Biggio§. Dept Exp. Medic.Univ. of Rome "Tor Vergata",00133 Rome, #Dept. Psych. UCSD,San Diego CA 92161,USA and §Dept. Exp. Biol. Univ. of Cagliari, 09123 Cagliari, Italy.

The progesterone metabolites allopregnanolone (5-alpha- pregnan-3alpha-ol-20one,AP) and allotetrahydrodeoxycorticosterone (5-alpha-pregnan-3-alpha,21diol-20 one, THDOC) are potent endogenous positive modulators of GABA$_A$ receptors. Their brain content is markedly increased by acute stressors known to decrease GABAergic neurotransmission. The relationship between GABAergic tone and brain cortical content of AP, THDOC and their precursors (pregnenolone and progesterone) was further studied in handling habituated male Sprague-Dawley rats (150-200g) following systemic injection of the GABA-depletor isoniazid (ISO), the anxiogenic beta- carboline derivative FG 7142 and the anxiolytic beta-carboline derivative abecarnil. A reduction in GABAergic transmission elicited by ISO (375 mg/Kg, s.c.) and FG 7142 (15 mg/Kg,i.p.) time-dependently increased the AP and THDOC brain cortical content (assayed by RIA, following extraction and HPLC purification). AP and THDOC values peaked 40-80 (+815% and +860%) and 30 min (+300% and +150%) following ISO and FG 7142, respectively. Pregnenolone and progesterone were also increased. Abecarnil (0.3 mg/Kg,i.p.), which per se slightly decreased AP in brain cortex, blunted the ISO-induced increase of neurosteroids. The inverse correlation between GABAergic tone and the brain concentrations of AP and THDOC, potent amplifyers of GABA action at GABA$_A$ receptors, points toward a physiological role for these neurosteroids in the modulation of central GABAergic transmission. CONGENITAL MYASTHENIC SYNDROME (CMS) DUE TO FRAMESHIFTING ACETYLCHOLINE RECEPTOR (AChR) ε SUBUNIT MUTATION
M. Milone, K.Ohno, J.N. Pruitt, J.M. Brengman, S.M.Sine, and A.G. Engel*, Mayo Clinic, Rochester, MN 55905.

To determine the basis of a severe CMS present since infancy, electrophysiological, ^{125}I-α-bungarotoxin binding, molecular genetic, and expression studies were carried out. The number of AChR/endplate (EP) was < 10% of normal. Miniature EP currents had markedly reduced amplitude and a prolonged monoexponential decay. Single channel AChR currents had amplitudes 75% of normal and burst durations with a minor brief component and a 3-fold prolonged major component, suggesting channels containing γ instead of ε subunits (γAChR). However, at 3 of 5 EPs, channel events clustered abnormally at low ACh concentration, which is not a property of γAChR. Mutational analysis revealed a homozygous 7-bp deletion in the ε-subunit gene at position 553 (ε553del7) predicting 6 missense amino acids followed by a stop codon in exon 7 and ε truncation before the M1 domain. An affected brother and unaffected parents had homozygous and heterozygous deletions, respectively. ε553del7 was previously observed by us as one of two heteroallelic ε mutations in a CMS (Ohno et al, Neurology 45: A283, 1995). cDNA cloning of the patient's ε subunit gene revealed 3 different transcripts: ε553del7; ε553del7 with exon 6 spliced out (Δ148S-183G), which restores the open reading frame; and ε553del7 with exon 6 spliced out and intron 11 spliced in. Expression of each transcript along with other subunit genes in HEK cells showed AChR expression reduced to 23%, 8% and 7%, respectively, but ACh binding studies suggested that ε-omitted $\alpha_2\beta\delta_2$ AChR, which is known to rapidly desensitize, was expressed. We hypothesize that EP AChRs comprise $\alpha_2\beta\delta\gamma$ type channels and possibly $\alpha_2\beta\delta_2$-type channels. Supported by NIH NS6277 and an MDA Research Grant.

MUSCLE CELLS FROM MDX (MUSCULAR DYSTROPHY) MICE HAVE AN INCREASED SUSCEPTIBILITY TO FREE RADICAL INDUCED INJURY,
T.A. Rando*, J. Dhawan, M.L. Whirl, A.A. Franco, Dept. of Neurology and Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Humans with Duchenne muscular dystrophy have defects in the dystrophin gene and express no dystrophin in skeletal muscle. The initial pathologic change in the disease is muscle fiber necrosis which leads to progressive muscle degeneration. However, the cause of this necrosis is unknown since some dystrophin-deficient muscles remain unaffected. To study the propensity of dystrophin-deficient fibers to undergo necrosis, we have developed an *in vitro* model system using muscle cells from the *mdx* mouse, a dystrophin-deficient strain in which the initial pathologic change is also muscle fiber necrosis. Muscle cells from *mdx* and control (C57) mice were purified from primary cultures, expanded, and differentiated to form myotubes. The C57 myotube cultures expressed dystrophin; *mdx* myotube cultures did not. The cultures were subjected to various forms of metabolic stress, and the susceptibilities of the two populations were compared in an assay of cell death. The two populations were equally susceptible to injury from the addition of the calcium ionophore A23187 to the medium or to withdrawal of serum from the medium. However, *mdx* myotube cultures were found to be more susceptible to a variety of pro-oxidants, including H_2O_2, menadione, and buthonium sulfoximine, compared with C57 cells. At concentrations of these compounds which resulted in the death of 50% of C57 cells, cell death in the *mdx* cultures ranged from 80-100%. Undifferentiated (myoblast) cultures from the two strains were equally susceptible to the pro-oxidants, suggesting that the difference in dystrophin expression (which occurs upon cellular differentiation) accounts for the different susceptibilities of the myotube cultures. We propose that the characteristic of dystrophin-deficient muscle that renders it susceptible to necrosis is an increased susceptibility to oxidative stress, and that enhanced antioxidant defenses could explain the resistance of certain dystrophin-deficient muscles to the degenerative process. Supported by grants from the Muscular Dystrophy Association and the American Academy of Neurology Education & Research Foundation.

CLONING AND CHARACTERIZATION OF A NOVEL MUSCLE-SPECIFIC PDZ-CONTAINING PROTEIN THAT IS MISEXPRESSED IN *MDX* MOUSE.
H. Xia* and D. S. Bredt, Department of Pharmaceutical Chemistry and Physiology, University of California at San Francisco, San Francisco, CA 94143-0444

Mutations of the skeletal muscle protein, dystrophin, lead to Duchenne muscular dystrophy (DMD). These mutations of dystrophin result in disruption of the dystrophin-associated glycoprotein complex. We recently identified that neuronal nitric oxide synthase (nNOS) is a enzyme component of the dystrophin complex and that nNOS is absent from skeletal muscle sarcolemma in patients with DMD and in*mdx* mice, which lack dystrophin. The N-terminus of nNOS, which contains a PDZ protein motif, directly binds to the PDZ domain of skeletal muscle a1-syntrophin, a dystrophin associated protein. To determine the cellular localization of other PDZ-containing proteins in skeletal muscle, we have used PCR to identify novel family members. One of the novel clones identified, tenatively named SK-2, encodes a novel 44 kD PDZ-protein that is restricted to skeletal muscle and heart. Western blotting shows that SK-2 redistributes from particulate to soluble fractions in skeletal muscle from *mdx* mouse. These studies may indicate that mislocalization of PDZ-proteins plays a general role in pathophysiology of Duchenne muscular dystrophy (DMD).

UBIQUITIN AND PHOSPHORYLATED HEAVY NEUROFILAMENT ARE MARKERS OF MOTOR NEURON DEGENERATION IN THE WOBBLER MOUSE.
E.P. Pioro*, T. Ishiyama, B. Klinkosz, H. Mitsumoto and B.D. Trapp. Depts of Neurology and Neurosciences, Cleveland Clinic Foundation, Cleveland, OH 44195.

The wobbler (wr) mouse is a spontaneous autosomal recessive mutant that has been extensively studied as an animal model of motor neuron disease (MND). Because ubiquitin and phosphorylated heavy neurofilament immunoreactivities (IRs) are regularly increased in spinal cord motor neurons of patients with amyotrophic lateral sclerosis (ALS), we examined these and other markers in the cervical spinal cord of symptomatic (>3-week-old) and presymptomatic (<3-week-old) wr mice. Equivalent changes in the wr mouse would support its use as a model of ALS and allow analysis of cellular events occurring early in neuronal degeneration. Compared to their normal littermates, 10-week-old wr mice had marked upregulation of ubiquitin IR in a subpopulation of ventral horn neurons. Increased ubiquitin protein levels were confirmed by immunoblot studies and mRNA levels are being measured. Similar changes were noted in 2-week-old affected animals but not in wr mice less than 10 days of age. This suggests that the increase in ubiquitin IR occurs at a time when vacuolar degeneration of motor neurons is known to begin – between 1 and 2 weeks of age. Phosphorylated heavy neurofilament IR was also increased in the perikarya of motor neurons only in affected wr mice. Studies are underway to determine whether these changes are primary or secondary to an earlier event in the pathogenesis of wr MND. (Supported by NIH K08-NS01846.)

SERA FROM PATIENTS WITH SPORADIC ALS SELECTIVELY ALTER RELEASE FROM TERMINALS OF VULNERABLE MOTONEURONS. D.R. Mosier*, L. Siklós, and S.H. Appel. Dept. of Neurology, Baylor College of Medicine, Houston, TX 77030.

Increased intracellular calcium, seen at neuromuscular junctions (NMJs) of amyotrophic lateral sclerosis (ALS) patients, and in mouse spinal motoneurons following passive transfer of sera from ALS patients (*Ann Neurol* **39**:203, 1996; *Synapse* **20**:185, 1995), may lead to motoneuron dysfunction in ALS. Extraocular motoneurons, which are preserved in ALS, express high levels of calcium-binding proteins (*Ann Neurol* **36**:846, 1994), which could modify disease expression. To better understand the regulation of calcium-dependent processes in resistant and susceptible motoneurons, we studied spontaneous release at NMJs of extensor digitorum longus (EDL) and extraocular muscles in BALB/c mice 24 hrs after i.p. injection of sera from patients with sporadic ALS or control diseases. In addition to observing selective increases in resting MEPP frequency, we found that MEPP amplitudes of ALS-treated NMJs in EDL frequently deviated from the usual Gaussian distribution. 40% of these ALS-treated NMJs exhibited significantly skewed or bimodal MEPP amplitude distributions, which appeared to result from the expression of a population of large-amplitude events. These abnormalities were seen at <5% of control NMJs. In contrast to EDL, a consistently higher MEPP frequency was observed at NMJs of extraocular muscles. More strikingly, treatment with ALS sera did not alter spontaneous release in extraocular muscles. These differences in spontaneous release and in susceptibility to passive transfer of ALS sera may suggest differences between spinal and extraocular motoneurons in the regulation of calcium-dependent processes, which could influence motoneuron dysfunction and/or injury in patients with ALS.

A NEUROMUSCULAR DEFICIT IN SOD1 DEFICIENT MICE. D. G. Flood*, A. G. Reaume, Y.-G. Lin, E. K. Hoffman, and R. W. Scott. Dept. of Molecular Biology, Cephalon, Inc., West Chester, PA 19380.

Numerous mutations in the cytoplasmic Cu/Zn superoxide dismutase gene (SOD1) have been found in familial amyotrophic lateral sclerosis (FALS). Some of these SOD1 mutations have been shown to cause FALS in transgenic mice. Although the SOD1 mutations cause FALS by a gain of function mechanism, a role for reduced Cu/Zn SOD in the progression of FALS cannot be ruled out. In order to address the role of reduced Cu/Zn SOD, we have generated mice by homologous recombination in embryonic stem cells that have the entire coding sequence for the mouse SOD1 gene deleted. Although overt motor neuron disease is not observed by 17 months of age (the oldest age tested), homozygous Cu/Zn SOD deficient mice (SOD1–/–) exhibit a progressive neuromuscular deficit, suggesting a role for Cu/Zn SOD in normal homeostasis of adult or aging motoneurons. At 4 months of age muscle biopsies from SOD1–/– mice showed subtle evidence for acute and chronic denervation, but there was no spinal cord motoneuron loss (Reaume et al., Nature Genetics, 13, 1996). At 6 and 9 months, muscles showed increased signs of chronic denervation. Quantification of fiber size and type in the soleus muscle of SOD1–/– mice, as well as in mice fed a vitamin E deficient diet, showed that the SOD1–/– mice differed from the pattern of change seen in the vitamin E deficient mice (model of acute peripheral neuropathy) and from the classic pattern of change seen in human motor neuron disease. SOD1–/– mice and vitamin E deficient mice showed a type 2A fiber predominance. Vitamin E deficient mice showed atrophy of both type 1 and 2A fibers, characteristic for acute peripheral neuropathy. SOD1–/– mice, in addition to atrophy of type 2A and 2B fibers in the gastrocnemius, showed type 1 fiber hypertrophy in the soleus. These changes suggest that a lack of Cu/Zn SOD results in changes consistent with a slowly progressive neuromuscular deficit.

MOTOR NEURONS ARE MORE VULNERABLE TO INJURY IN A TRANSGENIC MOUSE MODEL OF FAMILIAL ALS. A.Y. Chiu, M.E. Gurney*, E.W. Chen and S. Loera Div. of Neurosci., City of Hope Med. Ctr., Duarte, CA 91010, @ Upjohn, Kalamazoo, MI.

The mutation gly^{93}→ala of Cu,Zn superoxide dismutase is found in patients with familial amyotrophic lateral sclerosis (FALS) and causes progressive motor neuron disease when expressed in transgenic mice (Gurney et al., 1994 *Science 264:1772*). Although these animals are born with a full complement of motor neurons, there is marked loss of neurons innervating the limbs by 90 days of age when clinical disease begins to be detectable (Chiu et al., 1995 *Mol. Cell. Neurosci. 6:349*). The degree of cell loss varies between motor pools; the numbers of hypoglossal motor neurons appear little affected even at 125 days of age.

To test the hypothesis that this mutation renders a subset of motor neurons more vulnerable to damage, we compared the survival of hypoglossal motor neurons in transgenic and wild-type siblings following mild (nerve crush) or severe (chronic transection) injury to the peripheral nerve. In adult wild-type mice, more than half of the neurons survive chronic axotomy, compared with only a third of the population in age-matched mutant mice. Following nerve crush, mutant animals again lose 20% more neurons than wild-type animals. These results suggest that the mutation causes a subpopulation of motor neurons to become highly vulnerable so that these cells are easily lost following even mild forms of injury. (Supported by a grant from the ALS Association)

3-NITROTYROSINE IN ALS. M. Flint Beal*[1], Robert J. Ferrante[2], Russell T. Matthews[1], Neil W. Kowall[2] and Robert H. Brown[3]. [1]Neurology Service, Massachusetts General Hospital, Boston, MA 02114, [2]Geriatric Research Education Clinical Center, VA Medical Center, Bedford, MA 02173 and Day Neuromuscular Laboratory, Massachusetts General Hospital, Boston, MA 02114.

The pathogenesis of neuronal degeneration in both sporadic and familial amyotrophic lateral sclerosis (ALS) associated with mutations in superoxide dismutase may involve oxidative stress. 3-Nitrotyrosine is a marker for oxidative damage mediated by peroxynitrite. Malondialdehyde is a biochemical marker of lipid peroxidation and heme oxygenase-1 is induced by oxidative stress. Biochemical measurements showed increased 3-nitrotyrosine and its metabolite 3-nitro-4-hydroxyphenylacetic acid in the lumbar and thoracic spinal cord of ALS patients. Immunocytochemistry demonstrated increased 3-nitrotyrosine, hemoxygenase-1 and malondialdehyde staining in motor neurons of both sporadic and familial ALS patients. Oxidative damage may lead to nitration and cross-linking of neurofilament protein, followed by impaired axonal transport and death of motor neurons. Increased oxidative damage mediated by peroxynitrite may therefore play a role in the pathogenesis of both sporadic and familial ALS. Supported by NIA AG12992.

BRADYKININ INDUCED AMYLOID PRECURSOR PROTEIN SECRETION IN FIBROBLASTS FROM ALZHEIMER'S DISEASE, DOWN'S SYNDROME AND CONTROL DONORS. M. Racchi#, E. Barzaghi@, C.Meoni#, M. Trabucchi#, A. Bianchetti# and S. Govoni §*. #Alzheimer's Department, "Sacred Heart" Hospital, FBF, Brescia; @ Institute of Pharmacological Sciences, University of Milan, and § Institute of Pharmacology, University of Pavia, ITALY.

The processing of the amyloid precursor protein (APP) into non-amyloidogenic secreted fragments by "α secretase", is enhanced by the activation of phosphorylation processes, among which protein kinase C (PKC) activation is prominent. In addition a number of receptors coupled with activation of phospholipase C (PLC) could stimulate the non amyloidogenic secretory processing of APP. An example is the bradykinin (BK) receptor. In PC12 cells the treatment with BK could stimulate APP secretion. Altered function of the BK receptor has been observed in fibroblasts from Alzheimer's disease (AD) patients. An increased inositol 1,4,5 triphosphate accumulation has been correlated with an up-regulation of the BK receptors. Furthermore AD fibroblasts show an increased response to BK in terms of intracellular calcium levels. Moreover fibroblasts from AD and Down's syndrome patients present peculiar and distinct APP secretory responses to direct PKC activation with phorbol esters (M.Racchi et al. Neurosci. Lett. 201, 1-4, 1995; Soc. Neurosci. Abstracts 21, 989, 1995). Within this context, we treated fibroblasts with BK and observed a concentration dependent increase in secreted APP reaching a maximum (+240%) with 1μM BK and then plateauing. For control fibroblasts the EC50 calculated from the concentration response curve was 3nM, which is in the same order of magnitude of the Kd of BK for its receptors in human skin fibroblasts (1 nM). The effect of BK on APP secretion appears to be dependent on interaction of the ligand with the B2 type of BK receptors since the secretory response is blocked by simultaneous treatment with the selective B2 inhibitor HOE140 (300nM). In light of the described differences in BK responses in AD fibroblasts these observations suggest that BK might be a discriminative stimulus for APP secretion when applied to AD and DS fibroblasts.

THE EFFECT OF GLYCOSYLATION ON TACRINE-MEDIATED INHIBITION OF BETA-AMYLOID PRECURSOR PROTEIN SECRETION. K. Sambamurti*[1], L.M. Refolo[1], L. Sanders, L. McConlogue[2], M. Farlow[3] and D.K. Lahiri[3]. [1] Mayo Clinic, Jacksonville, FL 32224, [2] Athena Neurosciences, San Francisco, CA 94080 and [3] Department of Psychiatry and Neurology, Indiana University School of Medicine, Indianapolis, IN 46202.

Amyloid β-peptide that aggregates to form the core of senile plaques in Alzheimer disease, is generated from a family of large integral membrane glycoproteins, βAPP. Secreted derivatives of βAPP are the proteolytic cleavage products of full length βAPP. Cell culture studies have recently shown that, tacrine, which is used to improve memory and cognitive functions in some patients with AD, inhibits secretion of βAPP into the conditioned medium (Lahiri et. al. 1994). Here we have investigated how glycosylation of βAPP affects tacrine's ability to influence the secretion of βAPP. In this study, we have utilized a novel mutant CHO cell line ldlD which is conditionally deficient in N- or O-glycosylation in the absence of galactose (gal) or N-acetyl galactosamine (galNac; Krieger et. al. 1989). The cell line was transfected with constructs expressing wild type βAPP751, or various βAPP751 mutants. Lysates and culture media from cells grown in the absence or presence of gal and galNac were analyzed by western blots or by immunoprecipitation using anti-βAPP antibodies. βAPP and its mutant derivatives are efficiently cleaved and secreted from ldlD cells in either the presence or absence of sugars suggesting that glycosylation is not necessary for βAPP-secretase activity. The secreted βAPP derivatives are ~ 125- and ~100 kDa in the presence and absence of sugar respectively. To study the effect of tacrine in such a system, cells were treated with the drug and the level of secreted βAPP was analyzed. The effect of tacrine on the secretion of βAPP was found to be unaffected by the state of glycosylation of the wild type protein. The specific effects of glycosylation on the secretory processing of familial AD mutant βAPP derivatives are being analyzed and Aβ1-40 and Aβ1-42 species are being characterized by a sensitive ELISA test.

ADDITIVE EFFECTS OF BASIC FIBROBLAST GROWTH FACTOR AND PHORBOL ESTER ON BETA-AMYLOID PRECURSOR PROTEIN EXPRESSION AND SECRETION IN SKNMC HUMAN NEUROBLASTOMA CELLS. G.E. Ringheim*, Susan Aschmies, and Wayne Petko. Neuroscience Therapeutic Area, Hoechst Marion Roussel, Inc., Bridgewater, NJ 08807.

Expression of the beta-amyloid precursor protein (β-APP), a proteoglycan whose proteolytically-derived fragments have been implicated in the neuropathology observed in Alzheimer's disease, is regulated by a variety of stimuli including cytokines, phorbol esters, and growth factors. Here, we report the effects of basic fibroblast growth factor (bFGF) and the protein kinase C activator, phorbol 12-myristate 13-acetate (PMA), on β-APP expression and secretion in SKNMC human neuroblastoma cells. Treatment of the cells with bFGF for 24 h increased β-APP promoter activity 200%, cell-associated full-length protein 189%, and secreted amino-terminal fragments 192% relative to basal levels. Treatment of the cells with PMA for 24 h also up-regulated β-APP expression and secretion with increases of 170%, 112%, and 161% being observed for promoter activity, cell-associated full-length protein, and secreted amino-terminal fragments, respectively. The effects of bFGF and PMA on expression and secretion of β-APP were additive and distinct in that: (1) co-treatment of the cells with maximally stimulating doses of bFGF and PMA had an additive effect on both induced full-length protein expression (242%) and secretion of amino-terminal fragments (311%) relative to basal levels; (2) net levels of full-length protein expression and secretion induced by bFGF and PMA differed significantly from each other; and (3) down-regulation of phorbol ester-stimulated protein kinase C by pre-treatment of the cells for 24 h with 1 μM PMA failed to attenuate the bFGF-induced transcription or induced secretion of β-APP. IL-1 AND ANTI-INFLAMMATORY DRUGS MODULATE Aβ CYTOTOXICITY IN PC12 CELLS. M.O. Fagarasan, M Knight* and P.S. Aisen.Dept. Psychiatry, Mount Sinai Medical Center, New York NY 10029

The effects of interleukin-1β (IL-1) and several anti-inflammatory drugs on amyloid β-peptide ($A\beta_{1-42}$)-induced cytotoxicity of rat pheochromocytoma cells (PC12) were studied. The percent of living cells in culture after timed incubation with the various agents was measured by the indicator 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT assay). Incubation of PC12 cells with 10^{-6}M Aβ for 24 hr reduced the percent of living cells to 36%. Co-incubation with 10^{-7}M IL-1 had a synergystic effect to reduce the viable cells to 13%. Incubation of the cells with 10^{-6}M Aβ and 10^{-7}M of the anti-inflammatory agents, indomethacin, dexamethasone and chloroquine reduced the percent of viable cells to 51%, 48% and 44%, respectively, compared to 32% in the control. Thus the anti-inflammatory drugs attenuated the cytotoxic effects of Aβ.The concentration effect of these agents on Aβ-induced cytotoxicity were next studied. Indomethacin and chloroquine incubated over a concentration range of 10^{-7} to 10^{-4}M had a maximal effect of reducing cytotoxicity at 10^{-6}M, whereas, dexamethasone, studied from 10^{-8} to 10^{-5}M had a maximal effect at 10^{-6} M. These experiments support further study of anti-inflammation therapy in Alzheimer's disease.

CLUSTERIN (apoJ) INFLUENCES Aß1-42 INDUCED TOXICITY IN CULTURED PC12 AND PRIMARY NEURONS. T.E. Morgan*, I. Rozovsky, P.A. Wals, and C.E. Finch. Andrus Gerontology Center, Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191.

Clusterin (also known as apolipoprotein J) is associated with both aggregated Aß in senile plaques and soluble Aß in the CSF. We are examining the clusterin-Aß1-42 interaction(s) and how clusterin influences Aß1-42 toxicity. Recent evidence from our laboratory suggests that clusterin has the potential for enhancing or reducing Aß-induced toxicity. As previously published (Oda et al., Exp. Neurol. 1995), co-incubation of Aß1-42 with clusterin (1:1 mass ratio) results in a slowly sedimenting Aß-clusterin fraction that is toxic to cultured PC12 and primary cortical neurons. The supernatant fraction (16,000g/10') from Aß1-42 aggregated without clusterin is not significantly toxic. The rapidly and slowly sedimenting fractions from Aß1-42 aggregated in the presence of clusterin are toxic at a lower concentration than Aß1-42 aggregated alone. Thus, clusterin enhances Aß1-42 toxicity. Interestingly, preincubation of PC-12 cells with 25 nM clusterin partially protects these cells from aggregated Aß1-42 induced toxicity. Adding clusterin and aggregated Aß1-42 to the cultures simultaneously does not influence the degree of Aß1-42 induced toxicity. The protective effect of clusterin preincubation also occurs in cultured neurons exposed to excitotoxic levels of glutamate. Hence, clusterin may be beneficial if present in the cellular microenvironment prior to Aß exposure but detrimental if in the presence of Aß prior to cellular exposure. Supported by AG-13499 (CEF) and Alzheimer's Association FSA-95-033 (TEM).

764.6

A PEPTIDE TO THE PERLECAN BINDING DOMAIN OF THE BETA-AMYLOID PROTEIN (Aß) IS A POTENT INHIBITOR OF Aß-PERLECAN BINDING AND Aß FIBRILLOGENESIS IN VITRO AND IN VIVO. A.D. Snow, G.M.Castillo, J.A. Cummings, D. Nochlin*, W. Yang, K. Rimvall, M.J. Sheardown, and M. E. Judge. Dept. of Pathology, Neuropathology Labs, Box 356480, University of Washington, Seattle, WA 98195 and Novo Nordisk, 2760 Malov, Denmark.

Perlecan is a specific heparan sulfate proteoglycan consistently localized to beta-amyloid protein (Aß) deposits in the brain lesions of Alzheimer's disease (AD). Previously, we demonstrated that Aß 12-17 contains a perlecan binding site. In the present study we determined if a Perlecan Binding Domain Peptide (PBDP) was effective in inhibition of Aß-perlecan binding and Aß fibrillogenesis in vitro and in vivo. Using a solid phase binding assay, PBDP inhibited binding of Aß 1-40 to substrate bound perlecan. To assess the potential role of PBDP in Aß fibrillogenesis, a Thioflavin T fluorometry assay was used. Aß 1-40 or 1-42 at 25 μM in TBS (pH 7.0) was incubated at 37°C for 2 weeks alone or in the presence of PBDP. Aliquots were taken at 1 hr, 8 hrs, 1 day, 3 days, 1 week and 2 weeks. PBDP was effective in significantly inhibiting Aß 1-42 fibrillogenesis at all time points, with a significant 2-fold inhibition observed as early as 1 hour, and a maximum 4-fold inhibition at 2 weeks. PBDP also inhibited Aß 1-40 fibrillogenesis but only at early time points (maximum 1.8-fold inhibition at 8 hrs). Sprague-Dawley rats (6 per group) were then infused into hippocampus for 1 week with Aß 1-40 + perlecan or Aß 1-40 +perlecan + PBDP. 100% of animals (6 of 6) infused with Aß + perlecan demonstrated congophilic deposits (indicative of amyloid) at the infusion site in comparison to 33.3% of animals (2 of 6) following infusion with Aß + perlecan + PBDP. A significant 8.4-fold decrease in the extent of Aß amyloid deposition (as measured by blind scoring of Congo red stained sections) was also observed in animals infused with Aß + perlecan + PBDP compared to Aß + perlecan. These studies demonstrate that PBDP is a potent inhibitor of Aß-perlecan interactions and Aß fibrillogenesis and may serve as the basis for the development of a peptide therapeutic for AD amyloidosis. DISCOVERY OF PPI-368, A POTENT INHIBITOR OF AMYLOID β-PEPTIDE POLYMERIZATION M. A. Findeis, G. F. Musso, H. Benjamin, J. Chin, N. J. Hayward*, A. M. Hundal, L. Kasman, M. Kelley, J. J. Lee, M. Reed, J. Wakefield, S. M. Molineaux. Pharmaceutical Peptides Inc., Cambridge, MA 02139

Polymerization of amyloid β-peptide (Aβ) results in neuronal toxicity *in vitro* and formation of amyloid plaque which is associated with the onset and progression of Alzheimer's disease. Inhibition of the process by which Aβ assembles into extended arrays of antiparallel β-sheet and eventually into cross β-fibril-like structure is an appropriate target for therapeutic intervention to delay or prevent the progression of disease. Based upon the high affinity of Aβ for itself, it appeared desirable to explore the utility of this property for the design and synthesis of inhibitors of Aβ polymerization.

We have screened a series of compounds exploring the ability of Aβ-derived peptides to interact with Aβ and inhibit its polymerization. Peptides as short as 15-residues were found to have inhibitory properties. To enhance these properties, peptides were modified with a series of organic compounds to screen for combinations of pharmacophoric "**P**" groups and specificity conferring peptidic "**S**" groups with increased potency. Lead compounds resulting from this screen included **P** groups with a range of molecular characteristics such as shape and polarity. The lead **P** group alone was inactive in the screening assay and the peptidic **S** group had low activity, demonstrating the requirement of both groups acting synergistically.

Reducing the size of the **S** group from 15 to between 13 to 8 residues resulted in a significant loss of activity. Further reduction in the size of the **S** group to 5 or 6 residues resulted in recovery of activity comparable to the parent compound. Additional structure-activity studies allowed the refinement of the **S** group to a five-residue core region. In combination with the lead **P** group, the resulting lead compound, PPI-368, has a molecular weight of <1000 and structural characteristics consistent with favorable pharmaceutical properties. This compound is a potent inhibitor of Aβ polymerization and is a potential lead for the development of therapeutic agents for the treatment of Alzheimer's disease.

Support for this work was provided by PPI.

SERUM AMYLOID P AND PROTEOGLYCANS SHARE A COMMON BINDING MOTIF ON Aβ FIBRILS. Rekha Bansal and Kurt R. Brunden*. Gliatech Inc., 23420 Commerce Park Rd., Cleveland, OH 44122.

Proteoglycans and serum amyloid P (SAP) associate with amyloidotic deposits, including the senile plaques of Alzheimer's disease brain. We have previously demonstrated that a variety of proteoglycans bind the fibrillar form of Aβ, thereby protecting the amyloid peptide from proteolytic and cellular degradation. SAP has also been shown to specifically interact with fibrillar Aβ and inhibit its breakdown. These observations have led us and others to suggest that the binding of proteoglycans and SAP to Aβ may lead to increased plaque persistence. Given the similar actions of these amyloid-associated molecules, we have investigated whether proteoglycans and SAP bind a common motif on Aβ fibrils. Chondroitin sulfate proteoglycan (CSPG) or SAP were immobilized in 96-well plates, and varying concentrations of fibrillar Aβ in physiological buffer were added to the wells. Bound Aβ was subsequently quantitated using ELISA methodology. The binding constants for Aβ-CSPG and Aβ-SAP interactions obtained by this method were similar to those previously reported in the literature. Both CSPG and CS glycosaminoglycans were found to inhibit the binding of Aβ to immobilized SAP, and conversely SAP was found to prevent the binding of Aβ to immobilized CSPG. The diazo dye, Congo Red, which is classically utilized to stain fibrillar Aβ within senile plaques, was found to be an effective inhibitor of Aβ binding to both CSPG and SAP. These data suggest that proteoglycans and SAP bind to a common region on Aβ fibrils, and inhibitors of these interactions may be useful in increasing the susceptibility of senile plaques to enzymatic and/or cellular degradation. Supported by Gliatech Inc. and Janssen Pharmaceutica.

INHIBITION OF BETA-AMYLOID FIBRIL FORMATION BY SYNTHETIC PEPTIDES HOMOLOGOUS TO TRANSTHYRETIN AND AMYLOID BETA PROTEIN. D.Goldgaber.[1], M.P. Vitek[3], M. Tsiper[1], H. Wente[1], A. Wang[1] F.J. Salles[2]*, A.L. Schwarzman[1]. Dept. of [1]Psychiatry and [2]Pharmacology, SUNY, Stony Brook, NY 11794; [3]Dept. Neurology, Duke Univ., NC 27710.

We and others previously found that transthyretin (TTR) inhibits amyloid beta protein (Aß) aggregation and fibril formation. Using Congo Red binding assay and electron microscopy we investigated the effect of synthetic peptides homologous to the proposed Aß binding domain of TTR on aggregation and fibril formation of $A\beta_{1-40}$ and $A\beta_{1-42}$. Several of the tested peptides influenced amyloid formation. Synthetic peptides homologous to different region of $A\beta_{1-40}$ and its hydropathic analogs also demonstrated different ability to influence amyloid formation. Mutations of the key amino acid residues in the Aß binding domain of TTR or in Aß modified the effect of these peptides. Supported by NIH, Alzheimer's Association.

DEGRADATION OF AMYLOID β-PROTEIN BY A SECRETED METALLOPROTEASE IN NEURAL AND NON-NEURAL CELLS. W.Q. Qiu, Z. Ye, K.S. Kosik* and D.J. Selkoe. Center for Neurologic Diseases, Brigham & Women's Hosp./Harvard Med. Sch., Boston, MA

Aβ is the major component of senile plaques in Alzheimer's disease (AD). Much work has focused on the generation of Aβ from βAPP, but little is known about the endogenous proteolytic clearance of Aβ following its secretion. By mixing conditioned media (CM) of metabolically labeled APP-transfected CHO cells as a source of Aβ, and the CM of a variety of untransfected cultured cells, we observed a time-dependent decrease in the amount of Aβ in the mixed media. The factor principally responsible for the decrease was a secreted metalloprotease released by both neural and non-neural cells. The protease was fully inhibited by the metalloprotease inhibitor, 1,10-phenanthroline, and partially inhibited by EDTA. Although this inhibitor profile is similar to that of matrix metalloproteases, our protease was not activated by APMA and failed to bind gelatin-agarose, suggesting that it belongs to another class of metalloprotease. The Aβ-degrading protease degrades both $A\beta_{1-40}$ and $A\beta_{1-42}$ secreted by APP transfected cells. However, p3 and oligomeric forms of Aβ were resistant to degradation. Degradative products were identified by acid-urea PAGE. Different cell types showed different efficiencies of Aβ degradation: non-neural CHO cells and a murine microglial cell line, BV-2, produced more Aβ-degrading activity than other cell lines that we studied. We have partially purified the protease from BV-2 cells by sequential chromatography. Our findings demonstrate an Aβ-degrading metalloprotease that is constitutively secreted by neural and non-neural cells, including microglia, and is capable of clearing Aβ peptides under biologically relevant conditions. AXON GUIDANCE MECHANISMS AND PATHWAYS II

765.1

RETINOTOPIC ORDER IN DEVELOPING VISUAL PATHWAYS D.K. Chelvanayagam and L.D. Beazley* Zoology Department, The University of Western Australia, Nedlands, 6907, Australia.

Optic projections map topographically onto recipient brain nuclei. To further understand how these maps are formed, we examined the organization of optic axons in the visual pathway of a marsupial, the quokka wallaby, throughout development. Animals at 9-90 days were terminally anaesthetised and the brains dissected in culture medium. The tracers DiI and Di-ASP were applied to localised regions of the retina. After transport, brains were fixed in 4% paraformaldehyde, sectioned coronally at 100 µm and examined in the fluorescence microscope. Optic axons entered the corresponding regions of the optic disk, reflecting their retinal origin. Axons of ventral retinal origin entered the nerve ventrally, as 2 groups split by the remnant of the temporo-ventrally located optic fissure. These 2 groups remained ventrally located until half way along the nerve where they ascended to the dorsal region and maintained that location in the optic tract. Axons originating from dorsal retina entered the nerve dorsally, maintained a dorsal aspect initially and dived down through the core of the nerve to a ventral location; this translocation occurred at approximately one third along the optic nerve and continued in this position within the tract. Axons of temporal and nasal retinal origin were most predominant within their respective hemi-nerve, a feature maintained into the optic tract. These findings show that throughout development in the quokka, axons characteristic locations within the optic nerve, reflecting their retinal origin. This organisation may minimise the target territory that invading axons need to explore in order to form a retinotopic map.

765.2

LASERSCAN ANALYSIS OF THE FIBER COURSE IN THE CHICK RETINA. U. Rager and G. Rager*. Institute of Anatomy and Special Embryology, University of Fribourg, CH-1700 Fribourg, Switzerland.

Tracer injections using the anterograde transport have shown that peripheral temporal and nasal fibers, originating in corresponding sites and generated late in development, overlap in the temporal periphery of the optic nerve (Rager and Rager, Soc.Neurosci.Abstr., p.1559, 1995). Early generated retinal fibers, however, are represented in the dorsonasal periphery of the nerve. If this is the case, retrogradely transported tracers injected into the temporal periphery of the nerve should form a fiber bundle which bifurcates in the optic fissure towards the temporal as well as nasal periphery of the retina. Fibers stained in the dorsonasal periphery should also branch to nasal and temporal retinal fields but terminate more centrally. To test this hypothesis we injected the fluorescent tracers DiI into the temporal periphery and DiA into the dorsonasal periphery of the optic nerve and traced the fiber bundles back into the retina. In fact, the bifurcation of labeled fiber bundles was observed for both injection sites. Those experiments were selected where fiber bundles containing these tracers were found on the same retinal area which allowed also to study the question whether or not early and late generated fibers were separated in the fiber layer of the retina.

For this purpose retinal whole mounts were prepared and analyzed with the laserscan microscope (LSM 410 of Zeiss) by scanning through the optic fiber layer. The piles of focal planes were then cut parallel to the optic fissure. Early and late generated fibers could be distinguished by the wavelength of their fluorescence. Our preliminary results, obtained close to the optic fissure, suggest that in the nasal retina early and late generated fibers are mixed while in the temporal retina early generated fibers seem to be located deep in the optic fiber layer, later generated fibers more superficially. A mechanism has to be postulated by which late generated fibers are selectively directed to the temporal and early generated fibers to the dorsonasal periphery of the nerve. CHICK RETINOTECTAL MAP DEVELOPS PRIMARILY BY ARBORIZATION OF COLLATERAL BRANCHES. P.A. Yates*, G.C. Friedman, D.D.M. O'Leary, Molec Neurobio Lab, Salk Inst., La Jolla, CA.

The mature retinotectal projection in the chick is topographically ordered with the temporal-nasal axis of the retina projecting onto the rostral-caudal axis of the tectum. However, during development temporal axons initially overshoot their appropriate terminal zone (TZ) along the rostral-caudal axis and many are mispositioned along the medial-lateral axis. Topographic precision develops by a remodeling which involves course corrections, collateral branching, and the removal of aberrant axons, branches, and arbors (Nakamura & O'Leary, '89).

We have re-examined, in more detail, the developmental period spanning E10-E14, during which most collateral branching and remodeling occurs, to determine the extent to which axonal arbors are formed by collateral branches versus a terminal arborization of the primary axons. Focal DiI injections were made into temporal and nasal retina between E9 and E12, and the projection to the tectum was analyzed one to two days later. 95% of temporal axons initially elongate past their appropriate TZ. Both anterograde labeling from the retina and retrograde labeling from the tectum with DiI indicate that axons from temporal hemiretina are largely restricted to rostral hemitectum. These axons later extend collateral branches along their length, with a distribution along the rostral-caudal axis that is highest near the TZ, with over 70% directed toward it. Branches arborize in both correct and incorrect locations at E12, but by E13 arbors are predominantly found only on branches extending into the TZ. At E13, the majority of axons arborize in the TZ by extending one or more collateral branches into it; less than 1% of the axons have a terminal arborization outside of the TZ. These results indicate that collateral branching is the primary mechanism used by retinal axons to establish topographically ordered connections. (Supported by R01 EY07025 and F32 EY06550).

Target Recognition by Retinal Axons *in vivo*: a Role for FGF-2-binding Heparan Sulfates Andreas Walz*, Sarah McFarlane, Yardenah Brickman†, Victor Nurcombe†, Perry Bartlett‡ and Christine Holt
Biology Department, UCSD, La Jolla, CA 92093-0366, † Department of Anat and Cell Bio, University of Melbourne, Parkville Victoria 3052, Australia
‡ The Walter and Eliza Hall Institute of Medical Research, Royal Melbourne Hospital, Victoria 3050, Australia

Retinal axons diverge from a common axonal pathway upon entering their midbrain target, the optic tectum. This process relies upon the ability of growth cones to detect and respond to distinct molecular differences encountered at the target. One such molecule known to change expression pattern at the tectal border is fibroblast growth factor-2 (FGF-2) (McFarlane et al., 1995). Heparan sulfate (HS) is an essential co-factor for FGF signaling *in vitro* and is abundant in the developing brain. We report here that exogenous HS in the developing *Xenopus* optic projection disrupts target recognition, causing axons to by-pass their normal target, the optic tectum. Comparing several HS species demonstrated that the mistargeting activity associates with HS subdomains that bind FGF-2. Further, enzymatic removal of endogenous HSs reduces axon extension within the optic tract, giving rise to abnormally shortened projections. Addition of FGF-2 to enzyme-treated brains rescues the growth inhibition, but results in indiscriminate axon trajectories, suggesting that endogenous HSs is important not only for encouraging growth, but also for patterning guidance information. Our results demonstrate that distinct HSs influence axon behavior *in vivo* and that growth factors and glycosaminoglycans act to modulate not just growth, but also guidance in the developing CNS.

CELLULAR LOCALIZATION OF GUIDANCE COMPONENTS IN RETINOCOLLICULAR DEVELOPMENT
Roger W. Davenport*, Edda Thies, Matt Cohen, Phillip G. Nelson
Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892

Stereotypic precision of the topographic maps formed between retinae and their target nuclei relies in part on guidance components distributed across both retinal ganglion cells (RGCs) and their targets. This is generally true for both the avian retinotectal and rodent retinocollicular systems, despite differences which have been noted to occur during map formation. To study such guidance components, a number of assays have proven useful, yet have failed to distinguish between the two systems in cell culture. In this and the 2 adjacent abstracts, we examine with cellular and molecular resolution guidance components in the development of avian and rodent retino-target map formation. In the present experiments, we used a coculture system to assess directly the ability of dissociated superior collicular (SC) cells to express guidance components. RGC axons from chick and mouse were forced to encounter dissociated SC cells from rostral or caudal regions. The results confirm the repulsive characteristics of living caudal cells, which selectively prevent extension of axons from temporal regions of the retinae. To investigate cellular localization of guidance components in retinocollicular development, we examined encounters between RGC growth cones and individual target cells with time lapse video microscopy. Dramatic and selective repulsion was observed when temporal RGC axons encountered individual caudal SC cells, however, guidance components appear differentially distributed upon specific and distinguishable cell types and significant differences at the cellular level exist between avian and rodent systems. These results may elucidate key strategical differences between the formation of the retinotectal and retinocollicular systems and provide a system for further investigation into the cellular and molecular signals which guide neuronal development. This research was performed while RWD held a National Research Council-NICHD/NIH Research Associateship.

765.6

PIONEERING FIBERS SIGNAL TO TRAILING AXONS FASCICULATED WITH THEM DURING MUTUAL OUTGROWTH
Edda Thies *, Matt Cohen, Roger W. Davenport
Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892

During development of the nervous system, growth cones of pioneering fibers navigate by responding to a multitude of molecular cues in their complex surroundings. Thousands of axons which may follow a pioneering fiber could benefit from instructive guidance information relayed directly by the pioneering axon; however, it is not clear whether pioneering fibers can signal to fasciculating axons during their outgrowth. For example, can an error message be conveyed to trailing, fasciculated axons. In the retino-collicular system, the majority of retinal ganglion cell (RGC) axons fasciculate along other RGC axons as they extend toward their target area. In the present experiments, retinal explants of mouse or chick were placed in culture and allowed to extend fascicles of RGC axons toward co-cultured rodent superior colliculus (SC) cells. Time lapse video microscopy revealed that fascicles normally appear relatively smooth and quiescent. Within minutes after the lead growth cone encountered aversive cells, however, filopodia and/or lamellipodia emerge and extend orthagonally. These highly motile features were significantly related to the behavior of the pioneer growth cone, becoming evident as it collapsed and retracted. This occurred as much as 300 µm behind the lead growth cone within the first several minutes after cellular contact. At the limits of resolution with light microscopy, it remains impossible to decisively determine whether some of these observations are due to single axonal sprouting. Electron microscopy or direct manipulation of the axonal shaft will be necessary to resolve this issue. This mechanism of pioneering fibers signalling follower growth cones could efficiently restrict retinal axons from wrong target locations and indeed may function as a general mechanism throughout the nervous system. This research was performed while RWD held a National Research Council-NICHD/NIH Research Associateship.

ONTOGENY OF TECTO-ROTUNDAL PATHWAYS IN CHICKS (*GALLUS GALLUS*) DURING EMBRYOGENESIS: A FLUORESCENT CARBOCYANINE DYE STUDY. C.-C. Wu,* R. T. Nguyen, R. M. Russel, and H. J. Karten, Dept. of Neurosciences, U.C. San Diego Sch. of Med., La Jolla, CA 92093-0608

DiI, a fluorescent tracer, was used to study the establishment of connections from the optic tectum (TeO) to nucleus rotundus (Rt) during embryogenesis. DiI crystals were applied into different portions of TeO of formaline-fixed chicks from embryonic (E) day 5 to hatching. The brains were stored at 37°C for 6 to 12 months, sectioned coronally, and examined using fluorescence microscopy. Numerous DiI-labeled perikarya were found in the *stratum griseum centrale* (SGC) with processes extending throughout the *stratum griseum et fibrosum superficiale* (SGFS) into the outer layers of TeO. By E10, efferent axons of SGC neurons were seen ascending into the ipsilateral Rt where they arborized in the ventral two thirds of the nucleus. The dorsal part of the nucleus was free of DiI-labeled fibers. A few labeled fibers were observed lateral to the *decussatio supraoptica dorsalis* (DSD), dorsal to the optic tract. No DiI labeling was found in the contralateral Rt. On E14, diffuse arborizations of labeled tecto-rotundal fibers were observed to form an extensive fiber net throughout the entire rostrocaudal extent of ipsilateral Rt. At later stages, there was an increase in DiI-labeled processes seen in the ipsilateral DSD. En route to Rt, some labeled fibers sent collaterals to the posteroventral thalamic nucleus. Between E17 and E18, DiI-labeled fibers coursed through DSD to the contralateral Rt, where scattered fibers and terminals were first seen at the ventromedial border of the nucleus. The extent of DiI labeling in the contralateral Rt progressively increased until hatching, exhibiting a qualitatively similar but sparser distribution to that seen ipsilaterally. The present study provides the information of the temporal order of ontogeny of connections in the tecto-rotundal pathway during embryogenesis. Supported by EY06890 & NS24560 to H.J.K.

THE ROLE OF PIGMENT IN DIRECTING LATERALITY OF RETINAL GANGLION CELL AXONS: DARK-EYED ALBINO MOUSE
R.A. Rachel*, R.C. Marcus, and C.A. Mason. Dept. of Pathology and Ctr. for Neurobiology & Behavior, Columbia University P & S, New York, NY 10032.

In albino animals of many species, the ipsilateral retinofugal projection is decreased by approximately 50%. The specific role of the pigment pathway in directing retinal specification and pathway choice has been a long standing enigma. Anatomical studies of various pigment mutants have suggested that melanin in the retinal pigment epithelium is the crucial factor in pathway selection by retinal ganglion cells (RGCs), but the question of how a sequestered polymer in the outermost retinal layer affects RGC fate has not been explained. The goal of this study was to use a mutant, the dark-eyed albino, to help address the relative contribution of melanin vs. other components of the pigment pathway in RGC specification. This mutant has low levels of tyrosinase, the principal enzyme involved in pigment production. Importantly, retinal pigmentation occurs only postnatally, after RGCs have made their pathway choice. Thus, if the dark-eyed albinos have a decreased ipsilateral projection like albinos, melanin is likely to be responsible. A relatively normal pigmented phenotype, however, will implicate tyrsoinase or another molecule as the crucial factor. DiI labeling of the optic tracts to backfill RGCs giving rise to the ipsilateral retinal projection is being used to indicate which of these possibilities occurs.

We thank Dr. Friedrich Beermann for the dark eyed albino mice. Supported by NIH grant NS27615 (C.A.M.).

AXON PATHFINDING AND TARGET RECOGNITION IN THE DEVELOPING ADULT VISUAL SYSTEM OF DROSOPHILA

Q. Gong*, R. Rangarajan and U. Gaul

The Rockefeller University, 1230 York Ave., New York, NY 10021

The development of the adult fly visual system begins at the third instar larval stage. Photoreceptor cells send their axons to the optic lobe in a highly organized fashion through the optic stalk. Once the axons exit the stalk, they separate and form a fan like structure, sorting strictly according to their anterior-posterior and dorsal-ventral position in the retina. In addition to this retinotopic organization, photoreceptor axons recognize and project to different target regions. R1-R6 axons terminate in the lamina, the first optic ganglion, while R7-R8 axons project to the medulla, the second optic ganglion. To study the molecular mechanisms underlying neuronal connectivity, we have isolated mutants with disrupted retinal projections. A classical mutagenesis approach was taken using ethyl-methane sulfonate as the mutagen. We screened 5000 lines for their projection patterns using a lacZ reporter to visualize photoreceptor axons. We isolated 76 mutant lines and classified them in 4 main categories. 1) mutants with target recognition defects: axons stall in the lamina or overshoot to the medulla, 2) mutants with retinotopic map defects: (a). global defects: axons project to larger, smaller or asymmetric target fields forming abnormal fan structures (b). local defects: the overall fan structure is normal but there are local disruptions such as gaps and crowding of terminals in the target region, 3) mutants with stalk defects: the optic stalk does not form or is expanded, and 4) mutants with eye disk defects. We have characterized the mutants using markers for the cytostructures of the targets and the retina and have mapped select mutations to their chromosomal locations. Our future goals include cloning the genes and studying their functions in neuronal connectivity. Supported by NRSA 1F32EY06691

CONTROL OF OLFACTORY PROJECTIONS DURING METAMORPHOSIS IN *XENOPUS*. J. O. Reiss* and G. D. Burd. Dept. of Molecular and Cellular Biology, University of Arizona, Tucson, AZ 85721.

The olfactory system of the African Clawed Frog, *Xenopus laevis*, was used as a model to examine the developmental control of axonal projections. After metamorphosis, distinct peripheral olfactory epithelia (the principal cavity, or PC, and middle cavity, or MC) project to distinct regions of the main olfactory bulb. Early in metamorphosis, however, axons from the two cavities have overlapping projections in the ventral olfactory bulb. To determine whether interactions between the axonal populations are required for this metamorphic change in the olfactory projection pattern, the MC rudiment was unilaterally excised from early metamorphic (stage 55-57) tadpoles and the animals raised through the end of metamorphosis (stage 65-66). Operated animals were pre-labeled with ^{3}H-thymidine at stage 46 to provide an internal marker for the ventral bulb (Fritz, Gorlick and Burd, 1996). Cryostat sections were stained with peroxidase-conjugated soybean agglutinin (HRP-SBA) to label differentially projections from the PC (weakly staining) and MC (strongly staining). Alternate sections were processed for autoradiography. 3D reconstructions of the SBA-labeled region of the olfactory bulbs were prepared using Bioquant-OS2 software (R & M Biometrics, Inc). These reconstructions showed the PC projection on the lesioned side to extend somewhat further ventrolaterally than on the unlesioned side, into the dorsal part of the region normally occupied by the MC projection. This was confirmed by the ^{3}H-thymidine labeling pattern. Thus, interactions between PC and MC axons are partly necessary for the normal metamorphic change in the PC projection pattern. However, in cases with marked reduction of the MC a gap was left between strongly staining and weakly staining regions. Thus, either much of the normal change can occur in the absence of such interactions, or important interactions are occurring prior to the time of surgery. Research supported by NIH training grant #NS07363, and NIDCD grants #DC000189 and #DC00446.

DEVELOPMENT OF THE THALAMOSTRIATAL PROJECTION TO THE STRIATUM IN THE PRENATAL AND POSTNATAL RAT. V. Srivastava, C. H. Lam, H. Brust-Carmona*, and A. F. Sadikot. Montreal Neurological Institute, McGill University, Montreal, PQ. Center for Development and Technological Applications (CEDAT), Health Ministry, Mexico City D.F.

Development of the thalamostriatal projection in fetal and early postnatal rats was examined with anterograde labeling using the carbocyanine dye fast DiI (1,1-dilinoleyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate), or biotinylated dextranamine(BDA). Previous studies in adult rats have demonstrated that the thalamostriatal projection originates principally from the midline and intralaminar nuclei, in particular from the lateral part of the parafascicular nucleus(Pf). Placements of fast DiI crystals in the posterior thalamus of perfused fetal rats resulted in anterograde labeling of axons in striatum and cortex. At embryonic day 19, labeled axons emanated from the thalamus, but remained largely confined to the white matter ventral and posterior to the striatum. With increasing age up to embryonic day 21, greater numbers of labeled axons were seen in the striatum. Stereotaxic injections of BDA into the thalamus demonstrated that by postnatal day 1, the thalamostriatal projection terminated primarily in the matrix component of the striatum as revealed by immunohistochemistry for the calcium binding protein, calbindin-D28k. Thus, these preliminary observations suggest that in the rat thalamic afferents arrive in the striatum prenatally and selectively innervate the matrix compartment in the early postnatal period. PRIMITIVE BILATERAL CORTICOSPINAL PROJECTIONS ARE MAINTAINED ALONG WITH MOTOR FUNCTION IF ONE CORTICAL HEMISPHERE IS ABLATED DURING PATHWAY DEVELOPMENT

A. R. Bicknese*, K. C. Vitale, M. M. Pappas, A. Varma, P. Ramachandran, S. Talwar, A. Sharma Dept. Neurology, SUNY at Stony Brook, NY 11794

A common developmental mechanism is early exuberant overprojection followed by competition and elimination of collaterals to the specific mature pathway. Early competence to form multiple projections may underlie the ability of neonatal rats to recover motor function following cortical injury. After neonatal(<6 days) cortical ablation or sham lesions, the axon tracer DiI was placed on the intact cortex and the corticospinal pathway traced.

Within the brain stem, corticospinal axons form fascicles which decussated at the spinomedullary junction. Within this zone, some axons wandered from one fascicle to the other or crossed the midline. The fascicles consolidated into a dominant pathway in the hemicord contralateral to the injection site. Rare axons descended in the ipsilateral hemicord. Collateral projections extended from the axons. In neonates many collaterals from the dominant pathway cross the midline into the opposite hemicord, resulting in innervation of both hemicords. At maturity the collateral projections are limited to one hemicord. Thus, bilateral innervation was present during corticospinal development. The restricted adult pattern was derived from a more widespread, bilateral neonatal pattern.

Complete hemispherectomy terminated all axons from one hemisphere and thus competition for innervation sites. Neonates with complete hemispherectomy recovered bilateral motor function within hours of surgery. The neonatal corticospinal projections were analogous in lesion and control animals with bilateral projections to both hemicords from the dominant pathway and rare axons in the ipsilateral corticospinal tract. At maturity hemispherectomy animals were strikingly different from controls. Axons in the dominant pathway had extensive collaterals, many of which crossed the midline of the spinal cord and extended to the contralateral hemicord.

Thus, early ablation allowed bilateral projections to persist into adulthood which preserved motor function. The observed plasticity of motor function following early hemispherectomy was most likely from maintenance of bilateral collateral projections from the dominant corticospinal pathway. The small ipsilateral corticospinal pathway did not increase in size or number of collaterals after neonatal cortical ablation. Thus, it was unlikely to significantly affect the observed motor recovery of these animals. (NIH Grant 5KO1NS01728)

DECUSSATION OF DEVELOPING CORTICOSPINAL AXONS IN THE FERRET. N. R. Cohen, J. S. H. Taylor and R. W. Guillery* Dept Human Anatomy, Oxford University, South Parks Road, Oxford OX1 3QX, UK.

We have used WGA-HRP and DiI to trace developing ferret corticospinal axons through their decussation. Immunohistochemistry was used to investigate the glial environment in the region of the corticospinal decussation.

WGA-HRP was injected into the mid-cortex of neonatal ferrets. After overnight survival, coronal sections through the brainstem were treated with TMB showing that axons are already at the decussation at birth (E41-42), much earlier than a previous account for cat (Wise et al., 1977 Br Res 138: 538-544). DiI labelling confirms this finding and 3A10 staining of axons shows nerve bundles decussating in the caudal medulla prenatally (E39). Beyond the decussation, the axons pass into the lateral columns of the spinal cord as in cat and primates, not into posterior columns as in rodents.

Crossed and uncrossed corticobulbar fibres can be seen leaving the main pyramidal tract at midbrain, pontine and medullary levels. At the decussation most fibres cross the midline and turn laterally. A smaller group runs towards the midline but then turns laterally, remaining ipsilateral. A third group of fibres reaches the midline before continuing dorsally, forming the corticobulbar projection to the dorsal column nuclei. A fourth group of fibres that develops postnatally, remains ventral and uncrossed at the decussation.

In the pyramids, glia initially express vimentin but later express GFAP. At the decussation the glia in the pyramids express SSEA-1. The midline is vimentin positive and becomes disrupted as large fascicles of crossing axons pass through it.

ENTORHINAL AXONS ARE ABLE TO PERFORATE HIPPOCAMPAL FIELD CA3 IN ORGANOTYPIC SLICE CULTURE

Peter L. Woodhams and D. John Atkinson (SPON: Brain Research Association). Neurobiology Division, National Institute for Medical Research, London NW7 1AA, United Kingdom.

In growing towards their hippocampal targets, incoming afferent axons from the entorhinal cortex arrive at the subicular pole of the hippocampus where they turn back up towards the pia from the alveus, crossing (perforating) the subiculum and field CA1. It is notable that *in vivo* they normally never perforate the more distally situated field CA3. To address the question of whether a specific repulsive characteristic of field CA3 might explain this behaviour, artificial confrontations were set up *in vitro*. Embryonic entorhinal explants were placed in restricted contact with 8-day old rat hippocampal slices, orientated so that outgrowing axons could only grow into either the subiculum/field CA1 or field CA3 (with dentate gyrus as controls). Anterograde biotin-dextran labeling of projections after two weeks in culture showed that entorhinal axons perforated the stratum oriens, pyramidal cell layer, and stratum radiatum in CA3 just as readily as they did along their normal trajectory across CA1/subiculum. It is therefore concluded that spatiotemporal cues are more likely than specific chemorepulsive molecules to be involved in setting up this part of the entorhinal pathway.

EARLY NEURODEVELOPMENT IN *APLYSIA*, *LYMNAEA* AND *HELISOMA*, R.P. Croll* and E.E. Voronezhskaya. Dept. Physiol. & Biophysics, Dalhousie Univer., Halifax, N.S., Canada B3H 4H7 and Instit. Devel. Biol., Russian Acad. Sci., Moscow, Russia.

It is widely accepted that the foundations of the gastropod nervous system are laid down in the early to mid-veliger stage. The first central neurons are thought to appear in a generally rostrocaudal progression with the cerebral ganglia developing first, followed by the pedal ganglia and then by the more posterior ganglia of the abdominal loop. We have found, however, that FMRFamide-like immunoreactive (Fa-lir) cells first appear in posterior regions of the earlier trochophore stage embryo of the opisthobranch *Aplysia*. These cells have anteriorly directed fibres which eventually form what appears to be a scaffolding upon which the central ganglia and interconnecting pathways eventually develop (*Acta Biol. Hung.* 46:295-303). Similar Early, Fa-lir, Anteriorly Projecting (EFAP) cells have recently been described in very early veligers of pulmonates such as *Lymnaea* and *Helisoma* (*Dev. Biol.* 173:344-347). In addition, all these gastropod embryos also possess peculiar monoaminergic neurons which first appear prior to the formation of the cerebral ganglia and are located dorsolateral to the mouth. Together these findings indicate the need for a re-evaluation of current theories on the origins of the gastropod nervous system and on the developmental mechanisms mediating its formation.

SPECIFICITY OF LIM HOMEODOMAIN PROTEINS IN *DROSOPHILA* CENTRAL NERVOUS SYSTEM AND WING DEVELOPMENT. D. O'Keefe[1,2], S. Thor[2], S. MacFarlane*[1], A. Tomlinson[3], J.B. Thomas[2]. [1]Department of Neuroscience, UCSD, La Jolla, CA 92093. [2]Molecular Neurobiology Laboratory, The Salk Institute, La Jolla, CA 92037. [3]Department of Genetics and Development, Columbia University, New York 10032.

The LIM homeodomain family of transcription factors is expressed in subsets of differentiating neurons in both vertebrates and invertebrates, suggesting a role for these genes in controlling the identity of specific classes of neurons. Two *Drosophila* family members, *apterous* (*ap*) and *RK20*, are expressed in small, non-overlapping subsets of developing neurons. In addition, *ap* is expressed in the wing imaginal disc. *ap* function is required for correct pathway selection of the *ap* neurons, and for dorsal identity of cells in the wing disc. Using a transgene consisting of *ap* regulatory sequences fused to an *ap* cDNA, we observe a partial rescue of the *ap* CNS and wing phenotype. To address LIM homeodomain specificity, we have expressed *RK20* in *ap* neurons. This *ap-RK20* transgene is not able to rescue the *ap* mutant phenotype, indicating that Ap and RK20 are not interchangeable. Furthermore, to determine which domain confers specificity, we have generated chimeric Ap/RK20 proteins by swapping the LIM and homeodomain regions. These transgenes will be placed in an *ap* mutant background and assayed for their ability to rescue the *ap* phenotype. Supported by grants from the NIH, Pew Memorial Trusts, and Markey Fellowship.

DOWNREGULATION OF TYROSINE HYDROXYLASE (TH) mRNA IN SUPERIOR CERVICAL GANGLION IN TRANSGENIC ANIMAL EXPRESSING TH IN PINEAL GLAND. S. Cho*, O. Hwang, H. Baker, I. H. Son and T. H. Joh. Cornell Univ. Med. Coll. at The Burke Med. Res. Inst., White Plains, NY 10605.

We previously reported that transgenic animals expressing TH in pineal gland (PG) under control of a 6.1 kb tryptophan hydroxylase promoter showed dopamine production and decreased TH positive fiber density arising from the superior cervical ganglion (SCG) (Cho et al, PNAS 93:2862, 1996). The reduction in TH positive fibers could be attributed either to 1) reduced innervation from SCG to PG, or 2) decreased TH protein associated with normal innervation. To assess which mechanism underlies the altered innervation, immunocytochemical analysis was performed using neurospecific antisera. Neurofilament and PGP9.5 exhibited comparable immunoreactivity in control and transgenic PGs. The neuropeptide, NPY, also showed comparable fiber staining between control and transgenic PG while consistently fewer TH immunoreactive fibers were observed in transgenic PGs. These data suggest that fiber innervation is intact in the TH expressing transgenic PG. To determine if the decrease in TH protein is produced by a change in TH messenger RNA, the SCG was analyzed using *in situ* hybridization. Five out of 7 transgenic SCGs showed between a 20-40% reduction in TH mRNA compared to control ganglia, suggesting a downregulation of TH gene transcription in the transgenic SCG. These data indicate that altered target cell phenotype produced by TH expression in pinealocytes provides a retrograde signal that alters gene regulation in presynaptic cells. (Supported by NIH grant MH24285).

FORMATION AND SPECIFICITY OF SYNAPSES VII

IDENTIFICATION OF GENES INVOLVED IN SYNAPSE FORMATION BETWEEN IDENTIFIED MOLLUSCAN NEURONS USING SINGLE CELL mRNA DIFFERENTIAL DISPLAY. R.E. Van Kesteren, Z.-P. Feng, A.G.M. Bulloch, N.I. Syed and W.P.M. Geraerts*. Neuroscience and Respiratory Research Groups, University of Calgary, HSC, Calgary, AB, T2N 4N1, Canada; Department of Molecular Neurobiology, Vrije Universiteit, 1081 HV Amsterdam, The Netherlands.

Following target cell selection, the formation of synaptic connections between neurons is believed to depend upon changes in gene expression in both the pre- and the postsynaptic cell. Knowing the nature of these changes is important for our understanding not only of neural development, but also of neuronal plasticity, and regeneration of the nervous system following aging-, disease- or trauma-induced degeneration. Lack of suitable neuronal model preparations and of sensitive screening methods for differentially expressed genes, however, have so far hampered the identification of the genes involved. We have used a unique preparation of identified neurons from the snail *Lymnaea stagnalis* that selectively and reliably form specific synaptic connections *in vitro*. To identify mRNAs whose expression is changed upon target cell contact in either the pre- or the postsynaptic cell, and that have a potential role in the consolidation of the synapse, we employed differential display PCR (DD-PCR). Because PCR results can be highly variable when using small amounts of target cDNA (this has been described as the Monte Carlo effect – it is due to the relative high number of mRNAs that is present below a critical abundancy level and amplified at random), we first amplified the cDNA by synthesis of antisense RNA from a T7 RNA promoter that was included in the 3' end of the cDNA. This antisense RNA was subsequently reverse transcribed into cDNA and used in a DD-PCR, which resulted in highly reproducible differential displays from as little as 6 cells. Several target cell-induced and -repressed mRNAs were identified that potentially function in synapse formation. The identity of these mRNAs is currently being investigated.

***In vitro* synaptogenesis between the cell somata of identified *Lymnaea* neurons is independent of trophic and substrate molecules but requires protein synthesis.** Zhong-Ping Feng, Judith Klumperman, Ken Lukowiak and Naweed I. Syed*: Faculty of Medicine, University of Calgary, 3330- Hospital Drive, NW. Calgary, Alberta, Canada.

Neurotrophic factors, substrate adhesion molecules and protein synthesis are all necessary requirements for neurite outgrowth, however, their direct involvement in synapse formation has not yet been determined. To address this issue directly, we developed an *in vitro* model system where synapse formation could be investigated in the absence of neurite outgrowth. Specifically, we built upon a previously established soma-soma synapse model (Haydon, 1988 J. Neurosci. 8: 1032-1038) by reconstructing synapses between the neuronal somata *in vitro*. Individually identified interneurons RPeD1 and VD4 were isolated from the CNS of *Lymnaea stagnalis* and paired immediately in cell culture. On Poly L. Lysine coated dishes, containing brain conditioned medium (CM), mutual inhibitory synapses between the neuronal somata reformed within 4 to18 hrs. These soma-soma synapses were similar to those observed between the neurites of these cells either *in vivo* or *in vitro*. We provide morphological, electrophysiological and pharmacological evidence for these soma-soma synapses and demonstrate that they are indeed specific. To determine whether trophic molecules present in the CM and/ or Poly-L-Lysine substrate were necessary for these synapses to form, the cell pairings were performed in the absence of CM and Poly L. Lysine substrate (plain plastic or glass cover slips). Our data shows that neither CM nor Poly L. Lysine are required for synapse formation in this system. However, blocking protein synthesis by anisomycin (12.5 μg/ml) prior to cell pairings, prevented synapse formation between RPeD1 and VD4. Together, our data suggest that cell-cell contacts and signaling between specific partner cells, in the absence of extrinsic trophic and substrate molecules, are sufficient to trigger an inherent synaptic program in both RPeD1 and VD4.

REGULATED EXPRESSION OF SYNAPTIC VESICLE PROTEINS IN CULTURED HIPPOCAMPAL NEURONS. C. Daly and E.B. Ziff.* Howard Hughes Medical Institute, Dept. of Biochemistry, NYU Medical Center, New York, NY 10016.

We are studying the regulation of expression of synaptic vesicle proteins during synaptogenesis. Our studies employ dissociated rat hippocampal neurons (E18) in culture. During the days following plating, these cells extend neurites and form functional synapses with each other. We have employed a sensitive RNase protection assay to measure mRNA levels of synapsin I, synaptotagmin I, synaptobrevin II, and synaptophysin in these developing neurons. We have not observed any significant changes in the level of these mRNAs as the neurons undergo synapse formation. However, when the levels of the corresponding proteins were measured by immunoblot, we observed significant increases in all of these synaptic vesicle proteins. Thus, the regulation of synaptic vesicle protein expression during synaptogenesis in culture is the result of post-transcriptional mechanisms. This increase does not simply reflect an increase in all proteins involved in neurotransmitter release, since the level of syntaxin 1A, a plasma membrane protein involved in synaptic vesicle docking, does not change. We are currently defining more precisely the nature of this post-transcriptional regulation. Elucidation of the mechanisms controlling synaptic vesicle protein expression will yield important information regarding signals which influence presynaptic differentiation.

WNT-7A REGULATES THE NEURITE CYTOSKELETON AND THE LEVELS OF SYNAPTIC PROTEINS IN THE DEVELOPING CEREBELLUM. F. R. Lucas and P. C. Salinas*. Developmental Biology Research Centre, King's College London, 26-29 Drury Lane, London WC2B 5RL.

Wnt genes encode secreted proteins implicated in cell fate changes during development. They are found associated with the plasma membrane and extracellular matrix, and can act in an autocrine and paracrine fashion. We have found that *Wnt-7A* is expressed in cerebellar granule neurons from postnatal day 6 to 22, then declines to low levels in adult. The timing of *Wnt-7A* expression in granule cells coincides with their migration, maturation and formation of synapses with their presynaptic partners, the mossy fibres, and suggests that *Wnt-7A* is involved in the establishment of the cerebellar neuronal network. Neurite outgrowth and synaptogenesis require cytoskeletal reorganisation. Here we present evidence that *Wnt-7A* induces neurite spreading and increases levels of synaptic proteins in granule cells *in vitro*. Isolated granule cells cocultured with a *Wnt-7A* -expressing precursor cell line for 24 hours show and increase in surface area and complexity of shape when compared with the control. *Wnt-7A* induces increased levels of synaptic proteins in granule cells cocultured with the expressing cell line after 4 days *in vitro*. In addition, *Wnt-7A* increases axonal spreading and the levels of synaptic proteins in mossy fibres in vitro, suggesting that endogenous *Wnt-7A* may act as both an autocrine and paracrine factor. Thus, we conclude that Wnt proteins modulate the reorganisation of the cytoskeleton during neurite extension and the expression and localisation of synaptic proteins during synaptogenesis.

SYNAPSE FORMATION *IN VITRO* REQUIRES A GLIA-DERIVED SIGNAL. F. W. Pfrieger*, B. A. Barres. Dept. of Neurobiology, Sherman Fairchild Building, Stanford University, School of Medicine, Stanford, CA 94305-5401, USA.

In the developing nervous system, neuroglia guide the migration of neuronal somata and axons. The subsequent formation of synaptic connections, however, is still regarded as a process that involves only neurons. In order to test directly for a glial role in synaptogenesis, we studied synapse formation in cultures of purified rat retinal ganglion cells in the presence or absence of glial cells by whole-cell recording and immunostaining.

In glia-free cultures, retinal ganglion cells displayed only low levels of spontaneous synaptic activity (frequencies < 2 Hz) and formed few presynaptic terminals even when cocultured with purified collicular neurons, their natural target cells. Collicular glia increased synaptic activity by 100-fold, they increased the number of synapses by six-fold and they enhanced the frequency and amplitude of miniature postsynaptic currents. The increase in synaptic activity was mediated by a glia-derived soluble factor, since it was mimicked by glia-conditioned medium or feeding-layers of collicular glia as well as astrocytes and oligodendrocytes that were purified from rat optic nerve. Various growth factors that could be released by glial cells such as neurotrophins, neuregulins, GDNF, PDGF-AA, TGFα or β, BMP-2,-4,-7, HGF or basic FGF did not increase synaptic activity.

These results demonstrate that neurons require a signal from glial cells to form stable synapses and provide further evidence that the formation and function of synapses depend on an intimate relationship between neurons and glial cells.

ASTROCYTES ENHANCE SYNAPSE FORMATION BETWEEN CULTURED RAT HIPPOCAMPAL NEURONS. R.T. Doyle*, A.Araque and P.G. Haydon Laboratory of Cellular Signaling, Department of Zoology & Genetics, Iowa State University, Ames, IA 50011

A potential source of extrinsic regulatory factors that control synaptogenesis is the astrocyte. To test this possibility we have compared the formation of synapses between rat hippocampal neurons in cell culture in the presence and absence of co-cultured astrocytes.

E18 rat hippocampal cells were dissociated onto either a monolayer of cortical astrocytes or directly onto poly-L-lysine coated coverslips ("on glass") and the development of synapses were compared after eight days *in vitro*. As a rapid assay of synaptogenesis, we used an immunological screen. During synaptogenesis there are two distinct phases, initially synaptic proteins are detected both in the golgi apparatus, and in neuronal processes. However, after cultures mature and functional synapses have reliably formed, immunoreactivity is only detected in neurites. Immunostaining for synaptotagmin revealed a significant maturation of the hippocampal neurons when neurons were cultured either directly on astrocytes or, in an astrocyte conditioned medium. On glass 42%, while on astrocytes 83% of neurons displayed a mature immunoreactivity profile ($p > 0.001$).

Electrophysiological studies confirmed this significant effect of astrocytes on synaptogenesis since only 19% (19 of 95) of neuron pairs on glass had developed action potential evoked transmitter release while 75% (54 of 72) of neuron pairs on astrocytes developed functional synapses by day 8 *in vitro*. In addition to regulating the presence functional synapses, an ultrastructural examination of synapses revealed that astrocyte co-culture causes about a two-fold enhancement of the number of vesicles per synapse. Taken together, these data demonstrate that astrocytes provide significant extrinsic control over the formation of neuron-neuron synapses.

GEPHYRIN IS EXPRESSED IN CHICK CILIARY GANGLION NEURONS DURING SYNAPSE FORMATION. O.C.Ikonomov*, M. Kulesa, I. Persengieva and M.H. Jacob. Worcester Fdn. for Biomed. Res., Shrewsbury, MA 01545

Different neurotransmitter receptor types often function within a single neuron. For example, chick parasympathetic ciliary ganglion (CG) neurons express excitatory and inhibitory receptors: nicotinic AChRs that mediate excitatory synaptic transmission, and chloride-selective glycine and $GABA_A$ receptors, respectively. Gephyrin is a peripheral membrane protein implicated in the clustering of glycine receptors. We now show that gephyrin is expressed in chick CG neurons during synapse formation.

Gephyrin was detected in developing CG neurons by LM immunocytochemical staining with two different mAbs raised against rat gephyrin, mAbs 5a and 7a. A full-length chicken gephyrin cDNA clone (3.1 kb) was isolated from an embryonic chicken brain library and shown to be highly homologous to rat gephyrin, even in the 3' UTR. Specific primers were designed for RT-PCR amplification of the predominant gephyrin mRNA isoform expressed in the CNS. This gephyrin mRNA was detected in the embryonic chick CG, with the greatest rise in levels occurring during peripheral synapse formation. Target tissues induce the increase, at least in part, as demonstrated by lower gephyrin mRNA levels when the target tissue is surgically removed prior to synaptogenesis. Since functional glycine receptor expression follows a similar temporal pattern, the results suggest that gephyrin plays a role in localizing glycine receptors in chick CG neurons. Supported by NIH 21725.

RAPSYN / 43 KD PROTEIN CLUSTERS $GABA_A$ RECEPTORS *IN VITRO* W.D. Phillips*, S.-H. Yang, P.F. Armson and J. Cha. Dept. of Physiology, University of Sydney, NSW 2006 Australia.

Rapsyn / 43 kDalton protein closely associates with the cytoplasmic face of the postsynaptic nicotinic acetylcholine receptors (AChR) in skeletal muscle. When recombinant rapsyn was expressed in heterologous cell systems it formed discrete membrane domains into which co-expressed AChR became co-clustered, suggesting that it serves to cluster AChR in the postsynaptic membrane. Previous studies indicate that rapsyn does not non-specifically cluster various non-channel proteins in these heterologous cell systems. However, its specificity for clustering AChR remains to be properly defined. To examine this we co-transfected rapsyn into fibroblasts together with three subunits of the $GABA_A$ receptor (human α1, β1 and γ2). The subcellular distribution of rapsyn and the $GABA_A$ receptor in transfected cells was then examined by indirect immunofluorescence. In the presence of rapsyn, $GABA_A$ receptor formed discrete cell-surface clusters that co-localized precisely with the membrane domains formed by rapsyn. In contrast, rapsyn did not cluster co-expressed adult human skeletal muscle sodium channel (hSkM1). While rapsyn has not to date been isolated from brain, we have detected low levels of expression of rapsyn messenger RNA in telencephalon, diencephalon, cerebellum and brainstem by reverse transcriptase-polymerase chain reaction.

The ability of rapsyn to cluster $GABA_A$ receptor but not sodium channel suggests that rapsyn may recognise some structural feature/s common to AChR and $GABA_A$ receptor but not present on all ion channel types. Whether rapsyn is capable of interacting with other members of the AChR family of ligand-gated ion channels remains to be determined.

IDENTIFICATION OF PROTEINS THAT INTERACT WITH MOUSE RAPSYN IN THE YEAST TWO-HYBRID SYSTEM. R.G. Taylor, R.J. Kleiman*, and Z.W. Hall. Lab of Cell Biology, National Institute of Mental Health, NIH, Bethesda, MD 20892 and Dept. of Physiology, University of California, San Francisco, CA 94143.

Rapsyn (also known as the 43 kDa protein) is a cytoplasmic peripheral membrane protein that is involved in clustering the acetylcholine receptor (AChR) at the neuromuscular junction during synaptogenesis. The importance of rapsyn in this process is demonstrated by the absence of clustered AChRs in the endplate region of muscle from mice in which rapsyn expression has been eliminated by targeted disruption of the rapsyn gene [Gautam et al. (1995) Nature 377: 232-6]. These mice also exhibit a disruption of utrophin, syntrophin, and acetylcholinesterase localization at the synapse, suggesting that rapsyn has a broader involvement in organizing the postsynaptic apparatus than had been previously proposed. However, to understand rapsyn's role in the formation of the neuromuscular junction it will be necessary to identify which proteins interact directly with rapsyn. To achieve this goal, we have used the yeast two-hybrid method to screen for proteins that bind to rapsyn. Using a fragment of rapsyn (aa72-412) to screen a day 17 mouse embryo cDNA library, we recovered 21 positive clones, which we are currently sequencing to identify the proteins that they encode. We will also test the binding of these proteins to rapsyn-glutathione S-transferase fusion proteins.

Purified heregulins possess both ARIA and GGF activities

Andrew D.J. Goodearl* Kenneth M. Rosen & and Gerald D. Fischbach Neurobiology Department, Harvard Medical School, Boston MA 02115

Heregulins are a family of growth and differentiation factors that are expressed widely in both the central and peripheral nervous systems: specifically by sensory and sympathetic ganglia neurons, by all cholinergic neurons, including motor neurons, and also by certain non-cholinergic neurons. In the PNS, two major targets of heregulin action have been identified *in vitro:* (i) certain heregulins increase the rate of ACh receptor incorporation into the surface of myotubes (Acetylcholine Receptor Inducing Activity, ARIA), (ii) certain heregulins stimulate the proliferation of Schwann cells (Glial Growth Factor, GGF). Motor neurons, which express high levels of heregulin mRNAs, are in contact with both cell types at many stages of embryonic and adult life *in vivo*. We therefore undertook a comparison of isolated heregulins in these two assay systems to determine whether the different activities were restricted to different heregulin isoforms. Three heregulins from adult bovine pituitary glands (GGF-I, GGF-II & GGF-III,) were purified to homogeneity using GGF activity to follow the proteins during purification. When added to primary cultures of myotubes, all three preparations stimulated AChR incorporation, suggesting that each of these purified heregulins possess both ARIA and GGF activities. This hypothesis was confirmed by using fully purified recombinant heregulin β1 (GenBank accession #:L11264) which again was active in both assays. GGF and ARIA activities of heregulin β1 were both dose dependent with half maximal effects in the sub-nanomolar range. The ARIA activity saturated at 0.7nM whereas a higher dose was required for maximal Schwann cell proliferation (10nM). In summary, a single heregulin isoform secreted by motor neurons may act as a signal both to Schwann cells that envelope their axons and to myotubes, their synaptic partners. (Funded by NIH)

MOLECULAR CLONING OF THE MURINE P84 NEURAL ADHESION MOLECULE. S. Comu, W. Weng, S. Olinsky, W. Zhao, J.D. Hempel, C. Lagenaur, and V. Narayanan*. Department of Pediatrics, Neurology, and Neurobiology, University of Pittsburgh, Pittsburgh, PA.

P84 is a synapse-associated cell surface protein that promotes neuronal adhesion and neurite outgrowth in vitro. This protein is present on the surface of neurons, but not on astrocytes (GFA+) or oligodendrocytes (04+). The only region of the mouse embryo that expresses P84 is the developing floor plate (as early as E9). Postnatally, it is expressed widely in the central nervous system, in regions rich in synapses, appearing after the period of axon growth. This observation suggests that P84 may be involved in synapse formation. Cerebellar neurons cultured on P84 display neurite outgrowth characteristics quite different from neurons grown on L1 or NCAM. Affinity purified P84 migrates as three bands (167, 85, and 66 kDa) on SDS-PAGE.

Based on the amino acid sequence at the N-terminus and of an internal tryptic peptide segment, we designed degenerate (inosine-containing) primers. With these primers, 500 and 1200 bp segments of the P84 cDNA were PCR amplified. Sequences of these amplimers suggested that they were splicing variants. These P84 cDNA fragments detect a 4 kb mRNA on Northern blots, with a predominant CNS expression at all postnatal ages. Larger cDNA clones were obtained by screening a mouse brain cDNA library and by 5'- and 3'-RACE. The cDNA encodes a protein with a single transmembrane domain. The extracellular region contains domains that are similar to Ig-light chains, while the intracellular part of the protein has some sequence homology with protein tyrosine phosphatases. P84 is thus a new member of the immunoglobulin gene family, which may play a role in synaptogenesis. These results permit a molecular approach to the study of the signal transduction cascade triggered by contact between growth cones and their targets.

THE EXPRESSION OF A SYNAPSE ASSOCIATED PROTEIN REQURIES THREE DIMENSIONAL CYTOARCHITECTURE. Z. P. Mi,* and C. F. Lagenaur Dept. Neurobio., Univ. Pittsburgh, Pittsburgh, PA 15261.

Previous studies have shown that a cell adhesion molecule designated P-84 was detectable in the floor plate region of the spinal cord as early as E9. Widespread expression of P-84 was observed in a variety of CNS region postnatally. In this study, we further examined the features of P-84 expression in mouse retina and cerebellum by using immunohistochemistry and tissue culture. In retina, P-84 staining is only seen in inner and outer plexiform layers, two places where retinal synapses are located. On 0.2 μm retinal sections, P-84 staining in outer plexiform layer appeared as small ring or arc shaped structure, with the size and shape assembling to those of ribbon synapses in photoreceptor terminals. Strong staining was observed in cerebellar molecular layer and a more discrete staining pattern was revealed in granule cell layer where the staining is concentrated on synaptic glomeruli. These results suggest that P-84 is expressed on synapse associated structures (both ribbon and conventional synapses). To understand the possible role that P-84 plays in synapse formation and signal transduction, we made retinal organotypic and dissociated cell culture 3 days before the onset of P-84 expression in vivo and examined the cultures after 7 and 14 days in vitro. We found that P-84 is expressed on retinal explants but not on dissociated retinal cells, indicating that the induction of P-84 does not need intact visual pathway, but requires three dimensional cytoarchitecture.

CALCIUM-INDEPENDENT SYNAPTIC VESICLE RELEASE CAUSED BY NITRIC OXIDE DONORS AND ENDOGENOUS NITRIC OXIDE IN RAT HIPPOCAMPAL NEURONAL CULTURE. O. Sporns* and S. Jenkinson. The Neurosciences Institute, 10640 John J. Hopkins Drive, San Diego, CA 92121, USA.

While nitric oxide (NO) is known to participate in a wide variety of physiological processes, its role in neuronal development, especially synapse formation, is less clear. We studied the synaptic effects of exogenous and endogenous NO in cultures of E19 rat hippocampal neurons during synaptogenesis (5-13 days in vitro). Release of synaptic vesicles is monitored as a negative change in fluorescence ("destaining") of the previously loaded styryl dye FM1-43 at punctate spots corresponding to synaptic sites. We observed that several NO donors, including sodium nitroprusside (SNP), 3-morpholino-N-nitroso-aminoacetonitrile (SIN-1A), and S-nitroso-N-acetyl-D,L-penicillamine (SNAP, all 500 μM), cause release of synaptic vesicles. Magnitude and time course of the release are comparable to that elicited by strongly depolarizing stimulation (90 mM K^+) and release can be effected from a similar proportion of previously stained synapses. Fluo-3 calcium imaging of cells shows that, in contrast to potassium depolarization, NO does not trigger Ca^{2+} influx into synaptic compartments or cytoplasm. NO stimulated synaptic vesicle release occurs even in the absence of extracellular Ca^{2+} and after addition of 5 mM EGTA or 250 μM $CdCl_2$. We then investigated whether endogenous NO can also elicit vesicle release from presynaptic compartments. We show by immunocytochemistry that NO synthase is present along neurites of cultured hippocampal neurons. Application of NMDA in the presence of TTX, known to result in postsynaptic Ca^{2+} influx and NO synthase activation, produces destaining of numerous synapses. This effect is blocked by the simultaneous addition of an NO scavenger (Carboxy-PTIO) and by preincubation of cells with an NO synthase inhibitor (L-NMMA). The susceptibility of developing terminals to calcium-independent vesicle release mediated by endogenous NO suggests a novel physiological role for NO in synapse formation.

NEUROSERPIN mRNA EXPRESSION IN THE DEVELOPING AND ADULT NERVOUS SYSTEM OF THE MOUSE. S. Krueger, G.-P. Ghisu, T. Osterwalder, S. Schrimpf, and P. Sonderegger*. Institute of Biochemistry, University of Zurich, CH-8057 Zurich

Recently, a novel serine protease inhibitor of the serpin family has been identified in the chicken as an axonally secreted protein (Osterwalder et al., EMBO J., in press). The novel serpin is exclusively expressed in neural tissue; therefore it was termed *neuroserpin*. We have now cloned the cDNA of the murine neuroserpin by screening a P20 brain cDNA library with a cDNA fragment obtained by RT-PCR with degenerate primers. The mouse protein, as deduced from the cDNA sequence, exhibited 77% amino acid identity to chicken neuroserpin, 37% to mouse protease nexin-1 and 33% to mouse PAI-1. Northern blot analysis with RNA from adult mouse tissue revealed a restriction of neuroserpin mRNA expression to the nervous system. As demonstrated by *in situ* hybridization, neuroserpin is predominantly synthesized by neurons. Strong mRNA expression is observed in the neocortex, the olfactory bulb, the hippocampal formation, as well as in several structures of mid- and hindbrain. In the spinal cord, some motor-neurons as well as cells in the substantia intermedia and the dorsal horn expressed neuroserpin. During embryonic development of the mouse CNS, periventricular primary neuroepithelia were devoid of neuroserpin transcripts while the differentiating fields of most CNS regions expressed neuroserpin immediately on their appearance. In the developing retina, ganglion cells and amacrine cells became positive for neuroserpin mRNA around birth, at a time when ganglion cell neurites have already reached their targets.

NEUROSERPIN, AN AXONALLY SECRETED SERINE PROTEASE INHIBITOR, INHIBITS TPA AND UPA, BUT NOT THROMBIN T. Osterwalder, P. Cinelli, A. Pennella, S. Krueger, E. T. Stoeckli*, and P. Sonderegger, Institute of Biochemistry, University of Zurich, CH-8057 Zurich, Switzerland

Neuroserpin is an axonally secreted serine protease inhibitor which is expressed in neurons late during embryogenesis and in particular regions of the adult nervous system (Osterwalder et al., EMBO J. in press). We used an eucaryotic system based on the Ig⁻ mouse myeloma cell line J558L and vectors including a promotor of the Ig-κ variable region, an Ig-κ enhancer, and the exon encoding the Ig-κ constant region (Cκ) for the recombinant expression of neuroserpin as a native protein (cNS) or as a fusion protein with Cκ (cNS-Cκ). An antiserum was raised against the recombinant fusion protein. It precipitated the axonally secreted protein from DRG neurons and specificially recognized neuroserpin in Western blots.

To identify possibles target proteases, we investigated the capability of neuroserpin to form SDS-stable complexes with and to reduce the proteolytic activity of a variety of serine proteases *in vitro*. Consistent with its primary structure at the reactive site, neuroserpin is directed against trypsin-like proteases. While neuroserpin bound and inactivated plasminogen activators (tPA and uPA) at low concentrations, no inhibitory effect was seen toward thrombin. Since these or closely related proteases are thought to be involved in neurogenic processes, such as neurite outgrowth or activity-dependent rearrangement of synaptic connections, neuroserpin could exert a regulatory function during the development of the nervous system by specificially inactivating some of these proteases.

The project was supported by the Olga Mayenfisch Stiftung.

POSTSYNAPTIC ELEMENT IS PRIMARILY RESPONSIBLE FOR THE DELAY IN SYNAPTOGENESIS IN SYNAPSIN I-DEFICIENT NEURONS. A. Ferreira*, L. Li, L.-S. Chin, P. Greengard and K.S. Kosik. Center for Neurologic Diseases, Brigham and Women's Hospital, and Harvard Medical School, Boston, MA 02115 and Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

Synapsin I, a neuron-specific phosphoprotein, has been implicated in synaptogenesis and in the regulation of neurotransmitter release. In a previous study, we reported a retardation in process outgrowth and synapse formation in cultured hippocampal neurons from synapsin I-deficient mice. Here we investigated whether this delay in synaptogenesis was attributable to pre- or post-synaptic elements. The experimental paradigm used in this study involved the establishment of heterochronic co-cultures of neurons from wild type and synapsin I-deficient mice. Newly cultured axons from wild type and synapsin I-deficient neurons established synapses with mature wild type postsynaptic elements after 24 hr and 72 hr, respectively. In contrast, wild type and synapsin I-deficient postsynaptic elements were able to receive synapses after 4 and 9 days in culture respectively. This 5 days delayed competence of the synapsin I-deficient postsynaptic targets seems to be independent of their rate of growth, their pattern of branching and the compartmentation of dendritic markers. These results suggest a broad role for synapsin I in the structural development of the synapse, participating directly or indirectly in the maturation of both presynaptic and postsynaptic sites. MAP1B EXISTS IN POSTSYNAPTIC REGIONS OF SOME SYNAPSES IN CEREBRAL CORTEX OF ADULT RAT. K. Muramoto[1,4)]*, S-I. Kawakami[2,3)], M. Kawahara[1)], K. Kobayashi[1)], M. Ichikawa[2)] & Y. Kuroda[1)]. *[1)]Mol. & Cell. Neurobiol., and [2)]Dept.of Anat. & Embryol., Tokyo Metropol. Inst. for Neurosci., Fuchu, Tokyo 183, Japan, [3)]Schl. of Agricul. Sci., Nagoya Univ., Chikusa-ku, Nagoya 464-01, Japan, and [4)]Reseach Fellow of the Japan Soc. for the Promotion of Sci.*

Microtubule-associated protein (MAP) 1B is highly homologous to a proteoglycan-core protein, claustrin, with one transmembrane region and may be involved in synaptogenesis between rat cultured cortical neurons through its phosphorylation of the extracellular domain by ecto-protein kinase (Muramoto,K. et al., Biochem. Biophys. Res. Commun., 205, 1467, 1994). However, it remains unclear whether or not MAP1B molecules localize in synaptic structure in addition to neuronal processes and somata. In order to clarify the localization of MAP1B, we immunohistochemically stained the cerebral cortex of adult rats using specific antibody raised against MAP1B. MAP1B-immunopositive cells were distributed throughout the cerebral cortex and positive products were observed in neuronal cell bodies and dendritese. Interestingly, by the observation using electron microscope MAP1B-immunoreactivity was also recognized in some but not all synapses, where positive zone was the postsynaptic area including postsynaptic thickening and it was not detectable in presynaptic nerve terminals. The ratio of MAP1B-positive synapses to total was 48.1 %, the rest could not be stained by anti-MAP1B antibody. MAP1B-positive synapses were asymmetrical type and presynaptic terminals contained clear vesicles. The ratio of appearance for MAP1B-positive synapses was close to results that the continuous application of K-252b, an ecto-protein kinase inhibitor, gave rise to decreases in the number of synapses formed between cultured cortical neurons to 44.5 % against control cultures (Kuroda,Y. et al., Neurosci. Lett., 135, 255, 1992). These might indicate the existense of at least two types of synapses, MAP1B-positive and negative ones, as well as K-252b-inhibited and no-effective ones by another criterion for classification. It is also interested in the possibility that synapses whose formation are blocked by K-252b may be corresponded with MAP1B-positive ones. These results suggest that MAP1B play important roles in synaptic function including the synaptogenesis and synaptic plastisity.

POSSIBLE INVOLVEMENT OF KERATAN SULFATE PROTEOGLYCANS IN SYNAPSE FORMATION OF CULTURED RAT CORTICAL NEURONS. Y. Kaichi*, K. Muramoto , M. Kawahara , K. Kobayashi , Y. Kuroda . *Department of Molecular & Cellular Neurobiology, Tokyo Metropolitan Institute for Neuroscience, Fuchu-shi, Tokyo 183, Japan.*

In the mechanism of synapse formation, molecules which have extracellular domain are thought to participate in intercellular recognition. Recently, the sequence of rodent microtubule-associated protein MAP1B, which relates to synaptogenesis (Muramoto et al. Biochem. Biophys. Res. Commun., 205, 1467, 1994), was found to be highly homologous (80% homology) to a core protein of keratan sulfate proteoglycan (claustrin) from chick brain (Burg et al. J. Neurobiol., 25, 1, 1994). The roles of proteoglycan, especially keratan sulfate proteoglycan, in neural system have been poorly understood. So we applied the enzymes (from 3 to 10 DIV), which detach keratan sulfate from the core protein of proteoglycan, to cultured rat cortical neurons under synaptogenesis. Keratanase (0.5mU/ml, $P<0.01$) and keratanase II (10mU/ml, $P<0.05$) inhibited the frequency of synchronous oscillation of burstings observed by fura-2 multi-site Ca^{2+} fluorometry. The frequency is appeared to be proportional to the amount of synapses formed in the culture (Muramoto et al. Neurosci. Lett., 163, 163, 1993). The effect of keratanase was dose dependent. On the other hand, similar treatments with condroitinase ABC, heparitinase and heparinase did not show any significant changes of frequency. Observations by phase-contrast microscopy and immunostaining showed no significant morphological changes of neurons and their neurites in the presence of 0.5mU/ml of keratanase. These data suggest that keratan-sulfate chains of proteoglycan may play important roles in synapse formation between cortical neurons.

NAP-22, A DEVELOPMENTALLY REGULATED SYNAPTOSOMAL ESTERASE

Bruce Parsons[1], Anna Korenovsky[1], Daniel Wetzel* & Donald Landry[2] Departments of Psychiatry[1] and Medicine[2], College of Physicians & Surgeons, Columbia University, New York, NY 10032

We report here the purification, characterization and identification of a neuronal membrane protein from rat brain, which we have shown previously to be developmentally regulated. This protein migrates as a pure 58 kDa polypeptide band using two dimensional sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS/PAGE). Monospecific antibodies indicate that this protein is present in rat brain neurons, but not in glia, liver, kidney or spleen. Antigenic activity is greatest in cortex and hippocampus, lower in pons and medulla, and lowest in cerebellum. This 58 kDa polypeptide has alpha naphthyl esterase (NAE) activity, a novel property for a synaptic membrane protein. A Lineweaver-Burk analysis yields a Vmax of 3.6 ± 1.9 µM/min/mg protein and a Km of 26.3 ± 3.5 nM. Alpha NAE activity is inhibited by the serine protease inhibitor, phenylmethylsulfonyl fluoride (PMSF), and by calcium. Amino acid sequencing of 58 kDa revealed its identity as NAP-22, a neuronal protein which binds calmodulin. (NARSAD-BP).

GDNF APPLICATION INTO THE CEREBROSPINAL FLUID (CSF) PREVENTS AXOTOMY INDUCED DEATH OF ADULT RAT CORTICOSPINAL NEURONS (CSN) *IN VIVO*

C. M. Schacht[1], Q. Yan[2], P. Mestres[1], and K. M. Giehl[1], (SPON: European Neuroscience Association). [1]Anatom. Institut, Univ. des Saarlandes, Homburg, Germany. [2]Department of Neurobiology, Amgen Inc., Thousand Oaks, Ca, USA

Death of spinal motoneurons and CSN is observed in Amyotrophic Lateral Sclerosis (ALS). GDNF prevents axotomy induced and developmental death of spinal motoneurons. It was shown that intraparenchymal application of GDNF into the cortex can rescue CSN from axotomy induced death (Giehl et al., this meeting). With regard to the development of therapeutical strategies for ALS, CSF application of GDNF may be more relevant than its intracortical delivery as the diffusion of this neurotrophic factor within the neuropil is limited. Thus, it was tested if intraventricular GDNF infusion prevents axotomy induced death of CSN. Fast Blue labelled CSN were stereotaxically axotomized at internal capsule levels and GDNF was infused at the rate of 24 µl per day with a total dose of 300 µg into the lateral ventricle contralateral to the lesion side in order to avoid intraparenchymal GDNF contamination of the cortex of the lesion side for 7 days. CSN axotomy was veryfied by a second tracer injection into the corticospinal tract at cervical level C3. GDNF application by immunohistochemistry. GDNF application completely prevented CSN death with 97±6 % survival (mean±SEM, n=6) as compared to 63±3 % (n=4) for vehicle. In order to develop an alternative CSF application scheme for planned low dose experiments, GDNF was infused into the subarachnoidal CSF at the olfactory cisterna between the anterior pole of the cortex and the olfactory bulb for 7 days. Also this treatment prevented CSN death with 94±6 % (n=6) as compared to vehicle (64±3 %, n=6). These results show that GDNF infusion into the CSF can rescue CSN from axotomy induced death.

GDNF and GDNF antibodies were generously provided by Amgen Inc., Thousand Oaks. Supported by grants of the ZFK of the University of Saarland and the DFG to K.M.G. and P.M.

GLIAL-DERIVED NEUROTROPHIC FACTOR (GDNF) IMPROVES SPATIAL LEARNING IN AGED FISHER 344 AND LONG-EVANS RATS. M. Cullen, M. Baker and M. Pelleymounter*. Amgen, Thousand Oaks, CA 91320.

Recent data has shown that GDNF can partially protect medial septal cholinergic neurons from fimbria/fornix lesion-induced degeneration. If GDNF can protect septal-hippocampal neurons from lesion-induced degeneration, it may also be able to reverse age-induced degeneration in these neurons. To test this hypothesis, aged Fisher 344 or Long-Evans rats were separated into impaired and unimpaired groups based upon their performance in the Morris water maze, a task that is dependent upon the integrity of the septo-hippocampal system. Two weeks after the pretest, impaired aged rats were administered a bolus intraventricular (icv) injection of either GDNF (100 ug) or the PBS vehicle (2 ul). One week after the injection, rats were re-tested in the place version of the Morris task until they met a criterion performance based upon probe trial performance. Three weeks after GDNF injection, animals were sacrificed, so that hippocampal and septal ChAT, choline, glutamate and GABA uptake could be assessed. GDNF reduced both the latencies to find the hidden platform and the number of trials to criterion for place learning in Long-Evans and Fisher 344 aged rats. While GDNF did not significantly alter any of the hippocampal parameters that were measured, it did increase septal ChAT activity in aged, impaired rats. The increase in septal ChAT activity did not correlate with improved spatial learning, however. The neurochemical effects of GDNF in other tissues from these rats are currently under assessment. These data suggest that GDNF can improve age-induced cognitive dysfunction through an as yet unknown neurochemical mechanism.

NEUROTROPHINS AND GDNF PROTECT STRIATAL NEURONS FROM QUINOLINIC ACID-INDUCED EXCITOTOXICITY.

[1]E. Pérez-Navarro, [2]E. Arenas, [3]J. Reiriz, [2]I. Neveu, [1]N. Calvo and [1]J. Alberch* [1]Dept. Biologia Cel.lular i Anatomia Patològica. Fac. Medicina. Universitat Barcelona. 08036 Barcelona, Spain. [2]Dept. Medical Biochemistry and Biophysics, Lab. Molecular Neurobiology. Karolinska Institute, Stockholm S-171 77, Sweden. [3] Dept. Infermeria Fonamental i Medico-Quirúrgica. Universitat Barcelona, 08907 Hospitalet del Llobregat. Spain.

Intrastriatal injection of quinolinic acid (QUIN) has provided a very useful animal model for studying the pathophysiology of striatonigral degenerative disorders, as Huntington's disease. Neurotrophins and Glial cell line-derived neurotrophic factor (GDNF) promote the survival and/or differentiation of developing neurons and also protect mature neurons from various types of injury, including excitotoxicity. Although these trophic factors have been shown to be expressed in the neostriatum, our understanding of the actions of growth factors in this region is quite limited. In order to study the role of neurotrophic factors against QUIN excitotoxic lesions, stable cell lines secreting high levels of recombinant neurotrophins (NGF, BDNF, NT-3 or NT-4/5) or GDNF were transplanted into the neostriatum 24 hr before QUIN injection. GDNF was able to prevent the loss of calbindin- but not parvalbumin-immunoreactive neurons seven days after intrastriatal QUIN injection. We also examined whether neurotrophins were able to promote the survival or regulate the phenotype of different types of neurons present in the neostriatum: projection neurons and interneurons. We have performed *in situ* hybridization for GAD_{67}, ENK, PPTA and DYN (projection neurons) and ChAT, STT and NPY (interneurons). Levels of expression and cell numbers were measured in the neostriatum seven days after QUIN injection.

EFFECTS OF NEUROTROPHINS AND GDNF ON RAPHE SEROTONERGIC NEURONS IN VIVO.

Peter Åkerud, Isabelle Neveu and Ernest Arenas*. Laboratory of Molecular Neurobiology, Medical Biochemistry and Biophysics, Karolinska Institute, S-17177 Stockholm, Sweden.

The midbrain raphe nucleus provides the major source of ascending serotonergic innervation in the brain, participates in many neural functions and is severely affected by neurodegenerative disorders, including Alzheimer's disease. Raphe neurons are known to express receptors for neurotrophins (p75, trkA, trkB and trkC) during development and in the adult. In agreement, BDNF, and to a lesser extent NT3, have been shown to induce sprouting and increase serotonin metabolism, and to prevent the loss of axons and the decrease in serotonin content and uptake after chemical axotomy. GDNF has also been reported to increase serotonin metabolism in vivo. However, it is not known whether any of these factors may prevent the death of serotonergic neurons. In the present study we have used a 5,7-dihydroxytryptamine (5,7DHT) lesion model of neurodegeneration to investigate whether NGF, BDNF, NT3, NT4/5 or GDNF, delivered by stable cell lines grafted in the vicinity of the raphe, may prevent the death of serotonergic neurons, induce functional compensation or regulate phenotypic markers of raphe neurons in vivo. In this model, 5,7-DHT decreased the number of serotonin neurons by 50% and induced a marked axotomy of the surviving neurons. Neuroprotective effects of neurotrophins or GDNF may have potential application in the treatment of neurodegenerative diseases affecting raphe serotonin neurons. (Supported by Swedish Medical Research Council and Cancer Society, Jeanssonska Foundation and European Commission BIOMED2).

GDNF promote sprouting and functional recovery of the nigro-striatal dopaminergic system following terminal lesion with intrastriatal 6-OHDA.

C. Rosenblad*, A. Martinez-Serrano and A. Björklund. Wallenberg Neuroscience Center, University of Lund, Sölveg. 17, S-223 62 Lund, SWEDEN

Glial cell line-derived neurotrophic factor (GDNF), a member of the TGFß-family, is shown to protect nigrostriatal dopaminergic neurons both in vitro and in vivo after chemical or mechanical lesions. Here we have studied the capacity of GDNF to promote sprouting and restore function in rats with a partial lesion of the nigro-striatal system.

The animals were intra-striatally injected with 6-hydroxydopamine (6-OHDA) and, starting 4 weeks later, either GDNF (5µg/inj). or vehicle was injected intrastriatally every second day for 3 weeks. After injections of GDNF the assessment of forelimb function, employing a stepping test, showed that veh-injected animals were significantly impaired on the contralateral paw while GDNF treated animals performed significantly better and did not differ from the intact. Using BTCP binding autoradiography the number of high-affinity dopamine uptake sites in the denervated striatum was assessed at 5 rostro-caudal levels centred around the lesion. The GDNF injected animals showed on average a 4.2-fold increase in binding compared to the vehicle injected (63%-78% of the intact side vs. 10%-27% respectively for the two groups). The lesion area in GDNF treated animals assessed at the same 5 levels was reduced to 1/2 the size of the vehicle injected (47%-54%). The number of remaining TH-positive neurons in the nigra on the lesioned side was increased from 50% of the intact side in vehicle-treated animals to 70% in GDNF injected.

In conclusion, these findings show that delayed administration of GDNF into the lesioned striatum can stimulate regeneration of the nigrostriatal dopaminergic system and promote functional recovery in the rat Parkinson model. *Supported by the Swedish MRC*

GDNF PREVENTS AXOTOMY INDUCED DEATH AND ATROPHY OF ADULT RAT CORTICOSPINAL NEURONS (CSN) *IN VIVO*

K. M. Giehl*[1], Q. Yan[2], C. M. Schacht[1], and P. Mestres[1], [1]Anatomisches Institut, Univ. des Saarlandes, Homburg, Germany, [2]Department of Neurobiology, Amgen Inc., Thousand Oaks, Ca, USA

GDNF is a trophic factor for several neuronal populations involved in motor control. The present study evaluates the trophic actions of GDNF on CSN, an important CNS-motor projection into the spinal cord. Axotomy of adult rat CSN at internal capsule levels induces half of them to die, the surviving population displays severe atrophy (Giehl and Tetzlaff, EJN, 1996, in press). To evaluate the GDNF effect on these neurons, Fast Blue labelled CSN were axotomized at internal capsule level and GDNF was infused into the cortex of the lesion side at the rate of 24 µl per day with a total dose of 10, 20, 40, 100, or 300 µg for 7 days. CSN axotomy was veryfied by a second tracer into the corticospinal tracts at cervical level C3, GDNF application by immunohistochemistry. GDNF completely prevented axotomy induced death of CSN at 40 µg total delivery with 98±7 % survival (mean±SEM, n=5) in contrast to lesion only (53±3 %, n=8), vehicle (70±2 %, n=7), the 10 µg (76±3 %, n=6), 20 µg (79±4%, n=6), 100 µg (79±6 %, n=6), or 300 µg (68±3 %, n=5) delivery groups. Also the atrophy was attenuated or prevented by GDNF with 87±5% (percentage cross sectional area of axotomized CSN as compared to their unlesioned contralateral counterparts, n=5) at 10 µg, 91±7% (n=5) at 20 µg, 111±10% (n=4) at 40 µg, 86±5% (n=4) at 100 µg, and 90±7% (n=5) at 300 µg total delivery. In contrast, lesion only (53±3%, n=7) and vehicle (54±2%, n=5) displayed CSN atrophy. These results show that GDNF is able to prevent axotomy induced CSN death as well as their atrophy.

GDNF and GDNF antibodies were generously provided by Amgen Inc., Thousand Oaks. Supported by grants of the ZFK of the University of Saarland and the DFG to K.M.G. and P.M.

STRANDS OF EMBRYONIC MESENCEPHALIC TISSUE PROVIDE A NOVEL AND STABLE VEHICLE FOR DOPAMINE CELL PRESERVATION. W.M.Zawada*, E.D.Clarkson, J.M.Rosenstein+, P.Bell, C.Hutt, and C.R.Freed. Div. Clin. Pharmacol., Univ. Colorado Sch. of Med., Denver, CO 80262, and +Dept. Anat., George Washington Univ. Med. Ctr., Washington, DC 20037.

Embryonic dopamine (DA) neurons die after brain implantation and thereby limit the benefit of grafts for the treatment of Parkinson's disease. During preparation of cell suspensions for grafting, neurons suffer axotomy and disruption of the local cytoarchitecture. We have attempted to reduce these negative effects by maintaining tissue integrity after dissection. Ventral mesencephalic tissue from E15 rat or 7-8 weeks post-conception human embryo were pressure extruded throught a glass extruder (0.3 mm diameter). The tissue strands obtained were cultured in presence of 5% serum for 15 days. Some strands were sectioned after 3 days and dopamine neurons were identified by tyrosine hydroxylase (TH) immunoreactivity. Tissue strands permitted survival of twice as many rat DA neurons than dispersed preparations. Concentrations of homovanillic acid (HVA) correlated with the number of TH^+ cells (r=.9) in dispersed cultures (~ 1.3 pmoles/day/10^3 TH^+ cells). Cumulative HVA measurements revealed that after 9 days, cells in dispersed preparations ceased to produce HVA. In contrast, tissue strands continued HVA production at constant rate throughout the two weeks. The combination of IGF-I (150ng/ml) and bFGF (15ng/ml) increased HVA production by the dispersed cells 2-fold but had no effect on tissue strands. Ultrastructural studies were performed on human mesencephalic tissue strands after 1, 6, 30 and 60 days *in vitro*. At all times studied, healthy cells (including TH^+ cells), neurite bundles, and growth cones were coexisting with degenerating and apoptotic cells. These data indicate that embryonic tissue strands provide a better environment for dopamine cell survival than dispersed tissue despite some ongoing tissue degeneration. Supported by NS18639, GM07063, Natl. Parkinson Foundation.

767.8

EMBRYONIC MESENCEPHALIC TISSUE STRANDS SHOW GREATER DOPAMINE NEURON SURVIVAL AND BETTER BEHAVIORAL OUTCOME THAN CELL SUSPENSIONS AFTER TRANSPLANTATION IN PARKINSONIAN RATS. E.D. Clarkson*, W.M. Zawada, F.S. Adams, K.P.Bell, C.J. Hutt and C.R. Freed. U. Colorado School of Medicine., Denver, CO 80262.

The success of fetal neural tissue transplants as a clinical treatment for patients with Parkinson's disease has been limited by poor survival of transplanted dopamine neurons. To see if a new tissue preparation method improves survival, we have compared transplants of mechanically dispersed suspensions of ED 15 rat ventral mesencephalic tissue with transplants of tissue extruded through a 0.3 mm diameter glass extruder to form a strand. Tissue from only 1/2 of a ventral mesencephalon was used. Three months after transplantation, methamphetamine induced rotational behavior and surviving dopamine neurons were determined. In an effort to improve the behavioral effects of dispersed cell transplants, mesencephalic cells were cotransplanted with dispersed striatal cells and striatal cells treated for 2 hours with glial cell line-derived neurotrophic factor (GDNF, 100 ng/ml), insulin-like growth factor I (IGF-I, 1500 ng/ml), and basic fibroblast growth factor (bFGF, 150 ng/ml).

Results:

CONDITION	*% REDUCTION IN ROTATION*	*DOPAMINE NEURONS SURVIVING*
Strands	83 ± 9%	530 ± 112
Dispersed	32 ± 14%	117 ± 35
Striatal Cograft	54 ± 15%	215 ± 51
Cograft + GFs	65 ± 9%	95 ± 24

We conclude that transplants of tissue strands have better cell survival and behavioral effects than cell suspensions even when suspensions are supported with cografts of striatal cells and the growth factors GDNF, IGF-I and bFGF. Supported by NINDS NS 18639 and the National Parkinson Foundation.

POLYMER ENCAPSULATED GDNF-SECRETING CELLS REDUCE ROTATIONAL ASYMMETRY IN AN AXOTOMY MODEL OF PARKINSON'S DISEASE. J.L. Tseng*[1], E.E. Baetge[2], A.D. Zurn[1], and P. Aebischer[1]. [1]Gene Therapy Center, CHUV, Lausanne University Medical School, Lausanne, Switzerland 1011 [2]CytoTherapeutics, Inc., Providence, RI 02906

Glial cell-line derived neurotrophic factor (GDNF) exerts protective effects on dopaminergic (DA) neurons *in vivo*. These effects, though, were achieved with high-dose bolus injections of GDNF. It is unknown what effects continuous delivery of small amounts of GDNF will have on these cells. To that end we examined whether GDNF released from polymer-encapsulated genetically engineered cells is able to prevent the loss of tyrosine hydroxylase immunoreactivity (TH-IR) of the substantia nigra (SN) neurons of rats that have been subjected to a unilateral medial forebrain bundle (MFB) axotomy. Baby hamster kidney (BHK) cells transfected with the cDNA for GDNF were encapsulated in a polymer fiber and implanted unilaterally at a location lateral to the MFB and rostral to the SN. ELISA tests on the capsules show that they released approximately 5 ng GDNF/day. One week later, the MFB of these animals was unilaterally axotomized ipsilateral to the capsule placement. Seven days after, the animals were tested for amphetamine-induced rotational asymmetry and sacrificed. The striatum was excised and analyzed for catecholamine content, while the SN was immunostained for the presence of TH-IR. GDNF did not prevent the loss of dopamine in the striatum ipsilateral to the axotomy. However, GDNF significantly preserved the number of TH-IR neurons in the SN pars compacta (SNc) as compared to control (64.9±7.2 % vs. 27.2±3.5 %, $p<0.0003$). GDNF also significantly reduced the number of turns per minute ipsilateral to the lesion exhibited by the rats under the influence of amphetamine (5 mg/kg, i.p.) versus control (1.2±1.0 vs. 6.3±2.3, $p<0.05$). This could be due to neuronal plasticity in the dendro-dendritic connections within the SNc and between the SNc and the SN pars reticulata (SNr). These results suggest that GDNF is able to protect the nigral dopaminergic neurons from an axotomy induced lesion and improve pharmacological rotational behavior by a mechanism other than dopaminergic striatal reinnervation. Supported by the Swiss National Science Foundation and CytoTherapeutics, Inc.

GDNF PROMOTES THE DEVELOPMENT OF THE ADRENERGIC AND OTHER NEURONAL PHENOTYPES IN MOUSE TRUNK NEURAL CREST CULTURES. G. D. Maxwell*[1], K. Reid[2], A. Elefanty[2], P. F. Bartlett[2], and M.Murphy[2]. [1]Dept. of Anatomy, Univ. of Conn. Health Ctr., Farmington, CT and [2]Walter and Eliza Hall Institute, Melbourne, Australia

Growth of mouse trunk neural crest cultures with glial cell-derived neurotrophic factor (GDNF) resulted in a dramatic dose-dependent increase in the number of TH-positive cells which developed when 5% chick embryo extract was present in the medium. The TH-positive cells which developed had neuronal morphology and contained the middle and low molecular weight neurofilament proteins, but generally did not stain for peripherin or SCG10. Numerous TH-negative cells with the morphology of neurons which did stain for peripherin and SCG10 were also present. Analysis of the temporal response to GDNF revealed that 6-12 days in vitro was the critical period for the observed effect. In contrast to the effect of GDNF, growth with bone morphogenetic protein (BMP)-2, BMP-4, BMP-6, transforming growth factor (TGF) β-1, TGF β-2, and TGF β-3 elicited no stimulation above control values. The growth factor NGF was unable to substitute for GDNF, but NT-3 and FGF-2 elicited a response similar to that of GDNF. These results show that GDNF can act on precursor cells of the mouse trunk neural crest to promote the development of the adrenergic phenotype and other neuronal phenotypes.

This work was supported by NIH grant NS16115 and an NIH Fogarty Senior International Fellowship (GDM) and grants from the Windermere Foundation (PFB) and the National Health and Medical Research Council of Australia (PFB, KR, AE, and MM).

NEUROPROTECTIVE EFFECTS OF GDNF AGAINST 6-OHDA IN YOUNG AND AGED RATS. CM. Kearns* , DM. Gash and WA. Cass, Dept. of Anatomy and Neurobiology, University of Kentucky, Lexington, KY 40536.

In a recent study from our laboratory, an intranigral administration of glial cell line-derived neurotrophic factor (GDNF) 6 hr prior to an intranigral 6-OHDA neurotoxic lesion, completely protected dopamine neurons in the substantia nigra pars compacta and ventral tegmental area in young adult rats. To further characterize this neuroprotection, this study was designed to identify whether GDNF could elicit the same protective effect in aging rats. Forty-eight Brown Norway/Fischer 344 hybrid male rats were divided into the age groups of 3, 18 and 24 month old (n=8/group) prior to surgery. There were 2 groups per age : a) intranigral citrate + intranigral 6-OHDA and b) intranigral GDNF + intranigral 6-OHDA. The GDNF treated groups received an intranigral injection of 10μg GDNF. Six hours later, all animals received a unilateral 8μg/2 μl 6-OHDA infusion into the nigra. All brains were processed for HPLC. In the 3 month old GDNF recipients, striatal dopamine levels remained at normal levels while nigral dopamine levels were approximately 15% higher. However, in the citrate treated groups, there was a 72% loss of dopamine in the striatum and a 47% loss in the nigra. In the 18 month old rats, GDNF recipients showed a 7% loss of dopamine in both the striatum and nigra, whereas there was a 96% depletion of dopamine in the striatum and a 61% loss of dopamine in the nigra of the citrate treated animals. In the 24 month old rats treated with GDNF, there was a 35% loss of dopamine in the striatum and a 26% loss in the nigra. In the citrate treated animals, there was 90% dopamine depletion in the striatum and a 47% loss in the nigra. All these values were statistically significant, with the exception of the 24 month old nigras treated with vehicle vs. GDNF. Based on these neurochemical measures, GDNF protects dopamine neurons in the nigra of 3, 18 and 24 month old rats challenged with 6-OHDA, however this protection may be somewhat less effective in the 24 month old rats. EFFECT OF THE NEUROTROPHIC FACTOR GDNF ON TRANSPLANTED DOPAMINERGIC CELLS TREATED ACUTELY AT THE TIME OF TRANSPLANTION AND DURING HIBERNATION. E. Sanford, M. Hong, R. Poirier, M. Guido* and I. Mendez. Neural Transplantation Laboratory, Department of Neurosurgery, Faculty of Medicine, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7

Although recent work has demonstrated that infusion of the neurotrophic factors, including glial cell derived neurotrophic factor (GDNF), promote survival and differentiation of dopaminergic neurons in the brain, it is not clear whether these agents influence the survival of grafted cells exposed to them at the time of transplantation or during storage of cells in hibernation. To examine GDNF influence on dopaminergic cells transplanted into the brain acutely and following 6 days hibernation, fetal (E14) ventral mesencephalon cell suspensions (≅ 800,000 cells) were micrografted into the striatum of female Wistar rats (200-225 g) bearing unilateral 6-OHDA lesions of the nigrostriatal pathway. Animals receiving a intrastriatal graft of cells treated with GDNF (0.2 μg/μl cell suspension) at the time of transplantation demonstrated a significant improvement in amphetamine (5 mg/kg ip) induced rotation behaviour at 3 weeks following implantation. Similarly, animals receiving grafts of cells in hibernation for 6 days treated with GDNF (1 μg/ml hibernation medium) also demonstrated significant behavioural recovery at 3 weeks following implantation. Immunohistochemical analysis using an antibody against tyrosine hydroxylase (TH) revealed a large number of TH-positive cell bodies and fibers in the grafts in the striatum in both groups. Both behavioural recovery and immunohistochemical analysis were significantly improved compared to animals receiving grafts of dopaminergic cells alone. These findings provide evidence that GDNF influences the survival of dopaminergic cells when treated with neurotrophic factors at the time of transplantation and during hibernation. GDNF DELIVERED VIA AN ADENOVIRAL VECTOR (Ad) PROTECTS RAT DOPAMINERGIC (DA) NEURONS FROM DEGENERATION. DL Choi-Lundberg*, Q Lin[1], H Mohajeri[1], YN Chang[2], YL Chiang[2], CM Hay[2], BL Davidson[3] and MC Bohn[1]. [1]Dept of Neurobiology & Anatomy, University of Rochester, Rochester, NY 14642, [2]Genetic Therapy, Inc., Gaithersburg, MD 20878, [3]Dept of Internal Medicine, Univ of Iowa College of Med, Iowa City, IO 52242.

GDNF protects or restores DA neuronal phenotypic characteristics in several rodent and primate models of Parkinson's disease (PD). One approach for long-term delivery of GDNF to the nigrostriatal system may be through the use of gene therapy. Replication defective (E1a-, E3-) Ad-5 vectors encoding human GDNF or a 12 amino acid deletion mutant (m) GDNF under the control of the RSV promoter were constructed. PC12 cells infected with Ad GDNF secreted 1-4 ng/10^4 infected cells/day as determined by ELISA. Ad GDNF increased survival of embryonic day 14 DA neurons 60-80% compared to Ad mGDNF and no virus *in vitro*. The effects of Ad GDNF gene therapy were assessed in a 6-hydroxydopamine (6-OHDA) progressive lesion model (Sauer & Oertel, 1994, *Neurosci* **59**: 401-415). Adult Fischer 344 male rats were injected bilaterally in striatae with 0.2 µl of 2% fluorogold (FG) and unilaterally immediately dorsal to the substantia nigra (SN) with Ad GDNF, Ad mGDNF or no SN injection. One week following FG and Ad injections, rats received 16 µg of 6-OHDA unilaterally into the striatum at the same coordinates used for the FG injection and on the same side as the Ad injections. Gene therapy with Ad GDNF significantly protected DA neurons from cell death 6 weeks following the striatal 6-OHDA lesion. The ratio of FG+ neurons on the lesioned/unlesioned sides at the level of the medial terminal nucleus in the SN was 0.89±0.20 for Ad GDNF (n=5), 0.27±0.04 for Ad mGDNF (n=5) and 0.49±0.11 for no virus (n=4) ($p<0.007$ for GDNF v. mGDNF, $p<0.065$ for GDNF v. no virus, Fisher's post hoc pairwise comparisons). These results demonstrate that Ad GDNF is able to deliver a biologically effective level of neurotrophic support *in vivo* and may be useful for preventing degeneration of DA neurons in the human PD brain. GDNF EXERTS A SELECTIVE TROPHIC EFFECT ON A SUBPOPULATION OF MOTOR NEURONS IN A MOUSE MODEL OF ALS. M. L. Derby*[1], R. Giuliano[2], D. A. Figlewicz[2,3] and M. C. Bohn[2]. [1]Program in Neuroscience, [2]Dept. of Neurobiology & Anatomy and [3]Dept. of Neurology, Univ. of Rochester Medical Center, Rochester, NY 14642.

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disorder that affects upper and lower motor neurons (MNs). The action of GDNF as a potent neurotrophic factor for MNs suggests a therapeutic value of GDNF for ALS. To begin to address this issue, dissociated spinal MNs were cultured from E13 and E14.5 GIH transgenic mice which overexpress a mutant form of human Cu, Zn-superoxide dismutase-1 (SOD-1) that causes MN pathology (Gurney et al., *Science*: 264, 1994) and is known to cause familial ALS. The cultures were treated with human recombinant GDNF (100 ng/ml) and were analyzed for MN survival and morphology at 6 and 10 days *in vitro* (DIV) after staining for ChAT immunoreactivity. MNs from E13 mice survived significantly better than those from E14.5 mice (500-1300%) in both transgenic and non-transgenic cultures in the presence or absence of GDNF at 6 DIV. However, E14.5 transgenic MNs and the majority of E13 MNs (both transgenic and non-transgenic) did not display a survival effect in response to GDNF. In contrast to the majority of MNs, a distinct subpopulation of MNs was observed in GDNF treated E13 cultures characterized by a 2-3 fold larger soma, a conspicuously high level of ChAT immunoreactivity and unusually profuse neurite outgrowth. In non-transgenic cultures, this subpopulation constituted less than 0.25% of total MN number at 6 DIV and at 10 DIV was rarely observed. In the transgenic cultures, however, the subpopulation comprised 1% of total MN number at 6 DIV, and 81% of this subpopulation was still observed at 10 DIV. No MNs characterized as belonging to this subpopulation were identified in any E14.5 cultures or in any E13 cultures not treated with GDNF. These results suggest that GDNF therapy may be effective in familial ALS. (Supported from the Markey Charitable Trust & NIH R01 NS34101).

AGE-DEPENDENT DIFFERENTIAL REGULATION OF SENSORY NEUROPEPTIDES. J.E. Adler*. Dept. of Neurology, Veterans Administration Medical Center and Wayne State Univ. Sch. of Med., Detroit, MI 48201.

We have previously reported that substance P and somatostatin are differentially regulated in dorsal root sensory ganglia from neonatal rats. Nerve growth factor (NGF) increased both survival and substance P content of sensory neurons with little effect on somatostatin. Similar results were obtained from enriched cultures of adult dorsal root ganglion neurons: NGF doubled substance P but not somatostatin content or survival. To determine whether other glia-derived factors regulate neuropeptide levels, neonatal sensory neurons were exposed to other members of the neurotrophin family, ciliary neuronotrophic factor (CNTF) and glial cell-line derived neurotrophic factor (GDNF). GDNF was the only factor of those tested that increased substance P, attaining more than a 6-fold rise that was maximal at a dose of 10 ng/ml. Further, it potentiated the NGF-induced increase in substance P in neonatal sensory neurons but did not increase the number of neurons that stained for substance P-like immunoreactivity. The effect of GDNF on substance P diminished with age. In cultures of adult sensory neurons, it induced a minimal increase in substance P levels. However, somatostatin content of these neurons doubled in response to GDNF. Our results suggest that functionally distinct sensory neuropeptides may be differentially regulated and that the action of GDNF may change with age.

FUNCTION OF DIFFERENT FORMS OF GDNF ON CULTURED MOTOR NEURONS. R. Y. Xu*, D. Aparisio, C. Cole, D. Brankow, J. Delaney, B. Moellering, S. Liu, S. Kahn and J. Lile. Amgen Inc. Thousand Oaks, CA 91320

GDNF was originally discovered as a neurotrophic factor for dopaminergic neurons in vitro. It has also been shown to have potent trophic effects on developing motor neurons(MN) in vitro and reduce MN death in vivo. When expressed in CHO cells, GDNF is found in the conditioned medium as a variety of N-terminally truncated forms with Des31 homodimer as the primary species. In a series of experiments, we have used rat MN culture to test two truncated forms of GDNF and to compare their efficacy to native form of GDNF. By Chat assay, our results demonstrated similar ED50 values for Des31 and Des37 when compared to native GDNF in the culture. A neutralizing monoclonal antibody specific to GDNF also completely attenuated effects of Des31 and Des37 in the culture at similar concentration range. However, the two forms and native GDNF showed different responses in a sympathetic ganglion culture, implicating their potential difference in function among different populations of neurons. INTERACTIONS BETWEEN GDNF AND LEVODOPA: GDNF CAN REDUCE LEVODOPA REQUIREMENT AND THE OCCURRENCE OF LEVODOPA-INDUCED SIDE EFFECTS IN PARKINSONIAN MONKEYS. Y. Miyoshi*[1], Z. Zhang[1], A. Ovadia[1], P.A. Lapchak[2], D. Hilt[2], and D.M. Gash[1]. [1]Department of Anatomy and Neurobiology, University of Kentucky, College of Medicine, Lexington, Kentucky 40536. [2]Amgen, Inc., Thousand Oaks, California 91320.

Glial cell line-derived neurotrophic factor (GDNF) has been shown to exert potent neurotrophic effects on the nigrostriatal dopamine system and promote behavioral improvement in both rodent and primate models of Parkinson's disease (PD). Since levodopa still remains the most widely-used and effective single drug, it is important to investigate the interactions between levodopa and GDNF. In the present study, we have analyzed the dose response of hemiparkinsonian monkeys (female Macaca mulatta) to levodopa before and after intracerebroventricular GDNF administration to assess how GDNF and levodopa interact. Animals receiving GDNF injections did not display significant side effects, however, all of GDNF recipients showed some weight loss. In vehicle-treated monkeys, no difference in the dose response to levodopa was observed between pre- and post-injection tests. In contrast, the combination of GDNF and levodopa resulted in an enhanced functional improvement. GDNF shifted the dose response curve so that a response to lower dose of levodopa was evident. Statistically significant functional improvement from pre- to post-GDNF administration was observed for the following endpoints: lower limb rigidity, balance, food retrieval, posture, and total hemiparkinsonian score. Furthermore, GDNF did succeed in reducing the occurrence of levodopa-induced side effects including dyskinesias and abnormal species behavior (psychosis). These results suggest that GDNF is promising for treating patients of PD. Moreover, GDNF may be able to improve the quality of life of the late stage patients who are suffering from levodopa-induced side effects. Supported by Amgen, Inc.

DOSE RESPONSE TO INTRACEREBRAL GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) INJECTIONS IN RHESUS MONKEYS Z. Zhang*, Y. Miyoshi[1], A. Ovadia[1], P.A. Lapchak[2]—F. Collins[2], and D.M. Gash[1] 1. Anatomy and Neurobiology, University of Kentucky, Lexington, KY 40536; 2. Amgen, Inc., Thousand Oaks, CA 91320

Several groups, including ours, have recently demonstrated that GDNF exerts potent stimulatory effects on midbrain dopamine neurons in rodents and nonhuman primates. In our initial studies on rhesus monkeys with parkinsonian features induced by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), GDNF doses ranging from 100-450µg were used based on scaling up from effective doses in rats. The present study was designed to evaluate the dose response of MPTP treated rhesus monkeys to intracerebroventricular (ICV) injections of GDNF. Twenty-seven rhesus monkeys with stable hemiparkinsonian features were divided into six GDNF dose groups (vehicle, 10, 30, 100, 300 and 1000 micrograms), with 4 or 5 monkeys in each group. After a four week baseline period, monkeys received three ICV administrations, spaced at 4 week intervals, into the lateral ventricle on the dopamine depleted side. Standardized video taped behavior tests were conducted once a week, and the results evaluated by raters blinded to the test groups. Significant behavioral improvements were observed in animals receiving from 30µg-1000µg GDNF. Parkinsonian features showing statistically significant improvements were bradykinesia, rigidity in the upper and lower limbs, posture and balance. Based upon the degree of behavioral improvement, GDNF at doses of 30µg or higher were effective. Thus, GDNF is a potentially useful compound to treat motor deficits in parkinson's disease patients. COMPARISON OF GDNF OR BDNF TREATMENT ON GENE REGULATION IN NORMAL OR LESIONED FACIAL MOTONEURONS OF ADULT RATS. *C.R. Matheson*, J. Urich, F. Collins, A.A. Welcher, Q. Yan.* Depts of Neuroscience. and Immunology, Amgen Inc., Thousand Oaks, CA 91320.

The underlying causes for most motoneuron degenerative diseases such as amyotrophic lateral sclerosis (ALS) are not understood. Accordingly, the process is difficult to model in animals. We have set out to identify molecular endpoints as measures of adult motoneuron function in normal or axotomized rats. Such endpoints may be relevant to neurodegenerative diseases in the adult nervous system in which there is a prolonged period of neuronal dysfunction preceding neuronal death.

We describe the results of an *in situ* analysis of mRNA levels in normal or injured adult motoneurons treated with or without growth factors. We examined the following four classes of molecules (partial list).

1. Structural molecules (neurofilaments, tubulin, GAP-43)
2. Neurotransmitter or modulator (ChAT, CGRP)
3. Disease-related (SOD, glutamate transporter, c-jun)
4. Neurotrophic factors (BDNF, NT-3)

Analysis of the molecular changes observed suggests a surprising level of complexity at the level of gene regulation. In normal motoneurons, GDNF had a significant effect on the mRNA levels of several genes, while BDNF had no measurable effect. Both GDNF and BDNF had profound effects on the mRNA levels of a large number of genes in lesioned adult motoneurons. There was not a simple correlation between the changes in mRNA levels following injury or factor treatment.

A comparison of these results with the changes in gene regulation in ALS patients should start to identify the most appropriate molecular endpoints for modeling in animals.

INTRACEREBRAL ADMINISTERED GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) IN 6-OHDA LESIONED RATS: REDUCTION OF PARKINSONISM AND RESCUE OF DOPAMINERGIC PHENOTYPE. P.J. Miller*, F. Collins, S.S. Jiao and P.A. Lapchak. AMGEN Inc., Dept. Neurosci., MC 5-1-C, Thousand Oaks, CA 91320.

GDNF has been shown to be trophic for DA neurons in vitro and in vivo in unlesioned rats. We examined the potential of GDNF as a therapeutic agent in an animal model of Parkinson's disease to determine its mechanism of action. Rats received an injection of 6-OHDA (20 ug/4 uL) unilaterally into the medial forebrain bundle. At weekly intervals, behavioral performance as determined using apomorphine (0.05 mg/kg)-induced rotational behavior was measured. Within 5 weeks, a baseline dopaminergic deficit was established as evidenced by the presence of 650-700 rotations per hour. At this time, GDNF (100 or 1000 µg) was injected into the substantia nigra (SN). The injections of 100 and 1000 µg GDNF significantly reduced rotations by 50% and 80%, respectively, when measured 7 days following the injection. GDNF (100 or 1000 µg) when injected into the lateral ventricle (icv) also reduced (by 40-50%) rotational behavior in 6-OHDA lesioned rats. These results suggested that GDNF was increasing nigrostriatal dopaminergic tone, thus reducing the level of supersensitivity of dopaminergic receptors. The mechanism involved in the GDNF response was studied using tyrosine hydroxylase (TH) immunostaining. Following perfusion, sections were processed for TH staining. Image analysis revealed an almost complete loss of nigral TH+ve cells in vehicle-treated 6-OHDA lesioned rats. In contrast, approximately 30-40% of TH+ve cells were present in the SN of GDNF-treated rats, at least at the level of SN used for quantitation. This data suggests that GDNF reduces rotational behavior in parkinsonian rats, possibly by inducing the dopaminergic phenotype within the nigrostriatal pathway.

DISTRIBUTION OF ^{125}I-GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) IN THE CNS FOLLOWING AN INTRAVENTRICULAR (ICV) INJECTION: CORRELATION WITH THE PHARMACOLOGICAL EFFECTS OF ICV ADMINISTERED GDNF IN THE ADULT RODENT. D. Hilt*, D. M. Araujo, F. Collins, S.S. Jiao, P.J. Miller, and P.A. Lapchak. AMGEN Inc., Departments of Neuroscience MC 5-1-C and Clinical Development, Thousand Oaks, CA 91320-1789.

GDNF has been shown to be a potent neurotrophic factor involved in the survival of developing dopaminergic cells in culture. GDNF also induces the expression of the dopaminergic phenotype in rodents (Lapchak et al. Cell & Tissue Res. in press). In the present study, a single injection of [^{125}I]-GDNF (1 µCi/100 µg) was made into the lateral ventricle (ICV) of adult female Wistar rats. Rats were sacrificed at 1 hr, 24 hrs, 48 hrs, and 7 days following [^{125}I]-GDNF injection. At 1 hr, 24 and 48 hours following the injection of [^{125}I]-GDNF, labeling was found throughout the ventricular system (lateral, third and fourth ventricles), around the lateral ventricle ependymal cell layer, septum, hippocampus(HI), cerebral cortex (CX), substantia nigra(SN), caudate putamen(CP), hypothalamus (HY) and cerebellum. The neurochemical effects of ICV administered GDNF (0.1 µg to 1000µg) were also studied. GDNF significantly increased dopamine (DA) levels in the the CP(40%), HY(125%) and SN (100%) when measured 7 days following the ICV injection. The tissue content of DA in the CP was not significantly different from control when measured 14 days after the injection and nigral DA was only increased by 50% compared to control. There was also regulation of the DA metabolites HVA and DOPAC following GDNF administration. The study shows that ICV injected GDNF easily accesses basal ganglia structures, especially the SN. GDNF differentially increases dopaminergic tone within a variety of brain structures, the predominant durable effect occuring within the SN.

767.22

CHRONIC INTRAVENTRICULAR GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) INCREASES DOPAMINERGIC AND CHOLINERGIC MARKERS IN AGED F344 RATS. S.S. Jiao*, P.J. Miller and P.A. Lapchak. AMGEN Inc., Department of Neuroscience, MC 5-1-C, Thousand Oaks, CA 91320-1789.

GDNF has been shown to affect dopaminergic and cholinergic neuronal populations in young unlesioned or lesioned rats (reviewed in Lapchak et al. Cell and Tissue Research, 1996). However, it is not known if the response to GDNF is augmented during aging. The effects of chronic icv infusion of GDNF and nerve growth factor (NGF) were determined in young adult (3 month old) and aged (24 month old) F344 male rats. Growth factors were administered at a dose of 10µg/day for 14 days. Locomotor activity and weight changes were examined in all rats. Aged F344 rats showed significantly reduced (by 70%) locomotor activity compared to the young rats. In GDNF-treated rats there was increased locomotor activity in aged (170%) and young rats (100%) measured at 7 days. By 14 days after the start of infusion locomotor activity returned to pretreatment levels. Both GDNF and NGF reduced weight gain in young and old F344 rats by approximatley 10%. Two weeks following the start of either NGF or GDNF administration the rats were used for neurochemical analysis. GDNF significantly increased (by 150%) tyrosine hydroxylase (TH) activity in the substantia nigra of aged and young rats. NGF treatment had no effect on TH activity. However, GDNF and NGF increased (by 100-180%) choline acetyl-transferase (ChAT) activity in the septum of both aged and young rats. It is interesting to note that GDNF, like NGF, induced ChAT activity in young and aged rats. These findings indicate that certain dopaminergic and cholinergic neuron populations remain responsive to GDNF during the lifespan of the rat and may be involved in maintaining phenotypic expression within multiple neuronal populations.

TOPOGRAPHICAL DISTRIBUTION OF [^{125}I]-GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) IN THE CNS OF UNLESIONED AND MPTP-LESIONED RHESUS MONKEYS FOLLOWING AN INTRA-VENTRICULAR INJECTION: CORRELATION WITH PHARMACOLOGICAL ACTIVITIES OF ICV GDNF. F. Collins*[1], D. M. Gash[2], B. Hoffer[3], G. Gerhardt[3], S. S. Jiao[1], P. J. Miller[1], Ai Yi[2], A. Ovadia[2], Z. Zhang[2], and P.A. Lapchak[1]. AMGEN Inc., Department of Neuroscience, MC 5-1-C, Thousand Oaks, CA, 91320, [2]Univ. Kentucky, Anat. & Neurobiol. Lexington, KY. and [3]Univ. Colorado, Pharmacol., Denver, CO.

Recent pharmacological studies have shown that GDNF is a potent trophic factor for nigrostriatal dopaminergic neurons in many species (Lapchak et al., Cell and Tissue Res, 1996). The distribution of [^{125}I]-GDNF in unlesioned and MPTP-lesioned adult rhesus monkey brain was determined following stereotaxic injection into the lateral ventricle. In the rhesus monkey, 24-72 hours following an icv injection of [^{125}I]-GDNF we observed labeling around the lateral ventricle (ependymal cell layer), 3rd, and 4th ventricles, septum, substantia nigra, and cerebral cortex. Following a unilateral icv injection of [^{125}I]GDNF we observed bilateral distribution of the trophic factor. Our studies in MPTP-lesioned primates indicated that icv administered GDNF diminished behavioral deficits attributed to MPTP-induced degeneration of the nigrostriatal pathway. Parkinsonian monkeys respond with definite clinical improvement to GDNF following icv administration. In parkinsonian monkeys GDNF improves the following behavioral deficits: bradykinesia, rigidity, reduced fine motor control, posture and balance. The improvements in behavioral parameters are correlated with increases in dopaminergic markers (tyrosine hydroxylase and dopamine, HVA) in midbrain dopaminergic neurons suggest that GDNF may be exerting its effects by restoring dopaminergic tone.

767.24

THE BIOLOGICAL ACTIVITY OF N-TERMINALLY TRUNCATED FORMS OF GDNF ON CULTURED MESENCEPHALIC DOPAMINERGIC NEURONS. T.J. Zhang*[1], J. Lile[1], R. Rosenfeld[2], B. Moellering[2], C. Cole[2], R. Tamir[1], D. Brankow[3], G. Shimamoto[4], R. Lee[4], M. Mann[4], J. Delaney[4], D. Aparisio[5], S. Hu[3], F. Collins[1] and J-C Louis[1]. Departments of [1]Neuroscience, [2]Protein Chemistry, [3]Mammalian Cell Molecular Biology, [4]Process Science and [5]Analytical Resources, Amgen, Inc., Thousand Oaks, CA91320

When full-length GDNF was expressed in CHO cells, the predominant species (>90%) was the N-terminally truncated des31-GDNF; des32-GDNF and des36-GDNF were also found. In addition, des36-GDNF was purified from the conditioned medium of a mesencephalic glial cell line (mes21). Subsequently, we expressed three N-terminally truncated forms of GDNF (namely des31-, des32- and des37-GDNF) in *E.coli*, and compared their ability to stimulate dopamine (DA) uptake with full-length GDNF in cultures of E15 rat ventral mesencephalon. The truncated forms of GDNF were more potent than full-length GDNF in stimulating DA uptake. The ED_{50}s of the truncated forms of GDNF were 10-30 pg/ml, while the ED_{50} of full-length GDNF was 50-100 pg/ml. In contrast, in the E9 chick sympathetic neuron survival assay, des31-GDNF and des32-GDNF displayed only 30% of the bioactivity exerted by full-length GDNF, while des37-GDNF displayed only 1-2% of its activity. These results could be explained by: (i) a difference in the interaction of full-length GDNF and the truncated GDNFs with the GDNF receptor(s) and/or (ii) an increased stability *in vitro* of GDNF following N-terminal truncation. (Supported by Amgen, Inc.)

ADENOVIRUS MEDIATED GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) GENE TRANSFER AND EXPRESSION IN RAT BRAIN. D. M. Araujo*, D. Hilt, S. Hu, Z. Sheng, S.S. Jiao, P.J. Miller, and P.A. Lapchak. AMGEN Inc., Departments of Neurosci. MC 5-1-C, Immunology, Mammalian Cell Biol. and Clin. Devel., Thousand Oaks, CA 91320-1789.

GDNF has been shown to be trophic for DA neurons in vitro and in vivo in rodent and primate Parkinson's disease models (reviewed in Lapchak et al. Cell & Tissue Res. 1996). In the present study, adenovirus (AV) mediated GDNF gene transfer to neurons in the rat brain were tested. Two recombinant adenoviral vectors driven by a cytomegalovirus (CMV) promoter but with a deleted E1 viral protein coding region (titers 10^6-10^7 pfu/ml) were injected into the rat substantia nigra (SN). First, a vector with a ß-galactosidase (ß-gal) reporter gene insert (Ad.CMV.ß-gal) was used to determine if infection of CNS cells was possible. At 7 days following vector infusion (5 µl or 10 µl) we observed ß-gal expression in the injected SN; expression that was independent of the quantity of viral vector injected. The second vector containing a human GDNF gene (Ad.CMV.huGDNF) was injected into the SN. Seven days following the injection, rat brain tissue was used for immunocytochemistry. Brain slices (40 µm) were processed using a polyclonal antibody directed against GDNF. In these animals, diffuse GDNF immunolabeling around the injection site and throughout the SN was observed. This suggested that soluble GDNF was released from infected SN cells. Dense GDNF+ve fibers were also seen in ventral tegmental area (VTA), the SN reticulata and compacta and along the needle track. GDNF immunostaining was not observed in the brain on the side contralateral to the injection site. These data indicate that adenovirus vectors may eventually be practical to deliver GDNF locally to nigral/VTA neurons and that this delivery system may be useful to treat neurodegenerative diseases such as Parkinson's disease.

767.26

GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF) IMPROVES BEHAVIORAL DEFICITS IN 6-HYDROXYDOPAMINE (6-OHDA) LESIONED RATS: CORRELATION WITH THE EXPRESSION OF DOPAMINERGIC AND NONDOPAMINERGIC MARKERS IN THE NIGROSTRIATAL PATHWAY. P.A. Lapchak*, D.M. Araujo, F. Collins, D. Hilt,S.S. Jiao and P.J. Miller. AMGEN Inc., Departments of Neuroscience MC 5-1-C and Clinical Development, Thousand Oaks, CA 91320-1789.

GDNF has been shown to be trophic for DA neurons in vitro and in vivo in rodent Parkinson's disease models (reviewed in Lapchak et al., Cell & Tissue Res.1996). In the present study, we determined if neuropeptides known to be involved in nigrostriatal neurotransmission are affected by GDNF administration. 6-OHDA lesioned rats administered GDNF intranigrally (100 µg) respond with a significant (50-85%) reduction in the number of rotations measured following apomorphine (0.05 mg/kg, sc). In 6-OHDA lesioned rats, tyrosine hydroxylase (TH) activity is decreased by 60% and 70% in the nigra and striatum, respectively. GDNF treatment increased nigral (40-70%), but not striatal TH activity. We investigated the effects of 6-OHDA lesions on nigral and striatal dynorphin, enkephalin and substance P measured using radioimmunoassays. Striatal dynorphin and enkephalin were substantially increased (by 60-85%), whereas substance P levels were unaltered by the lesion. GDNF treatment attenuated the lesion-induced increase of striatal dynorphin, but did not markedly alter the levels of enkephalin or substance P. In the nigra, 6-OHDA lesions resulted in a slight increase in dynorphin levels (40%) but did not alter either enkephalin or substance P levels. In addition, GDNF (100 µg) did not significantly alter neuropeptide levels measured in the nigra. These results indicate that GDNF-induced behavioral improvements may involve alterations not only of dopaminergic neurotransmission, but also, peptidergic neurotransmission.

GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR IMPROVES MOTOR FUNCTION IN BILATERALLY 6-HYDROXYDOPAMINE LESIONED RATS. K. E. Bowenkamp,[1*] P. A. Lapchak,[2] B. J. Hoffer,[1,3] and P. C. Bickford.[1,4] Departments of Pharmacology[1] and Psychiatry[3], University of Colorado Health Sciences Center, Denver, CO 80262 and VAMC[4], Denver, CO 80220, and Amgen, Inc.[2], Thousand Oaks, CA 91320.

In order to evaluate the efficacy of GDNF in a model of advanced Parkinson's Disease, we studied rats with complete bilateral lesions of the nigrostriatal pathway. Adult male F344 rats were bilaterally injected into the medial forebrain bundles with 6-hydroxydopamine. Locomotor ability as measured by distance traveled in an open field over 20 min. as well as von Frey hair testing of the degree of sensorimotor neglect were monitored weekly. Rats demonstrating severe motor impairment and sensorimotor neglect were used in this study, and were sorted to achieve similar average behavioral scores between groups. After 2 weeks of pretesting, the rats received either 250 µg GDNF (Amgen, Inc.) or vehicle injected into the right lateral cerebral ventricle (ICV.) Three weeks later, an additional 500 µg GDNF or vehicle was injected into the contralateral ventricle. The rats were monitored for another 2 weeks before sacrifice. Behavioral results indicated von Frey hair scores were inconsistent between tests for each rat and revealed no significant change following GDNF delivery. However, GDNF recipients demonstrated significant improvement in spontaneous locomotor ability as compared to vehicle recipients ($p=0.05$, 2-tailed Conover test.) Immunohistochemical staining of tissue sections from matched pairs of rats revealed highly significant ($p<0.001$) increases in TH + nigral neurons and increased striatal TH+ staining intensity in 1 of the 2 pairs examined. This pair also demonstrated the most consistent behavioral improvement following GDNF treatment. These results suggest ICV GDNF improves motor ability and increases dopaminergic neural numbers in a rodent model of severe Parkinson's Disease.

GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR REVERSES MOTOR IMPAIRMENT IN AGED RATS. P. C. Bickford,[1,4*] K. E. Bowenkamp,[1] P. A. Lapchak,[2] and B. J. Hoffer.[1,3] Departments of Pharmacology[1] and Psychiatry[3], University of Colorado Health Sciences Center, and VAMC[4], Denver, CO 80262, and Amgen, Inc.[2], Thousand Oaks, CA 91320.

Aging is accompanied with declines in motoric ability which may be the result of deficits in central nervous system dopaminergic function. Glial Cell-Line Derived Neurotrophic Factor (GDNF) has been shown to have neuroprotective and restorative effects on dopaminergic neurons of the nigrostriatal pathway in young rats. In this study, 10, 40, or 60 µg GDNF or vehicle was injected intrastriatally in 16-17 month old F344 rats. Coordination and muscle strength as determined by performance on an inclined balance beam and a wire grip strength test were monitored for up to 5 weeks post-injection. GDNF elicited dose-dependent improvements in motor coordination without concurrent increases in strength. The highest dose tested produced greater than 79 % improvement in motor coordination, resulting in performance scores approaching those achieved by 3 month old rats tested concurrently. These findings indicate GDNF produces improvement in the motoric function of aged rats, which may be related to dopaminergic circuits.

NEUROTROPHIC FACTORS: BIOLOGIC EFFECTS—EGF, FGF, IGF, AND TGF

768.1

RADIAL MIGRATION OF SUBEPENDYMAL CELLS IN THE ADULT RODENT FOREBRAIN. S. Reid*, S.M. Patel, J.H. Fallon. Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

The neurotrophic factor, transforming growth factor alpha (TGFα), has been shown to have effects on numerous cell types *in vitro* and *in vivo*. Recently, it was shown to enhance proliferation of neuronal and glial precursors found along the lateral ventricle in the adult rodent forebrain. In the present study, we examined the effect of striatally infused TGFα on these proliferative cells *in vivo*. In addition, we lesioned the dopaminergic nigrostriatal pathway to determine whether dopamine denervation could influence the cells' proliferation or migration. Immunohistochemistry and other histological techniques were employed to characterize (1) the proliferative and migrational effects of the infusions and lesions and (2) the neurochemical phenotypes of the resulting cells. We found that striatally infused TGFα can induce cells in the subependymal zone to proliferate and migrate radially into the overlying striatum. The possible effect of dopamine denervation on the migration and proliferation is also discussed. Supported by NIH Predoctoral Traineeship NS07351-5, the American Foundation for Aging Research Graduate Fellowship, the University of California Chancellor's Fellowship and the UC Irvine Committee of 1000 Graduate Fellowship (all to S.R.), and the UC Irvine Committee for Instructional Development Fellowship (to S.P.).

TRANSFORMING GROWTH FACTOR β (TGF-β) MAY BE INVOLVED IN LONG-TERM SYNAPTIC FACILITATION IN *APLYSIA*. F.Zhang*, S.Endo, L.J.Cleary, A.Eskin, J.H.Byrne. Dept. of Neurobiology & Anatomy, Univ. of Texas Med. Sch., Houston, TX 77030, and Dept. of Biochem. and Biophys. Sci., Univ. of Houston, Houston, TX 77204.

A major focus of analyses of long-term memory is the identification and functional characterization of specific molecules involved in long-term synaptic plasticity. Recently, the level of mRNA for an *Aplysia-tolloid*/BMP(Bone morphogenetic protein)-1-like protein (apTBL-1) was found to increase in sensory neurons (SNs) of *Aplysia* after treatment with 1.5 h 5-HT or long-term sensitization training (Liu et al. 1995). *Drosophila tolloid* and human BMP-1 are believed to function as secreted metallo-proteases that activate TGF-β family proteins. As a first step to examine possible roles of apTBL-1 in long-term sensitization, we studied the long-term effects of human TGF-β1 on sensorimotor synapses in pleural-pedal ganglia. Amplitudes of EPSPs were examined before, after 24 h-exposure to TGF-β1, and 24 h after removal of TGF-β1. Application of 100 ng/ml TGF-β1 significantly ($p<0.005$) increased the synaptic efficacy at both 24 h (TGF-β1, 137±9% of baseline, n=12 vs. control, 95±7%, n=15) and 48 h (TGF-β1, 189±24%, n=12 vs. control, 118±17%, n=15). Excitability of SNs was also examined, but no significant change was observed. To study the relationship between TGF-β1-induced enhancement and 5-HT-induced facilitation, we examined whether one could occlude the other. 1.5 h application of 2 µM 5-HT was followed by 24 h treatment of TGF-β1. The EPSP amplitudes in the presence and in the absence of TGF-β1 were 149±12% (n=9) and 141±22% (n=8) at 24 h, and 223±54% (n=9) and 189±25% (n=8) at 48 h, respectively. There was no significant difference between the two treatments, so TGF-β1 and 5-HT may share common sites of action. These results suggest that TGF-β may be part of the cascade of events underlying long-term sensitization. Moreover, the results indicate that a signaling molecule used in development may also have functions in adult neuronal plasticity.

768.3

CHARACTERIZATION OF THE EFFECT OF A REDUCTION OR TOTAL ABSENCE OF TGF-ALPHA EXPRESSION ON THE SURVIVAL OF MESENCEPHALIC DOPAMINE NEURONS IN ADULT MICE M. Blum*. Fishberg Research Center for Neurobiology. Mt Sinai School of Medicine, New York, NY 10029.

TGF-alpha has been demonstrated to promote the survival and process outgrowth of mesencephalic dopamine neurons *in vitro*. High levels of TGF-alpha expression are normally detected in the striatum and expression of its receptor has been observed within midbrain dopamine neurons. However, it is unknown whether TGF-alpha is required for the normal development or survival of mesostriatal dopamine neurons. Recently it has been discovered that a spontaneous mutation arose in the waved-1 mouse strain that causes there to be reduced expression of TGF-alpha. Further characterization of these mice has revealed that the loss of TGF-alpha expression in the striatum is progressive. One week after birth the levels of TGF-alpha mRNA are reduced only by 50% whereas by adulthood there is a 90% loss of mRNA expression. In addition to the waved-1 mice, transgenic mice are also available in which the TGF-alpha gene has been knocked out. It is being determined with these two lines of mice whether a progressive loss or a total absence of TGF-alpha expression affects the survival of dopamine neurons. We have completed a pilot study using the optical dissector method described by West and Gundersen to obtain an unbiased estimate of the number of dopamine neurons. We observed approximately a 30% reduction in the number of tyrosine hydroxylase immunoreactive neurons in the substantia nigra with no change in the ventral tegmental area of 3.5 month old waved-1 mice compared to a normal (Swiss Webster) mouse strain. Thus, the results of these studies suggest that a TGF-alpha deficiency may compromise the survival of mesostriatal dopamine neurons. Currently, it is being assessed whether similar or greater losses in the number of tyrosine hydroxylase immunoreactive neurons occur in the substantia nigra of TGF-alpha knock-out mice. (Supported by NIH grant AGO 8538)

DIFFERENTIAL EXPRESSION OF NOVEL cDNAs IN RESPONSE TO TGF-ß1 IN ASTROCYTES AND C6 GLIOMA CELLS. **K.K. Krohn*. University of Heidelberg, Dept. of Anatomy and Cell Biology III, 69120 Heidelberg, Germany**

Activation of astrocytes and microglia is a well established phenomenon in response to experimental brain lession and during progression of neurodegenerative diseases. The glial reaction to changes in homeostasis includes activities that are very similar to the acute phase response in the peripheral immune system like recruitment of other cells, presentation of antigens, phagocytosis, detoxification and release of inflammatory molecules.

One of these inflammatory mediators is the cytokine transforming growth factor (TGF) -ß1, which has been recently established as a potent factor during glial reactions after brain lesion. This contribution extends earlier studies that address TGF-ß1 effects on gene expression in glial cells. In a Differential Display RT-PCR approach we screened for cDNAs that suggested a differential expression after treatment of C6-glioma cells with 0.2 to 5ng/ml TGF-ß1. Several candidates were cloned, sequenced and further evaluated. Most of the cDNAs do not show any homology to known sequences. Here we present two novel cDNAs that are differentially expressed in C6-glioma cells, rat cortical astrocytes and primary cortical neurons in response to TGF-ß1, TGF-ß3, fibroblast growth factor-2 and glial cell-line derived neurotrophic factor.

Characterization and identification of the coding region for the two gene responses might reveal new lession-related features of glial cells during brain injury and in the progress of neurodegenerative diseases. **(Supported by a DAAD grant and a Helmholtz scholarship by BMFT)**

ACTIVIN A IS NEUROTROPHIC TO VENTRAL HORN ACETYLCHOLINESTERASE (AChE)-POSITIVE NEURONS IN ORGANOTYPIC EXPLANT CULTURES OF SPINAL CORD. **Y.Nishida*, S.Okazaki and H.Kawai. First Dept. of Int. Med., Sch. of Med., Univ. of Tokushima, Tokushima, 770, Japan.**

Activin A is a member of the transforming growth factor-β superfamily and may enhance the survival of various neurons. We examined the effect of activin A on ventral horn AChE-positive neurons (VHANs) in organotypic explant cultures of spinal cord (OTC-SC) from neonatal rats. OTC-SCs were performed according to Delfs et al. (Brain Res., 1989). After 1 week *in vitro*, the cultures were devided into 3 groups. One was stained for AChE at 1-week-old. Other two were incubated in control medium or medium containing 20 ng/ml activin A (Ajinomoto Central Res. Lab., Kawasaki, Japan) for 1 week and then were stained for AChE and analyzed histochemically and morphometrically.

In all 3 groups, the major structures of the spinal cord were well maintained. AChE staining of 2-week-old cultures with and without activin A both looked similar to 1-week-old cultures. The mean area of VHANs in the 1-week-old culture, and in the 2-week-old culture groups with and without activin A was 210.8 ± 3.8, 222.0 ± 5.8, and 218.2 ± 5.9 μm^2 (mean ± SEM), respectively. The 1-week-old culture group had 166.5 ± 12.5 VHANs/ ventral horn, while the 2-week-old control group had 95.0 ± 7.1. This decrease was observed for VHANs both smaller than and larger than 500 μm^2 and was attenuated by treatment with activin A (119.6 ± 11.9).

These results indicate that activin A is neurotrophic to ventral horn AChE-positive neurons and might be useful for protecting against neuronal death in various neuronal disorders.

α2-MACROGLOBULIN MEDIATES TRANSFORMING GROWTH FACTOR α - INDUCED DECREASE IN SEPTAL CHOLINERGIC CELL EXPRESSION. I. E. Mazzoni * and R.L. Kenigsberg, Hôpital Ste-Justine, Montreal, Quebec, Canada. H3T 1C5.

We have shown that epidermal growth factor (EGF)/transforming growth factor α (TGFα) decrease ChAT activity and AChE in rat fetal medial septal cholinergic neurons in mixed neuronal-glial cultures indirectly via astroglia. However, the substances produced by astrocytes stimulated by these growth factors that mediate this cholinergic response awaited elucidation. Thus, in this study, we proceeded to identify the astroglial-derived molecule(s) induced by TGFα that decrease cholinergic expression. We found astroglia to respond to TGFα by releasing a soluble substance with cholinergic de-differentiating activity which has an apparent MW > 100 kDa, is heat sensitive and lost upon repeated free-thaw cycles. Although apparently a protein, this activity was not decreased but, surprisingly, enhanced by protease treatment. This property proved to be instrumental in its identification as α2-macroglobulin (α2-m), a high MW protease inhibitor, which in the CNS is synthesized by astroglia. In this regard, when immunoneutralizing antibodies against α2-m were added to the cultures, the decrease in ChAT induced by TGFα was almost completely abolished. Furthermore, TGFα appeared to upregulate the synthesis/release of α2-m from responsive astrocytes, as evidenced by immunoblots and a competitive ELISA for α2-m. Addition of native α2-m to the cultures had a slight inhibitory effect on ChAT activity. On the other hand, treatment with exogenous protease-activated α2-m had a biphasic effect on ChAT activity, inducing its dose-dependent increase followed by a marked and significant dose-dependent decrease. These results suggest that: 1) TGFα can upregulate the production and/or release of α2-m from astrocytes; 2) α2-m is (one of) the molecule(s) released by astrocytes stimulated by TGFα that decrease cholinergic cell expression in fetal medial septal cultures; 3) α2-m elicits its de-differentiating effects on cholinergic neurons when present in its protease activated conformation. We are currently extending these studies to more precisely characterize the mechanism of action of α2-m on these developing medial septal cholinergic neurons.

ACTIVIN EXERTS NEUROTROPHIC EFFECTS ON CULTURED HIPPOCAMPAL NEURONS. Y.Iwahori*, H.Saito, K.Torii and N.Nishiyama. Dept. of Chem. Pharmacol., Fac. of Pharmaceutic. Sci., The Univ. of Tokyo, Tokyo 113, Japan.

Activin is a protein belonging to transforming growth factor-β superfamily which has various biological activities, and trophic effects on peripheral neurons and cell lines have been reported. In this study, we have investigated the effect of activin on the survival in primary cultures of embryonic rat hippocampal neurons. Activin significantly supported neuronal survival at concentrations of over 10 ng/mL. This effect of activin (30 ng/mL) was markedly prevented by a protein synthesis inhibitor cycloheximide (0.1, 0.3 μM) and a voltage dependent Ca^{2+} channel blocker nicardipine (0.5, 1.0 μM). Furthermore, a tyrosine kinase inhibitor genistein (1.0, 3.0 μM) and a protein kinase C inhibitor calphostin C (10, 50 nM), but not Ca^{2+}/calmodulin kinase inhibitor KN-62, blocked the neurotrophic action of activin. In addition, depolarization-induced increase in intracellular Ca^{2+} concentration was significantly potentiated by activin treatment, which was inhibited by cycloheximide (0.1 μM).

In conclusion, activin supported cell survival of cultured hippocampal neurons by mechanisms which require new protein synthesis and Ca^{2+} entry via voltage dependent Ca^{2+} channels. In addition, activation of genistein-sensitive tyrosine kinase and protein kinase C may be involved in the neurotrophic effect of activin.

768.8

RECEPTIVITY OF OSTEOGENIC PROTEIN-1 (OP-1) - INDUCED DENDRITES TO AXONAL INNERVATION. G. Withers[1*], D. Higgins[2], D. Rueger[3], and G. Banker[1]. [1]Dept. of Neurosci., Univ. Virginia School of Medicine, Charlottesville, VA 22908, [2]Dept. of Pharmacol., State Univ. of New York, Buffalo, NY 14214, [3]Creative Biomolecules, Hopkinton, MA 01748

Previously we reported that OP-1, a member of the TGF-β superfamily, induced dendritic development in hippocampal cultured neurons, measured by increased dendritic length and branching (Withers et al., 1995, SFN Abstracts). Morphological development of dendrites was clearly accelerated, occurring over days rather than weeks, as is typical in these cultures. To determine if these dendrites were receptive to innervation, we looked for sites of presynaptic contact defined by puncta of synapsin immunoreactivity. After 3 - 8 days in OP-1, no typical synaptic contacts were observed although synapsin immunoreactivity was abundant in axons. This result raises two possibilities: 1) the OP-1 induced dendrites were not receptive to innervation; or 2) the poor growth of axons in these cultures prevented normal synaptic contacts from occurring.

To test the hypothesis that these dendrites would receive axonal contacts, we used a heterochronic culture technique. Cultured neurons were grown in the presence of OP-1 for three days. Then, new neurons were plated on top of these more mature neurons and fixed one day later. Previous work has shown that axonal contacts will form within 24 hours of plating if more mature dendrites are present within the culture (Fletcher et al., 1994, J. Neurosci.). Using this method, we found evidence of synapsin positive aggregates surrounding OP-1 induced dendrites, indicative of early stages of synapse formation. Further investigations will determine the density of these synaptic contacts and if postsynaptic development can be accelerated in these neurons. Supported by NS09652 (GW), NS23094 (GB).

NESTIN EXPRESSION IN BASAL FOREBRAIN NEURONS OF THE ADULT RAT DEFINE NOVEL RESPONSES TO bFGF AND DEAFFERENTATION

M.M. Dugich-Djordjevic*[1], B. Knusel[2], K. Pong[2], R. Somogyi[3], X. Wen[3] and R.D.G. McKay[1]. Laboratories of Molecular Biology[1] and Neurophysiology[3], NINDS, Bethesda, MD and Andrus Gerontology Center[3], USC, Los Angeles, CA.

The intermediate filament protein nestin is associated with proliferating, undifferentiated CNS cells during development. We have used in situ hybridization, RT-PCR and immunocytochemistry to describe the distribution of nestin mRNA and protein in the adult rat forebrain. We report the localization of nestin to novel areas of the adult rat forebrain. Furthermore, we show that nestin expression can be regulated by growth factors and deafferentation. Nestin is localized to cholinergic subpopulations of basal forebrain nuclei and within interneurons of the caudate-putamen. Nestin+ChAT+ cells comprise 30% of the total basal forebrain cholinergic population with all nestin positive neurons expressing ChAT. Transgenic mice with a tagged embryonic nestin promoter indicate that the expression of nestin in some of these cells is associated with the embryonic nestin promoter. Double ICC for BrDU and nestin revealed that nestin expression correlated well with proliferating populations within the SVZ and hypothalamic nuclei, but did not define proliferating cell populations basal forebrain regions. In the intact animal, 10d of treatment intrahippocampally with high dose bFGF significantly reduced the number of nestin+ cells by 30% in the MS/VDB complex and by 60% in the HDB, with no effect on ChAT expression. With lo dose bFGF, there was a reduction in all areas but only the HDB was significantly reduced by 65%. NGF or NT4/5 had no effect on nestin expression, but resulted in small increases in ChAT expression. Following unilateral fimbria-fornix lesion, nestin-IR was reduced to 60% of contralateral MS at 48h and increased to 113% of the contralateral MS at 7d. These data suggest that nestin expression in cholinergic forebrain neurons defines novel responses to neurotrophic factors and target-derived signals.

768.10

bFGF, BDNF AND CNTF PROMOTE THE SURVIVAL AND NEURITE OUTGROWTH OF CORTICAL NEURONS GROWN ON ARTIFICIAL SURFACES W. Ma*, M. Coulombe, J.J.Hickman, C. Montgomery, D. Jung Life Sciences Operation, Science Applications International Corporation, 1710 Goodridge Drive, McLean, VA 22102.

Cell environment plays a key role in neuronal development. To study this issue, we established an *in vitro* system that combines the use of a defined serum-free medium with a chemically defined surfaces. This system allows for the study of effects of growth factors on the survival and neurite outgrowth of cortical neurons grown on artificial substrata in a well-defined envionment. Cells were mechanically or enzymatically dissociated from the developing cerebral cortex of embryonic day 14, 16, 18, 22 and postnatal day 10 rats and cultured in serum-free MEM-N3 for 1, 4 and 7 days. The cells were grown on poly-D-lysine, a standard culture substratum, and silica substrates modified with artificial surfaces composed of silane self-assembled monolayers. The cell survival was assessed by a comparison of the number of cell surviving a given point relative to the number of cells survival at the time of the culture initiation. The extent of neurite outgrowth was characterized in terms of total process output, the mean arbor output, the number of arbors and cell body area. Results showed that hydrophilic surface, similar to poly-D-lysine, supported the growth of primary cortical neurons, whereas poor attachment and consequent poor cell survival and neurite growth occured in cultures grown on hydrophobic surfaces. However, the addition of bFGF, BDNF and CNTF increased the number of cell survival and neurite growth to various extents, sometimes with dramatic improvement. Double-immunofluorescence staining with a mixture of anti-glutamate and anti-GAD in sister cultures showed that the growth factors enhanced cell survival and neurite outgrowth for both glutamatergic and GABAergic neurons.

VENTRICULOMEGALY AFTER CHRONIC INFUSION OF FGF-2 INTO THE LATERAL VENTRICLES OF ADULT RATS. MA Mittler, MH Lebow, EG Stopa, V Kuo-LeBlanc, PT Chan, J Chodobska, A Chodobski, AM Gonzalez, A Baird, MH Epstein, and CE Johanson* Brown University School of Medicine, Rhode Island Hospital, Providence, RI; PRIZM Pharmaceuticals, San Diego, CA.

Growing evidence suggests that the choroid plexus synthesizes various growth factors normally found within the extracellular milieu of the central nervous system (CNS). Basic fibroblast growth factor (FGF-2), a heparin-binding growth factor found in high concentration in brain, has been shown to be involved in brain development, normal maintenance, and response to injury. FGF-2 mRNA, receptor, and protein have all been localized within the choroid plexus.

To assess the effects of FGF-2 on the CSF, choroid plexus and brain we continuously infused FGF-2 into the lateral ventricles of Sprague-Dawley rats (250-350 g). The rats were administered a dose of 1 ug/day (41.7 ng/hr) of FGF-2 (n=9) or inactive carrier solution (n=9) for a two week period using Alzet osmotic pumps. Following chronic infusion, subjects were transcardially perfused and their brains post-fixed with 4% paraformaldehyde in PBS. The brains were embedded in paraffin and representative coronal sections were obtained at the level of the anterior commissure. Ventricular area was measured using computer-based image analysis.

Rats treated with FGF-2 showed a significant increase in ventricular size (mean 6.567 mm^2) compared to controls (mean 2.864 mm^2) (p=0.0008). **Our findings support the hypothesis that FGF-2 may enhance CSF secretion, alter CSF absorption, and/or influence the osmotic regulation of the extracellular fluid volume within the CNS. In view of the increased synthesis of FGF following various types of brain injury, our data suggest that FGF-2 production by the choroid plexus may contribute to the development of hydrocephalus following brain injury.** (Supported by AG 10682, NS 27601, and the Rhode Island Hospital Research Fund.)

768.12

FIBROBLAST GROWTH FACTOR-2 INDUCES TYROSINE HYDROXYLASE GENE EXPRESSION IN PC12 CELL BY CALCIUM DEPENDENT AND INDEPENDENT MECHANISMS. H. Osaka*[1], A. Menezes[1], R. Zeman[2] and E.L. Sabban[1]. Depts of [1]Biochem. & Mol. Biology and [2]Cell Biol. & Anatomy, New York Med. Coll., Valhalla, New York 10595.

FGF-2 plays important roles in regulating differentiation, survival and gene expression in various cell types, including dopaminergic neurons. The mechanism by which FGF-2 mediates these effects is only partially understood. We examined the effect of FGF-2 on the expression of tyrosine hydroxylase (TH), the rate limiting enzyme in dopamine synthesis, in PC12 cells, and the possible involvement of alterations in $[Ca^{2+}]i$. Various concentrations of FGF-2 elevated TH transcription and increased TH mRNA levels about 3-fold that were sustained for over a week. Changes in $[Ca^{2+}]i$ were measured by ratioed Fura-2 fluorescence. FGF-2 at 30 ng/ml, sufficient to elicit neurite outgrowth, raised $[Ca^{2+}]i$ from about 50 to about 130 nM with delayed kinetics, maximal at 50 min. This rise was much greater than observed with NGF. The effects of perturbation of intracellular or extracellular calcium sources, and of calcium-dependent signalling pathways, on the elevation of TH mRNA by FGF-2 were examined. The results revealed that 30 ng/ml mediated its effect on TH gene expression in a calcium dependent fashion and inhibited by 1.5 mM EGTA if added within less than 50 min after FGF-2. In contrast, 300 ng/ml FGF-2 increased TH gene expression in a calcium independent manner, not inhibited by EGTA or KN-62. The results indicate that FGF-2 can regulate TH gene expression by multiple signalling pathways (Supported by NIH grant NS 28869).

bFGF PROTECTS DOPAMINE NEURONS FROM 6-OHDA TOXICITY: A ROLE FOR GLIAL GLUTATHIONE. J. G. Hou*, G. Cohen and C. Mytilineou. Fishberg Center for Neurobiology and Dept. of Neurology, Mt. Sinai Sch. of Medicine, New York, N.Y. 10029.

GDNF and bFGF have been shown to reduce damage to dopamine (DA) neurons in the 6-OHDA lesioned rat (Hoffer et al., 1994; Matsuda et al., 1992). We examined the effects of these growth factors in mesencephalic cultures treated with 6-OHDA. [^{3}H]DA uptake and tyrosine hydroxylase (TH) staining were used to assess damage to DA neurons. GDNF had no protective effect against 6-OHDA toxicity but bFGF conferred a significant protection on DA neurons. Exposure to 6-OHDA for 45 min. caused a 70% reduction in [^{3}H]DA uptake in controls, 75% in GDNF-, but only 37% in bFGF-treated cultures. The number of TH+ cells was reduced by 62% in controls and 58% in GDNF-treated cultures, whereas bFGF treatment completely prevented the loss of TH+ neurons. In contrast to GDNF which does not affect glial cell division, bFGF caused a >3-fold increase in astrocytes. Addition of the mitotic inhibitor FUDR to bFGF-treated cultures completely abolished the neuroprotective effects of bFGF, indicating that glial cells were providing the protection from 6-OHDA toxicity. Glial cells contain high concentrations of reduced glutathione (GSH) and are required to provide cysteine for GSH synthesis by neurons. GSH in bFGF treated cultures was 1.5-fold higher than controls and this increase was completely prevented by FUDR. Following 6-OHDA treatment there was a further increase in GSH in cultures treated with bFGF. This response was not observed in control cultures or in cultures treated with bFGF and FUDR. The protective effect of bFGF was also reduced by treatment with the GSH synthesis inhibitor L-buthionine sulfoximine (L-BSO, 10μM), which reduced GSH levels by 66%, suggesting that modulation of damage by glia may depend upon GSH. Supported by NIH grant NS-23017 and the Lowenstein Foundation.

768.14

SYNERGISTIC EFFECTS OF BASIC FGF AND TGF-ß1 ON ASTROCYTES *IN VITRO*. J. F. Reilly* and V. G. Kumari Department of Cell Biology & Human Anatomy, School of Medicine, University of California, Davis, CA 95616.

Following a traumatic injury to the central nervous system, astrocytes undergo proliferation and hypertrophy. The factors which initiate and maintain the astrocyte response to injury are poorly understood at the present time. Substantial evidence supports the involvement of basic fibroblast growth factor (bFGF) and transforming growth factor-ß1 (TGF-ß1). In the present study, secondary cultures of 95 - 99% pure astrocytes were treated with varying doses bFGF, TGF-ß1, or a combination of the two. Immunocytochemical staining for glial fibrillary acidic protein (GFAP) demonstrated that treatment with bFGF alone resulted in a change from a flat, polygonal morphology to a process-bearing phenotype, in a dose-dependent manner. Treatment with TGF-ß1 alone produced little effect on astrocyte morphology. Astrocytes treated with a combination of bFGF and TGF-ß1 also exhibited a morphological change, extending many processes and becoming stellate in appearance. Though similar to changes observed with bFGF alone, combined treatment produced a more rapid change and resulted in cells with longer and more numerous processes, suggesting a synergistic interaction between bFGF and TGF-ß1 in the regulation of astrocyte morphology. Treatment with bFGF also caused an increase in GFAP specific activity, while TGF-ß1 alone had no effect. Combination of bFGF and TGF-ß1 produced an increase in GFAP specific activity greater than that seen with bFGF alone. These data suggest a synergism between bFGF and TGF-ß1 which may play a role in the regulation of astrogliosis. *Supported by the Department of Veterans Affairs.*

REGULATION OF CONNEXIN(CX)43 FUNCTION AND EXPRESSION BY FGF-2 IN NEWBORN RAT ASTROBLASTS. B. Reuss, R. Dermietzel[a] and K. Unsicker. Depts of Anat. & Cell Biol., Univ. Heidelberg, INF 307, D-69120 Heidelberg, and Univ. Regensburg[a], Germany (SPON: ENA).

Astrocytes are coupled by gap junctions consisting of cx43, which permits formation of a functional syncytium. In several non-neural cell types cx43 expression seems to be influenced by exogenous FGF-2, a potent multifunctional cytokine. FGF-2 is abundantly found in the CNS and predominatly expressed and released by astroglial cells. We have studied potential effects of FGF-2 on expression and function of cx43 in primary rat astroblasts cultured from different brain regions. Confluent cultures from newborn rat hemispheres, striatum and mesencephalon were maintained for two days with low serum and were then exposed to FGF-2 (10ng/ml) for 48 hr. FGF-2-treated cultures showed a reduction in cx43 protein in cortical and striatal astroblasts as compared to controls. In contrast, no such changes could be observed in astroblasts derived from mesencephalon. Junctional coupling was also affected, as demonstrated by spreading of the fluorescent dye Lucifer Yellow to adjacent cells after microinjection. The percentage of coupled cells was significantly reduced in FGF-2 treated cultures from cortex and striatum, but not of mesencephalon. Our results suggest a novel, probably regionally distinct role of FGF-2 for the regulation of astroglial coupling, which may also be relevant in vivo. We speculate that regulation of cell-cell communication may be one important physiological function of astroglia-derived FGF-2.

CHRONIC FGF-2 TREATMENT INCREASES NMDA RECEPTOR DESENSITIZATION IN CULTURED HIPPOCAMPAL NEURONS BY A CYCLOHEXIMIDE-SENSITIVE MECHANISM THAT REQUIRES CALCINEURIN ACTIVITY. Adam L. Boxer* and Edward B. Ziff. HHMI/Dept. of Biochemistry, NYU Medical Center, 550 First Ave., New York, NY 10016

To investigate whether growth factors could regulate the properties of ionotropic glutamate receptors, whole cell currents were evoked by kainate (100μM) or NMDA (1, 5, 10, 50 or 100μM) in cultures of E18 embryonic rat hippocampal neurons treated with FGF-2 (10 ng/ml; 4, 24 or 120 hrs.), Brain Derived Neurotrophic Factor (BDNF, 10 ng/ml; 120 hrs), or Neurotrophin 3 (NT-3, 10 ng/ml; 120 hrs.). Although initial NMDA-evoked current density dose-responses were similar in control and growth factor treated cells, FGF-2-treated cells displayed increased sensitivity to NMDA receptor desensitization (50 3 sec. pulses/25 min. of 10 μM glutamate or NMDA: peak current ratio to 50 μM test pulse: 1.037±0.107 for controls, 0.737±0.067 after 24 hrs. FGF-2, 0.635±0.079 after 120 hours; $p<.02$ at 24hrs., $p<.005$ at 120 hrs.). Desensitization was prevented by removal of extracellular calcium, bath application of the non-specific calcium channel blocker, Cd2+ (100μM), by the inclusion of inhibitors of the calcium-dependent phosphatase, calcineurin (PP2B) in the pipet, but not by specific inhibitors of N-, L- or P/Q-type calcium channels. The FGF-induced increase in desensitization was evident within 4 hours of FGF-2 treatment and was blocked by cycloheximide (1μM) treatment, suggesting that it may depend on changes in gene expression. Although the change in desensitization correlated with an increase in expression of the calbindin D28 protein in pyramidal neurons, there was no detectable change in the expression of NMDA receptor or PP2B subunits by RT-PCR and western analysis. Consistent with the calcium-dependence of the effect, The FGF-induced change in desensitization was greater in electrophysiologically-identified (kainate-evoked current rectification) interneurons, than in pyramidal cells. These data suggest that FGF-2 alters the ability of neurons to respond to pathological stimuli that increase intracellular calcium levels by two independent mechanisms: increased NMDA receptor desensitization in both pyramidal cells and interneurons and increased calcium buffering in pyramidal cells.

Induction of Tyrosine Hydroxylase in hNT Neurons. M. Schinstine*, N.D. Stull and L. Iacovitti. Dept. of Neurobiology & Anatomy, MCP/Hahnemann Univ., Philadelphia, PA 19102.

Previous studies in our laboratory have demonstrated that the combination of a growth factor, i.e., aFGF, bFGF, or BNDF, and an activating factor(s), e.g., catecholamines, IBMX, forskolin, and/or TPA, can induce the expression of tyrosine hydroxylase (TH) in non-catecholaminergic (CA), striatal neurons grown *in vitro*. In these cultures, it appears that aFGF, IBMX, forskolin, and TPA together elicit the greatest increase in the number of TH immunoreactive neurons. To date, we have been able to stimulate TH expression only in primary cell culture; experiments using a variety of striatal cell lines have not been successful. The ability to induce TH in non-CA cell lines may have great import to cell transplantation and developmental studies. In the present experiment, we have explored the possibility of inducing TH in neurons (hNT) that have been differentiated from NT2 human teratocarcinoma cells by retinoic acid. Our results indicate that aFGF, in concert with IBMX, forskolin, and/or TPA, upregulates the expression of TH in hNT cells. The magnitude of TH expression increases with increased time in culture, i.e., cultures maintained for 7 days are more immunoreactive for TH than cultures maintained overnight. hNT cells demonstrating intense TH immunoreactivity are typically pyramidal with long neuritic processes. There are few, if any, TH-positive neurons in control cultures. Importantly, undifferentiated NT2 cells did not exhibit TH immunoreactivty, nor could TH be induced with aFGF and activating factors. These results demonstrate that TH expression can be induced in newly differentiated human neurons. Further biochemical and molecular characterization will be presented.

MAXIMAL INDUCTION OF TYROSINE HYDROXYLASE IN STRIATAL NEURONS REQUIRES ACTIVATION OF MULTIPLE PATHWAYS. X. Du* and L. Iacovitti Dept. of Neurobiology and Anatomy, Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA. 19102

We have previously demonstrated that induction of the catecholamine (CA) biosynthetic enzyme tyrosine hydroxylase (TH) in cultured non-CA neurons from the mouse striatum requires the synergistic interaction of two partner substances; acidic fibroblast growth factor (aFGF) and a CA neurotransmitter. The intracellular pathways mediating these events are not yet understood. However, in cells where the TH gene is constituitively expressed (ie. PC12 cells), stimulation of cAMP-dependent protein kinase (PKA) and protein kinase C (PKC) are involved in the up-regulation of TH transcription. In this study, we therefore examined whether stimulation of PKA and PKC signaling pathways in the presence or absence of aFGF and/or DA leads to TH gene activation in striatal neurons. Cultures of E13 mouse striatum were grown one hour in defined medium prior to overnight treatment with aFGF (100ng/ml) and/or dopamine (DA) (20μM), the PKA activators forskolin (F; 50μM) and 3-Isobutyl-1-methylxanine (IBMX; 0.25mM) and the PKC activator 12-o-tetradecanoyl-phorbal-13-acetate (TPA; 200nM). In the absence of aFGF, no induction of TH was observed in cultures treated with any of the individual pathway activators. Activation of PKA and PKC pathways together yielded barely detectable (15%) induction; further supplementation with DA increased levels up to 30%. When aFGF was included with activators of 1 signaling pathway, TH induction increased to 45-55%. When 2 or more pathways were activated in the presence of aFGF, induction increased to maximal levels (70-80%). In all cases, induction was partially blocked by alpha-amanitin and completely inhibited by actinomycin D and cycloheximide. We conclude that TH transcription and translation can be initiated in striatal neurons via activation from a variety of different signaling pathways (PKA, PKC, DA) working in synergy with aFGF. Activation of multiple pathways simultaneously with aFGF yields maximal effects (Supported by NIH NS 24204).

INSULIN EFFECTS ON THE CONCENTRATION OF IRS-1 AND MAPK IN CULTURED FETAL RAT NEURONS. R. Schechter* and J. Gaskins. William K. Warren Medical Research Institute of the University of Oklahoma Health Sciences Center, Tulsa, OK 74136.

We studied the presence of insulin receptor substrate 1 (IRS-1) and mitogen activated protein kinase (MAPK) within the 19 day gestational age neuron and astrocyte cell cultures. The neurons were grown in defined media: DMEM/F12 with putrescine, transferrin, selenium, and progesterone. The astrocytes were grown in DMEM-10% fetal calf serum. The cells were lysed, and IRS-1 and MAPK were purified using Dynabeads-280 conjugated with goat anti-rabbit antibody (Dynal) coupled with rabbit anti-IRS-1 or MAPK (UBI). Western blot of the crude lysate and the purified proteins showed the presence of IRS-1 and MAPK within the fetal neuron and astrocyte cell cultures. Neuron cell cultures were stimulated with different concentrations of insulin -- 10ng, 100ng and 500 ng/ml -- and subjected to densitometry. A two fold increase of IRS-1 concentration was shown within the control and the 10ng/ml, but there was no difference among the insulin concentrations. Insulin at 5ng/ml was used to stimulate the fetal neuron cell cultures which were studied at different times (0, 30, 60, 90 and 120 minutes) for the presence of IRS-1 and MAPK. Results showed a significant decrease in the concentration of IRS-1 at 90 and 120 minutes compared to time 0 ($P<0.05$). A 40% decrease from time 0 was observed at 30 minutes with a return to 85% of baseline at 60 minutes. It decreased significantly at 90 (50%) and 120 (70%) minutes from time 0. No significant difference in the concentration of MAPK was observed at any time. Thus, IRS-1 and MAPK are present within the fetal neuron and astrocyte cell cultures, and we can hypothesize that insulin may regulate IRS-1, but not MAPK.

ESTROGEN AS NEUROTROPHIC FACTOR-INDUCER WITH EMPHASIS ON INSULIN-LIKE GROWTH FACTOR I. A. S. Shingo, J. Semba*, R. Miyoshi[1], E. Shimizu, S. Kito. The Univ. of the Air,Chiba, Japan 261, [1]Div. of Basic Med. Sciences, Royal Free Hospital Sch. of Med., London.

In our previous studies, it was revealed that estrogen increased a survival rate of cultured rat limbic neurons at concentrations of 10^{-9} M to 10^{-6} M. In relation with these results, the mechanism of estrogen's role as neurotrophic factor-inducer was studied being focused on insulin-like growth factor I (IGF-I) mRNA expression. A single injection of 500 μg/kg estradiol induced IGF-I mRNA in both cerebral cortex and hippocampus after 5 to 7 days. There were no significant expressions of IGF-II and hepatocyte growth factor (HGF) mRNAs. An intraperitoneal injection of 12mg/kg kainic acid caused estrogen receptor induction in the frontal cortex and hippocampus especially in the CA-3 region as observed by immunohistochemistry and *in situ* hybridization, while it caused no significant IGF-I mRNA expression. Nevertheless, coinjection of estrogen with kainic acid induced more intense and earlier expression of IGF-I mRNA than that observed by single injection of estradiol. These results indicated that estrogen played a role in neuronal plasticity at brain injuries through IGF-I mRNA expression.

This study was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, Japan.

IGF-1 TREATMENT PRIOR TO THE PERIOD OF PROGRAMMED CELL DEATH RESCUES LUMBAR SPINAL MOTONEURONS IN CHICK EMBRYOS. A.P.D'Costa,* S.Wang, D. Prevette and R.W. Oppenheim. Dept. of Neurobiology & Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27157.

After lumbar spinal motoneurons (MNs) become post-mitotic between E2 and E4.5, they extend axons toward and innervate skeletal muscle from E4.5-E6. Between E6 and E10, 50% of MNs undergo programmed cell death. Since insulin-like growth factor-1 (IGF-1) and IGF-1 receptors have been detected as early as E2, we examined the effect of IGF-1 treatment between E4 and E6 on later MN survival. IGF-1 was administered daily (5ug/inj) either from E4.5-E6 or E6-E9. Embryos were sacrificed on E10. MN counts revealed a 31% in the group treated from E6-9. A similar increase (28%) was also evident in the group treated from E4.5-E6 only. MN number on E6 was not changed with IGF-1 treatment. In another experiment, embryos were treated with daily injections of glial derived neurotrophic factor (GDNF), ciliary neurotrophic factor (CNTF) or brain-derived neurotrophic factor (BDNF) from E6-E9 with or without prior IGF-1 administration. Preliminary data revealed that MN number in embryos pretreated with IGF-1 were approximately 12% higher than treatment with BDNF and CNTF alone. These results suggests that IGF-1 may play a role in the differentiation of spinal MNs by increasing trophic factor responsiveness. Studies are in progress to examine the effects of early IGF-1 treatment on muscle innervation patterns and synapse formation. (Supported by NIH NS 20402)

GLYCOSAMINOGLYCAN AND INSULIN-LIKE GROWTH FACTOR TREATMENT OF RAT NEONATAL PERIPHERAL NERVE LESIONS. A. M. Di Giulio*, L. Vergani, A.Torsello, L. Cattaneo, E.E. Muller and A. Gorio, Dept. Medical Pharmacology, University of Milano, Via Vanvitelli 32, Milano, Italy

Left sciatic nerve of neonate rats was crushed 48 hours after birth, a group of animals was treated daily, starting 48 hours after lesioning, with glycosaminoglycans (GAGS) (5 mg/kg), another one with insulin-like growth factor I (IGF-I) (20 microg/kg) and the last one with saline.We assessed EDL reinnervation 20days later. Combined AChE-silver impregnation staining showed that in saline treated rats 62% of muscle fibres were reinnervated, while 75% and 92% were reinnervated in IGF-I and GAGS treated rats respectively. Muscle fibre morphometry revealed a high percentage of small atrophic fibers in the denervated muscle of saline treated rats, such number was reduced significantly by IGF-I treatment. GAGS promoted the recovery of normal muscle trophism significantly better than with IGF-I. Both IGF-I and GAGS treatments increase NGF mRNA abundance in lesioned nerves and denervated EDL fast muscle. Also IGF-Ia and IGF-Ib mRNA increased in denervated EDL of drug treated rats. No changes in trophic factor mRNA were observed in denervated soleus slow muscle. Both agents markedly increased IGF-I levels in serum and in denervated muscles, also insulin-like growth factor binding proteins 3 and 1 were augmented by IGF-I and GAGS. Protein mono-ADP-ribosylation is affected by both agents only in the fast muscle. In conclusion we observed that both IGF-I and GAGS promoted muscle reinnervation and trophism after neonatal sciatic nerve injury, however GAGS treatment showed superior results compared to IGF-I.

THE ROLE OF IGF-1 IN PERIPHERAL NERVE REGENERATION: STUDIES IN IGF-1 TRANSGENIC MICE. E. D. Rabinovsky*, M.M. Kattash, S.M. Shenaq, F. DeMayo, R. Schwartz. Div. Plastic Surgery, and Dept. Cell Biology, Baylor College of Medicine, Houston TX. 77030

Insulin-like growth factor (IGF) is important for the development and regeneration of muscle and nerves. To study the effect of local expression of IGF-1 in muscle on peripheral nerve regeneration, IGF-1 transgenic mice were engineered to overexpress IGF-1 in skeletal muscle using the alpha-skeletal actin promoter. The sciatic nerves of age and weight matched IGF-1 transgenic mice (IGF-1 positive [N=8]) and littermate controls (IGF-1 negative [N=8]) were unilaterally crushed. The animals were evaluated for nerve conduction and muscle weight after 2, 3, and 4 weeks. The non-crushed side served as internal controls. Nerve conduction in non-injured nerves averaged 35.5 +\- 5.0 m/s. In both nerve injured transgenic and control mice, nerve conduction was not evident and gastrocnemius, soleus and tibialis muscle decreased 50%. After 3 weeks, nerve conduction in the gastrocnemius and tibialis muscles was 10.6+\- 2.8 m/s in IGF-1 transgenic mice, however nerve conduction was not detected in nerve injured controls. Muscle weight in IGF-1 transgenic mice were 80% of non-injured controls in IGF-1 transgenic animals compared to 60% in nerve injured control mice. Four weeks after nerve crush, IGF-1 transgenic mice had conduction rates of 22.5 +\- 3.4 m/s while non-transgenic controls had rates of 12.0 +\- 3.5 m/s. Muscle weights in nerve injured IGF-1 transgenic animals were 90% of non-injured muscle compared to 75% in controls mice. These studies show that local overexpression of IGF-1 in skeletal muscle can enhance peripheral nerve regeneration. We postulate that IGF-1 may be affecting regeneration by direct action on muscle or by retrograde transport to nerve cell bodies.

THE EFFECTS OF IGF-I ON THE SURVIVAL AND DIFFERENTIATION OF CEREBELLAR GRANULE CELLS. X Lin* and R. F. Bulleit. Dept. of Pharmacology, Univ. of Maryland Sch. of Med., Baltimore MD 21201.

Insulin-like growth factor I (IGF-I) may provide trophic support for developing cerebellar granule neurons. We examined the effects of IGF-I on the survival and differentiation of purified granule cells maintained *in vitro*. Granule cells, from postnatal day 7 CD-1 mice, were cultured in minimal medium consisting of minimal essential medium with 6mg/ml glucose (MEM). IGF-I or other growth factors were added in this minimal medium to test their effects on the survival and differentiation of granule cells. 40 ng/ml IGF-I was found to have a significant effect in promoting granule cell survival, with ~70% of cells surviving after 6 days in culture. Cells maintained for 6 days in MEM alone or with the addition of 40 ng/ml BDNF, or bFGF didn't survive. Differentiated neurons continued to need IGF-I for their survival, since withdrawal of IGF-I at day 5 rapidly led to granule cell death. IGF-I also appears to stimulate cell division. IGF-I increased ^{3}H-thymidine incorporation over the first 24 hours of culture. These observations suggests that the number of live cells in IGF-I treated cultures may be a product of both the stimulation of cell division and the promotion of cell survival. To investigate the role IGF-I plays in granule cell differentiation, we examined RNA expression for the transcription factor MEF2A and the $GABA_A$ receptor $\alpha 6$ subunit, two granuel neuron markers. In IGF-I treated cultures there is an increase in the expression of MEF2A and GABAα6 over 6 day in culture similar to the increase observed during *in vivo* cerebellar development. To test between an instructive and permissive role for IGF-I on differentiation we are using N-acetyl cysteine (NAC; 5 mM), an antioxidant, to maintain cell survival in the absence of IGF-I. Can granule cells in the absence of IGF-1 express MEF2A and GABAα6?

DEVELOPMENTAL STAGE-DEPENDENT CONTROL OF CEREBELLAR CELL POPULATIONS BY INSULIN-LIKE GROWTH FACTOR I L.Torres-Aleman* and M.P. Nieto-Bona Cajal Institute, CSIC. 28002 Madrid. Spain.

Insulin-like growth factor I (IGF-I) is present in cerebellum early in development. In vitro developing cerebellar cultures release increasing amounts of IGF-I throughout time. Although IGF-I is a potent growth factor for cultured cerebellar neurons, its possible physiological significance is not yet established. Thus, we investigated the role of IGF-I in the control of the development of the different cell types present in the cultures. Using antisense oligonucleotides of IGF-I that partially blocked endogenous IGF-I synthesis, we found that Purkinje cell differentiation was blocked at early but not at later stages in vitro. Antisense treatment of the cultures at times where glial cells start to grow block mitogenesis of presumptive glioblasts and elicited a marked decrease in the number of early differentiating astrocytes. While addition of IGF-I to the cultures at early stages increased the number of all types of dividing cells, induction of c-Fos expression by IGF-I was observed in IGF-I-sensitive dividing glioblasts but not in neurons, in where basal levels of c-Fos expression were already high. Neither the mitogenic effects of IGF-I nor the induction of c-Fos in glioblasts was seen at later stages in vitro. Thus, although cerebellar cells are continuously exposed to IGF-I, the trophic effects of IGF-I on each type of target cell are limited to specific periods of their development.

INSULIN-LIKE GROWTH FACTOR-I AS A PROTECTIVE SIGNAL FOR APOPTOSIS OF DEVELOPING CEREBELLAR GRANULE NEURONS. M. Tanaka[1], T. Nagatsu[2,*] and T. Marunouchi[1]
[1]Div. of Cell Biol., [2]Div. of Mol. Gen. II, Inst. for Comprehens. Med. Sci., Fujita Health Univ., Aichi 470-11, Japan.

Insulin-like growth factor (IGF)-I is thought to play some important roles in brain development, but its precise functions and underlying mechanisms remain unclear. In the present study, we examined the effects of IGF-I on cell death of developing granule neurons using the organotypic slice culture system of 9-day-old rat cerebellum (Brain Res. 641:319-327, 1994). Instead of intact IGF-I, we used des (1-3) IGF-I which lacks the first three amino acids and has a lower affinity for IGF binding proteins (IGFBPs), in order that the applied IGF-I might not inactivated due to the binding to IGFBPs derived from horse serum supplemented in the culture medium. In the absence of des (1-3) IGF-I, apoptosis of granule neurons in the external granular layer (EGL) occurred after active proliferation during the early culture period (Neurosci. Lett. 199:37-40, 1995). In contrast, such apoptosis was scarcely observed in the internal granular layer. The amount of the apoptosis of EGL neurons peaked at 3 days in vitro (DIV). Des (1-3) IGF-I (65-650 ng/ml) prevented this apoptosis. Intact IGF-I had only a weak effect and IGF-II had no effect in the prevention of this apoptosis. Des (1-3) IGF-I did not significantly affect the proliferation of granule neurons during the early culture period. At 3 DIV with des (1-3) IGF-I, the rescued EGL neurons were no longer proliferative and expressed the marker proteins for differentiating granule neurons. Thus, des (1-3) IGF-I prevented apoptosis of developing granule neurons at some specific time in final cell division and/or the postmitotic and premigratory stage. Furthermore, high concentration (25 mM) of K^+, which is known to exert a protective effect on apoptosis of granule neurons in dissociated culture, could not mimic the effect of des (1-3) IGF-I. These results suggest that des (1-3) IGF-I may prevent apoptosis of developing granule neurons through a distinct mechanism from that of high K^+ at the specific stage in their development. (Supported by a grant-in-aid from Fujita Health Univ.)

IGF-1 ENHANCES RECOVERY OF NERVE FUNCTION AND INCREASES IGFBP2 AFTER BILATERAL CRUSH OF THE SCIATIC NERVE BY AN INSULIN RECEPTOR INDEPENDENT MECHANISM. P.C. Contreras*, M. Miller and R.V. Bhat. Cephalon Inc., Dept. of Pharmacology, West Chester, PA 19380. Recent evidence suggests that repeated injections of 1 mg/kg of insulin-like growth factor-1 (IGF-1) is maximally efficacious at enhancing the recovery of nerve function after bilateral crushes of sciatic nerves. The majority of IGF-1 responses are mediated via the Type I IGF receptor, however IGF-1 also has low affinity for the insulin receptor. To determine the functional specificity of IGF-1 response, we have compared the effects of chronic administration of rhIGF-1 with that of insulin in mice with bilateral crushes of sciatic nerves. Chronic administration of 1 mg/kg of rhIGF-1 to these mice caused a comparable decrease in plasma glucose to 1 U/kg of insulin with maximal effects at 0.5h after the last of a series (17) of injections. However, chronic administration of rhIGF-1 (1 mg/kg), but not insulin (1 and 10 U/kg), enhanced recovery of nerve function as measured by the ability to grip an inverted screen. Since we have previously shown that efficacious doses of rhIGF-1 increase plasma levels of IGFBP2, we next determined whether insulin mimics this effect. An increase in IGFBP2 was observed in mice receiving rhIGF-1 but not insulin indicating that this response was mediated via the IGF-1 receptor and not the insulin receptor. Taken together, our results suggest 1) a decrease in plasma glucose is not a prerequisite for neuroprotective functions and 2) the beneficial effects observed on injured sciatic nerves are specific to rhIGF-1 and are mediated via the IGF-1 receptor and not the insulin receptor.

768.28

rhIGF-1 Protects Against Motoneuron Loss Following Nerve Transection in Adult Mice. J.A. Gruner,* L. Wagner, A.Y. Chiu#, M.S. Miller, P.C. Contreras. Dept. of Pharmacology, Cephalon, Inc., West Chester, PA 19380; #Div. Neurosciences, City of Hope Med. Ctr., Duarte, CA.

IGF-1 prevents the loss of developing neurons both *in vivo* and *in vitro*. In adult animals, it enhances sprouting, nerve regeneration, and functional recovery in models of neuropathy, and is clinically beneficial in the treatment of ALS. Here we report that IGF-1 can also promote survival of motoneurons (MNs) in adult rodents. We chose to evaluate the efficacy of rhIGF-1 on hypoglossal (HG) MNs. Chiu previously found that approximately 50% of hypoglossal (HG) MNs are lost following transection of the HG nerve in adult mice. The time course of MN loss was initially established by sacrificing mice up to 21 days following transection. Mature (55-65 days) female B6SJLF-1/J mice were anesthetized and a segment of the HG nerve removed to prevent regeneration. Sections through the HG nucleus were stained with cresyl violet and neurons with visible nucleoli were counted. Cell loss was assessed by calculating the percent cell reduction on the lesioned side relative to the intact side. MN losses at 1, 3, 7, 14, and 21 days following lesion were (mean ±SEM) -5±2%, 1±2%, 23±2%, 46±4%, and 53±4%, respectively. Thus maximal cell loss occurred between 3 and 14 days following transection and plateaued thereafter.

To evaluate the potential of IGF-1 to promote MN survival, 2 groups of mice were administered rhIGF-1 as either a single dose (200 μg in gelfoam at the site of transection), or by the more clinically relevant route of daily injections at 1 mg/kg/d, sc. for 2 wks. A third group received vehicle by daily sc. injection. All 3 groups were sacrificed 2 wks. post lesion. MN loss was significantly reduced by both the single and daily sc. treatments (30±2% and 33±2%, respectively) relative to vehicle (46±4%; $p \leq 0.01$). Thus, rhIGF-1 rescued approximately 30% of HG MNs in this *in vivo* model of neuronal loss in adult mice. These data suggest that the beneficial effects of IGF-1 in ALS patients could involve preventing MN loss.

ANOMALOUS ASTROCYTE DEVELOPMENT AND APOPTOSIS IN EGF RECEPTOR KNOCKOUT MOUSE BRAIN. R.J. Hussain[1], L.A. Chan[1], K.J. Tatsukawa[1], P.J. Miettinen[2,3,4], J. Wiesen[4,5], Z. Werb[2,3,4,5], R. Derynck[2,3,4,6], and H.J. Kornblum[1*], Depts. of [1]Molec. and Med. Pharm. and Peds., UCLA, LA, CA 90095, [2]Growth and Dev., [3]Anat., [4]Dev. Biol., [5]Cell Biol., and [6]Lab. of Radiobiol. and Environ. Health, UCSF, CA 94143-0640.

Previous studies have demonstrated that ligands acting at the epidermal growth factor receptor (EGF-R) promote astrocyte proliferation, neuronal survival and differentiation, and neural stem cell proliferation *in vitro*. However, the role of the EGF-R *in vivo* remains unclear. In order to study the function of EGF-R in astrocyte development, we examined the expression of glial fibrillary acidic protein (GFAP) mRNA by *in situ* hybridization, using ^{35}S-labeled cRNA, and protein expression by immunocytochemistry in postnatal EGF-R knockout and littermate control mice. P0 knockout mice expressed neither GFAP mRNA nor protein in the glia limitans, whereas controls did. From P3 onwards, knockout mice displayed some hybridization in this region but to a lesser degree than did controls. By P6, localized accumulation of GFAP mRNA and protein appeared in the piriform cortex of the knockouts and at later ages, astrocytes were seen to accumulate in the neocortex. Altered GFAP mRNA and protein expression in the olfactory bulb was also observed in the knockouts. By P6 and older, dense expression of mRNA was seen in the internal granule cell layer of the olfactory bulb of the knockouts; little hybridization was present in this area in controls. In order to determine whether this accumulation of astrocytes was the result of gliosis due to programmed cell death, we tested for apoptosis using TUNEL labeling. By P6, TUNEL-positive cells were present in the regions of anomalous GFAP expression in the piriform cortex, neocortex, and olfactory bulb of the knockout mice. Because olfactory internal granule cells are GABAergic, we examined the developmental expression of GAD67 mRNA in the olfactory bulb of wild type and knockout mice. While distribution of GAD67 mRNA was similar in wildtype and knockout mice on P1, GAD67 mRNA was noticeably diminished in the knockout olfactory bulb granule cell layer by P7. These studies demonstrate that: 1) EGF-R activation is not absolutely required for the genesis of astrocytes in the central nervous system. However, EGF-R expression may be important in the timing of normal astrocyte development. 2) Stimulation of EGF-R by its ligands may be required for cell survival in multiple brain areas, including GABAergic internal granule cell neurons of the olfactory bulb. (Supported by NIH/NINDS and the Dept. of Energy)

NEUROTROPHIC FACTORS: BIOLOGIC EFFECTS—CNTF, LIF, AND INTERLEUKINS

769.1

LEUKEMIA INHIBITORY FACTOR IS AN AUTOCRINE FACTOR FOR SYMPATHETIC NEURONS. J. G. Cheng* and P. H. Patterson. Division of Biology, Caltech, Pasadena, CA 91125.

It is known that increasing cell density or reducing the frequency of medium exchange can accelerate the phenotype switch of cultured rat sympathetic neurons. This switch is reflected by the upregulation of mRNAs for choline acetyltransferase and several neuropeptides. The mRNA profile under high cell density conditions is similar to that of neurons treated with neuropoietic cytokines such as leukemia inhibitory factor (LIF). Since application of anti-LIF antibodies to high density cultures can inhibit this phenotypic switch, we examined the expression of LIF in primary neuronal cultures. LIF mRNA can easily be detected by RT-PCR. In addition, Western blot analysis reveals LIF in the neuronal lysate as well as in conditioned medium. LIF *in situ* hybridization in conjunction with MAP2 immunostaining indicates that most cells expressing LIF mRNA are neurons. It is also of interest that not all MAP2$^+$ neurons are LIF$^+$. Since the sympathetic neurons contain LIF receptors, it is likely that LIF can act as an autocrine factor.

REGULATION OF NICOTINIC RECEPTOR SUBUNIT TRANSCRIPTS IN THE SUPERIOR CERVICAL GANGLION (SCG) AFTER AXOTOMY. Y. Zhou, E. Deneris and R. E. Zigmond*. Dept of Neurosciences, Case Western Reserve University, Cleveland, OH 44106-4975

Synaptic transmission in the SCG is primarily mediated by acetylcholine acting via nicotinic cholinergic receptors. Five nicotinic receptor subunits, α3, α5, α7, β2 and β4, are expressed by postganglionic neurons. In a number of instances in the nervous system the levels of molecules related to synaptic transmission are decreased after axotomy, whereas levels of molecules involved in regeneration are increased. In this study, we investigated the regulation of nicotinic receptor subunit expression in the rat SCG after axotomy. By Northern blot analysis, it was found that levels of α3, α5, α7 and β4 transcripts decreased dramatically. The decrease began within hours after the internal carotid nerve and the external carotid nerve were cut, and reached their lowest levels (< 20% of control level) at 2- 3 days after treatment. The expression gradually recovered, approaching more than 50% of control levels by 14 days. In contrast, the β2 transcripts remained relatively unchanged after axotomy. When SCGs were dissected and placed into organ culture for 48 hours, the levels of the same four subunit transcripts, α3, α5, α7 and β4, decreased even further than that after axotomy in vivo. Interestingly, the level of β2 transcripts remained unchanged even after explantation. These results indicate that the expression of nicotinic receptor subunit transcripts is differentially regulated after axotomy.

Both LIF and NGF have been shown to play a role in the regulation of gene expression in SCG neurons. In LIF knock-out mice, a decrease in the expression of the receptor subunit α3, α7 and β4 transcripts was also observed after axotomy, although the decrease appeared smaller than that in wild-type mice. In organ culture of rat SCG, 200ng/ml NGF partially reversed the decrease of α3, α5, α7 and β4 subunit transcripts. It appears that while both LIF and NGF may play a role in the regulation of the subunits, other factors are also involved. Supported by NS12651.

769.3

REGULATION OF GALANIN AND NEUROPEPTIDE Y (NPY) IN INTACT SYMPATHETIC NEURONS BY NERVE GROWTH FACTOR (NGF) AND LEUKEMIA INHIBITORY FACTOR (LIF). A. M. Shadiack*, S. A. Vaccariello and R. E. Zigmond. Dept. of Neurosciences, Case Western Reserve University, Cleveland, OH 44106

Adult sympathetic neurons exhibit neurotransmitter plasticity in response to axotomy. The expression of NPY and tyrosine hydroxylase (TH, the rate-limiting biosynthetic enzyme for norepinephrine) decreases, while the expression of galanin and vasoactive intestinal peptide (VIP) increases. The injury-induced cytokine LIF plays a role in these changes. We also have shown that blockade of the target-derived neurotrophin NGF by treatment with an NGF antiserum (αNGF) *in vivo*, by itself, can induce neuropeptide changes in intact rat sympathetic and sensory neurons qualitatively similar to those produced by axotomy. To ascertain if LIF plays a role in the effects of αNGF in the superior cervical sympathetic ganglion (SCG), we treated normal mice or LIF knock-out mice with αNGF by systemic injection. Although levels of TH and galanin mRNA were unaffected after αNGF treatment in both groups, levels of NPY mRNA were lower in the wild-type as well as the LIF$^-$ mice. These data suggest that the decrease in the expression of NPY due to NGF blockade is not mediated by LIF. To see what effects NGF administration has on NPY, we placed rat SCG in culture (a condition in which axotomy-induced phenotypic changes occur) with or without NGF. The levels of NPY mRNA in the presence of NGF remained higher than in the absence of NGF but did not equal the levels in uncultured SCG, suggesting that factors other than NGF play a role in NPY regulation *in vivo*.

While our lab has shown that exogenous LIF administration further increases the peptide changes after axotomy, it has little, if any, effect on peptide expression in intact sympathetic neurons. To determine if blockade of NGF increases the responsiveness of intact neurons to LIF, we exposed SCG of rats injected with αNGF to LIF. Levels of galanin mRNA were 2.4-fold higher in the αNGF/LIF-treated as compared to αNGF/placebo-treated SCG. Similar treatment did not influence NPY mRNA levels. These data bring to light a novel interaction between LIF and NGF influencing neuropeptide expression. Supported by NS17512 and NS12651.

769.4

INHIBITION OF GALANIN EXPRESSION IN EXPLANTS OF ADULT SUPERIOR CERVICAL GANGLIA (SCG) BY AGENTS THAT ELEVATE CYCLIC AMP. R .P. Mohney* and R. E. Zigmond. Dept. of Neurosciences, Case Western Reserve University, Cleveland, Ohio 44106

The neuropeptides galanin and VIP are induced in adult rat SCG under many of the same conditions. For example, both peptides increase in sympathetic neurons after explantation, after axotomy, and after administration of 6-hydroxydopamine or antiserum raised against NGF. The rat VIP gene contains a cyclic AMP (cAMP)-responsive element, and we have previously shown that VIP expression in adult rat SCG explants is increased by agents that elevate cAMP within this ganglion. We now report that these agents have the opposite effect on galanin gene expression.

Prior to being placed in culture, ganglia contain only very low levels of galanin-immunoreactivity (IR) as measured by radioimmunoassay, whereas ganglia cultured for 48 h in defined medium contain high levels of galanin-IR. When ganglion explants were treated with forskolin, dibutyryl cAMP, VIP, or secretin (all of which elevate cAMP levels in the SCG), levels of galanin-IR were reduced 45-80% compared to those found in control cultures. By Northern blot analysis, levels of galanin mRNA in ganglia cultured for 24 h in the presence of forskolin, VIP, or dibutyryl cAMP were reduced approximately two-fold compared to control cultures. These observations suggest that elevations in cAMP levels are capable of inhibiting the normal expression of galanin peptide and mRNA in cultured sympathetic neurons, and are in apparent contrast to data reported by others using primary cultures of bovine chromaffin cells in which galanin protein and mRNA are upregulated in response to stimulation with forskolin. Both the human and bovine galanin gene and upstream sequences have been cloned, but neither has been shown to contain a classical cAMP-response element. We conclude that the molecular mechanisms underlying the regulation of the galanin gene in response to cAMP-elevating agents in rat sympathetic neurons are distinct from those in bovine chromaffin cells. Furthermore, these data demonstrate that the expression of galanin and VIP in cultured sympathetic neurons is differentially modulated by agents that increase cAMP levels. Supported by NS17512.

LIF IS RETROGRADELY TRANSPORTED BY SMALL DIAMETER SENSORY NEURONS *IN VIVO*. S.W.N.Thompson, A.B.Vernallis†, J.K.Heath†, and J.V.Priestley*. Division of Physiology, UMDS, St. Thomas' Hospital, Lambeth Palace Rd. London SE1 7EH UK and † School of Biochemistry, University of Birmingham, Birmingham B15 2TT UK.

Leukemia inhibitory factor (LIF), a neuroactive cytokine, has been shown to be rapidly upregulated at the site of a peripheral nerve injury and exogenous application will produce a reduction in the mechanical threshold of the hindpaw flexor reflex in the rat. Although LIF is known to be retrogradely transported following intraneural or subcutaneous injection, the population of sensory neurones responsive to LIF remains unclear. To determine the population of LIF-responsive neurones in the adult rat DRG we have demonstrated retrograde axonal transport of biotinylated LIF. Two microlitres of PBS containing 36ng of cys-hLIF-biotin-BMCC together with 2μL PBS or competing agent was injected into the sciatic nerve at the level of the obturator tendon. Following a 24 hr recovery period animals were deeply anaesthetised, perfused transcardially with 4% paraformaldehyde and the L4 and L5 dorsal root ganglia removed. Ganglia were cryoprotected with 20% sucrose and 8μm sections cut on a cyrostat. Sections were incubated with Avidin-Biotin Complex and the DAB reaction product was used to reveal LIF responsive neurones. 24% of neurones within the L4 and L5 DRG exhibited retrograde transport of Biotin-LIF. DAB staining was inhibited by a 400 fold excess of unlabelled LIF indicating a specific receptor-mediated mechanism. The cell-size distribution of neuronal profiles indicated the majority of retrogradely labelled cells were small (mean diameter 20.1±0.52μm, n=157. 87% with diameter<30μm). These data suggest that LIF may interact with small diameter sensory neurones and contribute to mechanisms of neuropathic injuries.

LIF INDUCES GAL BUT NOT VIP-IMMUNOREACTIVITY IN SMALL DIAMETER RAT SENSORY NEURONS *IN VIVO*. A.Southall, A.B.Vernallis†, J.K.Heath†, and S.W.N.Thompson*. Division of Physiology, UMDS, St. Thomas' Hospital, Lambeth Palace Rd. London SE1 7EH UK and † School of Biochemistry, University of Birmingham, Birmingham B15 2TT UK.

Leukemia inhibitory factor (LIF) is retrogradely transported *in vivo* following intraneural or subcutaneous injection and will influence neuropeptide content of rat DRG neurones *in vitro*. It is unclear however if LIF will induce neuropeptide expression in sensory neurons *in vivo* and if this may contribute to changes in neuropeptide levels following axotomy. We have investigated the induction of galanin (GAL) and vasoactive intestinal polypeptide (VIP) immunoreactivity (IR) in the L4 and L5 DRG following a single sciatic intraneural injection of LIF. Results were compared with the induction of these peptides following L4 and L5 spinal nerve ligation. GAL-IR was observed 1,2,3 and 5 days following spinal nerve ligation. GAL-IR was present in small and medium diameter neurons (29% of neurons, mean diameter 22.7±0.3μm, 3 days post ligation). In uninjured animals GAL-IR was present 1,2 and 3 days following 500ng rhLIF injection. The percentage of neurones exhibiting GAL-IR (17%) and their size distribution following LIF injection was significantly different compared with spinal nerve ligation (20.4±0.3μm, $p<0.0001$, *t-test*, 3 days post ligation). VIP-IR was confined to small diameter neurones following spinal nerve ligation (22% of total population, 5 days post ligation). VIP-IR was not detected in uninjured animals up to three days following LIF injection. Neither sham ligation nor vehicle injection raised the levels of GAL-IR or VIP-IR above baseline levels at any time point. These results suggest that the upregulation of LIF which occurs following peripheral nerve injury may contribute to the induction of GAL-IR but not VIP-IR in sensory neurons *in vivo*. Thus increased LIF levels alone appear insufficient to account for axotomy-induced alterations in neuropeptide levels in sensory neurons *in vivo*.

Adenoviral Gene Transfer to Enhance the Survival and Differentiation of Sympathoadrenal Precursor Cells. C.R. Brunetti and L.C. Doering*. Institute of Molecular Biology and Division of Anatomy, McMaster University, Hamilton, Ontario L8N 3Z5 Canada

Our laboratory is studying genetic modifications by adenoviral (Ad) expression vectors that drive the viability and maturation of neural precursor cells. One type of cell under study includes the MAH cell - a sympathoadrenal precursor cell immortalized with a v-*myc* oncogene.

A number of Ad expression constructs including Ad5-βgal (reporter gene system), Ad5-CNTF (secreted ciliary neurotrophic factor) and Ad-p75 (human neurotrophin receptor, gift from M.V. Chao) were used to study the efficiency of infection and the patterns of transgene expression in MAH cells grown in culture.

After 24 hours post-infection with Ad5-CNTF, 5.0% of MAH cells showed intense expression of CNTF. Differentiated cells with large somas and processes similar to sympathetic neurons were observed. Immunoprecipitation studies indicated that infected MAH cells also synthesize and secrete CNTF into the tissue culture media. Experiments are in progress to assess the time course and features of differentiation in MAH cells that overexpress the human p75 low affinity NGF receptor.

Although adenovirus can infect nearly 100% of MAH cells in culture, expression of the gene product is variable - the level of transgene signal and the number of cells expressing high amounts of the gene product show considerable variation according to the vector used.

DIFFERENCES OCCUR IN THE REGENERATIVE RESPONSE TO GROWTH FACTORS PROVIDED AFTER AN ACUTE OR CHRONIC SPINAL CORD INJURY J.H. Ye and J.D. Houle*, Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR. 72205

Axon regeneration by chronically injured supraspinal neurons can be enhanced by exposure to growth factors (Ye and Houle,'96). The present study tested whether acute treatment with one factor, followed later by a second factor, could promote regeneration by more neurons. After a C3 hemi-section in adult rats, gel foam saturated with ciliary neurotrophic factor (CNTF) and True Blue (TB) was placed into the cavity and replaced with fresh factor on day 4. On days 28 and 31 either CNTF or basic fibroblast growth factor (bFGF) saturated gel foam was placed into the cavity. On day 35 an autologous peripheral nerve graft was apposed to the rostral cavity wall. Four weeks later the distal graft end was exposed to Nuclear Yellow (NY). Animals were sacrificed 2 days later and serial sections through the brain were examined for double labeled (TB+NY) neurons. The total number of regenerating neurons was significantly increased when CNTF was pro-vided acutely, followed by a delayed treatment with bFGF (CNTF/bFGF), compared to only a delayed treatment with bFGF (-/bFGF). An enhanced regenerative response by neurons of the reticular formation, raphe, vestib-ular nuclei and locus coeruleus was observed. The regenerative response to acute and delayed treatment with CNTF (CNTF/CNTF) or bFGF (bFGF/bFGF) was not different from delayed treatments only (-/CNTF or -/bFGF, respectively). These results indicate beneficial effects when two different factors are provided in a staggered treatment pattern. Immediate treatment with CNTF may stabilize injured neurons thus enhancing the regenerative response to later treatment with bFGF. CNTF was supplied by Regeneron Pharmaceuticals, Inc. Supported by NIH NS26380.

TRANSGENIC OVEREXPRESSION OF CNTF PREVENTS AXOTOMY INDUCED DEATH OF CORTICOSPINAL NEURONS. J.T. Henderson#, K.L. Fernandes, J.C. Roder# and W. Tetzlaff*. Depts. of Zoology and Surgery, Univ. of British Columbia, Vancouver, BC, V6T 1Z4 and #Samuel Lunenfeld Institute, Toronto, Ont, M5G 2H8.

We have previously shown that axotomy of rat corticospinal neurons (CSN) in subcortical layers leads to degeneration of 40-50% of CSN within 7 days. This could be prevented by exogenous application of BDNF or NT-3 (Giehl and Tetzlaff, Eur. J. Neurosci. June 1996), as well as CNTF. We have now tested whether transgenic murine lines expressing CNTF show increased survival of axotomized CSN neurons. Transgenic line 6 expresses a secreted form of CNTF from the NSE promoter, line 10 a secreted form of CNTF from the GFAP promoter, and line 11 a non-secretory CNTF from the actin promoter. For positive identification of CSN Fast Blue was injected into the corticospinal tract of the cervical spinal cord. 7 to 14 days later the axons of the CSN were axotomized at subcortical level with a stereotaxic wire knife. Fast Blue filled neuronal profiles, larger than 5 μm diameter, were counted in every 4th 20 μm section through an area extending 2 mm in an anterior-posterior direction through the site of the lesion. There was no obvious difference in the absolute number of CSN on the side contralateral to injury between the different transgenic groups and control animals. Both transgenic as well as control animals showed cellular atrophy of the axotomized CSN. Cell counts indicate that line 11 mice expressing actin-driven CNTF (non-secretory) showed a mean CSN survival of 84 % (n=2). In contrast, heterozygous animals with lower levels of transgene expression showed a mean survival of 71.5 % of corticospinal neurons (n=4). Mice from line 6 with NSE-driven CNTF (secretory) showed no significant rescue effect (64.7 %, n=3). Line 10 has not yet been analyzed. It remains to be shown whether these data are corroborated by different numbers of apoptotic cell nuclei. This study suggests that "non-secretory" CNTF expression may convey protection to but does not prevent atrophy of CSN. Supported by MRC of Canada, the Neuroscience Network, and the Rick Hansen M.I.M. Foundation.

APOLIPOPROTEIN E3 BINDS TO AND POTENTIATES THE BIOLOGIC ACTIVITY OF CILIARY NEUROTROPHIC FACTOR. C. R. Gutman*, K. H. Weisgraber[Ψ], W. J. Strittmatter[§] and W. D. Matthew. Dept. of Neurobiology and [§]Depts. of Medicine (Neurology) and Neuroscience, Joseph and Kathleen Bryan Alzheimer's Disease Research Ctr, Duke Univ. Med. Ctr., Durham, NC 27710; [Ψ]Gladstone Inst. of Cardiovascular Disease, Cardiovascular Research Inst., Dept. of Pathology, Univ. of San Francisco, CA 94140

The central nervous system responds to injury with increased local expression of ciliary neurotrophic factor (CNTF) and apolipoprotein E (apoE). CNTF and apoE share several similar properties including four-helix bundle tertiary structures and the ability to form homodimers. These similarities led us to determine whether CNTF and apoE form a heterodimer and whether apoE modulates the activity of CNTF. Using in vitro gel shift assays we have shown that apoE3 forms a high avidity complex with recombinant human CNTF (generously provided by Regeneron Pharmaceuticals). This interaction is isoform specific: apoE3 forms an SDS-stable complex with CNTF; apoE4 does not. The apoE3 isoform is distinguished from the apoE4 isoform by a cysteine-arginine substitution at residue 112. We next examined the effect of apoE on the survival promoting activity of CNTF in serum-free hippocampal cultures. As previously reported, apoE alone promotes the survival of hippocampal neurons (Huang et al., 1995). In addition, we have demonstrated that apoE3 potentiates the survival promoting activity of CNTF for hippocampal neurons. We are currently studying the in vitro effects of apoE4 on neuronal survival. *Supported by: the Joseph and Kathleen Bryan Research Foundation to C.R.G.; N.H.L.B.I. CARDIOTROPHIN-1 (CT-1), A CYTOKINE SECRETED BY EMBRYONIC MUSCLE, SUPPORTS LONG-TERM SURVIVAL OF A SUB-POPULATION OF MOTONEURONS C.E. Henderson*, V. Arce, T. Swanson[1], R. Vejsada[1], R.A. Pollock, M. Armanini[2], K. Dudley, H. Phillips[2], A. Rosenthal[2], A. Kato[3], D. Pennica[1]. INSERM U.382, IBDM, Campus de Luminy - Case 907, 13288 MARSEILLE Cedex 09, France; Depts. Molecular Biology[1] and Neuroscience[2], Genentech, Inc., So. San Francisco, CA 94080; Div. Neuromus. Res. & Pharmacol.[3], Geneva, Switzerland.

Cardiotrophin-1 (CT-1), a recently-discovered cytokine related to CNTF and LIF, is expressed at high levels in embryonic limb bud. Furthermore, it is synthesized and secreted by differentiated myotubes in culture. Using a new culture system for purified spinal motoneurons from E14 rat embryos, recombinant muCT-1 strongly enhanced their survival (EC_{50} = $2x10^{-11}$ M). Up to 16 d in culture, 45% of motoneurons were supported by 10 ng/ml CT-1; they showed highly-differentiated morphology and extensive neurite outgrowth. In vivo, CT-1 protected neonatal spinal motoneurons against the effects of axotomy. The neurotrophic action of CT-1 (but not of LIF) on motoneurons was inhibited by prior incubation of the cells with PIPLC, suggesting that CT-1 may act through a GPI-linked component. Since no binding of CT-1 to CNTFRα was detected, it is likely that a novel cytokine receptor alpha-subunit is involved. Our data suggest that CT-1 may be of importance in normal motoneuron development, and as a tool for slowing motoneuron degeneration in human diseases.

MAMMALIAN RETINAL PIGMENT EPITHELIAL CELLS IN CULTURE ARE RESPONSIVE TO CILIARY NEUROTROPHIC FACTOR AND LEUKEMIA INHIBITORY FACTOR. M.E.M. Kelly*, S.K. Gupta, C.A. Jollimore, M.J. McLaren@ and G. Inana@. Depts. Pharmacology and Ophthalmology, Dalhousie Univ., Halifax, NS, B3H 4H7, and Bascom Palmer Eye Inst.@, Univ. Miami School of Medicine, Miami, FL 33101.

The retinal pigment epithelium (RPE) is a specialized monocellular layer of polarized epithelial cells located between the neural retina and choroid layers of the eye. Due to both its common origin from the optic neuroepithelium and close apposition with the neural retina, the RPE may be responsive to paracrine signals, such as growth factors and hormones, which emanate from the retina and other ocular sources. Our previous studies have confirmed the expression of mRNAs encoding two subunits of the ciliary neurotrophic factor (CNTF) receptor complex in the developing rat posterior eye-cup (Gupta et al. 1995, Can. J. Physiol. Pharm. 73:Ax-Aix), therefore we investigated whether primary cultures of RPE cells and RPE cells of an immortalized cell line, BPEI-1, would be responsive to the neurokines CNTF and leukemia inhibitory factor (LIF). The survival of cultured RPE cells in defined medium following serum withdrawal was investigated during a subsequent 102 hr period, either in the presence of 40 pM recombinant rat CNTF or murine LIF. Cell survival after treatment was determined by counting cell nuclei after cell lysis using Zapoglobin. The survival of primary cultured RPE cells and the BPEI-1 cell line was significantly enhanced over serum-free conditions upon addition of either CNTF or LIF to the culture medium ($n=15$; $P<0.01$). This increased cell survival was not due to cell proliferation since immunocytochemical "continuous" labelling using bromodeoxyuridine demonstrated that the number of labelled cell nuclei was not significantly different in CNTF and LIF treated cultures compared to the serum-free group. These studies suggest that CNTF and LIF are potent trophic factors for RPE cells *in vitro* and may serve as candidate therapeutic agents in degenerative conditions that affect the RPE (supported by NSERC).

EXOGENOUS CNTF, BUT NEITHER NT-4 NOR GDNF, ENHANCES PERIPHERAL NERVE REGENERATION IN ADULT ANIMALS. C.F. Da-Silva[1]*, R.D. Lainetti[1], F.C. Pereira[2] and R.S. Pires[1]. Depts. of Histology[1] and Anatomy[2], University of Sao Paulo, SP 05508-900, Brazil.

Neurotrophic factors CNTF, NT-4 and GDNF can promote the survival of axotomized PNS neurons in neonatal animals. Here we tested their effects on regenerating peripheral neurons in adult animals. The sciatic nerve of 12 adult male C57BL/6J mice was transected and its proximal and distal stumps were sutured into a polyethylene tube (PT), leaving a 4-mm gap. The animals were divided into 4 groups of 3 mice each and implanted with PTs filled with one of the following solutions: (1) collagen (Vitrogen, 2.4 mg/ml) + cytochrome C (a protein used as a control for neurotrophic factors); (2) collagen + CNTF; (3) collagen + NT-4; (4) collagen + GDNF. All solutions (2 μl/tube) were made up in 1:1 volume ratio, with 50 μg/ml of neurotrophic factor per tube. After 4 weeks, the PTs with the regenerated nerve cables were processed for total myelinated axon counts. CNTF injected mice regenerated significantly more axons (2619±63) compared to control cyt. C animals (1338±200) ($P<0.05$); no significant difference was found among cyt. C, NT-4 (1417±199) and GDNF (1772±276) implanted animals. The L_5 dorsal root ganglion (DRG) was also removed from the same mice, and serially sectioned (5 μm) for sensory neuron counts. No significant difference was found in the number of DRG neurons among the experimental groups (cyt. C=528±42; CNTF=651±36; NT-4=680±52; GDNF=670±31), but all had significantly fewer sensory neurons compared to non-operated animals (1112±63) ($P<0.01$). These results indicate that locally applied CNTF, but neither NT-4 nor GDNF, stimulates peripheral nerve regeneration in adult animals, and that the CNTF effect is due to a neurite-promoting activity and not a survival action on axotomized neurons.

CNTF PROTECTS STRIATAL OUTPUT NEURONS FROM QUINOLINIC ACID TOXICITY. K.D. Anderson*, N. Panayotatos, T.L. Corcoran, S.J. Wiegand and R.M. Lindsay. Regeneron Pharmaceuticals, Inc., Tarrytown, NY 10591

Experiments were conducted to determine whether administration of brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), neurotrophin-3 (NT-3), or ciliary neurotrophic factor (CNTF) can protect striatal output neurons in adult rats exposed to an excitotoxic insult that mimics Huntington's disease. The NMDA receptor agonist, quinolinic acid (50 nmol), was injected into the left striatum 3-4 days or 7 days after the start of continuous intrastriatal infusion of purified, recombinant neurotrophic factor (human NGF, 10.8 μg/day; human BDNF or NT-3, 12.0 μg/day; rat CNTF, 9.4 μg/day). Analysis of Nissl-stained brain sections demonstrated no significant sparing of medium-sized striatal neurons in BDNF-, NGF- or NT-3-treated brains. In marked contrast, survival of medium-sized neurons was significantly greater ($p=0.04$) in rats treated with CNTF compared to rats treated with vehicle alone (mean percent neuron survival ± SEM, relative to intact side: 69 ± 17 and 29 ± 11%, respectively). Comparable neuron protection was obtained in a similar experiment using a polypeptide CNTF receptor agonist, Axokine 1 (Ax1). In two additional experiments, significant neuron sparing occurred when quinolinic acid was injected 3 days after the end of a 4-day infusion of Ax1, or when a daily intrastriatal injection of Ax1 (0.4 μg/day) was given for 3 days before and 1 day after injection of quinolinic acid. The striatal neuron populations protected in these paradigms are the same ones selectively lost in Huntington's disease. Research supported by Regeneron Pharmaceuticals, Inc.

CNTF EXHIBITS NEUROTROPHIC EFFECTS WITHOUT APPARENT MYOTROPHIC EFFECTS. M.W. Harty* and D.R. Sengelaub. Program in Neural Science, Indiana University, Bloomington, IN 47405.

Ciliary neurotrophic factor (CNTF) has been shown to have both neurotrophic and myotrophic effects in a variety of systems, and CNTF receptor components have been found in both neural and muscular sites. We assessed potential neurotrophic effects of CNTF on motoneurons in the retrodorsolateral nucleus (RDLN) of rats. The RDLN target muscle, the flexor digitorum brevis (FDB; an intrinsic foot muscle) was also examined for potential myotrophic effects.

Counts of RDLN motoneurons were made in normal animals at embryonic (E) days E18, E20, E22, and postnatal (P) days P4, P10, and P120 in 10 µm, cresylecht violet stained, paraffin sections. Approximately 1600 RDLN motoneurons were present at E18; this number declined to about 600 by P10 and was stable through P120. To determine if RDLN motoneurons could be rescued with neurotrophic treatment, CNTF (.5ug) was injected daily into the FDB on P1-P5. Volumes of FDB muscles measured in 10 µm, Miligan's trichrome stained, paraffin sections, and counts of RDLN motoneurons (prepared as above) were made at P5 in both CNTF and untreated rats. CNTF treatment resulted in a significant increase (15%) in RDLN motoneuron number; no difference in FDB volume was found. These data suggest that the neurotrophic effect observed with CNTF treatment can occur in the absence of apparent myotrophic effects. Supported by Indiana University, Grant-In-Aid of Research.

INFLUENCE OF COCAINE ON THE JAK-STAT PATHWAY IN THE MESOLIMBIC DOPAMINE SYSTEM. M.T. Berhow*, N. Hiroi, L. A. Kobierski^, S.E. Hyman^ and E. J. Nestler. Laboratory of Molecular Psychiatry, Yale School of Medicine, New Haven, CT 06508; ^Molecular and Developmental Neuroscience, Massachusetts General Hospital, Charlestown, MA 02129.

Chronic exposure to cocaine induces biochemical adaptations within the rat ventral tegmental area (VTA), a brain region rich in dopaminergic neurons implicated in the reinforcing and locomotor activating properties of cocaine. Some of these changes are mimicked by chronic CNTF infusions in the same brain area. We show here that chronic cocaine regulates the CNTF signal transduction pathway specifically in the VTA. There is an increase in immunoreactivity of JAK2, a CNTF-regulated protein tyrosine kinase, in the VTA following chronic but not acute cocaine administration. This increase is not seen in several other brain regions studied. Furthermore, this increase in JAK2 is not seen after chronic administration of other psychotropic drugs and was not observed for JAK1. The increase in JAK2 levels is associated with an increased responsiveness of the system to acute CNTF infusion into the VTA, as measured by induction in this brain region of STAT DNA binding activity and of Fos-like proteins, two known functional end-points of JAK activation. Double-labeling immunohistochemistry shows that JAK2 immunoreactivity in the VTA is enriched in dopaminergic and non-dopaminergic cells, both of which exhibit increased JAK2 immunoreactivity after chronic cocaine treatment. In related studies, we have shown that chronic intra-VTA infusion of CNTF alters locomotor sensitization to cocaine. Together, these findings suggest a scheme whereby some of the effects of chronic cocaine on VTA dopaminergic neurons are mediated directly by regulation of the JAK-STAT pathway in these cells as well as, perhaps, indirectly by regulation of this pathway in non-dopaminergic cells. (Supported by DA10160).

CNS ALTERATIONS IN IL-6 AND SOLUBLE IL-6 RECEPTOR α DOUBLE TRANSGENIC MICE: *J. Weis*[*1], *M. Peters*[2], *S. Rose-John*[2]. *Technical Univ.*[1], *Aachen, and Univ. of Mainz*[2], *Germany.*

Interleukin-6 (IL-6) is a pleiotropic cytokine with a wide range of effects on various cell types predominantly of the immune and nervous systems. Increased levels of IL-6 have been linked to several neurological disorders such as AIDS dementia and Alzheimer's disease. In transgenic mice overexpressing IL-6 in astrocytes, prominent cerebral alterations including marked gliosis have been found (Campbell et al. PNAS 90:10061-5, 1993). Systemic overexpression of IL-6 in transgenic mice, on the other hand, has not yet been reported to inflict major CNS damage.

The specific component of the tripartite IL-6 receptor system, IL-6 receptor α (IL-6Rα), is bioactive in a membrane bound and in a soluble (s) form. In the present study, mice overexpressing human IL-6 (driven by MT promoter) and human sIL-6Rα (controlled by PEPCK promoter) in liver cells were examined. Mice of both lines did not show any neurological abnormalities. Only minor, if any, increase in reactive astrocytes was noted by GFAP immunohistochemistry of brain sections of IL-6 overexpressing mice, even though effects of IL-6 overexpression (e. g., liver damage, plasmocytomas) were noted in these mice. However, double transgenic mice derived from crosses of both lines showed prominent neurological symptoms such as tremor, gait abnormalities, and paresis, and widespread, massive CNS gliosis was detected.

These results demonstrate that, in contrast to systemic overexpression of IL-6 alone, simultaneous systemic increases of IL-6 and sIL-6Rα levels cause marked CNS damage. (Supported in part by DFG grants to SR-J)

IL-1RA INDUCES APOPTOSIS IN ORGANOTYPIC SLICE CULTURES OF DEVELOPING MOUSE HIPPOCAMPUS. C. F. Ide*, A. M. Jelaso and I. Castellon. Tulane/Xavier Center for Bioenvironmental Research and Dept. of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118.

Interleukin-1ß (Il-1ß) and its type 1 receptor are expressed in all hippocampal regions in organotypic slice cultures of mouse hippocampus created on postnatal day 7 and assayed through the first week in vitro. To determine if the type 1 receptor regulates apoptosis during this period, cultures were treated with vehicle, Il-1ß, IL-1ß type 1 receptor antagonist (Il-1ra), or both Il-1ß and Il-1ra for 7 days in vitro, and then assayed for number of apoptotic cells/unit area using the terminal transferase reaction. Il-1ß treated cultures showed no significant differences from vehicle treated cultures in apoptotic rate. Il-1ra treated cells showed significant increases in apoptotic rate in the CA fields and in subicular tissue compared to vehicle treated cultures ($p=0.002$) or to Il-1ß treated cultures ($p=0.007$). Co-treatment with Il-1ß rescued cells from the effects of Il-1ra. Thus, Il-1ß acting through its type 1 receptor, may serve as a survival factor for developing hippocampal cells. Supported by DoD/DNA grant 93-DNA-2 and DoE-EM grant DE-FG01-93-EW532023.

NEUROTROPHIC FACTORS: BIOLOGIC EFFECTS—NEUROTRANSMITTERS

770.1

SEROTONIN SPECIFIC REUPTAKE INHIBITOR (SSRI) INDUCES DENDRITIC ELONGATION AFTER LONG-TERM FOCAL CEREBRAL ISCHEMIA IN THE ADULT RAT CORTEX. J.A. Strafaci, V. DeCrescito, D. Quartermain*, A. Shemer, and E.C. Azmitia Dept. of Biology, New York Univ., NY, NY 10003

This research investigates the role of 5-hydroxytryptamine (5-HT) in reversing the long term (>10 days) changes in cortical morphology induced by focal cerebral ischemia. Sertraline, a SSRI, was used to increase the presence of 5-HT and examine its effects on neuronal dendrites after permanent occlusion of the left middle cerebral artery in adult rats. Eleven days after surgery rats were given Sertraline (10 mg/kg i.p.) for three consecutive days, and perfused on the following day. Using computer-assisted morphometrics (OPTIMAS ver. 5.1), we analyzed MAP-2 immunocytochemistry corresponding to dendrite fibers in the parietal cortex. We examined MAP-2-IR and extracted size and density values using a constant region-of-interest (ROI) of 500,000µm^2. Without drug treatment, the lesion resulted in a uniform loss of dendritic fiber density and size attributes when compared to control. Average fiber length decreased by 12.4% ($p\leq0.001$), range of fiber length decreased by 44.3% ($p\leq0.01$), average maximum fiber length decreased by 37.7% ($p\leq0.01$), total fiber count decreased by 27.8% ($p\leq0.05$), and the percentage of fibers longer than 100µm decreased by 49.5% ($p\leq0.01$). The sum of fiber lengths within the ROI, as an indication of total MAP-2-IR, also decreased by 37% ($p\leq0.01$). In contrast, however, dendritic fiber morphology in Sertraline treated lesions was statistically insignificant from control levels in all cases. These findings strongly suggest that the serotonergic system plays a vital role in cortical dendrite regeneration after long-term cerebral ischemia. (Research supported by a gift from Pfizer, Inc.)

BDNF AND S100β: TROPHIC INTERACTIONS ON CULTURED SEROTONERGIC NEURONS

M. Nishi[1]*, P.M. Whitaker-Azmitia[2] and E.C. Azmitia[1]. 1. Dept. Biology, NYU New York, NY 10003, 2. Dept. Psychiatry, SUNY, Stony Brook, NY 11794.

Brain-derived neurotrophic factor (BDNF) is known to exert a multitude of trophic effects on diverse neuronal populations, including central serotonergic and dopaminergic neurons. In vivo, the action of BDNF persists for many weeks after the end of treatment. This long-term action may involve activation of the trophic activity of glial cells. Recently, it has been shown that a cultured rat cortical glial cells respond to BDNF. BDNF affects dopaminergic and serotonergic neurons through trkB receptor and glial cells through truncated trkB receptor. Glial cells release S100β which has trophic effects on serotonergic neurons. Are some of the trophic effects by BDNF mediated via S100β?

The effects of BDNF and S100β on serotonergic properties were investigated in fetal rat raphe primary cultures grown in serum-free condition. While BDNF (50 ng/ml) promoted the number of serotonin (5-HT) immunoreactive (IR) neurons (+75%), S100β (10 ng/ml) did not show a significant increase. BDNF stimulated the morphological and phenotypic differentiation of serotonergic neurons by increasing the soma size of 5-HT-IR neurons (+35%), tryptophan hydroxylase immunoreactivity (+40%) and the frequency of calbindin-IR neurons (+30%). In contrast, S100β promoted the extension of serotonergic fibers (+100%), but not soma size. BDNF treatment also enhanced S100β immunoreactivity on astrocytes. The 5-HT uptake capacity with serotonergic neurons was also significantly increased by BDNF (+80%) and S100β (+35%). An antibody to S100β blocked the increase of soma size and 5-HT uptake capacity with serotonergic neurons. These results suggest that BDNF and S100β are active protein growth factors on serotonergic growth and BDNF may have trophic interactions with S100β. (NIA #1 P01 AG10208)

COMPARISON OF 5-HT1A RECEPTOR AND GR AGONIST ON RESTORING HIPPOCAMPAL GRANULE NEURONS IN ADRENALECTOMIZED (ADX) RATS. **J. Huang* and E. C. Azmitia. Department of Biology, New York University, NY, NY 10003.**

Serotonin and glucocorticoids have been shown to be powerful differentiating factors during development. After damage induced by a serotonin specific neurotoxin (PCA), both Dex and 5-HT1A agonist restored normal morphology. Furthermore, after removal of adrenal steroid by ADX, Dex and RU28362 reversed the loss of granule neuronal morphology even after several months. In short term ADX, there is evidence of cell degeneration in the granule neurons as indicated by pyknotic cells. In this report, we compared the trophic action of 5-HT1A agonist and Dex on granule cell pathology.

Female rats (200mg) were used. Rats were ADX or sham operated. Two weeks after ADX, a 5-HT1A agonist (ipsapirone; 1mg/kg) was injected ip into rats, and Dex (10mg/L) was supplied in drinking water for three days. The brains were processed for MAP-2 immunocytochemistry.

After ADX, MAP-2 IR decreased in the molecular layer, and pyknotic cells increased in the granular layer of the superior blade of dentate gyrus. Ipsapirone and Dex treatment both increased the MAP-2 IR. Both of the treatment seem to decrease the pyknotic cells in the superior blade of the granular layer. The treatment with both agonist increased the MAP-2 IR more than either drug alone. These studies indicate that 5-HT-1A agonist and Dex may be acting by parallel mechanisms. Current studies are exploring whether the pyknotic cells are apoptotic. (NIA grant# 1 P01 AG10208)

VASOACTIVE INTESTINAL PEPTIDE MODULATES MOTONEURON DIFFERENTIATION IN THE RAT SPINAL CORD. H. Xie and L. Ziskind-Conhaim*. Dept. of Physiology and Ctr. for Neuroscience, University of Wisconsin, Madison, WI 53706.

Differentiation of motoneuron electrical properties is delayed in the presence of TTX, probably as a result of blocking Ca^{2+}-dependent synaptic release of neurotrophic agent(s) (Xie and Ziskind-Conhaim, J. Neurosci. 1995). This study was designed to examine whether activity-dependent release of endogenous vasoactive intestinal polypeptide (VIP) contributed to motoneuron development in spinal cord explants. VIP is present in the dorsal horn, and effectively increases neuronal survival in electrically inactive dissociated spinal cord cultures (Brenneman et al., Cell Biol. 1987). Our data demonstrated that exogenous VIP (0.2 nM) reversed the effects of TTX on motoneuron resting potential, action potential threshold, and ability to fire repetitive action potentials. The regulatory actions of VIP were blocked by its receptor antagonist, VIP_{10-28} (10 nM). In electrically active explants, VIP did not increase the rate of motoneuron differentiation, but VIP_{10-28} delayed the differentiation of action potential threshold and maximum rate of rise. These findings suggested that activity-dependent release of endogenous VIP contributed to developmental changes in motoneuron electrical properties.

Exogenous VIP significantly increased the frequency of spontaneous synaptic activity, and the effect was not blocked by VIP_{10-28}. These results suggested that different mechanisms may be responsible for VIP-mediated regulation of electrical properties and synaptic activity. Supported by NIH grant NS23808 to L. Z-C.

770.5

VASOACTIVE INTESTINAL PEPTIDE PREVENTS EXCITOTOXIC CELL DEATH IN THE DEVELOPING BRAIN. P. Gressens *, S. Marret, J. M. Hill, D.E. Brenneman, I. Gozes, M. Fridkin and P. Evrard. Lab. Dev. Neurol., Hôp. Robert-Debré, Paris & Neonatol. Dep., CHU, Rouen, France; Sect. Dev. & Mol. Pharmacol., NICHD, NIH, Bethesda, MD, USA; Dep. Chemical Pathol, Tel Aviv Univ, Tel Aviv, Israel.

Ibotenate, a glutamatergic analog, induces brain lesions in developing mouse which strikingly mimic human microgyria (when injected at P0), and transcortical necrosis and white matter cysts observed in human perinatal hypoxic/ischemic lesions (when injected at P5). Vasoactive intestinal peptide (VIP) has potent growth-related actions that influence cell mitosis and neuronal survival in cell culture. The goal of the present study was to assess the protective role of VIP against excitotoxic lesions induced by ibotenate in the developing mouse brain. Co-treatment with 1µg VIP and 5-10 µg ibotenate induced an 85% protection of microgyric-like cortical lesions (at P0) and of white matter cysts (at P5). VIP protective effects were reproduced by stearyl norleucine VIP, a VIP agonist which does not activate adenylate cyclase. Forskolin, a cAMP analog, and pituitary adenylate cyclase activating peptide (PACAP-38) did not reproduce VIP protection. Thus, VIP and VIP analogs acting through a cAMP independant mechanism, could represent potential new avenues in the prevention of excitotoxic lesions in the developing human brain. 770.6

INHIBITION OF THE NICOTINIC-TYPE ACETYLCHOLINE RECEPTOR EPSILON SUBUNIT mRNA EXPRESSION BY SOMATOSTATIN (SST) M. Peng, Z. Liu, L. Conforti and D. Millhorn*. Dept. Molecular and Cellular Physiology, Univ. of Cincinnati Sch. of Med., Cincinnati, OH 45262

The developmental regulation of the ε subunit of the nicotinic acetylcholine receptor (nACh-R) in skeletal muscle is believed to be mediated by a protein tyrosine phosphorylation/dephosphorylation process. The activation of somatostatin (SST) receptor (SST-R) has been shown to stimulate tyrosine phosphatase activity(*Proc. Natl. Acad. Sci. USA* 91:2315, 1994). SST is expressed transiently in motor neurons (hypoglossal nucleus) in 0-14 day rats after birth (Dev. Brain Res. 60: 241, 1991). In order to investigate the significance of the transient expression of SST, we performed Northern blot analysis and RT-PCR to determine if the SSTR is expressed in muscle and if stimulation of SSTR alters the expression of the ε subunit. We found that SSTR2A, 3 and 4 are expressed transiently in muscle with a time course that correlates with the transient expression of SST in motoneurons. We used primary cultures of rat skeletal muscle (21 day fetus) to determine if SST is involved in regulation of the ε subunit gene expression. We found that SSTR2A, 3 and 4 are present in the fetal rat skeletal muscle primary culture. The primary cultured skeletal muscle cells were treated with either sodium orthovanadate (protein tyrosine phosphatase inhibitor, 20-40 µM) or SST-14 (50nM-400nM) or both in serum free medium for 48 hours. The expression of nACh-R ε mRNA was increased by sodium orthovanadate which indicates a role for tyrosine phosphatase in regulation of ε gene expression. SST caused down-regulation of the elevated ε mRNA stimulated by vanadate. These findings suggested that SST acting via the SSTR may function as developmentally regulated neurotrophic factor in the rat skeletal muscle. Activation of SSTR might function to stimulate protein tyrosine phosphatase activity. Supported by HL33831 and HD28948

NEUROTROPHIC EFFECT OF GABA ON CULTURED RAT STRIATAL NEURONS. Y.Ikeda*, N.Nishiyama, H.Saito and H.Katsuki. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo 113, Japan.

GABA is the main inhibitory transmitter at central synapses in adult mammals. However, a number of recent studies indicated that GABA depolarizes various types of neurons when they are underdeveloped. In this study, in order to clarify the functional role of GABA in developing brain, we investigated the effects of GABA on the survival of embryonic rat striatal neurons. A disperse neuron cell culture was prepared from embryonic rat and drugs were added in the culture medium a day later. The number of surviving neurons were counted after three days exposure to the drugs. GABA significantly enhanced neuronal survival in concentration-dependent manner (1-100 µM). This effect of GABA (100 µM) was blocked by a $GABA_A$ receptor antagonist bicuculline (100 µM), but not by a $GABA_B$ receptor antagonist 2-hydroxysaclofen (100 µM). Furthermore, nifedipine (3 µM) and nicardipine (5 µM), inhibitors of L-type voltage-dependent Ca^{2+} channel, prevented the trophic effect of GABA. Therefore, we examined the effect of GABA on intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) using fura-2. In about 50% of neurons, application of GABA (10, 100 µM) for 30 s induced $[Ca^{2+}]_i$ increase (Δ= about 60 nM), which was abolished by excluding the extracellular Ca^{2+} or treatment with nicardipine (5 µM). Bicuculline (150 µM) inhibited the GABA-induced increase in $[Ca^{2+}]_i$, and $GABA_A$ receptor agonist muscimol (1, 10 µM) mimicked the effect of GABA. Furthermore, furosemide (1 mM), an inhibitor of $Na^+/K^+/2Cl^-$ cotransport, abolished the GABA-induced $[Ca^{2+}]_i$ elevation. These results indicate that $GABA_A$ receptor stimulation induced Ca^{2+} mobilization through L-type voltage-dependent Ca^{2+} channel, which finally resulted in neurotrophic effect of GABA. This GABA-induced Ca^{2+} mobilization may be due to the elevated level of $[Cl^-]_i$ in immature neurons, since furosemide antagonized it completely.

GRANULE NEURON REGULATION OF PURKINJE CELL DEVELOPMENT: STRIKING A BALANCE BETWEEN NEUROTROPHIN AND GLUTAMATE SIGNALLING. M.E. Morrison* and C.A. Mason. Dept. of Pathology, Ctr. for Neurobiology and Behavior, Columbia University, NY, NY 10032.

Granule neurons, the presynaptic afferents of Purkinje cells, are potent regulators of Purkinje cell differentiation. Purified cultures of Purkinje cells survive poorly, never extending dendrites, while Purkinje cells cocultured with granule neurons survive better, developing dendrites with spines. Here we address whether neurotrophins are involved in granule neuron influences on Purkinje cell development. Purified mouse Purkinje cells were cultured alone or together with purified granule cells, with and without neurotrophins, anti-neurotrophin blocking antibodies, and/or glutamate receptor antagonists. Cultures were fixed at 6 or 14 days in vitro, and Purkinje cells were visualized by immunostaining with an antibody against calbindin-D28k.

In perinatal cultures, NT-3 and CNTF decrease and BDNF or NT-4 increase survival of Purkinje cells cultured alone. In Purkinje cell-granule neuron cocultures, however, BDNF or NT-4 decrease Purkinje cell survival. This decrease is overcome by addition of anti-BDNF blocking antibody, suggesting that BDNF in excess of that provided by the granule cells becomes toxic to Purkinje cells. Treatment of these cultures with CNQX, a specific non-NMDA receptor antagonist, also rescues Purkinje cells, implicating glutamate excitotoxicity as a mechanism of BDNF-induced death. Analysis of dendritic differentiation in these cultures is ongoing. These results suggest that Purkinje cell development requires a precise balance between neurotrophin and glutamate signalling, and strengthen the link between neurotrophin- and activity-dependent development.

(Growth factors generously provided by Dr. G. Yancopoulos, Regeneron. Anti-neurotrophin antibodies supplied by Dr. J. Carnahan, Amgen. Supported by NIH grant NS16951 (CAM) and NRSA Award NS09864 (MEM).)

770.9

COMPARISON OF TRH AND GLUTAMATE IMPLANTS IN PROXIMITY TO TRIGEMINAL MOTONEURONS: CRANIOFACIAL EFFECTS, K.E. Byrd*[1], M.J. Sukay[1], M.W. Dieterle[1], T.C. Marting[1], L. Yang[1], D. Teomim[2], and A.J. Domb[2]. [1]Dept. of Anatomy, Indiana Univ. Sch. of Med., Indianapolis, IN 46202 and [2]Sch. of Pharm., Hebrew Univ. of Jerusalem, Israel.

In order to determine the relative effects of TRH and glutamate upon trigeminal motoneurons (TMNe) and neuromusculoskeletal structures they influence, biodegradable microspheres (Mathiowitz et al., 1988; Byrd et al., 1992; Byrd and Hamilton-Byrd, 1994) containing 10% TRH (Bachem, CA) and 10% glutamate in polyanhydride (FAD-SA), in 1:1 ratio made in 200 μm dia. along with identical-size blank microspheres with no neuroactive substance. TRH, glutamate, and blank ($\bar{X}$±sd densities of 19.63±11.77, 15.44±4.91, and 17.10±4.94 mg/mm^3 each) microspheres were stereotactically implanted approximately 900 μm rostral to the left-side trigeminal motor nucleus of 35 day-old Sprague Dawley rats (10 rats each group); all rats were killed at 14 and 21 days postoperative. Both TRH and glutamate rats showed significant skeletal alterations compared to blanks; TRH rats had larger implant-side masticatory muscles and TMJ alterations, however.

CALCITONIN GENE RELATED PEPTIDE (CGRP) PROMOTES DIFFERENTIATION OF RAT MESENCEPHALIC DOPAMINERGIC NEURONS IN VITRO. **S. Bürvenich, K. Unsicker, and K. Krieglstein***
Anatomy&Cell Biology, Univ. Heidelberg, INF 307, D-69120 Heidelberg.

CGRP has previously been shown to increase intracellular cAMP-levels in a number of target tissues. Recent findings suggest that the activation of the cAMP signaling pathway promotes development and long-term survival of mesencephalic dopaminergic (DAergic) neurons in vitro. In the present study we investigated the effect of CGRP α on mesencephalic DAergic cells cultured from E14 Wister rats. Factors were first added to serum-free cultures after 24 h and then every two days. Tyrosine hydroxylase immunocytochemistry and ^{3} H-DA uptake were analyzed after 3 to 16 days in vitro (DIV). Light microscopy showed an increased number of neurites and longer stained processes in the CGRP-treated (10-1600 ng/ml) as compared to control cultures. This effect was first apparent at DIV4 and maximal at DIV8. However, CGRP treatment did not lead to prolonged neuronal survival under these culture conditions. DA uptake was not elevated by CGRP between DIV3 and DIV6, when DA uptake increased rapidly in control cultures. However, CGRP significantly enhanced DA uptake beyond levels induced by FGF-2 at this time point. This synergism could be observed until DIV16. From DIV6 to DIV11, CGRP by itself (10-800ng/ml) led to a significant increase in DA uptake (up to 4-fold). Our data indicate that the differentiation promoting effect of CGRP on DAergic neurons is restricted to a late and short time period in DAergic neuron development. Furthermore, CGRP apparently employs pathways regulating DA uptake different from those activated by FGF-2. These results also demonstrate differences in the capacity of CGRP and mechanisms directly elevating intracellular cAMP levels (e.g. dbcAMP, forskolin, IBMX) in the promotion of DAergic neuron differentiation and survival. **Supported by BMBF**

NEUROTROPHINS, NEURO-ACTIVE AMINO ACIDS AND THE MITOCHONDRIAL RESPIRATORY CHAIN TOGETHER MAINTAIN NEURONAL SURVIVAL AND FUNCTION. A. El Idrissi, C. Harris, E. Trenkner*. NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314

Individual neurons require extracellular environments to develop, mature and survive. These are controlled by growth factors, neuroactive amino acids, and by mitochondrial energy metabolism. This study examines some of the conditions by which these factors regulate neuronal survival and vulnerability to external stimuli.

Developing mouse cerebellar granule cells (GC) maintained under different culture conditions (in the presence or absence of glia, serum or serum-free growth supplement) were utilized to investigate the interaction between these factors. We have examined cell survival (using FDA/PI staining) $^{45}Ca^{2+}$ influx, energy metabolism (rhodamine 123 uptake) and protein kinase C (PKC) activity under various culture conditions.

We found that BDNF, bFGF, and taurine exert trophic effects on GC and protect neurons against glutamate excitotoxicity. These effects were more pronounced when GC were cultured in the absence of astroglia cells and/or serum. Under these culture conditions, mitochondrial energy levels were reduced, rendering the GC more vulnerable to glutamate excitotoxicity. Similar results were obtained when mitochondrial energy levels were reduced with the uncoupler FCCP. Horse serum inhibited glutamate-induced $^{45}Ca^{2+}$ uptake. Glutamate induced $^{45}Ca^{2+}$ uptake was down-regulated by taurine, BDNF, and bFGF, suggesting intracellular calcium modulation as neuroprotective mechanism. Taurine, BDNF, and bFGF down-regulate glutamate-induced PKC activity. An additive effect of taurine and bFGF on $^{45}Ca^{2+}$ uptake was observed in serum-free media.

These data confirm and extend our model that a balanced interaction between signalling molecules must be maintained for a functioning neuronal network.

(Funded by New York State Office of Mental Retardation and Develpmental Disabilities).

NUTRITIONAL AND PRENATAL FACTORS: DIETARY AND ENVIRONMENTAL FACTORS

771.1

BEHAVIORAL DEVELOPMENT AND COGNITIVE PARAMETERS OF THE OFFSPRING ARE AFFECTED BY MATERNAL ESSENTIAL FATTY ACID DEFICIENCY M. Dierssen*[1], S. García-Calatayud[1,2], I.F. Vallina[1], C. Baamonde[1], J. Flórez[1], M. García-Fuentes[2], J.I. Ruiz[3], P. Sanjurjo[3]. Dept. Physiology & Pharmacology[1] and Pediatrics[2], Univ. Cantabria, Santander, Lab. Metabolism[3], Univ. Hosp. Cruces, Bilbao, Spain.

The influence of essential fatty acids (EFA) deficient maternal feeding on plasma and milk triglycerides fatty acids composition and on developmental and behavioral parameters of the progeny was studied in Wistar rats. Female young rats were fed with either conventional (C) or deficient (D) diets for 3 months. After that period the levels of EFA (%) in D rats were reduced in plasma[linoleic acid (LA): from 18.5±0.04 to 2.36±0.13; α-linolenic acid (LNA) from 0.43±0.2 to trace]. After mating, C and D diets were maintained during pregnancy and lactation. Reproductive parameters were adversely affected by EFA deprivation. D dams showed smaller litter size (12.6±1.24 pups in C and 8.66±0.92 pups in D) and D pups showed lower birth weight ($p<0.05$). Levels of milk triglycerides EFA (%) were reduced in D dams (LA: 9.6±0.4 *vs* 0.48±0.01; LNA: 0.46±0.06 *vs* 0.007±0.004). D pups showed skin disturbances in the tail. Hindlimb grasp and cliff aversion reflexes were delayed but startle reflex was premature compared to C pups. At weaning, C and D pups showed slight differences in general activity during specific phases of the light/dark cycle, a decreased number of rearings in the open field (5.5±0.6 in C *vs* 3±0.6 in D during 5 min) and no differences in anxiety levels in the elevated plus maze. D pups showed an impaired retention of a previously learned aversive habit in the passive avoidance test (latencies in the retest session (day 8th posttraining): 478.5±62.3 sec in C *vs* 221.7±65.4 sec in D, $p<0.05$, Student t test). Sustained pregestational EFA deficiency resulted in a reduction of dams EFA plasma and milk concentrations, and seemed to affect somatometric, developmental and cognitive parameters in the offspring. (Supported by grants from Fundación Marcelino Botín and FISS 96/1279).

771.2

MID-GESTATIONAL EXPOSURE TO ALL-TRANS RETINOIC ACID: 1. EFFECTS ON BRAIN STEM NUCLEI. R.R. Holson*, R.A. Gazzara, S.A. Ferguson and J. Adams[1]. National Center for Toxicological Research, Jefferson, AR 72079, [1]Dept. Psychology, Univ. Massachusetts, Boston, MA 02125.

We have previously reported that 10 mg/kg (p.o.) all-trans retinoic acid (RA) given to pregnant rats daily over gestational days (GD) 11- 13 is highly lethal to offspring (Holson et al., *Soc. Neurosci. Abstr.*, 21, p.553, 1995). Exposed pups are alive at birth, but none live beyond 72 hr due to an inability to nurse. At lower doses (2.5 mg/kg, p.o.) pups survive, and at 4 weeks of age have reduced weight of cerebellum. To further investigate these effects, albino rat dams were dosed with RA as above. Viable fetuses were killed by decapitation on GD 21. Brains were removed, fixed in Bouin's, paraffin-embedded and sectioned coronally at 10 μm. Every fourth section was mounted and stained with cresyl violet. The brain stem was then scanned under low magnification, and cross-sectional area of nuclei which appeared to be abnormal was measured. Three nuclei were identified as being grossly affected by RA exposure. These were the pontine nucleus, the inferior olive, and the area postrema. Total area of all sections through the pontine nuclei in RA-exposed pups was 42% of control. Area of the principal nucleus of the inferior olive was 63% of control. Area postrema was not smaller after RA exposure, but appeared to be less cell-dense. The hypoglossal nucleus was normal. We conclude that RA exposure at this developmental stage selectively targets a subset of brainstem nuclei. The involvement of major cerebellar afferent nuclei could explain later RA effects on cerebellum at lower doses. Supported by DHHS/FDA/NCTR.

771.3

MID-GESTATIONAL EXPOSURE TO ALL-TRANS RETINOIC ACID: 2. EFFECTS ON THE FOREBRAIN, R.A. Gazzara*, R.R. Holson, S.A. Ferguson and J. Adams[1]. National Center for Toxicological Research, Jefferson, AR 72079, [1]Dept. Psychology, Univ. Massachusetts, Boston, MA 02125.

We have previously shown (Gazzara et al., *Soc. Neurosci. Abstr.*, 21, p. 553, 1995) that all-trans retinoic acid (RA) at 2.5 mg/kg (p.o.) given to pregnant rats daily over gestational days (GD) 11-13 produces a significant reduction in the weight of the neostriatum (NS) when measured at 28 days of age. To further investigate these effects on the neostriatum and other forebrain nuclei in the basal ganglia, we administered RA (10 mg/kg, p.o.) or vehicle daily over GD 11-13 to pregnant rats. On GD 21 we sacrificed the dams and removed the fetuses by C-section. After decapitation, their brains were removed, fixed, paraffin-embedded and sectioned coronally at 10 µm. Cross-sectional areas of the following nuclei were examined: neostriatum, ventral striatum (VS), and globus pallidus (GP). In addition we examined the subventricular zone (SVZ) adjacent to the neostriatum which contains newly-formed cells, some of which are destined for the neostriatum. There were no significant areal differences between the NS, VS, GP or SVZ of the RA-treated animals (n=6) and the control animals (n=6). We did, however, discover evidence of disorganization in the cytoarchitecture of several cortical areas (e.g., cingulate, insular, pyriform cortices) as well as the hippocampal formation and the subiculum in 4 out of 6 animals. Thus we conclude that RA exposure at this developmental stage does not alter gross development of the overall areas of these forebrain regions (although subsequently their weights may be affected), but does affect the cytoarchitecture of forebrain cortical areas, perhaps by disrupting cell migration. Supported by NCTR/FDA/DHHS.

771.4

ALTERATIONS IN THE BEHAVIOR OF ADULT RAT PROGENY AFTER PRENATAL EXPOSURE TO FLUOXETINE HCl. G. T. Livezey*, S.T. Yilk, K. Olson and C. V. Smith. Dept. Obstetrics & Gynecology, Univ. of Neb. Coll. of Med., Omaha, NE 68198.

This experiment is part 2 of a study of the effects of prenatal exposure to the serotonin uptake inhibitor, fluoxetine HCl, on the behavior, EEG and brain-specific receptors of the mature offspring. Twenty-four adult female Sprague-Dawley rats received 0, 1, 5 or 12 mg LZ/ kg p.o.(gastric lavage)once daily, for 28 days prior to breeding, during breeding and throughout their 21-day gestation. The behavior of the male and female offspring was evaluated at 9 months of age. We have used a modified radial arm maze (RAM) test which incorporates measures from the open field test, hyponeophagia model of anxiety test, Olton's original RAM test and other parameters of our own design. The permanent changes in both the spontaneous and evoked EEG of exposed offspring has been previously reported (Neuro-behavioral Teratology Society, June 1996). Here we describe the spontaneous and evoked behavioral changes and discuss correlations with the EEG data. Supported by the Leland J. and Dorothy H. Olson Center for Women's Health

EARLY EXPOSURE TO A HIGH-FAT DIET ALTERS THE DENSITY OF HYPOTHALAMIC DYNORPHIN NEURONS IN THE NEONATAL RAT. C. Bjenning*, A-V Dadacay and S. F. Leibowitz. The Rockefeller University, New York, NY 10021.

Malnutrition during pregnancy may, in the developing fetus, alter brain neurochemicals that control food intake and body weight, possibly resulting in long-term effects on eating behavior. This study focuses on the effects of high-fat versus low-fat nutrient diets on the number of dynorphin immunoreactive (DYN-IR) nerve cells in hypothalamic nuclei of the neonatal rat.

Pregnant dams were divided into three groups and exposed to either a high-fat (HF; 66%), medium-fat (MF; 30%) or a low-fat (LF; 13%) nutrient diet from the second trimester until their pups were weaned, at postnatal day 21 (P21). The litters were culled to 10 pups at birth (P1), and the remaining pups were sacrificed at P7, P14 and P21. At sacrifice, the pups were weighed and plasma was sampled and analyzed for cortisol, glucose and insulin. The brains were perfused with a 4% formaldehyde solution, sunk in sucrose, sectioned on a cryostat and processed for immunohistochemistry. Sections were incubated with a DYN antiserum and analyzed for the number of DYN-IR nerve cells/hypothalamic nucleus.

The weight gain was equal for the pups on the different diets. Plasma cortisol levels were highest in offspring from dams on a HF diet compared to pups on MF or LF diets . Plasma glucose levels were elevated in the HC diet group. Examination of DYN-IR in the hypothalamic nuclei showed an increase in the number of DYN-IR neurons with an increase in dietary fat. Analysis of DYN neurons in the PVN revealed a greater number in HF diet pups (120±8; $p< 0.05$) compared to MF diet pups (46±9; $p< 0.05$) and HC diet pups (14±3; $p< 0.05$). A similar pattern was found in the SON.

THE TRANSFER OF NON-STEROIDAL DIETARY ESTROGENS INTO BRAIN. P. H. Gamache,*[1] T. J. Maher,[2] K.D.R. Setchell,[3] T.-H. Wu,[2] and L. N. Acworth[1,2]. ESA Inc.[1], Chelmsford, MA 01824, Div. of Pharm. Sciences, Mass. Coll. of Pharmacy & AHS[2], Boston, MA 02115 and Children's Hospital Medical Center[3], Cincinnati, OH 45229.

The isoflavones, daidzein (Dz) and genistein (Gs) are found in high concentrations in soy protein, a staple of many Asian diets. These phytoestrogens and their metabolites, if ingested in large amounts have potent adverse biological effects in animals, while in humans the effects are consistent with hormonal actions at the level of the hypothalamus that may be beneficial in protecting against hormone-dependent diseases. It is not known if phytoestrogens are capable of penetrating the blood-brain barrier, and therefore we have investigated the ability of isoflavones, when administered orally or intraperitoneally, to appear in the CNS. A simple, highly sensitive method was developed for the determination of plasma, tissue, and microdialysate fluid isoflavones that utilized HPLC with coulometric array detection. Unconjugated and conjugated isoflavones were determined by differential enzymatic hydrolysis of samples obtained from Sprague-Dawley rats. Plasma concentrations of free/conjugated Dz, Gs and the metabolite equol were 1.9/284.0, 1.1/45.2, and 3.9/144.0ng/mL, respectively. In brain cortical tissue, concentrations of free/conjugated Dz and Gs were 2.3/4.7 and 0.3/0.3ng/g tissue, respectively. When Gs (1mg/kg ip) was administered, plasma and cortical tissue Gs levels increased to 7.6/383.0ng/mL and 2.0/8.8ng/g, respectively. When striatal microdialysates were collected, free isoflavones were undetectable, however the output rates of conjugated Dz and Gs and a metabolite 4-ethylphenol (4eP) were detected at levels of 3.1, 9.0 and 4.4 pg/15min, respectively in basal conditions. After ip Gsthere was a 6-fold increase in Gs in the striatal microdialysate fluid after 15mins and a 15-fold increase in 4eP after 30mins. These findings demonstrate that isoflavones are capable of transfer from the peripheral circulation to the CNS and pose questions regarding their potential biological actions in the brain. PREVENTION OF HYPERGLYCEMIA-INDUCED NEURAL TUBE DEFECTS BY FOLINIC ACID IN VITRO, K. Fechtel, Y. Peng and P. G. Smith*. Smith Mental Retardation Research Center, Univ. of Kansas Sch. of Med., Kansas City, KS 66160

The prevention of neural tube defects (NTDs) by folate supplementation in the maternal periconceptual period is well established in human clinical studies; however, mechanistic studies in animal models have been limited. We have employed the explanted rat embryo as an in vitro model in which morphological, molecular and prevention outcomes can be assessed for hyperglycemia-induced NTDs. When embryos are cultured for 30 hours in rat serum supplemented with 4mg/ml D-glucose, 70-80% exhibit exencephaly. Using in situ hybridization to sectioned rat embryos we demonstrate that the developmental control genes Hoxb-1 and Krox-20 are disrupted during the teratogenic process resulting in NTDs. When 20µg/ml folinic acid is added to the culture medium one hour prior to the construction of hyperglycemic serum, approximately 80% of the open neural tube defects are prevented. However, outcome assessment of treated embryos indicates that a closed neural lesion remains in the majority of embryos which is evident at both the morphological and molecular levels.

IMPRINTING EFFECT OF UTEROPLACENTAL INSUFFICIENCY UPON POSTNATAL BRAIN NEUROPEPTIDE Y AND CORTICOTROPIN-RELEASING FACTOR CONCENTRATIONS. P.A. Rajakumar, R.A. Simmons, S.U. Devaskar. Depts. of Pediatrics, Univ. of Pittsburgh, Magee-Womens Research Institute, Pittsburgh, PA 15213, and Northwestern Univ., Chicago, IL 60614.

Postnatal appetite control and body weight gain pattern are regulated by a balance between various hypothalamic neuropeptides. Of these, the orexigenic neuropeptide Y (NPY) and the anorexigenic corticotropin releasing factor (CRF) play a major role. To determine whether in-utero metabolic and hormonal alterations can influence the postnatal expression of NPY and CRF, we used a maternal uterine artery ligation rat model with intra-uterine growth restriction , hypoglycemia, and hypoinsulinemia (IUGR; n=35) along with sham operated controls (CON; n=37). Brain NPY and CRF mRNA and peptide levels were assessed by Northern blots and radioimmunoassays. A 40-75% increase in fetal brain NPY mRNA (0.8 kb) and protein levels was noted in the IUGR vs CON ($p<0.05$). In contrast, no change in fetal CRF mRNA (1.4 kb) or peptide concentrations was observed. Subsequent to the removal of the nutritionally restrictive environment, despite the normalization of plasma glucose and insulin levels, a persistent 50% increase in brain NPY levels was noted between 1d and 21d postnatal ages ($p<0.05$). Postnatal CRF mRNA and protein levels increased 2.5-fold in the IUGR vs CON, constituting a premature surge ($p<0.05$). These neuropeptide changes in the IUGR progeny were associated with a 20-40% decline in body weights despite ad libitum access to suckling. We conclude :1) IUGR pretranslationally alters the balance between the brain NPY and CRF concentrations; 2) despite normalization of the hormonal and metabolic environment, a change in the hypothalamic peptide levels persists; 3) this altered neuropeptide balance is associated with a diminished postnatal body weight gain pattern. We speculate that IUGR has an imprinting effect upon hypothalamic neuropeptides which in turn permanently affect the body weight gain pattern. [Supported by NIH-HD-25024]

ARACHIDONIC ACID METABOLISM IN ASTROCYTES. G.Y. Sun,* D. Xue and S. McGuire. Biochemistry Department and Nutritional Sciences, Univ. Missouri, Columbia, MO 65212

Besides supplying nutrients to neurons, astrocytes also play an important role in mediating cellular responses to injury. It has been shown that astrocytes respond to pro-inflammatory cytokines, e.g., tumor necrosis factor α (TNFα) and interleukin 1β (IL-1β) by inducing the release of secretory phospholipase A_2 ($sPLA_2$) and generation of prostaglandins. In this study, we examined both the effects of Ca^{2+} mobilizing agonists and elevated glucose on arachidonic acid (AA) metabolism in an immortalized astrocyte cell line (DITNC). [^{14}C]AA was incorporated into cellular phospholipids within 4 hr with highest labeling of phosphatidylethanolamine plasmalogen (Pepl). Stimulated AA-release in these cells was observed in response to ATP (through activation of the purinergic receptors), A23187 (Ca^{2+}-ionophore) and thimerosal (a Ca^{2+}-mobilizing agent). However, neither TNFα, IL-1β or interferon γ stimulated AA release from the prelabeled cells. Chelating extracellular Ca^{2+} in the medium by prior incubation of cells with excess EGTA completely abolished AA release. Analysis of the cellular phospholipids indicated that AA release was contributed mainly from phosphatidylcholine (PC) and PEpl. When DITNC cells were cultured in a medium containing either 5.6 or 22 mM glucose, no obvious difference in cell viability was observed, but cells cultured in the high glucose medium were more active in uptake of the labeled AA into phospholipids as well as their response to A23187. These results demonstrate stimulation of a Ca^{2+}-dependent phospholipase A_2 in astrocytes by Ca^{2+} mobilizing agonists but not by cytokines. Also, AA metabolism in these cells can be altered by the levels of glucose in the culture medium (Supported by MU Research Board Grant and AA 06661 from NIH).

DECREASED TESTOSTERONE AND INCREASED CORTISOL IN NEONATES OF MOTHERS WHO SMOKED DURING PREGNANCY N.E. Del Valle[1], J. A. Capriles[2] and A.C. Segarra*[1] University of Puerto Rico, Physiology Department[1] and Municipal Hospital, Department of Pediatrics[2], Medical Center, San Juan, Puerto Rico 00936.

Prenatal nicotine administration in rats decreases testosterone levels in the fetal (Lichtensteiger and Schlumpf, 1985, Pharmacol. Biochem. Behav.23: p 439) and adult (Segarra and Strand, Brain Res.1989, 480: p151) male rat and affects the process of sexual differentiation of the brain. We decided to investigate if smoking during pregnancy had an effect on neonatal testosterone levels. A sample of newborn children in the San Juan area Municipal Hospital was taken for a prospective longitudinal study. Each week, ten neonates, 5 males and 5 females, of less than 18 hrs were randomly selected to participate in the study. Urine samples of the newborn were collected and assessed by radioimmunoassay for cocaine, nicotine, testosterone and cortisol. In our sample, we found decreased total testosterone and increased cortisol levels in the urine of neonates of mothers who smoked during pregnancy. No significant change was observed in these hormones in neonates of mothers who abused cocaine. We are currently investigating if these changes are correlated with changes in the maternal hormonal millieu.

ALTERATIONS IN NEUROTRANSMITTER AND METABOLITE LEVELS WITHIN THE HYPOTHALAMUS OF RATS PRE - AND POSTNATALLY EXPOSED TO ALCOHOL. T.D. Tran and S.J. Kelly*. Dept. Psychology, University of South Carolina, Columbia, SC 29208.

Animal models of Fetal Alcohol Syndrome typically involve using prenatal or postnatal methods of administration. The effects of alcohol exposure have varied with respect to the type of neurotransmitter changes observed in structures such as the hypothalamus. This may reflect differences in the timing of the exposure on developing neural systems. The first 23 days of gestation in rats is equivalent to the first and part of the second trimesters in humans with respect to brain growth; the first 10 postnatal days in rats is equivalent to the latter part of the second and third trimesters. We implemented a three trimester model of alcohol exposure in which both the pregnant dams and their pups were exposed to relatively high doses of ethanol to determine whether basal levels of neurotransmitters and their metabolites are altered within the hypothalamus. From gestational day 0 through 23, ethanol-treated dams were intubated with 2.5 g/kg ethanol in milk formula. Mean blood-alcohol concentrations were 130.9 ± 23.85 mg/dl for dams. Two control groups of dams were either intubated with milk alone or did not receive intubation. From postnatal day 2-10, pups of ethanol-treated dams were intubated with 3.0 g/kg ethanol in milk formula. Two hours later, they received milk formula alone. Two control groups of pups either underwent intubation procedures without milk and ethanol or no intubation. BAC's for ethanol pups reached 234.8 ± 13.14 mg/dl. Rats were weaned at 21 days and group-housed. No differences in body weight were found between groups. At adulthood, each rat was decapitated and its hypothalamus was dissected free. Samples were assayed using high performance liquid chromatography (HPLC) with electrochemical detection. Neurotransmitters and metabolites detected were noradrenaline, dopamine, 5-HT and 5-HIAA. Alcohol-exposed rats showed trends in increased dopamine and 5-HIAA levels compared to intubated and nontreated control rats. These results suggest that alcohol exposure during all three trimester equivalents in rats alters basal hypothalamic neurotransmitter levels.

MATERNAL ETHANOL INFUSION INCREASES PGE CONCENTRATION IN THE CEREBRAL CORTEX OF THE IMMATURE FETAL SHEEP. JD Reynolds, DH Penning, KA Kimura, F Dexter, JL Henderson, B Atkins, D Poduska, JF Brien*
Depts. Anesthesia and Obstetrics, U. Iowa; Dept. Pharm & Tox, Queen's U., Canada.

Ethanol-induced increase of fetal prostaglandin E concentration ([PGE]) may play a role in the fetotoxic effects of prenatal ethanol exposure. Using the technique of *in utero* microdialysis, the present study tested the hypothesis that *in vivo* ethanol exposure increases [PGE] in the intact cerebral cortex of the immature fetal sheep. Pregnant sheep (n=4) at 90-days gestation (term=147 days) were catheterized, and a microdialysis probe was placed stereotaxically in the fetal parietal cortex. The animals were studied 3 days after surgery. Ethanol (1 g/kg body weight) was given to the ewe as a 1-h iv infusion. Dialysate fractions were collected at 1 h intervals for 5 h before, during, and up to 8 h after ethanol infusion onset. [PGE] was measured by RIA. Basal fetal and maternal plasma [PGE] were 423 ± 98 and 528 ± 133 pg/ml, respectively, and were not changed by ethanol. Fetal cerebral cortical [PGE] was increased by ethanol:

Fetal Cerebral Cortical Dialysate [PGE]			
Sheep #	Basal (mean ± SD) (pg/ml)	Peak After Ethanol (pg/ml)	Fraction After Ethanol Infusion Onset
1	16 ± 2	149	6 - 7 h
2	18 ± 5	223	7 - 8 h
3	63 ± 24	132	1 - 2 h
4	65 ± 28	106	1 - 2 h

The data demonstrate that ethanol increases [PGE] in the immature fetal parietal cortex: there was variability in the magnitude of this increase and in time of occurrence. The data indicate that ethanol stimulates PGE production within the immature fetal brain, as fetal and maternal plasma [PGE] were not changed. Supported by the Carver Research Fund, U. Iowa, and the MRC of Canada.

EFFECTS OF MATERNAL ETHANOL CONSUMPTION AND BUSPIRONE TREATMENT ON DOPAMINE AND NOREPINEPHRINE REUPTAKE SITES IN OFFSPRING. J.L. Eriksen, R.A. Gillespie, W.H. Simmons* and M.J. Druse-Manteuffel The Neuroscience Program and the Mol. Cell. Biochemistry Dept., Loyola U. Chicago, Stritch School of Medicine, Maywood, IL 60153

Previous studies from this laboratory demonstrated the maternal treatment with the serotonin$_{1A}$ (5-HT$_{1A}$) agonist, buspirone, could prevent many of the damaging effects of *in utero* ethanol exposure on the developing serotonergic system. Although buspirone treatment exerted positive effects on the serotonergic system of ethanol-exposed offspring, its effects on other developing neurotransmitter systems were unknown.

The present report investigated the effects of maternal buspirone treatment on dopamine (DA) and norepinephrine (NE) reuptake sites in multiple brain areas from the 19 day offspring of control and ethanol-fed dams. The results demonstrate that maternal buspirone treatment did not alter the concentration of DA or NE reuptake sites. No significant ethanol-associated changes were detected. While buspirone exerts positive effects on the developing 5-HT system of ethanol-exposed rats, it does not appear to damage the development of DA or NE systems.

SPREADING DEPRESSION INDUCED THE EXPRESSION OF THE 27-kDa HEAT SHOCK PROTEIN (HSP27) IN ASTROCYTES OF THE RAT CORTEX. J.-C.L. Plumier*, H.A. Robertson, and R.W. Currie. Laboratory of Molecular Neurobiology, Faculty of Medicine, Dalhousie University, Halifax, Nova Scotia B3H 4H7, Canada.

We examined temporal and spatial distributions of Hsp27 immunoreactivity (Hsp27-IR) following cortical injury and KCl-induced spreading depression:
1. Cortical application of KCl induced Hsp27 expression in astrocytes of the ipsilateral parietal cortex, piriform cortex but not in astrocytes of the retrosplenial cortex of adult rats. In rats pre-treated with NMDA antagonist, MK-801, a compound known to inhibit spreading depression and subsequent astrogliosis, there was a significant reduction of KCl-induced Hsp27-IR in the parietal cortex. These results suggest that Hsp27-IR could be used as a marker of reactive astrocytes.
2. Analysis of Hsp27-IR after mild cortical injury suggests that astrogliosis due to spreading depression did not originate from the injury site and spread throughout the ipsilateral parietal cortex but rather appeared in small clusters of astrocytes throughout the superficial layers of the cortex that eventually joined each other and then recruited astrocytes from deeper cortical layers.
3. While spreading depression induced Fos immunoreactivity, a marker for cellular activity, throughout the entire ipsilateral cortex, Hsp27-IR was not detected in the retrosplenial cortex. However, Hsp27-IR could be induced in the retrosplenial cortex following MK-801 systemic administration, demonstrating that astrocytes of the retrosplenial cortex are capable of expressing Hsp27. These results suggest that spreading depression induced a complex astroglial response that varied according to brain region and could be dissociated from neuronal activity measured by Fos immunoreactivity.

DOWN-REGULATION OF GLIAL VOLTAGE GATED SODIUM CHANNELS AFTER REACTIVE GLIOSIS *IN SITU*. R. Jabs*, I.A. Paterson and W. Walz. Dept. of Physiology, Univ. of Saskatchewan, Saskatoon, S7N 5E5, Saskatchewan, Canada.

Membrane currents of hippocampal glial cells, located in gliotic brain slices of adult rats, were analyzed applying the whole cell patch clamp technique. To induce reactive gliosis, rats were given a single peritoneal injection of kainic acid. Degree of following seizures was rated ascending from 1-6. Rats which exhibited seizures of level 3 or higher showed, within 3 days, a marked loss of pyramidal cells (>60 % in CA1 and CA3) and an increase in the density of GFAP immunostaining representing an apparent increase in the number and size of astrocytes in all layers of the hippocampal CA1 subfield. We analyzed changes in properties of voltage gated channels on GFAP(-), presumably immature astrocytes located in thin vital slices of this reactive hippocampal tissue. Under control conditions depolarizing voltage steps induced, in this subtype of glial cells, a fast net inward current (157+/-65 pA, n=11) with an activation time of about 1 ms and a reversal potential close to 80 mV; typical for sodium currents. In contrast, in reactive tissue this current component was either completely abolished (9 out of 12) or greatly reduced (to 49 %, n=3).

We conclude that *in situ* GFAP(-) glial cells are also responding to brain injury.

Supported by MRC of Canada and the Humboldt Foundation (Germany)

772.3

IONIC STABILIZATION AT THE LESION SITE MAY ATTENUATE REACTIVE GLIOSIS IN SPINAL CORD INJURY. S. Klepper, C. Barrett, G. Markelonis, and T.H. Oh.* Dept. Anatomy, Univ. of Maryland Sch. of Med., Baltimore, MD 21201

Recent work has linked lowered pH and increased intracellular calcium to an increased intensity of GFAP immunoreactivity in astrocytes *in vitro* (Oh et al., *Glia* **13**:319, 1995), and *in vivo* (Klepper et al., Brain Res. **695**: 245; 1995). As Guth et al., (*Exp. Neurol.* **88**:45, 1985; *Exp. Neurol.* **126**:76; 1994) could attenuate CNS injury by infusing triethanolamine buffer (TREA) into the site of spinal cord compression, we used their model to investigate further the role of pH and Ca^{++} on reactive astrocytes following CNS injury *in vivo*. Female Fisher (180-200 g, non-pregnant) were assigned to one of four treatment/control groups (5 animals/group). Each animal was first anesthetized, and an upper thoracic laminectory was performed, the dura mater exposed and the spinal cord compressed for 1 second with jeweler's forceps. After the crush lesion, a cannula was secured above the lesion site and the surgical wound was closed. The compression site was irrigated twice daily for three days with one of the following regimens: saline (vehicle control), TREA (pH 7.3, pH control), Verapamil HCL (VHCL, a dihydropyridine inhibitor of transmembrane calcium flux, pH 5.9), and no infusion. Animals were perfused and the cord was fixed in Bouin's overnight. The tissue was embedded in paraffin and cut at 10 μm. Immunocytochemistry with polyclonal anti-GFAP (1:500 dilution; Dako A/S, Denmark) showed pronounced reactive gliosis at the lesion site of saline-infused or no-infusion animals, a clear trend in reduction in immunoreactivity in VHCL-infused animals, and a marked diminution of immunoreactivity with TREA infusion. These results suggest that ionic stabilization by maintaining physiologic pH and by reducing transmembrane calcium flux via blockade of L-type calcium channels may reduce reactive gliosis thus contributing to the formation of a microenvironment favorable for neuron survival and CNS regeneration. (Supported by NIH Grant NS 34534-THO).

772.4

S100β PROTEIN EXPRESSION IS CORRELATED WITH AXONAL OUTGROWTH. B.S. McAdory, J. Knapp, L.J. Van Eldik, and J.J. Norden*. Dept. of Cell Biology, Vanderbilt University School of Medicine, Nashville, TN 37232

S100β, a protein synthesized and released by astrocytes, is a member of the EF-hand Ca^{2+}-binding protein family. It has been postulated that S100β may play a role in axonal outgrowth as well as in some forms of synaptic plasticity. In order to begin to dissect its possible role in axonal outgrowth, we have studied its expression pattern in growth during development and lesion-induced collateral sprouting. For the developmental study, tissue sections from rats staged from postnatal day zero to adult were immunoreacted with an S100β–specific antibody and analyzed by light microscopy. It was shown that S100β protein expression appeared to peak in astrocytes around P10 and decreased thereafter until it reached its adult expression pattern. These findings were further evaluated using a semi-quantitative ELISA to assay protein levels at these stages. In the adult CNS, axonal growth and synapse formation can be induced by lesioning certain pathways, such as the perforant pathway that innervates the dentate gyrus. Lesions were made in adult male rats and the animals were sacrificed at varying timepoints after lesioning. Fixed tissue sections were analyzed by light microscopic immunocytochemistry for S100β expression. It was found that S100β is upregulated in reactive astrocytes between 6 and 9 days post lesion, after which its expression decreases until it reaches its pre-lesion level. Thus, S100β is upregulated when axon outgrowth is most proliferative in development and during lesion-induced collateral sprouting.

THE INDUCTION OF HEAT SHOCK PROTEINS IN BRAINS OF LEAD EXPOSED RATS PRECEDES ASTROCYTE REACTIVITY F. Capani, A. Selvín-Testa*, C.F. Loidl, J.J. López-Costa and J. Pecci-Saavedra. Instituto de Biología Celular. Facultad de Medicina. U.B.A. Paraguay 2155, Buenos Aires, 1121, R. Argentina.

Chronic postnatal lead exposure produces transient astrocytic hypertrophy in hippocampus and cerebral cortex. This is evidenced by an increase of glial fibrillary acidic protein (GFAP) immunoreactivity from 60 to 90 days of exposure. To investigate the early events that lead caused in mature astrocytes and neurons after weaning, the exposure (1g%, w/v) was started 90 days prior to mating and prolonged until 4 months of age. We used heat shock protein 70 kDa (HSP), GFAP, and vimentin (VIM) immunocytochemistry, electron microscopy, and a computer assisted image analysis in postnatal (PN) rats from 21 to 90 days old. Induction of HSP in astrocytes and in non pyramidal neurons (21-60 PN) in hippocampus and cerebral cortex was detected. Astroglial edema without neuronal necrosis (21-45 PN) was observed prior to the hypertrophic changes in astrocytic cytoskeleton marked with GFAP and VIM (60-90 PN). Lead exposure in the period of rapid brain growth induces stress response in mature neurons and astroglial cells, previous to the increment of astrocytic cytoskeletal proteins (GFAP and VIM). The induction of HSP in neuronal cells, prior to astrocyte reactivity may explain the increased susceptibility of neurons to harmful effects of lead. Neurotoxic effects also restore the capacity to express VIM in mature astrocytes of hippocampus and cerebral cortex in young rats indicating a selective vulnerability of these regions. Supported by CONICET and U.B.A.

772.6

CAPABILITY OF REACTIVE GLIOSIS DEVELOPS PRENATALLY IN THE DIENCEPHALON BUT NOT IN THE CORTEX. M. Kálmán*, B. Ajtai and L. Kállai, Dept of Anatomy, Semmelweis Univ. of Medicine, Budapest, Hungary, H-1450

Reactive gliosis is supposed to be a limiting factor for the regeneration of central nervous tissue. At the early stage of development, the central nervous system still has a fair regenerative capacity. In the present study our goal was to estimate the age when the brain tissue gains capacity of reactive gliosis and we found a meaningful difference between the cortex and the subcortical (diencephalic) regions.

At embryonic days E18, E19 and E20, rat embryos were exposed with the corresponding segment of uterus horn, and stab wounds were performed through the uterine wall into the developing cortex and then the embryos were repositioned into the abdominal cavity. The surgery was performed in a deep ketamine-xylazine anaesthesia. Similar telencephalic lesions were performed on neonatal animals (P0), too. From birth, animals were sacrificed on every postoperative day, and the brains were immersed into 4% buffered paraformaldehyde solution for three days. Series of vibratome sections were processed for immunohistochemistry against glial fibrillary acidic protein.

In the animals lesioned at E18 or 19, a typical reactive gliosis developed around the diencephalic lesions by the 4th postoperative day while no lesions appeared in the cortex. When the lesions were performed at E20 and P0, an atipically weak and transient glial reaction was observed in some cases in the cortex, too.

We suppose that the capability of reactive gliosis develops at different age in the different brain structures, i. e. when they reach a critical stage of their histogenesis.

This study was supported by an ETK grant of the Semmelweis University of Medicine.

HUMAN ASTROCYTOMAS EXPRESS TENASCIN-C AND TENASCIN-X. K.Hasegawa[1,2], T. Yoshida[1], K. Matsumoto[3], T. Tanaka*[2], S. Waga[2] and T. Sakakura[1]. [1]Dept. of Pathology and [2]Neurosurgery, Mie Univ. Sch. of Med., Tsu, Mie 514 Japan. [3]Dept. of Evolutionary Genetics, National Institute of Genetics, Mishima, Shizuoka 411 Japan.

Tenascin(TN)s are a family of extracellular matrix (ECM) glycoproteins. The first member of this family, tenascin-C (TN-C), is expressed in a varitety of tumors including human astrocytomas. Tenascin-X (TN-X) is the newest member of the TN family and the expression in tumors has not been examined. We identified that tumor cells derived from human glioma (U-251MG, A-172 and T98G) and mouse glioma (203 glioma) express not only TN-C but also TN-X. Using anti-human TN-C monoclonal and anti-mouse TN-X polyclonal antibodies, we also studied the expression of TN-C and TN-X immnohistochemically in human astrocytomas (7 low-grade astrocytomas, 11 anaplastic astrocytomas, and 12 glioblastomas) and 5 normal brain tissues obtained from autopsy cases. In high-grade astrocytomas, TN-C is more highly expressed among tumor cells and in tumor vessels than in low-grade astrocytomas. In contrast, TN-X is more strongly expressed in the perivascular stroma of the low-grade astrocytomas than that of normal brain tissues. These results suggest that the expression of TN-C and TN-X is reciprocal, and that they play distinct roles in tumor angiogenesis.

772.8

BOTH DIRECT AND INVERSE CORRELATIONS BETWEEN GFAP EXPRESSION AND GLIOBLASTOMA TUMOR CELL GROWTH. K.G. Murphy, H.S. U and J.D. Hatton.* *Division of Neurosurgery, UC San Diego, La Jolla, CA 92093*

Expression of GFAP is correlated with the differentiation of astrocytes. Investigations of a causative relationship between GFAP expression and glioma tumor cell growth have produced inconsistent results. To study this relationship, we isolated clones from the human glioblastoma cell line U373-MG. One clone (GFAP-) displayed consistently low GFAP expression (only about 7% of cells were positive by immunocytochemistry), while a second clone (GFAP+) displayed consistently high GFAP expression (about 80% positive cells). Treatment with 1mM dbcAMP greatly down-regulated GFAP expression in both clones. We compared the morphology, doubling time, saturation density and anchorage independent growth of these clones. Both cell lines have ameoboid as well as stellate components in culture. The doubling time of the two clones was not significantly different; however, the GFAP- line had a higher saturation density than its counterpart. The GFAP+ cell line displayed an advantage in an anchorage independent growth (3.7 colonies per 10X field in soft agar cultures versus 2.2 colonies per field). The two cell lines display different colony conformations: the GFAP+ cell line forms compact, well-defined spherical colonies while the GFAP- cell line forms broad, spreading colonies with vague boundaries. Although the GFAP+ cell line displays increased colony growth, it is the GFAP- cell line which appears more aggressive by nature of its decreased contact inhibition and invasive colony formation. These results suggest a direct correlation between GFAP expression and some measures of tumor cell growth, and an inverse correlation with measures of tumor invasion.

EFFECT OF CORTICOSTEROIDS ON GFAP AND MBP GENE EXPRESSION IN CULTURES OF TYPE 1 ASTROCYTES AND OLIGODENDROCYTES. R.C. Melcangi(1), V. Magnaghi(1), I. Cavarretta(1), M.A. Riva(2) and L. Martini(1)*. (1) Dep.Endocrinology, U. of Milan; (2) Di.Bi.T., S. Raffaele Hospital, Milan, Italy.

Neurons and glia convert hormonal steroids into 5α-reduced metabolites through the action of the 5α-reductase-3α-hydroxysteroid dehydrogenase system (5α-R-3α-HSD). In the present experiments, we have considered the effects of some corticoids, in their native (corticosterone and deoxycorticosterone, DOC), or 5α-reduced molecular forms (dihydrocorticosterone, DHC; dihydrodeoxycorticosterone, DHDOC) on gene expression of specific astrocyte (glial fibrillary acidic protein, GFAP) and oligodendrocyte (myelin basic protein, MBP) cellular markers. The results obtained using cultures of rat type 1 astrocytes have shown that corticosterone is able to significantly increase GFAP mRNA levels after 6 and 24 hours of exposure. No significant effects are induced by treatments with DHC. DOC proved to be ineffective on GFAP gene expression at all times of observation, while its 5α-reduced metabolite DHDOC decreased GFAP mRNA levels at 6 and 24 hours. DHDOC was also able to decrease mRNA MBP levels in rat oligodendrocyte cultures. On the contrary, DOC, corticosterone and DHC were not able to change, at any time of exposure, the levels of MBP mRNA. In conclusion, the data indicate that: 1) corticosteroids may affect the synthesis of specific markers in glial cells; 2) the effects on astrocyte and oligodendrocyte markers appear to be substantially different, since corticosterone increases GFAP and is ineffective on MBP; 3) the 5α-reduced derivative of DOC diminishes the expression of both GFAP and MBP; 4) the results imply a role of the enzymes 5α-R and 3α-HSD in glial physiology. LYMPHOKINE(S) RELEASED BY ACTIVATED T HELPER CELLS INCREASE GLUCOSE UTILIZATION BY ASTROCYTES. Naichen Yu* and F.E. Bloom. Department of Neuropharmacology, The Scripps Research Institute, La Jolla, CA, 92037

A great deal of evidence indicate that cytokines play an important role in the pathogenesis of HIV-1-associated neurological disorders. Our previous results show that pro-inflammatory cytokines, such as TNF-α and IL-1α, as well as lymphokine, such as IFN-γ, enhance glucose utilization by cultured mouse astrocytes. Here we tested whether the activated T helper cell (Th) stimulated by specific antigen change the energy demand of astrocytes. After 24 hour incubation with the supernatants (final concentration, 10% v/v) from stimulated Th1 or Th2, glucose utilization of astrocytes (reflected by 20 min. 2-DG uptake) increased up to 50% over basal level whereas there were no increases in controls. Furthermore, the 2-DG-uptake-stimulating effects of those polarized Th1 and Th2 were partially blocked by anti-IFN-γ antibody suggesting IFN-γ might be one of the mediators involved in the glucose utilization enhancement effects. Our preliminary results suggested that activated Th(s) could change astrocyte function, namely glucose utilization, possibly mediated by released lymphokine(s). The investigation of the mechanisms underlying this phenomenon is under its way. Supported by MH 47680.

Interleukin-1β Mediated Signal Transduction in Astroglial Cells. Amandip K. Utal, Anissa L. Stopka, Gail Seigel* and Paul D. Coleman. Dept. of Neurobiology & Anatomy, University of Rochester Medical Center, 601 Elmwood Ave., Rochester, NY.

One of the changes in the course of a normally aging brain is reactive astrocytosis. Of the various cytokines known to affect astroglial cells, we have chosen to focus upon the effect of the cytokine interkeukin 1-β (IL-1β). IL-1β causes astrocytes to become more reactive and in some cases to proliferate. We are investigating the mitogenic effect and signal transduction by IL-1β on two types of astroglial cells; U373 cells which are a human astrocytoma cell-line, and primary rat astrocytes.

The proliferative effect of IL-1β was asssayed by tritiated thymidine incorporation. Recombinant human IL-1β induced mitogenesis of U373 cells in a dose-dependent fashion but was unable to cause a similar effect in primary rat astrocytes. 10% fetal bovine serum in the tissue culture medium was able to induce tritiated thymidine incorporation in the rat astrocytes, an effect that IL-1β was unable to modulate.

Several signal transduction mechanisms were investigated: (1) IL-1β was unable to activate phosphatidylcholine-specific phospholipase C in astrocytes as assayed by incorporation of tritiated choline into cellular phospholipids. Phorbol myristate acetate, a phorbol ester and activator of protein kinase C was shown to activate this pathway in these cells, (2) production of diacylglycerol, a lipid second messenger, was not increased in IL-1β - treated astrocytes as compared to untreated cells, (3) IL-1β did not activate sphingomyelinase in astrocytes, and (4) IL-1β activates MAP kinase in both U373 cells (the earliest at 20 min) and primary rat astrocytes. RECIPROCAL INTERACTION BETWEEN CATECHOLAMINES AND "IMMUNE ACTIVATION" BY LIPOPOLYSACCHARIDE IN RAT ASTROCYTE CULTURES. K. A. Sherman* and P. E. Gottschall. Dept. Pharmacol. & Therap., Univ. So. Florida Coll. Med., Tampa, FL 33612

Evidence implicates "immune activation" and inflammatory products of glia in age-related neurodegenerative disorders, i.e., Parkinson and Alzheimer diseases. With age- or disease-related loss of catecholamine systems, metabolism of transmitter released by surviving neurons is likely shifted to a glial compartment. In this study we show that treatment of astrocyte cultures with lipopolysaccharide (LPS, 2 μg/ml), an immune activator, has a pronounced effect on uptake and metabolism of dopamine (DA). Conversely, brief exposure to catecholamines including norepinephrine and isoproterenol suppresses the induction of matrix metalloproteinases (MMPs) after 48 hr LPS.

In control astrocytes from rat neonatal forebrain, 10 μM DA was taken up and metabolized by deamination and O-methylation in about equal proportion, as determined by HPLC-EC assay of 3,4-dihydroxyphenylacetic acid (DOPAC), 3-methoxytyramine (3-MT) and homovanillic acid (HVA). LPS treatment for 48 hr produced a marked shift in the metabolism of DA to predominance of the O-methylation pathway: DOPAC was reduced 70 to 80% (per well or per mg protein, respectively). HVA was less affected and 3MT increased in proportion to the increase in protein. DA deamination remained entirely dependent on monoamine oxidase A (MAO-A) (>95% reduction after clorgyline). Glial uptake and metabolism of DA was inhibited to the same extent (40% - 50%) by the catecholamine transport inhibitor, nomifensine (10 μM). The compensatory increase in 3MT when deamination was blocked by clorgyline was less after LPS. When O-methylation was blocked by OR-486 (0.1 μM), DOPAC increased markedly in both control and LPS-treated cultures, but was still considerably less after LPS than in control astrocytes.

NITRIC OXIDE PRODUCTION IN HUMAN ASTROCYTES IS MODULATED BY CYTOKINES. J. Fujiyama, Y.B. Lee, D.G. Walker, S.U. Kim*. Division of Neurology, Department of Medicine, University of British Columbia, Vancouver, Canada.

Recent studies have suggested that nitric oxide (NO) generated by inducible nitric oxide synthase (iNOS) in the central nervous system (CNS) causes injury and cell death of neurons and oligodendrocytes in human neurological diseases. Recent clinical trials have shown that recombinant human interferon-β (IFN-β) was effective in reducing exacerbations in relapsing-remitting multiple sclerosis (MS). To investigate mechanisms underlying the beneficial effects of IFN-β in MS, the modulatory effects of IFNs on NO production in cultured human astrocytes were determined. Purified populations of astrocytes and microglia were prepared from human fetal brains of 12-20 weeks' gestation. A 4-day treatment with IFN-γ plus interleukin-1β (IL-1β) significantly increased the production of NO in astrocytes but not in microglia, while IFN-β exhibited a dose-dependent inhibitory effect on IFN-γ plus IL-1β-mediated NO production. Results obtained by RT-PCR analysis also demonstrated that the iNOS mRNA level induced by IFN-γ plus IL-1β was considerably reduced by the addition of IFN-β. The antagonistic effect of IFN-β against IFN-γ and IL-1β's stimulative activity of NO production demonstrated in cultured human astrocytes suggests that interferons serve as regulators of astrocytic NO production at sites of reactive lesions of MS and other human neurological diseases. NITRIC OXIDE SYNTHASE IN THE REGENERATING NERVOUS SYSTEM OF THE MEDICINAL LEECH. O.T.Shafer and C.L.Sahley*. Dept. of Biological Sciences,Purdue University, West Lafayette, IN. 47907

Activation of Nitric Oxide Synthase (NOS) in response to neuronal injury has been detected in several organisms. We have investigated the role of active NOS in the regenerating nervous system of the medicinal leech, *Hirudo* medicinalis. Through the use of NADPH diaphorase staining, an indicator of active NOS, we have shown that this protein is activated within minutes of injury to segmental connectives. The injury, delivered by a pinch with fine forceps, was immediately followed by intense staining for NADPH diaphorase activity, indicating the presence of active NOS. Sights of injury stained positively for active NOS well beyond 48 hours after *in vivo* pinches were delivered to segmental connectives. Furthermore, the staining remained localized to the site of injury, never staining beyond the pinch. Following crushes to leech segmental connectives microglia actively migrate to the site of injury. Our staining results suggested that Nitric Oxide (NO) might be involved in the rapid microglial accumulation that follows injuries to connectives in the medicinal leech. Culturing pinched connectives either in the presence of the NOS inhibitor, L-nitro-arginine-methyl-esther (L-NAME), or its inactive isomer D-NAME showed that NO may serve as a stop signal for migrating microglia. For short regeneration times (2-6 hrs) the distributions of microglia about the sites of lesions were virtually indistinguishable. However, after 24 hours of regeneration D-NAME treated chords, just like untreated chords, showed tight aggregates of microglia within the area of injury while L-NAME treated chords displayed a diffuse un-aggregated distribution, spread well beyond the sight of injury. Our results suggest that NO serves as signal for microglia to stop at the sites of injury resulting in the accumulation and aggregation of these cells at the sites of regenerating axon outgrowth. NADPH-DIOPHORASE HISTOCHEMISTRY LABELS IDENTIFIED GLIAL CELLS IN EMBRYONIC LEECHES. B.K. Modney* & C.L. Sahley. Dept. of Biol., Cleveland State Univ. Cleveland OH, 44115; Dept. Biol. Sci., Purdue Univ., W. Lafayette, IN 47907

Nitric oxide (NO) is thought to be an important signaling molecule for normal neuronal development. NADPH histochemical staining of the CNS labels cells that contain various isoforms of nitric oxide synthase. In adult leeches, immunocytochemical studies using antibodies to nitric oxide synthases have confirmed results obtained using NADPH histochemistry. In the present experiments, leeches *(Hirudo medicinalis)* were stained using NADPH histochemistry between 6 and 14 days of embryonic development. A clear developmental pattern emerged. From days 9 to 11 (about 1/3 through development) identified glial cells stained heavily compared to the surrounding tissue. Of the eight glial cells present in each ganglion, the pair of neuropil glia, which ensheathe processes and synapses within each ganglion, stained consistently. The six packet glia, which surround neuronal cell bodies, stained less reliably and not before day 10. The single pair of connective glia, which ensheathe axons that travel between ganglia, also stained heavily between day 9 and 11. Around day 12 to day 14 many cell bodies and fibers within ganglia stained. Axons also stained in the connectives at this time, while the staining intensity of the connective glia decreased. The differential staining patterns seen during these time periods suggest that NO could play several different roles in development of the leech nervous system. Since glial staining is most intense between days 9 and 11, a time when neurons are beginning to undergo axonogenesis and synaptogenesis, the present results suggest that the glial cells and NO might be particularly important in the early stages of these processes. In addition it appears that neurons also signal using NO, but at a later time when synaptic connections are being established, stabilized and/or refined. DEVELOPMENT OF GLIAL CULTURE SYSTEMS TO EXPLORE THE NEUROPROTECTIVE MECHANISM OF THE IMMUNOSUPPRESSANT, FK506. A. Iwashita, G.R. May & S.P. Butcher* Fujisawa Institute of Neuroscience, Department of Pharmacology, University of Edinburgh, EH8 9JZ, Scotland, UK

FK506 has a powerful neuroprotective effect in a rat model of focal cerebral ischaemia (Sharkey & Butcher, 1995). However, the mechanism of this neuroprotective activity is unclear. Interleukin-1 (IL-1) has been implicated in neurodegenerative processes (Rothwell & Hopkins, 1995) and has been shown to be produced by astrocytes and microglia (Hopkins & Rothwell, 1995). As an immunosuppressant, FK506 may be expected to modify the production of cytokines within the brain and this may contribute to its neuroprotective activity. In the present study we have developed cultures of astrocytes and microglia in order to determine whether FK506 influences the production of IL-1β evoked by bacterial lipopolysaccharide (LPS).

Astrocytes were isolated from primary mixed cerebrocortical cultures from 1 day old mice by overnight shaking to remove microglia, oligodendrocytes and type 2 astrocytes, and were identified by immunostaining with an antibody against glial fibrillary acidic protein. Production of IL-1β was elicited by 24 h exposure to LPS (10 $\mu g\ ml^{-1}$) and quantified by enzyme-linked immunosorbent assay (ELISA). Co-administration of FK506 (10^{-8} - 10^{-5} M) had no effect on the production of IL-1β (LPS alone elicited 289 ± 11 $pg\ ml^{-1}$, and in the presence of 10^{-5} M FK506, 312 ± 13 $pg\ ml^{-1}$; $P > 0.05$). As FK506 does not appear to modify IL-1β production in astrocytes, cultures of microglia were purified from cortical cultures and identified by immunocytochemistry using a Mac-1 antibody. The effects of FK506 on IL-1β production in this system will be presented.

PROSTAGLANDIN E_2 INDUCES bFGF EXPRESSION IN CULTURED RAT MÜLLER CELLS. T.Cheng, R. Wen, W. Cao, and R. H.Steinberg*. Depts. of Physiology and Ophthalmology, UCSF, San Francisco, CA 94143.

We investigated the induction of bFGF expression by prostanglandin E_2 in cultured rat Müller cells. Müller cells were obtained from neonatal rat retinas and cultured in EMEM eagle with 10% fetal calf serum up to 4 passages. Northern blot analysis revealed that expression of bFGF was induced with PGE_2 as low as 0.1 μm and the maximal up-regulation of bFGF (3.5 fold) was observed with 10 μm of PGE_2. The time-course study (with 10 μm of PGE_2) showed that the induction was transient in nature: up-regulation of bFGF mRNA was seen as early as 1 hr after addition of PGE_2. It reached a maximum at 2 hr, and then declined to the baseline level by 24 hr. Both the protein kinase inhibitor, H-7, and the PKA inhibitor, H-89, blocked the induction, while a specific PKC inhibitor, GF 109203X, failed to inhibit the induction. In addition, PKC down-regulation with PMA did not block the induction by PGE_2. Forskolin also stimulated bFGF mRNA expression.These findings indicate that PGE_2 transiently induces bFGF expression in cultured Müller cells through the PKA pathway, and raise the possibility that endogenous PGE_2 stimulates bFGF expression in Müller cells *in vivo* under conditions where PGE_2 may be increased, such as mechnical injury.

DIFFERENTIAL DISPLAY OF BASIC FGF-TREATED CORTICAL TYPE I ASTROCYTES: REGULATION OF a NOVEL cDNA IN VITRO AND IN VIVO . M.R. Varia* D.G. Schaar, J. Wagner, C.F. Dreyfus and I.B. Black. Department of Neuroscience & Cell Biology, RWJ Medical School/UMDNJ, Piscataway, NJ 08854

Previously we defined a model of astrocytosis in which cultured cortical type I astrocytes treated with basic fibroblast growth factor (bFGF, 10 ng/mL), a protein upregulated in some forms of astrocytosis, elicited specific changes in both known and novel genes. To further characterize a profile of gene regulation in astrocytes, we used differential display, a highly sensitive, rapid differential cloning technique (Liang and Pardee, *Science*, 1992, 257:967-971). Display of cDNA from both 4 and 24 hr bFGF-treated cortical astrocytes revealed unique patterns of gene expression, which were regulated in a temporal fashion. For example, clone 4.1 (c4.1), a novel cDNA identified by the display is regulated in bFGF-treated cultured cortical astrocytes, as confirmed by northern analysis. To determine whether regulation in culture reflects regulation in vivo, bFGF (5ng/ g) was injected sc in neonatal rats (Wagner JP, Soc. Neur. Abs.,1995). By northern analysis, we found that short term treatment for 8 or 24 hrs yielded dramatic increases in c4.1 mRNA. However, treatment with bFGF (2X daily) over a 9 day period resulted in low levels of c4.1 mRNA in the cortex, similar to PBS injected controls. These results raise the possibility that at sites of injury/disease where bFGF is upregulated, c4.1 may be one of the early genes that is induced. Our data indicate that regulation in culture may indeed mimic regulation in vivo and that the culture model may be useful in defining genes in disorders characterized by astrocytosis. EXPRESSION OF THE LIM-PROTEIN GENE *Lmo1* CHARACTERIZES SUBPOPULATIONS OF ASTROCYTES IN THE CNS OF TRANSGENIC MICE. L.S. Campos* G.L. Hinks and M.V. Sofroniew. MRC Cambridge Centre for Brain Repair, University of Cambridge, and Parke-Davis Neuroscience Research Centre, Forvie Site, Cambridge CB2 2PY

LIM proteins contain cysteine-rich motifs thought to be involved in protein-protein interactions. Some LIM proteins contain DNA binding homeodomains, LIM-only proteins do not. *Lmo1* codes for a LIM-only protein identified initially as a potential oncogene in a human T-cell leukemia. Transgenic mice expressing a *Lmo1*-promoter 1-*lacZ* fusion gene construct show reporter protein (ß-galactosidase, ß-gal) activity in selected regions of the developing CNS (Nature 344:158). Here we report that ß-gal is immunohistochemically detectable in restricted populations of both neurons and glia in various CNS regions throughout the adult life of these transgenic mice. *In situ* hybridization using a radiolabelled oligonucleotide probe confirmed *Lmo1* mRNA in comparable regions in the brains of non-transgenic adult mice. ß-gal immunoreactive cells with the typical appearance of astrocytes were present in certain areas of the olfactory bulb, striatum, hypothalamus, hippocampus, midbrain and cerebellum. In some regions, these cells observed anatomically recognized boundaries. Some of these cells showed co-localisation with GFAP in uninjured brain. After injury there was no increase in the number of ß-galactosidase expressing cells, but more of these were GFAP positive. This transgenic model may provide a useful means of studying astrocyte heterogeneity in the CNS.

CEREBRAL CORTEX AND LIMBIC SYSTEM: MOLECULAR EXPRESSION PATTERNS

773.1

EARLY EXPRESSION OF GAD65 IN THE LOWER INTERMEDIATE ZONE OF THE DEVELOPING RAT NEOCORTEX. S.T. Dupuy*, B.A. Havens, and C.R. Houser. Dept. of Neurobiology, UCLA, Los Angeles, CA 90095.

Several previous studies have reported different patterns of expression for the two isoforms of glutamate decarboxylase (GAD) during CNS development, with GAD67 being present early and GAD65 appearing at more mature stages. In order to determine if this is a general principle of GABA system development, immunohistochemical methods were used to localize GAD67- and GAD65-containing neurons within the rat neocortex at embryonic (E) and early postnatal (PN) ages. The neocortex was chosen since several groups of early appearing GABA neurons, i.e. those in the marginal zone, subplate, and lower intermediate zone (LIZ), have been described in this brain region. GAD65-containing neurons were detected as early as E15 in all three regions and were particularly prominent within the LIZ of the lateral cortex, where GABA neurons have been demonstrated previously at this age. These GAD65-containing neurons appeared to constitute the majority of the total neuronal population within the LIZ as revealed by MAP-2 immunohistochemistry. GAD67-containing neurons were also detected within this zone, although their numbers were considerably less than those labeled for GAD65. From E17 to early PN ages, GAD65-labeled neurons were distributed throughout the entire lateral-medial extent of the LIZ, and the difference in labeling for the two GAD isoforms within this zone persisted. This difference was even more striking in the adjacent lateral ganglionic eminence where GAD65 was observed as early as E15 with virtually no detection of GAD67 in this same region. Thus, GAD65 is expressed quite early in several brain regions and may contribute to GABA production at very early stages of CNS development. Supported by NS33360.

773.2

ULTRASTRUCTURE OF GAD-IMMUNOREACTIVE PROCESSES IN THE EARLY POSTNATAL RAT HIPPOCAMPAL FORMATION. N. Zhang*, S.T. Dupuy and C.R. Houser. Dept. of Neurobiology, UCLA, and VA Medical Center, Los Angeles, CA 90095.

At late prenatal and early postnatal ages, a rich plexus of glutamate decarboxylase (GAD)-labeled processes is present in the developing apical dendritic layers of the rat hippocampus and dentate gyrus, and the present goal was to determine the ultrastructural characteristics of these structures. In the dentate gyrus at postnatal day 1, many of the labeled profiles resembled growth cones or immature axonal processes, and GAD-immunoreactivity was distributed relatively homogeneously throughout these structures. Very few definitive GAD-labeled synapses were observed in the dentate gyrus at this age. In contrast, GAD-labeled structures in CA3 appeared more mature and included axon terminals which contained high concentrations of vesicles and some mitochondrial profiles. Prototypic synaptic contacts were observed between labeled terminals and the proximal apical dendrites of CA3 pyramidal cells as well as immature dendritic profiles within strata lucidum and radiatum. Even when distinct synaptic contacts were not evident, putative synaptic vesicles were often found in clusters adjacent to the plasma membrane of axon-like processes, and GAD immunoreactivity was concentrated at these sites. The GAD-labeled processes are likely to be the major sites of GABA synthesis and release in the hippocampal formation at early postnatal periods when GABA exerts predominantly depolarizing effects. The presence of GAD-containing axon-like profiles in developing dendritic layers is consistent with a purported role for GABA in stimulating neurite outgrowth and synaptogenesis. 773.3

EXPRESSION OF THE NICOTINIC ACETYLCHOLINE RECEPTOR α4 ISOFORM IN THE DEVELOPING HUMAN CEREBRAL CORTEX H. Schröder[1*], R.A.J. DeVos[2], G.van Noort[2], A. Wevers[1], S. Nowacki[1], N. Moser[1], U. Schütz[1], and A. Maelicke[3] [1]Inst. II für Anatomie, Univ. zu Köln, D-50931 Köln, FRG, [2]Laboratorium Pathologie Oost Nederland, NL-7512 AD Enschede, The Netherlands, [3]Inst. für Physiologische Chemie und Pathobiochemie, Univ. Mainz, D-55128 Mainz, FRG.

In addition to synaptic transmission nicotinic acetylcholine receptors (nAChR) are involved in regulation of neural growth cone behavior. In rat brains, nAChR gene expression starts early in fetal development [*Schröder et al., Soc Neurosci Abstr 21:1509 (1995)*]. We have started a comparative study on the nAChR isoform mRNA expression in selected areas of the human cerebral cortex during fetal development.

We studied the expression of the - in the adult brain - widespread α4 subunit in human fetal frontal cortex around weeks 20 (n=5) and 38 (n=5) of gestation by in situ hybridization using a digoxigenin-labeled riboprobe. Hybrids were detected by use of an alkaline phosphatase-coupled digoxigenin-antibody and a color substrate reaction.

As early as week 20 α4 transcript-expressing cells are present in the telencephalic neuroepithelium and in the cortical plate. Around birth, the distribution of α4 mRNA-containing neurons very much resembles that seen previously in the adult human cerebral cortex [*Wevers et al., Mol Brain Res 25:122-128 (1994)]* with the majority of pyramidal cortical neurons displaying the α4 hybridization signal.

While cholinergic innervation of rat cerebral cortex develops after birth, the human cortical plate is reached and invaded by cholinergic fibers during the 25th to 30th week of gestation. Developing neurons of the human cerebral cortex rather than those of the rat may be a target for acetylcholine- and nAChR-mediated regulation of neuronal migration. Further developmental histochemical studies on the human and rat cerebral cortex will render more detailed informations on this important issue.

IDENTIFICATION OF BASAL FOREBRAIN CHOLINERGIC NEURONS IN LIVING TISSUE SLICE AND CELL CULTURES. R.T. Robertson*, D.H. Ha, J. Baratta, K.J. Claytor, J. Ingeman, J. Yu and J.H. Weiss. University of California, Irvine, CA 92717.

Significant progress has been made in recent years in characterizing the neurochemical phenotypes of neurons. For the most part, however, such characterization has occurred only after the animal or culture has been sacrificed and the tissue has been fixed and processed by histochemical or immunocytochemical techniques. Identification of neurons, based upon their neurochemical phenotype, while still in the living state would be of tremendous value to studies that attempt to study specified subsets of neurons. Experiments presented here investigated fluorescence techniques to identify basal forebrain cholinergic neurons (BFCNs) in living preparations. The 192-IgG antibody to the low affinity NGF receptor (p75) was linked to the fluorophore Texas Red (TR). Our rationale (similar to that of Wiley for the use of 192-IgG-saporin) was that BFCNs would selectively incorporate the IgG antibody, with attached fluorophore, and transport it retrogradely to label the somata. The 192-IgG-TR conjugate was injected intraventricularly in young rats or added to the growth medium of cell cultures or slice cultures. Sections of whole brains displayed a pattern of neuronal labeling identical to the distribution of BFCNs. Cultures displayed neuronal labeling suggestive of BFCNs as well as labeled astrocytes. Tissue processed for AChE histochemistry or ChAT immunocytochemistry will determine if labeled neurons are cholinergic. Preliminary data indicate that this procedure is a valid means of identifying BFCNs in freshly cut sections from whole brain or in living cultures. *Supported by NIH grant NS 30109.*

773.5

PRENATAL DEVELOPMENT OF NADPH-DIAPHORASE REACTIVITY IN THE HUMAN HIPPOCAMPAL FORMATION. X. X. Yan*[1] and C. E. Ribak.[2] [1]Dept of Anatomy & Neurobiology, Hunan Medical University, Changsha 410078, P.R. China; and [2]Dept of Anatomy & Neurobiology, UCI, Irvine, CA 92717.

Nitric oxide (NO) plays a role in axonal outgrowth, synaptic formation and plasticity. Alterations in nitric oxide synthase (NOS) reactivity have been reported in schizophrenia, Alzheimer's disease and aging. To determine the normal development of NOS reactivity in the human hippocampus, we studied fetuses aged from 13 weeks (W) of gestation to term using a histochemical method for nicotinamide adenine dinucleotide phosphate-diaphorase (NADPH-d). Heavily stained bipolar somata were seen in the ventricular and intermediate zones in the Ammon's horn by 13W, and then in strata radiatum and lacunosum-moleculare. They stabilized in number and location by 24W, but became the largest, spiny, and frequently multipolar, NADPH-d neurons at 28W up to term. Moderate reactive, non-spiny and medium-sized bipolar or multipolar somata appeared by 20W in all subfields, and were most common in the dentate gyrus. Lightly stained small round or stellate cells emerged in Ammon's horn and dentate gyrus after 32W. Labelled processes distributed in the dentate gyrus and stratum oriens of CA1-3 before 20W, and then increase in all areas with increasing age. By term, the plexus was densest in the hilus, followed by strata radiatum, pyramidale, lacunosum-moleculare, and oriens of Ammon's horn. The processes were frequently associated with blood vessels, especially those in the hippocampal fissure. NADPH-d reactivity in pyramidal cells in CA1-3, subiculum and entorhinal cortex and in granule cells of the dentate gyrus was very strong at earlier stages (13-24W), but reduced at later ages, particularly in those in the CA3 to the dentate gyrus. The results show a differential developmental pattern of hippocampal NADPH-d neurons and a transient overexpression of the enzyme in the pyramidal and granule cells, and spatial association of the cells and their processes with blood vessels. Supported by National Educational Committee of China and NSF grant IBN 9422392.

THE EMERGENCE OF DIAPHORASE-POSITIVE NEURONS IN THE CORTICAL SUBPLATE OF HUMAN FETUSES. **L. deAzevedo[2], M. Rocha[1], C. Hedin-Pereira*[,1], J.G. Franca[3] and R. Lent[1]. [1]Depto. de Anatomia, Inst. de Ciências Biomédicas, UFRJ, Rio de Janeiro 21941-590; [2]Inst. Fernandes Figueira, FIOCRUZ, Rio de Janeiro 22250-020; [3]Prog. de Neurobiologia, Inst. de Biofísica, UFRJ, Rio de Janeiro 21941-590, Brazil.**

We have studied the occurrence and distribution of cells that may employ nitric oxide (NO) as a messenger during human cortical development, by histochemical labelling of the enzyme NADPH-diaphorase, implicated in the synthesis of NO. Four brains were removed from human fetuses at 18 (n=2), 25 (n=1) and 30 (n=1) weeks post-ovulatory (wpo), deceased some days after spontaneous delivery. The brains were fixed 1-5 hours after death, by immersion in 4% paraformaldehyde for 24-48 h. Blocks of tissue including the medial cortex were removed, cut in a vibratome into 300 μm coronal sections, and reacted with NADPH for the histochemical detection of diaphorase. No positive cells were detected in the 18 wpo tissue, although clear labelling was apparent within the endothelial cells of brain capillaries. On the other hand, tissue both from the 25 and the 30 wpo fetuses showed numerous diaphorase+ cells in the cortical subplate. The density of these cells increased from ventral to dorsal, being lower in the cingulate area than in the supramarginal cortex. The morphology of the positive cells was multiple and typical of neurons, including bipolar and multipolar cells with very long dendrites, and inverted pyramids. No positive cells were present in the cortical plate in any of the cases examined. We concluded that neurons in the human cortical subplate start to express diaphorase, and probably become able to sinthetize NO, during the fifth month of gestation. *Financial support*: CNPq, Finep.

NADPH-DIAPHORASE IN THE DEVELOPING CHICK FOREBRAIN A.Stamatakis, H.Barbas*#, C.R.Dermon. Dept. Biol., Crete Univ., Heraklion, Crete, Greece, #Dept. Health Sci., Boston Univ., Boston, MA 02215, USA.

Nitric oxide, produced by neurons that are positive for nitric oxide synthase (NOS), has been considered a retrograde messenger involved in synaptic plasticity and refinement of neuronal connections. We studied the expression of NOS during late development of the chick forebrain, at times coinciding with cell migration, synapse formation and elimination, cell death, and establishment of functional networks. We applied nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) histochemistry to identify NOS positive neurons and fibers at embryonic days E9, E11, E13, E15, E17, E19 and posthatching days P1, P5, P10 and P20 in the chick telencephalon. Golgi-like NADPH-d positive neurons first appeared at days E11 and E13 in structures that are homologous to the mammalian basal ganglia (paleostriatum augmentatum and primitivum, lobus paraolfactorius) and in the olfactory tubercle. Moreover, positive fibers were noted in the lateral forebrain bundle, anterior commissure and invaded the nucleus basalis (Bas), bulbus olfactorius and hyperstriatum intercalatum supremum (HIS). Between days E13 and E15, Golgi-like positive neurons were found in the dorsal ventricular ridge (neostriatum, hyperstriatum accessorium and Bas), which are the avian counterpart of the mammalian cortex. In addition, at day E15, groups of lightly stained neurons with no apparent labeled processes, appeared in the neostriatum, ectostriatum and hyperstriatum. In contrast with neurons which were robustly labeled, their number peaked at day E19 and then gradually decreased from posthatching days 1 to P20, with the exception of those in the ectostriatum, which disappeared at day P10. Anterograde labeling in the telencephalon was present at day E11 in the Bas, HIS, and bulbus olfactorius, and increased in density with age. Specifically, in bulbus olfactorius it assumed a characteristic laminar distribution. These data suggest that NOS positive neurons may have an important role in late developmental events and in the establishment of mature connections and normal cytoarchitecture of the avian telencephalon. POSTNATAL DEVELOPMENT OF GABA, PARVALBUMIN, AND CALBINDIN -IMMUNOREACTIVITY IN FERRET PRIMARY SENSORY CORTEX. D.E. Newman, H.L. Gonzalez, A.B. Wormington and S.L. Pallas*. Div. of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

The calcium binding proteins parvalbumin (PV) and calbindin (CB) are found in different subtypes of cortical GABAergic neurons. We showed previously that neonatal diversion of retinal axons into the ferret auditory pathway causes a decrease in PV-immunoreactivity (ir) and an increase in CB-ir in primary auditory cortex (AI). Here we describe the normal development of PV and CB-ir neurons in AI in order to determine whether the experience-induced changes in the "rewired" AI might represent stabilization of an early developmental pattern. We also describe how the maturation pattern of PV and CB compares with that of GABA itself, and how the pattern in AI compares with that in primary visual cortex (V1). The advantage of ferrets for this type of chemoarchitectonic study is the relative immaturity of their cortex at birth compared to cats, rats, or monkeys.

We find that GABA, PV and CB-ir exhibit different developmental patterns, suggesting that they play different roles in cortical maturation. Densities of GABA, PV, and CB-ir neurons peak by postnatal day (P) 7. GABA-ir declines slowly, but PV and CB-ir drop sharply by P20, suggesting that certain neurons either die or stop expressing PV or CB. GABA-ir maintains a uniform distribution across the cortical layers. PV-ir appears earlier than CB-ir and follows the inside-out pattern of cortical migration, with an adult pattern resembling that of GABA. CB-ir attains a bilaminar pattern by adulthood, but at P60, CB-ir neurons are widely distributed, similar to what is seen in rewired AI. Thus, the increased CB-ir triggered by retinal input may represent the stabilization of the P60 pattern. We observe developmental differences between AI and V1 which may underlie differences in their response properties, and which may provide a substrate for plasticity. DEVELOPMENTAL EXPRESSION OF A NOVEL GENE (PK134) MAPPED ON HUMAN CHROMOSOME 7q22, Hyun Kim*, Chang Mi Kim, Yong Hyuck Chun, Young-Suk Suh, and Sun-Hwa Park.Department of Anatomy, Korea University College of Medicine, Seoul, Korea.

Recently, it has become clear that a new technique is needed to rapidly isolate genes with known chromosomal locations that encode proteins with specific biological functions. We have developed one such a method and applied it to search for genes that may play a functional role during the development of the central nervous system. We prepared cDNAs from 18 week-old human fetal brain and used as probes for fluorescence *in situ* hybridization on human chromosomes. The bands that showed strong hybridization signals with the cDNA probes were microdissected and amplified by PCR. DNA sequence analysis and *in situ* hybridization histochemistry (ISHH) identified a novel neuron specific gene, called PK134, which is located on human chromosome 7q22. ISHH of developing and adult rats revealed that PK134 expression was restricted to the nervous system. In the prenatal stages, low levels of PK134 mRNA were found in the cerebral cortex. After birth, the level of expression remained low until postnatal day (PN) 7 when the expression was abruptly increased in the entorhinal cortex. After PN 7, the expression of PK134 transcript was gradually downregulated, and the transcript was not found in the adult brain. Our findings suggest that PK134 encodes a novel neuron specific gene located on human chromosome 7q22 that is expressed for a certain critical period during neuronal development, and that the PK134 gene product may play an important role in entorhinal cortex development.

LOCALIZATION OF GAP-43, BDNF AND EGF-R mRNA TO THE HUMAN DORSOLATERAL PREFRONTAL CORTEX DURING POSTNATAL DEVELOPMENT. C. Shannon Weickert*, M. J. Webster, T.M. Hyde, J.E. Kleinman, D.R. Weinberger and M.M. Herman. Clinical Brain Disorders Branch, NIMH Neuroscience Center, Washington, DC 20032

We have begun to identify the spatial and temporal expression of proteins implicated in growth and plasticity of cortical neurons of the human dorsolateral prefrontal cortex (area 46) by employing *in situ* hybridization histochemistry for the mRNA's. We examined the mRNA for the neuron-specific presynaptic growth associated protein-43, (GAP-43), which is a marker of neuronal plasticity. We have also mapped out expression sites for Brain Derived Neurotrophic Factor (BDNF) mRNA and Epidermal Growth Factor Receptor (EGF-R) mRNA in order to begin to discern potential trophic relationships between human cortical neurons and their targets. We have focused on 5 postnatal time points: 2-4 months, 8-11 months, 14-15 years, 17-18 years and adults. Highest GAP-43 mRNA levels were found in layers IV and VI at all developmental time points examined, whereas in the adult the most intense mRNA signal was found in cortical layers II-III. Throughout postnatal development, EGF-R mRNA was most abundant in cortical layers II and V/VI, while BDNF mRNA was highest in layers V/VI. Layer V/VI of the postnatal developing human prefrontal cortex contains GAP-43, EGF-R and BDNF mRNA; this suggests that all three proteins may be colocalized to cortical-striatal neurons and/or cortico-cortical projection neurons and that all three proteins may be involved in coordinating the postnatal development of projection neurons of the human prefrontal cortex. SYNAPTOGENESIS AND DEVELOPMENTAL EXPRESSION OF GLUTAMATE 2/3 RECEPTORS ON HILAR MOSSY CELLS OF RAT DENTATE GYRUS REVEALED BY INTRACELLULAR LABELING AND IMMUNOCYTOCHEMISTRY.

I. Spigelman[1]*, B. Sun[1], X. X. Yan[2] and C. E. Ribak[2]. [1]UCLA School of Dentistry & Brain Research Institute, Los Angeles, CA, 90095-1668; and [2]UCI Department of Anatomy & Neurobiology, Irvine, CA, USA, 92717.

Hilar mossy cells play important roles in signal processing in hippocampal neuronal circuitry and are most sensitive to excitotoxic damage, particularly in adulthood. To understand more about the development of hilar neuronal circuitry and whether age-dependent vulnerability of mossy cells is related to the expression of specific glutamate receptors, electrophysiologically identified mossy cells in slices from rats between postnatal days (P) 7 and 30 were labeled by Neurobiotin (Vector), processed for glutamate receptor 2/3 (GluR2/3) immunoreactivity and examined by electron microscopy. In electrophysiological recordings, the intrinsic membrane properties and synaptic responses of mossy cells to perforant path stimulation exhibited considerable developmental changes between P7 and P30. Digit-like spines were occasionally seen at P7, but commonly at P14, on the soma and dendrites, with many of them extending between mossy fiber terminals that frequently formed synapses on the somal surface and dendritic trunk, or at the base of the spines. Mossy terminals infrequently formed invaginated axosomatic or axodendritic synapses. By P30, large, branching spines were seen on the soma and proximal dendrites forming multifolded and interdigitized synaptic contacts with mossy fiber terminals. GluR2/3 immunoreactive somata were sparse in the hilus at P7. Bipolar or multipolar somata with enlarged proximal dendrites were observed by P14 and demonstrated mossy cell characteristics. The time course of GluR2/3 expression on mossy cells coincides with the reported age-dependent sensitivity of mossy cells to excitotoxic stimuli. These results support the hypothesis that maturation of synapses contributes to the development of excitotoxic vulnerability of mossy cells. Also, spine development on mossy cells differs from that of CA3 pyramidal cells since mossy cell spines surround mossy fiber terminals, whereas CA3 cell spines are enveloped by these terminals.

THE ROLE OF NORADRENERGIC NEUROTRANSMISSION IN THE FRONTAL CORTEX DEVELOPMENT.

I.PODKLETNOVA[1,2], V.RAEVSKY[2], H.ALHO [3,4]*

International School of Neurosci., Univ. of Tampere, Finland[1]; Institute of Higher Nervous Activity and Neurophysiology, RAS, Moscow, Russia[2]; Laboratory of Neurobiology, Medical School, University of Tampere, Tampere, Finland[3]; National Public Health Institute, P.O.Box 350, 00101 Helsinki, Finland[4].

The influence of neonatal administration of 6-hydroxydopamine (6-OHDA) on the maturation of frontal cortex was studied using 10-30 days-old rats. Distribution of neurons and their terminals in cortex of 6-OHDA treated rats differed from control littermates in all tested time points. In upper (I-III) layers of cortex tyrosine hydroxylase immunolabelling revealed from 50% (10 days old) to 80% (30 days old) loss of noradrenergic terminals. The total amount of GABA-ergic neurons (GABA-LI and GAD-LI) in I-III layers of cortex was two fold decreased. The intensity of immunostaining in GABA-labeled neurons was 52% reduced after 6-OHDA treatment. Compared to their littermates treated rats had poor ability in serching, skills performance and orienting in the new environment. Our findings indicate that without noradrenergic influence GABAergic interneurons in frontal cortex may not develop normally, which could explain the observed alterations in behavior.

EXPRESSION OF BCL-2 IN THE DEVELOPING CAT AND FERRET CEREBRAL CORTEX. N.E.J. Berman*. Dept. of Anatomy and Cell Biology, University of Kansas Medical Center, 3901 Rainbow Blvd., Kansas City KS, 66160

Bcl-2 is a membrane associated protein which protects cells from naturally occuring cell death, or apoptosis. Patterns of expression of bcl-2 were examined in ferret and cat cerebral cortex to determine the relationship between expression of this protein and regions thought to undergo naturally occuring cell death during development. Ferret brains were examined at 13 ages from P1 to P71. Cat brains were examined at weekly postnatal intervals. In the P1 ferret brain, migrating neurons in the intermediate zone, subplate, and cortical plate of all cortical areas expressed bcl-2. By P14 only occasional neurons were stained in the intermediate zone and subplate, but staining of neurons in layer II remained until at least P63. In the cat, the developmental pattern of bcl-2 staining was remarkably area dependent. At P1, staining was present in neurons of layers II and VI/subplate in all cortical areas. By P14, layer II staining had disappeared from cingulate cortex and areas 17 and 18. Staining of neurons in layer VI/subplate persisted in areas 17 and 18 until at least P28. Bcl-2 staining was especially prominent in layer II of pyriform cortex at all ages examined. Bcl-2+ glia were present in the thalamus until P28, but were not present in the cerebral cortex at any of the ages examined. These results suggest an areal and laminar difference in the exposure of developing cerebral cortical neurons to apoptosis inducing signals. Early loss of bcl-2 expression in cingulate cortex correlates with a high incidence of cell death in that region. Supported by MH38399.

CEREBRAL CORTEX AND LIMBIC SYSTEM: FUNCTION

774.1

ABNORMAL PREFRONTAL CORTICAL REGULATION OF STRIATAL DOPAMINE RELEASE AFTER NEONATAL MEDIAL TEMPORAL-LIMBIC LESIONS IN THE RHESUS MONKEY. B.S. Kolachana*, R.C. Saunders, J. Bachevalier † and D.R. Weinberger. Clinical Brain Disorders Branch, NIMH Neuroscience Center at St. Elizabeths, Washington, DC 20032 and †Dept. Neurobiol. & Anat., Univ. Texas Sch. Med. Houston, TX 77225.

The neurodevelopmental hypothesis of schizophrenia suggests that early structural damage to medial temporal limbic brain areas results in impaired connectivities between the prefrontal cortex (Pfc) and temporo-limbic brain regions resulting in dysfunction of various neurotransmitter systems including dopamine (DA) (Weinberger et al., 1992). We have shown that neonatal limbic lesions of the medial temporal lobe result in abnormal DA neurotransmission in the caudate nucleus (Cd) (Kolachana et al., 1995). We have also demonstrated that augmentation of Pfc monoaminergic activity inhibits DA release in the Cd (Kolachana et al., 1995). In this study, using *in vivo* microdialysis, we examined whether Pfc regulation of Cd DA release is affected by neonatal medial temporal-limbic lesions by studying two groups of adult monkeys: normal adults (N=2) and monkeys who had undergone surgical removal of temporo-limbic areas including the hippocampus and entorhinal cortex in the first 3 weeks of their post-natal life (N=2). Under isofluorane gas anesthesia, the monkeys had microdialysis probes positioned 4 each in the medial bank of the principalis sulcus and the Cd. The probes were perfused with normal CSF and samples collected and assayed for DA. After a 4-hr baseline collection, 25uM D-amphetamine was infused through the Pfc probes for 75 min, followed by normal CSF perfusion for 2 hr before termination of the study. Preliminary results indicate that in contrast to normal controls and our earlier observation, DA overflow in the Cd was elevated (20-50%) in monkeys who received limbic lesions as neonates. In this experiment and our previous study, DA overflow was attenuated (25-40%) in normal adult monkeys following the Pfc monoaminergic augmentation. These data suggest a phenominological change in the Pfc regulation of striatal DA function resulting from neonatal limbic damage in the non-human primate. These observations are consistent with the notion that maldevelopment of medial temporal-limbic region may have a significant role in the DA dysfunction associated with schizophrenia. *Supported by IRP-NIMH*

INCREASED THIGMOTAXIS AND REDUCED EXPLORATORY ACTIVITY IN F-52 DEFICIENT MICE. D.P. Wolfer*, M. Wu, H.-P. Lipp and S. Tonegawa. Inst. of Anatomy, Univ. of Zürich, CH-8057 Switzerland and Center for Memory and Learning, MIT, Cambridge, MA 0213.

F52 deficient mice have been generated by the gene targeting technique. They manifest severe neural tube defects leading to high prenatal lethality. Surviving mice, however, show a peculiar phenotype characterized by callosal agenesis and reduced thickness of neocortex and retina, lamination being preserved (Wu et al., PNAS 93, 2110-2115, 1996). Twenty-four mice balanced for mutation and sex were tested in the spatial and cued version of the swimming navigation task and in open-field exploration as described elsewhere (Müller et al., Cell 79, 755-765, 1994).

The F52 knockout mice showed mildly impaired acquisition in swimming navigation learning which was mainly due to increased thigmotaxis. Spatial memory during the probe trial revealed intact spatial memory in both wildtype and mutant mice. Swimming speed and other motor variables such as floating were equal in both groups. Cued water escape learning with a visible platform revealed again thigmotactic behavior of the mutants yet no gross performance differences. In the open-field, F52 knockouts were significantly less active during the first exposure, but there were no differences on the next day.

We conclude that inspite of their massively decreased cortical volume, surviving F52 mutants show decent spatial learning abilities and intact spatial memory in water escape learning, and do not appear to be handicapped by the changes in their retinae. Initial exploratory activity is strongly reduced, however, entailing lack of overnight habituation. The most likely common factor underlying both thigmotaxis and low open-field activity would seem to be increased fear and/or poor coping with fear-inducing situations. Since other studies in our laboratory have shown that agenesis of the corpus callosum is of little relevance for swimming navigation, F52 knockout mice may prove to be an interesting model for assessing behavioral and physiological consequences of changes in cortical thickness and, perhaps, of altered neuronal density. 774.3

DEVELOPMENT OF VIGILANCE STATE-DEPENDENT MODULATION OF HIPPOCAMPAL PAIRED-PULSE RESPONSE. J.H. BLAISE, R.J. AUSTIN-LaFRANCE, P.J. MORGANE* and J.D. BRONZINO. Dept. of Engineering and Computer Science, Trinity College, Hartford, CT 06106.

Field potentials were recorded from the granule cell layer of the hippocampal dentate gyrus in response to paired-pulse stimulation of the perforant pathway in freely moving rats at 15-, 30-, and 90-days of age. Pulse pairs were applied over a range of interpulse intervals (IPI) during the vigilance states of quiet waking (QW), slow-wave sleep (SWS) and REM sleep. Differences between the population spike amplitude (PSA) of the first and second evoked response were used to construct a paired-pulse index (PPI) indicative of the modulation of granule cell excitability during these states. Comparison of PPIs obtained from the different age groups during QW indicated a developmental progression involving the early inhibitory, facilitatory, and late inhibitory phases of granule cell modulation usually identified in adult rats. This progression was characterized by markedly lower levels of early inhibition (IPI = 20-30 msec.), an absence of facilitation (IPI = 50-150 msec.), and a relative lack of late inhibition (IPI = 300-1000 msec.) in 15-day old rats when compared to 90-day old animals. Values of the PPI obtained from 30 day old rats fell intermediate between the 15- and 90-day old groups. Age comparisons within the two sleep states indicated state-dependent changes in PPI occurred only in 90-day olds, with an absence of facilitation seen in both SWS and REM sleep in these animals. Thirty and 15-day old animals showed no significant changes in PPI across all vigilance states. Results suggest that extrahippocampal afferents from the medial septum, median and dorsal raphé, and locus coeruleus, which play a central role in vigilance state oscillations may be functionally immature at 15- and 30-days of age. (Supported by NSF Grant # BCS-9208128)

SYNAPTIC RULES FOR DEVELOPMENT OF INHIBITORY CONNECTIONS IN CEREBRAL CORTEX. O. V. Favorov* and D. G. Kelly, Departments of Biomedical Engineering and Statistics, University of North Carolina, Chapel Hill, NC27599-7575.

What are the synaptic rules that guide the development and strength of inhibitory connections in cerebral cortex? Does the strength of an inhibitory connection depend positively on the correlation in behaviors of the pre- and postsynaptic cells ("covariant" synaptic rule), analogous to the Hebbian rule that guides excitatory connections? Or does it depend negatively on that correlation ("contravariant" rule), or might it be independent of the correlation ("indiscriminate" rule)? These three possibilities were explored in a neural network model of the cortical upper layers, in which lateral excitatory connections were Hebbian, while inhibitory connections followed one of the three rules. The network was stimulated with a repertoire of input patterns until plastic connections settled into a stable pattern.

The contravariant rule limited severely the network's stimulus representational capacities: the network split into two mutually antagonistic subpopulations, and consequently had only two functional states. The other two rules each conferred distinct representational properties on the network. The indiscriminate rule established *positive associative links* between cell ensembles representing co-occurring stimulus features: the presence of one feature activated not only its own ensemble but that of the other feature as well. The covariant rule established *negative associative links*: the absence of an expected feature was emphasized by the suppression of its cell ensemble. A network with two inhibitory cell classes, each obeying either the covariant or indiscriminate rules, was most versatile: through selective modulation of the classes the network was able to exhibit either of the two described behaviors, or to represent veridically the features actually occurring in the stimulus. The covariant rule is proposed to control the connectivity of basket cells in neocortex, whereas the indiscriminate rule is proposed to control the connectivity of other inhibitory cells, such as chandelier cells.

DYE COUPLING AMONG NEURONS OF THE DEVELOPING FASCIA DENTATA, J.H. Haring*, W. Yan and K.M. Faber. Dept. of Anatomy and Neurobiology, Saint Louis Univ. Sch. of Med., St. Louis, MO 63104.

Dye coupling among dentate granule cells is a well-known phenomenon and transient dye coupling among different neuronal types has been reported during development in several brain regions. We have been studying the effects of 5-HT on the development of dentate granule cells. The purpose of this study was to determine whether postnatal age and/or 5-HT depletion are factors affecting dye coupling in the fascia dentata. Granule cells were impaled and filled with Neurobiotin in *in vitro* hippocampal slices prepared from ether-anesthetized rats. Neurobiotin is a small molecule that readily passes through gap junctions and frequently produces complete fills of dye coupled neurons. Control experiments suggest that the results reported here are due to dye coupling and not to neuronal uptake of Neurobiotin leaked into the extracellular space during the filling of an impaled neuron. At all ages studied (P14-P120) filling of one granule cell most commonly resulted in 2 or 3 well-filled granule cells. Occasionally, as many as seven granule cells were labeled from a single impalement, but in these cases most of the neurons were not completely filled. Rarely, only a single neuron was recovered suggesting that dye coupling between dentate granule cells is not universal. The presence of dye coupling of granule cells and the numbers of cells coupled to an impaled neuron did not vary either as a function of age or experimental treatment. In contrast to dye coupling among granule cells, dye coupling between granule cells and cells with interneuronal morphology was not observed after P14. This suggests that during development synaptically related granule cells and interneurons may be first linked by gap junctions.

EARLY NETWORK OSCILLATIONS IN THE DEVELOPING HIPPOCAMPUS E. Hanse, O. Garaschuk and A. Konnerth.
SPON: European Neuroscience Association.
I. Physiologisches Institut, Univ. des Saarlandes, D-66421 Homburg, Germany.

By applying whole-cell recordings and fura-2 calcium imaging to neonatal rat hippocampal slices we identified a new, massive form of developmentally regulated neuronal activity in the CA1 region of the hippocampus. The activity consisted of large intracellular Ca^{2+} transients of 1-4 s duration occurring synchrounsly in the vast majority of pyramidal neurons 3-10 times every minute. These early network oscillations (ENOs) are restricted to the first two postnatal weeks and they peak in intensity around postnatal day 2-3. The ENOs were totally blocked by TTX, bicuculline and by removing Ca^{2+} from the external solution. They were also substantially reduced by CNQX, APV and by a reduction in temperature from 33° to 20° C. Each of the spontaneous Ca^{2+} transients was associated with a train of action potentials riding on a depolarizing wave. The switch to voltage-clamp recording mode prevented the generation of the Ca^{2+} transients in a given cell, but revealed bursts of $GABA_A$-receptor mediated synaptic currents that were strictly correlated with the Ca^{2+} transients in the neighboring pyramidal neurons. Application of the $GABA_A$ agonist muscimol mimicked the spontaneous Ca^{2+} transients in the pyramidal neurons. The efficacy of muscimol in evoking Ca^{2+} transients decreased during development in parallel with the gradual disappearance of the ENOs. These results identify a new form of network oscillations in the neonatal hippocampus which are primarily driven by the depolarizing action of synaptically released GABA. We propose that the ENOs, restricted to an intense period of postnatal hippocampal development, promote neuronal differentiation, neurite outgrowth and the initial wiring of the hippocampal neuronal network. POSTNATAL DEVELOPMENT OF LOW [Mg^{2+}] OSCILLATIONS IN SOMATOSENSORY CORTEX. A.C. Flint*, U.S. Maisch, A.R. Kriegstein. Dept. Neurol., Columbia P&S, NY, NY 10032

In slices of adult somatosensory cortex, a prominent form of rhythmic activity can be induced by lowering $[Mg^{2+}]_0$ to unblock NMDA receptors. It has been suggested that the rhythmic activity seen under these conditions is dependant on the activity of a population of intrinsically burst-firing (IB) cells that are unique to cortical layer V. In the present study, we use whole-cell patch clamp techniques in slices made from neonatal rats to study the development of 0 [Mg^{2+}] oscillations and the development of IB cells. Recordings from cells in the upper layers at P7, P17, and P19 in zero [Mg^{2+}] indicate that dramatic changes occur postnatally in the network activity induced under these conditions. At P7, cells did not display organized bursts of activity, but rather showed trains of single APs on a background of synaptic activity. In contrast, at P19, cells displayed organized 0.5-4 sec. bursts of activity separated by periods of relative silence. Recordings made at P17 were suprisingly found to be less organized than the P19 recordings. Field potential recordings made at P7 and P19 confirm a developmental change in the network properties revealed by low [Mg^{2+}]. Whole-cell recordings made in layer V in 1 mM [Mg^{2+}] never displayed the typical firing characteristics of IB cells prior to P12. Between P13 and P19, however, an increasing number of cells recorded in layer 5 were found to have IB characteristics. In addition, application of NE, which inhibits burst-firing of IB cells, significantly altered the pattern of discharge in P19 slices undergoing zero [Mg^{2+}] oscillations. These data serve to strengthen the role of IB cells in the generation of low [Mg^{2+}] oscillations and provide a novel experimental model for distinguishing neonatal and adult forms of rhythmic activity.

SEROTONERGIC MODULATION OF GAP JUNCTION COUPLING IN THE DEVELOPING RAT SOMATOSENSORY CORTEX B. Roerig* and B. Sutor
Department of Neurobiology, Duke University Medical Center, Durham, NC 27710 and Institute of Physiology, University of Munich, D-80336 Munich, Germany

At neonatal stages primary sensory areas of the rodent neocortex receive a transient serotonergic hyperinnervation which plays a crucial role during the formation of thalamocortical projections. During this period pyramidal cells are interconnected via gap junctions. Serotonin (5-HT) modulates thalamocortical transmission, but its effects on gap junction coupling have not been investigated. To address this question single layer II\III pyramidal cells in coronal slices from rat somatosensory cortex were injected with the gap junction permeable tracer neurobiotin. On postnatal days 7-10 the average number of cells coupled to the injected neuron was 24.6 (+\- 4.3, n=21). Following preincubation with 5-HT (30 µM) the size of dye-coupled clusters was reduced to 7.7 (+\- 3.5, n=17). This effect was reversible; cluster size was comparable to control conditions if slices survived in 5-HT free solution for 1 h. Acute application of 5-HT induced a reversible increase in input resistance, indicating alterations in electrotonic cell properties following uncoupling. The uncoupling effect of 5-HT was mimicked by the 5-HT_2 receptor agonists α-methyl-5-hydroxytryptamine (30 µM) and R (+) -1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane hydrochloride (30 µM) and suppressed by the 5-HT_2 receptor antagonist ritanserin (30 µM), suggesting the involvement of 5-HT_2 receptors. Injection of the IP_3 receptor antagonist heparine (200 mg\ml) or preincubation with the protein kinase C (PKC) inhibitor NPC 15437 (100 µM) also antagonized the 5-HT effect, indicating that uncoupling involves IP_3 receptor mediated Ca^{2+} release from intracellular stores as well as PKC mediated phosphorylation. In conclusion, our results suggest that one developmental function of serotonin might be the regulation of electrical and metabolic coupling via gap junctions. FUNCTIONAL THALAMOCORTICAL CONNECTIONS DEVELOP DURING EMBRYONIC PERIOD IN THE RAT: AN OPTICAL RECORDING STUDY. S. HIGASHI*, Z. MOLNAR[1], T. KUROTANI, H. INOKAWA and K. TOYAMA, Dep. of Physiol., Kyoto Pref. Univ. of Med., Kawaramachi Hirokohoji, Kyoto 602, Japan [1]Univ. Lab. of Physiol., Univ. of Oxford, Parks Road, Oxford, OX1 3PT UK

Our previous optical recording study using voltage-sensitive dyes (RH482) in rat thalamocortical slice preparations has demonstrated that the somatosensory thalamocortical synaptic transmission functions already at birth. In the present study, we extend our investigation to embryonic stages (E16-21).

At E17, ventrobasal nucleus (VB) stimulation elicited spike-like responses which propagated from the thalamus through the primitive internal capsule (pIC) to the border between the cortical plate (CP) and subplate (SP). These fast activations seemed to represent fiber responses, since the application of a NMDA and AMPA receptor antagonist mixture had no effect on them. Following this spike-like response, slow depolarization started to appear within the pIC at E18, in the SP and layer VI at E19-20 and in the entire CP at E21 to birth. Since these slow responses lasted more than 300 ms and were abolished by the glutamate receptor antagonists, they seemed to be due to the thalamocortical synaptic transmission. The depolarization seen in the pIC was more intensive than in the SP at the same age. After the recording, the slices were subjected to anatomical examination. Insertion of a small DiI crystal into VB revealed the advancing thalamocortical fibres in the pIC and SP and backlabelled cells in the pIC. No retrogradely labelled cell appeared in the SP or CP in any of the slices at these prenatal ages, suggesting that the corticothalamic projections had not invaded the thalamus yet.

These results suggest that thalamic afferents are able to conduct action potentials to the SP as early as at E17 and that synaptic transmission starts to work at the SP and at the lower layer of the CP at E19, one or two days after the arrival of the thalamic afferents to the developing cortex.

SPONTANEOUS CALCIUM TRANSIENTS IN DEVELOPING FERRET SOMATOSENSORY CORTEX. R.V. Sonty*, S.L. Palmer, S.L. Juliano, Anatomy, Cell Biology, and Neuroscience, USUHS, Bethesda, MD 20814.

Clustered intrinsic connections in ferret somatosensory cortex develop from a less organized network at birth. Important to mechanisms of patchy intrinsic connection formation is an understanding how cells identify themselves as members of a particular cluster. It is likely the process is activity-dependent, so that neighboring cells receiving common inputs are synchronously driven, leading to reinforcement of synaptic linkages and the formation of a group. To test this idea, we examined cytosolic calcium transients (as an indicator of neuronal activity) in ferret somatosensory cortical slices, using fluo-3AM and time-lapse digital confocal microscopy, on postnatal days 1, 2, 6, 7, and 14. On P1-2, a prominent, thin band of active cells occur in (immature) layers 5 and 6. Fainter, less-dense, active cells are also seen in the sub- and cortical plates. By P6-7, active cells are found in all layers of the cortex (except layer 1). On P14, active cells are occasionally seen as linear arrays. Cells at all ages exhibited spontaneous transients at an average rate of 1 per 2-4 minutes. Fourier transforms on time-series data did not reveal any significant periodicity in the onset of spontaneous transients for the cells examined. Correlations in the firing of cell pairs from the deeper layers were examined on P1 and 14. Cross-correlation analysis revealed few correlations for cell pairs on P1, whether they were situated close (<450 μm) or at a distance (>450 μm). On P14, many proximate cell pairs showed significant correlations, with distant cell pairs showing fewer correlations. In addition, on P6, spontaneous calcium transients were minimally effected by octanol (a gap junction blocker), but were reduced by TTX. These data support the notion that by the end of the second postnatal week an onset of synaptically-driven, synchronous activity of neighboring neurons may serve as a basis for identifying a cell as a member of a particular cluster. RETINAL WAVES CAN PRODUCE RETINOTOPY IN A MODEL OF LGN DEVELOPMENT WITHOUT LONG-RANGE LATERAL CONNECTIVITY. G. L. Haith* and D. J. Heeger, Dept. of Psychology, Stanford Univ., CA 94305.

Purpose: To model the development of retinotopy in the LGN.
Background: During development ganglion cells fire bursts of spontaneous activity that propagate across the retina. These *waves* appear to be critical for the proper development of retinotopy in the LGN (Goodman and Shatz, *Cell*, 72:77-98, 1993), but are not incorporated in current models of sensory map development. Instead, current models rely on long-range center-surround lateral connectivity. But there is no evidence for such connectivity in the LGN.
Methods: The algorithm consists of three steps. First, new geniculate activities are computed as a weighted linear sum of current retinal and geniculate activities. The lateral connectivity in the LGN is local; each geniculate neuron receives inputs from itself (with fixed negative weight) and from its 4 nearest neighbors (with fixed positive weight). Secondly, the retina-to-LGN weights are updated using a modified Hebbian rule, $\delta w_{ij} = h\, w_{ij}\, r_i\, l_j$, where the weight change (δw_{ij}) is the product of the retinal activities (r_i), the steady-state geniculate activities (l_j), the current weights (w_{ij}), and the learning rate (h). Thirdly, the weights are normalized such that the total connection strength of each neuron stays constant. The model was run with various spatiotemporal patterns of spontaneous retinal activity.
Results: Wave-like retinal activity was found to support the development of retinotopy. Both the spatiotemporal correlations in a single wave and the sequential nature of the waves were important. Random points or clusters of activity did not support the development of retinotopy.
Conclusion: Our model demonstrates that wave-like inputs and minimal lateral connectivity, used with a simple Hebbian learning scheme, are adequate to establish retinotopy.

SPATIAL AND TEMPORAL PROPERTIES OF SPONTANEOUS WAVES IN THE DEVELOPING RETINA, M. B. Feller*, D. Butts, H. Aaron, D. Stellwagen, D. Rokhsar, C. J. Shatz, Howard Hughes Medical Institute, Department of Molecular and Cell Biology, and Department of Physics, University of California, Berkeley, CA 94720-3200.

Spontaneous waves of correlated activity sweep across the ganglion cell layer of neonatal mammalian retinae. Using fluorescence imaging techniques, we have found that individual waves recorded from the ferret retina are confined to spatially restricted domains that form a mosaic pattern over the entire ganglion cell layer. The structure of these domains is determined at least in part by a refractory period which prevents the activation of a group of cells for 40-60 seconds immediately following their participation in a wave, though not all domain boundaries are defined by previously detected waves. The boundaries are not set by anatomical structures since all retinal locations are equally likely to participate in or to initiate a wave. A given wave's velocity varies between 100-300 microns/sec with brief periods of rapid acceleration (greater than 500 microns/sec), suggesting that more than one mechanism is involved in propagating the excitation. A computer model suggests wave propagation among a uniform population of ganglion cells is not sufficient to describe the distribution of domain sizes we observe and that a second cell type is required. This observation is consistent with the finding from fluorescence imaging that amacrine cells also participate in the waves.

CIRCADIAN RHYTHM IS NECESSARY FOR THE NORMAL DEVELOPMENT OF THE EYE. Tong Li[1], David Troilo[2], and Howard C. Howland*[1] [1]Section of Neurobiology and Behavior, Cornell University, [2]New England College of Optometry, Boston, MA.

We have shown that rearing chicks for several weeks under constant light (CL) at normal levels disrupts normal ocular development resulting in severe hyperopia caused principally by corneal flattening (Li et al., 1995 Vision Research, 35:1203). In this study we ask whether these changes are related to a general need for some amount of darkness for normal vegetative function, or to an ocular growth mechanism with a circadian rhythm component. Our approach was to monitor eye growth and refractive state while varying the length and temporal pattern of the dark phase in a 24 hour period. We raised 7 groups of 10 white leghorn Cornell K-strain chicks under either 0 (CL), 1, 2, 3, 4, 6 or 12 hrs of darkness(d) per day. To vary the strength of the diurnal rhythm, an additional 3 groups of 20 chicks each were given 4 hrs of darkness distributed differently over 24 hours (4hr block randomly placed in 24 hr period,4 1-hr blocks distributed randomly during 12 hr night-time, 4 groups of (1 hr d+5hr l)). Refractive states and corneal curvature were measured by IR photoretinoscopy and IR keratometry respectively. The axial length of the ocular components were measured by A-scan ultrasonography. Four hrs of darkness per day, given in one block, was sufficient to totally eliminate CL effects.Shorter periods of darkness reduced CL effects proportionately to their length. The groups with different distributions of 4 hrs of darkness exhibited constant light effects in inverse proportion to the strength of their circadian rhythm. These results support the view that circadian rhythm is important for the normal development of the eye and refractive state.Supported by NIH grant EY-02994 & USDA NYC 191409 to HCH, and EY-11228 to DT.

THE PAIRED-LIKE HOMEODOMAIN-CONTAINING PROTEIN PHOX2 IS EXPRESSED IN VERTEBRATE RETINA. J.A. Martinez* and C.J. Barnstable, Neuroscience Program, Yale University School of Medicine, New Haven, CT.

In order to better understand the process of cellular differentiation in the vertebrate retina, we have been characterizing the transcriptional regulatory mechanisms of rod opsin gene expression in mammals. The photopigment opsin is one of the first cell type-specific markers expressed in differentiating retinal rod photoreceptors. Transgenic studies have identified 200 bp upstream of the opsin gene required for its retina-specific expression. This region contains a palindromic binding site for paired class homeodomains. This site is present in the promoters of photoreceptor-specific genes and is conserved across species, being found in Drosophila opsins and arrestin, as well as in human and bovine opsins.

We have screened a human retinal cDNA expression library with probes containing this paired homeodomain element from the human opsin promoter. We have isolated the human homologue of the mouse paired-like homeodomain protein Phox2. While initially characterized in PNS noradrenergic tissues, it also appears to be expressed in the CNS. RT-PCR on mouse retinas from different stages detected expression at E14 through the adult, as well as in the Y79 human retinoblastoma cell line. This pattern of expression suggests a role for this factor in retinal development as well as maintenance of cell phenotype.

Protracted loss of retinal ganglion cells following the period of naturally occurring cell death in mice lacking the *bcl2* gene

A.Cellerino[A] *, T. Michaelidis[C], M. Meyer[C], M. Bähr[B] and H. Thoenen[C A]
Dept of Ophtalmology and [B] Dept.of Neurology, University of Tübingen, Germany and [C] Max-Planck Institute for Psychiatry, dept. Neurochemistry Munich, Germany

Over-expression of the antiapoptotic gene *blc2* in neurons reduces cell death during development[1]. Targeted inactivation of the *bcl2* locus causes aditional loss of motor- and peripheral neurons following the phase of naturally occurring cell death[2]. Here we investigated the survival of retinal ganglion cells (RGCs) in *bcl2* null-mutant mice at different developmental stages. The number of RGCs was estimated by counting axons in the optic nerve at postnatal day 10 (P10), i.e. at the end of the period of naturally occurring cell death, and P60-P75. RGC numbers was not reduced at P10 (controls 58.300, SEM=3.500, n=4; mutants 53.200, SEM=3.600, n=5). P60-P75 mutant mice showed a reduction of 30% in the number of retinal ganglion cell axons (controls 53.000, SEM=1800, n=6; mutants 37.800, SEM=1850, n=4; t-test: p=0.0005). Our results show that either RGCs do not require blc-2 for survival during naturally occurring cell death or its absence can be compensated during this period by complementary changes in expression of other apoptotic or anti-apoptotic genes. The product of the *bcl2* gene becomes essential for maintenance of RGCs during late postnatal development however.

ENDOGENOUS SOMATOSTATIN (SS) INFLUENCES THE DEVELOPMENT OF ROD BIPOLAR CELLS IN THE RABBIT RETINA. G. Casini*, L. Trasarti, L. Andolfi and P. Bagnoli. Dept. of Environmental Sciences, Tuscia University, 01100 Viterbo, and Dept. of Physiology and Biochemistry, University of Pisa, 56123 Pisa, Italy.

SS has been shown to play morphogenetic roles both in *in vivo* and *in vitro* preparations of developing nerve cells. In the rabbit retina, SS is expressed by a population of displaced amacrine cells, and mature morphologic characteristics are expressed by most retinal cells around postnatal day (PD) 10-12, which is the time of eye opening. Rod bipolar cells (RBCs) are specifically labeled by antibodies directed to protein kinase C (PKC). In the present study, we induced SS depletion using intraocular injections of cysteamine (3 mM) from PD 2 to PD 10 repeated every other day. Retinas were collected at PD 11 and treated for PKC immunocytochemistry. In treated retinas, many RBC axons (which are normally directed towards the inner plexiform layer-IPL) are seen to cross the outer plexiform layer and run towards the corneal surface. In addition, RBC axons that are correctly directed to the IPL are often observed to by-pass the IPL and continue their course in the ganglion cell layer. Experiments in progress using intraocular injections of SS agonists (SMS 201995, CGP 23996) and an antagonist (cyclo-SS) indicate that SS depletion specifically affects the development of RBCs. The present results suggest that SS exerts a permissive role to establish the pathway for correct growth of RBC axons in the developing retina.

ULTRASTRUCTURAL LOCALIZATION, EXPRESSION AND ACTIVATION STATE OF NEUROFILAMENT KINASES DURING CNS DEVELOPMENT. I.Sanchez [1, 2], L. Hassinger[1], T. Wheelock[1], C. Santeufemio[1], G. Hauser*[2], R.A Nixon[1,2]. [1]Laboratories for Molecular Neuroscience, McLean Hospital, [2] Department of Psychiatry, Harvard Medical School, Belmont,MA 02178.

Phosphorylation within the carboxyl-terminus of the high molecular weight neurofilament subunit (NF-H) influences the local accumulation of neurofilaments (NF) by modulating their transport dynamics, and interneurofilament spacing. To understand the regional regulation of NF-H carboxyl-terminus phosphorylation, we determined the timing of individual phosphorylation events as recognized by phospho-epitope specific monoclonal antibodies SMI31, SMI34, and RT97 in relation to changes in NF-H expression (SMI33) and the *in vivo* activities of neurofilament kinases during the postnatal development of retinal ganglion cells (RGCs). Total NF-H, first detectable with SMI33 by postnatal day 9 (P9), increased 3-fold by day 12 and nearly plateaud by P30 (5-fold increase). SMI31 epitope levels rose 50-fold over the total increase in NF-H protein by P120. In contrast, SMI34 was detected as early as P9, when NF-H levels were very low, and plateaud by P12. By contrast, the RT97 epitope, associated with most acidic NF-H phosphovariants by 2D PAGE, was first detected between P21 and 30 and rose sharply to P120. Two protein kinases known to phosphorylate NF-H *in vitro*, erk2 and cdk5, were enriched in RGCs and were detected on neurofilaments as determined by immunocytochemistry and immunoelectron microscopy, respectively. Moreover, the activities determined after immuno-precipitating each kinase from optic nerve homogenates parallel closely their respective protein levels until the fourth postnatal week. Thereafter, although both erk2 and cdk5 protein levels decrease, their activity remained unchanged. Thus, the localized, sustained increase in neurofilament phosphorylation during late postnatal development may be regulated by the regional increase in the activation state of the neurofilament-kinases. RETINAL DEVELOPMENT IN THE EMBRYONIC *BST* MOUSE.
Q. Tang*, D.S. Rice, R.W. Williams and D. Goldowitz. Dept. of Anat. & Neurbiol., Univ. of Tenn. Coll. of Med., Memphis, TN 38163.

Belly spot and tail (*Bst*), a semi-dominant mutation on mouse Chr 16, is characterized by dramatic reductions in cell numbers in ganglion cell layer and (to a lesser extent) inner nuclear layer of one or both retinas (Rice et al., 1995). It is unclear whether the mutant phenotype is a result of reduced cell proliferation or increased cell death during embryonic development. To address this question, we examined retinas of *Bst/+* mice and wildtype (+/+) littermates at E11.5, E12.5, and E13.5. Timed-pregnant dams were injected with 5'-bromo-2'-deoxyuridine 1 hr prior to sacrifice. At E11.5, the most obvious difference between groups was noted at the optic fissure (OF). Fusion of the neural retina has begun in the +/+, but not in the *Bst/+* embryos. However, the pigment epithelium appears to fuse normally in the mutants. The aberrant folding of neural retina near the OF, a characteristic feature of the adult *Bst/+*, is observed as early as E12.5. By E13.5 fusion of the OF is complete in the +/+, whereas gaps persist in the *Bst/+* mice. Despite the somewhat smaller dimension of the *Bst/+* eye compared to that of the +/+ mice at E13.5, mean retina cell densities and proliferative indices do not differ markedly between the groups. It is unlikely that reduced cell proliferation is a major cause of the *Bst/+* phenotype. There are few pyknotic figures in the *Bst/+* and +/+ retinas at E11.5-13.5. However, significant increase in cell death has been observed in the ganglion cell layer of newborn *Bst/+* retinas. These observations indicate that the *Bst/+* phenotype probably stems from a disruption of developmental cues occurring prior to E11. Retinal development (e.g., OF fusion) is consequently delayed. The cell loss seen in the newborn *Bst/+* retina is the cumulative effect of the earlier perturbations. The differences in the severity of mutant phenotype, both between littermates and between the two sides of a single affected individual, may all be attributable to fluctuations in developmental timing. *Supported by NEI R01-9586.*

PROTEINS THAT INTERACT WITH THE NORRIE DISEASE GENE PRODUCT NORRIN IN THE DEVELOPMENT OF RETINA, EAR, AND COGNITIVE FUNCTION. S. K. Lockwood and K. B. Sims*. Molecular Neurogenetics, Massachusetts General Hospital, Charlestown, MA 02129.

Norrie disease is an X-linked, recessive neurodegenerative disease that produces congenital retinal dysplasia and blindness in affected males and may result in progressive sensorineural hearing loss and cognitive impairment. The Norrie disease gene (NDP) sequence predicts the formation of a protein 133 amino acids in length with an N-terminal signal peptide, suggesting that it may be a secreted protein. Computer modeling of protein structure suggests that norrin is a member of a family of growth factors, including NGF, TGFβ2, and PDGF, that contain a cysteine knot motif.

A search for protein interactors has been initiated using the yeast two-hybrid system (Gyuris *et al.*, 1993. Cell 75:791-803). A fusion of the C-terminal 130 amino acids of norrin to the LexA protein DNA-binding domain was constructed to serve as a bait to screen for interactors in an acid fusion library produced from 22-week old human fetal frontal cortex (D. Krainc, unpubl.). Successful interaction activates transcription from *lacZ* and *LEU2* reporter genes. Approx. 5 million transformants have been screened, from which over 40 classes of library plasmids, some of which are from overlapping cDNAs, have been obtained. Specificity tests indicate that the majority of interactor classes are specific to the norrin bait. Southern analysis will be done to determine the number of discrete genes.

Norrin-specific interactors will be tested further utilizing the GST fusion system and eventually coimmunoprecipitation. DNA sequencing of candidate interactor classes, which may suggest that one or more of these interactors is a receptor, is now in progress. Should interaction with multiple proteins be indicated, this may help to explain the action of norrin in diverse tissues. In situ hybridization and immunocytochemistry are planned. (NIH Grant # R1EY10611A01)

775.10

TRANSIENT EXPRESSION OF SNAP-25 IMMUNOREACTIVITY DURING DEVELOPMENT COINCIDES WITH THE DIFFERENTIATION OF CHOLINERGIC AMACRINE CELLS IN THE RETINA OF THE BRAZILIAN OPOSSUM. M.H. West Greenlee*[1,2,3], T.K. Gray[1], C.D. Jacobson[1,2,4] and D.S. Sakaguchi[1,2,3]. [1]Department of Zoology and Genetics, [2]Neuroscience Program, [3]Signal Transduction Training Group, and [4]Department of Veterinary Anatomy, Iowa State University, Ames, Iowa 50011.

In the present study we have used immunohistochemistry to examine the expression of the synaptic terminal-associated protein, SNAP-25, in relation to the differentiation of cholinergic neurons in the developing retina of the opossum, *Monodelphis domestica*. *Monodelphis* is a small pouchless marsupial whose young undergo a protracted period of postnatal development. The majority of visual system development is postnatal, and eye opening occurs at about 35 days postnatal (PN). During development of the retina, SNAP-25-like immunoreactivity (-IR) exhibited a distinct, transient pattern of expression. At approximately 15PN, SNAP-25-IR was present in a subset of cells in the inner nuclear layer (INL) and the ganglion cell layer (GCL), and by 25PN clearly labeled processes in sublamina 2 and 4 of the inner plexiform layer (IPL). Similarly, choline acetyltransferase (ChAT)-IR was first detected at 15PN in a subset of somata within the INL and GCL and processes throughout the IPL. By 25PN ChAT-IR was segregated within sublamina 2 and 4 of the IPL. Based on the patterns of IR, it is likely that these ChAT-IR neurons are starburst amacrine cells. Double-labeling analysis at 20, 25 and 35PN revealed that the distribution of SNAP-25-IR co-localizes with ChAT-IR. However, in the adult retina, while ChAT-IR neurons retained their distinctive pattern of immunoreactivity, SNAP-25-IR in the INL, IPL and GCL was considerably more diffuse. Bromodeoxyuridine (BrdU) birthdating analysis provided evidence that ChAT-IR amacrine cells are born at least as early as 4PN. Taken together, these results support the idea of a developmental role for SNAP-25 in the differentiation of cholinergic amacrine cells in the *Monodelphis* retina. Supported by grants from the ISU Biotech Council, the Carver Trust and the NSF.

MATURATIONAL GRADIENTS IN THE RETINA OF THE FERRET.
B.E. Reese[1]*, P.T. Johnson[1] and G.E. Baker[2]. [1]Neuroscience Research Institute and Depts of Psychology and Molecular, Cellular and Developmental Biology, UC Santa Barbara, and [2]Dept of Anatomy, University of Oxford.

We have examined the site for the initiation of retinal maturation in the ferret. Fetal and postnatal ferret retinas were fixed with 4% paraformaldehyde and then processed using standard immunohistochemical, DiI-labelling and Nissl-staining techniques to reveal a variety of maturational features including 1) two indices of early differentiation of the first-born retinal ganglion cells, the presence of ß-tubulin and of neuron-specific enolase; 2) the receding distribution of chondroitin sulfate proteoglycans within the inner retina; 3) the distribution of the first ganglion cells to grow axons along the optic nerve; 4) the emergence of the inner plexiform layer; 5) the emergence of the outer plexiform layer; 6) the onset of synaptophysin-immunoreactivity within the OPL; 7) the differentiation of calbindin-immunoreactive horizontal cells; 8) the onset of rhodopsin expression in photoreceptor cells; and 9) the cessation of proliferative activity at the ventricular surface. While we were able to define distinct maturational gradients associated with many of these features of inner and outer retinal development, with dorsal retina commonly maturing before ventral retina and with the peripheral retina maturing last, none showed a clear initiation in the region of the developing area centralis. Rather, maturation began in the peripapillary retina dorsal to the optic nerve head, consistent with previous studies on the topography of ganglion cell genesis in the ferret (J. Comp. Neurol. **341**, 464-475). These results make clear that the order of retinal maturation and the formation of the area centralis are not linked to one another, at least not in the ferret.

RHODOPSIN EXPRESSION IN THE DEVELOPING FERRET RETINA.
P.T. Johnson, G.H. Jacobs* and B.E. Reese, Neuroscience Research Institute and Depts of Molecular, Cellular and Developmental Biology and Psychology, University of California at Santa Barbara, CA 93106-5060.

We have examined the onset of rhodopsin expression in relation to other features of outer retinal development. Postnatal ferret eyes were sectioned at 16µm and immunostained to reveal the distribution of rhodopsin as well as that for calbindin, neuron-specific enolase, synaptophysin and a cell cycle-specific nuclear antigen (Ki67) to identify the position of horizontal cells, of synaptic vesicle protein, and of proliferating neuroepithelial cells in the outer retina, respectively. Primary antibodies were visualized with the ABC procedure. The Rho4D2 monoclonal antibody was a gift from R. Molday.

On the day of birth, a minority of cells in the neuroblast layer stain heavily for rhodopsin. Staining is throughout the membrane, defining the cell body as well as radially-oriented processes. These immature rod cell bodies are positioned primarily in the outermost parts of the neuroblast layer, but they commonly spare the outermost row of cell bodies containing mitotic profiles and postmitotic cones. Occasionally, immunoreactive somata are found at the innermost margin of the neuroblast layer, adjacent to the IPL. Outer processes extend to the ventricular surface, and will form the future inner and outer segments in the ventricular cleft at later postnatal stages, while the inner processes extend as far as the IPL. These inner processes eventually retract into the outer parts of the retina since they extend beyond the horizontal cell plexus and the future OPL. They are also devoid of synaptophysin, extending beyond the synaptophysin-rich portion of the outer retina at this stage. During the first two postnatal weeks, the rhodopsin-positive row of somata increases to approximately 10 cells thick; a few of these are positioned immediately vitreal to a well-differentiated OPL, and only a minority of the immunoreactive cells in the ONL now possess inner processes extending beyond the OPL. Immunoreactive apical processes have only just begun to differentiate beyond the outer limiting membrane at these ages.

These results show that rod opsin protein is synthesized as rods become postmitotic; that the protein is present well in advance of outer segment differentiation; and that immature rods transiently extend (axon-like?) processes beyond the level of the OPL.

Supported by NIH grant EY-08415

INVOLVEMENT OF *NeuroD*, A bHLH FACTOR IN THE VERTEBRATE RETINAL DEVELOPMENT.
I. Ahmad*. Dept. of Cell Biology and Anatomy, University of Nebraska Medical Center, Omaha, NE 68198.

We have shown that the bHLH transcription factor *Mash-1* may regulate the opsin gene expression by binding to the E-box element, $E_{opsin\text{-}1}$ during photoreceptor differentiation (Dev. Brain Res. 90:184-189, 1995). However, the E-box elements in other photoreceptor-specific genes appear to interact with retinal factors other than *Mash-1* (Soc. Neurosci. Abst. 21:1556, 1995). This observation suggests that bHLH factors other than *Mash-1* are also involved in retinal development. One such factor could be *NeuroD*, a vertebrate homologue of *Drosophila* proneural genes. To investigate the role of *NeuroD* in retinal development we have cloned *NeuroD* cDNA from rat retina and using the cDNA as a probe we can detect the transcript of ≈ 3kb corresponding to the full length *NeuroD* mRNA in the developing retina of both rat and chick. This observation suggests a conserved role for *NeuroD* in retinal development. To understand the involvement of *NeuroD* further we have studied the temporal and spatial aspects of its expression. Analysis of temporal pattern of *NeuroD* gene expression in rat shows that it is expressed throughout the retinal development. However, the levels of *NeuroD* transcripts are significantly higher at late-neurogenesis (E19-PN3) than at early-neurogenesis (E12-E14). Preliminary in situ hybridization analysis shows that the *NeuroD* transcripts are predominantly localized in the outer neuroblast layer in E19 and PN1 retina. These results suggest the involvement of *NeuroD* in retinal development, particularly during late-neurogenesis. Supported by NIH EY10313.

775.14

DEVELOPMENTAL EXPRESSION OF THE *FAS*/APO (APOPTOSIS)-1 RECEPTOR IN THE EMBRYONIC AND POSTNATAL RAT EYE.
C. H. Kim*, Z. F. Cheema and R. C. Miranda, Dept. Human Anatomy and Medical Neurobiology, Texas A&M University College of Medicine, College Station, TX 77843

The *Fas*/Apo-1 receptor is a member of the tumor necrosis factor receptor (TNFr) family. *Fas* initiates apoptotic cell death in lymphoid tissue, without *de novo* mRNA and protein synthesis. This suggests that the *Fas* receptor is mechanistically proximate to the initiation of cell death. In this study we examined the temporal and spatial expression of *Fas*/Apo-1 mRNA in the embryonic day 13 to postnatal day 1 rat eye. Digoxigenin-labeled anti-*Fas* mRNA oligonucleotide probes were used to localize *Fas* mRNA *via* non-isotopic in-situ hybridization. Our data suggests that *Fas* mRNA is localized in the lens and retina. More specifically, *Fas* is expressed in the epithelial cells of the lens equator, suggesting that this receptor may play a role in the terminal differentiation of lens fiber cells. Within the retina, *Fas* mRNA was expressed primarily within the retinal ganglion cell layer suggesting that this receptor may also interact with the development of retinal-diencephalic or retinal-mesencephalic projections. The spatial localization of *Fas* mRNA, suggests that this receptor may play a role in the early development of the mammalian eye. Current research is focused on the examination of the role of the *Fas* receptor in the development of the eye. *Supported by funds from Texas A&M University.*

SPATIAL PATTERNS OF RETINOID RECEPTOR GENE EXPRESSION PATTERNS IN THE CHICKEN RETINA.
F. HOOVER* and J.C. GLOVER, Dept. of Anatomy, University of Oslo, 0317 Blindern, Oslo, Norway.

Some retinoids are believed to function as signaling molecules that bind to nuclear receptors and regulate gene transcription. The retinoid signaling system has been implicated in retinal development and differentiation. Several recent studies have characterized the spatiotemporal expression patterns of specific retinoids and retinoid synthesizing enzymes in the developing chicken retina. However, the expression patterns of the retinoid receptors in the retina remain poorly characterized. To address this issue, we have used non-radioactive in situ hybridization to localize retinoid receptor transcripts encoding the RARβ, RARγ, RXRα, RXRγ genes in the chicken embryo.

We have characterized the expression patterns of the retinoid receptor genes at day 10 (d10) of chicken development, a time when most retinal neurogenesis is complete and the photoreceptor layer (PRL) and ganglion cell layer (GCL) are distinct. We detected RXRγ transcripts throughout the PRL and in a few cell bodies located between the PRL and GCL. We detected RXR α transcripts in the PRL, the GCL and in a thin band of cells located between the PRL and GCL. We detected RAR γ expression at low levels in the PRL and at higher levels within the GCL. We did not detect any RARβ1 transcripts in the d10 retina. These results indicate multiple and possibly complementary roles for the retinoid receptors in regulating neuronal differentiation in the chicken retina. Supported by the Norwegian Research Council.

RETINOTOPIC ANALYSIS OF RESPONSE PARAMETERS IN THE SUPERIOR COLLICULUS OF RCS RATS FOLLOWING RETINAL PIGMENT EPITHELIAL CELL TRANSPLANTATION.
Y. Sauve*, H. Klassen, S.J.O. Whiteley, T. Litchfield, R.D. Lund. Institute of Ophthalmology, London EC1V 9EL, UK.

Electrophysiological recordings from the superior colliculus (SC) were used to evaluate the functional efficacy of retinal pigment epithelial (RPE) cell transplants in RCS rats. Healthy RPE cells were harvested from young adult Lister Hooded rats and grafted to the subretinal space of dystrophic RCS rats at 4 weeks of age. At 12 or more weeks of age single and multi-unit receptive fields (RFs) were mapped over the SC, contralateral to the grafted eye, in response to photic stimulus presentation. These results were compared with data from pigmented dystrophic and non-dystrophic RCS rats which had not received grafts.

A progressive loss of spatially localized RFs occurs in non-grafted dystrophic animals. This was absent at 12-14 weeks in rats with successful RPE grafts. Additional evidence of graft-related functional benefits was provided by analysis of SC response latency: successful RPE grafts showed markedly improved values across the visual field compared to non-grafted dystrophics. These results were consistent for ON and OFF latencies across both nasal-temporal and dorsal-ventral axes, and became increasingly pronounced at lower stimulus intensities. Even in the best cases, however, latency was prolonged compared to non-dystrophic animals. Grafts of lesser efficacy had latencies intermediate between those of the best grafts and the non-grafted dystrophics.

These results indicate that early RPE cell transplantation can improve multiple aspects of central visual responsiveness as compared to untreated dystrophic RCS rats.

EARLY DEFECTS IN RETINAL MORPHOGENESIS LEAD TO RETINAL AND OPTIC STALK CHANGES IN THE TRANSGENIC *KRD* MOUSE. D.C. Otteson[1], J. Kameoka[2], J. Perlman[2], E. Shelden[1], M. Meisler[3], P.F. Hitchcock[1, 2] * Depts. of Anatomy and Cell Biology[1], Opthomology[2], Human Genetics[3], University of Michigan, Ann Arbor. MI.

Krd (*Kidney and retinal defects*) transgenic mice carry a 7 cM deletion of Chromosome 19 which includes the *Pax2* locus (Keller et al., 1994. Genomics, **23**:309). Previous studies have indicated that laminar defects and cellular hypoplasia in retina, as well as malformations in optic disc and optic stalk, have their basis in early embryogenesis. (Hitchcock et al., 1995. Soc. of Neurosciences Abstracts, **21**:1556). We have extended our observations to earlier timepoints to identify initial defects which may underlie the later malformations. At optic vesicle stage (E9.5), no differences are observed between normal embryos and their *Krd/+* sibs. During the formation of the optic cup at E10.5, the ventricular lumen in *Krd/+* embryos remains open within the eye cup and distal optic stalk and the embryonic fissure fails to extend into the optic stalk. We have further examined these defects using computer assisted 3-D reconstructions of video images from serial histological sections. Malformations in central retina and in the optic disc observed at later stages in *Krd/+* mice, are a logical consequence of an initial failure of normal morphogenic movements preceding fusion of the ventral embryonic fissure and formation of the optic disc. The regions of initial optic stalk malformation correspond to regions of Pax2 expression as identified by polyclonal antibodies to Pax2 (a gift from G. Dressler), suggesting that haploinsufficiency of *Pax2* may contribute to the abnormalities seen in *Krd* heterozygous mice. INSULIN-LIKE GROWTH FACTOR I (IGF-I) BINDING IN THE ADULT GOLDFISH RETINA.

S.E.M. Boucher* and P.F. Hitchcock. The University of Michigan, Depts. of Ophthalmology and Anatomy and Cell Biology and The Neuroscience Program, Ann Arbor, MI.

Results from eyecup-culture studies indicate that IGF-I is mitogenic for the pluripotent neural progenitors residing in the circumferential germinal zone (cgz) in the retina of the adult goldfish (S.E.M. Boucher and P.F. Hitchcock, Soc. Neurosci. Abstr., Vol. 21, p. 1556, 1995) As an extension of these studies, we used ^{125}I-IGF-I binding to identify IGF-I binding sites in the goldfish retina. Eyecups were incubated for five hours at 4°C in defined media containing 5 nM ^{125}I-IGF-I alone or mixed with 100 fold molar excess of unlabeled IGF-I, IGF-II, des(1-3)IGF-I or insulin. Eyecups were rinsed, fixed, embedded in resin and 1 µm thick sections mounted onto slides. The slides were processed for emulsion autoradiography. Video images of silver grains overlying retinal sections were captured and exported into NIH Image for quantitative analysis. This revealed specific binding of ^{125}I-IGF-I in the inner plexiform layer (ipl) and, consistent with our previous results, over cells in the cgz. Unlabeled ligands competed with ^{125}I-IGF-I binding with the following relative efficiencies: IGF-I ≈ des(1-3)IGF-I > IGF-II. Insulin was ineffective. These results suggest that type I IGF receptors and IGF binding proteins are present in the adult goldfish retina and IGF-I may be a native molecule that controls the proliferation of pluripotent neuroepithelial cells in the cgz. Supported by NIH (NEI) grants EY07060 and EY07003 (CORE) and The Research to Prevent Blindness.

MODIFIED Na+ CHANNEL DISTRIBUTION IN DEVELOPING AND ADULT HYPOMYELINATING TRANSGENIC MICE I. Vabnick[1*], A. Messing[2], S.Y.Chiu[2], S.R. Levinson[3], M. Schachner[4], & P. Shrager[1]. [1]Dept. Physiol., Univ. of Rochester, Rochester, NY 14642; [2]Univ. Wisconsin-Madison, WI ; [3]Univ. Colorado, Denver CO; [4]Neurobiol., ETH, Zurich.

The Na channel (NaCh) distribution within the sciatic nerve of transgenic mice with hypomyelinating peripheral neuropathies was observed by indirect immunofluorescence. Schwann cells expressed either the A chain of diphtheria toxin (DT-A) or a temperature-sensitive mutant of the large T-antigen (tsa-1609) each regulated by the 5' flanking sequence from the rat P0 gene. DT-A expression causes Schwann cell death. During the first postnatal week, axons had few NaCh aggregates. In contrast, normal mice by postnatal day 7 had nearly completed node formation. However, at later times in DT-A affected mice, large expanses of axon had clearly elevated levels of NaChs. In addition, action potentials in adult nerves propagate, but at a very low velocity. This is consistent with the lack of myelin and upregulation of axonal NaChs. In transgenic mice expressing tsa-1609, Schwann cells appeared to be arrested in a premyelinating state. Strings of spherical Schwann cells associated one to one with axons and labeled weakly with an antibody against MAG. Most importantly, the majority of axonal segments associated with these cells lacked NaCh aggregates, but had rather uniform and intense label. This suggests that a myelinating phenotype is required to induce NaCh aggregation.

CLONING OF THE HUMAN OLIGODENDROCYTE-SPECIFIC PROTEIN (OSP) HOMOLOGUE. A. Buznikov, T. Vu, H. Kornblum, K. Chen, J.M. Bronstein*. Depts. of Neurology and Pharmacology and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90095.

Oligodendrocyte-specific protein (OSP) is a CNS-specific myelin protein which appears to be the CNS PMP-22 homologue. The precise function of OSP is unknown but may regulate oligodendrocyte growth and differentiation. A humoral response directed against OSP has been detected in patients with multiple sclerosis (MS). Since OSP maybe involved in human disease, we isolated and characterized the human cDNA homologue. A human spinal cord phage cDNA library was screened with murine OSP ORF cDNA and a 2.3 kb cDNA was isolated. The nucleic acid sequence of the human ORF is 85% identical to that of the mouse and the predicted amino acid sequences are 77% identical. The murine 7 amino acid OSP peptide to which antibodies are directed against in MS is 100% identical to the human homologue. The 3' untranslated region of the human cDNA was approximately 50% identical to that of the mouse cDNA. Northern blot analysis revealed one major transcript in adult human brain of approx. 2 kb. *In situ* hybridization using anti-sense 35-S-cRNA demonstrated specific cellular localization compared to sense controls. The identity of the stained cells is being determined using double *in situ* hybridization. Our results demonstrate that OSP is highly conserved in evolution suggesting an important role in normal oligodendrocyte development and function.

PMP22 PROTEIN EXPRESSION IN TREMBLER-J MICE. L. Notterpek*, G.J. Snipes° and E.M. Shooter. Dept. Neurobio., Stanford Univ. Sch. of Med., Stanford, CA 94305 and °Montreal Neurological Inst. McGill Univ., Montreal, Quebec H3A 2B4

A nonconservative (L16P) mutation in the peripheral myelin protein 22 (PMP22) gene is associated with the trembler J (Tr-J) neuropathy in mouse and human. We hypothesize that this mutation affects myelin biosynthesis. To study this, sciatic nerves of genotyped homozygous (Tr-J/Tr-J), heterozygous (Wt/Tr-J) and normal (Wt/Wt) mice were examined in parallel. As expected, Western blot analysis indicate that in adult Wt/Tr-J animals the level of PMP22 is markedly decreased, similar to myelin basic protein (MBP) and protein zero (P0), while myelin associated glycoprotein (MAG) is largely unaffected. The decrease in myelin proteins is associated with an increase in the lysosomal membrane glycoprotein (LAMP-1). In Wt/Tr-J mice PMP22 contains predominantly endoglycosidase H (endoH) resistant oligosaccharides, while a significant fraction of PMP22 from Wt/Wt animals is endoH sensitive. The Tr-J mutation also alters the glycosylation profile of P0. The endoH resistant fraction of P0 is significantly greater in Tr-J/Wt as compared to normal animals. While the overall PMP22 protein levels are severely reduced in adult Wt/Tr-J nerves, immunocytochemical studies show an intracellular accumulation of PMP22 (Wt and mutant) in some but not all of Schwann cells. The immunolabeling experiments confirmed the decrease in myelin membrane components and the increase in lysosomal compartments in affected nerves. The observed differences in P0 and MBP protein levels between Wt/Wt and Wt/Tr-J mice are less pronounced at postnatal day 18, while PMP22 is already markedly decreased. In 18-days-old Tr-J/Tr-J nerve homogenates there is no detectable immunoreactive PMP22 protein and the levels of P0 and MBP are very low. These studies suggest that the Tr-J mutation alters the intracellular processing of PMP22 (and perhaps P0) and that the mutant protein is likely degraded in lysosomes. This research is supported by funds from APA, MDA and NIH to EMS, MRC and FRSQ to GJS, and Giannini Foundation, NMSS and NIH to LN.

POSTTRANSCRIPTIONAL REGULATION OF THE ALTERNATIVE *PMP22* TRANSCRIPTS BY THEIR 5'- AND 3'-UNTRANSLATED REGIONS. F. Bosse, J. Brodbeck and H.W. Müller*. Molecular Neurobiology Lab., Departement of Neurology, Heinrich-Heine-University Düsseldorf, D-40225 Düsseldorf, Germany.

The gene of the Peripheral Myelin Protein *PMP22* generates two different mRNAs, *CD25* and *SR13* (Bosse et al., 1994, J. Neurosci. Res. 37: 529-537), which differ significantly in their 5'-untranslated regions (5'-UTR), but are identical in their coding region and 3'-UTR. The *PMP22* gene consists of two alternative exons 1 (exon 1a and 1b) plus four additional exons. Two distinct promotors direct the transcription of the exon 1a and 1b, respectively.

To characterize the influence of the 5'- and 3'-UTRs on the post-transcriptional regulation of the two alternative *PMP22*-transcripts, we created constructs containing one of the two alternative *PMP22* 5'-UTRs upstream of the *CAT*-reporter gene coding region. In order to ensure the maintenance of the original *PMP22* transcription start site and the *PMP22* ATG-context we used a PCR-mediated cloning strategy. Furthermore, taking into account possible functional interactions between the 5'-UTR and the 3'-UTR, we generated constructs which also contained the *PMP22* 3'-UTR in addition to the 5'-UTR. To examine the effect of these 5'- and 3'-UTRs on gene expression in vitro, we transiently transfected NIH3T3-fibroblasts and rat Schwann cells under different culture conditions.

The major findings of these studies are: i) both alternative *PMP22* 5'-UTRs modulated a forskolin-stimulated increase of CAT expression under growth conditions; ii) only constructs containing the gas3 homologous *SR13* 5'-UTR were significantly induced in their CAT expression under conditions of growth arrest by serum depletion; iii) constructs containing the common *PMP22* 3'-UTR caused a 5-10 fold decrease of CAT-protein synthesis under all conditions examined; iv) the reduced CAT expression in *PMP22* 3'-UTR containing constructs cannot be explained by a reduced rate of transcription or intensified reporter-transcript degradation. INCREASED P0 GLYCOPROTEIN GENE DOSAGE CAUSES A DYS-MYELINATING PERIPHERAL NEUROPATHY IN TRANSGENIC MICE.
L. Wrabetz[1]*, ML. Feltri[1], A. Quattrini[1], M. Arona[1], B. Trapp[2], A. Messing[3]. [1]S. Raffaele Scientific Institute, DIBIT, Milan, Italy 20132; [2]Dept. of Neurosciences, Cleveland Clinic Foundation, Cleveland, OH 44195; and [3]School of Veterinary Medicine, University of Wisconsin, Madison, WI 53706.

Increased gene dosage for myelin genes such as PMP 22kD and PLP results in dysmyelination in the peripheral and central nervous system. To determine whether the maximum expression of other myelin genes must also be carefully regulated to ensure normal myelination, we prepared transgenic mice containing extra copies of the P0 glycoprotein gene. We engineered a new transgene, mP0TOTA, from the complete mouse P0 gene that contains 6 kilobases of 5' upstream region, all exons and introns, and the natural polyadenylation signal. To measure whether expression of this transgene depended on its insertion site, we substituted a lacZ open reading frame for the Po ATG start of translation to create mP0TOTA[nlacZ]. Four of six independent lines of mP0TOTA[nlacZ] transgenic mice expressed significant levels of β-galactosidase in Schwann cells in peripheral nerve. In parallel, two independent insertions of mP0TOT (unaltered P0 gene) in transgenic mice developed dysmyelinating neuropathy. These mice manifested weakness, tremor and a gait disorder resulting in premature death. Preliminary morphological analysis showed a remarkable paucity of myelin in sciatic nerves of these mice. These data suggest that mP0TOTA is able to drive significant expression of heterologous genes specifically in Schwann cells in peripheral nerve. In addition, normal myelination depends on gene dosage of even the most abundantly expressed myelin gene, P0 glycoprotein.

ABNORMAL NERVE CONDUCTION STUDIES REFLECT HYPER-MYELINATION IN MICE EXPRESSING A TARGETED ANTAGONIST OF THE POU TRANSCRIPTION FACTOR SCIP.
P.L. Bieri , E. Pereira, S. Seto, J.C. Arezzo, D.E. Weinstein.* Albert Einstein Coll. of Med., Bronx, NY 10461.

Transgenic mice which express a dominant-negative antagonist of the POU transcription factor SCIP, termed ΔSCIP, develop a disabling peripheral neuropathy. The neuropathy is thought to be related to developmentally precocious Schwann cell differentiation, resulting in a reduction in the median size of myelinated axons, and an increase in total myelin. To characterize the functional deficits resulting from the ΔSCIP mutation, a series of nerve conduction studies in ΔSCIP transgenic animals was undertaken.

Caudal and bilateral tibial nerve compound responses were recorded in 4 ΔSCIP and 6 wild type adult littermates. Tibial F wave minimum and maximum latencies were recorded from 50 consecutive trials, and the range determined as the difference between maximum and minimum latencies. Caudal nerve amplitudes were significantly higher in the ΔSCIP mice ($p=.02$), with responses that were shorter in duration, whereas onset latencies were not significantly different between groups. Tibial nerve distal onset latencies and motor amplitudes were not significantly different, however the tibial F wave range was smaller in the ΔSCIP mice compared to controls. Minimum F wave latencies showed no difference between groups, but maximum latencies were less variable and earlier in the ΔSCIP than the wild type animals ($p=.02$). These results suggest that the ΔSCIP mutation results in an increased synchrony of conduction within nerves, which may be explained by the relative uniformity of axonal diameter caused by exuberant myelination. They also demonstrate the sensitivity of the F wave measurement in detecting conduction abnormalities in mice with genetically constructed myelinopathies. Supported by HD 01799.

MICE DEFICIENT IN P0 AND THE MYELIN-ASSOCIATED GLYCOPROTEIN (MAG) SHOW THAT MAG IS INVOLVED IN SPIRALLING OF SCHWANN CELL PROCESSES AROUND AXONS IN THE PNS.
S. Carenini*, D. Montag, M. Schachner and R. Martini. Department of Neurobiology, Swiss Federal Institute of Technology, CH-8093 Zürich, Switzerland.

Whereas mice deficient in the myelin component P0 show severely disturbed myelin formation in the PNS, peripheral myelin is entirely normally formed in young mice deficient in MAG. Since in normal mice both components are colocalized during spiral formation, it is possible that P0 can compensate for the loss of MAG in MAG-deficient mice. On the other hand, mice deficient in P0 show a strong upregulation of MAG in the abnormal myelin sheaths which may be indicative of a compensatory role of MAG in the absence of P0. To investigate the possibility that both molecules can partially substitute for each other during particular steps of myelination, we generated double mutants lacking both MAG and P0. In 10-day-old P0-deficient mice, about 14% of all axon-Schwann cell units remain arrested at the 1:1 ratio, while the remaining profiles succeed in forming spiralling loops. Mutants lacking both P0 and MAG show an aggravated phenotype, in that the number of axon-Schwann cell units arrested at the 1:1 ratio is increased to 38% at the expense of axon-Schwann cell units with spiralling loops. Thus, when myelin forming Schwann cells are confronted with the absence of P0, formation of spiralling loops strongly depends on the presence of MAG. These findings show that P0 and MAG play partially interchangeable roles during myelin spiralling in the PNS.

PROMYELINATING SCHWANN CELLS EXPRESS TST-1/SCIP/OCT-6 IN REGENERATING NERVE
E. J. Arroyo*[1], J. Bermingham[2], M. G. Rosenfeld[2], and S. S. Scherer[1]. [1]University of Pennsylvania • Dept. of Neurology • Philadelphia, PA 19104 • [2]Howard Hughes Medical Institute • University of California, San Diego • La Jolla, CA 92093.

Tst-1/SCIP/ Oct-6 (tst-1) is a member of the POU-homeodomain family of transcription factors. Members of this family have been shown to regulate cellular differentiation of a number of cell types. Tst-1 is expressed by Schwann cells (SC) in developing and regenerating peripheral nerves, and axon-SC interactions regulate its expression. Recently, we generated tst-1 "knockout" mice by replacing the tst-1 open reading frame with the ß-gal gene. Because ß-gal is expressed instead of tst-1, it allowed us to determine the ultrastructural features of the Schwann cells expressing tst-1. By examining the developing nerves that have been treated with X-gal by electron microscopy, we found that tst-1 was mainly expressed in promyelinating SC, which are the immediate precursors of myelinating SC. There was transient expression in myelinating SC but almost no expression in bundling or non-myelinating SC. In crushed nerves, in which axonal regeneration occurs, tst-1 is predominately expressed in promyelinating SC. These data shows that tst-1 is transiently expressed during development and regeneration in promyelinating SC, probably in response to an axonal signal mediated by cAMP.

PATHOPHYSIOLOGY OF INCOMPLETE REMYELINATION IN THE AXON: A STUDY USING AN ELECTRODIFFUSION MODEL
J.A. Halter and A.R. Blight*, Div. Restorative Neurol & Human Neurobiol, Baylor Coll. Med., Houston, TX 77030, and Div. Neurosurgery, Univ. North Carolina, Chapel Hill, NC 27599

Axonal conduction block produced by demyelination can reverse following redistribution of Na channels along the internodes, which allows continuous rather than saltatory conduction. Remyelination may also permit recovery of saltatory conduction, but it is limited in mammalian CNS and often results in thin myelin sheaths. Several computer-based mathematical models have confirmed that complete loss of myelin over a number of internodal segments should result in conduction block. Initial attempts to examine the significance of partial remyelination, using models that lump together myelin and axolemmal elements, indicate that even a few myelin layers should be sufficient to restore conduction. By contrast, animal models of spinal cord injury indicate the presence of conduction deficits associated with areas of incomplete remyelination. This could be because incomplete sheath formation a) prevents redistribution of Na channels, b) electrically shields such channels from activation, c) insufficiently reduces internodal capacitance to allow saltatory conduction, and/or d) restricts diffusion of ions into and out of the periaxonal space. This study explores the implications of thin myelination, using a model that includes a comprehensive simulation of morphological specializations, major ionic conductances, diffusion pathways, and energy-dependent ion exchange (Halter and Zupan, Soc.Neurosci.Abst. 21:64, '95). This first application of a distributed-parameter, electrodiffusion model of the axon shows that conduction deficits are increased by thin myelination, at least partly as a result of the shielding effect of the myelin sheath on internodal sodium channels and the restriction of periaxonal diffusion of cations. Supported by the Vivian L. Smith and Whitaker Foundations, and by grant NS-33687 from NIH/NINDS.

qkI PROTEINS ARE UNDETECTABLE IN MYELINATING CELLS OF QUAKING MUTANT MICE.
R. J. Hardy, V. L. Friedrich, Jr.*, R. A. Lazzarini, Q. Chen†, T. Ebersole† and K. Artzt†. Brookdale Center for Molecular Biology, Mount Sinai School. of Medicine, New York, NY 10029 and †Dept. of Zoology, University of Texas at Austin, Austin, TX

qkI is a recently described gene which lies adjacent to the deletion breakpoint in the quaking mutation and is expressed in a variety of tissues in wildtype mice, including brain (Ebersole et al, 1996, *Nature Gen.*12: 260-265). The qkI gene encodes 3 mRNAs of 5, 6 and 7kb whose coding regions differ in their carboxy termini. Antibodies raised against C-terminal peptides predicted by these specific sequences were used to localize each of the 3 predicted qkI proteins, qkI-5, qkI-6 and qkI-7, in P14 wildtype mice. In brain, all 3 antibodies show strong immunolabeling in oligodendrocytes and also in Bergmann glia, and weak immunolabeling in other astrocytes. No immunoreactivity is seen in neurons. In sciatic nerve, all 3 antibodies label myelinating Schwann cells (SCs) but non-myelinating SCs are only weakly labeled. Interestingly, qkI-5 is restricted to the nucleus in all these cell types. By contrast, qkI-6 and qkI-7 are primarily localized to the cytoplasm of perikarya and proximal processes.

We have also investigated the localization of the three qkI proteins in quaking mutant mice. We found that all three proteins are expressed in Bergmann glia and weakly in astrocytes and non-myelinating SCs. However, in contrast to wildtype mice, we found that qkI-6 and qkI-7 are entirely absent from both oligodendrocytes and myelinating SCs. By contrast, qkI-5 is strongly expressed in oligodendrocytes and myelinating SCs of quaking mice.

In wildtype mice, qkI proteins are expressed in all glia but are most abundant in myelinating cells. Although qkI proteins are expressed in a variety of cell types, the absence of qkI-6 and qkI-7 from myelinating cells in dysmyelinating quaking mutants suggests they play an important role in myelination.

Supported by NIH grant NS33165.

THE ROLE OF THE GAP JUNCTION PROTEIN CONNEXIN32 IN MYELINATING SCHWANN CELLS. L. J. Bone, S. S. Scherer*, and R. J. Balice-Gordon. University of Pennsylvania School of Medicine, Philadelphia, PA 19104

Mutations in the gap junction protein connexin32 (Cx32) cause the X-linked form of Charcot-Marie-Tooth disease (CMTX), a progressive, demyelinating, peripheral neuropathy. Cx32 is expressed by myelinating Schwann cells and is localized principally to Schmidt-Lanterman incisures and paranodal regions, both regions of non-compact myelin. The expression of Cx32, like that of other myelin-related genes, is regulated by axon-Schwann cell interactions. Levels of Cx32 mRNA and protein increase during development and fall after axotomy, but return to normal if the axons regenerate and are remyelinated.

To determine whether there are functional gap junctions in peripheral nerve, we injected 5,6-carboxyfluorescein (376 MW) and rhodamine- or fluorescein-conjugated dextran (3,000 MW) into myelinating Schwann cells of teased, living, mouse sciatic nerve fibers. Confocal analysis of injected fibers showed that 5,6-carboxyflourescein, but not 3,000 MW dextran, passes through the incisures to the thin innermost layer of cytoplasm adjacent to the axon. These results suggest that there is a radial pathway for diffusion of small molecules across the myelin sheath. Preincubating the teased fibers in octanol, known to uncouple gap junctions, blocks the ability of 5,6-carboxyfluorescein to label the cytoplasm adjacent to the axon. This suggests that the radial pathway across the myelin sheath is dependent on functional gap junctions. This work was supported by grants from the American Academy of Neurology (Murray M. Stokely Award) and the NIH (NS34373).

ELECTRICAL SIGNALS INFLUENCE MYELIN GENE EXPRESSION L. D. Hudson* and D. v. Agoston. Lab. of Developmental Neurogenetics, NINDS and MCN, LDN, NICHD, NIH, Bethesda, MD 20892

In the developing nervous system, a network of growth factors and other signalling molecules operates to activate the expression of myelin genes in oligodendrocytes. Controls of myelin gene expression must also exist in the adult nervous system to maintain the appropriate amount of myelin for each ensheathed neuron. We found that differentiated oligodendrocytes are capable of responding to signals of electrical origin with altered expression of the myelin-specific gene, proteolipid protein (PLP). The electrical stimulation of the rat CG4 cell line displayed a strong frequency dependence, with low frequency stimulation being the most effective way to alter the level of PLP mRNA. Myelin gene expression was also affected when CG4 cells were chemically depolarized, most dramatically with stimuli that directly affect potassium channel function. Our results suggest that electrical signalling from neurons may provide a feedback mechanism by which oligodendrocytes maintain myelin in the mature nervous system.

DEVELOPMENTAL AND REGIONAL EXPRESSION PATTERNS OF SPLICE VARIANTS OF THE DYSTROPHIN FAMILY MEMBERS IN RAT BRAIN. P. Bassand, L. Ferhat, W. Ferhat, A. Bernard, Y. Ben-Ari, D.L. Kaufman*#, and M. Khrestchatisky. Université René Descartes. Paris V. INSERM U-29, 123 Bd de Port-Royal, 75014 Paris France. # Dept. of Molecular and Medical Pharmacology, UCLA LA, CA 90095-1735. USA.

Dystrophins constitute a large family of submembrane cytoskeletal proteins which link the cytoskeleton (actin) to the extracellular matrix (agrin, laminin) via transmembrane receptor proteins. Alternative splicing regulates interactions of dystrophins with the syntrophins/87K and dystrophin-associated glycoprotein families of cytosolic and transmembrane proteins. Our interest in synaptic plasticity and the absence of systematic characterization of the dystrophin family in the developing rat brain prompted us to analyze the developmental and regional expression patterns of the major splice variants of dystrophin family members in the rat CNS. We used *in situ* hybridization and semi-quantitative RT-PCR to decipher the expression patterns of Dp427 (brain and Purkinje isoforms), Dp140, Dp116, Dp71, Dp40 and G-utrophin isoforms, in the olfactory bulb, cortex, cerebellum, and hippocampus. LA-PCR allowed us to analyze the specific splice variants of a given isoform from its full-length PCR amplification. Dp40 and Dp116 were expressed at lower levels when compared to all other variants and all dystrophins exhibited complex patterns of expression with a decrease of expression in the hippocampus between P10 and P14 suggesting cytoskeletal reorganizations.We are currently studying the intracellular distribution and interactions with the cytoskeleton of several dystrophin isoforms after cell transfection using FLAG-tagged dystrophins, obtained after modification of a eukaryotic expression vector. P.B and L.F are recipients of AFM fellowships (Association Française Contre les Myopathies). Supported by a grant from the AFM.

IMMUNOLOCALIZATION AND BIOCHEMICAL CHARACTERIZATION OF DYSTROPHIN ISOFORMS IN SYMPATHETIC GANGLIA OF NORMAL AND *MDX* DYSTROPHIC MICE. P. Paggi[1*], M.E. De Stefano[1], M.L. Zaccaria[1], M. Cavaldesi[2], R. Medori[3] and T.C. Petrucci[2]. [1]Dip. Biol. Cell., Univ. "La Sapienza", 00185 Roma and [2]Ist. Sup. San., 00161 Roma, Italy; [3]Lilly Deutschland, 62350 Bad Homburg, Germany.

Studies of the subcellular localization of specific proteins can give an insight into their possible functional role. For this purpose, we studied the subcellular distribution of dystrophin (DYS) isoforms in normal mouse superior cervical ganglion (SCG) and compared it with that in the SCG of *mdx* dystrophic mice, which lack full length DYS (427 kDa). Immunoelectron microscopy showed DYS immunoreactivity in ganglionic neurons, satellite cells and Schwann cells, associated with several cytoplasmic organelles and with specialized membrane domains, including synaptic- and non synaptic (*adherens* junctions) contacts. The absence of immunostaining observed at the majority of postsynaptic densities and at all *adherens* junctions in *mdx* dystrophic mouse SCG demonstrates that only full length DYS (427 kDa) is present at these contacts in normal mouse SCG. Immunoblot analysis, using different polyclonal antibodies, has revealed, beside full length DYS, the presence of several DYS isoforms that account for the staining observed in *mdx* dystrophic mouse SCG. The selective labeling of functionally different cytoplasmic and plasma membrane sites suggests a role for DYS and its isoforms in the organization and stabilization of different specialized neuronal domains. *Supported by Telethon funds #85 to RM and Fondazione Cenci Bolognetti to MEDS.*

GANGLIOSIDE UPTAKE BY BRAIN CELL MEMBRANES: EFFECT OF PROTEOLYTIC ENZYMES. H. Young, Z. Christian, R. Cabeza, L. N. Irwin*. Dept. Biol. Sci., Univ. of Texas at El Paso, El Paso, TX 79968

Exogenous ganglioside uptake provides a tool for the study of ganglioside interactions with other components of brain cell membranes. To determine the role of proteins, we have treated synaptosomes with proteolytic enzymes prior to exogenous ganglioside exposure. Rat cerebellar synaptosomes were prepared by density gradient centrifugation, treated with 0.1% trypsin or 0.05% papain, then incubated for 90 min with [3H]-gangliosides. Total gangliosides were extracted, isolated, separated by TLC, and counted. Pretreatment with trypsin inhibited ganglioside uptake by 64%, but no effect was seen with papain. Thus cell surface proteins removed by trypsin but not papain facilitate uptake of gangliosides. Uptake of gangliosides was also suppressed by pretreatment in acidic buffer (pH 6.2) but enhanced with alkaline (pH 7.8) buffer. The differential influence of proteolytic enzymes and pH on ganglioside incorporation points to specific protein-ganglioside interactions in brain cell membranes. *Supported by RCMI Grant 5G12RR08124, NIH, and by an endowment from J. Edward and Helen M. C. Stern. H. Young and Z. Christian are Howard Hughes Research Institute scholars.*

LOCALIZATION OF α_5 and β_1 INTEGRIN mRNA IN THE ADULT RAT HIPPOCAMPUS. S.Y.Grooms* and L.S.Jones. Developmental Biology & Anatomy, University of South Carolina, School of Medicine, Columbia, SC 29208.

Integrins are a superfamily of heterodimeric transmembrane proteins, consisting of noncovalently linked subunits that attach the cytoskeleton to the extracellular matrix and adjacent cells. These proteins also transduce signals from the extracellular environment to the inside of the cell. Individual integrin subunits, such as β_1 and α_5, have been shown to mediate specific functions in a variety of cells. These adhesion molecules are likely to function in the stabilization of axonal and dendritic processes and may also participate in neuronal remodeling following kainate-induced seizure activity. Such neuronal plasticity may be partially mediated by integrins functioning in cell-matrix or cell-cell attachment during outgrowth of neuronal processes, or perhaps in the remodeling of synaptic connections. However, there is currently little evidence demonstrating the presence of integrins in the adult CNS. We have used non-isotopic *in situ* hybridization to localize β_1 and α_5 integrin message in the adult rat hippocampus. Digoxigenin-labeled RNA was transcribed from β_1 and α_5 cDNA and alkaline hydrolyzed to produce 200 base pair probes. Both the antisense and the sense strands were allowed to hybridize to cellular mRNA in fixed brain tissue sections. Single-stranded RNA (unhybridized) was then digested with RNase, leaving only the mRNA-digRNA hybrids, which were then incubated with anti-digoxigenin Fab fragments conjugated to alkaline phosphatase. Detection of the specific RNA message was accomplished using bromochloroindolyl phosphate and nitroblue tetrazolium in an alkaline phosphatase reaction. The localization of the RNA message indicates that most hippocampal pyramidal cells and dentate granule cells express both β_1 and α_5 integrin mRNA as do some cells scattered in other layers. Detection of these subunits in the hippocampal perikarya is further evidence that integrins are present in the hippocampus and may participate in neuronal functions in the mature central nervous system. INTEGRIN SUBUNITS α_3, α_5, AND β_1 ARE PRESENT IN THE NERVE TERMINALS OF THE CHOLINERGIC SYNAPSE OF MARINE RAY ELECTRIC ORGAN. W.J. Sunderland and Steve S. Carlson*. Dept. of Physiology and Biophysics, University of Washington, Seattle, Wa. 98195.

The neuromuscular junction is a highly specialized cell-cell interface. The nerve terminal shows a polarized structure with synaptic vesicles collecting at pre-synaptic sites directly opposite of post-synaptic clusters of nicotinic acetylcholine receptor (NAChR). The intervening extracellular matrix (ECM) contains unique components such as acetylcholine esterase, agrin and S-laminin. It has been hypothesized that receptors in the pre-synaptic membrane may interact with the synaptic ECM to establish and maintain the nerve terminal's polarity. To search for putative receptors we have adapted a method from Miljanich (1982) for the immunopurification of nerve terminals from the electric organ of marine rays. We begin with the standard synaptosomal preparation which is far from pure as indicated by the presence of NAChR, an indicator of post-synaptic contamination, and laminin and indicator of ECM. We further purify nerve terminals by immunoprecipitating with an antibody directed to an epitope of the SV2 proteoglycan that appears on the nerve terminal surface. These immunopurified membranes show greatly reduced levels of NAChR, but still contain laminin. In addition it is possible to immunoprecipitate nerve terminals with an anti-laminin antibody. We conclude that laminin is bound to the surface of our immunopurified nerve terminals. The form of laminin on the nerve terminal stains with both an anti-S-laminin anti-sera (GP-1) and with an anti-HNK-1 antibody. In searching for possible receptors for laminin we have probed these membranes with anti-bodies specific to several integrin subunits, and have found the α_3, α_5, and β_1 subunits to be present. We are working to determine if any of these integrin subunits are acting as receptors for laminin bound to the nerve terminal surface. This work was supported by NIH NS 22367 (SSC) and PHS NRSA T32 GM07270 from NIGMS (WJS).

LOCALIZATION AND SEIZURE-REGULATION OF INTEGRIN β1 mRNA IN ADULT RAT HIPPOCAMPUS. J. Pinkstaff*[1], J. Detterich[1], G. Lynch[2], and C.M. Gall[1,2]. Depts. of [1]Anatomy and Neurobiology & [2]Psychobiology, University of California, Irvine, CA 92717

Integrins are a family of membrane-bound adhesion receptors which recognize extracellular matrix proteins and contribute to several types of cell-cell interaction. Recent evidence suggests that integrin proteins also play a role in the stabilization of hippocampal long term potentiation but the cellular compartment of this activity is not known. To identify the cells which express integrin in adult hippocampus, and determine if expression is responsive to neuronal activity, the present study used *in situ* hybridization to localize mRNA for the integrin β1 subunit in tissue from untreated control rats and experimental rats killed at a range of time points after the placement of a focal electrolytic lesion in the right dentate gyrus hilus. The hilus lesion (HL) generates bilateral, recurrent limbic seizures from 2-10 h after surgery. Low levels of β1 mRNA were detected in control hippocampi predominantly in the pyramidal neurons of field CA3 but also in association with glia in all subfields. In experimental seizure rats, β1 mRNA was elevated bilaterally first (4 and 8 h post-HL) within the pyramidal cells, and at later intervals (18 - 24 h post-HL) within both pyramidal cells and broadly distributed glia. At 48 h post-HL, hybridization returned to control levels in most areas, remaining elevated only around the lesion site. These results demonstrate that in adult hippocampus both neurons and glia express integrin β1 mRNA and that expression by both cell types is responsive to intense neuronal activity. These data also support the previous results demonstrating a functional fibronectin receptor is present in adult hippocampus. (Supported by NS26748 and BNS9024143)

FAST MIGRATING CEREBROSIDES (FMCs) IN DEVELOPING BRAIN, S. Dasgupta and E.L. Hogan*. Neurology Dept, Med Univ SC, Charleston, SC 29425.

Several Fast Migrating Cerebrosides (FMCs) have been identified in developing rat brain. They appear during the early stages of myelinogenesis (Postnatal 10; P10), increase until P25-P30 and maintain this concentration as adults. We have purified several FMCs from bovine brain by column chromatogarphy. These are alkali labile (0.1N NaOH/MeOH, at 37°C for 30 min) compounds and the hydrolyzed products comigrate with NFA/HFA cerebroside. Four of these FMCs are hydrolyzed by weak acid (0.3N HCl/MeOH) under identical conditions. Galactose was the only carbohydrate identified by GC as an alditol acetate. We have developed a permethylation procedure under neutral conditions; employing this technique we have tentatively elucidated their anomeric configurations. They appear to have tetra-, tri-, di- and monoacyl groups linked to the galactosylceramide. The identification of the terminal galactose (2,3,4,6-OMe_4) and both acid and alkali lability of some FMCs strongly suggest a novel linkage between the fatty acyl/aldehyde group and the ceramide base of the cerebroside. The following results suggest that some of these FMCs may be myelin components: (1) identification of C24 fatty acyl/aldehyde group, (2) comigration of the hydrolyzed product with HFA cerebroside and (3) coappearance of FMCs with galactosylceramide (which is a myelin marker) during brain development and myelinogenesis. (Supported partly by NIH/NINDS NS31355 and SC State Appropriation CR21.)

A POSSIBLE MOLECULAR DIFFERENTIATION OF SUBSTANCES RECOGNIZED WITH *VICIA VILLOSA* LECTIN ON PYRAMIDAL AND NONPYRAMIDAL NEURONS, J. Ohyama, H. Ojima*, and K. Kishi. 1st Dept. Anat., Toho Univ. Sch. Med., Tokyo, 143 Japan

In the guinea pig, unlike other mammals, both pyramidal (P) and nonpyramidal (NP) neurons are known to be enwrapped perineuronally by substances recognized with a lectin, *Vicia villosa* (VVA). Staining with fluorescent dye-conjugated VVA revealed that their cell body, dendrites, and axon initial segment were outlined by VVA-recognized substances in a similar manner. This apparent similarity in the lectin staining might suggest that substances surrounding the neurons with totally different morphology are identical. By applying various antibodies which recognize extracellular matrix molecules, we have explored if molecular composition of perineuronal substances associated with two different types of neurons is similar or not.

Double staining with a VVA lectin and a monoclonal antibody, MAb 473, labeled almost identical populations of P and NP neurons, but the antibody stained outline of P neurons much less weakly than that of NP neurons. Intense staining around NP neurons and weak staining around P were both eliminated by pretreatment of sections with a protease free chondroichinase ABC. P and NP neuronal types in these enzyme-treated sections, however, were similarly outlined with another monoclonal antibody, 1B5.

These results suggest a possible difference in molecular composition of the perineuronal substances associated with the two distinct cortical neuronal populations of the guinea pig.

EXPRESSION OF NEURAL CELL ADHESION MOLECULE (NCAM) IN ASTROCYTIC TUMORS: AN INVERSE CORRELATION WITH MALIGNANCY. H. Sasaki, K. Yoshida*, M. Inaba, M. Hoshi, H. Kamiguchi, M. Otani, S. Toya, and T. Kawase. Department of Neurosurgery, School of Medicine, Keio University, Tokyo 160, Japan.

Expression of neural cell adhesion molecule (NCAM) in astrocytic tumors and the relationship between NCAM expression and the degree of malignancy was investigated. The expression of NCAM was examined in 44 astrocytic tumors (11 astrocytomas, 20 anaplastic astrocytomas, and 13 glioblastomas) by Western blot analysis, and the degree of sialylation was also studied by neuraminidase digestion. Subsequently, the amount of each NCAM band was quantified, and the correlation was investigated to the histology, the extent of hyperintense area on T2 weighted MR images, presence or absence of dissemination, and proliferating cell indices (PCIs) determined by MIB-1 immunohistochemistry. The degree of NCAM expression varied, however, the band of 145kD and the band migrating around 120kD were mainly expressed, the 180kD band less frequently, and the 170 band rarely. The degree of sialylation of NCAM in astrocytic tumors has proved to be almost identical to that of normal brain. The degree of the expression of each major band (180, 145, and 120kD) was shown to be inversely well correlated with all indices of malignancy employed, and NCAM expression was barely detectable in such advanced tumors as glioblastomas and anaplastic astrocytomas either with dissemination or high PCIs. We have provided the first direct evidence that NCAM is down-regulated in the development of malignant potentials of astrocytic tumors, and reduced NCAM expression might be involved in the malignant evolution of astrocytic tumors. Supported by grants from Keio University.

THE GENERATION AND CHARACTERISATION OF A NEURAL CELL LINE OVEREXPRESSING α2,6(N) SIALYLTRANSFERASE. Kieran C. Breen*, Astrid Potratz, Niki Georgopoulou and Konrad Sandhoff. Dept. of Pharmacology, University of Dundee, Scotland and Institute for Organic Chemistry and Biochemistry, University of Bonn, Germany.

The negatively charged sugar, sialic acid, plays a major role in the control of cell-cell interaction. In the nervous system, for example, the function of the neural cell adhesion molecule, NCAM, is carefully controlled during development by its sialylation state. As the functional consequences of altered neural cell sialylation are poorly understood, the generation of clonal neural cell lines over-expressing individual sialyltransferase enzymes would be a useful tool with which to study altered neural cell sialylation.

B104 mouse neuroblastoma cells were stably transfected with the cDNA coding for α2,6 (N) sialyltransferase. 14 clones were obtained with sialyltransferase activity ranging up to 20 times control levels. Lectin blot analysis of the clones demonstrated an increase in staining of the *Sambucus nigra* lectin which detects α2,6 linked sialic acid, and this was in agreement with enzyme activity. There was a parallel decrease in staining with the *Maackia amurensis* lectin which labels α2,3-linked sialic acid, indicating that the individual sialyltransferase enzymes compete for penultimate galactose acceptor sites.

There was an inverse relationship between cell adhesivity to a fibronectin substrate and STN activity suggesting that the negatively charged sugar acts to modulate cell-substrate interaction. These cells will provide an ideal model system with which to further investigate the effect of altered sialic acid on cell function.

This study was supported by the British-German Academic Research Collaboration Programme.

A POLYMERASE CHAIN REACTION (PCR) - BASED APPROACH TO THE SEARCH FOR NOVEL CHOLINERGIC-SPECIFIC I-TYPE LECTINS IN BRAIN. C.B. Zeller, R.L. Schnaar, and R.E. Shapiro*. Departments of Neurology and Pharmacology, The Johns Hopkins School of Medicine, Baltimore, MD 21205.

I-type lectins are a subclass of glycoproteins of the immunoglobulin superfamily which bind sialic acid. Known I-type lectins include myelin-associated glycoprotein (MAG) and Schwann cell myelin protein (SMP) of the nervous system, and sialoadhesin (SN), CD22, and CD33 of the immune system. It has been proposed that MAG on adaxonal myelin membranes binds to neuronal surface carbohydrates to influence neurite outgrowth. Of all glycoconjugates tested *in vitro*, MAG bound most potently to the ganglioside GQ1bα [*PNAS USA* 93:814-818 (1996)]. However, *in vivo*, MAG exists in myelin membranes irrespective of the neurotransmitter phenotype of the myelinated axon, whereas GQ1bα is only expressed on the surfaces of cholinergic neurons and their processes. We therefore hypothesize that, *in vivo*, GQ1bα binds to unidentified brain I-type lectins. To search for such proteins, we have adopted a PCR-based approach to amplify novel sequences from cDNAs generated from mRNAs from several adult rat brain regions. The PCR primers for these reactions consist of degenerate oligonucleotide sequences based on either (i) broad sequence conservation among the five known I-type lectins, or (ii) close sequence conservation between MAG and SMP, particularly in presumptive β-strand regions homologous to those regions of SN and CD22 required for sialic acid binding. We observed that certain paired combinations of these PCR primers amplified DNAs from cDNA templates from some cholinergic brain regions, but could not do so from cDNA templates from some non-cholinergic tissues (e.g. cerebellum). These amplified DNAs also had electrophoretic mobilities and restriction endonuclease susceptibilities different from those of either MAG or SMP. Sequencing of these PCR products is underway. [NINDS KO8 NS01518 & P.V.A. / S.C.R.F.]

LIPIDS ASSOCIATED WITH GLYCOPROTEINS MEDIATING AXONAL TARGETING IN LEECH. B. Zipser* and R. I. Hollingsworth. Depts. Physiol. and Biochem., Michigan State University, East Lansing, MI 48824.

To characterize the carbohydrate moieties that mediate the targeting of leech sensory afferent neurons, we immunopurified neuroepithelial leech protein. After hydrazinolysis, we separated carbohydrates from lipids. GC, GC-MS, 1 and 2 dimensional ^{1}H NMR showed that lipids associated with the immunopurified glycoproteins consisted of glycolipids containing rhamnose, fucose, galactose, mannose and glucose in a ratio of 15:10:8:3:2. There were no phospholipids. However, lipids extracted from whole leech had three major classes of phospholipids, phosphatidylinositol, phosphatidylserine and the predominant phosphatidylcholine. There was no phosphatidylethanolamine. NMR and UV absorption spectra using the orcinol/HCl/$FeCl_3$ assay showed the presence of sialic acid. Both GC-MS and ^{1}H NMR TOCSY and DQF-COSY indicate that sphingosine is not present. This suggests that sialic acid is attached to glycolipids with a different anchor, probably a diacylglycerol. NIH NS25117

777.13

A BRAIN ORPHAN RECEPTOR THAT HAS HOMOLOGY TO IMMUNE ANTIGEN RECEPTORS. S. Sano*, H. Ohnishi, M. Kubota. Mitsubishi Kasei Inst. of Life Sci., Machida, Tokyo 194, JAPAN

We previously found a membrane-bound glycoprotein, 1D4 antigen, that was specific to the brain among rat tissues by immunoblotting. Expression of the glycoprotein increased postnatally and was maintained in the mature brain. In this study, we cloned the cDNA encoding this protein. 1D4 antigen is characterized by a V-type immunoglobulin domain, two C1-type immunoglobulin domains and a cytoplasmic region containing two tyrosine-based activation motifs (TAMs) that are variants of the antigen receptor signaling motifs. The overall structure was similar to those of immune antigen receptors. To elucidate functional roles of 1D4 antigen, we initially examined its tyrosine phosphorylation. 1D4 antigen was one of major endogenous substrates of protein tyrosine kinases in crude brain suspensions. Cross-linking 1D4 antigen on transfected Jurkat cells induced tyrosine phosphorylation of the cytoplasmic TAMs and the phosphorylated 1D4 antigen recruited a tyrosine phosphatase, SH-PTP2. These findings suggest that 1D4 antigen functions as a receptor and transduces a signal by using the tyrosine-phosphorylated motifs. This orphan receptor may participate in a major signal transduction passway through tyrosine phosphorylation in the brain.

EFFECTS OF THE MUTATIONS OF VAMP-2 IN THE FORMATION OF MULTICOMPLEXES. N. Salem and R. Kelly *, Dept of Biochemistry and Biophysics, UCSF, San Francisco, CA 94143

Using the two-hybrid system in yeast and a series of deletions and point mutations, we delineate the domains of VAMP-2 required for the formation of complexes with either SNAP-25 either syntaxin 1A. Deletions within the conserved domain of VAMP-2 eliminated binding to either syntaxin or both syntaxin and SNAP-25. Syntaxin 1A and SNAP-25 binding were reduced by the M46A mutation (reduced endocytosis and SV targeting) and enhanced by the N49A mutation (enhanced synaptic vesicle targeting). This suggests a correlation between the membrane trafficking phenotype of the two VAMP-2 point mutants and their competence to form complexes with either syntaxin and SNAP-25. Moreover, in PC12 cells stably transfected with different VAMP-TAg mutants, VAMP associates in different molecular weight complexes (40, 65, 100, 140 kD) in presence of a cross linking agent. These complexes do not contain syntaxin 1A, or SNAP-25, or synaptophysin. The 40 kD complex corresponds to a dimer of VAMP-TAg. The high molecular weight complexes are formed preferentially with the N49A mutant compared to wild type VAMP or other mutants, suggesting that VAMP has to associate with an other protein or with itself to be sorted to the synaptic vesicle. These complexes are also present in rat brain synaptic vesicle treated with a cross linker indicating that they are of a physiological relevance. Swiss National Science Foundation.

NEUREXIN AT THE ELECTRIC ORGAN SYNAPSE A.B. Russell, W.L. Stahl* and S.S. Carlson. Department of Physiology and Biophysics, University of Washington, Seattle, WA 98195

Various studies have demonstrated that the ability of the neuron to relocate itself to the original synaptic location during nerve regeneration depends on the presence of the basal lamina that ensheathes the muscle fiber. There are specific types of extracellular matrix (ECM) proteins present only at the synaptic location of the basal lamina. Presumably, there are receptors present on the neuron with the ability to recognize these specific synaptic ECM molecules during the process of establishing and the subsequent maintenance of the synapse. Our lab is working on identifying these receptors using the highly homologous synapse of the electric organ from the marine ray, *Discopyge ommata*.

Neurexin is a strong candidate for a synaptic ECM receptor. This transmembrane protein is limited to the synaptic region of the neuron, the protein contains regions homologous to previously identified ECM proteins, and the extracellular domain of neurexin undergoes extensive variability due to alternate splicing. Our hypothesis is that a neurexin with a defined extracellular domain will interact with a specific ECM protein at the neuromuscular junction and related synapses.

We have been successful in cloning a neurexin from an electromotor nucleus (EMN) cDNA library from the marine ray, *Discopyge ommata*. The cDNA library is prepared from the neurons innervating the electric organ. Sequence analysis indicates electric organ neurexin is 78.4% identical to rat neurexin IIIα. Rabbit antisera were generated to a Glutathione-S-Transferase (GST) fusion protein containing the intracellular domain of electric organ neurexin. With the antibodies, electric organ neurexin was detected on western blots of 8M urea extracts of ECM, but not detergent extracts, prepared from marine ray electric organ. This suggests the neurons of the electric organ express a neurexin tightly associated with the ECM. We are currently exploring this association. This work was supported in part by a NASA-GSRP Fellowship, the Keck Foundation and NIH Grant NS22367.

BIOCOMPATIBILITY OF CNS IMPLANTS COATED WITH SILKLIKE POLYMERS CONTAINING ELASTIN, FIBRONECTIN, OR LAMININ CELL BINDING MOTIFS. K.S. O'Shea*[1], C. Buchko[2], Y. Shen[2], R.A. Altschuler[3], P. Finger[3], J.A. Wiler[3], J. Cappello[4], and D.C. Martin[2]. Depts. of Anatomy & Cell Biology[1], Materials Science and Engineering[2], the Kresge Hearing Research Institute[3], Univ of Michigan, Ann Arbor, MI, and Protein Polymer Technologies, Inc.[4], San Diego, CA.

In order to test coatings designed to improve tissue-implant interaction, 6-0 polypropylene sutures were coated with protein polymers produced in *E. coli* which were engineered to contain repeating silk like domains (GAGAGS) combined with extracellular matrix cell binding motifs, e.g., the RGD sequence from fibronectin (SLPF), IKVAV from the laminin alpha chain (SLPL), or an elastin repeat (VPGVG; SELP). Suture coated with each polymer, uncoated suture, and suture coated with SLPF and a layer of mouse Schwann cells were placed in guinea pig cortex and cell reaction to implants was assessed at 3 weeks and 12 weeks in Epon sections. At both time points, there was slight tissue reaction to the implants, with a small 10-50 um thick rim of astroglia present at the interface. Neurons appeared morphologically normal, although there was some re-orienting of processes toward the SLPL coated implants. Current investigations are in progress to extend these observations to nine months, with the long term goal of improving implant stability and reducing glial reaction to CNS implants. Supported by NIH NINDS Contract No. NO1-NS-5-2322, and NIH NCRR P41-RR09754.

EXPRESSION OF CHEMOTACTIC RECEPTORS ON HUMAN NEUROBLASTOMA CELLS. S. R. Barnum, J. Jones, R. A. Wetsel and K. Spiegel*. Department of Microbiology, University of Alabama at Birmingham, Birmingham, AL 35294.

Increased expression of chemotactic receptors in the CNS in inflammatory conditions, such as meningitis, suggests that these receptors may play a role in the inflammatory response. The functional roles played by chemotactic receptors in the CNS will, in part, be determined by the range of cellular expression of the receptors. Thus, we have examined neuroblastoma cell lines for their ability to express the receptors for C5a (C5aR), interleukin-8 and N-formyl-Met-Leu-Phe. All three receptors were expressed on SK-N-SH and SK-N-MC neuroblastoma cell lines at levels greater than or equal to what we have reported for astrocytes and microglia as determined by flow cytometry and indirect immunofluorescence. As expected for terminally differentiated cells, the levels of mRNA for the receptors are nearly undetectable by Northern blot analysis. Western blot analysis demonstrated that the C5aR on neuroblastoma cells has an apparent molecular weight of 45 kDa comparable to that seen on myeloid cells. These data demonstrate that neuroblastoma cells express several chemotactic receptors and suggest the possibilty of novel functional roles for these receptors in the CNS. This work was supported by NIH grants NS-29719 (SRB) and AI 25011 (RAW).

EXPRESSION OF α1,2-FUCOSYLTRANSFERASE GENE SUPPRESSES AXONAL OUTGROWTH OF NEURO2A CELLS. S. Hitoshi, N. Kojima, S. Kusunoki§, I. Kanazawa§, T. Kagawa#*, K. Ikenaka# and S. Tsuji. Molecular Glycobiology, RIKEN, Saitama, §Dep. of Neurology, Tokyo Univ., Tokyo, and #Lab. of Neural Information, Okazaki National Res. Inst., Aichi, Japan.

Axonal outgrowth of cells of Neuro2a, a mouse neuroblastoma cell line, was suppressed on expression of the β-galactoside α1,2-fucosyltransferase (α1,2-FT) gene. We recently cloned three types of rabbit α1,2-FT: one (RFT-I) is a H-blood type α1,2-FT, and the others (RFT-II and III) Se-type α1,2-FTs. RFT-I showed comparable Km values for type 1 (Galβ1,3GlcNAc), 2 (Galβ1,4GlcNAc), and 3 (Galβ1,3GalNAc) oligosaccharide acceptors, whereas RFT-II and III exhibited higher affinity to type 1 and 3 acceptors than type 2 ones. Neuro2a cells expressing RFT-I (N2A-RFT-I) and RFT-III (N2A-RFT-III) contained a large amount of fucosyl GM1 instead of GM1 and GD1a, major gangliosides in the parent Neuro2a cells, whereas Neuro2a cells expressing RFT-II (N2A-RFT-II) showed a subtle change in the ganglioside pattern. Type 2 glycochains of glycoproteins on N2A-RFT-I but not on other Neuro2a variants were α1,2-fucosylated and recognized by UEA-1 lectin. N2A-RFT-II and parent Neuro2a cells showed axonal outgrowth in serum-free medium on the exogenous addition of GM1, whereas N2A-RFT-I and III cells exhibited multiple neurite sprouts but not axonal outgrowth. This phenotype was fully recovered by N2A-RFT-I and III cells on the addition of D-threo-1-phenyl-2-decanoylamino-3-morpholino-1-propanol and α-L-fucosidase to the culture medium, which resulted in marked reduction of fucosyl GM1 expression. These results suggested that expression of α1,2-FT, and subsequent formation of fucosyl GM1, modifies the response of neuronal cells to stimuli that induce axonal extension.

LOWER TOTAL SERUM CHOLESTEROL IN PATIENTS WITH MAJOR DEPRESSION. H. U. Kötter*, [!]H. Hampel and H. J. Möller. Psychiatric Hospital, Ludwig-Maximilian-University, Munich, Nussbaumstr. 7, 80336 Munich, Germany; [!] National Institutes of Health, National Institute on Aging, Laboratory of Neuroscience, Bldg 10, 6 C 414, Bethesda, MD.

Alterations of the lipid metabolism as possible pathogenetic factors in Major Depression [MD] are discussed in literature (1). A correlation of lower cholesterol and MD could be demonstrated (2, 3). In addition, the risk of suicide seems to increase with the decline of serum cholesterol (2, 4).

In our investigation we raised the question how the total serum lipid composition is altered in MD compared to healthy age matched controls.

Blood levels of total cholesterol and triglycerides were examined in 65 patients with MD (50 female and 15 male). Comparisons were obtained from values of a normal population study (n=30,000).

Our findings demonstrate a significant lower total cholesterol in MD compared to healthy control subjects ($p < 0.01$), however, there was no significant difference in triglyzeride concentration.

In conclusion, our data support the hypothesis of low cholesterol being a possible pathogenetic factor for major depression.

CHANGES IN PHOSPHOLIPID METABOLISM ARE INVOLVED IN THE DIFFERENTIATION OF SODIUM BUTYRATE TREATED-C6 GLIOMA CELLS. S. H. Sun*, H-C Ou, T-H Jang, L-B Lin and H-M Huang[†] Ins. of Neuroscience, National Yang Ming University, Taipei and [†]Department of Education and Medical Research, Taichung Veterens General Hospital, Taichung, Taiwan, Republic of China

We examined the changes in phospholipid metabolisms of sodium butyrate-treated C6 glioma cells. Treatment of 2.5 mM sodium butyrate for 24 hr induced an increase in the activity of glutamine synthetase and a decrease in thymidine incorporation suggesting that these cells were under differentiation. Similar treatment was associated with (1) increased arachidonic acid incorporation into phosphatidylcholine (PC) and (2) decreased arachidonic acid incorporation into phosphatidylinositol (PI). However the de novo synthesis of PI, phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2) were not altered, whereas the basal level and the histamine-stimulated inositol monophosphate (IP) accumulation were decreased in the sodium butyrate-treated cells. Furthermore the transient $I_{1,4,5}$ P_3 (IP_3) production by a receptor-binding assay were also decreased. Taken together, these results indicated that alterations in phospholipid metabolisms were associated with changes in glutamine synthetase activity and thymidine incorporation in these cells, and the decreased IP_3 production from decreased phosphoinositides hydrolysis may play a pivotal role in sodium butyrate induced cell differentiation.

CENTAURIN α: A NOVEL PHOSPHATIDYLINOSITOL (3,4,5)-TRISPHOSPHATE BINDING PROTEIN FROM RAT BRAIN L.P. Hammonds-Odie, T.R. Jackson#, A.A. Profit^, I.J. Blader, C.W. Turck@, G.D. Prestwich^, and A.B. Theibert*, Neurobiol. Res. Ctr., Univ. AL, Birmingham, AL 35294, #Babraham Inst. Lab. Mol. Signalling, Dept. Zoology, Cambridge CB2 3ES, UK, ^Dept. Chemistry & Biochemistry and Cell Biology, SUNY, Stony Brook, NY 11794, and @Howard Hughes Med. Inst., Univ. CA San Francisco, San Francisco, CA 94143

We have purified and cloned a 46 kDa protein from rat brain, named centaurin α, using an affinity resin based on a phospholipid analog of inositol (1,3,4,5)-tetrakisphosphate ($InsP_4$). Displacement of [^{3}H]-1-*O*-(3-(4-benzoyldihydrocinnamidyl)propyl)-$InsP_4$ photoaffinity labeling demonstrates that centaurin α bound phosphatidylinositol (3,4,5)-trisphosphate ($PtdInsP_3$) with highest affinity (IC_{50} = 120 nM), followed by $InsP_4$ (620 nM), $PtdInsP_2$ (1.5 μM), and $InsP_3$ (>3 μM). Tryptic peptide data was used to generate a PCR product for screening a rat brain cDNA library. A 2450 bp clone, encoding a novel protein of 419 amino acids, was obtained. Centaurin α is highly enriched in brain, and contains a novel putative zinc finger motif with homology to recently identified yeast GCS1 protein and liver Arf GTPase activating protein. Cosedimentation with f-actin suggests that centaurin α may also be an actin binding protein. We propose that centaurin α is a candidate $PtdInsP_3$ receptor which may link the activation of phosphoinositide 3-kinase to responses in the brain.

THE MICROTUBULE ASSOCIATED PROTEIN TAU BINDS TO INOSITOL PHOSPHOLIPIDS. L.A. Flanagan*, C.C. Cunningham, K.S. Kosik, and P.A. Janmey. Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115.

Phospholipids have been shown to bind to cytoskeletal proteins and affect cytoskeletal assembly. Particularly, the phospho-inositide PIP2 binds to several actin-associated proteins and constitutes a link between signal transduction cascades and the reorganization of the actin cytoskeleton. Phosphoinositides may also bind microtubule associated proteins, since previous studies show that PI dissociates the microtubule associated protein MAP2 from microtubules and interferes with MAP2 cross-linking of actin. We used EM, fluorescent labelling, and dynamic light scattering to show that PIP2 directly binds to recombinant human tau purified from Sf9 cells through an interaction that is not solely electrostatic. Binding of PIP2 to tau alters the chemical reactivity of the single cysteine in three repeat tau and changes the fluorescence of labels attached at that site, suggesting that this residue is involved in PIP2 binding or that the PIP2 interaction alters the structure of this region of tau. Interestingly, tau-PIP2 mixtures exposed to calcium form filaments that contain both tau and PIP2, although the relationship of these filaments to PHF is unclear. Tau's binding to phospholipids may mediate its association with the plasma membrane in transfected cells (Brandt et al., JBC 131: 1327, 1995). Supported by NIH grants to KSK and PAJ.

RETROVIRAL-MEDIATED EXPRESSION OF GPI-ANCHORED HUMAN PLACENTAL ALKALINE PHOSPHATASE IN CEREBELLAR GRANULE NEURONS IN VITRO. K.M. Kollins*, S.K. Powell, and R.J. Rivas. Dept. of Zoology, Univ. of Maryland, College Park, MD 20742.

The glycosyl phosphatidylinositol (GPI) lipid anchor, which acts as an apical targeting signal in polarized epithelial cells, has been hypothesized to act as an axonal targeting signal in neuronal cells (Dotti et al., 1991. *Nature* 349: 158-161). In order to determine whether exogenous GPI-anchored proteins are targeted to the axonal domain in primary neurons, the GPI-anchored protein human placental alkaline phosphatase (PLAP) was introduced into mouse cerebellar granule neurons in vitro using the murine-specific, replication-defective retroviral vector, MFG-PLAP. Purified P4-P6 granule cells were infected with a MFG-PLAP retroviral stock obtained through the transfection of the BOSC-23 packaging cell line, and were cultured as cellular re-aggregates on an untreated glass substratum to stimulate granule cell precursor proliferation. To more easily visualize PLAP localization in single granule cells, re-aggregates were dissociated with papain 24 h after infection, and plated as monolayers on poly-lysine coated microwells to induce neurite formation. At 4 days post-dissociation (DPD), neurons were fixed and stained for alkaline phosphatase expression using a chromagen reaction (BCIP/NBT); a 65°C pre-incubation effectively inhibited endogenous alkaline phosphatase activity and allowed for specific PLAP visualization. At 4 DPD, PLAP expression was observed on approximately 20% of the dissociated neurons. PLAP expression was equally vigorous on both the cell bodies and neurites of infected cells as evidenced by the staining of thin unipolar neurites that resembled granule cell axons (average length=442 μm; n=44), and short, thick multipolar neurites that resembled dendrites. These studies suggest the PLAP may be non-polarized in cerebellar granule cells at 4 DPD. Current immunocytochemical studies using monoclonal antibodies against PLAP are directed towards characterizing PLAP targeting and localization as a function of neuronal differentiation. Supported by American Paralysis Association grant RB1-9501.

EXPRESSION OF LAMPREY NEUROFILAMENT IN NON-NEURONAL CELLS. G. Zhang, G. Hall, A. J. Jacobs and M.E. Selzer* Department of Neurology, University of Pennsylvania Medical Center, Philadelphia, PA 1910

The growth cones of regenerating lamprey axons lack filopodia and lamellipodia and are densely packed with neurofilaments (NFs). This suggests that regeneration in lamprey axons might be mediated by transport of NFs into the growth cone. In order to test this hypothesis it will be necessary to manipulate the expression of NF in axotomized neurons. As a first step, we have cloned the lamprey NF subunit (NF180) into a plasmid expression vector and expressed it in an immortal fibroblast cell line . Previous work in our laboratory has suggested that the NFs of lamprey are homopolymers of this peptide, as opposed to the three subunit heteropolymers of mammalian NFs. A full length NF180 cDNA was created from two plasmids (pBluescript), LIF22 and LIF13, which were screened from a lambda-gt11 library constructed from the brains of larval wild-type *Petromyzon marinus* lampreys. LIF22 contains the ATG translation start codon (nucleotide 122). LIF13 overlaps with the 3' end of LIF22 and contains the TGA stop codon at nucleotide 3452. The full length NF180 cDNA was subcloned into a eukaryotic expression vector driven by the CMV promoter (pRC/CMV) at HindIII/XbaI sites and transfected into NIH 3T3 cells by the DNA-calcium phosphate coprecipitation technique. The transfected cells were examined by immunostaining with several NF180-specific mAbs. NF180 positive cells were heavily stained by phosphate-independent antibodies binding to either the core or tail, but poorly stained by phosphorylation-dependent antibodies. The expressed protein was evenly distributed in the cytoplasm and processes of the cells. By *in situ* hybridization, NF180 message was found mostly in the perinuclear cytoplasm. Western immunoblotting of transfected cell homogenates with NF180-specific mAbs revealed an appropriate band that migrated at 180 kDa. EM studies are under way to determine whether NF180 self-assembles into filaments. A previous study suggested that transfecting 3T3 cells with human *tau* resulted in elongation of cell processes. Preliminary morphometric analysis of NF180-transfected cells suggested that the lengths of their processes were not different from those of controls. Supported by NIH grant NS14837.

REDUCTION OF NEUROFILAMENT LIGHT SUBUNIT ALTERS THE DISTRIBUTION AND AMOUNT OF F-ACTIN IN DOPAMINERGIC NEURONS. R. Hao, V. Kalabokis, LS. Fu, P. L. Iversen, M. Ebadi and R. F. Pfeiffer*. Depts. of Neurology, Univ. of Tennessee Col. of Med. Memphis, TN 38163, Pharmacology, Univ. of Nebraska Col. of Med., Omaha, NE 68198, and Biology, Brandeis Univ., Wultham, MA 02254.

In previous studies, we have found that neurofilament, especially NF-L, and G-actin form direct physical interactions in vitro. In order to determine if the interaction between NF-L and actin plays any functional role in neurons, we examined the effect of NF-L on the polymerization of actin using purified NF-L and brain actin. The Kd of NF-L for G-actin was determined as 6 μM and the critical concentration was 0.4 μM. NF-L also decreased the initiation of polymerization of actin. The effects of NF-L on the regulation of the polymerization of actin in neurons may depend on the level of actin available for polymerization, the affinity of NF-L for actin, the ratio of NF-L to G-actin. To examine whether changes in the ratio of NF-L:G-actin affects the polymerization of actin in DA neurons, we reduced the expression of NF-L in rat mesencephalic culture by using antisense oligodeoxynucleotide (ODN). After 48 h incubation with 30 μM antisense NF-L ODN, the DA neurons displayed prominent morphological changes. In addition, the amount of F-actin increased significantly compared to that in the untreated control culture. The high affinity DA uptake was reduced by approximately 79% compared to the untreated culture. The effect of antisense NF-L ODN on DA uptake was dose dependent. Our results suggest that interaction between NF-L and G-actin may play a prominent role in the regulation of the polymerization of actin in early developmental stages of DA neurons.

INCREASED RATIO OF NEUROFILAMENT (NF) SUBUNITS NF-H AND NF-M TO NF-L SEVERELY ALTERS CYTOSKELETON AND NEARLY ELIMINATES DENDRITES IN MOTOR NEURONS. J.-M. Kong and Z.-S. Xu*. Worcester Foundation for Biomedical Research, Shrewsbury, MA 01545

Motor neurons are one of the largest polarized cells in vertebrates. They possess one of the most extensive dendritic arborization at one end and the longest axons at the other end. Ample evidence has indicated that neuronal cytoskeletal components, particularly microtubule and actin, are indispensable for the development of normal neuronal architecture. As one of the major constituents of neuronal cytoskeleton, NFs are known to promote radial axonal growth. Whether they also play a role in the development of normal dendritic arborization is not clear. Here we show that over-expression (by 2 folds) of either NF-H or NF-M reduces dendritic arborization by 60% and 30%, respectively. Although over-expression of NF-L alone does not affect dendritic arborization, when its level is elevated simultaneously with either NF-H or NF-M, it reverses the reduction of dendritic arborization. Over-expression of both NF-H and NF-M almost eliminated dendritic arborization (reduced by 90%). By immunofluorescence, we show that increasing both NF-H and NF-M leads to NF aggregation, a segregation of NF network from microtubule (MT) network and a depletion of NFs from dendrites. Increasing NF-L, however, leads to mingling of the NF and MT networks, and transport of NFs into dendrites. Thus, accumulation of NF-H and NF-M dissociates NFs from MTs and blocks transport of NFs into dendrites, leading to dendritic attrition. These changes are highly reminiscent of motor neuron pathology in amyotrophic lateral sclerosis (ALS), suggesting that alteration in NF subunit composition may occur in ALS.

A NEW ROLE FOR DYNEIN AND DYNACTIN IN SLOW AXONAL TRANSPORT? J.F. Dillman III, L.P. Dabney, S. Karki[1], E.L.F Holzbaur[1], B.M. Paschal[2], and K.K. Pfister*, Dept of Cell Biol, Univ. of Virginia School of Medicine, Charlottesville, VA 22908, [1]Univ of Penn School of Veterinary Medicine, Philadelphia, PA, [2]Dept of Cell Biol, Scripps Research Inst, La Jolla CA.

Materials are moved from the cell body to the synapse via fast and slow axonal transport. The mechanisms of fast axonal transport, the anterograde and retrograde movements of membranous organelles by kinesin and cytoplasmic dynein, are known. However, little is known about the mechanism of movement of microtubules (MTs) and neurofilaments in slow component a (SCa), and of microfilaments (MFs) and other proteins in slow component b (SCb). It has been proposed that MTs move in slow transport by sliding. Dynein is an obvious candidate to generate MT-sliding in the axon, based on its polarity of force generation and evidence that other members of the dynein family slide MTs in flagella. To test this, we determined the axonal transport profile of dynein. We found that the bulk of the dynein is associated with slow axonal transport. Segmental analysis revealed that this dynein is associated not with the slower moving MTs of SCa, but with faster moving SCb. Furthermore, this pool of SCb dynein binds MTs in an ATP-sensitive manner *in vitro*. This suggests a model in which dynein associated with SCb transiently interacts with MTs to slide them down the axon at the slower rate of SCa. Our data predict that dynein is somehow linked to the SCb complex of proteins. We postulate that dynactin cross-links dynein to the SCb complex of proteins. Dynactin binds dynein *in vitro*, and contains a filament subunit composed of actin-related protein (Arp) and actin which could be involved in cross-linking dynactin to the actin MFs in SCb. To test whether dynactin is properly positioned to function as a cross-linker in this context, we compared the axonal transport profiles of dynactin and dynein. We have found that the bulk of dynactin is also associated with SCb of axonal transport. Thus, dynactin is properly positioned to cross-link dynein to the SCb transport complex. We are currently investigating the functional properties of SCb dynein and dynactin to determine if they are consistent with our model. (Supported by a grant to KKP from NINDS).

MITOCHONDRIAL TRANSPORT IN DENDRITES: MOVING AND STATIONARY SUB-POPULATIONS IN HIPPOCAMPAL NEURONS IN CULTURE. L.A. Ligon, G.A. Banker, and O. Steward* Department of Neuroscience and the Neuroscience Graduate Program, University of Virginia Health Sciences Center, Charlottesville, VA 22908.

Mitochondria are densely distributed throughout axons and dendrites, but little is known about the mechanisms that regulate their movement or their steady-state distribution. To begin to address this issue, we have developed an approach to track mitochondrial movements in living hippocampal neurons maintained in culture. Mitochondria within hippocampal neurons that had been grown in culture for 14-17 days were labeled with a fluorescent dye that is sequestered in mitochondria (MitoTracker®). Mitochondrial movements were then assessed using time-lapse fluorescence microscopy. The present study focuses on mitochondria within dendrites. Labeled mitochondria were found to move bidirectionally within dendrites at a mean rate of about 0.8 μm/second, and peak rates of up to 4 μm/second. Quantitative analyses revealed that over a 1 minute analysis interval, 30-40% of the labeled mitochondria exhibited movement while 60-70% remained stationary. Over a 60 minute analysis interval, the proportion of mitochondria exhibiting some movement increased to 60-70% while the remainder remained stationary throughout. These results suggest that one regulatory mechanism may be control of the transitions between the stationary and moving states. It is possible that the stationary mitochondria in dendrites are positioned near postsynapstic sites. To evaluate this question, we compared the distribution of stationary mitochondria with the distribution of synapses (as revealed by immunocytochemistry for synapsin1). Quantitative analyses revealed no obvious relationship between the positioning of stationary mitochondria and the distribution of synapses along the dendrites. These results document the feasibility of an approach to evaluate the mechanisms of mitochondrial movement within neurons and the factors that control their steady-state distribution. CHAPSYN-110, A NOVEL ION CHANNEL CLUSTERING PROTEIN OF THE PSD-95 FAMILY: DIFFERENTIAL ACTIVITY, LOCALIZATION AND HETEROMULTIMERIZATION. E. Kim*, K.-O. Cho[1], A. Rothschild and M. Sheng, Howard Hughes Medical Institute and Dept. of Neurobiology, Mass General Hospital and Harvard Medical School, Boston, MA 02114; [1]Dept. of Cell Biology, Baylor College of Medicine, Houston, TX 77030.

Members of the PSD-95 family of synaptic proteins interact with NMDA receptors and Shaker-type voltage-gated K^+ channels. The interaction occurs between the cytoplasmic C-terminal tail of channels and the PDZ domains of PSD-95 family members. Coexpression of Shaker-type K^+ channels with PSD-95 in heterologous cells induces formation of clusters in which both proteins are colocalized, suggesting PSD-95 can anchor and concentrate channels at synaptic sites. We have recently isolated a novel third member of the family, named chapsyn-110. To understand reasons for multiplicity of these proteins, we have compared their channel clustering behavior, cellular expression pattern, subcellular localization and heteromultimerization. Chapsyn-110 and PSD-95 form discrete surface clusters when coexpressed with K^+ channels in heterologous cells whereas SAP97 forms cytoplasmic clusters. All three proteins show distinct, but not mutually exclusive, distributions in the rat brain. At the subcellular level, Chapsyn-110 shows a somatodendritic expression pattern in contrast to SAP97 and PSD-95 which show axonal, and mixed presynaptic and somatodendritic distribution respectively. Chapsyn-110 proteins, like PSD-95, are tightly associated with postsynaptic density and most interestingly form heteromultimers with PSD-95 but not with SAP97. Heteromultimers of Chapsyn-110 and PSD-95 may function as a molecular scaffold to recruit a wide range of membrane proteins and signaling molecules at the postsynaptic site.

GENETIC INTERACTIONS AMONG DIVERSE MEMBERS OF THE KINESIN MOTORS IN THE NERVOUS SYSTEM OF C. ELEGANS. Z. K. Siddiqui, M. Y. Ali, M. L. A. Khan, M. A. Shakir, and S.S. Siddiqui*. Laboratory of Molecular Biology, Dept. of Ecological Engineering. Toyohashi University of Technology. Toyohashi 441, Japan.

Members of the kinesin motor family are microtuble based ATPase proteins involved in the transport of diverse cellular cargo. To study the role of different kinesins in neural development, we have identified 15 kinesins in *Caenorhabditis elegans*, in collaboration with the genome and cDNA sequencing projects. In particular, homologs of the mouse KIF4, yeast KIP2, human mitotic KLP, and squid KLC and KRP 115 have been identified and mapped on six linkage groups. In addition, three genetic loci *osm-3*, *unc-104*, and *unc-116* have been previously characterized at the molecular and cellular levels; mutants in these genes are affected in chemosensory, motor; and in touch receptor and motor neurons, respectively. An *osm-3 ::lacZ* fusion gene (Tabish et al., 1995) has been used to generate transgenic animals in different genetic background of the neural mutants. Our results suggest that multiple kinesin proteins are required in a cell specific way, during embryonic and postembryonic neural development. Supported by the Ministry of Education, Science and Culture, Human Genome Project, Okawa Foundation,and the NEC Corpn. Japan.

TRANSLATION INHIBITION DOES NOT INTERFERE WITH THE MIGRATION OF ARC mRNA INTO DENDRITES C.S.Wallace[1*], G.L. Lyford[2], P.F. Worley[2,3], O. Steward[1]. Dept of Neurosci.[1], Univ. of VA, Charlottesville, VA 22908, Dept of Neurosci.[2], and Neurology[3], Johns Hopkins Univ. School of Medicine, Baltimore, MD, 21205

Arc is is an immediate early gene (IEG) that encodes a cytoskeleton-associated protein (Lyford et al., 1995, Neuron, **14**:433-445;known also as arg3.1 ; Link et al., 1995, PNAS, **92**:5734-5738). The mRNA for *Arc* is one of the few mRNAs that comes to be localized in dendrites. After induction by intense neuronal activity (for example, an electroconvulsive seizure (ECS) or long-term potentiation (LTP)), the Arc transcript migrates rapidly into the dendrites of granule cells of the dentate gyrus, extending throughout the molecular layer within hours. The present study evaluates whether the mRNA is targeted to dendrites by a signal in the nascent peptide or by a signal in the mRNA . If targeting were based on the nascent peptide, dendritic translocation of *Arc* mRNA should be disrupted by inhibiting protein synthesis. Rats received cycloheximide (CHX; 20 or 50 mg/kg, IP) 15 minutes prior to a stimulus that induces Arc (ECS). Control animals received ECS alone. *Arc* mRNA migrated into dendrites of dentate granule cells in both CHX/ECS and ECS only rats. The mRNA for another IEG (NGFI-A) was superinduced by CHX/ECS relative to ECS, but remained in the cell body. These results suggest that newly-synthesized Arc mRNA is targeted for dendritic transport by a signal in the mRNA itself.

THE N-TERMINUS OF SCG10 DETERMINES ITS TARGETING TO MEMBRANES AND TO THE GOLGI COMPLEX REGION. G. Di Paolo*, R.J. Lütjens, S.A. Stimpson, A. Osen-Sand, S. Catsicas, and G. Grenningloh. GLAXO IMB, 14 ch. des Aulx, 1228 Plan-les-Ouates/Geneva, Switzerland.

SCG10 is a neuron-specific, growth-associated protein which is related to the ubiquitous phosphoprotein stathmin. Whereas stathmin is localized to the cytosol, SCG10 is membrane-associated. Previous studies have suggested a role for stathmin in intracellular signalling for proliferation and differentiation of various cell types. Recently it has been described as a protein interacting with tubulin dimers and increasing the catastrophe rate of microtubules. The specific function of SCG10 is unknown, but since many structural features are shared between the two proteins, SCG10 might perform a similar function in neurons. Although stathmin and SCG10 share 74% amino acid identity, they differ in their N-terminal region. SCG10 has an extension of 34 amino acids containing a stretch of 12 hydrophobic amino acids including cysteines 22 and 24 which are potential sites for palmitoylation. In order to analyze the mechanism responsible for the differential subcellular localization of stathmin and SCG10 and to investigate the role of this N-terminal domain, we transfected COS-7 cells with vectors expressing various constructs. We subsequently revealed the localization of the proteins by indirect immunofluorescence. Wild-type stathmin was widely distributed throughout the cytoplasm, whereas SCG10 localized exclusively to the Golgi complex region. A mutant of SCG10 lacking the N-terminus showed the same subcellular localization as stathmin, whereas chimeric proteins in which the N-terminus of SCG10 was fused to stathmin or to the heterologous protein β-galactosidase were targeted to the Golgi. Finally, we demonstrated that SCG10 undergoes palmitoylation in COS-7 cells and that it partly accounts for its membrane binding property. Altogether, these expreriments showed that the amino-terminus of SCG10 is necessary and sufficient for the localization of the protein to the membrane and the Golgi complex region. Palmitoylation in addition to intrinsic structural features lying in the N-terminus sequence are required for its membrane affinity.

PULSE-LABELED TUBULIN IS RETAINED ALONG GROWING AXONS. P.N. Hoffman* Departments of Ophthalmology & Neurology, The Johns Hopkins School of Medicine, Baltimore, MD 21287.

Studies examining the behavior of fluorescent tubulin in the neurons of intact embryos demonstrate the presence of stationary axonal microtubules. In contrast, *in vivo* pulse-labeling studies have emphasized the movement of tubulin in the slow component wave. In these studies, radioactive amino acids (e.g., ^{35}S-methionine) are injected in the immediate vicinity of neuron cell bodies and the distribution of pulse-labeled proteins along axons is analyzed at several post-labeling intervals. The goal of the present study was to determine whether significant amounts of pulse-labeled tubulin are retained along developing axons after passage of the slow component wave. The direct diffusion of radioactive precursor from the injection site results in the local synthesis of labeled tubulin by non-neuronal cells (e.g., Schwann cells) in nerve fibers. In the present study, tubulin was labeled by injecting ^{35}S-methionine into the L5 dorsal root ganglia of 3-week-old rats. The distribution of pulse-labeled tubulin was selectively examined in axons using immunoprecipitation with a monoclonal antibody directed against class III β-tubulin, a neuron-specific isotype that is located in axons but not in non-neuronal components of nerve fibers. The velocity of slow axonal transport is much greater in developing than mature neurons, and the slow component wave has reached the distal portion of the nerve by 7 days after labeling. At both 7 and 14 days after labeling (as well as at later times), significant amounts of pulse-labeled tubulin were retained along sensory axons after passage of the slow component wave. These studies demonstrate that tubulin conveyed by slow axonal transport accumulates along developing axons, presumably contributing to the growth of stationary microtubules.

These studies were supported by grant NS32724 from NIH.

ENDOSOMAL INTERMEDIATES IN THE GENERATION OF SYNAPTIC VESICLES IN VITRO. L. Clift-O'Grady, C. Desnos, P. Lledo* and R.B. Kelly, Dept. of Biochemistry and Biophysics, UCSF, San Francisco, CA 94143-0534

Synaptic vesicle biogenesis can be observed in vitro using homogenates of PC12 cells (Desnos et al., 1995). Homogenates generated from cells labeled in vivo at 15°C with an antibody, [^{125}I]-KT3, to the epitope-tagged variant of a synaptic vesicle protein, VAMP/synaptobrevin, are free of labeled synaptic vesicles. When these homogenates are incubated with ATP and brain cytosol at 37°C, newly synthesized, labeled synaptic vesicles form. When the homogenates are analyzed prior to incubation, labeled membranes are found in sucrose gradient peaks with the density of plasma membrane or of endosomes. Removal of plasma membranes from the homogenate did not remove the capacity to generate synaptic vesicles in vitro; removal of endosomal membranes destroyed that capacity. Appearance of label in synaptic vesicles correlated with loss of label from the endosomes, consistent with a precursor-product relationship. Incubation of the donor membranes in the presence of GTPγS inhibited synaptic vesicle formation but, generated denser organelles that may be coated intermediates. Endosomes labeled under the same conditions with [^{125}I]-transferrin had a density and size different from endosomes containing the synaptic vesicle marker VAMP. Such endosomes could not generate transferrin-containing vesicles with the size or density of synaptic vesicles.

Funding for this work was provided by NIH.

ANALYSIS OF THE MURINE GEPHYRIN GENE: IDENTIFICATION OF ITS PROMOTOR REGION AND EVOLUTIONARILY CONSERVED DOMAINS

Joachim Kirsch*, Heinrich Betz, and Markus Ramming Dept. of Neurochemistry, Max-Planck-Institute for Brain Research, Deutschordenstr. 46, 60528Frankfurt, Germany

The peripheral membrane protein gephyrin is essential for the postsynaptic localization of the inhibitory glycine receptor and thought to link the receptor complex to the subsynaptic cytoskeleton. Various gephyrin transcripts have been identified in rat brain and non-neuronal tissues that differ by four oligonucleotide cassettes in the 5' coding region. Here, we analyzed genomic clones covering the murine gephyrin gene and its promotor sequences. The coding region is distributed over >200 kb and split into 25 exons. Four of these exons correspond to the alternatively spliced cassettes in the previously identified gephyrin variants. The putative promotor region of the gephyrin gene contains several SP1 consensus sites, which may account for its ubiquitous and strong expression. Reporter gene constructs derived from different fragments of the 5' region upstream of the transcription start site were efficiently expressed in both a fibroblast and a neuronal cell line. The N- and C-terminal regions of gephyrin encoded by exons 3 - 7 and 14 - 25, respectively, are homologous to bacterial, invertebrate and plant proteins involved in the biosynthesis of the molybdenum cofactor, indicating an old phylogenetic origin of the corresponding genomic regions. Exon 12 of the gephyrin gene encodes an amino acid motif, which displays high sequence identity to the microtubule binding domains of MAP2 and tau, and therefore may mediate the high-affinity binding of gephyrin to microtubules. Supported by grants from DFG.

PRESYNAPTIC MECHANISMS IV

779.1

MODULATION OF P-TYPE CALCIUM CURRENTS AT THE CALYX OF HELD BY METABOTROPIC GLUTAMATE RECEPTORS.

I. D. Forsythe*, M. Barnes-Davies, T. Tsujimoto§, K. Onodera§ and T. Takahashi§. Dept. of Cell Physiology and Pharmacology, Univ. Leicester, Leicester, LE1 9HN UK; §Dept. of Neurophysiology, Inst. for Brain Res., Faculty of Medicine, Univ. Tokyo, Tokyo, 113 Japan.

Direct patch-clamp recordings have been achieved from a large mammalian presynaptic terminal called the calyx of Held (Forsythe, J. Physiol. 479, 381, 1994). The synapse is found in the medial nucleus of the trapezoid body and uses glutamate as a transmitter. Using this preparation we have simultaneously measured the presynaptic calcium current and the excitatory postsynatic current in order to examine the mechanism by which presynaptic mGluRs modulate transmitter release.

Transverse slices of the brain stem were prepared from Lister hooded or Wistar rats (8-18 days old). Whole-terminal recordings were made with pipettes containing (in mM): N-methyl-D-glucamine 160 or 130 CsCl, TEA 10, HEPES 40, $MgCl_2$ 1, EGTA 0.5, Na_2Phosphocreatine 12, K_2ATP 2, Na_2GTP 0.5. The presynaptic calcium current (I_{pCa}) was of a high voltage-activated subtype, with a peak inward current at around -20 mV and a reversal potential around +50 mV. Both the EPSC and I_{pCa} were completely blocked by agatoxin-IVA, indicating that P-type channels are solely responsible for triggering transmission at this site. Bath application of mGluR agonists, 1S3S aminocyclopentane-dicarboxylate or L-2 amino 4-phosphono -butyrate (L-AP4) depressed I_{pCa}. In simultaneous recordings from the terminal and its post-synaptic target, the depression of the EPSC paralleled that of I_{pCa}. Double logarithmic plots of EPSC amplitude versus I_{pCa} during application of L-AP4 or changes in $[Ca^{2+}]_0$ had similar slopes, fitted by a power function of around 2. We conclude that mGluR agonists can inhibit transmitter release by modulation of presynaptic voltage-dependent P-type calcium channels.

KAPPA-OPIOIDS MODULATE SECRETION VIA INHIBITION OF N-, L- AND P/Q-TYPE Ca^{++} CURRENTS IN RAT NEUROENDOCRINE NERVE TERMINALS.

K.I.Rusin*, D.R.Giovannucci, E.L.Stuenkel and H.C.Moises. Dept. of Physiology, University of Michigan, Ann Arbor, MI 48109-0622.

Whole cell patch-clamp recordings and time-resolved membrane capacitance measurements (C_m) were obtained from nerve terminals acutely dissociated from neurohypophysis of adult rats to investigate modulation of Ca^{++} currents and secretion by activation of opioid receptors. Three components of high-threshold current were distinguished on the basis of their sensitivity to blockade by ω-CgTxGVIA, nicardipine and ω-CTxMVIIC. Bath superfusion of the κ-opioid selective agonist U69,593 (0.3-1 μM) reversibly suppressed the peak amplitude of Ca^{++} currents by 36.3 ± 6.0% (18 of 26 terminals), and this was associated with concomitant reductions in the slow phase of C_m increases to step depolarizations (n=11). By contrast, currents and C_m responses were unaffected by the μ-opioid agonist DAGO (1-3 μM, n=7) or the δ-agonist DPDPE (1 μM, n=4). The inhibitory effect of U69,593 was reduced by ω-CgTxGVIA (0.5 μM) in 8 of 10 terminals, and in 4 of these administration of nicardipine (10 μM) eliminated the opioid-sensitive current that remained after blockade of N-type channels. A small ω-CgTxGVIA/ nicardipine-resistant component of opioid-sensitive current was observed in 2 additional terminals, and this was blocked by ω-CTxMVIIC (1 μM). Opioid effects on C_m responses were attenuated after selective blockade of N-, L- or P/Q-type current components, suggesting that κ-opioid inhibition of neurosecretion from neurohypophysial nerve endings is mediated at least in part by reduction in voltage-dependent Ca^{++} influx through these Ca^{++} channel types. 779.3

THE INVOLVEMENT OF KAPPA OPIOID RECEPTORS IN THE RELEASE OF OXYTOCIN FROM SPINAL CORD SYNAPTOSOMES

M. Schneider*, I. Wong, and J. Haldar Dept. of Biological Sciences, St. John's University, Jamaica, NY 11439.

Recent results from our laboratory suggest that N-type calcium channels are present in spinal cord synaptosomes and are involved in KCl-induced oxytocin (OT) release in vitro(1). Previously we have demonstrated that OT release from spinal cord synaptosomes is regulated by opioid peptides(2). Since it is known that kappa (κ) opioid receptors are linked to voltage dependent calcium channels, our current experiments were designed to determine if opioid induced inhibition of spinal cord OT release involves κ receptors. For our present experiments, synaptosomes were prepared from the spinal cord of the rat. Following homogenization in 320mM sucrose containing 5mM HEPES, tissue was centrifuged at 600g, and then at 3,100g (x 3), followed by a centrifugation at 12,000g. Pellets obtained by this centrifugation process were used for all experiments. Synaptosomes were treated by incubating in either a control solution (mM): NaCl 154, KCl 5.6, $MgCl_2$ 1, HEPES 10, glucose 10, and BSA 0.025%, or test solution, (mM) NaCl 103.6, KCl 56, $CaCl_2$ 2.2, $MgCl_2$ 1, HEPES 10, glucose 10, and BSA 0.025%. Following incubation in the control solution, synaptosomes were preincubated with either the specific κ receptor antagonist nor-Binaltorphimine (nor-BNI), or agonist U-50488, or with nor-BNI followed by U-50488 prior to the application of a 56mM depolarizing stimulus. Our results demonstrate that pretreatment of spinal cord synaptosomes with the κ opioid receptor agonist U-50488 prior to a 56mM KCl stimulus causes inhibition of OT release which can be reversed by first incubating the tissue with the specific κ receptor antagonist nor-BNI. In conclusion, κ opioid receptors are present in spinal cord synaptosomes and are involved in OT release in vitro. GABA-DEPENDENT GENERATION OF ECTOPIC ACTION POTENTIALS IN THE RAT HIPPOCAMPUS.

H. Kawasaki, M. Methot, V. Tancredi* and M. Avoli. Montreal Neurological Institute and Dept. of Neurology and Neurosurgery, McGill University, Montreal, Quebec, H3A 2B4, Canada

Rat CA3 pyramidal neurons were recorded intracellularly with K-acetate-filled microelectrodes during application of 4-aminopyridine (4AP, 50μM) and ionotropic excitatory amino acid antagonists in a hippocampal slice preparation. Under these experimental conditions spontaneous, synchronous GABA-mediated potentials occurred; they were associated with an intracellular sequence of early hyperpolarization, long-lasting depolarization (LLD) and late hyperpolarization. Action potentials of variable amplitude were seen at the peak of the early hyperpolarization and during the LLD rising phase; the occurrence of these action potentials was not prevented by membrane hyperpolarization. Application of 4AP to medium containing excitatory amino acid antagonists revealed that the action potentials of variable amplitude occurred only after appearance of the LLD. These action potentials were still recorded in the presence of the $GABA_B$ receptor antagonist CGP-35348 (0.5-1mM), but were reduced by the $GABA_A$ receptor antagonist bicuculline methiodide (BMI, 10μM). Localized application of BMI (50μM) or tetrodotoxin (TTX, 1μM) to the CA1 stratum radiatum blocked the action potentials of variable amplitude. These effects were not observed when BMI or TTX were applied locally to the CA3 stratum radiatum, although both drugs made LLDs disappear. Our findings indicate that the action potentials of variable amplitude recorded in CA3 pyramidal neurons during 4AP application are generated at or near the terminal region of the Schaffer collaterals and thus they represent TTX-sensitive ectopic action potentials that are caused by the occurrence at this site of a bicuculline-sensitive (and thus $GABA_A$-mediated) mechanism. MUSCARINIC AUTORECEPTORS MODULATE ACETYLCHOLINE (ACh) RELEASE IN CAT MEDIAL PONTINE RETICULAR FORMATION (mPRF). M.T. Roth*, M.A. Fleegal, R. Lydic, and H.A. Baghdoyan. Department of Anesthesia, The Pennsylvania State University, College of Medicine, Hershey, PA 17033.

Postsynaptic muscarinic receptors (mAChRs) are presumed to exist in the mPRF since microinjection of muscarinic agonists causes a REM sleep-like state which is blocked by muscarinic antagonists (*Neuropsychopharmacology 2:67 1989*). Presynaptic mAChRs have been shown to be present in rat striatum (*J. Pharmacol. Exp. Ther. 273:273, 1995*), hippocampus, and medial septal area (*Eur. J. Pharm. 294:155, 1995*), and the present study is testing the hypothesis that presynaptic muscarinic autoreceptors modulate ACh release in the mPRF. Cats (N=5) were anesthetized with halothane, and recordings were made of end-tidal carbon dioxide and halothane concentrations, oxygen saturation, blood pressure, temperature, EEG, EMG, and EOG. A microdialysis probe was placed in the mPRF and perfused with Ringer's solution until stable levels of ACh were demonstrated. The mAChR antagonist, scopolamine (6 concentrations ranging from 0.1 nM to 100 nM), then was administered by dialysis for 90 min. Samples were collected every 10 min and injected into an HPLC system for analysis of ACh. Mean ACh release during Ringer's dialysis (control) was 0.28 ± 0.07 pmol/10 min (n = 10 samples). The lowest concentration of scopolamine to cause a significant increase in ACh release (0.39 ± 0.07 pmol/10 min, n = 18) was 0.3 nM. There was a dose-dependent increase in ACh release with increasing scopolamine concentrations ($F = 15.5$; d.f. = 6, 186; $p<0.01$) suggesting that as more autoreceptors were blocked, more ACh was released. To the best of our knowledge, these are the first microdialysis data demonstrating that muscarinic autoreceptors are present in the mPRF of cat.

THE EFFECT OF CHRONIC CLONIDINE TREATMENT ON TRANSMITTER RELEASE FROM SYMPATHETIC VARICOSITIES OF THE MOUSE VAS DEFERENS. J. J. Morgan[a], R. Einstein[b], M. J. Christie[b]* and N. A. Lavidis[a], [a]Narcotics Research Laboratory, The Institute for Biomedical Research and [b]Department of Pharmacology, University of Sydney, N.S.W., Australia, 2006.

α_2-adrenoceptor agonist (clonidine) and opiate agonist (morphine) decrease evoked transmitter release from sympathetic varicosities of the mouse vas deferens. The decrease in release is achieved without any noticeable change in the shape of the nerve terminal impulse (NTI). The inhibitory effect of morphine on transmitter release is reduced during chronic morphine treatment (CMT) of animals. Furthermore acute morphine withdrawal from CMT induces an enhancement of transmitter release. In this study we examined the effect of chronically clonidine treating animals on transmitter release efficacy.

Mice were treated twice per day with clonidine (1 - 5 mg/kg) for between 3 and 9 days. Vasa deferentia were isolated and treated with $DiOC_2$ (0.1μM) and fluoresced to visualise the sympathetic varicosities. Microelectrodes with tip diameters of 10 to 20 μm were placed over 3 to 5 varicosities to record the NTIs, spontaneous excitatory junctional currents (SEJCs) and excitatory junctional currents (EJCs). In most (11/14) control (untreated) preparations bath applied clonidine (1μM) completely abolished EJCs but did not affect SEJC frequency. For the remaining 3 preparations the EJCs were greatly reduced. In chronically clonidine treated (CCT) preparations bath applied clonidine (1μM) did not abolish EJCs when the preparations were from animals CCT for more than 7 days. In CCT preparations acute withdrawal of clonidine from the bathing solution induced a significant ($P < 0.05$) increase in EJCs and SEJC frequency.

The present results indicate that CCT induces an increase in the efficacy of neurotransmission. This observation and previously reported chronic morphine effects on neurotransmission from the same preparation indicate that chronic administration of agents which have presynaptic inhibitory effects on neurotransmitter release triggers an increase in the efficacy of neurotransmission.

PRESYNAPTIC ACTIONS OF BACLOFEN IN THE DORSAL HORN OF THE NEONATAL RAT SPINAL CORD. Y. Hori*, K. Kanda and N. Hirai. Dept. of Physiol., Dokkyo Univ. Sch. of Med., Mibu, Tochigi 321-02, JAPAN

Whole-cell recordings were made from dorsal horn neurons in neonatal rat spinal cord slices. Excitatory postsynaptic currents (EPSCs) evoked by electrical stimulation were reversibly inhibited by bath application of a GABAB agonist, baclofen (1-10 μM). Baclofen also suppressed the frequency of miniature EPSCs recorded in the presence of tetrodotoxin without affecting the distribution of their amplitude suggesting the presynaptic actions of baclofen.

Primary afferent fibers were stained with calcium indicator fluo-3. Using a confocal laser scanning microscopy, individual primary afferent fibers were visualized in the dorsal horn of neonatal rat spinal cord slices. Electrical stimulation elicited an abrupt change in fluo-3 fluorescence measured in a single enlargement of fibers (e.g., a presumed presynaptic terminal). This fluorescent transient was reversibly attenuated by baclofen.

The amplitude of EPSCs was markedly inhibited by ω-agatoxin VIA and inhibited to a lesser extent by ω-conotoxin GVIA. In the presence of either toxin, the remaining EPSCs were further inhibited by baclofen. Application of both toxins markedly inhibited EPSCs and baclofen exerted no significant effects on the remaining EPSCs. In addition, barium did not alter the inhibitory effects of baclofen.

These observations suggest the possibility that the presynaptic action of baclofen is mediated via modulation of both P- and N-type calcium channels. (Supported by funds from Kyorin University School of Medicine and Tokyo Metropolitan Institute of Gerontology)

MODULATION OF GABAERGIC SYNAPTIC TRANSMISSION BY ADENOSINE A1 RECEPTORS IN RAT SUBSTANTIA NIGRA PARS RETICULATA NEURONS IN VITRO. K.-Z. Shen* and S. W. Johnson. Department of Physiology and Pharmacology, Oregon Health Sciences University, Portland, OR 97201.

Whole-cell patch clamp recordings were made from the substantia nigra pars reticulata (SNr) neurons in the rat midbrain horizontal slices. The inhibitory postsynaptic current (IPSC) mediated by $GABA_A$ receptors was evoked by stimulation of the slice in the presence of APV (50 μM) and CNQX (10 μM). Adenosine produced a reversible and dose-dependent depression of the peak IPSC amplitude with an IC_{50} value of 108 ± 17 μM. Adenosine failed to inhibit the transient outward current evoked by pressure-ejection of GABA, suggesting that adenosine acts presynaptically to reduce GABA release from nerve terminals. The depressant action of adenosine was mimicked by the A_1 receptor agonists with the rank-order potency as: CPA > CHA > RPIA > NECA > CADO. The selective A_{2A} agonist CGS 21680 (3 μM) had no effect on the $GABA_A$ IPSCs. The selective A_1 receptor antagonist DPCPX competitively blocked this presynaptic inhibitory effect of adenosine and CPA. The K_D value of DPCPX was 9 nM. None of the adenosine agonists and antagonists caused any discernable postsynaptic effect. These results indicate that endogenous adenosine in the SNr inhibits $GABA_A$ receptor mediated synaptic transmission by acting at a presynaptic A_1 receptor. (Supported by PHS grant MH 40416.)

NEUROPEPTIDE Y INHIBITS PRESYNAPTIC Ca INFLUX AT THE CA3-CA1 SYNAPSE OF RAT HIPPOCAMPUS. J. Qian*, W.F. Colmers and P. Saggau, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030

Presynaptic voltage-dependent calcium channels (VDCCs) play an important role in controlling neurotransmitter release. Various neurotransmitters and neuropeptides presynaptically modulate synaptic transmission. In the present study, the calcium indicator Fura-2 was used to investigate presynaptic modulation of VDCCs by Neuropeptide Y (NPY) receptors at the CA3-CA1 synapse of rat hippocampal slices. Stimulation-evoked presynaptic calcium transients ($[Ca_{pre}]_t$) and field excitatory postsynaptic potentials (fEPSPs) were simultaneously measured. The relationship between presynaptic calcium influx and synaptic transmission was investigated.

Application of 1μM $hPYY_{3-36}$ (PYY), an active C-terminal fragment of human PYY and a potent agonist of NPY Y_2 receptors, inhibited $[Ca_{pre}]_t$ by 20%. This resulted in reducing synaptic transmission by about 60% which reflects an about 4th power relationship between $[Ca_{pre}]_t$ and transmitter release (Wu & Saggau, 1994). Of the total amount of inhibition of $[Ca_{pre}]_t$ (20%), about 5% was contributed by N-type Ca channels and 5% by P/Q-type Ca channels; the remaining 10% was due to the inhibition of unidentified VDCCs which are resistant to both ω-CgTx GVIA and ω-Aga IVA. At this synapse, about 20% of $[Ca_{pre}]_t$ was ω-CgTx GVIA-sensitive, while 33% was ω-Aga IVA-sensitive, resulting in a relative percentage inhibition of 25%, 15% and 21% for N-, P/Q- and unidentified VDCCs, respectively.

Previous experiments with other neuromodulators, including adenosine (Wu & Saggau, 1994), baclofen (Wu & Saggau, 1995) and muscarine (Qian & Saggau, *submitted*) revealed differential inhibition of presynaptic VDCCs. The pattern of inhibition of VDCCs caused by these modulators was quite similar, i.e., sparing ω-Aga IVA-sensitive Ca channels, but distinct from the pattern of inhibition observed with application of PYY. The possible involvement of potassium channels in presynaptic inhibition by activation of Y_2 receptors is currently under investigation.

Adenosine A_1 Receptors Presynaptically Inhibit Muscarinic Cholinergic EPSPs in the Rat Hippocampus. R.A. Morton and C.H. Davies. (SPON: Brain Research Association) Department of Pharmacology, University of Edinburgh, 1 George Square, Edinburgh, EH8 9JZ, UK.

Stimulation of septo-hippocampal cholinergic fibers in *stratum oriens* produces a slow muscarinic cholinergic excitatory post-synaptic potential (EPSP) in CA1 pyramidal neurones of the rat hippocampus. This pathway is believed to be particularly important in learning and memory in the vertebrate central nervous system. As such, mechanisms that control this synaptic input are of particular interest. In this respect, we have demonstrated previously that adenosine A_1 receptors inhibit muscarinic EPSPs in CA1 pyramidal neurones (Morton & Davies, *J. Physiol.*, 1996). Here we focus on whether this effect is pre- or post-synaptically mediated.

Extracellular recording from *stratum radiatum* and intracellular current clamp recording from CA1 pyramidal neurones was used to compare known pre- and post-synaptic effects of the adenosine receptor agonist 2-chloroadenosine (CADO) with its effect on muscarinic EPSPs. CADO caused a concentration dependent presynaptic inhibition of field recorded glutamate EPSPs (n=4) with an IC_{50} of 0.6 μM. Postsynaptically, CADO caused a hyperpolarization (up to 15 mV) and a concomitant reduction in input resistance (n=4) with an EC_{50} of 2.7 μM. The IC_{50} for the depressant action of CADO on cholinergic EPSPs was 0.4 μM, which is comparable with the IC_{50} for the presynaptic inhibition of glutamatergic EPSPs. All these effects were reversed by DPCPX (200 nM). In a separate series of experiments, brief bath applications of carbachol caused consistent depolarizations and increases in input resistance. These effects were unaffected by CADO (1 μM; n=4) but were abolished by atropine (1-5 μM; n=3).

These data suggest that CADO exerts its inhibitory effect on muscarinic cholinergic synaptic transmission by inhibiting acetylcholine release via presynaptic adenosine A_1 receptors. (R. Morton is an M.R.C. funded Ph.D. student).

Tubocurarine and nicotine decrease inhibition in hippocampal slices but only tubocurarine induces multiple population spikes.

P.A. Ferchmin* and Vesna A. Eterović. *Center for Molecular and Behavioral Neuroscience, Department of Biochemistry, Universidad Central del Caribe, Bayamón, Puerto Rico 00960.*

Nicotinic transmission is difficult to detect in hippocampus. Therefore, we used nicotinic agonist and antagonist to assess the role of this system on neuronal excitability. Tubocurarine and nicotine induced paired-pulse facilitation in area CA1 when stimulating with an interpulse interval of 20 msec. Tubocurarine, but not nicotine, simultaneously induced robust secondary population spikes in the conditioning and test responses. The estimated EC_{50} for tubocurarine was 30 μM. Bicuculline and tubocurarine had a similar effect, although bicuculline was active at lower concentrations. The three drugs inhibited pharmacologically isolated pIPSPs.

Hexamethonium (5 mM) did not interfere with the effect of nicotine. α-Bungarotoxin at 10 nM and 1 μM induced paired-pulse facilitation. Epibatidine (100 pM and 100 nM) was not very active. We postulate that nicotine and tubocurarine affect a different subpopulation of GABAergic interneurons or synapses by modulating presynaptic nicotinic receptors. It is also possible that the effect of tubocurarine is mediated by non-nicotinic receptors. Supported by NIH-MBRS06SGM50695 and RCMI RRO3O35.

DIFFERENT MECHANISMS OF PRESYNAPTIC INHIBITION VIA α2A AND GABAB RECEPTORS IN RAT CENTRAL AMYGDALA NEURONS.

T. Yamagami[1], M. Yoshimura[1], I. Nose[2], T. Akasu[1]*, H. Higashi[1]
Dept. Physiol.[1] and Psychiat.[2], Kurume Univ. Sch. Medicine, Kurume 830, Japan.

Whole cell patch clamp recordings were made from central amygdala neurons in rat brain slices to study the effects of noradrenaline (NA) and baclofen (Bac) on evoked EPSCs and miniature EPSCs (m-EPSCs). The postsynaptic effects of NA and Bac were prevented by injection of GDP-β-S, Cs, and TEA through the recording electrode. NA (30 μM) and Bac (10 μM) depressed the amplitude of evoked EPSCs by 70-85 %, and these effects were prevented by pre-treatment with pertussis toxin. The NA effect was mimicked by the α2 agonist clonidine, and abolished by the α2 antagonists idazoxan and yohimbine. A β agonist isoproterenol, and the antagonist prazosin, which blocks α1, α2B, and α2C-adrenoceptors, had no significant effect. In the presence of Ba^{2+} (1-2 mM), NA and Bac still reduced the amplitude of evoked EPSCs. Bac decreased the frequency of m-EPSCs, while NA had no significant effect. These observations suggest that although both NA and Bac presynaptically inhibit the release of transmitter through pertussis toxin-sensitive G protein, the primary target of NA and Bac at presynaptic terminals is likely to be different.

779.13

ACTIONS OF Sr^{2+} ON DEPOLARIZATION-INDUCED SUPPRESSION OF GABAergic IPSCs IN THE CA1 REGION OF THE RAT HIPPOCAMPUS *IN VITRO*.

W. Morishita* and B. E. Alger. Department of Physiology, The University of Maryland School of Medicine, Baltimore, MD 21201.

Depolarization-induced suppression of GABAergic inhibition (DSI) is characterized by a transient suppression of spontaneous and or evoked IPSCs following a brief (~ 1 s) depolarization of the postsynaptic membrane potential to 0 mV. In the present investigation, the whole cell voltage-clamp recording technique was used to examine the effects of the divalent cation Sr^{2+} on DSI of evoked IPSCs recorded from CA1 pyramidal cells in the continuous presence of CNQX (20 μM) and APV (50 μM). DSI was induced in media which included 4 mM Ca^{2+} and 4 mM Mg^{2+}. When Ca^{2+} was replaced with an equimolar concentration of Sr^{2+} the amplitude of the evoked IPSC was reduced by ~ 50% (n=7). Moreover, DSI was reduced or abolished by Sr^{2+}. While partial recovery of DSI could be attained by increasing the stimulation intensity, it was reliably produced by increasing the duration of the postsynaptic depolarization. Close examination of the evoked IPSCs revealed that Sr^{2+} induced asynchronous events during the decay phase of the IPSC. These events appeared to be the same amplitude as miniature IPSCs. During DSI the amplitude of the evoked IPSC as well as the frequency of the asynchronous events was markedly reduced.

Taken together, these results indicate that unlike Ca^{2+}, Sr^{2+} is less effective in initiating the DSI process. The data support the conclusion that the depolarization-induced suppression of evoked IPSCs is expressed presynaptically. Supported by NIH grant NS 30219 to B. E. A.

779.14

MUSCARINIC RECEPTOR ACTIVATION OF INTERNEURONS SUSCEPTIBLE TO DEPOLARIZATION-INDUCED SUPPRESSION OF INHIBITION (DSI)

L.A. Martin* and B.E. Alger, Dept. Physiol., Univ. Maryland, Sch. Med., Baltimore, MD 21201.

Depolarization-induced suppression of inhibition (DSI) is the phenomenon observed in hippocampal pyramidal cells and cerebellar Purkinje cells in which depolarization of the postsynaptic cell produces a transient decrease in the $GABA_A$-mediated inhibitory postsynaptic currents (IPSCs) recorded in that cell. DSI of hippocampal spontaneous IPSCs (sIPSCs) is rare under control conditions, yet it occurs readily in the presence of ≥ 1 μM carbachol and is blocked by 1 μM atropine. We recorded sIPSCs from CA1 pyramidal cells in the in vitro slice using the whole cell voltage clamp technique with high Cl^- electrodes. During bath application of 50 μM APV, 10 μM CNQX, and 3 μM carbachol, DSI was produced by a 1 sec depolarizing voltage step from a holding potential of -70 mV to 0 mV. The increase in sIPSCs and DSI that occur in carbachol can be abolished by pirenzepine at doses as low as 100 nM, suggesting that the effects are mediated by m1 receptors.

To determine if the carbachol enhancement of DSI was simply a consequence of its increasing total IPSC activity, we investigated DSI in the presence of 10 μM norepinephrine (NE), 8 mM $[K^+]_o$, or APV/CNQX alone. Modest DSI (approximately 30%) was observed with NE. However, very little DSI was evident in elevated K^+. In some cells, addition of APV and CNQX causes approximately a 3-fold increase in sIPSC activity with negligible effects on DSI. Hence, a generalized increase in sIPSCs is not sufficient for inducing DSI. Rather, carbachol may activate a subset of interneurons that is susceptible to DSI. To test this idea, we evoked IPSCs by stimulating in s. oriens, s. pyramidale or s. radiatum. Stimulation of either the s. oriens or s. radiatum appears to be more effective than s. pyramidale at producing DSI of evoked IPSCs. Supported by NS30219 and NS22010 to B.E.A.

779.15

EFFECTS OF N-ETHYLMALEIMIDE ON RAT HIPPOCAMPAL GABAERGIC SYNAPTIC TRANSMISSION.

S.A.Kirov*, W. Morishita and B.E.Alger, Dept. Physiol. Univ. Maryland Sch. Med., Baltimore, MD 21201.

N-ethylmaleimide (NEM) is a sulfhydryl alkylating agent that blocks pertussis toxin sensitive G-protein-mediated actions and appears to be a useful tool for the electrophysiological study of G-protein-related phenomena in the vertebrate CNS. We have previously reported (Alger, et al., Soc. Neurosci. Abstr. 21, 1093, 1995) that NEM blocks depolarization-induced suppression of inhibition (DSI), i.e. the transient decrease in $GABA_A$ IPSCs that follows the activation of CA1 pyramidal cells with brief trains of action potentials or a voltage step. This result supports the hypothesis of G-protein involvement in DSI, but the site of action of NEM in blocking DSI remains unclear. To address the issue of whether NEM can have presynaptic or postsynaptic effects we examined the amplitude and frequency of miniature IPSCs (mIPSCs) on voltage clamped CA1 pyramidal cells in the presence of tetrodotoxin (500 nM). NEM (300 μM) gradually and significantly ($t(10)=5.7$, $p<0.05$, n=6) increased mIPSC frequency from 4.4±0.8 Hz in control to 33.9±5.1 Hz indicating a presynaptic action of NEM on GABA release. On the other hand the Kolmogorov-Smirnov test reveals a significant difference ($p < 0.005$, n=6) between cumulative amplitude distributions of mIPSC amplitudes, suggesting a change in quantal size. NEM did not alter iontophoretic THIP responses, however. NEM had essentially the same effects on mIPSCs in the absence of external Ca^{2+} (8 mM Mg^{2+} present) even with 100 μM EGTA also present (n=4) indicating its actions on mIPSCs were Ca^{2+}-independent. This work was supported by NS 22010 and NS 30219.

779.16

PRESYNAPTIC INHIBITION OF SYNAPTIC VESICLE DYNAMICS IN CULTURED RAT HIPPOCAMPAL NEURONS.

J. S. Isaacson* and B. Hille, Dept. of Physiol. and Biophys., Univ. of Washington, Seattle, WA 98195.

GABA and adenosine modulate synaptic transmission by inhibitory effects on nerve terminals. Although Ca channels are thought to play an important role in this modulation, activation of presynaptic receptors also depresses the frequency of Ca channel-independent miniature EPSCs. To study the influence of presynaptic receptors on synaptic vesicle recycling, we have used the activity-dependent dye FM1-43.

FM1-43 (10 μM) was loaded into presynaptic terminals of cultured hippocampal neurons during extracellular electrical stimulation (10-20 Hz, 30s). After a further 60s incubation, cells were washed in dye-free solution for >5 min. Fluorescent puncta were studied using cooled-CCD imaging in the presence of $GABA_A$ and glutamate receptor antagonists.

Exocytosis was measured as dye de-staining evoked by field electrical stimulation. De-staining was action potential- and Ca channel-dependent since it was abolished in the presence of TTX (1 μM) or Cd^{2+} (200 μM). The $GABA_B$ agonist baclofen (25-50 μM) or adenosine (100 μM) markedly reduced rates of exocytosis evoked by stimulation at 1-4 Hz but had little effect on release elicited at higher frequencies (10-20 Hz).

The impact of baclofen on endocytosis was also studied. Following a brief tetanus to initiate exocytosis (20 Hz, 5s), dye was applied after a 15s delay. Vesicles endocytosed during the delay will escape labeling, while those retrieved after the delay are labeled. Labeling was determined for terminals loaded in the presence and absence of baclofen during the 15s delay period. Baclofen had no significant effect on the fraction of the vesicle pool labeled .

The lack of effect of neurotransmitters on endocytosis and the frequency-dependent inhibition of exocytosis suggest that late Ca channel-independent steps of exo- and endocytosis may not be the crucial targets for the modulation of nerve-evoked synaptic transmission.

DISTINCT CLASSES OF CALCIUM CHANNELS MEDIATE GABA RELEASE FROM DISCRETE POPULATIONS OF HIPPOCAMPAL INHIBITORY SYNAPSES.

J.C. PONCER, R.A. MCKINNEY, B.H. GÄHWILER and S.M. THOMPSON*
Brain Research Institute, University of Zurich, CH-8029 Zurich, Switzerland

The calcium channel subtypes governing GABA release from inhibitory terminals were pharmacologically identified using paired recordings from inhibitory and pyramidal cells in area CA3 of rat hippocampal slice cultures. In 7 of 8 pairs in which the cell body of the interneuron was located within st. radiatum, unitary IPSPs were entirely abolished by application of 1-2μM ω-Conotoxin MVIIA, a specific blocker of N-type calcium channels. In contrast, when inhibitory cells were recorded within st. oriens, ω-Conotoxin MVIIA only weakly affected unitary IPSP amplitude (-11±3 %, n=3). In such pairs, however, the P-type channel blocker ω-Agatoxin IVA (200 nM) irreversibly abolished transmission (n=9 of 9 pairs). When transmission had been abolished by either toxin, the IPSP could not be restored by elevating external Ca^{2+} concentration from 3 to 10 mM or by applying a train of depolarizing pulses to the presynaptic interneuron (8 pulses at 20 Hz), suggesting GABA release from inhibitory synapses was triggered by Ca^{2+} influx through one predominant channel subtype.

Inhibitory cells were filled with biocytin for further reconstruction of axonal arbor using confocal or standard microscopy. Axons of inhibitory cells recorded from st. oriens or st. radiatum arborized in distinct areas, suggesting they may contact different regions of somato-dendritic membrane of pyramidal cells.

We conclude that at least two populations of hippocampal inhibitory cells express distinct calcium channels at their terminals. This difference may have important implications on the function and the modulation of inhibitory synapses.

MECHANISMS OF NEUROTRANSMITTER RELEASE III

780.1

AMPEROMETRIC MEASUREMENT OF SYNAPTIC VESICLE QUANTAL RELEASE IN MIDBRAIN DOPAMINE NEURONS: MODULATION BY L-DOPA. E.N. Pothos*, I. Ryjak, and D. Sulzer, Dept. Neurol & Psychiatry, Columbia Univ & Dept Neurosci, NYSPI, NY, NY 10032.

L-DOPA increases the quantal size of dopamine (DA) release from large dense core vesicles in PC12 cells, a previously unidentified form of synaptic plasticity (Pothos et al. 1996, J. Neurochem 66:629). However, it has not been clear whether such an effect occurs in midbrain dopamine (DA) neurons, the pharmacologically appropriate cell type. We adapted amperometric detection techniques (Wightman et al. 1991, PNAS 88:10754) to postnatal midbrain DA neurons in culture (Rayport et al. 1992, J.Neurosci. 12:4264). In control cultures, a variety of secretagogues induced relatively small, rapid events with an average height of 7.5±0.3 pA (mean ± s.e.m., n=56), an average width at half-height ($t_{1/2}$) of 80±34 μsec and an average quantal size of 1778±88 molecules (assuming two electrons donated per DA molecule). We also observed apparent overlapping events combining at least two spikes with an average size of 6269±1357 molecules (n=21). In age-matched sister cultures, the average quantal size of the single events increased to 4593±707 molecules after preincubation with 20uM L-DOPA for 30 min (n=35, p<.01), the average height increased to 16.79±1.9 pA, and the average $t_{1/2}$ to 129.7±46 μsec. To our knowledge, this is the first study to characterize quantal release from CNS neurons by electrochemical techniques and demonstrates that quantal size can be modulated by pharmacological intervention. The results suggest that manipulations of cytosolic DA synthesis modify quantal size by altering the DA concentration gradient across the vesicle membrane.

L-DOPA POTENTIATES NGF-DEPENDENT PROCESS OUTGROWTH AND SYNAPTIC VESICLE-LIKE QUANTAL RELEASE EVENTS IN PC12 CELLS. B.-C. Sun*, MA Mena, V. Davila, and D. Sulzer. Dept Neurol & Psych, Columbia Univ, Dept Neuroscience, NYSPI , NY 10032.

L-DOPA is neurotrophic factor for dopamine (DA) neurons, promoting cell survival and process arborization (Mena, this meeting). To characterize this response, we examined PC12 cells, which form neurites following nerve growth factor (NGF) exposure. Only 0.2% of NGF-naive cells had processes, while L-DOPA (50μM for 24h) induced neurites in 21.5±1.0% of cells. L-DOPA potentiated process outgrowth in NGF-treated cultures (50 ng/ml), increasing cells that express processes from 61±4.2% to 99±3.2% and promoting arborization. We used amperometry to examine quantal release from processes. NGF-treated PC12s were previously found to display quantal events likely corresponding to large dense core vesicles (LDCV; Zerby & Ewing 1996, Brain Res, in press). We stimulated cells with 80mM KCl and placed electrodes on process varicosities. More release events occurred in combined L-DOPA/NGF-treated cells (52±10/ stimulation) than NGF alone (9±2/ stimulation). The average quantal size was greater with L-DOPA/NGF (91,300±8,700 molecules, assuming 2e⁻/DA) than NGF alone (40,800±6,500, p<.01). For both, the mean width at half-height was 3ms. Release occurred as either separate events or in bursts of 2-5 vesicles within 100-200ms. In some NGF/L-DOPA-treated cells, much faster amperometric events (width at half-height = 101±3μs) with a small quantal size (18,300±1,100 molecules) were found. These are reminiscent of the smaller synaptic vesicle population in leech neurons (Bruns 1995, Nature) and midbrain DA neurons (Pothos, this meeting). Therefore, L-DOPA/NGF promotes a phenotype that may more closely resemble DA neurons in that elaborate processes are formed and quantal events observed that may correspond to LDCV and small synaptic vesicles. TWO MODES OF RETROGRADE SIGNALING OPERATE AT CA3-CA1 HIPPOCAMPAL SYNAPSES.

J. Noel*, A. Bergamaschi & A. Malgaroli; DIBIT, Scientific Institute S. Raffaele and CNR Cellular Molecular Pharmacology / B. Ceccarelli Ctrs, University of Milano.

Hebbian models of synaptic plasticity envisage retrograde mechanisms which are strictly dependent on synaptic activation. We have found evidence for an additional "constitutive" Ca^{2+} dependent retrograde action at CA3-CA1 hippocampal synapses which sustains basal and potentiated quantal release. This conclusion was reached by applying a dual wc recording approach onto individual postsynaptic CA1 neurons. Quantal properties were monitored throughout the experiment in the wc perforated patch recording mode (to avoid cytosolic wash out), while later on a second wc electrode approached the same pos-synaptic soma to deliver intracellularly various compounds. The introduction of the Ca^{2+} buffer BAPTA (10 mM) in the internal milieu of the postsynaptic cell reduced pre-synaptic release probability when free $[Ca^{2+}]$ was set below resting values (<5 nM) (see figure). This was a very reproducible effect which developed rather quickly, along a few minutes from break-in. Thus a constitutive Ca^{2+} dependent retrograde signalling is operative at CA3-CA1 synapses and this mechanism was found to require CaMKII activity and to cooperate with "regulated" retrograde signals such as nitric oxide (NO). Indeed the presynaptic component of long-term potentiation could be elicited only when both classes of retrograde signalling are fully operative.

THE ROLE OF DIFFERENT TYPES OF VOLTAGE-DEPENDENT CALCIUM CHANNELS IN THE ELECTRICALLY- EVOKED ADENOSINE RELEASE.

F. Pedata, S. Latini, R. Corradetti* and G. Pepeu. Dept. of Pharmacol., Univ. Florence, Italy

The aim of the study was to characterize the calcium-dependence of adenosine (ADO) release. The release of endogenous ADO evoked by 5 min electrical field stimulation at a frequency of 10 Hz was investigated in superfused rat hippocampal slices (400 μm thick). ADO was assayed by reverse-phase HPLC coupled with UV detector or, to avoid interference from peptide toxins, with fluorimetric detection (Pedata et al. J. Neurochem. 61, 284, 1993). In this condition the release is completely tetrodotoxin sensitive and Ca^{++}dependent (Pedata et al. Naunyn-Schmiedeberg's Arch Pharmacol. 344, 538, 1991). The ADO release in the presence of the L-channel activator Bay K 8644 was 170 ± 19 % (n=9, p<0.05) of the control value. The L-channel antagonist nifedipine (100 nM) antagonized the effect of Bay K 8644 but did not affect the evoked ADO release by itself. In presence of the N-channel blocker ω-conotoxin GVIA (10 μM) or of the P channel blocker ω-agatoxin IVA (200 nM), the ADO release was reduced by 78 ± 3 % (n=4, p<0.007) and by 76 ± 5 % (n=6, p< 0.001) in comparison to the control values respectively. In the presence of the two toxins together the ADO release was still reduced by 70%. The data indicate that while the L-type calcium channels are involved in the regulation of the evoked-ADO release only when activated by Bay K 8644, both the P- and N-channels play a role in the calcium entry involved in the coupling process between electrical stimulation and adenosine release.

CARRIER-MEDIATED GABA RELEASE INDUCED BY HIGH $[K^+]_o$ AND LOW $[Na^+]_o$ INCREASES WHOLE CELL CONDUCTANCE IN HIPPOCAMPAL NEURONS. H. L. Gaspary* and G. B. Richerson, VAMC & Yale University, New Haven, CT, 06510.

During seizures and ischemia, extracellular K^+ rises and the transmembrane Na^+ gradient runs down. This would be predicted to cause reversal of the Na^+-dependent, electrogenic GABA transporter, but it is not known whether release of GABA via this mechanism causes significant electrophysiologic effects. Whole-cell patch-clamp recordings were made from hippocampal neurons in primary dissociated culture. Solutions were designed to block all ion channels except chloride channels, with intracellular TEA (40 mM) and cesium (≈100 mM), and extracellular Ca^{2+} (0.5 mM), Cd^{2+} (100uM), TEA (2mM), TTX (1uM), APV (50uM) and CNQX (10uM). The bath solution contained normal Na^+ (151 mM) and K^+ (3 mM). Brief exposure to 12 mM K^+ and 0 mM Na^+ (choline substituted) using pressure microejection resulted in an increase in whole-cell conductance that was reversibly blocked by picrotoxin (50uM) and bicuculline (500uM). The reversal potential of the response was equal to, and shifted appropriately with, the Nernst potential for Cl^-. The response was inhibited by the GABA transporter antagonist SKF 89976A (40uM; kindly provided by SmithKline Beecham). We propose that low Na^+ and high K^+ stimulates nonvesicular release of GABA from neighboring neurons or glia, which then activates $GABA_A$ receptors on the recorded neuron. These responses were often large (4-5 nS). When the same experiments were performed in the presence of 2mM Ca^{2+} and 0 mM Cd^{2+}, the $GABA_A$ receptor-mediated conductance was approximately 1.5x greater than that induced in Cd^{2+}, suggesting that Ca^{2+}-independent, carrier-mediated GABA release comprised a substantial portion of the total GABA release induced by this stimulus. The ionic conditions used here, which mimic ionic changes present during seizures and ischemia, stimulate functionally relevant amounts of carrier-mediated GABA release. This nonvesicular release may be a target of gabapentin and other novel anticonvulsants. (Supported by EFA and AHA).

EXTRACELLULAR ATP INHIBITS EXOCYTOSIS VIA INHIBITION OF CALCIUM CURRENTS IN RAT ADRENAL CHROMAFFIN CELLS.
W. Lim[1], S.J. Kim[2], H.D. Yan[1] and J. Kim[1]*. [1]Dept. of Physiology and Biophysics, Seoul Nat'l. Univ. Coll. of Med., Seoul, Korea 110-799, and [2]Biomedical Research center, Korean Institute of Science and Technology, Seoul, Korea

In chromaffin cells, ATP is stored in secretory vesicles in high concentration and co-released with catecholamines after stimulation. It has been suggested that ATP might play a role in the regulation of exocytosis of the chromaffin cells. To study the effects of ATP on exocytosis, we activated calcium currents (I_{Ca}) by various depolarizing pulses and the resultant change of membrane capacitance (C_m) was monitored. When three 500 ms depolarizing pulses from -70 mV to 10 mV were delivered at 4500 ms interval, ATP (0.01-1 mM) inhibits both I_{Ca} and depolarization-induced C_m changes reversibly and dose-dependently. Maximal inhibition of exocytosis was about 80% at 1 mM. ATP itself did not evoke exocytosis. We also tested ATP effect on exocytosis induced by short repetitive stimulation: each stimulus has 50 ms duration and was applied at three different frequency (6.7 Hz, 3.3 Hz, 1.7 Hz). Although Inhibitory effects of ATP were the same as the above results, two remarkable features were observed. First, C_m changes induced by high frequency stimulation (35% inhibition) was inhibited by ATP less than by low frequency stimulation (60% inhibition). Second, ATP did not inhibit immediately releasable pool, which is discernible at high frequency stimulation. These results suggests that extracellular ATP plays a regulatory role in exocytosis of chromaffin cells, importance of which is dependent on cellular activities.

BAPTA-AM FAILS TO ATTENUATE SYNAPTIC TRANSMISSION IN CA1 HIPPOCAMPAL NEURONS FOLLOWING BRIEF HYPOXIA.
Aviv Ouanounou, Marc R. Pelletier* and Liang Zhang. Playfair Neuroscience Unit, Toronto Hospital Research Institute, Depts of Physiology and Medicine (Neurology), University of Toronto, Toronto, ON, Canada M5T 2S8.

We have shown that application of BAPTA-AM at low μM concentrations attenuated synaptic field potentials in the CA1 region of rat hippocampal slices (Ouanounou et al., 1996, *Neuroscience*, in press). In the present experiments, we examined whether synaptic transmission in the CA1 region of the hippocampus is affected similarly by BAPTA-AM following a brief hypoxic-hypoglycaemic challenge in brain slices. Conventional brain slices were prepared from Wistar rats and maintained in ACSF bubbled with 5% CO_2-95% O_2. Hypoxic-hypoglycaemic (H-H) challenge consisted of perfusing slices for 3-4 min with glucose-free ACSF, which was bubbled with 5% CO_2-95% N_2. Extracellular potentials were recorded 3-6 hours following the H-H challenge. In control slices, which did not experience the H-H challenge, extracellular application of BAPTA-AM (10-50 μM, 15-20 min) caused a reduction in amplitude of synaptic field potentials by ≈ 40%. In slices that experienced the H-H challenge, evoked synaptic field potentials were not different compared to the control group; however, application of BAPTA-AM failed to attenuate the synaptic potentials. We are currently investigating the mechanisms underlying this differential effect we observed for BAPTA-AM.

COLOBOMA HYPERACTIVE MUTANT MICE EXHIBIT REGIONAL AND TRANSMITTER SPECIFIC DEFICITS IN NEUROTRANSMISSION.
P.P. Mehta¶*, J. Raber¶#, M. Kreifeldt¶, L.H. Parsons¶, F. Weiss¶, F.E. Bloom¶, and M.C. Wilson¶ ¶Department of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037; #New affiliations: Gladstone Molecular Neurobiology Program and Department of Neurology, University of California, San Francisco, CA 94141

The mouse mutant coloboma (*Cm/+*), which bears a deletion on chromosome 2 including the gene encoding the synaptic protein SNAP-25, exhibits profound spontaneous hyperactivity and other neurophysiological deficits, and has been proposed as a model for attention-deficit hyperactivity disorder. SNAP-25, together with syntaxin and VAMP/synaptobrevin forms a core complex thought to provide docking and to mediate vesicular fusion for release of both classical neurotransmitters and neuropeptides. The neurochemical basis for the behavioral abnormalities of *Cm/+* mice, and potentially the role of SNAP-25 in regulating neurotransmission were investigated by comparing the release of specific neurotransmitters *in vitro* from synaptosomes and slices of selected brain regions of SNAP-25 deficient *Cm/+* and normal *+/+* wildtype mice. Despite the global reduction of SNAP-25, the calcium-dependent release of glutamate, the monoamines dopamine (DA) and serotonin (5-HT), and the peptides arginine vasopressin (AVP) and corticotropin-releasing factor (CRF) were affected quite differently. Glutamate content and KCl-stimulated release was reduced by 30% in cortical synaptosomes of *Cm/+* mice. In dorsal striatum, but not ventral striatum, KCl-stimulated release of DA was completely blocked and 5-HT was significantly attenuated in *Cm/+* mutants consistent with the involvement of deficient striatal DA and 5-HT release in hyperactivity. Further, acetylcholine failed to stimulate hypothalamic CRF release from *Cm/+* slices, but restraint stress still induced plasma corticosterone in mutant mice, indicating a role for AVP in the activation of the HPA axis. These results suggest reduced SNAP-25 expression may contribute to regional- and neurotransmitter-specific deficiencies that underlie distinctive behavioral and neurophysiological abnormalities including hyperactivity. TEMPERATURE DEPENDENCE OF EVOKED GLUTAMATE AND CGRP RELEASE FROM RAT DORSAL SPINAL CORD IN VITRO.
D.M. Dirig* and T.L. Yaksh.Pharmacology & Anesthesiology, Univ. of Calif., San Diego,CA 92093

Hypothermia is commonly used to prevent neurologic degeneration during cardiac bypass and neurosurgery. Hypothermic neuroprotection has been suggested to be mediated by suppression of excitotoxin release, which is elevated during neuronal ischemia and trauma. This study examined the temperature sensitivity of spinal glutamate and CGRP under in vitro normoxic conditions. Release was evoked from Sprague-Dawley rat dorsal spinal cord slices by either 60mM Potassium or 10μM Capsaicin in oxygenated ACSF. Temperature was monitored using a chamber-mounted thermistor and maintained by a water bath in which perfusion chambers were immersed. Release was evoked from 40-8°C. Potassium-evoked glutamate release demonstrated a marked suppression with mild hypothermia (34°C). Capsaicin did not evoke glutamate release. CGRP demonstrated a steep temperature dependency at 34° C, but release could still be evoked as low as 8° C. Calcium-dependency of release of both transmitters was shown using calcium-free ACSF with EGTA. These results support the hypothesis that hypothermic neuroprotection is mediated through inhibition of excitotoxin release. These studies also suggest that there may be other generalized temperature-responsive mechanisms governing transmitter release.

ACTIVATION OF CALCIUM RECEPTORS INHIBITS ^{3}H-GABA RELEASE IN THE HIPPOCAMPUS.
N. Alasti , A.L. Mueller , K.V. Rogers*. NPS Pharmaceuticals, Inc., Salt Lake City , Utah 84108.

Extracellular calcium is the primary physiological regulator of parathyroid hormone secretion from the parathyroid gland and calcitonin secretion from thyroid C cells. The G protein-coupled receptor that mediates this response has been cloned and characterized and this calcium receptor (CaR) is expressed in a variety of CNS regions, including the hippocampus. The function of this receptor in the CNS is unknown, however, immunocytochemical analysis has shown expression of the CaR on nerve terminals suggesting that it might act to modulate neurotransmitter release in response to changes in extracellular calcium. To test this hypothesis, we investigated whether calcium and an organic agonist to the calcium receptor (NPS R-467) would modulate the release of ^{3}H-GABA from hippocampal minces. Cortical tissue, where CaR-expressing cells are rare, was also tested. Minces from adult male rats were loaded with ^{3}H-GABA and washed in buffer containing 5 mM KCl and 0.5 mM $CaCl_2$. Buffer containing 25 mM KCl and 0.5 mM $CaCl_2$ was used to stimulate ^{3}H-GABA release with and without the addition of either 0.1 or 1 μM NPS R-467. The less active enantiomer, NPS S-467, and 2 mM $CaCl_2$ were also tested. NPS R-467, but not S-467, caused a statistically significant and dose-dependent inhibition of KCl-induced ^{3}H-GABA release. 1μM NPS R-467 or 2 mM $CaCl_2$ reduced ^{3}H-GABA release by approximately 30% ($p<0.05$). Inhibition of GABA release by NPS R-467 was not observed in cortical minces; thus the inhibitory action of CaR agonists on GABA release correlates with CaR expression in these regions. (Funded by NPS Pharmaceuticals, Inc.)

RESPONSE OF HIPPOCAMPAL SYNAPTIC VESICLE DOCKING AND FUSION PROTEINS TO [CALCIUM] & DEPOLARIZATION IN KINDLED AND NAIVE RATS. J.T.Slevin*, S.W.Whiteheart and T.C.Vanaman. Veterans Administration and University of Kentucky Med. Center, Lexington, KY 40536.

Whole hippocampal homogenates were sedimented at 100,000 x g to separate membrane and cytosol fractions. Membrane fractions were then stripped with a TRIS-Triton buffer; 25 μg samples of these solubilized factors and of the original homogenate supernatant fraction were subjected to standard SDS-PAGE. Portions of the pelleted membrane fractions were subjected to centrifugation through a gradient of percoll (yielding a highly enriched synaptosomal preparation) or sucrose (enriched synaptic vesicle preparation). These samples were disrupted in SDS buffer; 5 and 10 μg aliquots were run directly on SDS-PAGE. All samples were then electroblotted onto nitrocellulose and subjected to successive ECL-immunoblot analysis (probe, strip and reprobe) with antisera to NSF, α and β SNAPs, synaptotagmin, syntaxin 1 A/B, VAMP-2, and TAP. Components such as NSF and SNAPs which cycle from cytosol to membrane were present in both fractions of the crude hippocampal homogenate, while syntaxins were present only in the 100,000 x g pellet fraction, as expected. β-SNAP, previously shown to be brain specific and enriched in hippocampus, predominates in the synaptosomal compartment further suggesting a primary role in neurosecretion. Regardless of presence or absence of Ca^{+2}, no SNAP proteins were detected in the enriched vesicle fraction. No differences were detected in the relative amounts of the various components in hippocampi from control vs kindled rat brain, ipsilateral or contralateral to the entorhinal kindling electrode. Support: VA Research Service.

MODULATION OF STIMULATION-EVOKED NEUROTRANSMITTER RELEASE FROM RAT BRAIN SLICES BY THE ANTICONVULSANT GABAPENTIN. D.J. Dooley*[1], N. Suman-Chauhan[2] and Z. Madden[2]. [1]Dept. of Neuroscience, Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Co., Ann Arbor, MI 48106 and [2]Parke-Davis Neuroscience Research Centre, Cambridge, England CB2 2QB.

The mechanism(s) of action of gabapentin ((GP) Neurontin®) remains unclear even though the drug prevents seizures and has potential efficacy in several other neurologic and psychiatric disorders. One putative mechanism is a modulation of central neurotransmission possibly by GP binding to the Ca^{2+} channel $\alpha_2\delta$ subunit. In the present study, GP was tested for effects on the release of endogenous or tritiated GABA, glutamic acid (GLU)/D-aspartic acid (D-ASP), and noradrenaline (NA) from superfused rat brain slices. GP (100 μM) did not alter K^+-evoked GABA and GLU/D-ASP release. The K^+-evoked NA release was, however, inhibited (IC_{50} = 8.9 μM; submaximal inhibition of 33% (0.1-1 mM)), whereas electrically-evoked NA release was practically unchanged. GP (100 μM) did not affect veratridine- and tyramine-induced, Ca^{2+}-independent NA release. The preferential inhibitory effect of GP on Ca^{2+}-dependent, K^+-evoked NA release appears to reflect a negative modulation of the role of Ca^{2+} in subserving this release. This type of modulation may underlie the wide safety margin of GP: beneficial effects in certain pathological states without compromising normal (action potential-mediated) neurotransmission.

L-DOPA MODULATION OF DOPAMINE AND DOPAC OUTPUT FROM THE CORPUS STRIATUM OF INTACT AND 6-OHDA LESIONED MALE RATS: EFFECTS OF DOSE AND MODE OF INFUSION. K. Xu* and D.E. Dluzen. Dept. of Anatomy, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272-0095.

In the first experiment, we tested the effects of two 20 min infusions of 5 μM L-DOPA with a 60 min interval between infusions. In the second experiment, we repeated this protocol using 50 μM L-DOPA. There was an overall significant difference in the dopamine (DA) output between intact and 6-OHDA lesioned rats for both doses. Moreover, in Experiment 1, the 5 μM L-DOPA produced a peak DA response to the second infusion which was significantly higher than that of the first infusion in the intact, but not the 6-OHDA lesioned, rats. In Experiment 2, the 50 μM L-DOPA group showed no significant differences in DA output between the two infusions for both intact and 6-OHDA lesioned rats. In contrast to DA responses, there were no overall significant differences in DOPAC output between intact and lesioned rats for both doses. However, for both doses tested, the peak DOPAC output from the second infusion was significantly increased in lesioned, but not intact rats. The data suggest that L-DOPA evoked DA output is differentially modulated as a function of the L-DOPA dose used, and that lesions of the striatal dopaminergic system alter these responses through changes in DA intraneuronal metabolism as revealed by DOPAC output. (Supported by NIH grant to D. E. Dluzen)

COMPARISON OF DEPOLARIZATION-INDUCED VERSUS UPTAKE INHIBITOR-EVOKED GLUTAMATE AND ASPARTATE ACCUMULATION IN RAT BRAIN USING *IN VIVO* MICRODIALYSIS. G. Battaglia and D. D. Schoepp* Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, 46285, U.S.A.

The effects of local perfusion with veratridine, a sodium channel activator, and L-*trans*- pyrrolidine-2,4-dicarboxylate (t-PDC), an inhibitor of high affinity, sodium-dependent glutamate transport, on glutamate (glu) and aspartate (asp) extracellular levels were monitored using *in vivo* microdialysis of freely-moving animals. Veratridine (5, 20, and 100 μM) and t-PDC (1, 5, and 25 mM) dose-dependently increased extracellular glu and asp levels in striatum. Veratridine (100 μM) greatly increased glu and asp to 29- and 40-fold over basal levels, while 25 mM t-PDC increased asp and glu to 46- and 30-fold over basal levels, respectively. Veratridine (100 μM) and t-PDC (25 mM) also increased glu and asp extracellular levels in hippocampus and amygdala. In the striatum, hippocampus or amygdala, veratridine-evoked increases in glu and asp were completely abolished by tetrodotoxin (TTX, 2 μM). However, in the striatum, TTX partially reduced t-PDC-induced glu and asp increases to about 50%. In the hippocampus or amygdala, TTX had no significant effects of t-PDC-induced glu release, but TTX partially reduced asp release in the amygdala. These data demonstrate that depolarization-evoked release of excitatory amino acids involves the release of neuronal activity-dependent vesicular stores of neurotransmitter. However, overflow of glu and asp via transporter inhibition with t-PDC also involves exchange of glu and asp via a carrier-dependent mechanism.

NEUROTRANSMITTERS RELEASED BY α-LATROTOXIN (αLTX) AND ELECTRICAL FIELD STIMULATION (EFS) IN THE PIG URETHRA V. Werkström, K. Persson*, L. Ny and K.-E. Andersson, Department of Clinical Pharmacology, Lund University Hospital, Lund, Sweden.

The effects of αLTX, a neurotoxin believed to cause massive release of neurotransmitters by an exocytosis mechanism in the nerve terminal, was investigated on the spontaneously developed muscle tone in the female pig urethra. In this preparation, relaxation of the smooth muscle is considered to be non-adrenergic, non-cholinergic (NANC) in origin, and mediated partly by nitric oxide (NO), and partly by an as yet unidentified mediator.

In the presence of the NO-synthesis inhibitor L-NOARG (0.3 mM), EFS (1-50 Hz) evoked frequency-dependent contractions, reaching a maximum of 8 ± 3 mN at 40 Hz. In comparison, treatment with αLTX (1 nM) evoked a contraction of 1.4 ± 0.4 mN. The contractions evoked by EFS were unaffected by scopolamine (Scop.; 1 μM), but abolished by phentolamine (Pha.; 1 μM). In the presence of either Pha. or Scop., αLTX evoked a relaxation. In another series of experiments, EFS evoked frequency-dependent relaxations in the presence of Pha. and Scop. At low frequencies (<12 Hz), the relaxations were rapid, whereas at frequencies higher than 12 Hz, they were biphasic, consisting of a rapid first phase followed by a more long-lasting second phase. A maximum amplitude was obtained at 30 Hz, and amounted to 63 ± 6 %. L-NOARG abolished the relaxations at low frequencies, as well as the first phase of the biphasic relaxation. The second phase was not affected by treatment with L-NOARG. In the presence of Pha. and Scop., αLTX evoked a long-lasting relaxation of 67 ± 9 %, which was reduced to 27 ± 4 % in the presence of L-NOARG.

These results suggest that αLTX has the ability to release "classical" transmitters (i.e. noradrenaline and acetylcholine), as well as NO and another inhibitory NANC mediator from nerve terminals in the urethra.

INHIBITION OF ELECTRICALLY-STIMULATED [^{3}H]GLUTAMATE RELEASE BY THE LARGE-CONDUCTANCE CALCIUM-ACTIVATED POTASSIUM (MAXIK$^+$) CHANNEL OPENER NS-1619. H.L. Wiener*, G.P. Thalody, and J.R. Torrente, CNS Drug Discovery, Bristol-Myers Squibb Co., 5 Research Pkwy., Dept. 404, Wallingford, CT 06492.

During ischemic brain damage, excess release of the excitatory amino acid glutamate may damage brain tissue by a multi-faceted process. Since stroke-related damage can potentially be reduced by limiting glutamate release, we developed an assay that measures the amount of preloaded [^{3}H]glutamate released from rat hippocampal slices in response to electrical stimulation. NS-1619 (1,3-dihydro-1-[2-hydroxy-5-(trifluromethyl)phenyl)-5-(trifluromethyl)-2*H*-benzimidazol-2-one) opens neuronal and vascular smooth muscle maxiK$^+$ channels. In addition, NS-1619 blocks voltage-dependent potassium channels and L-type calcium channels in vascular smooth muscle. The present studies investigated the ability of NS-1619 to modulate electrically-stimulated [^{3}H]glutamate release in rat hippocampal slices *in vitro*. NS-1619 inhibited [^{3}H]glutamate release in a concentration-dependent and saturable manner. To test the hypothesis that maxiK$^+$ channel opening by NS-1619 contributed to its ability to attenuate [^{3}H]glutamate release, NS-1619 was assayed in the presence of iberiotoxin (IbTX), a highly specific blocker of the maxiK$^+$ channel. Although 100 nM IbTX did not itself affect [^{3}H]glutamate release, it prevented NS-1619 -induced inhibition of [^{3}H]glutamate release. That the response to NS-1619 was IbTX-sensitive suggests that NS-1619 inhibits electrically-stimulated [^{3}H]glutamate release in hippocampal slices *in vitro* by opening the maxiK$^+$ channel.

EXPRESSION OF DISTINCT CYCLIC NUCLEOTIDE-GATED CHANNEL GENES IN THE MAMMALIAN CNS. P. A. Kingston*, F. Zufall, G. M. Shepherd, C. J. Barnstable. Section of Neurobiology, Department of Ophthalmology and Visual Science, Yale University School of Medicine, New Haven, CT 06520.

Cyclic nucleotides can regulate neuronal activity, in part by controlling membrane potential and intracellular calcium levels through direct activation of cyclic nucleotide-gated (CNG) non-selective cation channels. Distinct types of CNG channel underlie sensory transduction in vertebrate photoreceptors and olfactory receptor neurons. We previously detected expression of CNG channels ouside the retina and olfactory epithelium, and have now found the separate types expressed in common regions of the brain and, furthermore, colocalized in common cell types. Primers for several regions of the rod retinal and olfactory CNG channel principal subunits were used to amplify cDNA reverse transcribed from adult rat cortex, cerebellum, and olfactory bulb in a polymerase chain reaction (PCR). The identities of PCR products were confirmed with Southern blots, while Northern blot and sequencing experiments confirmed the presence of distinct CNG channel transcripts in the cerebellum. In situ hybridization experiments with RNA probes for multiple regions of the CNG channel transcripts labeled various cell types in regions of the CNS including cortex, hippocampus, cerebellum, and olfactory bulb. Cells in components of the basal ganglia were not labeled. There were no consistent differences between hybridization patterns for the distinct channel probes, and at least some of these cell populations appear to express both retinal and olfactory channel subunits.

These findings suggest that many CNS neurons may use CNG channels to mediate the effects of both cAMP and cGMP, and raise the additional possibility that distinct subunits are combined to form novel CNG channels. Further studies using electrophysiological and single cell PCR methods to explore CNG channel function in the CNS are underway.

Supported by grants from the NIH (CJB, FZ, GMS) and NSF (PAK).

5-HT_3 RECEPTOR CHANNEL DESENSITIZATION IS MODULATED BY CYTOPLASMIC CALCIUM. S. Jones and J.L. Yakel*. Lab. of Cellular and Molecular Pharmacology, National Institute of Environmental Health Sciences/NIH, Research Triangle Park, NC 27709.

Whether or not cytoplasmic calcium ($[Ca^{2+}]_{in}$) can modulate the rate of desensitization of the 5-HT_3 receptor, the serotonin receptor that incorporates an ion channel, was investigated in NG108-15 neuroblastoma/glioma hybrid cells. Immediately after break-in during a whole-cell recording, the rapid application of 5-HT (50 μM) at a holding potential of -70 mV elicited an inward current response that declined in the continued presence of agonist (i.e. desensitization) with a biphasic time course. Using a potassium gluconate-based internal solution that buffered calcium with EGTA (5 mM and 0.5 mM Ca^{2+}), the fast decay phase (immediately after break-in) averaged 170±39 msec and comprised 74±2% of the fit, and the slow phase averaged 2.78±0.25 sec and comprised 20±2%. Upon repeated applications of 5-HT at 4 min intervals to allow complete recovery of desensitization, the rate of desensitization greatly slowed (i.e. decelerated). At 20 min after break-in, the fast time constant of decay increased to 656±250 msec with its extent decreasing to 52±9%. The slow time constant also increased to 4.20+0.94 sec with its extent increasing to 44±8% during this time. As dialysis of the cell is most likely responsible for this deceleration, perforated-patch recordings were performed; under these conditions, the kinetics of desensitization did not significantly decelerate with time. To test for a role of $[Ca^{2+}]_{in}$ in this deceleration, EGTA and calcium were replaced with BAPTA (20 mM). Under these conditions, there also was no deceleration; in fact at 20 min, the rate of desensitization actually was faster with BAPTA. This data clearly suggests that $[Ca^{2+}]_{in}$, via an unknown mechanism, alters 5-HT_3 receptor channel desensitization.

DEVELOPMENTAL CHANGES IN GABA-MEDIATED TRANSMISSION AT THE CEREBELLAR GOLGI CELL-GRANULE CELL SYNAPSE OF THE RAT Mark Farrant*, Stephen G. Brickley and Stuart G. Cull-Candy
Dept. Pharmacology, University College London, London WC1E 6BT, UK.

GABA-mediated inhibition of the cerebellar granule cell plays an important role in the control of the mossy fibre-Purkinje cell circuit. We have made whole-cell voltage-clamp recordings from internal granule cells in parasagital slices (150-250μm) prepared from the cerebella of 7-, 14-, 21-, and 28-day-old (P7, 14, 21, and 28) rats, as previously described (Kaneda *et al.*, J. Physiol. 485, 419-435, 1995). Spontaneous TTX- and bicuculline-sensitive synaptic currents were recorded in the presence of CNQX, AP5 and strychnine. The decay of these $GABA_A$ mediated synaptic currents (sIPSCs) was best described by a dual exponential function at all ages but the decay was much faster in older animals. At P7 (-70mV, 22-25°C) the fast time constant of decay (τ_f) was 17.2±1.2ms (50.4±2.7%; mean±s.e.m.) and the slow time constant (τ_s) was 63.0±4.4ms (n=16), whereas at P14 τ_f=10.2±1.1ms (70.3±4.1%) and τ_s=58.7±5.7ms (n=18). By P21-28 the current decay was faster still, with τ_f=5.5±0.4ms (73.6±3.9%) and τ_s=32.6±4.7ms (n=4). At P14 there was a striking increase in the background current noise in those cells which exhibited sIPSCs. At P7, the mean holding current (I_H) at -70mV was -11.6±1.6pA and the current variance was 1.1±0.3pA^2 (n=24), whereas at P14 I_H was -21.2±2.9pA and the variance was 13.7±2.3pA^2 (n=46). The increased background noise, present after P7, was completely blocked by $GABA_A$ receptor antagonists and a large proportion was both action potential- and Ca^{2+}-dependent. Thus, tonic activation of $GABA_A$ receptors results from synaptically released GABA. Between P7 and P21, although there is an 8-fold reduction in charge transfer by discrete IPSCs, this may be counteracted by the development of the background conductance.

SPONTANEOUS SYNAPTIC ACTIVITY IN AMACRINE AND GANGLION CELLS OF MOUSE RETINA. N. Tian*, T. Hwang and D.R. Copenhagen. Depts. of Ophthalmology and Physiology, UCSF School of Medicine, San Francisco, CA, 94143-0730.

Spontaneous synaptic activity (SSA) was recorded using perforated patch, whole cell recording methods. The experiments were performed in mouse (C57BL/6J) retinal slice preparations; these events were recorded as brief inward currents at a holding potential of -70 mV. Age-dependent and cell-specific differences in the frequency of SSA were investigated. Additionally, pharmacological antagonists were used to identify these neurotransmitter-gated currents.

These results show that: 1) The frequency of SSA in ganglion cells from younger animals (6 weeks, n=12, 173/min) is about five times higher than that from older animals (5 months, n=4, 38/min), indicating an age-dependency of ganglion cell SSA; 2) In the younger age group, the frequency of SSA in ganglion cells (n=12, 173/min) is about 60 times higher than the SSA recorded from amacrine cells (n=10, 3/min); 3) Ganglion cell SSA could be recorded in the presence of either the glutamate receptor antagonists (AP7 and CNQX) or in the presence of inhibitory neurotransmitter antagonists (picrotoxin and strychnine), suggesting that ganglion cells are activated directly by both excitatory and inhibitory neurotransmitters; 4) Further dissection of the inhibitory inputs using AP7 and CNQX and either picrotoxin or strychnine revealed that both glycinergic and GABAergic events contribute to SSA in these ganglion cells. We interpret these results to indicate that mouse ganglion cells are directly activated by synaptic inputs from glutamatergic, GABAergic and glycinergic neurons.

AMINO ACID NEUROTRANSMITTER RECEPTORS IN PANCREATIC ISLET CELL LINES C.D.Weaver[1], J.G.Partridge[1], T.L.Yao[1], J.M.Moates[2], M.A. Magnuson[2], T. A.Verdoorn[1]
[1]Dept. of Pharmacology, [2]Dept. of Molecular Physiology and Biophysics, Vanderbilt Univ. Med. Sch., Nashville, TN 37232-6600.

We have studied the expression and functional properties of AMPA, GABA-A, and inhibitory glycine receptors in the insulinoma cell line GK-P3. We have also characterized the properties of AMPA and kainate type glutamate receptors and GABA-A receptors in the glucagon-secreting cell lines αTC-6 and αTC-9. Patch clamp electrophysiology revealed functional AMPA receptors in 57.3% of 89 GK-P3 cells with an average steady state amplitude of 37.7±6.7 pA (300 μM glutamate). Glutamate receptors were detected in 50.0% of 68 αTC cells and produced currents averaging 7.5±1.7 pA (300 μM glutamate). The Ca^{2+}:Na^+ permeability ratios for glutamate receptors found in these cell lines were 0.046±0.02 (n=7) and 0.109±0.042 (n=8) for the GK-P3 and αTC cells respectively. These data indicate that the majority of AMPA receptors in these cells probably contain an edited GluRB subunit. However, 3 out of 15 cells displayed a significantly higher Ca^{2+} permeability suggesting that some of these cells express Ca^{2+} permeable AMPA receptors. NMDA receptors were not detected in any cells tested (n=11). GABA receptors were expressed in 15.4% of 65 GK-P3 cells with currents averaging 82.4±41.9 pA (30 μM GABA) and in 59.7% of 74 αTC cells with an average amplitude of 113.2±42.3 pA (30 μM GABA). Inhibitory glycine receptors were observed in 97.2% of 72 cells tested. Glycine elicited currents averaged 145.4±21.8 pA. (100 μM glycine). These receptors have properties that are indistinguishable from their neuronal counterparts with an EC_{50} for glycine of 109.7±15.0 μM (n=11) and a Cl^-:HCO_3^- permeability ratio of 5.56±0.39 (n=4). Glycine currents were completely blocked by 1 μM strychnine (n=12) and 80±3.3% (n=4) by 50 μM Zn^{2+}. Glycine receptors were not detected in 34 αTC cells tested. Although glutamate and GABA receptors have previously been detected in pancreatic islet cell lines, this is the first report of glycine receptors in these cells. These islet cell lines offer an opportunity for investigation of neuronal-like glutamate, GABA, and glycine receptors in cell lines which naturally and stably express these receptors. This may provide unique advantages for studying the regulation of subunit assembly and expression of these amino acid neurotransmitter receptors. Supported by NS 30945 and NS 09788.

DIFFERENCES IN ISOLATED RECEPTOR POTENTIALS AND INPUT/OUTPUT FUNCTIONS IN RABBITS EXPOSED TO COCAINE DURING GESTATION T.J. TEYLER* and J.Z. LITTLE Dept. of Neurobiology, Northeastern Ohio Univ. Coll. of Med., Rootstown, Ohio 22472

We evaluated pharmacologically isolated receptor populations in rabbits prenatally exposed to cocaine and in age matched controls. Using hippocampal slices from rabbits 30-40 days old we evaluated the input/output functions and isolated receptor responses to stimulation of Schaffer collaterals in area CA1. Input/Output curves were created by measuring the amplitude of dendritic field EPSPs at a range of stimulus intensities. These responses were plotted and compared to responses from control animals. Isolated receptor populations were compared on measures of amplitude and duration. Receptor populations examined include AMPA, NMDA, GABAa and GABAb. Differences in response kinetics and their underlying mechanisms will be discussed.

ASTROCYTE UP-REGULATION OF AMINO ACIDS-INDUCED CURRENTS IN CULTURED EMBRYONIC RAT HIPPOCAMPAL NEURONS IS DIFFERENTIALLY SENSITIVE TO ß-AMYLOID PROTEIN. Qi-Ying Liu*, Anne E. Schaffner and Jeffery L. Barker. Lab. of Neurophysiology, NINDS, National Institutes of Health, Bethesda, MD 20892.

Embryonic (E19) rat hippocampal neurons were cultured on poly-D-lysine (PDL) or a monolayer of postnatal cortical astrocytes to reveal putative changes in neuronal physiology that involve astrocyte-derived signals. Kainate and NMDA currents as well as GABA- and glycine-induced Cl^- currents were quantified using whole-cell patch-clamp recordings. The amplitude and density of these currents in neurons grown on astrocytes were significantly greater than those recorded in neurons grown on PDL after 1 day in culture. To test the effects of neurotoxic and gliotoxic agents on the expression of neuronal agonist receptors, astrocytes were treated with 0.5 µM ß-amyloid protein (1-40) for 24 hours before neurons were plated. This treatment significantly depressed the ability of astrocytes to up-regulate $GABA_A$, kainate and NMDA currents but not glycine current. These preliminary results indicate that up-regulation of different classes of functional amino acid receptors by astrocytes includes processes that are differentially sensitive to ß-amyloid proteins.

NMDA-receptors Are Expressed By Intrinsic Neurons Of Rat Larynx. B. Robertson[1], R. D. Dey[1], L. J. Huffman*[2] and Sami I. Said[3]. Departments of Anatomy[1] and Physiology[2], West Virginia University, and Health Effects Laboratory Division[2], National Institute For Occupational Health and Safety, Morgantown, WV, 26506 and University Medical Center, Stony Brook and Northport VA Medical Center, Northport, NY 11794[3].

Overactivation of NMDA receptors, a major mechanism of central neurotoxicity, has recently been shown to trigger acute injury in rat lungs (Neurosci. 65: 943, 1995). NMDA-receptors have not been localized in the lung or airways, but neurons of the myenteric plexus in the rat express mRNA for NMDA-receptors (Neurosci. Lett. 144:229, 1992). Furthermore, a population of glutamate-containing nerve fibers originating from cell bodies in the nucleus ambiguus project to intrinsic neurons of the rat larynx (J. Auton. Nerv. Sys. 123:175, 1991). We hypothesized that the neurons innervated by glutamate-containing fibers may express NMDA-receptors. Sections of rat larynx were immunocytochemically labelled for NMDA2B-receptor using a specific antibody (Upstate Biotech, Lake Placid, N.Y.). NMDA-receptor immunoreactivity was observed in cell bodies of individual neurons located in the laryngeal submucosa and also in neurons of ganglia associated with nerve trunks on the external surface of the laryngeal skeletal muscle. VIP-immunoreactivity was colocalized in some of the same neurons. These findings suggest that NMDA-receptors are expressed in neurons of the rat larynx and are colocalized with VIP. The possible involvement of NMDA receptors identified on airway neurons in mediating NMDA-induced lung injury remains to be determined. Supported by HL30450 and VA Research Funds.

782.2

CO-LOCALIZATION OF NMDA AND NON-NMDA RECEPTORS IN THE NEURONS OF THE ROSTRAL VENTROMEDIAL MEDULLA. Y.Y. Lai*, J.P. Wu, J.S. Kuo, and J.M. Siegel. Taichung Veter. Gen. Hosp., Taiwan; Dept Psychiat., Sch. Med., UCLA and VAMC, North Hills, CA 91343.

Microinjection of NMDA agonists into the nucleus magnocellularis (NMC) of the medulla produces locomotion or muscle tone facilitation, while microinjection of non-NMDA agonists into the same site produces muscle tone suppression. The present study was undertaken to identify the neuronal distribution of receptor types in the NMC responsible for these effects. Six cats were perfused intracardially with Ringers' saline followed with 3% paraformaldehyde. Brain tissue was cut at 50 µ, and then processed with a combination of NMDAR1 (PharMingen) and one of the following receptor antibodies: GluR1 (Chemicon), GluR2/3 (Chemicon) and GluR4 (Chemicon). DAB was used to visualize the final products of NMDA receptor immunohistochemistry, while BDHC was used to identify the product of non-NMDA receptor immunohistochemistry. Neurons single labelled with NMDAR1, GluR1, GluR2/3 and GluR4 receptors, as well as NMDAR1 double labelled with non-NMDA receptor immunohistochemistries were found in the NMC. We conclude that NMDA and non-NMDA agonists microinjected into the NMC activate distinct but overlapping populations of neurons.

SYNAPTIC COLOCALIZATION OF AMPA AND NMDA RECEPTOR SUBUNIT PROTEINS IN RAT SENSORY-MOTOR CORTEX W.G.M. Janssen, G.W. Huntley, J.H. Morrison*. Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, NY 10029.

Light microscopic and electrophysiological studies have demonstrated that both AMPA and NMDA glutamate receptors (GluRs) are widely distributed and functionally operational in neocortical circuits. However, their precise synaptic distribution and the degree to which they are colocalized at individual synapses have yet to be elucidated. Moreover, the specific GluR subunit profile of identified afferent pathways in neocortex is unknown. In this study, we used subunit-specific antibodies combined with single and double-labeling postembedding immunogold techniques (Phend et al., J. Histochem. Cytochem., 1995) to investigate the synaptic distribution and co-localization of AMPA subunits GluR2/3 and the obligatory NMDA receptor subunit NMDAR1 (NR1) in rat sensory-motor cortex. Analyses demonstrated subsets of synapses which were immunoreactive for 1) only GluR2/3; 2) only NR1; 3) both GluR2/3 and NR1; and 4) asymmetrical synapses that were unlabeled for either antibody. In addition, a new GluR2 specific monoclonal antibody (see Vissavajjhala, et al. this meeting) demonstrated that GluR2 is synaptically localized in rat sensory-motor cortex at a subpopulation of asymmetrical synapses, suggesting that the GluR2/3 labeling was likely to at least in part, reflect the presence of GluR2 at neocortical synapses. While these studies have not allowed for precise linkage between identified excitatory circuits and specific GluR family and subunit representation, ongoing studies combining postembed immunogold double-labeling techniques with anterograde transport are underway to investigate such links. The present data provide anatomical evidence for a complex array of AMPA and NMDA mediated synapses such that at a given synapse AMPA receptors may be represented alone, NMDA receptors represented alone, or both may be present, and potentially activated simultaneously. Supported by NIH grant AG06647.

782.4

CALCIUM-BINDING PROTEINS PARVALBUMIN, CALBINDIN AND CALRETININ DISPLAY DIFFERENTIAL COLOCALIZATION PATTERNS WITH GLUTAMATE RECEPTOR SUBUNIT PROTEIN GLUR2 IN MACAQUE MONKEY AREA V1. J.H. Morrison, P. Vissavajjhala, D.M. Blumberg, Y. Hu, W.G.M. Janssen, and P.R. Hof*. Fishberg Res. Ctr. for Neurobiol., Mount Sinai Sch. Med., New York, NY 10029.

The glutamate receptor subunit protein GluR2 critically influences the function of AMPA receptors by determining their permeability to calcium ions. Several studies have shown that GluR2 is differentially expressed in the vertebrate central nervous system. In the present study, we quantified the degree to which the CaBPs parvalbumin (PV), calbindin (CB), and calretinin (CR) were colocalized with GluR2 immunoreactivity in distinct populations of interneurons in the macaque monkey primary visual cortex. Using a monoclonal antibody to GluR2 (Vissavajjhala et al., 1996), and commercial polyclonal antisera to CaBPs, we observed that the three subgroups of CaBP-containing neurons exhibited substantial differences in laminar colocalization patterns of GluR2 immunolabeling. CR-positive cells showed the largest differences with up to 82% colocalization in layers II and IVC, 66% in layer III, while only 39% was observed in layers V-VI. GluR2 was present in 80% of the CB-positive neurons in layers II and IVC, whereas layers III and V-VI yielded 69 and 75%, respectively. The vast majority of PV-positive neurons contained GluR2 immunoreactivity, with 95% in each of layers II-IVB, IVC, and V-VI. Overall, 66% of CR-positive, 76% of CB-positive, and 95% of PV-positive neurons also contained GluR2. These populations represent a fraction of the total number of GluR2-immunoreactive neurons, as GluR2 is largely distributed in many classes of neurons in area V1, including pyramidal cells and interneurons. These data contrast with studies of CaBP-containing hippocampal interneurons in rats, which appear to be devoid of GluR2 labeling (Leranth et al., 1996). It is possible that major differences in GluR2 expression in interneuron subsets exist not only among mammalian species, but also between hippocampal and neocortical regions. GluR2 may thus differentially regulate calcium fluxes through AMPA receptors in distinct pools of cortical interneurons identified by the presence of CaBPs. Supported by NIH AG06647.

CHARACTERIZATION OF MONOCLONAL ANTIBODIES AGAINST IONOTROPIC GLUTAMATE RECEPTORS. P. Vissavajjhala*, T. Moran, Y. Hu, G. Velucelebi and J. H. Morrison. Fishberg Research Center for Neurobiology, Box 1065, Mount Sinai School of Medicine, New York, NY 10029 and SIBIA, La Jolla, CA 92037.

The ionotropic glutamate receptors (GluR) (both NMDA and AMPA/KA types) are heteromeric multi subunit proteins with each class consisting of a unique set of subunits. While there is extensive homology across subunits within a class, we have been successful in generating subunit specific monoclonal antibodies (MAb) that are highly characterized and useful for high resolution, dissection of the subunit representation at identified excitatory synapses in rat, monkey and human brains. The trpE fusion proteins of the N-terminal portions of the cloned, individual GluR subunits were used as antigens to raise the MAbs (GluR 1: 189-449; GluR 2: 175-430; GluR 3: 245-451; GluR 5 : 233-518; GluR 6: 200-376 amino acid residues of rat GluRs and NMDAR 2A: 1099-1213; NMDAR 2B: 1033-1161 amino acid residues of human NMDARs). The individual cDNAs of rat GluR subunits were expressed by transient transfection in HEK(293) cells. The cells were processed for immunocytochemical staining and the cell extracts for Western blot analysis. Each MAb was tested against the entire panel of transiently expressed GluRs (1-7) or NMDARs (NR 1a, b, 2a, b, c, and d) of rat for its specificity or cross reactivity against a mock transfected (the carrying vector without any cDNA) control. So far, from the initial screening we were able to identify three such MAbs specific for GluR 2, two for GluR 6, and one each for NMDAR 2A and 2B. The further characterization of one of the GluR 2 specific MAb (6C4), demonstrated the GluR 2 subunit in the dendrites of hippocampus and neocortex of rat brain sections at the light microscopic level and at the post-synaptic specialization in EM localization. These AMPA/KA and NMDA receptor subunit specific antisera will be particularly useful to develop comprehensive high resolution subunit-specific GluR profiles for identified excitatory circuits in rat, monkey and human brain. Supported by NIH AG06647.

DORSAL HORN NEURONS EXPRESSING CALCIUM-PERMEABLE AMPA RECEPTORS IDENTIFIED WITH THE COBALT STAINING TECHNIQUE C. Albuquerque, C.J. Lee, T.B.Allen, J.G. Gu* & A.B. MacDermott Department of Physiology and Cellular Biophysics and Center for Neurobiology and Behavior, Columbia University, New York NY 10032

Ca^{2+}-permeable AMPA receptors (CPARs) are expressed by embryonic dorsal horn neurons growing in culture (Reichling & MacDermott, 1993). We have adapted the method of cobalt staining originally developed by Pruss et al., (1991) to our dorsal horn neuron cultures to follow developmental changes in CAPR expression. First we confirmed that Co^{2+} permeates through CPARs but not through NMDA receptors or voltage-gated Ca^{2+} channels. Using fura-2 imaging at 360 nm excitation, the Ca^{2+}-insensitive excitation wavelength for fura-2, Co^{2+} entry was detected as Co^{2+} quenching of fura-2 fluorescence. When NMDA, kainate or high-potassium saline was applied to cells physiologically identified as CPAR-positive, only kainate induced detectable fura-2 quenching. For cobalt staining, dorsal horn cultures (from E16 rat embryos) were exposed to 250 µM kainate, in the presence of 5 mM $CoCl_2$ for 20 min, washed, and stained as in Pruss et al. (1991). Expression of CPARs was low during the first 5-6 days in culture, indicated by the majority of neurons showing little or no cobalt staining. CPAR expression levels increased dramatically with time in culture, such that after two weeks, the majority of dorsal horn neurons stained strongly with cobalt after kainate challenge. This staining could be blocked by the addition of 50 µM CNQX at the time of kainate application. The time course of increased CPAR expression coincides with the period of rapid synaptogenesis in embryonic spinal cord cultures, as verified by immunofluorescent staining with anti-synaptophysin antibody. Supported by NIH and The American Paralysis Association.

A GLUR2 SELECTIVE ANTIBODY SHOWS THAT GLUR2 AMPA RECEPTOR PROTEIN EXPRESSION VARIES AMONG HIPPOCAMPAL AND CEREBRAL CORTICAL NEURONS. R.S. Petralia*, Y-X. Wang, E. Mayat and R.J. Wenthold, Lab. of Neurochemistry, NIDCD, NIH, Bethesda, MD 20892.

The physiological properties of AMPA receptors depend on subunit composition. AMPA receptor complexes containing GluR2 are impermeable to calcium; conversely, AMPA receptors containing any combination of GluR1,3,&4 but lacking GluR2 readily pass calcium. All previous attempts to develop a GluR2-specific antibody (Ab) produced antibodies which cross-react with other AMPA receptor subunits - most commonly with GluR3 (i.e., GluR2/3 Abs). Thus, we have developed a GluR2 Ab which is highly specific. The peptide was conjugated to BSA through a cysteine attached to the C-terminus of the peptide and the resulting antiserum was affinity-purified in a two-part procedure. Rats were perfused with 4% paraformaldehyde with or without 0.1% glutaraldehyde for pre-embedding immunoperoxidase and immunofluorescence methods. This is the first study to show directly that telencephalon neurons *in vivo* contain significant amounts of GluR2 protein; in contrast, many neuron populations of the brain stem and spinal cord have little or no GluR2, while having significant amounts of GluR3 (as determined by GluR2/3 Ab staining). This indicates that, with the exception of some interneuron populations, most telencephalon neurons bear at least some calcium-impermeable AMPA receptors; in contrast, many brain stem structures contain mainly calcium-permeable AMPA receptors. Colocalization studies indicate that, in cerebral cortex/hippocampus neurons, the ratio of AMPA receptor subunit protein varies in neurons, suggesting that the number of calcium-impermeable AMPA receptor channels varies among neurons. Ultrastructural studies in the hippocampus reveal that, contrary to some findings, calcium-impermeable AMPA receptors are not limited to neuronal somas, but are found in spines along dendrites. (Supported by the NIDCD Intramural Program)

782.8

AMPA RECEPTOR SUBUNITS EXPRESSED BY SINGLE ASTROCYTES IN THE JUVENILE HIPPOCAMPUS. C. Steinhäuser*, G. Seifert, L. Rehn and M. Weber. Institute of Physiology I, University of Jena, D-07740 Jena, Germany.

The subunit composition of native AMPA receptor (AMPA-R) channels is well described in neurons but much less information is available on glial cells. Evidence from recombinant receptor studies suggests that the expression of distinct subunits determines the specific functional properties of the receptor channel.

We have previously shown that glial cells in hippocampal brain slices express different types of voltage and ligand gated ion channels. In the present study, we combined the patch clamp technique with the reverse transcription-polymerase chain reaction (RT-PCR) to correlate the expression of gene transcripts with functional properties of AMPA-R in single identified glial cells of the hippocampus. The cells were freshly isolated from the stratum radiatum of the CA1 subregion and were identified as immature astrocytes due to their morphological, immunocytochemical, and electrophysiological characteristics. After recording, the cells were harvested, and RT-PCR was performed with the same individual cell to investigate the subunit composition of glial AMPA-R.

Our results suggest the expression of a heteromeric subunit architecture. In all cells, the GluR2 subunit was present which is known to confer a low Ca^{2+} permeability to the receptor complex. Most frequently, we met co-expression of GluR2 and GluR4. These results confirm the predictions deduced from our recent findings on functional properties of AMPA-R in the same cell type. The preferential expression of GluR2/GluR4 distinguishes the glial cells from the different neuronal cell types in the hippocampus. Since the relative abundance of GluR2 and GluR4 mRNAs controls both the gating properties as well as the Ca^{2+} permeability of AMPA-R, variable expression of these gene transcripts enables a very sensitive and wide-range tuning of astroglial receptor functioning.

COEXPRESSION OF THE GLUR5-7 KAINATE RECEPTOR SUBUNITS AND TYROSINE HYDROXYLASE IN THE VENTRAL MESENCEPHALON. S. Bischoff[1]*, S. Leonhard[1], J. Barhanin[2] and S. Heinemann[3], [1]Ciba, Basel, Switzerland, [2]CNRS, IPMC, Valbonne, France, and [3]Salk Institute, La Jolla, CA 92037, USA.

The kainate receptor subunits GluR5, 6 and 7 are all expressed in the VTA-substantia nigra complex with diverse spatial distribution patterns (Bischoff and Heinemann, Neurosci. Abstr. 336.4, 1995). In this study, we examined the expression of GluR5-7 at the cellular level to find out whether it occurs in dopaminergic (DAergic) neurons. We performed in situ hybridization experiments on mouse brain coronal sections using simultaneously ^{35}S-labeled GluR and digoxigenine-labeled tyrosine hydroxylase (TH) riboprobes. GluR7 displayed high expression in all neurons (but not glial cells) in the VTA and in the substantia nigra pars compacta (SNc). Virtually all cells exhibiting TH mRNA were also expressing the GluR7 gene. GluR7 mRNA was also observed in a small number of cells (20%) that were TH negative. GluR6 was moderately expressed in a limited number of cells in the VTA and SNc (especially in the ventro-medial tier), that were not TH positive. Finally, GluR5 exhibited a very restricted expression pattern: labeled mRNA was only detected in the ventral SNc, but not in the dorsal, the lateral or the ventro-medial aspects, nor in the VTA. All GluR5-expressing cells were also TH positive. In conclusion, as KA2 usually coexpresses with GluR6 and KA1 is absent in this complex, GluR7 represents the major kainate receptor subunit within the mesencephalic DAergic neurons. The GluR5 gene is also present in some DAergic neurons, but only in a very restricted part of the SNc. Finally, the GluR6 gene is clearly not a constituent of DAergic neurons. This study provides evidence that in most VTA-SNc DAergic neurons, GluR7 does not assemble with any of the other known kainate receptor subunits. Supported by NINCDS grants to S.H. (NS11549 and NS28709) and the McKnight Foundation (S.H.).

COLOCALIZATION OF THE MU OPIOID AND NMDAR1 GLUTAMATE RECEPTORS IN THE SHELL OF THE RAT NUCLEUS ACCUMBENS K.N. Gracy*, A.L. Svingos, and V.M. Pickel., Department of Neurology and Neuroscience Division of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Mu-opioid receptors (MOR) and N-methyl-D-aspartate (NMDA) -type glutamate receptors have overlapping distributions in the shell of the nucleus accumbens, where their ligands have been implicated in opiate withdrawal and the mediation of locomotor activity. We examined the ultrastructural basis for functional interactions involving MOR and NMDAR1 in the shell of the nucleus accumbens of the adult rat brain. Tissue sections through this region were dually labeled with antisera against each receptor. Immunogold-silver labeling for MOR was mainly seen at extrasynaptic sites along the plasma membrane of spiny dendrites most of which received asymmetric excitatory-type synapses from unlabeled terminals. Immunoperoxidase labeling for NMDAR1 was also intensely localized to extrasynaptic plasma membranes of small dendrites and dendritic spines but also showed a more diffuse labeling of asymmetric postsynaptic junctions and cytoplasmic organelles. These dendrites often contained detectable MOR-like immunoreactivity (MOR-LI). Axons and axon terminals were less frequently immunoreactive for MOR and/or for NMDAR1. The terminals containing one or both markers usually formed asymmetric synapses with unlabeled dendritic spines. These results suggest that ligands of MOR and NMDAR1 dually modulate the nucleus accumbens 1)mainly through direct effects on the excitability of spiny neurons and 2) less prominently through presynaptic effects on excitatory afferents. THE EXPRESSION OF THE AMPA RECEPTOR IN THE DEVELOPING RODENT BASAL GANGLIA. M. W. Jakowec*, V. Jackson-Lewis, J. W. Langston, and S. Przedborski. The Parkinson's Institute, Sunnyvale, CA, 94089 and, Department of Neurology, Columbia University, NY, NY, 10032.

We are interested in determining the expression patterns of the AMPA receptor subtype of the glutamate receptor in the developing basal ganglia. We have used immunocytochemistry with antibody probes against GluR1, 2/3, and 4 and in situ hybridization with riboprobes which recognize the full length subunit transcript and oligoprobes which recognize either the flip or flop transcript isoform. Our results indicate that the GluR1 receptor subunit transcript is developmentally regulated in the striatum; it is expressed at high levels in the neonatal striatum but shows reduced expression in the adult. The subunit transcript for GluR2 also appears to be developmentally regulated but less dramatically than GluR1. Both the flip and flop isoforms of GluR1 and GluR2 are expressed. The transcripts for GluR3 and GluR4 are detectable at levels much lower levels but do not appear to be developmentally regulated. Results with immunocytochemistry supports the observations found using in situ hybridization.

ORGANIZATION OF AMPA RECEPTOR SUBUNITS AT A GLUTAMATE SYNAPSE: A QUANTITATIVE IMMUNOGOLD ANALYSIS OF THE INNER HAIR CELL-AFFERENT DENDRITE SYNAPSE IN THE RAT ORGAN OF CORTI. O.P. Ottersen[1], A. Matsubara[1,2], J.H. Laake[1], E. Rinvik[1]* and S.-i. Usami[2]. [1]Department of Anatomy, Institute of Basic Medical Sciences, University of Oslo, P.O. Box 1105 Blindern, N-0317 Oslo, [2]Department of Otorhinolaryngology, Hirosaki University School of Medicine, Hirosaki, 036 Japan.

Sensitive immunogold procedures based on freeze substituted tissue, Lowicryl resins, and postembedding labelling with 15 nm or 1.4 nm gold particles (the latter made visible by silver enhancement) were used to investigate the arrangement of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors (GluR1-4) at the inner hair cell-afferent dendrite synapse in the rat organ of Corti. This synapse was used as an experimental model since it exhibits a presynaptic body that defines the center of the synapse and the preferential site of exocytotic release. Single and double labelling with different gold particle sizes indicated that GluR2/3 and GluR4 subunits were colocalized throughout the postsynaptic density (compatible with their forming heteromeric receptors), with a maximum distance of 300 nm from the presynaptic body and with higher concentrations peripherally (peak at about 200 nm) than centrally (near the presynaptic body). Up to 60 silver enhanced gold particles occurred per profile of postsynaptic density. Very little immunolabelling was found at extrasynaptic membranes and in the interior of the postsynaptic element, but some GluR4 subunits appeared to be expressed presynaptically. Antibodies to GluR1 produced no labelling at the inner hair cell synapse but they did label synapses in coprocessed hippocampal sections. The present data indicate that AMPA receptor subunits are inserted into the postsynaptic membrane in a very precise manner.

ANALYSIS OF C-TERMINAL SPLICE VARIANTS OF THE NMDA NR1 SUBUNIT IN SPINAL CORD USING SEQUENCE SPECIFIC ANTISERA. M. J. Iadarola*, D.J. Kim and R. M. Caudle. NAB, NIDR, NIH, Bethesda MD, 20892

The primary transcript of the NR1 subunit of the NMDA receptor can undergo three alternative splicing events yielding 8 possible splice variants. Differential splicing of the three cassettes can have profound effects on channel conductance and regulatory processes. Two alternative splice cassettes, C1 and C2, can alter the C-terminus of the receptor. Removal of C2 alters the translation stop and produces a new short reading frame of 22 amino acids. The presence or absence of the C2 cassette allows the NR1 splice variants to be divided into two groups that can be distinguished using C-terminal specific antisera. We have examined the expression of these sets of receptors by western blot and immunocytochemical methods. Rabbit polyclonal antisera were generated against 2 synthetic peptides conjugated to MBS derivatized KLH. The peptide within the intact C-terminus (i.e. with C2 not spliced out) was PRRAIEREEGQLQLC, this recognizes splice variants A,B,C,F (A1 Ab). The sequence within the alternatively spliced C-terminus (i.e. C2 spliced out) was QYHPTDITGPLNLSDPS[C]. This recognizes splice variants D,E,G (D2 Ab). Both sera were antigen affinity purified against immobilized target peptide and both sera recognized an ~110 kDa protein on western blots of crude membranes prepared from spinal cord or brain. Immunocytochemical localization in spinal cord suggested differential cellular localizations for the two sets of splice variants. Subunits lacking the C2 cassette (D2 Ab) were densely represented on neuronal perikarya and dendrites in all spinal laminae, although some were stained darker than others. Staining for subunits containing the C2 cassette (A1 Ab) were located in axons in all spinal laminae. Perikarya and dendrites were lightly reactive, with well stained perikarya occurring infrequently. Staining and reactivity on western blots could be blocked by adsorption with the antigenic peptide but not by unrelated peptide. Our data suggest the possibility of a differential cellular localization of alternatively spliced NR1 subunits in spinal cord neurons. IRP/NIDR/NIH

NMDA RECEPTOR-1 SPLICE VARIANTS: DIFFERENTIAL CELLULAR EXPRESSION IN THE CENTRAL NERVOUS SYSTEM OF THE ELECTRIC FISH *APTERONOTUS LEPTORHYNCHUS*. D. Bottai[1], B. Ellis[2], L. Maler*[2] and R. J. Dunn[1] (1) Mc Gill University Montreal Gen. Hosp. (2) University of Ottawa.

Recently much attention has been focused on the NMDAR channel complex because of its proposed role in brain development, learning and neurodegeneration. The NMDA receptor contains two different types of subunits, NR1 and NR2 (A, B, C, D). The NR1 gene has 22 exons, three of which (exons 5, 21 and 22) undergo alternative splicing that can generate eight splice variants.

In the present work we have analyzed the distribution of NR1 mRNA isoforms in different regions of the central nervous system (CNS) of the electric fish *Apteronotus lepthorynchus*, a useful model for the study of sensory transmission. NR1 expression was detected in all regions of the CNS, but at different levels. The highest level of expression was found in forebrain, lower levels in the electrosensory lateral line lobe (ELL) and very low levels in cerebellum. *In situ* hybridizations show that NR1 transcripts are highly expressed in pyramidal and granular cells of the ELL. In contrast, only low levels were seen in polymorphic cells although these cells receive abundant glutaminergic inputs.

Exon 5, which is present in the NR1b transcript, is highly conserved between fish and rat (20/21 AA). We have examined the relative abundances of NR1a and NR1b transcripts using RNase protection and *in situ* hybridization methods. We found the highest relative level of NR1b in ELL and brainstem, while forebrain contains mainly NR1a transcript.

NMDA RECEPTOR EXPRESSION IN IDENTIFIED NEURONS DURING DEVELOPMENT. G. Nase[1], J. Weishaupt[2], P. Stern[1], W. Singer[1] and H. Monyer*[2]. [1]MPIH, Deutschordenstr. 46, D-60528 Frankfurt, [2]ZMBH, Im Neuenheimer Feld 282, D-69120 Heidelberg.

N-methyl-D-aspartate (NMDA) receptors are thought to be involved in experience-dependent plasticity of the developing mammalian cortex. NMDA receptor-mediated excitatory postsynaptic currents (EPSCs) in the visual cortex seem to be regulated by neural activity during a critical period in early postnatal development and shorten in parallel with the reduction in synaptic plasticity. In recombinant binary NR1-NR2 channels the gating properties of the NMDA channel are determined by the NR2 subunit, with NR1-NR2A showing the fastest whole cell kinetics. It is unclear so far whether a change in the relative expression levels of the transcripts encoding the four NR2 subunits NR2A-D underlies the observed experience-dependent change in NMDA receptor mediated EPSC kinetics. If so, one would predict a difference in the relative abundance of mRNAs encoding NR2A-D. Furthermore, this ratio should be sensitive to treatments, affecting the critical period in visual development. Hence, we investigated NMDA receptor subunit expression in layer IV pyramidal cells in acute brain slices of P12 and P25 rats. Pyramidal cells were identified based on their morphology and action potential pattern and the molecular analysis was performed using the single cell RT-PCR method. The expression of NR2C and NR2D at both time points is either absent or fairly low in this cell population. The expression levels of NR2A and NR2B on the other hand are developmentally controlled. The data indicate a decrease of NR2B mRNA relative to that of total NR2 mRNA from 79% ± 5.7 (mean ± s.e.m., n=17) at P12 to 55.9% ± 13 (n=10) at P25 whilst there is an increase in the relative amount of NR2A mRNA from 15% ± 4.9 (n=17) at P12 to 33.3% ± 11 (n=10) at P25. Additional experiments will address the question whether developmental changes of NR2 subunit expression will be altered by dark-rearing.

CLONING AND ANALYSIS OF ALTERNATIVELY SPLICED ISOFORMS OF AMPA RECEPTORS FROM CHICK. A. Ravindranathan*, T. N. Parks and M. S. Rao. Department of Neurobiology and Anatomy, University of Utah School of Medicine, Salt Lake City, UT 84132.

AMPA receptor subunits (GluRs 1-4) in rodents exist as two alternatively spliced isoforms, termed *flip* and *flop*, which differ in their functional properties. To demonstrate the presence of alternatively spliced AMPA receptors in the chick brain, we PCR-amplified and cloned the *flip* and *flop* isoforms for each AMPA receptor subtype from E17 chick brain using degenerate primers. Sequence analysis showed that the alternatively-spliced isoforms for each AMPA receptor were similar to each other except in the *flip/flop* splice domain. The cloned fragments also showed a high degree of homology (~ 89%) with the corresponding rat AMPA receptor splice variant. Restriction endonucleases that distinguish between the isoforms were identified and then used to determine relative levels of *flip* and *flop* in the chick brain. These isoforms have distinct levels of expression in the brain with the *flop* isoform expressed at consistently higher levels in the midbrain and cerebellum. In addition to the *flip* and *flop* isoforms, we have cloned two other variants of GluR4. One of these is similar to GluR4c, a variant previously cloned from a rat cerebellar cDNA library. Chick GluR4c exists as both *flip* and *flop* isoforms which show differences in their spatial and temporal expression. The other variant, a shorter version of GluR4, lacks the *flip/flop* segment as well as the GluR4c splice region. These two isoforms of GluR4 are now being further characterized.

OVEREXPRESSION AND PURIFICATION FROM E. COLI OF A SYNAPTIC MEMBRANE GLUTAMATE BINDING PROTEIN. S. Islam*, R. Pal, K.N. Kumar, and E.K. Michaelis. Dept. of Pharmacol. & Toxicol. and Ctr. for Neurobiol. & Immunol. Res., Univ. of Kansas, Lawrence. KS 66045

Bacterially expressed receptors have been shown to retain their ligand binding properties, making bacteria useful sources for overexpression of such proteins (JBC 268:7885, 1993). Previous reports from our laboratories described the isolation and characterization of a complex of synaptic membrane proteins exhibiting the properties of an NMDA-sensitive receptor-ion channel (JBC 269:27384, 1994). The cloned glutamate binding protein (GBP) from this complex has been subcloned into the pET system and overexpressed in bacteria under the control of a T7 RNA polymerase. The expressed protein has been purified from the inclusion bodies by extraction with Triton X-100/CHAPS detergent solution, affinity chromatography on an L-glutamate-derivatized trisacryl matrix, and continuous elution electrophoresis. The purified protein retained its glutamate binding activity and the pharmacological characteristics present in the purified brain protein. The antibodies raised against the brain protein recognize the GBP from *E. coli*, and antibodies raised (by Promega) against the *E. coli*-expressed protein recognize the brain protein. When the antibodies directed against the expressed protein were examined in immunohistochemical studies of rat brain, they showed the same pattern of immunoreactivity as we have reported for the antibodies directed against the purified brain protein. Based on the similarities between the *E. coli* expressed protein and the brain GBP, we are currently using the former to perform a series of structural investigations on this protein. QUANTITATIVE DISTRIBUTION OF EXCITATORY AMINO ACID BINDING IN TWO CEREBELLAR MUTANT MICE. C. Strazielle, R. Lalonde*, M.I. Botez, and T. Reader. Université de Montréal, Centre de Recherche en Sciences Neurologiques, Montréal, Canada H3C 3J7 and Université de Nancy 1, Laboratoire de Neuro-anatomie fonctionnelle, France.

The localization of glutamate and kainate binding sites was determined by quantitative receptor autoradiography in normal mice and two cerebellar mutant mice: lurcher and dystonia musculorum (dt). Lurcher mutants are characterized by degeneration of Purkinje cells and granule cells. The dt mutants are characterized by degeneration of spinocerebellar tracts and dystrophic sensory nerve fibers. In lurcher mutants, the number of glutamate and kainate receptor sites corrected for surface tissue loss in the cerebellum was reduced in comparison to normal mice by over 80%. No change was detected in dt mutants. Cerebellar cell losses in lurchers include those with glutamate and kainate receptors, whereas in dt mice these receptors are preserved.

MOLECULAR CHARACTERIZATION OF GLUTAMATE RECEPTORS IN RAT HEART. **S. Gill; O. Pulido*; R. Mueller. Pathology Section, Toxicology Research Div., Bureau of Chemical Safety; Food Dir., HPB, Health Canada, Ottawa, Ontario, Canada K1A 0L2.**

A family of glutamate receptors mediate neurotransmission of excitatory amino acids in brain. The AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid) glutamate receptors (GluR) and kainate receptors are a subclass of ionotropic glutamate receptors that form cation selective channels. Many xenobiotics that interfere with ion channels are known to induce cardiotoxicity. Knowledge of glutamate receptors outside the CNS and their possible involvement in excitotoxicity in peripheral sites is very limited. Clinical data such as palpitations associated with the ingestion of monosodium glutamate suggest cardiovascular effects. The purpose of this study was to assess the presence of glutamate receptors in the rat heart using molecular biology techniques. The ionotropic glutamate receptors GluR3, GluR4, GluR7 and Kainate 1 were cloned from the total RNA of the rat heart using PCR. The individual PCR products were cloned and sequenced. The sequence of these clones showed high homology to the glutamate receptors in the rat brain. These receptors were further characterized by western analysis and in situ hybridization. Immunohistochemical studies were also consistent with these findings.

MODULATION OF EXCITABILITY IN RAT SPINAL PREGANGLIONIC NEURONS BY THYROTROPIN-RELEASING HORMONE (TRH). M. Kolaj*[1], S. Shefchyk[2] and L. P. Renaud[1]. [1]Neuroscience, Loeb Research Institute, Ottawa Civic Hospital and Univ. Ottawa, Ottawa, Ontario, CANADA K1Y 4E9, [2]Department of Physiology, Univ. Manitoba, Winnipeg, Manitoba, CANADA R3E 0W3

TRH, one of the principal hypothalamic peptides involved in the regulation of thyroid-stimulating hormone secretion from the anterior pituitary is also present in many extrahypothalamic regions. It is presumed that in these regions, including spinal cord, TRH may have a neurotransmitter or neuromodulator role. We used whole-cell patch-clamp techniques to examine the action of bath applied TRH on sympathetic preganglionic neurons (SPNs) in neonatal rat (11-21 days) spinal cord slices. SPNs were identified by retrograde labelling with dextran tetramethyl rhodamine lysine from the adrenal gland. Under current-clamp conditions the application of TRH produced reversible depolarization which was accompanied by a decrease in membrane conductances in most tested cells. In cells clamped to -55mV, TRH induced a reversible dose-dependent inward current due to reduction in a membrane potassium ion conductance. The response persisted in the presence of tetrodotoxin suggesting a postsynaptic site of action. Intracellular dialysis with GTP-γ-S, a non hydrolysable analogue of GTP significantly enhanced the amplitude and duration of the TRH effect. These results indicate that the activation of TRH receptors on SPNs is mediated through the activation of a G-protein(s). This action may contribute to the CNS regulation of sympathetic autonomic nervous system function. Supported by MRC and the Heart and Stroke Foundation of Canada.

PITUITARY ADENYLATE CYCLASE-ACTIVATING POLYPEPTIDE AND THYROTROPIN-RELEASING HORMONE COLOCALIZES IN NEURONS OF THE RAT HYPOTHALAMUS. G. Légrádi, J. Hannibal and R. M. Lechan.* Division of Endocrinology, New England Medical Center Hospital, Boston, MA 02111 and University Dept. of Clinical Biochemistry, Bisjepberg Hospital, Copenhagen, Denmark.

Pituitary adenylate cyclase-activating polypeptide (PACAP) is present in many regions of the hypothalamus including the paraventricular nucleus (PVN). Since its distribution is similar to that of TRH, we investigated the topographical relationship between these two peptides in the rat hypothalamus. Using a well-characterized mouse monoclonal antibody against PACAP (1:5) and a rabbit polyclonal antiserum against TRH (1:6,000), we found that PACAP-immunoreactivity (ir) and TRH-ir extensively coexist in perikarya of the medial preoptic area, lateral hypothalamus and the perifornical cell group. Coexistence of the two peptides in perikarya of the PVN was limited to a few neurons in the medial and periventricular subdivisions. Numerous beaded nerve fibers with PACAP-ir, however, were closely apposed to TRH neurons in the PVN indicating possible synaptic contacts. These findings demonstrate the common association between PACAP and TRH in the hypothalamus, indicating that PACAP might act as an important cofactor in the function of TRH neurons. The potential interaction between PACAP-containing neuronal processes and TRH neurons in the PVN suggests that PACAP may modulate the secretion of TRH destined for regulation of anterior pituitary TSH.

783.3

DISTRIBUTION OF PITUITARY ADENYLATE CYCLASE ACTIVATING POLYPEPTIDE (PACAP) IMMUNOREACTIVITY IN THE HYPOTHALAMUS AND EXTENDED AMYGDALA OF THE RAT. H.D. Piggins*, J.A. Stamp, B. Rusak, and K. Semba. Depts. of Anatomy & Neurobiology, and Psychology, Dalhousie University, Halifax, CANADA B3H 4H7.

PACAP is found in two forms of 27 and 38 amino acids (PACAP-27 and PACAP-38 respectively) in the mammalian central nervous system. Using novel polyclonal antibodies to these two forms of PACAP, we examined the distribution of PACAP immunoreactivity in the rat hypothalamus and in a number of extrahypothalamic areas. The patterns of immunostaining for PACAP-27 and PACAP-38 were similar: prominent terminal labelling was present in the retrochiasmatic area, median eminence, and posterior periventricular nucleus of the hypothalamus as well as the bed nucleus of the stria terminalis (BNST) and amygdaloid complex. After colchicine treatment, immunopositive cell bodies were found in the preoptic region of the periventricular zone of the hypothalamus, the suprachiasmatic (SCN) and paraventricular hypothalamic nuclei, the retrochiasmatic area, arcuate nucleus, ventromedial hypothalamus, and tuber cinereum, and the lateral mammillary and supramammillary nuclei. In all these areas, immunolabelling appeared to be specific since it was abolished by preabsorption of primary antisera with the appropriate PACAP peptide. In addition, however, the number of immunopositive cells in the SCN was reduced by preabsorption of PACAP-27/38 antisera with vasoactive intestinal polypeptide, suggesting that a subpopulation of cells in the SCN express a peptide which has significant sequence homology with both PACAP-27/38 and vasoactive intestinal polypeptide. The distribution of PACAP immunoreactivity throughout the hypothalamus, BNST, and amygdala suggests the involvement of PACAP in limbic, autonomic, and neuroendocrine functions.

PITUITARY ADENYLATE CYCLASE ACTIVATING POLYPEPTIDE (PACAP) EXPRESSION IN SYMPATHETIC PREGANGLIONIC NEURONS INNERVATING THE SUPERIOR CERVICAL GANGLION. M.M. Beaudet*, K.M. Braas & V. May. Dept. of Anat. & Neurobiol., Univ. of Vermont Coll. of Med., Burlington, VT 05405.

Pituitary adenylate cyclase activating polypeptides (PACAP27 and PACAP38), members of the VIP/secretin/glucagon peptide family, have diverse effects on neuroendocrine tissues and cells of the sympathoadrenal lineage. PACAP peptides regulate superior cervical ganglion (SCG) neuronal catecholamine and neuropeptide Y levels and secretion through activation of specific isoforms of the type I PACAP-selective receptor. Sympathetic preganglionic neurons in the intermediolateral column of the thoracic spinal cord provide the primary afferent projections to the SCG, suggesting that they may be one of the endogenous sources of regulatory PACAP for the SCG. Spinal cord segments from thoracic levels T1-T4 contained approximately 17 pmol PACAP38 immunoreactivity/g wet weight. Using primers specific for neuronal PACAP, reverse transcription polymerase chain reaction of total RNA from T1-T4 spinal cord segments identified PACAP mRNA expression. To demonstrate the expression of PACAP in preganglionic neurons projecting to the SCG , the SCG was decentralized and the cervical sympathetic trunk retrogradely labeled with fluorogold. Cryosections of T1-T4 were examined for fluorescent labeling and subsequently processed for *in situ* hybridization histochemistry using a digoxigenin-labeled PACAP riboprobe. Comparison of the fluorogold and digoxigenin labeling demonstrated that a substantial population of preganglionic sympathetic neurons projecting to the SCG express PACAP mRNA. These results suggest that a population of preganglionic neurons of the thoracic spinal cord which project to the SCG are capable of synthesizing PACAP, and may regulate sympathetic neuronal function. Additional studies are examining colocalization of PACAP and other transmitters/peptides. Supported by HD27468 and NS01636 (VM) and VHA9506248S (KMB).
