Neurons of the superior cervical ganglion (SCG) synthesize a number of neuropeptides and neurotransmitters, and expression of these substances is regulated by both anterograde and retrograde signals. Previous studies demonstrated that PACAP27 and PACAP38 are among the peptides synthesized and released by principal neurons of the rat SCG (Brandenburg *et al.*, Neurosci Abstr 21:1598). The contributions of anterograde and retrograde signals in the regulation of sympathetic neuron PACAP have been examined *in vivo*. The preganglionic cervical sympathetic trunk (decentralization) and the postganglionic internal and external carotid nerves (axotomy) of adult male rats were cut; additional animals underwent either decentralization or axotomy alone. Following combined axotomy/decentralization, PACAP38 peptide content increased over 40-fold compared to control ganglia, whereas NPY levels were unchanged. By comparison, the same treatment elevated VIP expression approximately 20-fold (Hyatt-Sachs *et al.*, J Neurosci 13:1642). Decentralization alone resulted in less than a 2-fold increase in PACAP peptide levels. Thus, similar to other neuropeptides, target-derived factors appear to have a greater impact on PACAP expression than presynaptic input. Current studies are examining whether changes in PACAP38 levels are paralleled by increases in pro-PACAP mRNA and reflect a change in the amount of peptide per neuron and/or a change in the number of neurons expressing the peptide. These results demonstrate that SCG PACAP is plastic in nature and can be regulated by a combination of anterograde and retrograde signals, thereby adding another level of complexity to the neurochemical profile of sympathetic neurons. MULTIPLE ACTIONS OF PITUITARY ADENYLATE CYCLASE ACTIVATING POLYPEPTIDE (PACAP) ON RAT SYMPATHETIC PREGANGLIONIC NEURONS IN VITRO. S. Y. Wu* and N. J. Dun. Dept. of Anatomy & Neurobiology, Medical College of Ohio, Toledo, OH 43614.

PACAP-like immunoreactive nerve fibers have been detected in the rat intermediolateral cell column and other sympathetic nuclei. Effects of PACAP-38 or PACAP-27 on sympathetic preganglionic neurons (SPNs) of immature rat spinal cord slices were studied by the whole-cell patch technique. PACAP (1-10 nM) by superfusion produced an intense neuronal discharge with or without a membrane depolarization; the discharge lasted from minutes to over 1 hr. PACAP by pressure ejection also caused in the majority of SPNs a slow depolarization associated with an increase of membrane resistance. PACAP induced a biphasic response: a fast followed by a slow depolarization in a small number of SPNs. The phasic response was associated with a decrease of membrane resistance. The slow depolarization induced by PACAP was not blocked by prior superfusion of the slices with the type II PACAP receptor antagonist PACAP (6-38, 30 nM), but was prevented by MDL-12,330A (25 μM), an adenylate cyclase inhibitor. Vasoactive intestinal polypeptide, which is structurally related to PACAP, had no significant effect on SPNs. In addition to the membrane effects, PACAP (10-30 nM) selectively enhanced the NMDA-receptor mediated excitatory postsynaptic potentials (EPSPs) evoked by dorsal root stimulation. PACAP had no significant effect on AMPA-receptor mediated EPSPs evoked by stimulation of the lateral funiculus. Similarly, PACAP selectively increased the membrane depolarizations elicited by exogenously applied NMDA but not by AMPA. The present study shows that PACAP exerts at least three distinct effects on SPNs: a fast and slow depolarization that may be coupled to different ionic channels and a selective enhancement of NMDA-receptor mediated responses. EFFECTS OF PACAP AND EGF ON PROLIFERATION AND MAP KINASE IN CULTURED RAT ASTROCYTE

I. Moroo[1], I. Tatsuno[2,3], T. Tanaka[2], D. Uchida[2], A. Hirai[2], K. Kawasaki[4]*and Y. Saito[2], Depts. of [1]Neurology and [2]Internal Medicine 2, Chiba Univ. Sch. of Med.; [3]Health Science Center, Chiba Univ., Chiba; [4]Shionogi Research Labs., Shionogi Co. Ltd., Osaka, Japan.

Astrocytes are one of the most important subtypes of glia since they are reported to have multiple important roles in support of neuronal functions, especially after injury through the production of neurotrophic factors (NTs) and/or its proliferation. Neuropeptides have been reported to play an important role for the regulation of these functions. Pituitary adenylate cyclase activating polypeptide (PACAP) could be one of these important neuropeptides since it was reported that astrocytes posses an abundant number of its receptor and PACAP stimulates the accumulation of cAMP. Recently we found that PACAP stimulates the production of IL-6, one of NTs. In the present study, we focused the effect of PACAP on the proliferation (uptake of [^{3}H]thymidine) and the activation of MAP kinase (the altered electrophoretic mobility in Western blot analysis and the phopholiration against myelin basic protein), which is a critical step of the intracellular signals for the proliferation, with stimulation of epidermal growth factor (EGF). EGF stimulated its proliferation in a dose-dependent manner with the activation of MAP kinase and reached a plateau at 1 ng/ml. PACAP38 increased the proliferation of astrocyte stimulated by EGF at as low a concentration as 10^{-13}M in an additive manner with the activation of MAP kinase, however, which decreased its proliferation and activity of MAP kinase from 10^{-9}M in a dose-dependent manner. These data suggested that PACAP38 modulates the proliferation of astrocyte induced by EGF in a biphasic manner and the MAP kinase could be one of the important intracellular signals for PACAP to modulate the proliferation.

SUPRESSION OF VIP-BINDING SITES IN ARTERIES OF THE HAMSTER SEMINAL VESICLE FOLLOWING CASTRATION. S. Gulbenkian*, C.P. Barroso, F. Afonso, M. Castro Caldas, M.S. Pinho and L. Mata. Lab. of Cell Biology, Gulbenkian Inst. of Sci., 2781-Oeiras, Portugal.

We investigated the presence and distribution of vasoactive intestinal polypeptide (VIP) binding sites in arteries supplying the hamster seminal vesicle before and after castration.

Young adult male hamsters were castrated by scrotal route and sacrificed 15 days later. Seminal vesicles were dissected out and processed for receptor autoradiography. Unfixed cryostat sections (12 µm) from intact and castrated hamsters, were incubated with 0.125 nM ^{125}I-VIP either in the absence or in the presence of 1.250 µM unlabeled VIP to assess specific or non-specific binding, respectively. Autoradiograms were obtained by dipping in LM1 (Amersham), exposed for 24 hours at 4°C, and analyzed by a computerized image analysis system (JAVA V1.40-Jandel Scientific). Results were compared by one way analysis of variance (ANOVA).

Our results show that VIP-binding sites are localized in the gland muscle coat and arterial smooth muscle. Although a 15 day-period of castration has no effect on the binding of ^{125}I-VIP to the gland muscle coat, it abolishes the binding to the vascular smooth muscle.

Our results indicate that VIP-binding sites in arteries supplying the hamster seminal vesicle are under androgenic control and are more sensitive to androgen deprivation than VIP-binding sites associated to the gland muscle coat.

COMPARATIVE DISTRIBUTION OF SOMATOSTATIN ANALOGS TO TARGET TISSUES. T.P. Davis, A. Erenberg, S.C. Moreau, J.E. Taylor*, and T.J. Gillespie. Department of Pharmacology, The University of Arizona, Tucson, AZ 85724 and Biomeasure, Inc., Milford, MA 01757 USA.

Somatostatin receptors (SSr) are abundant in brain, pituitary, pancreas, adrenals, gut, stomach, kidney and lung. Many cancer tumors such as pituitary adenomas, carcinoids, pancreatic carcinomas, meningiomas, small cell lung carcinomas (SCLC), prostate, and some breast tumors are markedly elevated in SSr. BIM23014 (Nal-C-Y-W-K-V-C-T-NH2) a somatostatin analog has been used in treatment of acromegaly, SCLC, and prostate cancer. In this study, we compared in time course manner, the *in vivo* (rat) distribution of BIM23014, to newer analogs BIM23190 (N-hydroxyethylpiperazinyl-acetyl-F-C-Y-K-Abu-C-T-NH2) and BIM23197 (HEPES-F-C-Y-W-K-Abu-C-T-NH2). Time to peak tissue distribution following s.c. injection with I-125 labeled peptide was 20 to 30 min for most tissues. Tissue distributions of BIM23190 and BIM23197 were remarkably similar, but they differed considerably from that of BIM23014. Peak concentrations of BIM23190/197 (% injected dose/g tissue) were several fold higher (3 to 19) in stomach, large intestine, kidney, pituitary, seminal vesicles, and adrenal than those of BIM23014. Peak concentrations of BIM23014 however were 3 fold higher in lung and small intestine than those of BIM23190/197. Total clearance of BIM23014 (150 ml/kg/hr) was lower than that of BIM23190 (188 ml/kg/hr) or BIM23197 (194 ml/kg/hr). BIM23014 was much less stable *in vivo* than BIM23190/197. Radioactivity extracted from plasma obtained 1h post injection, contained 10% intact BIM23014, and 86 and 81% intact drug from BIM23190 and BIM23197 treated rats respectively. Due to higher distribution to target tissues, and greater *in vivo* stability, BIM23190/197 may prove clinically superior to BIM23014 for most applications. SOMATOSTATIN DEPRESSES EXCITATORY BUT NOT INHIBITORY POSTSYNAPTIC CURRENTS IN RAT CA1 HIPPOCAMPAL NEURONS. M. Tallent* and G.R. Siggins. Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037

The neuropeptide somatostatin (SST) has been reported to elicit both excitatory and inhibitory effects in the hippocampus; therefore the role of SST in this brain region remains controversial. Because SST is co-localized with the inhibitory neurotransmitter GABA in interneurons, it is speculated to play a role in inhibitory neurotransmission. To determine how SST might be involved in hippocampal synaptic transmission, we used intracellular voltage-clamp recording to examine SST effects on pharmacologically isolated, monosynaptic currents in CA1 pyramidal cells in the rat hippocampal slice preparation. We placed a bipolar stimulating electrode in the stratum oriens or locally across the pyramidal cell layer to elicit excitatory (EPSC) or inhibitory (IPSC) postsynaptic currents, respectively. We used three different stimulus strengths to generate input/output curves. Bath application of 1 μM SST inhibited NMDA and non-NMDA EPSCs to a similar degree. A maximal inhibition of 30-40% occurred 4-5 minutes after onset of SST superfusion. We observed little attenuation of the SST effect over the time-course of application (up to 20 minutes), indicating that rapid desensitization does not occur. In contrast, SST did not modulate either $GABA_A$-or GABA-mediated IPSCs, even when applied for up to 25 minutes. Selective attenuation of excitatory input to CA1 neurons suggests that the net effect of SST on pyramidal cells is inhibitory; thus SST appears to be acting synergistically with GABA. Our results differ from previous findings in which current-clamp was used to show that SST preferentially inhibited composite IPSPs in rabbit (Scharfman and Schwartzkroin, Br. Res., 1989, 493: 205-211) and guinea pig (Xie and Sastry, Br. Res., 1992, 591: 239-47) CA1, with little or no effect on composite EPSPs. These discrepancies could arise from lack of isolation of synaptic components or other methodological differences. *Supported by NIH grants MH 44346 and AA 07456.*

CORTISTATIN, A NOVEL NEUROPEPTIDE WITH NEURONAL DEPRESSANT AND SLEEP - MODULATING PROPERTIES. L. de Lecea[1]*, J.R. Criado[2], O. Prospero[2], K.M. Gautvik[1], P. Schweitzer[2], G.R. Siggins[2], S.J. Henriksen[2], J.G. Sutcliffe[1]. Depts. of Molecular Biology[1] and Neuropharmacology[2] ,The Scripps Research Institute, La Jolla, CA 92037

We report the cDNA cloning of an mRNA encoding the precursor of a novel neuropeptide, cortistatin, whose deduced amino acid sequence shares 11 of 14 residues with somatostatin. Preprocortistatin is expressed postnatally in the rat brain in a subset of cortical and hippocampal interneurons that partially overlap with those expressing somatostatin. Synthetic cortistatin binds to somatostatin receptor subtypes in vitro with selective affinities and, like somatostatin, induces neuronal hyperpolarization and enhances the voltage-dependent potassium M-current. Intracerebroventricular administration of cortistatin enhances slow-wave sleep and antagonizes the effects of acetylcholine on different measures of cortical excitability, suggesting a mechanism of cortical synchronization related to sleep.

EFFECTS OF NOCICEPTIN ON EXCITATORY AND INHIBITORY SYNAPTIC TRANSMISSION IN THE RAT SPINAL DORSAL HORN. J.T. Liebel, D. Swandulla, K. Brune* and H.U. Zeilhofer. Institute of exp. and clin. Pharmacology, University of Erlangen, D-91054 Erlangen, Germany.

Nociceptin is a putative endogenous peptide agonist at the opioid receptor-like receptor 1 (ORL_1), which is not activated by "classic" opioidergic agonists. In this study we have investigated wether nociceptin affects synaptic transmission in the dorsal horn of the rat spinal cord.
250 μm thick transverse slices were prepared from the lumbar spinal cord of 7 to 15 day old rats. Neurons in laminae I-IV of the dorsal horn were visuallized using an infrared-DI contrast enhancement. Postsynaptic currents were evoked by electrical stimulation of the dorsal root or the dorsal root entry zone using a suction electrode and recorded using the whole-cell mode of the patch-clamp technique. Neurons were perfused with K-gluconate based solution containing 3 mM ATP, 0,1 mM GTP and 5mM QX-314 to block voltage-gated Na^+ currents in the postsynaptic neuron.
EPSCs and IPSCs were recorded in the presence of strychnin (2μM) and picrotoxin (50μM) or AP5 (50μM) and NBQX (10μM), respectively. Application of 10μM nociceptin lead to a significant inhibition of excitatory and inhibitory synaptic transmission. The amplitudes of glutamatergic EPSCs were reversibly reduced by 56% +- 0.033 SD (n=6), while the amplitudes of inhibitory synaptic transmission were reduced by 51% +- 0.02 SD (n=6)

784.2

EFFECTS OF OPIOID ACTIVATION ON PRO-TRH GENE EXPRESSION IN RAT BRAIN. O. Kim, A. Gutierrez, D. Sullivan, A. Dutt[1], A. Winokur[1], and T. Stanton*. Dept. of Biol. Sci., CSU, Long Beach, CA 90840, and [1]Dept. of Psychiat., Univ. of Pennsylvania, Philadelphia, PA 19104.

Based on the ability of thyrotropin-releasing hormone (TRH) to modulate brain arousal level and to inhibit the development of physical dependence and tolerance to morphine, we hypothesized that TRH neural activity increases in response to opioid activation. To test this supposition, we performed *in situ* hybridization with quantitative autoradiography to compare the level of proTRH mRNA in rats exposed to morphine for 72 hrs (via subcutaneous interscapular pellets) with control rats that were implanted with placebo pellets. Analysis of the data showed that whereas morphine-induced changes in the level of proTRH mRNA were apparent, they were not substantial. In view of TRH's reported ability to reduce the effects of morphine physical dependence and tolerance, our preliminary results suggest that if TRH neural activity is raised in homeostatic opposition to elevated central opioid action, the increase in TRH activity must be of small magnitude. OPIOID GROWTH FACTOR FUNCTIONS TO TONICALLY INHIBIT DNA SYNTHESIS OF ORGAN DEVELOPMENT IN RATS DURING FETAL LIFE. I.S. Zagon*, Y. Wu and P.J. McLaughlin. Department of Neuroscience and Anatomy, Penn State University College of Medicine, Hershey, PA 17033.

The endogenous opioid growth factor (OGF), [Met^5]-enkephalin, and its receptor, zeta (ζ), modulate postnatal development of the rat. To examine whether prenatal growth is governed by opioids, time-mated Sprague-Dawley rats were injected on gestation day 20 (E20) with either 10 mg/kg OGF, 20 mg/kg of the opioid antagonist naltrexone hydrochloride (NTX), or sterile water (CO); [^{3}H]-thymidine was given 1, 2, and 3 hr after drug injection. Four hr post-drug injection, females were euthanized, and fetuses removed and processed for autoradiography. Labeling indexes (LI) of organs representative of ectodermal (cerebellum, telencephalon, spinal cord, dorsal skin), mesodermal (vertebrae, ribs, adrenal cortex, heart), and endodermal (dorsal tongue epithelium, intestinal crypt epithelium, lung, liver) derivation were ascertained. Acute exposure to NTX significantly elevated DNA synthesis in all structures examined, with increases of 15% (skin) to 198% (telencephalon) in LIs from CO values detected. OGF exposure decreased DNA synthesis 9% (cerebellum) to 45% (heart) from CO levels. These data suggest that an endogenous opioid system functions to regulate DNA synthesis during organogenesis in the prenatal rat, and that a native opioid tonically inhibits cell generation. Supported by NIH grants HL53557 and NS20500.

784.4

NEONATAL RESPONSES TO A SURROGATE NIPPLE: ROLE OF MU OPIOID SYSTEMS. E.I. Varlinskaya, E.S. Petrov, L.A Becker, and W.P. Smotherman*, Center for Developmental Psychobiology, Binghamton University - SUNY, Binghamton, NY 13902-6000.

Pharmacological blockade of mu opioid receptors in the rostral and caudal parts of the brain alter perioral responsiveness in the E20 rat fetus and the one-day-old rat pup. Blockade of caudal mu opioid receptors decreases fetal and neonatal responses to perioral tactile stimulation while blockade of rostral receptors increases response to perioral stimulation including oral capture and grasping of a surrogate nipple. One-day-old rat pups show a transient suppression in body weight gain after central administration of the mu opioid antagonist drug CTOP. These results suggest an involvement of the mu opioid system in the regulation of suckling behavior. The cesarean-derived rat pup, lacking any experience at the nipple, will attach to and ingest fluids from a surrogate nipple permitting experimental study of early suckling/ingestive behavior. In a procedure involving presentation of the surrogate nipple, blockade of caudal mu opioid receptors increases the latency to the first nipple attachment whereas blockade of rostral receptors decreases the latency to the first attachment, but also increases the number of disengagements from the nipple. These findings suggest that there are at least two populations of mu opioid receptors that play different roles in the regulation of suckling behavior. Caudal receptors regulate the initiation and termination of a suckling bout, while rostral receptors play a role in the continued attachment to the nipple.

PREPROENKEPHALIN AND PREPROTACHYKININ mRNA'S IN THE RAT STRIATUM: AGING AND HALOPERIDOL EFFECTS. F.Tang* and S.M. Lau, Department of Physiology, Faculty of Medicine, University of Hong Kong, Hong Kong.

The effect of aging on the response of neuropeptide gene expression in the rat striatum to dopamine receptor blockade has been studied. The rats used in this study were male, and were 3 months, 12 months and 24 months old, with or without haloperidol treatment for 3 weeks. Preproenkephalin and preprotachykinin mRNA's were measured in the striatum by solution hybridization-RNase protection assay. Aging had no effect on preproenkephalin mRNA levels but decreased preprotachykinin mRNA levels in middle-aged and old rats. Haloperidol increased striatal preproenkephalin mRNA level in rats of all ages, but decreased striatal preprotachykinin mRNA level only in the young. It is concluded that aging may have different effects on the enkephalin and substance P systems, and that the change in the response of preprotachykinin mRNA contents to haloperidol in old rats might be due to a change in the dopamine system of the striatum of these rats.

RELEASE DYNAMICS OF METHIONINE-ENKEPHALIN (M-ENK) AND NEUROTENSIN (NT) FROM PREGANGLIONIC AXON TERMINALS IN CAT SYMPATHETIC GANGLIA. M.E. Zetina, G. González, F. Díaz and M.A. Morales*. Depto Biologia Celular, IBM, UNAM, México D.F. 04510

While NT is released and depleted only under frequencies higher than 10 Hz, (Maher et al, 1991) m-enk also seems to be released and used up at 5 Hz (Zhang et al, 1993). To morphologically test this apparently diferent frequency dependent release, we investigated the effect of prolonged stimulation at 5 and 40 Hz on the release and depletion of m-enk and NT in the superior cervical ganglion (SCG) and stellate ganglion (SG) of the cat. We also studied if these peptides, as NT in other regions (Beaudet et al, 1994), are internalized as soon as they bind to their receptors.

A dense network of m-enk and NT immunoreactive (m-enkIR, NTIR) fibers were found throughout the SCG and SG. NTIR was more abundant in the SG. This labeling disappeared after transection of preganglionic nerves, supporting the extrinsic, probably preganglionic origin of these fibers. In both ganglia, most of m-enkIR and NTIR fibers were clearly reduced by 40 Hz, 20 min. stimulation, while 5 Hz, 160 min. stimulus failed to reduce the labeling. At 40 Hz, mainly in the SG, besides the reduction of positive fibers, numerous cell bodies showed NTIR and less cells were m-enkIR, suggesting an internalization process of these peptides once they have been released. To further explore this internalization process we tested the NT antagonist SR 48692 (Gully et al, 1993) in order to occupy NT receptors and, in this way, to avoid internalization and, consequently, labeling of cell bodies. Surprisingly, the antagonist not only interfered with the internalization but reduced the release at 40 Hz as well. These results confirm the requirement of m-enk and NT of high frequency stimulation to be released and expended, but do not account for the depletion of m-enk at 5 Hz. They also support the proposal of peptide internalization in these ganglion cells and finally, suggest an autoregulated control, triggered by receptor occupancy, of peptide release dynamics. **Supported by DGAPA IN-204093.**

DISTRIBUTION OF ORPHANIN FQ PEPTIDE IN RAT AND GUINEA-PIG GASTROINTESTINAL TRACT: COMPARISON WITH MET-ENKEPHALIN AND DYNORPHIN 1-17 PEPTIDES. D. Bagnol†, A. Mansour, R. Reinscheid#, H. -P. Nothacker#, O. Civelli#, S. J. Watson*, Mental Health Research Institute Ann Arbor, MI 48109 USA, #Hoffmann-La Roche, Basel, Switzerland. †Bdidier@umich.edu.

The newly discovered peptide orphanin FQ (17 aa) share structural similarities with dynorphin 1-17 and binds selectively to the orphanin receptor. To delineate the possible actions of the orphanin FQ peptide in the gastrointestinal tract we investigated its localization by using an antibody raised against its cloned sequence in rat and guinea-pig colon and compared these results with the distribution of Met-enkephalin (ME) and dynorphin 1-17 (Dyn)

The results indicate the presence of numerous immunoreactive fibers in longitudinal and circular muscle layers and a greater density in the myenteric plexus. The density of immunoreactive fibers is greater in guinea pig than in rat. Occasionally immunoreactive perikarya of Dogiel type I are present in myenteric plexus. In addition, numerous small perikarya corresponding to interstitial cells are found associated with myenteric plexus and with the submucosal border of the circular muscle. The later form a very dense network of perikarya connected by fibers. No differences are seen between the two species concerning the number of immunoreactive perikarya. The density of ME and Dyn immunoreactive fibers is similar with orphanin FQ peptide immunoreactivity. Like with orphanin peptide, few ME and Dyn immunoreactive perikarya are found in myenteric plexus. In contrast, no interstitial cells were seen immunoreactive for ME and Dyn.

In conclusion, the results indicate a strong presence of the orphanin FQ peptide in rat and guinea pig gastrointestinal tract. These findings support the idea that orphanin FQ peptide might play a different role compare to ME and Dyn in gastrointestinal physiology.

ELECTROPHYSIOLOGICAL AND NEUROANATOMICAL STUDIES OF ORPHANIN FQ (OFQ). J.A. McDougall, A. Bonci[1], C. Fiorillo, T. Darland, N.B. Mercuri[1], G. Bernardi[1], G. Zhang, C. Carey[2], R.J. Kayton[2], R.G. Allen[2], J.T. Williams and D.K. Grandy*. Clinica Neurologica Dip. Sanità di Roma, Rome, Italy[1]; CROET[2] and the Vollum Institute, OHSU, Portland, OR 97201.

Imbalances in monoamine neurotransmission underlie many psychiatric and neurological disorders including depression, schizophrenia and drug abuse. The brain areas principally responsible for the production of noradrenaline (NA), dopamine (DA) and serotonin (5-HT) are the locus coeruleus (LC), the ventral midbrain (ventral tegmental area, VTA; substantia nigra pars compacta, SNc) and the dorsal raphe (DR), respectively. Since *in situ* hybridization and immunohistochemical studies revealed OFQ and its receptor in these brain areas we explored the peptide's electrical effects in monoaminergic neurons. Whole cell recordings from NA neurons in the LC revealed that 100 nM OFQ produced an outward current (~200 pA) similar to 10 µM [met]^{5}enkephalin. Current clamp recordings from DA neurons in the VTA/SNc and 5-HT neurons in the DR expressed an OFQ-mediated hyperpolarization of 15 mV. Whole cell recordings made from LC, DR, VTA/SNc showed a dose-dependent effect with EC$_{50}$'s of 38 nM, 44 nM and 79 nM, respectively. The reversal potential of the current produced by 1 µM OFQ was about -100 mV, close to the predicted equilibrium potential for potassium ions. These data not only suggest that OFQ is a potent regulator of monoamine neuron activity but may also provide a framework for understanding some of the peptide's anti-opioid actions. This research was supported by DA08562 (DKG) and DA08163 (JTW).

SPECIFIC CHOLECYSTOKININ BINDING IN MEMBRANES OF RAT MIDBRAIN AND MES-23.5 CELLS. J-L. Redondo*, T.E.Tenner, Jr., P.J. Syapin, J. Koss and A.S. Freeman. Department of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

The purpose of this study was to define cholecystokinin (CCK) receptors in rat midbrain as well and in a dopaminergic cell line of mesencephalic origin (MES-23.5) with a classical receptor binding protocol. First, optimal binding conditions were determined with rat cortical membranes: ^{125}I-CCK-8S binding was time- and temperature-dependent, with maximum binding at 21°C compared to 37°C. At 21°C, equilibrium was achieved at 30-60 min and lasted for ≥ four hr. To define specific binding, 1 μM CCK-8S was used. Binding was linear up to 250 μg protein/assay tube. Thus, subsequent studies were performed at 21°C, 2 hr and 25-150 μg protein/tube. With optimal binding conditions established in cortical tissue, CCK binding in both MES-23.5 cell and rat midbrain membranes was characterized. Specific and saturable CCK binding was observed in both MES-23.5 cell membranes, and rat midbrain (ventral tegmental area and substantia nigra) membranes. In displacement experiments, preliminary results show an order of potency of CCK-8S > CCK-4 and PD-135158 (CCK-B antagonist) > lorglumide (CCK-A antagonist) in rat midbrain membranes.

Electrophysiological, behavioral and neurochemical studies suggest the presence of functional CCK-A and CCK-B receptors in rat midbrain. Midbrain CCK binding studies have been few and limited to autoradiography. Our characterization of midbrain CCK receptors by radioligand binding will complement existing data on function. MES-23.5 cells may prove to be a useful model system to study CCK receptor function with regard to DA cell regulation.

ALLATOSTATIN IMMUNOREACTIVITY IN THE STOMATOGASTRIC NERVOUS SYSTEM OF DECAPOD CRUSTACEANS. P. Skiebe* and C. Dietel, Freie Universität Berlin, Institut für Neurobiologie, Königin-Luise-Str. 28/30, D-14195 Berlin, Germany.

The stomatogastric nervous system (STNS) has developed into a model system for studying the modulation of neural networks. A surprisingly large number of modulators have been identified in this system. To better understand their function, both the developmental and the evolutionary history of particular modulators present need to be examined. We have chosen to work with the allatostatin (AST) peptide family, which was isolated from insects. The ASTs have been shown to occur in a number of invertebrates. AST-like immunoreactivity has been found in the nervous system of numerous insects, and in crustaceans, arachnids and mollusks. The ASTs are particularly interesting since they are the first peptides with inhibitory effects on the stomatogastric networks.

As a first step in addressing evolutionary questions, we are comparing the occurrence and the physiological effects of AST within the STNS of several decapod crustaceans including crabs, lobsters and crayfish. Whole-mount immunocytochemistry with anti-*Diploptera* AST-1 antibody demonstrated the presence of AST-like peptides in the paired commissural ganglia (CoG), in the oesophageal ganglion (OG), in the stomatogastric ganglion (STG) and in their connecting nerves, not only in *Cancer borealis*, but also in the European *C. pagurus* and in *Homarus americanus*. Within the CoGs, cell bodies, neuropil and many connective fibers were stained. In the OG, 2 cell bodies with axons in the inferior ventricular nerve were immunoreactive, whereas in the STG, extensive neuropil, but no cell bodies were stained. The gastropyloric receptor neurons are also immunoreactive: 2 pair in *C. borealis*, 4 pair in *H. americanus*, but only 1 pair in *C. pagurus*. Physiological data show that AST also inhibits the networks of *C. pagurus* indicating that its inhibitory function may be conserved.

ISLET AMYLOID POLYPEPTIDE AND CGRP ARE DOWNREGULATED IN SENSORY NEURONS UPON SCIATIC AXOTOMY. H. Mulder, Y.-Z. Zhang, N. Danielsen*, F. Sundler. Dept. of Physiol. and Neurosci., Lund Univ., Sweden.

Islet amyloid polypeptide (IAPP) is structurally related to calcitonin gene-related peptide (CGRP) and is implicated in glucose homeostasis and diabetes pathogenesis, due to its presence in insulin cells and amyloidogenicity in non-insulin dependent diabetes mellitus. We have demonstrated that IAPP is also expressed in a population of CGRP-expressing sensory neurons in the rat. To explore the role for IAPP in sensory neurons, we investigated its expression upon axotomy; adult rats (n=36) were subjected to unilateral sciatic nerve transection with or without subsequent epineurial nerve suture and examined by use of quantitative *in situ* hybridization and immunofluorescence. In L4-L5 DRGs on the uninjured side, IAPP mRNA- and CGRP mRNA-containing neurons constituted 27±2 and 47±1%, respectively, of the total number of nerve cell bodies. For IAPP, on the side of transection these numbers were significantly reduced to 17±2, 16±2 and 14±2% at day 3, 10 and 30 after nerve transection; those for CGRP were significantly reduced to 41±1, 35±2 and 37±3 at the same time points; these alterations occurred irrespective of nerve suture. In individual nerve cell bodies the levels of IAPP and CGRP mRNA were significantly reduced in rats subjected to nerve transection alone at day 3 and 10, whereas mRNA levels were statistically unaffected in rats in which the nerves had been sutured. At day 30 nerve suture no longer counteracted the axotomy-induced downregulation of IAPP and CGRP mRNA. Immunofluorescence confirmed the reduction seen in cell numbers expressing IAPP and CGRP and also demonstrated a decreased density of IAPP- and CGRP-containing nerve fibers in the dorsal horns. In conclusion, our study shows that expression of IAPP and CGRP is coordinately downregulated upon axotomy. Thus, it is not likely that these peptides play a crucial role in the adaptation of sensory neurons to nerve injury.

EFFECT OF CALCITONIN GENE-RELATED PEPTIDE (20-29) ON REGULATION OF MICROCIRCULATION N.Balashov.*, V.Akopian, S.Burov, G.Vlasov. Sechenov Institute of Evolutionary Physiology and Biochemistry, St.Petersburg, Russia, 194223.

The main idea of our investigation is to study structure-activity in the molecule of CGRP (Calcironin Gene-Related Peptide) , which has been shown to be a very potent vasodilator, to find one or some shorter active fragments, taking part in regulation of microcirculation.

Earlier, we have investigated some N-and C- truncated CGRP fragments and found out that -(20-29) is the most active on arterial, venous and lymphatic microvessels of the rat mesentery by the method of vital television mycroscopy with the computer processing of videorecords of the experiments. It's effect can be compared with the effect of the whole molecule. It was an active vasodilator on arteriols and venuls, with arteriols were dilated on 60 % occasions and venuls-on 80 % occasions. But this fragment acted as a vasoconstrictor on lymphatic microvessels: during the action the microvessel diameter was decreased by 20 % compared with the initial diameter and contractility was a 4-5 fold increase in one minute. Perhaps, discrepancy of the effects of this fragment on the blood and lymphatic vessels is connected with the receptor heterogenity.

Have found that CGRP(20-29) is biologically active we continued our structure-activity investigations with the truncated fragments CGRP(21-29), (22-29), -(23-29) and -(24-29). Only fragments -(22-29) and -(23-29) seemed to exhibit some vasodilator activity, but their effect was much less potent compared with the fragment (20-29) one.

Our results confirm the common thesis of cascade reactions of the polyfunctional peptides, when some biological effects can be realized not only by the whole molecule of such peptide, but also its some fragments. Also our findings suggest that aminoacid sequence of CGRP fragment, CGRP (20-29), is optimal for demonstrating it's biological activity and further cutting its structure is not effective. LONG TERM INTEGRITY OF NEUROPEPTIDE LEVELS IN RENAL AFFERENT NERVES AFTER RETROGRADE LABELLING WITH FLUOROGOLD. Elena Doutova* and Nicholas G. Moss. Department of Physiology, University of North Carolina, Chapel Hill, NC 27599-7545

Neuropeptide levels in primary afferent neurons are significantly deranged following axotomy. This can complicate the interpretation of retrograde axonal tracing studies in which the retrograde marker is applied to the cut ends of peripheral nerve bundles. In this study we have investigated the feasibility of long term retrograde marking of renal afferent neurons by application of fluorogold (FG) to uncut renal nerve bundles in the rat. FG was applied to uncut nerve bundles in 3 rats (UNCUT) and cut nerve bundles in 3 rats (CUT). After two weeks dorsal root ganglia were prepared for immunohistochemical studies and the presence of CGRP and SP was determined in labelled renal afferent somata. Data were compared to 3 control rats (CON) in which renal afferent nerves were labelled with FG 3 days before fixation. Data are shown in the table as number of cells positive or negative for each peptide and frequency of positive cells (%+). Immunofluorescence intensities are mean values ± SEM on a scale of 0 - 3.

	CGRP+	CGRP-	%+	Intensity	SP+	SP-	%+	Intensity
CON	72	12	86	2.0±0.2	46	38	55	0.9±0.1
UNCUT	46	12	79	1.5±0.2	21	37	36*	0.6±0.1
CUT	49	8	16*†	0.3±0.1*†	2	47	4*†	0.1±0.1*†

*= significantly different from CON. † = significantly different from UNCUT.

These data demonstrate that FG can be used as a retrograde label for renal afferent somata after application to uncut nerve bundles. This procedure preserves CGRP levels which are virtually eliminated in cut nerves. SP is also preserved but to a lesser degree. Supported by NIH grant HL48219

CALCITONIN GENE-RELATED PEPTIDE IN RAT OBTURATOR MOTONEURONS AND ANTERIOR GRACILIS MUSCLE ENDPLATES. H.L. Fernandez*, G.S. Ross and I. Nadelhaft. Research & Development Service, Veterans Administration Medical Center, Bay Pines, FL 33505.

Calcitonin gene-related peptide (CGRP) has been implicated in the "trophic" regulation of acetylcholine receptors (AChR) in the mammalian neuromuscular system. We have recently reported that this 37 amino acid peptide may also participate in the regulation of tetrameric acetylcholinesterase (G_4 AChE) in endplate regions of the rat fast-twitch anterior gracilis muscles (AG). Inasmuch as CGRP exhibits a wide but heterogeneous distribution in different types of skeletal muscles, it was important to determine whether CGRP is expressed by obturator nerve motoneurons which innervate AG muscles and is actually present in the motor nerve terminals. To this end, we identified those motor neurons supplying AG muscles by retrograde labeling with intramuscularly administered fluorogold and examined their CGRP content by immunocytochemical means. In turn, the presence of CGRP in motor endplate regions of AG muscles was evaluated via immunocytochemistry and radioimmunoassay. Results show that most, if not all, of the motoneurons innervating AG muscles effectively express CGRP. The neuropeptide is subsequently supplied to the corresponding nerve terminals by axonal transport and can be detected in AG muscle motor endplates which have been identified by AChE immunocytochemistry or AChR labeling with rhodamine-tagged bungarotoxin. These data, together with earlier findings using this preparation, further support our hypothesis that motoneuron-derived CGRP participates in the "trophic" control of G_4 AChE at the adult neuromuscular junction. (Funded by the **VETERANS ADMINISTRATION**).

DISTRIBUTION OF SECRETONEURIN-LIKE IMMUNOREACTIVITY IN THE RAT AUTONOMIC GANGLIA. S. L. Dun C. C. Lai[1], S. Y. Wu[1], N. J. Dun[1*], A. Saria[2] and R. Fischer-Colbrie[3]. Dept. of Anatomy & Neurobiology, Medical College of Ohio, Toledo, OH 43614[1] and Depts. of Psychiatry[2] and Pharmacology[3], University of Innsbruck, Innsbruck, Austria.

Secretoneurin (SN) is a 33 amino acid peptide generated by proteolytic processing of secretogranin II. Distribution of SN-like immunoreactivity (SN-LI) was studied in the adult rat autonomic ganglia with a rabbit polyclonal antibody against the peptide. In the superior cervical, stellate and other paravertebral ganglia, varicose SN-LI fibers were seen surrounding virtually all ganglion cells. Small diameter cells that may correspond to small intensely fluorescent (SIF) cells were intensely labeled with SN-LI. Postganglionic neurons appeared to exhibit low levels of SN-LI. SN-LI nerve fibers formed a varicose plexus underneath the capsule of adrenal gland and some of the fibers penetrated the cortex and reached the medulla. Chromaffin cells, which were surrounded by intensely labeled SN-LI fibers, appeared to be lightly labeled. In the thoraco-lumbar spinal cord, SN-LI fibers were noted projecting into the intermediolateral cell column (IML) and other sympathetic nuclei. A few lightly labeled somata were occasionally seen in the IML area. Chronic decentralization of cervical sympathetic nerve trunk caused a near total disappearance of SN-LI fibers in the cervical ganglia. Further, double-labeling experiments showed that SN-LI appeared to colocalize with choline acetyltransferase-like immunoreactivity in the same nerve fibers surrounding the postganglionic neurons. These findings suggest that SN-LI fibers in the sympathetic ganglia are probably preganglionic in origin. In the major pelvic ganglia, many ganglion cells, some of which exhibited moderate SN-LI, were surrounded by varicose SN-LI fibers. Varicose SN-LI fibers were seen forming a pericellular network around many myenteric ganglion neurons. The result demonstrates an extensive innervation of SN-LI fibers to various autonomic ganglia and adrenal chromaffin cells. (Supported by NS18710 & HL51314).

ANNEXIN-IMMUNOREACTIVE PROTEINS IN THE NERVOUS SYSTEM AND EYE OF *APLYSIA* AND *HELIX*. **A. Hermann*, R. Donato[+] and H. Kerschbaum.** Dept. of Animal-Physiology, Univ. of Salzburg, Inst. of Zoology, Hellbrunnerstr. 34, A-5020 Salzburg, Austria, and [+]Dept. of Exp. Med. and Biochem. Sciences, University of Perugia, Italy.

Annexins are calcium-dependent phospholipid binding proteins which in *Aplysia* appear to be involved in the regulation of the circadian rhythm of the eye by modulating the arachidonic acid metabolism (Raju et al., J. Neurochem., *61*, 1226, 1993). We studied the distribution of annexin I- and annexin V-like proteins in the eye and central nervous system of the mollusks, *Aplysia californica* and *Helix pomatia*, using immunocytochemistry. Annexin I-immuno-reactive material in *Aplysia* is localized in sensory and corneal cells of the eye and in distinct neurones of the cerebral, buccal, and abdominal ganglia, where it is exclusively located in bag cells. Annexin V-immunoreactive neurones are restricted to the pleural ganglia of *Aplysia*. In *Helix* annexin I-immunoreactive neurones are present in the cerebral, buccal, visceral, pedal, and left and right parietal ganglia. Annexin V-immunoreactive neurones are present in left and right pleural, left and right parietal, visceral, and pedal ganglia.

The cellular localization of annexins suggests their involvement in intracellular signalling mechanisms which ultimately may modulate egg-laying or circadian rhythmicity.

REGULATION OF CILIA BY TPEP, A NEUROPEPTIDE FROM IDENTIFIED MOLLUSCAN NEURONS. A.O.Dennis Willows*, G. A. Pavlova, and N.E. Phillips. University of Washington Friday Harbor Laboratories, Friday Harbor WA 98250.

Ciliated cells occur widely in animals, and are often responsible for the motile force underlying various processes including mucus transport, locomotion, reproduction, respiration, circulation and feeding. We have identified molluscan brain cells in the pedal ganglia innervating the ciliated foot epithelium upon which the animal crawls. They contain three similar peptides (TPeps) which when directly applied to isolated patches of foot epithelium, increase the transport rate of cilia on its surface. These 11-amino acid neuropeptides enhance ciliary transport at a threshold below 10 nM and increase transport rate in a dose dependent manner to 10^{-5}M, where rate is doubled. TPeps also increase the beating rate of isolated cells of the pedal epithelium suggesting that the effect is direct and not mediated by intervening cells. Identified pedal neuron 21, known to drive ciliary activity on the foot responsible for locomotion in the intact animal, is immunoreactive to TPep-antiserum, suggesting that TPeps are involved in control of locomotion under normal circumstances. TPep antiserum binds specific cells in brain, foot, and oviduct of diverse mollusca. We suggest that TPeps regulate activity of ciliated cells responsible for molluscan pedal locomotion and that there may be homologous peptides controlling ciliated cells in other tissues and organisms. OPIOID RECEPTORS V

786.1

PHARMACOLOGICAL CHARACTERIZATION AND MUTAGENESIS OF THE ORPHANIN RECEPTOR., A. Ardati, F. Meng# R Henningsen, R.K. Reinscheid, F. Monsma, H. Akil# and O. Civelli*. PRPN , Hoffmann-LaRoche, Basel. # MHRI, University of Michigan.

We have recently identified Orphanin FQ (OFQ) as an endogenous ligand, for an orphan opioid-like receptor (hereafter referred to as OFQ-R). In order to pharmacologically study the interaction of OFQ to its receptor, we developed a biologically active synthetic Tyr^{14} substituted OFQ analog which bound to the OFQ-R in a reversible, saturable fashion and with high affinity. Binding kinetics studies revealed a fast association rate and a slow dissociation rate of the peptide in CHO cell lines expressing the OFQ-R. OFQ binding was particularly sensitive to Na^+ ions as addition of 5 mM NaCl increased the K_d by 3-fold with no detectable specific binding at 120 mM NaCl, whereas 5mM Mg^{++} was sufficient for high affinity and specific binding. We have also found that tissue distribution of OFQ binding sites correlates well with receptor mRNA distribution: a high level of expression in the hypothalamus and hippocampus, and lower levels of OFQ-R in the thalamus and cortex. Low binding was detected in cerebellum and midbrain, none in the pituitary or adrenals. We have previously shown that OFQ does not bind to the opioid receptors. To further our study of the binding specificity of OFQ, chimeric constructs of OFQ-R and Kappa opioid receptors were generated. Sequential replacement of TM3 to TM5 in the OFQ-R by kappa sequences resulted in a loss of OFQ binding activity. Similarly, replacement of these domains in the kappa receptor by OFQ-R sequences resulted in a gain of OFQ binding with affinities 10-fold lower than wild type OFQ-R. Taken together these results may delineate the OFQ binding pocket.

PHARMACOLOGICAL CHARACTERIZATION OF ORPHANIN FQ/NOCICEPTIN: ANALGESIA AND HYPERALGESIA IN THE CD-1 MOUSE **G.C. Rossi*, E.A. Bolan, L. Leventhal, G.W. Pasternak. The Cotzias Laboratory of Neuro-Oncology, Department of Neurology Memorial Sloan-Kettering Cancer Center, New York, NY U.S.A. 10021**

Recently, a new family of peptides was identified by two groups as the endogenous ligand for the ORL_1/KOR-3 receptor and called orphanin FQ (Reinscheid et al, 1995) or nociceptin (Meunier et al, 1995). Orphanin-FQ/nociceptin (OFQ/N) binds to the expressed KOR-3/ORL_1 receptor with high affinity, but is virtually inactive against traditional opioid receptors (Meunier et al, 1995). As previously reported, OFQ/N produces hyperalgesia in the tailflick assay at short time periods, an action opposite to that typically seen with opioid peptides. However, additional time courses (30-60 min following intracerebroventricular, i.c.v., injection) have revealed that the hyperalgesic activity quickly converts to an analgesic response, which is decreased by traditional opioid antagonists (diprenorphine, naloxone, and naltrexone). Antisense studies confirm the role of KOR-3/ORL_1 receptor in these studies. An antisense oligodeoxynucleotide sequence from exon 1 of the KOR-3/ORL_1 clone, which was previously shown to be inactive against $kappa_3$ analgesia significantly decreases OFQ/N hyperalgesia. However an antisense sequence in exon 3 of the KOR-3/ORL_1 clone is inactive against OFQ/N hyperalgesia despite retaining its ability to block $kappa_3$ (NalBzoH) analgesia. This inconsistency raises the possibility of alternative splicing of a common gene. These studies, as well antisense studies, confirm a role of the KOR-3/ORL_1 receptor in OFQ/N analgesia.

786.3

STRUCTURE AND FUNCTION OF KOR-3/ORL-1 OPIOID RECEPTOR BY A CHIMERIC APPROACH, **Y.X. Pan*, J.Xu, J.Ryan-Moro, J.Mathis, J.S.H. Hom,J.F.Mei and G.W.Pasternak. The Cotzias Laboratory of Neuro-Oncology, Department of Neurology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021**

The cloning of a delta opioid receptor (DOR-1) quickly led to the identification of another member of the opioid receptor family from mouse (KOR-3), human (ORL-1) and other species. The relationship of this receptor to the traditional opioid receptors has been unclear. Evidence from a kappa$_3$ receptor mAb and an antisense mapping studies suggests that KOR-3 may be a splice variant of the kappa$_1$ receptor. The identification of an endogenous peptide ligand, orphanin FQ/nociceptin, for the KOR-3/ORL-1 receptor provides a valuable tool to study the pharmacology of this receptor. To further explore the structure and function of this receptor, two chimeric receptors, in which the first coding exon of KOR-3 was replaced with those of MOR-1 and DOR-1, respectively, have been constructed. Using ^{125}I-[Try^{14}]OFQ/N, the pharmacological profile of the chimeras as well as wild-type KOR-3 receptor has been characterized in membranes of CHO cells stably transfected with these constructs. The results showed that the replacement of exon 1 in KOR-3 receptor by exon 1 of either MOR-1 or DOR-1 has similar binding profiles with those of the wild-type KOR-3 receptor, further supporting similarities between KOR-3 and the traditional opioid receptors. (YXP is supported by an Aaron Diamond Postdoctoral Fellowship.)

786.4

HETEROGENEITY OF ORPHANIN FQ/NOCICEPTIN BINDING IN MOUSE BRAIN, J.P. Mathis*, J.P. Ryan-Moro, A.H. Chang, J.S.H. Hom and G.W. Pasternak The Cotzias Laboratory of Neuro-Oncology, Department of Neurology, Memorial Sloan Kettering Cancer Center, New York, NY 10021.

Orphanin FQ/nociceptin (OFQ/N) has been demonstrated to be a highly potent ligand for the ORL-1/KOR-3 receptors (Meunier *et al.*,1995; Reinschied *et al.*,1995). Substitution of Tyr for the Leu^{14} in OFQ/N does not change the potency of OFQ/N in cyclase assays in ORL-1/KOR-3 transfected cells. Characterization of ^{125}I[Tyr^{14}]-OFQ/N binding in mouse brain homogenates produced a curvilinear Scatchard plot. Nonlinear regression analysis revealed two sites differing in affinities by approximately 200 fold with K_d values in the pM range. Competition studies demonstrated that OFQ/N had an $IC_{50} < 0.2$ nM and a Hill slope less than 1 suggesting binding heterogenity. Dynorphin A 1-17, dynorphin A 1-9 and dynorphin B 1-13 all demonstrated affinity for this receptor with IC_{50} values ranging from 75 to 500 nM. A series of mu, delta,and kappa$_1$ opioids did not readily compete binding, with IC_{50} values above 10 μM. NalBzoH, a kappa$_3$ ligand, did compete binding with an IC_{50} of about 400 nM. OFQ/N inhibited forskolin stimulated adenylate cyclase in mouse brain homogenates in a dose dependent manner with a IC_{50} value less than 1 nM. OFQ/N does not have appreciably high affinity for mu, delta or kappa opioid binding sites.

786.5

Orphanin FQ inhibits voltage-gated calcium channels expressed in CA3 neurons of the rat hippocampus. F. Knoflach, R. K. Reinscheid, O. Civelli and J. A. Kemp. (SPON: Brain Research Association). Preclinical CNS Research, Pharma Division, F. Hoffmann-La Roche Ltd., 4070 Basel, Switzerland.

Orphanin FQ (OFQ) has recently been reported to be an endogenous ligand for the "orphan" opioid-like receptor, LC132. Activation of the LC132 receptor by OFQ in transfected cell lines results in the inhibition of forskolin-stimulated cAMP production. In neurons, receptors which negatively regulate cAMP formation often couple to the inhibition of voltage-gated calcium channels (VGCCs). Therefore, we examined the effect of OFQ on VGCCs of freshly dissociated CA3 pyramidal neurons. OFQ reversibly inhibited VGCCs in a voltage- and concentration-dependent manner with mean (±S.E.M.) pEC_{50} and Hill coefficient values of 7.0±0.07 nM, and 1.5±0.08, respectively (n=5). The near maximum inhibition of the peak current amplitude by OFQ (1 μM) amounted to 31±2.2% of control (n=15). Since naloxone (10 μM), a broad spectrum opioid receptor antagonist, did not reduce the effectiveness of OFQ (300 nM), opioid receptors could not account for the effect of OFQ on VGCCs (n=4). The involvement of G-proteins in the inhibition of VGCCs by OFQ was confirmed by showing that OFQ had no effect in neurons pre-incubated for 24h with pertussis toxin (200 ng/ml; n=6) and that the effect of OFQ became irreversible when GTP-γ-S (100 μM; n=4) was present in the pipette. To determine which subtypes of VGCCs were affected by orphanin FQ, selective calcium channels blockers were used. The effect of OFQ could be attributed to an inhibition of L, N and P/Q-type channels (31±9.2%, 57±6.1% and 44±2.7% depression of the peak current amplitude, respectively; n=7-8). These data describe the first cellular, physiological consequences of OFQ receptor activation in neurons. The finding that OFQ inhibits L-, N- and P/Q-types of voltage-gated calcium channels suggests that this new transmitter system may play an important role in the regulation of cell excitability and neurotransmitter release.

786.6

FUNCTIONAL COUPLING OF THE NOCICEPTIN RECEPTOR WITH THE G-PROTEIN-ACTIVATED K$^+$ (GIRK) CHANNEL. K. Ikeda[1, 2]*, K. Kobayashi[3], T. Takahashi[3], T. Kobayashi[4], T. Ichikawa[4], T. Kumanishi[4], H. Kishida[1], R. Yano[1] and T. Manabe[3]. [1]Lab. for Cellular Information Processing, [2]Lab. for Synaptic Function. FRP, Inst. of Phys. and Chem. Res. (RIKEN), Saitama, Japan, [3]Dept. of Neurophysiol., Inst. for Brain Res., Faculty of Medicine, Univ. of Tokyo, Tokyo, Japan, [4]Dept. of Mol. Neuropathol., Brain Res. Inst., Niigata Univ., Niigata, Japan.

Nociceptin is a heptadecapeptide which was recently isolated from brains. It induces hyperalgesia, in contrast to the analgesic effects of opioid ligands, although it and its receptor structurally resemble opioid peptides and opioid receptors, respectively. To investigate the molecular mechanism underlying nociceptin functions, we performed Xenopus oocyte expression assays, in situ hybridization histochemistry and electrophysiological analyses of neurons. Nociceptin induced a current in Xenopus oocytes which were co-expressed the nociceptin receptor and the G-protein-activated K$^+$ channel (GIRK1). In situ hybridization study indicated that the nociceptin receptor mRNA and GIRK1 mRNA co-exist in various neurons including hippocampal pyramidal cells. When nociceptin was applied to a mouse hippocampal CA3 pyramidal cell under whole-cell voltage-clamp at around resting potential, an outward current response was observed. Electrophysiological analyses of this response indicated that the direct action of nociceptin on the pyramidal cell induces hyperpolarizing currents via inward-rectifier K$^+$ channels. We conclude that the nociceptin receptor is functionally coupled with the GIRK channel in the brain, and that nociceptin can modulate the excitability of neurons via this coupling.

CHARACTERIZATION OF PEPTIDE ANTISERA TO NOCICEPTIN/ ORPHANIN FQ. J.A. Fein, H.A. Lam, N.T. Maidment, A.M. Tan, T. Phan, C.J. Evans, and B. Anton*. Dept. of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, California 90024.

A monoclonal antibody has been raised to the opioid receptor-like (ORL$_1$) protein and used to elucidate its immunohistochemical localization in the rat central nervous system (J. Comp. Neurol. 368(2): 229-251, 1996). An endogenous peptide ligand for ORL-1 (nociceptin/orphanin FQ) has been isolated from mammal brain and was found to modulate nociception and motor activity in mice. In the present study we report on the generation and immunological characterization of five peptide rabbit antisera used for immunodetection of nociceptin/orphanin FQ. Antisera recognized immobilized synthetic nociceptin/orphanin in antibody capture ELISA assays. Furthermore, a solid-phase RIA was developed to assess antisera specificity and peptide quantity. Our results showed that the five antisera recognized the C-terminus of nociceptin/orphanin FQ. In addition, the RIA allowed detection of this peptide at the femtomole level . The antisera cross-reacted <0.1% dynorphin A at the IC_{20} level, a peptide with high structural homology to nociceptin/orphanin FQ. Experiments are in progress to measure peptide content in dissected brain areas. These antisera are also been used for immunolocalization of orphanin FQ in the rat central nervous system . Preliminary results show specific immunoreaction in many cell bodies and processes widely distributed throughout the rat central nervous system.

EXPRESSION OF NOCICEPTIN RECEPTOR MESSAGE IN PORCINE GASTROINTESTINAL TRACT. M.A. Osinski, M.S. Pampusch, M.P. Murtaugh, and D.R. Brown*. Dept. of Veterinary PathoBiology, Univ. Minnesota, St. Paul, MN 55108.

The novel opioid-like nociceptin receptor and its putative ligand have recently been described. Limited studies of the biological effects of nociceptin suggest that its actions may be antithetical to those of the classic opioid compounds. Because opioids have dramatic effects on secretory and motor events within the gastrointestinal tract, we wished to determine if the nociceptin receptor is present in this organ-system.

Utilizing reverse transcription-polymerase chain reaction (RT-PCR), we isolated a fragment of the nociceptin receptor from porcine brain. A complete open reading frame was obtained by applying 5' and 3' RACE-PCR methodologies. The deduced protein coding region of the isolated nucleotide sequence is 90.5% identical to the human receptor sequence.

Oligonucleotide primers for a hemi-nested RT-PCR assay were designed from the porcine sequence and RNA from various regions of the GI tract was screened for the presence of nociceptin receptor message. Receptor message was detected in esophagus, stomach, duodenum, jejunum, ileum and distal colon. Pieces of ileum which had been dissected into crude epithelial, submucosal, and smooth muscle layers revealed the presence of message in the submucosal and smooth muscle layers, but not in epithelium. These results suggest nociceptin plays a role in GI function. Studies are currently in progress to examine this hypothesis. This research was supported by ADAMHA training grants T32 DA07234 and T32 DA07239 (M.A.O. and M.S.P., respectively) and NIDA research grant DA-08010 (M.P.M.).

786.9

LOCALIZATION OF THE ORPHANIN FQ IN THE RAT CNS: AN IMMUNOHISTOCHEMICAL AND *IN SITU* HYBRIDIZATION STUDY. A. Mansour,*S. Burke, R. Reinscheid , H.-P. Nothacker , R. J. Pavlic, H. Akil, O. Civelli , and S. J. Watson. University of Michigan, Ann Arbor, MI 48109 USA and Hoffmann-La Roche, Basel, Switzerland

The recently cloned orphanin FQ peptide shares a number of sequence similarities with dynorphin 1-17. This study examines the localization of the orphanin FQ peptide using immunohistochemical and *in situ* hybridization techniques. Polyclonal antibodies were generated to the orphanin FQ peptide and Zamboni-perfused floating rat brain sections were examined. To visualize the orphanin FQ mRNA, one of two cRNA probes was used; a 719 base cRNA extending 35 bases from the 5'UT to the protein coding region and a 3' directed probe. Orphanin FQ immunoreactive fibers are densest in the medial (Me) and central (Ce) nuclei of the amygdala, bed nucleus stria terminalis (BNST), lateral (LS) and laterodorsal (LSD) septum, medial (MPOA) and lateral preoptic (LPOA) areas, arcuate nucleus (Arc) and median eminence. Within the median eminence, immunoreactive fibers are localized in both the internal and external layers, with a preponderance of fibers in the lateral external layer. Scattered cells and fibers are also seen in the lateral hypothalamus (LH), ventral tegmental area (VTA) and locus coerulus. The orphanin FQ mRNA localization largely overlaps the immunohistochemical distribution with high levels of expression in the Me, Ce, BNST, LS, LSD, MPOA, LPOA, and Arc. The high levels of orphanin FQ peptide and mRNA expression in limbic and hypothalamic nuclei as well as the dense localization of fibers in the median eminence suggests that this novel neuropeptide may modulate emotional responsiveness and hormonal release in addition to it's nociceptive effects. This work is supported by Grants DA02265 and DA08920.

Orphanin FQ precursor: Possible existence of additional bioactive peptides

Hans-Peter Nothacker*, Robert A. Henningsen, Rainer K. Reinscheid, Frederick J. Monsma Jr. & Olivier Civelli. Hoffmann-La Roche, PRPN, CH-4070 Basel, Switzerland.

We have cloned both the human and rat cDNAs encoding the OFQ precursor proteins, in order to investigate whether the sequence relationships existing between the opioid and OFQ systems are also found at the polypeptide precursor level, in particular whether the OFQ precursor would encode several bioactive peptides as do the opioid precursors. The entire precursor protein displays structural homology to the opioid peptide precursors, especially preprodynorphin and preproenkephalin. The predicted amino acid sequence of the OFQ precursor contains a putative signal peptide and one copy of the OFQ sequence flanked by pairs of basic amino acid residues. C-terminal to the OFQ sequence, the human and rat precursors contain a stretch of 28 amino acids which is 100% conserved and thus may encode novel bioactive peptides. Two putative peptides part of this stretch were synthesized but were found to be unable to activate the OFQ receptor suggesting that if they are produced *in vivo*, these peptides would likely recognize receptors different from the OFQ receptor. During the cloning of the human OFQ precursor we isolated two alternative splicing products which give rise to additional bioactive peptides coded by the human OFQ precursor. We verified the possibility of alternative splicing by elucidating the structure of the OFQ precursor gene. We found that the organization of the OFQ gene is similar to that of the opioid precursor genes except in the carboxyterminal part where alternative splicing occurs.

Structure-activity relationships of orphanin FQ and the message-address concept

Rainer K. Reinscheid*, Ali Ardati, Hans-Peter Nothacker, Frederick J. Monsma Jr. & Olivier Civelli. Hoffmann-La Roche, PRPN, CH-4070 Basel, Switzerland.

The heptadecapeptide orphanin FQ (OFQ) is an endogenous ligand to an opioid-like G protein-coupled receptor. Although the primary structure of OFQ exhibits some similarity to the opioid peptides, OFQ is not recognized by opioid receptors, nor does the OFQ receptor bind opioid ligands. In order to investigate the structural determinants of this ligand/receptor selectivity, we conducted a systematic structure-activity relationships (SAR) study on OFQ to characterize which sites of the molecule are important for receptor activation. Alanine- and D-amino acid-scanning mutagenesis revealed several residues in the aminoterminal half of OFQ which participate in both receptor binding and activation. Most strikingly, the Phe^1 position could be changed to a tyrosine without loss of biological activity. Interestingly, none of the truncated peptides which might be generated by cleavage at pairs of basic amino acids within OFQ, were able to bind to the receptor, suggesting that the OFQ receptor seems to require recognition of the complete peptide molecule for activation. We thus concluded that the mode of interaction of OFQ with its receptor may be different from that of the opioid peptides with their respective receptors and might therefore account for the observed selectivity. The results of our SAR studies allowed us to design a universal agonist which combines the important structural features of both OFQ and dynorphin A.

[D-$Pen^{2,5}$]ENKEPHALIN MEDIATED ANTINOCICEPTION IS RESISTANT TO δ OPIOID RECEPTOR ANTISENSE OLIOGONUCLEOTIDE MODULATION IN THE RAT. G.L. Fraser*[1,2], D.P. Ménard[1], K. Payza[1] and C. Wahlestedt[1,2]. [1]Astra Pain Research Unit, 275 boul. Armand-Frappier, Laval, Québec. CANADA H7V 4A7 and [2]Department of Pharmacology and Therapeutics, McGill University, 3655 rue Drummond, Montréal, Québec, CANADA H3G 1Y6

[D-$Pen^{2,5}$]Enkephalin appears to have a unique pharmacological profile in comparison to other putative δ opioid selective peptide agonists such as deltorphin II based on radioligand binding data and behavioral assays in rodents measuring nociceptive responses to acute noxious stimuli. Thus, it is postulated that the antinociceptive response to [D-$Pen^{2,5}$]enkephalin is not mediated exclusively by the cloned δ opioid receptor. In order to investigate this matter, an antisense oligonucleotide was administered into the rat intracerebroventricular space (*i.c.v.*) in order to selectively inhibit δ opioid receptor mediated antinociception.

Antinociceptive responses to deltorphin II and the non-peptide δ opioid selective agonist SNC-80 administered *i.c.v.* were significantly attenuated (>60%) in antisense-treated rats tested in the paw pressure and tail flick behavioral assays. Conversely, the antinociceptive response to [D-$Pen^{2,5}$]enkephalin in δ antisense-treated rats was not significantly different from mismatch or saline-treated controls although the antinociceptive response to [D-$Pen^{2,5}$]enkephalin does appear to be mediated by an opioid receptor as it is naloxone-reversible. Scatchard binding assays performed with δ opioid selective radioligands on rat brain homogenates confirmed that antisense treatment attenuated the response to δ agonists by reducing the δ opioid receptor population.

These data suggest that the antinociceptive effects of deltorphin II/SNC-80 and [D-$Pen^{2,5}$]enkephalin are mediated by different opioid receptor mechanisms where deltorphin II and SNC-80 are antinociceptive in the rat *via* interaction with the cloned δ opioid receptor.

CONTRIBUTION OF OPIOID RECEPTORS ON PRIMARY AFFERENT VERSUS SYMPATHETIC NEURONS TO PERIPHERAL OPIOID ANALGESIA. M. Schäfer*[1,2], L. Zhou[1,2], C. Stein[2]. [1]Preclin. Pharmacol., DIR/NIDA/NIH, [2]Dep. of Anesth., JHU, Baltimore, MD 21224.

Opioid receptors are synthesized in dorsal root ganglia (DRG) and transported into peripheral terminals of primary afferent neurons (PAN). Activation of such receptors results in potent analgesia which is most prominent in inflammation. Previous studies suggest an upregulation of peripheral opioid receptors during inflammation while expression of μ-opioid-receptor mRNA in DRG does not change. This study investigates a possible upregulation of opioid receptors in sympathetic postganglionic neurons (SPN) and evaluates the differential contribution of PAN and SPN to the peripheral analgesic effects of opioids. In Wistar rats with Freund's adjuvant (FCA) induced hindpaw inflammation, antinociceptive effects of intraplantar (i.pl.) [D-Ala^2, N-Me-Phe^4,Gly-ol^5]-enkephalin DAMGO (2.5-20 μg) and [D-$Pen^{2,5}$]-enkephalin (DPDPE, 25-100 μg i.pl.) were evaluated by a paw pressure test. These effects increased linearly at 6, 12 and 24 hours, but did not change between 24 and 96 hours of inflammation. Pretreatment with capsaicin (30, 50, 70 mg/kg s.c. over 3 days) reversed the development of hyperalgesia in inflamed paws and almost abolished antinociceptive effects of DAMGO and DPDPE compared to vehicle treated animals. In contrast, pretreatment with intraperitoneal 6-hydroxydopamine (75mg/kg s.c. 3 days after FCA) did not change the hyperalgesia and reduced DAMGO and DPDPE effects significantly less. These results suggest that opioid receptors are present on both PAN and SPN. However, the former contribute to a greater extent to peripheral analgesic effects of opioids than the latter.

786.14

EFFECT OF CAPSAICIN ON THE EXPRESSION OF CLONED OPIOID RECEPTORS IN DORSAL ROOT GANGLIA. Q. Zhang [1,2] M. Schäfer[1,2], C.Stein[2]*. [1]Preclin. Pharmacol, DIR/NIDA/NIH, [2]Dept of Anesth. Johns Hopkins Univ., Baltimore, MD 21205, USA.

The goal of this study was to assess the localization of mu-, delta- and kappa-opioid receptors (MOR, DOR, KOR) on capsaicin-sensitive versus-nonsensitive neurons within dorsal root ganglia (DRG) in normal vs. inflamed hindlimbs of rats. We examined this by immunohistochemistry with antibodies MOR1, DOR1 and KOR1 (kindly provided by Dr. Robert Elde). Peripheral tissue inflammation was produced by injection of Freund's complete adjuvant (FCA) into the right hindpaw of rats. Capsaicin was injected (s.c.) once a day for three days up to a total dose of 150mg/kg. FCA induced a distinct increase in the percentage of MOR1-positive neurons and a decrease in that of DOR1- and KOR1-positive neurons in the ipsilateral DRG. In rats without inflammation capsaicin significantly decreased the percentage of neurons staining for all three opioid receptors. In rats with inflammation, capsaicin significantly reduced the percentage of MOR1 and DOR1 but not of KOR1. Our study shows 1) inflammation increases the percentage of MOR but decreases DOR and KOR 2) A significant portion of mu- and delta-opioid receptors are located on capsaicin-sensitive neurons both in normal and inflamed hindlimbs.

COEXPRESSION OF MU OPIOID AND SUBSTANCE P RECEPTOR-LIKE IMMUNOREACTIVITY IN A SUBPOPULATION OF DORSAL HORN NEURONS IN THE RAT H. Liu*, R. Elde and A.I. Basbaum, Depts. Anat. and Physiol. and W. M. Keck Fdn. Ctr. for Integrative Neuroscience, UCSF, San Francisco, CA and Depts. Cell Biol. and Neuroanatomy, U. Minnesota, Minn., MN.

Opioids regulate nociceptive transmission via presynaptic inhibition of substance P (SP) release from primary afferent C-fibers and by hyperpolarizing dorsal horn neurons. To specifically identify dorsal horn neurons that could be targetted both by opioids and SP, we used a double label EM immunocytochemistry protocol to study coexpression of the mu opioid (MOR) and SP receptors (SPR). We perfused male rats with 4% form, 1% glut and 0.2% picric acid and immunostained vibratome sections of the lumbar cord, first for the SPR (ABC method/DAB as chromogen) and second with a MOR antiserum, (1.0 nm gold with silver-enhancement). We performed several controls to rule out crossover of the two rabbit antisera.

SPR-ir is concentrated on the plasma membrane of both cell bodies and dendrites; there is no axon terminal labeling. In laminae I-II, postsynaptic MOR-ir is also concentrated on the plasma membrane, however, we also recorded significant cytoplasmic label. At asymmetrical synaptic junctions, postsynaptic MOR-ir is located just lateral to the postsynaptic density. We also recorded presynaptic MOR-ir, in terminals that contain round, clear and dense core vesicles; labelling was often associated with the dense core vesicles. We found that 78% of SPR-ir cell bodies and 60% of SPR-ir dendrites in lamina I contain MOR-ir. By contrast, 68% of MOR-ir cell bodies and 53% of MOR-ir dendrites express the SPR-ir. Our results indicate that even though only a small percentage of neurons in lamina I express the SPR-ir (<10%), many of these express MOR-ir. Since SPR-ir neurons are rarely found in lamina II it is unlikely that there is a significant functional convergence of SP and opioids in this region. Rather, our results indicate that exogenous or endogenous opioids can counteract SP-mediated nociceptive transmission via direct postsynaptic inhibition of lamina I nociresponsive neurons that coexpress the opioid and SP receptors. EFFECTS OF SCIATIC NERVE TRANSECTION ON δ-OPIOID RECEPTOR IMMUNOREACTIVITY IN THE SUPERFICIAL DORSAL HORN IN THE RAT. B. Robertson[1], R. Elde[2] and G.Grant*[1]. [1] Department of Neuroscience, Karolinska Institutet, S-171 77 Stockholm, Sweden and [2] Department of Cell Biology and Neuroanatomy, University of Minnesota, Minneapolis, Minnesota 55455, U.S.A.

The superficial layers of the dorsal horn of the spinal cord, regions of termination of nociceptive fibres, are known to be important sites for antinociception produced by both μ- and δ-opioid receptor agonists. With the recent cloning of the δ-opioid receptor (DOR), antibodies to the different regions of the predicted protein has been generated (Dado et al., NeuroReport 5:341-344, 1995). Light microscopic immunofluorescence studies have shown that this antiserum (DOR442) stains a dense plexus of what are thought to be axonal structures in the superficial dorsal horn, and the tract of Lissauer. The staining of fibres decreased dramatically following dorsal rhizotomy, indicating that DOR to a large extent is localized on primary afferent fibres (Dado et al., NeuroReport 5:341-344, 1995).

The present study was undertaken to examine the effect of sciatic nerve transection on DOR immunoreactivity (IR) in the superficial dorsal horn. Female Sprague Dawley rats were subjected to unilateral sciatic nerve transection at the mid thigh level. After 7 and 16 days, 4 and 7 weeks, and one year survival, the L5 spinal cord segment was examined for the presence of DOR IR, using the DOR442 antiserum. At 7 days, normal levels of DOR IR were found bilaterally in the superfical dorsal horn. At 16 days to 7 weeks, however, there was a clear reduction in DOR IR in the sciatic nerve territory in the superfical dorsal horn ipsilateral to the nerve transection. Preliminary observations suggest that DOR IR has returned to almost normal levels after one year survival.

These results show that peripheral nerve injury dramatically reduces the level of DOR IR in the superficial dorsal horn after short survival times and suggests recovery after long survival.

MU AND DELTA OPIOID RECEPTORS ARE REDUCED IN THE NUCLEUS TRACTUS SOLITARIUS FOLLOWING LESIONS OF THE NODOSE GANGLION. B.E. Maley* and C.E. Helm. Dept. of Anatomy and Neurobiology, Univ. Kentucky Med. Ctr., Lexington, KY 40536.

Opioid peptides are known to have profound effects on the cardiovascular and respiratory system, in part, by exerting their actions in the nucleus tractus solitarius. In the present study we report drops in mu and delta opioid receptors following lesions of the nodose ganglion. Male Sprague-Dawley rats had a unilateral nodose ganglionectomy on their left side 10-14 days prior to sacrifice. The animals were perfused intracardially with 4% paraformaldehyde in Sorenson's phosphate buffer, pH 7.4. Following fixation the caudal brainstem containing the nucleus tractus solitarius was sectioned at 50μm in the coronal plane. Sections were immunostained with the peroxidase, anti-peroxidase method for both mu and delta opioid receptors. Ipsilateral to the lesion mu opioid receptors were reduced in the caudal two thirds of the nucleus. At caudal levels there were drops in mu opioid receptor immunostaining in the commissural region, while at intermediate levels mu opiate receptor immunostaining was reduced in the nucleus along its border with the area postrema as well as on the dorsal surface near the fourth ventricle at slightly more rostral levels. Mu opioid receptors were not noticeably reduced in the rostral third of the nucleus. Loss of delta opioid receptors, although less, occurred in similar regions of the nucleus.

Results from this study suggests that mu and delta opioid receptors are associated with vagal afferent fibers to the nucleus solitarius since lesions of the nodose ganglion leads to reductions in both opioid receptors. Delta opioid receptors have been found associated predominately with presynaptic terminals, accounting for their loss following nodose ganglionectomies. Mu opioid receptors have been found both on postsynaptic and presynaptic structures, suggesting that the loss of vagal afferents may affect mu opioid receptors transynaptically.

OPIOID RECEPTORS: SIGMA RECEPTORS

787.1

A NALOXONE-SENSITIVE, HALOPERIDOL-SENSITIVE, [^{3}H](+)SKF-10047-BINDING PROTEIN FROM RAT LIVER AND RAT BRAIN MEMBRANES: AN OPIOID/*SIGMA* RECEPTOR? T.-P. Su* and L-I Tsao. Molecular Neuropsychiatry Section, Neuroscience Branch, Division of Intramural Research, National Institute on Drug abuse, NIH, Baltimore, MD 21224.

The *sigma* "opioid" receptor was hypothesized by Martin *et al.* (*JPET* 197:517, 1976) as a naloxone-sensitive receptor mediating psychotomimesis of (±)SKF-10047 (*N*-allylnormetazocine; S). However, using [^{3}H](±)S, [^{3}H](+)S, and many other radioligands, a naloxone-insensitive, non-opioid *sigma* receptor which differs from the *sigma* "opioid" receptor has been reported. The biochemical identification of the *sigma* "opioid" receptor, however, remains to be determined. In an attempt to purify the non-opioid *sigma* receptor *via* an affinity chromatography, we have incidently purified a protein from rat liver and rat brain which appeared to resemble the *sigma* "opioid" receptor. CHAPS-solubilized extracts from liver and brain membranes were adsorbed to a DAPE [*N*-(2-[3,4-dichlorophenyl]ethyl)-*N*-(6-aminohexyl)-(2-[1-pyrrolidinyl)ethylamine]-containing Sephadex and the adsorbed proteins eluted by haloperidol. The affinity-purified proteins retained high affinity for [^{3}H](+)S (Kd's = 165 nM and 208 nM respectively for liver and brain) and exhibited only three protein bands in the SDS/PAGE (31 KDa, 65 KDa, and >97 KDa). [^{3}H](+)S binding to the protein was inhibited by the following drugs in the order of decreasing potency: (+)pentazocine > (-)pentazocine > (±)cyclazocine > (-)morphine > (-)naloxone > haloperidol > (+)S > DADLE > (-)S. The following ligands for the non-opioid *sigma* receptor bound poorly to the protein: BMY-14802, PRE-084, progesterone, DTG, and (+)3-PPP. The naloxone sensitivity and the benzomorphan-binding property of the affinity-purified protein indicated that it may represent the *sigma* "opioid" receptor proposed by Martin and coworkers. PHOTOAFFINITY LABELING STUDIES OF SIGMA-1 RECEPTOR WITH [^{3}H]AZIDONE-100 IN THE PRIMARY CULTURED NEURONAL CELLS AND THE PC-12 CELLS. H.Yamamoto[1], A.Nakazato[4], N.Sagi[1], T.Yamamoto[1,2], M.Watanabe[1], Y.L.Murashima[3]*, S.Chaki[4] and S. Okuyama[4]. [1]Dept. of Psychopharmacol., [3]Dept. of Neurophysiol., Tokyo Inst. Psychiatry, Tokyo 156, [2]Mol.Recog., Yokohama City Univ., Yokohama 236, [4]Taisho Pharmaceutical Co., Ltd., Saitama 330, Japan

Previous studies from our laboratory have shown that a time- and temperature-dependent internalization of sigma-1 ligand binding sites has occurred in the primary cultured neuronal cells (Soc.Neurosci.Abstr., Vol.21 (2), p.1622). To clarify whether the internalization process of sigma-1 ligands is due to ligand alone or ligand-receptor complex, we carried out a photoaffinity labeling of sigma-1 receptor using a photoactive sigma-1 selective ligand [^{3}H]azidoNE-100. Primary cultured neuronal cells in DMEM were incubated with [^{3}H]azidoNE-100 at 37°C, washed with PBS and then with acidic high sodium solution to wash out surface-bound radioactivity. By irradiation at 365nm, polypeptides of 29kDa and approx. 45-50kDa were labeled. Both labeled compounds increased in a time-dependent manner at 37°C, while the presence of 1 μM haloperidol abolished labeling of 29kDa but not that of 45-50kDa. These result suggest that photoaffinity labeled polypeptides of 29kDa is the haloperidol-sensitive sigma-1 receptor and internalization of sigma ligand-receptor complex may play a role in intracellular signaling via sigma-1 receptor.

In addition, we performed photoaffinity labeling with [^{3}H]azidoNE-100 using membranes from PC-12 cells, since PC-12 cells have [^{3}H]NE-100 binding sites similar to sigma-1 receptor. The photoaffinity labeling of PC-12 membranes had shown three main bands including polypeptide of 29kDa, supporting previous report that PC-12 expresses sigma-1 receptor.

787.3

PUTATIVE σ_3 SITES IN MAMMALIAN BRAIN HAVE HISTAMINE H_1 PROPERTIES. C.E. Owens*, R.B. Mailman, S.D. Wyrick, R.G. Booth. Division of Medicinal Chemistry, School of Pharmacy & UNC Neuroscience Center, University of North Carolina, Chapel Hill, NC 27599.

We recently described a CNS binding site that is recognized by 1-phenyl-3-amino-1,2,3,4-tetrahydronaphthalenes (phenylaminotetralins, PATs) associated with stimulation of brain dopamine synthesis [*Mol. Pharm.* (1993) **44**: 1232]. The stimulatory effects are blocked by the sigma (σ) antagonist BMY-14802, suggesting a σ receptor-mediated effect. Extensive ligand binding and autoradiographic studies with [^{3}H]-(1*R*,3*S*)-(-)-*trans*-1-phenyl-3-(*N*,*N*-dimethylamino)-tetralin ([^{3}H]-PAT) indicate that this binding site is distinct from σ_1/σ_2 receptors as well as other known CNS sites. The function, distribution, and ligand binding profile of [^{3}H]-PAT sites, however, is similar to that of σ_1/σ_2, prompting the designation σ_3. Upon further characterization of the σ_3 pharmacological profile, we discovered that several tricyclic antidepressants (TCAs) bind with high affinity (0.1-10 nM) to [^{3}H]-PAT σ_3 sites (rank order of affinity: doxepin>amitriptyline=imipramine>nortriptyline>desipramine). TCAs recognize not only monoamine transporters but other CNS sites including cholinergic, α_1 adrenergic, and histamine H_1 receptors. Radioligand binding assays and brain distribution studies indicate that the σ_3 site is clearly distinct from monoamine transporters as well as adrenergic and cholinergic receptors. On the other hand, the rank order of affinity of H_1 receptor ligands at [^{3}H]-PAT labeled σ_3 sites is promethazine>triprolidine>(+)-chlorpheniramine>diphenhydramine>>>histamine, consistent with H_1 receptor pharmacology. Moreover, the affinity of structurally diverse ligands (including antihistamines, TCAs, and neuroleptics) at H_1 [*Proc. Natl. Acad. Sci.* (1978) **75**: 6290] and σ_3 sites correlates well (r^2=0.82). The density of H_1 and σ_3 sites in guinea pig brain also is similar (B_{max}=98 and 38 fmol/mg prot, respectively) and the brain distribution overlaps (high density in hippocampus and accumbens and moderate density in striatum). The proposed σ_3 site has many features in common with histamine H_1 receptors and current studies are focusing on testing the hypothesis that [^{3}H]-PAT-labeled σ_3 sites may represent a subclass of brain histamine H_1 receptors. 787.4

MODULATION OF BRAIN DOPAMINE SYNTHESIS *IN VIVO* BY A PUTATIVE σ_3 AGONIST VIA A G-PROTEIN RECEPTOR MECHANISM N.Y. Choksi*, S.D. Wyrick, R.G. Booth. Div. of Medicinal Chemistry, Univ. of North Carolina, Chapel Hill, NC, 27599

A series of 1-phenyl-3-amino-1,2,3,4-tetrahydronaphthalenes (phenylaminotetralins, PATs) are proposed to modulate brain dopamine (DA) biosynthesis through interaction with a novel guanine nucleotide binding protein (G-protein) coupled sigma (σ) receptor subtype, termed σ_3. Brain receptor mapping studies indicate that putative σ_3 sites, labeled with [^{3}H]-(1*R*,3*S*)-(-)-*trans*-1-phenyl-3-(*N*,*N*-dimethylamino)-1,2,3,4-tetrahydronaphthalene ([^{3}H]-(-)-H_2-PAT), are highly localized in limbic areas of mammalian forebrain, particularly the nucleus accumbens. Using an *in vivo* presynaptic receptor model, icv administration of (±)-*trans*-H_2-PAT to rats modulates DA biosynthesis in the nucleus accumbens in a biphasic manner. At 0.4 to 40 nmole/kg, (±)-*trans*-H_2-PAT stimulates DA synthesis (*ca.* 200%) vs. saline-treated animals. At 90 to 900 nmole/kg, (±)-*trans*-H_2-PAT dose-dependently decreases DA biosynthesis to control levels, indicating that (±)-*trans*-H_2-PAT produces complex effects on DA metabolism *in vivo*. Studies that suggest other σ receptor subtypes are G-protein coupled prompted us to evaluate if σ_3 receptors also couple to G-proteins. Preliminary results show that addition of a non-hydrolyzable guanine triphosphate analog [Gpp(NH)p] decreases [^{3}H]-(-)-H_2-PAT specific binding *ca.* 20% from untreated tissue, suggesting that [^{3}H]-(-)-H_2-PAT labeled σ_3 receptors belong to the G-protein coupled receptor family. The signal transduction pathway associated with (-)-H_2-PAT labeled σ_3 receptors is currently under evaluation. [Support: NINDS NS35216, RBI/NIMH Chemical Synthesis Program, Pharmacy Foundation and the University of North Carolina]

787.5

IBOGAINE AND IBOGAMINE MODULATE INTRACELLULAR CALCIUM LEVELS VIA INTERACTION WITH SIGMA-2 RECEPTORS. W.D. Bowen*[1], B.J. Vilner[1], U.K. Bandarage[2], and M.E. Kuehne[2]. [1]Unit on Receptor Biochem. and Pharmacology, Lab. Med. Chem., NIDDK, NIH, Bethesda, MD 20892 and [2]Dept. Chemistry, Univ. Vermont, Burlington, VT 05405-0125.

The mechanisms underlying the anti-addictive and neurotoxic effects of ibogaine are not clear since it lacks high affinity for most brain neurotransmitter receptors examined to date. We have shown that 1) ibogaine and its natural congeners, ibogamine and tabernanthine, are selective sigma-2 ligands with moderate affinity [Ki = 137 - 201 nM] (*Eur. J. Pharmacol.* 279:R1, 1995), and 2) sigma-2 ligands produce both a rise in intracellular Ca++ ([Ca++]i) by release from intracellular stores and a decrease in depolarization-induced Ca++ influx through voltage-dependent calcium channels (*Soc. Neurosci. Abstr.* 21: 1608, #631.3, 1995). We thus examined the ability of ibogaine and related compounds to modulate [Ca++]i in indo-1 loaded human SK-N-SH neuroblastoma cells. Ibogaine and ibogamine (10 - 100 µM) produced a dose-dependent increase in [Ca++]i. The range of percent stimulation for ibogaine and ibogamine was 13-45% and 27-156%, respectively. Noribogaine (O-desmethyl ibogaine) and (-)-coronaridine, both weak or inactive at sigma sites, were without effect at 100 µM. This profile is consistent with mediation through sigma-2 sites. The ibogaine-induced rise in [Ca++]i was still observed in Ca++-free medium and was eliminated by pretreatment of cells with thapsigargin, consistent with release of Ca++ from intracellular stores. Ibogaine-related compounds were examined for effects in depolarization-induced Ca++ influx into SK-N-SH cells. Ibogaine, ibogamine, nor-ibogaine, or (-)-coronaridine (10 - 100 µM) was added to cells, and 5 - 10 min allowed to elapse to allow Ca++ levels to return to near baseline. Cells were then depolarized with 55 mM KCl. Ibogaine and ibogamine inhibited the K+-induced rise in [Ca++]i. However, nor-ibogaine and (-)-coronaridine had no effect. Thus, ibogaine appears to act as a selective sigma-2 receptor agonist. These results may have implications for the in vivo effects of ibogaine.

787.6

EFFECTS OF SIGMA RECEPTOR LIGANDS ON RAT SUPERIOR CERVICAL GANGLION NEURONS IN VITRO. B.J. Vilner* and W.D. Bowen. Laboratory of Medicinal Chemistry, NIDDK, NIH, Bethesda, MD 20892.

Sigma ligands exert marked effects on the morphology and viability of cell lines as well as mixed primary cultures of rat nervous system (*J. Neurosci.* 15:117, 1995; *Soc. Neurosci Abstr.* 20:747, 1994). Cultures of rat superior cervical ganglion (SCG), a component of the sympathetic nervous system, allow assessment of drug effects on a relatively pure population of NGF-dependent neurons without the influence of glia, epithelial cells, and fibroblasts. SCG cultures can also allow assessment of effects on early neuronal development such as cell attachment and process outgrowth. The effects of haloperidol, reduced haloperidol (RHAL), and BD737 (sigma-1/sigma-2 ligands) and CB64D (a selective sigma-2 ligand) were assessed on the development of pure neuronal cultures by adding sigma ligands (3 - 100 µM) at the time of cell plating and observing effects for up to 5 days. With 30 µM at 20h, cells were alive but without processes and dead or damaged by 44h. With 10 µM, cells could attach and extend process, but damage or loss of processes was noticeable by 44h and cells were dead by 5d. In the presence of 3 µM, cultures appeared to develop normally, but with significant damage to processes noticeable at 5d. Effects on mixed SCG cultures (drugs added 7 - 10 days after plating when more non-neuronal cells are present) were similar except that effects were more dependent on chronic exposure. For example, effects of 3 µM sigma ligand were not observable until about 14d of culture and did not produce rounding and/or cell death until about 21d. Thus, low concentrations (3 µM) of sigma ligands did not appear to inhibit initial development (cell attachment and process outgrowth), but did have significant neurotoxic effects during extended exposure. Also, non-neuronal supporting cells may provide protection from effects of sigma ligands. These sigma ligands also inhibited depolarization (55 mM KCl)-induced calcium influx in SCG neurons with a profile consistent with sigma-2 sites. Thus, sigma-2 receptor activation appears to affect cell morphology and to regulate Ca++ influx, making SCG neurons a suitable model system.

787.7

ELECTROPHYSIOLOGICAL EFFECTS OF SIGMA LIGANDS ON MIDBRAIN DOPAMINERGIC NEURONS. B. Gronier* and G. Debonnel. Dept of Psychiatry, McGill University, Montreal, Qc, Canada, H3A 1A1

Using extracellular unitary recordings and microiontophoresis, the present studies were undertaken to investigate *in vivo* the effects of selective sigma (σ) ligands on the spontaneous neuronal firing activity, as well as on the NMDA-induced activation and the dopamine-induced suppression of firing, of rat A9 and A10 dopaminergic (DA) neurons. In both A9 and A10, the selective σ1 ligand JO-1784, iontophoretically applied or intravenously administered, had no effect on the spontaneous firing activity, nor did it change the neuronal response to NMDA and DA. On the other hand, microiontophoretic application of S 21378, another selective σ1 ligand, increased the neuronal firing activation induced by NMDA and had a slight activating effect on the spontaneous activity of both A9 and A10 neurons. Cumulative doses of the selective σ1 ligand S 21377 (100 µg/kg, i.v.) and of the preferential σ1 ligand S 21272 (30 µg/kg, i.v.) progressively increased the firing activity of both A9 and A10 neurons. These effects were more robust in A9 than in A10. At a higher dose (1.2 mg/kg, i.v.), S 21377 increased slightly but significantly the neuronal response to NMDA in A10. None of these 3 compounds had any effect on the DA-induced suppresssion of firing.

These findings suggest that σ1 ligands may exert a modulatory effect on the firing activity of dopaminergic neurons, either by modifying the spontaneous activity, or by altering GLU/NMDA neurotransmission. The lack of effect of the selective σ1 ligand JO-1784, further supports the existence of different subtypes of σ1 receptors. (Supported by the F.R.S.Q.)

SELECTIVE σ_1 RECEPTOR AGONISTS AND NEUROSTEROIDS ATTENUATE ß[25-35]-AMYLOID PEPTIDE-INDUCED AMNESIA IN MICE THROUGH A COMMON MECHANISM. T. Maurice* and A. Privat. I.N.S.E.R.M. U. 336, E.N.S.C.M., 34053 Montpellier, France.

An important neuromodulatory role of sigma$_1$ (σ_1) receptor ligands concerns the mnesic processes. This was demonstrated on the pharmacological amnesia models induced by the muscarinic antagonist scopolamine and by the NMDA receptor blocker MK-801. We recently described the amnesia model induced in mice by ß[25-35]-amyloid peptide (Maurice et al. Brain Res. 706:181-193, 1996). ß[25-35], administered centrally in an aggregated form, induces rapidly mnesic deficits, that can be alleviated by cholinomimetics or by agonists of the NMDA/glycine modulatory site. In this study, we examined the ability of σ_1 ligands to reverse the ß[25-35]-induced amnesia in mice. Furthermore, neuroactive steroids, such as progesterone (Prog), pregnenolone (Preg), dehydroepiandrosterone (DHEA), and their sulfate esters, have been shown to interact with σ_1 receptors, particularly with their effects on NMDA-evoked responses. We thus also examined the neurosteroidal effects on ß[25-35]-induced amnesia. Memory was evaluated 7 days after central injection of ß[25-35] (3 nmol), using spontaneous alternation in the Y-maze, or after 14 days, using step-down type passive avoidance. The selective σ_1 ligands (+)-pentazocine and PRE-084 attenuated, in a dose-dependent and bell-shaped manner, the ß[25-35]-induced deficits on both tests. Their effects were antagonized by haloperidol and BMY-14802. Preg, PregS, DHEA, and DHEAS, but not Prog, also attenuated the ß[25-35]-induced amnesia. Prog behaved as an antagonist, since it blocked the steroidal effects. Furthermore, haloperidol blocked the steroidal effects, whereas Prog antagonized the σ_1 agonists effects, demonstrating a crossed pharmacology between the two systems. These results demonstrate that the therapeutic relevance of the anti-amnesic effects of σ_1 ligands, in pathologies affecting the cholinergic and/or glutamatergic systems, and that some behavioral properties of steroids may indeed involve an interaction with the σ_1 systems. *Supported by INSERM*

CHRONIC INTRAVENTRICULAR INFUSION OF BD1047 and BD1063, SIGMA RECEPTOR ANTAGONISTS, CAUSE TRANSIENT CELL DAMAGE. B.Q.H. Nguyen*, A.C. Zambon, B.R. de Costa, A.G. Kanthasamy, D.D. Truong and R.R. Matsumoto. University of California Irvine, Dept. of Neurology, Irvine, CA 92717; NIDDK, Laboratory of Medicinal Chemistry, Bethesda, MD 20892.

BD1047 and BD1063 are novel ligands that appear to act as antagonists at σ receptors. In rats, the ligands have no effects on their own, but can attenuate dystonia and orofacial dyskinesias induced with the high affinity σ ligands DTG and haloperidol. Since previous experiments have shown that BD1047 and BD1063 produce cytotoxic effects in C6 glioma cultures, we tested whether this cytotoxicity was also manifested *in vivo*. Rats received chronic intraventricular infusion of BD1047 or BD1063 (in artificial CSF, 10 nmol/hr), or artifical CSF alone for 1, 7 or 14 days via osmotic minipumps. Histological sections were then processed for Nissl and GFAP staining; 46 areas of the brain were examined for cell loss and glial proliferation. As compared to CSF treatment, there was slight, but noticeable changes in the cortex and certain limbic areas (arcuate, habenula, amygdala) after 1 and 7 days of treatment with BD1047. With BD1063 teatment, mild damage was seen in the cortex, substantia nigra, some limbic and motor nuclei after 7 days. All of these alterations appear to be transient because after 14 days of treatment, the morphology of the neurons appeared normal. The mechanism(s) underlying these transient effects have yet to be determined. (Supported by MH50564)

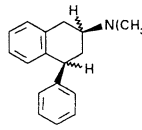
DEVELOPMENT OF A SELECTIVE ANTAGONIST FOR THE [^{3}H]-(–)-*TRANS*-H$_2$-PAT BINDING SITE E.C. Bucholtz, C.E. Owens, S.D. Wyrick*, R.B. Mailman, N.S Kula, R.J. Baldessarini, R.G. Booth. McLean Hospital and Harvard Medical School, Belmont, MA 02178 & Div. of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27599



cis- H$_2$PAT

We previously reported that (–)-*trans*-1-phenyl-3-dimethylamino-1,2,3,4-tetrahydronaphthalene [(–)-*trans*-H$_2$-PAT] stimulates tyrosine hydroxylase (TH) and dopamine synthesis (45% over basal at 1μM in rat brain) through interaction with a novel CNS binding site (*Mol. Pharmacol.* **1993**, *44*, 1232). This novel site originally was designated sigma$_3$ (σ_3) based on three findings: the blockade of functional effects by the σ antagonist BMY-14802, a σ-like ligand binding profile, and a σ-like brain distribution. (±)-*Cis*-H$_2$-PAT has no effect on TH activity (0.1–100 μM), and completely blocked (±)-*trans*-H$_2$-PAT induced stimulation of TH activity. The enantiomers of (±)- *cis*-H$_2$-PAT were recently resolved (*Soc. Neurosci. Abs.* **1995**, *21*, 1610), and preliminary data indicate (–)-*cis*-H$_2$-PAT binds with moderate affinity (K0.5= 12 nM) to [^{3}H]-(–)-*trans*-H$_2$-PAT labeled sites. In addition, (–)-*cis*-H$_2$-PAT exhibits only three-fold selectivity over (+)-*cis*-H$_2$-PAT for these sites. These data suggest that this blockade of TH may not be stereospecific. Recently radioreceptor assays demonstrated that (–)-*trans*-H$_2$-PAT also has high affinity (K0.5= 1.6 nM) for histamine H$_1$ recep-tors, and that the pharmacological profile of [^{3}H]-(–)-*trans*-H$_2$-PAT sites is similar to that of histamine H$_1$ receptors (see C.E. Owens *et. al.*, this meeting). Therefore, the PAT series of ligands may be valuable tools for probing the structure and function of the histamine H$_1$ receptor and potentially identify H$_1$ receptor subtypes.[Support: NINDS NS35216, Pharmacy Found. and Univ. of North Carolina, and RBI/NIMH Chemical Synthesis Program]

CATECHOLAMINE RECEPTORS: REGULATION OF GENE EXPRESSION

HALOPERIDOL, GENETICS AND THE C-FOS RESPONSE. N. Patel*, B. Hitzemann and R. Hitzemann. Departments of Psychiatry and Neurobiology, SUNY at Stony Brook, NY 11794-8101 and Research and Psychiatry Services, VAMC, Northport, NY 11768.

We have previously shown that there are marked differences in the ED_{50} for haloperidol-induced catalepsy between the DBA/2 (D2) and C57BL/6 (B6) inbred mouse strains (0.4 vs 3.8 mg/kg, respectively). This difference is not the result of differences in haloperidol pharmacokinetics; further, the difference in sensitivity is seen with all typical high-potency neuroleptics but not the low-potency neuroleptics which have significant D_1 antagonist activity. We previously reported that the haloperidol-increase in c-Fos expression within the striatum was modestly greater in the responsive D2 as compared to the non-responsive B6 strain (Patel et al. 1995). We have now compared the c-Fos response in these strains at "downstream" regions within the striatopallidal circuit. After saline injection no significant c-Fos IR response was noted in either strain for the globus pallidus (GP), the entopeduncular nucleus (EPN) and the substantia nigra zona reticulata (SNr). However, the D2 strain showed a remarkably greater c-Fos response in all three regions. Depending on the rostral/caudal and dorsal/ventral level examined, the differences were > 100% in the GP, 80% in the EPN and > 300% in the SNr. These data suggest the main locus of the genetic difference is not in the striatum but other aspects of the striatopallidal circuit. Supported in part by VA Research and MH 51372.

MODULATION OF APOMORPHINE INDUCED ROTATIONAL BEHAVIOUR AND NEUROLEPTIC INDUCED IMMEDIATE EARLY GENES BY PROLYL-LEUCYL-GLYCINAMIDE (PLG), AND ITS NOVEL ANALOGUES M. C. Ott*[1], R. K. Mishra[1], R. L. Johnson[2]
1 Dept. Biomed. Sci., McMaster Univ., Hamilton, Ont., Canada
2 Dept. Medicinal Chem., Univ. of Minnesota, Minneapolis, MN, USA

Previously our laboratory has demonstrated that PLG an endogenous brain derived peptide, and its synthetic analogues can modulate dopamine receptor sensitivity in several in vivo and in vitro paradigms. In order to extend our understanding of the molecular mechanism of PLGs actions within the basal ganglia, several structurally constrained synthetic PLG analogues have been synthesised. These synthetic analogues were screened using the 6-hydroxydopamine lesion animal model and were assessed for their ability to modulate dopamine receptor supersensitivity by the potentiation of apomorphine induced rotational behaviour. Recent studies have shown a link between dopamine receptor activity and immediate early gene expression (IEGs). It has been hypothesized that the induction of IEGs within the basal ganglia by acute treatment with typical neuroleptics may be related to the extrapyramidal side effects associated with chronic neuroleptic use. PLG and those analogues which were seen to be potent modulators of dopamine receptor activity were tested for their ability to modulate c-fos induction by acute haloperidol within the striatum and nucleus accumbens. Preliminary studies suggest that PLG may enhance the expression of c-fos caused by typical neuroleptic drugs.

A FUNCTIONAL EVALUATION OF HUMAN DOPAMINE D2 RECEPTOR FOLLOWING SITE DIRECTED MUTAGENESIS. A. E Fletcher, M. Graziano, R. Syed, K. L Hadingham* and S.B Freedman. Neuroscience Research Centre, Merck Sharp and Dohme, Terlings Park, Eastwick Road, Harlow, Essex UK CM20 2QR.

Site directed muatagenesis of the human Dopamine D2 receptor has identified serine residues in the TM5 region as critical for the binding of agonists to the receptor (Fletcher *et al* NeuroSci Abs.1993). We have now evaluated the role of these serine residues in determining agonist efficacy and affinity at the human D2 receptor. The affinities of a number of structurally diverse agonist were determine using a GTP-γ S binding assay to CHO cell lines stably expressing the hD2 and S193A, S194A and S197A mutant dopamine receptors. Data obtained using the S193A mutant receptor, revealed a marked decrease in agonist affinity for dopamine and 6,7-ADTN, whilst a small, but significant, decrease in the affinity of PHNO. In contrast, mutation of the S194A and S197A residues evoked no significant change in agonist affinity across a wide range of agonist, with the exception of S197A and quinpirole where a small but significant decrease in affinity was observed. No significant decrease in efficacy was observed for any of the mutation when compared with the wild type receptor. These data, together with radioligand studies of the mutant receptors support a role for the serine 193 residue in the binding of agonists to the hD2 receptor.

HALOPERIDOL RESPONSE MAPS TO THE PIEBALD AND BROWN BUT NOT THE ALBINO LOCUS. E. Rasmussen*, L. Cipp, E. Mahjubi, R. Hitzemann. Departments of Psychiatry and Psychology, SUNY at Stony Brook, NY 11794-8101 and Research and Psychiatry Services, VAMC, Northport, NY 11768.

During the selection of the neuroleptic-responsive (NR) and neuroleptic non-responsive (NNR) mouse lines (Hitzemann et al. 1991), it was noted that albinism markedly increased in the NR line and disappeared from the NNR line. Conversely, the piebald marking slowly increased during selection in the NNR line. Piebald was never detected in the NR line. To confirm these associations of coat color and sensitivity for haloperidol-induced catalepsy, we examined 550 F_2 animals formed from a cross between the BALB/c (albino) and LP (piebald, agouti) strains. The phenotypic extreme very responsive (RR) and very non-responsive (NN) individuals were identified using a two-step challenge procedure. 26/90 NN individuals but only 6/86 RR individuals were piebald ($X^2=14.2$, $p < 0.0005$). This association is of interest since the piebald locus (*s*) is located near the *Htr2* gene on chromosome 14. The association of this chromosome 14 QTL with haloperidol response was genotypically confirmed ($p < 10^{-5}$) in the entire sample of NN and RR individuals using microsatellites near the *s* locus. Albinism was not different between the NN and RR individuals but brown coat color was more prevalent in the RR (50/86) as compared to the NN (35/90) individuals ($X^2=6.5$, $p < 0.01$). The *b* locus is found on chromosome 4. Funded by MH-51372.

TWO DISTINCT PROMOTERS DRIVE TRANSCRIPTION OF THE HUMAN D_{1A} DOPAMINE RECEPTOR GENE

S.-H. LEE, J. F. Bishop* and M. M. Mouradian. Genetic Pharmacology Unit, Experimental Therapeutics Branch, NINDS, Bethesda, MD 20892.

The human D_{1A} dopamine receptor gene has a G-C rich, TATA-less promoter located upstream of a small, non-coding exon 1 which is separated from the coding exon 2 by a 116 bp long intron. Serial 3' deletions of the 5' non-coding region of this gene, including the intron and 5' end of exon 2, resulted in dramatic decrease in transcriptional activity of the upstream promoter in two D_{1A} expressing neuroblastoma cell lines SK-N-MC and NS20Y. To investigate the function of this region, the intron and 245 bp at the 5' end of exon 2 were investigated. Transient expression analyses using various CAT constructs showed that the transcriptional activity of the intron is higher than that of the upstream promoter, in an orientation dependent manner indicating that the D_{1A} intron is a strong promoter. Primer extension and ribonuclease protection assays revealed that transcription driven by the intron promoter is initiated at the junction of intron and exon 2 and at a cluster of nucleotides located 50 bp downstream from this junction. The same transcription start sites are utilized by the CAT constructs employed in transfections as well as by the D_{1A} gene expressed within the human caudate. Competitive co-transfection using the intron as competitor confirmed the presence of trans-acting factors at the intron. These data taken together indicate that the human D_{1A} gene has two functional TATA-less promoters both in D_{1A} expressing cultured neuroblastoma cells and in the human striatum.

REGULATION OF THE RAT D_2 DOPAMINE RECEPTOR GENE PROMOTER BY SP1.

S. Yajima and M. M. Mouradian*. Genetic Pharmacology Unit, Experimental Therapeutics Branch, NINDS, Bethesda, MD 20892.

The D_2 dopamine receptor is an important mediator of the motor, behavioral and endocrine effects of central dopaminergic neurotransmission. We had previously found that the negative modulator located in the 5' flanking region of this gene includes an Sp1 consensus sequence and three consecutive TGGG repeats to which Sp1 and another unknown nuclear factor bind. We also cloned Sp1 from a cDNA library of the D_2 expressing murine neuroblastoma cell line NB41A3. In the present study, we investigated the regulation of this modulator sequence by Sp1 in the *Drosophila melanogaster* Schneider's SL2 cell line. The latter cells are the only higher eukaryotic cells known to be devoid of endogenous Sp1 and thus represent a suitable system to study Sp1 function in vivo. We constructed an Sp1 expression plasmid by subcloning the murine Sp1 cDNA downstream of the drosophila metallothionein promoter. This construct was used for co-transfections along with several CAT reporter plasmids which include different portions of the D_2 gene 5' flanking sequence. The results showed that each of the reporter constructs could be activated by Sp1 in a concentration dependent manner. We also compared the ability of Sp1 to activate the D_2 promoter and the SV40 promoter. Using an equal amount of the Sp1 expressing plasmid for co-transfections, the D_2 promoter was activated by about three fold, whereas the SV40 promoter by about 20 fold. These observations indicate that Sp1 is an activator of the D_2 gene and that the negative regulatory factor remains to be identified.

MODIFIED DOPAMINE RECEPTOR EXPRESSION *IN VITRO* USING AN ADENOVIRAL VECTOR

Mark Knapp, Albert H.C. Wong, Oscar Schoots, Zdenek Pristupa*, Hubert H.M. van Tol. Molecular Neurobiology Lab, Clarke Institute of Psychiatry, Toronto, Ontario.

The aim of this work was to validate the methodology of modifying dopamine receptor expression in tissue cultured cells, using a recombinantly engineered adenoviral vector; and as a first step in developing *in vivo* gene transfer strategies to modify DA receptor expression. The vectors were prepared by cotransfecting HEK 293 cells with plasmids containing parts of the adenoviral genome and the D2, D4.2, D4.4, D4.7, and Luciferase genes. The resultant replication-deficient viruses were infected into HeLa, COS-7, CHO-K1, GH4-C1, SK-N-MC, LMTK$^-$ and primary pituitary cell cultures. Receptor expression and function was measured by saturation binding analysis, competition binding analysis, coupling to adenyl cyclase and Prolactin release. The D2 and the D4 sequences are reliably expressed *in vitro* resulting in overexpression of the receptors. Using a recombinantly engineered, replication-deficient adenovirus to induce overexpression of dopamine receptors *in vitro* is a feasible technique which can now be utilized for *in vivo* gene transfer by stereotactic microinjection to modify dopamine receptor expression in experimental animals. These experiments will provide greater understanding of the function of dopamine receptors in normal neurophysiology, and as therapeutic targets in schizophrenia.

DOPAMINE D_2 AGONIST-ELICITED CORTICAL FOS EXPRESSION IS NOT ATTENUATED BY $D_2/D_3/D_4$ ANTAGONIST PRETREATMENT: EVIDENCE FOR A NOVEL D_2-LIKE RECEPTOR.

C. D. Young* and A. Y. Deutch. Department of Psychiatry & Pharmacology, Yale University School of Medicine, New Haven, CT 06510, and Psychiatry Service, VAMC, West Haven, CT 06516.

The atypical antipsychotic drug (APD) clozapine induces Fos protein in the rat medial prefrontal cortex (PFC) and thalamic paraventricular nucleus (PV), but numerous other typical and atypical APDs do not. This suggests that the PFC and PV may serve as important therapeutic sites of clinically effective APDs. We have reported previously that neither D_1- nor D_2-like receptor antagonists replicate the actions of clozapine (CLZ) on PFC Fos expression. Similarly, attempts to mimic CLZ's actions with 5-HT_2, α_1 adrenergic, and muscarinic cholinergic agents also failed to induce PFC and PV Fos. However, DA agonists such as apomorphine induce PFC and PV Fos, suggesting that CLZ-elicited Fos expression is related to an increase in extracellular DA, but the agonist-induced PFC Fos is not blocked by pretreatment with D_1 or D_2 antagonists. These data have led to the suggestion that an as-yet cloned DA receptor subserves CLZ's unique profile. To test this hypothesis more directly, we treated adult male Sprague-Dawley rats with the D_2-family agonist quinpirole (QUIN; 0.5 mg/kg, s.c.), which increased PFC and PV Fos as determined by immunoblots. However, pretreatment of rats with the $D_2/D_3/D_4$ antagonist sulpiride (200 mg/kg, s.c.) failed to block QUIN's induction of PFC and PV Fos. The inability of sulpiride to block QUIN-elicited Fos expression suggests that a novel DA receptor present in the PFC and PV may subserve the unique actions of CLZ.

788.9

EXPRESSION OF α1-ADRENOCEPTOR SUBTYPES IN THE UTERINE ARTERIES OF VIRGIN AND POSTPARTUM RATS.

E.A. Wang, A.L. Oaklander*. Department of Neurosurgery. The Johns Hopkins University School of Medicine, Baltimore, MD, 21287.

During the late stages of pregnancy, vasomotor nerves innervating uterine blood vessels degenerate in the body of the uterus. Concurrently, uterine blood vessels increase in diameter (Osol and Cipolla. Am J Ob Gyn, 168:268, 1993). These changes may increase the probability of post-partum uterine hemorrhage. We hypothesized that this pregnancy-related plasticity of axons would be associated with changes in specific subtypes of α-adrenoceptors (αAR). These receptors mediate the effects of both sympathetic innervation and circulating catecholamines on uterine vascular caliber.

Segments of the uterine artery and the segmental (radial) arteries (which branch towards the body of the uterus) were dissected from virgin and immediately-postpartum Sprague-Dawley rats (200-350 g) and individually homogenized. A micro-scale magnetic RT-PCR assay method (Oaklander and Ekenberg, Nature, 371: 631, 1994) was used to isolate mRNA and synthesize cDNA from the samples. These underwent the polymerase chain reaction using primer sets specific for the rat α_{1A}, α_{1B}, and α_{1D} subtypes. Expression of GAPDH was also measured to control for sample size. PCR products underwent gel electrophoresis, bands were digitized, and normalized values were compared. All 3 αAR subtypes were expressed in uterine and segmental arteries. The concentration of the α_{1D} subtype, however, was less in arteries from postpartum rats than in arteries from virgin rats. These data indicate that a compensatory increase in this receptor does not occur during pregnancy-induced uterine denervation.

DOPAMINE D_2 RECEPTOR INDUCTION OF G-PROTEIN IMMUNOREACTIVITY AND mRNA EXPRESSION IN RAT PITUITARY INTERMEDIATE LOBE.

S.A.Sands*, D.S.Dickerson, and B.M.Chronwall. School of Biological Sciences, University of Missouri-Kansas City, Kansas City, MO 64108.

Stimulation of dopamine D_2 receptors inhibits POMC biosynthesis and α-MSH secretion in melanotropes. These effects are mediated by the G_i and G_o proteins and are reversed by stimulating receptors linked to the G_s protein. Melanotrope activity is increased by haloperidol, a D_2 receptor antagonist, and decreased by bromocriptine, an agonist. Both the short and long isoforms of the D_2 receptor increase following chronic haloperidol treatment, but only the short isoform decreases following chronic bromocriptine treatment (Chronwall et al., 1994). Similarly to the receptor isoforms, specific G protein α subunits may also alter in pattern of expression.

Using immunohistochemistry and *in situ* hybridization, this study examined changes in G_i, G_o, and G_s protein and mRNA expression following chronic treatment with bromocriptine or haloperidol. $G_{i\alpha3}$ and G_o immunoreactivities increased following bromocriptine treatment, while G_s and $G_{i\alpha1/2}$ did not change. G_s immunoreactivity increased after haloperidol treatment, while $G_{i\alpha1/2}$, $G_{i\alpha3}$, and G_o did not change. G_i and G_o mRNA increased following bromocriptine treatment and decreased following haloperidol treatment, while inverse results were observed with G_s mRNA. These results suggest D_2 receptor activation can specifically modulate $G_{i\alpha3}$, G_o, and G_s expression.

REPETITIVE FIRING DEFICITS IN BRAIN-DERIVED NEUROTROPHIC FACTOR KNOCKOUT MICE. T. Rothe, R. Bähring, P. Carroll[1], H. Thoenen[1] and R. Grantyn*. Dev. Neurobiology, Humboldt Univ. Inst. for Physiol., D-10117 Berlin, and [1]Dept. of Neurochemistry, Max Planck Institute for Psychiatry, D-82152 Martinsried, Germany

Survival of retinal ganglion neurons (RGNs) in culture and RGN regeneration *in vivo* improves in the presence of brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family. As repetitive firing requires correct interplay of several ion conductances it may be a sensitive indicator for inappropriate channel expression and/or distribution due to the absence of BDNF. Patch clamp recording was performed in retinal whole mount preparations from postnatal BDNF-deficient mice (BDNF-/-), heterozygous mice (BDNF+/-) and corresponding controls (BDNF+/+). Animals of different age (P1-11) were tested for the capacity of RGNs to generate full-blown single action potentials (excitability) and to translate steady depolarization into trains of action potentials (repetitive firing). In all three groups the fraction of excitable RGNs increased with age (BDNF+/+ animals: 94% at P1-2, 100% at P7-11; BDNF+/-: 73% at P1-2, 100% at P7-11; BDNF-/-: 73% at P1-2, 81% at P7-11). Repetitive firing was seen on day 7 in most RGNs from normal and heterozygous animals, whereas at this age of life RGNs from BDNF-/- only started to acquire this property (BDNF+/+: 13% at P1-2, 76% at P7-11; BDNF+/-: 3% at P1-2, 60% at P7-11; BDNF-/-: 0% at P1-2, 15% at P7-11). Moreover, in cells with repetitive discharge f-i slopes were significantly lower in BDNF-/- animals, as compared to BDNF+/+ or BDNF+/-. In general, acquisition of repetitive firing was accompanied by a significant decrease in whole cell input resistance and a steep increase in the density of Na^+ currents. The latter occurred at different times in BDNF+/+ (P1 to P2), BDNF+/- (P2 to P4-6) and BDNF-/- (P4-6 to P7-11). Together, our results suggest that chronic deficits in BDNF supply can reduce activity in the optic tract and thereby impair activity-dependent formation of the visual pathway.

ACTIVITY OF HISTAMINE METABOLITES AFTER MICROINJECTION INTO THE RAT RED NUCLEUS. Ryan C. Beard, Tammy B.-H. Lee and Rae R. Matsumoto*. Department of Neurology, University of California Irvine, Irvine, CA 92717.

Microinjections of histamine into the red nucleus of Sprague Dawley rats have previously been shown to cause dystonic head postures. Because the metabolites of histamine have been shown to be biologically active in other systems, the histamine metabolites, t-methylhistamine, t-methyl imidazoleacetic acid, and imidazoleacetic acid, were tested for activity in the red nucleus. Saline, a vehicle control, and histidine, the histamine precursor, were also tested. The compounds (up to 10 nmol/0.5 µl) were unilaterally microinjected into the rat red nucleus and the resulting head angles quantified. All of the metabolites, t-methylhistamine, t-methyl imidazoleacetic acid, and imidazoleacetic acid, caused dystonic head postures ($P<0.05$ compared to control microinjections of saline). Although imidazoleacetic acid is also known to be a GABA-A agonist, this mechanism cannot account for the postural changes elicited by imidazoleacetic acid because the GABA-A agonist muscimol produced dystonic head postures in the opposite direction from imidazoleacetic acid. The mechanism(s) underlying the activity of t-methylhistamine and t-methyl imidazoleacetic acid are also unknown at this time. Since past findings suggest that histamine metabolites have the potential to be involved in many important functions in the brain, studies are currently underway to determine the mechanism(s) through which the metabolites act. (MH50564)

789.2

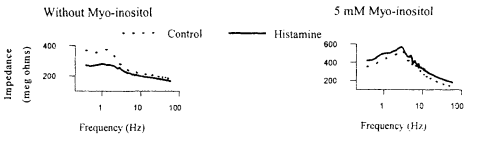
CHRONIC INFUSION OF [S]α–FLUOROMETHYLHISTIDINE (αFMHis): INSIGHTS ABOUT OXIDATION OF HISTAMINE AND ITS POOLS IN BRAIN. G D Prell*, A M Morrishow, N Srivastava and A-Ch Granholm Dept. Pharmacology, Mt. Sinai Med. Cen., NY, NY 10029 and Dept. Basic Science, Univ. Colorado HSC, Denver, CO 80262

Histamine in brain is synthesized by histidine decarboxylase (HD). and metabolized postsynaptically by histamine-N-methyltransferase (HMT) to form *tele*-methylhistamine (t-MH), then *tele*-methylimidazoleacetic acid (t-MIAA). They are indices of brain histamine turnover. We showed that imidazoleacetic acid (IAA), a $GABA_A$ agonist and histamine's peripheral metabolite, is in brain where its levels increased after HMT inhibition. ^{3}H-histamine (icv) was oxidized to IAA in rats, a process increased after HMT inhibition. Thus histamine can be oxidized in brain. But does this occur physiologically? To study this process, rats were infused >4 weeks (10 mg/kg/d) with αFMHis, an irreversible inhibitor of HD. Compared to saline-infused or untreated controls, rats given αFMHis showed marked reductions: depletions (% controls) of t-MIAA> t-MH> histamine in all regions. But IAA levels were unchanged. Thus, unlike periphery, most IAA in brain may not normally derive from histamine. There oxidation appears to be *conditional* (e.g. after HMT inhibition). αFMHis's effects on histamine are greatest for its rapid turnover pools. Residual histamine in treated rats [with levels (% controls) highest in midbrain, hippocampus and striatum: 60, 52, 52%, resp. where t-MIAA levels were low: 9, 10, 20%, resp.] could be consistent with a very slow histamine turnover pool. This pool, yet to be identified, likely differs from mast cells present mainly in thalamus. Immunohistochemical studies are underway to identify this residual pool(s) of histamine in brain. (NINDS-NS-28012)

789.3

HISTAMINE MODULATES ION CHANNELS QN RAT NEOCORTICAL NEURONS. R.S. NEUMAN*, C. GILES, F-J. KONG AND E. PUIL. Fac. of Med., Memorial University, St. John's, Nfld., Canada A1B 3V6 and Fac. of Med., University of British Columbia, Vancouver, British Columbia, Canada.

We are investigating the action of histamine on the impedance (Z) amplitude profile (ZAP) of cortical neurons in an *in vitro* slice preparation. Employing whole cell recording we observed that 17 µM histamine produced a frequency-dependent decrease in input impedance (Fig., left; ZAP at -70 mV). This voltage-dependent decrease was unexpected since activation of receptors that couple to phospholipase C (PLC), such as the histamine H_1 receptor, typically increases input impedance by reducing a leakage conductance. Substrate for PLC is limited in cortical slices and substrate levels may be further reduced by dialysis with the whole cell electrode. Perfusing 5 mM myo-inositol, to increase substrate, resulted in a voltage- and frequency-dependent increase of input impedance in response to histamine (Fig.,right; ZAP at -70 mV; different cell).



Our observations suggest that in the absence of added myo-inositol the H_2 receptor dominates the response to histamine. With increased substrate levels for PLC there is a complex interplay between the H_1 and H_2 receptors with respect to modulating ion channels and influencing neuronal excitability. Supported by the MRC(C).

STRUCTURAL AND FUNCTIONAL ANALYSIS OF THE HUMAN HISTAMINE H1 RECEPTOR GENE. Katsumi Fujimoto[1], Kazuichi Sakamoto[2], Seiji Ito[2], Satoshi Ogino[1], Hiroyuki Fukui*[,3]. [1]Sch. Allied Health Sci. and [3]Dept. Pharmacol. II, Facl. Med., Osaka Univ., Suita 565, Japan and [2]Dept. Cell Biol., Osaka Biosci. Inst., Suita 565, Japan.

The histamine H1 receptor mediates immune hypersensitivity in peripheral tissues and neurotransmission in the central nervous system. Two classes of histamine H1 receptor mRNAs, 3.0 kb and 3.5 kb, were expressed in various human peripheral tissues but only 3.5 kb mRNA was expressed in the brain. Southern blot analysis of genomic DNA suggested that the two classes of mRNAs were derived from a single gene. To determine polyadenylation site and transcription initiation site of the H1 receptor gene, we examined 3'-terminal and 5'-terminal of mRNA by rapid amplification of 3'-cDNA ends (3'-RACE) and primer extension methods, respectively. A polyadenylation site was determined at 260 nucleotides downstream from translation termination site. Potential polyadenylation signal sequences were located at 14 nucleotides downstream from the polyadenylation site. Two transcription initiation sites were found at positions of -41 and -118 nucleotides upstream from translation initiation site. The promoter activity of the 5'-upstream region was studied by transient transfection assays in which putative promoter fragments were fused to a promoterless firefly luciferase reporter gene. The region between -263 and -6 was sufficient for the transcription of the H1 receptor gene, and promoter activities were detectable in two regions between -263 and -138, and between -138 and -6. The region between -1270 and -1126 may be related to suppress the H1 receptor gene expression. We found that phorbol 12-myristate 13-acetate (PMA) enhanced the promoter activity of the H1 receptor gene. The region between -138 and -6 was sufficient for the induction by PMA. Grants-in-aid for JSPS fellows.

MECHANISMS OF LIGAND RECOGNITION AND RECEPTOR ACTIVATION IN THE HISTAMINE H1 RECEPTOR. Kazumi Ohta[1], Daisuke Yamamoto[2], Hiroyuki Kagamiyama[1], Naoyuki Inagaki*[,3], Katsumi Fujimoto[4] and Hiroyuki Fukui[5]. [1]Dept. Biochem. and [2]Biomed. Comput. Ctr., Osaka Med. Coll., Takatsuki 569, Japan, [3]Lab. Cancer Ctr. Res. Inst., Nagoya 464, Japan and [4]Sch. Allied Health Sci. and [5]Dept. Pharmacol. II, Facl. Med., Osaka Univ., Suita 565, Japan.

Histamine regulates many functions as a neurotransmitter in the central nervous system (CNS) through the histamine H1 receptor. H1 receptor belongs to be a family of guanine-nucleotide-binding-protein (G-protein)-coupled receptors and is coupled to phospholipase C. The stimulation of the receptor induces the accumulation of inositol phosphates (IPs) and Ca^{2+} mobilization. To investigate mechanisms of ligand recognition and receptor activation in the histamine H1 receptor, we constructed mutant H1 receptors and the three dimensional (3D) model of the human H1 receptor on the basis of the structure for bacteriorhodopsin. The structural homologies between H1 receptors and other biogenic amine receptors suggest that in the human H1 receptor some amino acid residues could associate with agonists. The 3D model of the human H1 receptor indicates that these amino acid residues could interact with agonists and other residues could interact with antagonists. To clarify roles of these amino acid residues, we exchanged these residues for other ones by site-directed mutagenesis and investigated binding abilities to some ligands and agonist-induced IPs accumulations in mutant H1 receptors. We here demonstrate that Asp in transmembrane domain III is the binding site for ligand amino-moieties and some residues could interact with the ring structure of agonists and two ring structures of antagonists. From these findings, we try to approach two problems; how agonists activate the H1 receptor and why antagonists can bind to the H1 receptor without activating the receptor. A grant from Japan Research Foundation for Clinical Pharmacology.

HISTAMINE H_3-RECEPTOR ACTIVATION REDUCES K^+-EVOKED [^{3}H]-GABA RELEASE IN RAT SUBSTANTIA NIGRA PARS RETICULATA SLICES BY ACTING ON THE COMPONENT DEPENDENT ON DOPAMINE D_1-RECEPTOR ACTIVATION. M. García[1], J. Aceves[1], B. Florán[1], J. Sánchez*[1], J.M. Young[2] and J.A. Arias-Montaño[1]. [1]Depto. de Neurociencias, CINVESTAV-IPN, 07000 México, D.F., México and [2]Department of Pharmacology, University of Cambridge, U.K.

Histamine H_3-receptor activation inhibits whereas dopamine D_1-receptor activation potentiates K^+-evoked [^{3}H]-GABA release from rat substantia nigra pars reticulata (SNr) slices (J.A. Arias-Montaño *et al.*, Soc. Neurosci. Abs. 21: 653.11; B. Florán *et al.*, Neurosci. Lett. 116: 140). The aim of the present work was to investigate whether H_3-receptors modulate GABA release by counteracting the effect of D_1-receptors.

Coronal slices (300 μM thick) from SNr of acutely (24 hrs) reserpinised rats were labelled with [^{3}H]-GABA in Krebs-Henseleit buffer (37°C) and perfused with the same buffer (0.5 ml.min^{-1}). Fractions (2 ml) were collected and analised by liquid scintillation spectrometry. Under these conditions the H_3-agonist immepip (1 μM) failed to reduce K^+-evoked [^{3}H]-GABA release. However in the presence of the D_1 agonist SKF-38393 (10 μM) [^{3}H]-GABA release was augmented by 155 ± 9% and this effect was antagonised (77 ± 7% inhibition) by immepip (1 μM). The immepip-mediated inhibition was blocked by thioperamide (1uM), a H_3 antagonist. These results indicate that histamine modulates the component of K^+-evoked-[^{3}H]-GABA release dependent on D_1-receptor activation.

ANTIMIGRAINE AND SEDATIVE ACTIVITY OF SCH 50971: A NOVEL, ORALLY-ACTIVE HISTAMINE H_3 RECEPTOR AGONIST

R.L. McLeod*, F. DeGennaro, M. del Prado, R. Duffy, R.W. Egan, W. Kreutner, R. McQuade and J.A. Hey. Allergy, Schering-Plough Research Institute, Kenilworth, NJ

We studied the actions of Sch 50971, a novel histamine H_3 receptor agonist in a neurogenic inflammation model of migraine, and characterized its potential sedative activity. Sch 50971 given i.v. and p.o. inhibited neurogenically-induced plasma protein extravasation in the dura mater of guinea pigs. The active doses of Sch 50971 were 3 mg/kg, i.v. and 10 mg/kg, p.o., which produced a 40% and 42% decrease in plasma protein extravasation, respectively. These effects were blocked by the histamine H_3 antagonist thioperamide (3.0 mg/kg, i.v.). In sedation studies Sch 50971 (0.3 - 3.0 mg/kg, p.o.) potentiated pentobarbital-induced loss of righting reflex in guinea pigs (ED_{40} = 7.0 mg/kg). The sedative activity was blocked by i.c.v. thioperamide (10 μg). The sedative activity of Sch 50971 was also examined in conscious animals using EEG activity, locomotor activity and sleep. Sch 50971 (10 mg/kg, p.o.) depressed locomotor activity, increased total sleep time and produced EEG patterns consistent with physiological sleep.

In conclusion Sch 50971 is a novel, orally active agonist of histamine H_3-receptors that may ameliorate the sequelae of migraine by activation of histamine H_3 receptors and displays sedative activity. Sch 50971 also decreases motor activity and promotes EEG activity consistent with physiological sleep.

LABELLING OF CRF_1 RECEPTORS IN HOMOGENATES OF RAT CEREBELLUM USING [^{3}H]-UROCORTIN. G.J. Kilpatrick, V. Meyer, S. Henriot, E. Kitas, J. Martin* and J-L. Moreau. Pharma Division, Preclinical Research, F. Hoffmann-La Roche Ltd., 4002-Basel, Switzerland.

Urocortin is a newly identified 40 amino acid peptide with homology to CRF and a high affinity for CRF receptors (Vaughan et al., Nature, 378, 287-292, 1995). We now report on the binding of [^{3}H]-urocortin to homogenates of rat cerebellum, an area rich in CRF_1 receptor mRNA (see Chalmers et al., Trends Pharmacol. Sci. 17, 166-172, 1996).

Tris buffer (50mM, pH 7.0) containing $MgCl_2$ (10mM), EGTA (2mM), BSA (0.1%), bacitracin (0.1mM) and aprotonin (100 kiu/ml) was used. The binding assay (300μl, 2h at 22°C) contained washed rat cerebellar membranes (300 vol), [leu (9)-^{3}H]-urocortin (104 Ci/mmol [synthesised by Amersham International], routinely 0.2nM) and competing agents or buffer vehicle. Non-specific binding was defined using N-Butyl-N-[2,5-dimethyl-7-(2,4,6-trimethylphenyl)-7H-pyrrolo[2,3-d]pyrimidin-4-yl]-N-ethylamine (CP 154,526, 1μM). Bound and free ligand were separated by filtration (Millipore Durapore® hydrophilic filters, 0.45μm).

Data are mean ± SEM, n=3. At 0.2nM, specific binding of [^{3}H]-urocortin was routinely 65% of total binding. Saturation analysis revealed a single site with a Kd of 0.32±.04 nM and Bmax of 9.0±1.1 fmol/mg tissue. Inhibition constants (pKi) for various agents revealed a pharmacology consistent with the CRF_1 receptor: Urocortin, 9.2±0.1, CP154,526 9.0±0.1 urotensin1 8.6±0.1, hCRF 8.2±0.1 & sauvagine 8.1±0.1.

We conclude that [^{3}H]-urocortin labels CRF_1 receptors in rat cerebellum. This radioligand should be a useful tool for the study of CRF receptors.

SUBCELLULAR LOCALIZATION OF HIPPOCAMPAL CHOLINERGIC NEUROSTIMULATING PEPTIDE (HCNP) IN PERIPHERAL AUTONOMIC NERVOUS SYSTEM. E. Katada, S. Mitake, Y. Otsuka*, K. Ojika. 2nd Dept. of Int. Med., Sch. of Med., Nagoya City University, Nagoya 467, Japan.

A novel peptide, HCNP from young rat hippocampus is involved in the development of specific cholinergic neurons in vitro (K. Ojika, et al; Brain Res., 572: 164-171, 1992). Our previous immunohistochemical studies have suggested that in the rat central nervous system HCNP-related molecules involved in the function of 1)autonomic nervous system, 2)sensory system, 3)high intellectual system, 4)extra-pyramidal system, and 5)neuro-endocrine system (S. Mitake, et al; Brain Res., 706: 57-70, 1996). In the peripheral nervous system, HCNP-immunoreactivity has been also detected in the dorsal root and sympathetic ganglia, myenteric and submucosal plexus, and nerve endings around small blood vessels (E. Katada, et al; Neurochem Res 20: 319-320, 1995). The present study was conducted to investigate the electron microscopic localization of HCNP in sympathetic ganglia and small intestine of 11-day-old rat. By immuno-electron microscopic technique (pre-embedding method), HCNP was found in large cytoplasmic granules of the small granule-containing cells and in synaptic terminals to the soma of a ganglion cell in the superior cervical ganglia. HCNP positive nerve terminals were found in the myenteric plexus close to the smooth muscle cells. In the submucosal plexus, synaptic vesicles with HCNP in a nerve terminal in contact with a ganglion were found. HCNP positive synaptic vesicles were also found in the nerve endings around small blood vessels. These findings suggest that HCNP may act as neuromodulator in the autonomic and enteric nervous system.

VASOPRESSIN-INDUCED NEUROTROPHISM AND GENE EXPRESSION IN CULTURED CORTICAL NEURONS. Qi Chen,* Alex Monreal, Steven S. Schreiber and R.D. Brinton. Dept. Molecular Pharmacology & Toxicology, Univ. of Southern California, Pharmaceutical Sci. Ctr., 1985 Zonal Ave., Los Angeles, CA. 90033.

Our early autoradiographic evidence of recognition sites in the cerebral cortex for the neuropeptide vasopressin (Brinton et al. PNAS 1984, Chen et al. *Hippocampus*, 1993) and our recent detection of V1a vasopressin receptor mRNA in cortical neurons document the existence of vasopressin receptors in the cerebral cortex and specifically in cortical neurons. Based on these findings, we have pursued the functional significance of V_1 receptors in cultured cortical neurons by investigating the impact of V1 receptor activation on the cortical nerve cell growth of and on cortical neuron gene expression. Neurons derived from E18 fetal rat cerebral cortex were cultured in serum free media as described in Brinton et al. 1994 in the absence or presence of varying concentrations of V1 receptor agonist for 24 hrs. Neurons (n = 65 cells/condition) were videomicroscopically recorded and morphologically analyzed blind to the experimental condition. Exposure to V1 agonist significantly increased the growth of cortical neurons as indicated by a significant increase in the length of neurites ($p<.01$), the number of branches ($p<.001$), branch length ($p<.01$), the number of branch bifurcation points ($p<.01$) and in the number of microspikes ($p<.01$). The dose response profile of V1 agonist-induced neurotrophism exhibited an inverted-U shaped function with 100 nM inducing the greatest increase in cortical nerve cell growth. The inverted-U shaped dose response is consistent with all V1 agonist responses that we have previously observed and is entirely consistent with a calcium dependent process. In addition, our preliminary evidence indicates that V1 receptor activation in cortical neurons induces immediate early gene expression that is consistent with a neurotrophic function.

790.4

Vasopressin-Induced Calcium Signaling in Cultured Cortical Oligodendrocytes. M.C. Son* and R.D. Brinton. Molecular Pharmacology & Toxicology, University of Southern California, Los Angeles, CA. 90033.

Our early autoradiographic evidence of recognition sites in the cerebral cortex for the neuropeptide suggested a widespread expression of V_1 vasopressin receptors vasopressin (Brinton et al. PNAS 1984, Chen et al. *Hippocampus*, 1990). Our most recent studies to determine the cellular localization of V1aR mRNA have demonstrated expression in cultured cortical oligodendrocytes (Yamazaki et al., 1996). Based on these findings, we have pursued the signal-transduction mechanism associated with V_1 receptors in cultured cortical oligodendrocytes using a selective V_1 vasopressin receptor agonist. Twenty-four day old enriched cultures of oligodendrocytes were exposed to varying concentrations of V_1 receptor agonist for 60 minutes followed by an analysis of phosphoinositide accumulation (IP_1) as described in Brinton et al. 1994. The dose-response of V_1 agonist-induced accumulation of $[^3H]IP_1$ was concentration dependent and showed a significant increase at 100 nM V_1 agonist (162.2% $\pm$ 8.0, $p<0.05$) and 250 nM (187.6% $\pm$ 8.7, $p<0.01$). These results demonstrate that vasopressin induces calcium signaling in cortical oligodendrocytes through PIP_2 hydrolysis. Future studies will investigate V_1 agonist-induced regulation of intracellular calcium using calcium fluorometry analysis, extracellular Ca^{2+} uptake using radiolabeled $^{45}Ca^{2+}$, and the specific types of Ca^{2+}-channel responsible for the influx of calcium by using specific Ca^{2+}-channel blockers in cultured cortical oligodendrocytes.

VASOPRESSIN-TREATED ASTROGLIA PRODUCES GLIAL CONDITIONED MEDIUM WHICH PROMOTES THE GROWTH OF NEURONS DERIVED FROM RAT CEREBRAL CORTEX.

R.S. Yamazaki*, T. Ward and R.D. Brinton. Dept of Molecular Pharmacology & Toxicology, & STAR Program, University of Southern California, Pharmaceutical Sciences Center, 1985 Zonal Ave., Los Angeles, CA 90033

Our previous research using RT-PCR has documented the expression of mRNA for the V1a subtype of vasopressin (AVP) receptor in astroglia of the cerebral cortex (Yamazaki et al., *Molec Brain Research* [submitted]). Based on this finding, together with recent reports on glial-derived neurotrophic factors, we hypothesized that activation of vasopressin receptors would induce astroglia to release factor(s) which would promote neuronal growth. Enriched astroglia derived from E18 rat cerebral cortex were grown to confluence in 10% serum-containing medium (SCM) and then serum-starved for 3 days. Media was then discarded and astroglial cells were incubated for 24 hours in either 1% SCM as control (C-GCM), or 1% SCM plus 100 nM AVP (AVP-GCM). C-GCM and AVP-GCM were harvested and applied to cultured cortical neurons for 24 hours. C-GCM-treated-, and AVP-GCM-treated-neurons were videomicroscopically recorded and morphologically analysed, blind to the experimental condition. AVP-GCM treated neurons exhibited markedly greater growth compared to C-GCM treated neurons as indicated by a significant increase in neurite length ($p<.005$), number of branches ($p<.05$), branch length ($p<.05$), and number of microspikes ($p<.05$). These data suggest that vasopressin-treated astroglia secrete a factor or factors into the medium which promotes neuronal growth. Studies to determine changes in neurotrophin mRNA expression in AVP treated cortical astroglia are in progress.

SR48692 DISCRIMINATES BETWEEN SUBTYPES OF THE NEUROTENSIN RECEPTOR IN HUMAN BRAIN HOMOGENATES. X. P. Zeng, F. Le and E. Richelson*. Laboratory. of Neuropsychopharmacology, Mayo Clinic Jacksonville, Jacksonville, FL 32224

Evidence exists for subtypes of the neurotensin receptor (NTR) (Le et al., 1996). The new nonpeptide NTR antagonist SR48692 blocks many, but not all of the effects of neurotensin, suggesting that it has selectivity for a subtype of the NTR. Therefore, we used this antagonist in binding assays to investigate the regional distribution of putative NTR subtypes in human brain tissue obtained at autopsy. Competition binding against 1 nM $[^3H]NT$ was carried out in tissue homogenates of human cortex, caudate, substantia nigra, periaqueductal gray, amygdala, hypothalamus, and thalamus. Compared to NT, which had a low equilibrium dissociation constant (K_d =1 to 7 nM) indicating a high affinity for all brain regions and for Chinese hamster ovary cells expressing the molecularly cloned human NTR, the binding affinity for SR48692 fell into two groups: high affinity (K_d = 3 - 9 nM) in caudate, substantia nigra, amygdala, hypothalamus and thalamus; and lower affinity (K_d= 30 and 60 nM, respectively) in cortex and periaqueductal gray. Furthermore, unlike NT, SR48692 (up to 10 μM) competed for a maximum of only 70 - 90% of the specific binding of $[^3H]NT$ and its slope factor for binding (0.5 or less) in each of these brain regions was significantly different from unity. These data support the hypothesis that more than one subtype of the NTR exists in human brain and that SR 48692 can be used in binding assays to discriminate between these subtypes. (Supported by Mayo Fdn. and NIMH grant MH27692).

IMMUNOHISTOCHEMICAL DISTRIBUTION OF THE 5 SOMATOSTATIN RECEPTOR (SSTR) SUBTYPES IN RAT CEREBRAL CORTEX. U. Kumar, S.C. Patel, and Y.C. Patel*. Fraser Labs, McGill University, Montreal, Canada H3A 1A1 and Neurobiology Res. Lab. VA, CT. 06111.

Somatostatin is produced in many brain neurons and exerts effects on motor, sensory, behavioural, cognitive, and autonomic functions. These actions are mediated by SSTRs of which a family of 5 distinct subtypes (SSTR1-5) has now been identified. To understand the function of each individual subtype, we have mapped the distribution of SSTR1-5 in the adult rat brain using anti-peptide rabbit polyclonal antibodies directed against the extracellular domains of each SSTR, and biotin-avidin enhanced immunocytochemistry. Immunoreactive specificity was confirmed with preimmune serum and preabsorbed antibodies. SSTRs were expressed in a distinctive pattern in frontal, somatosensory, occipital, and temporal cortex as well as in limbic structures (hippocampus, amygdala, entorhinal, pyriform cortex), SSTR types 2 and 3 being the predominant species followed by SSTR4 and SSTR1. SSTR5 was the least expressed subtype. SSTR1-4 were abundantly expressed in neurons of the deeper cortical layers with long immunopositive axons which traversed from the soma to the outer layer. In contrast, SSTR5 occurred in occasional interneurons in the same area. Cortical and medial nuclei of amygdala expressed SSTR3 > SSTR2 = SSTR1 > SSTR4. The central nucleus of amygdala expressed only SSTR3 and 4. These results represent the first demonstration of all 5 SSTRs in cerebral cortex. They reveal a wide and abundant distribution of SSTRs with a characteristic subtype-selective and region-specific distribution. The heterogeneous morphology of SSTR positive cortical neurons suggests SSTR modulation of local and projection neurons in the cortex.

790.8

DIFFERENTIAL EXPRESSION OF THE 5 SOMATOSTATIN RECEPTOR (SSTR) SUBTYPES IN RAT STRIATUM. Y.C. Patel, U. Kumar, H.H. Zingg* and S.C. Patel. Fraser Labs, McGill University, Montreal, Canada H3A 1A1 and Neurobiology Res. Lab. VA, CT. 06111.

Medium sized aspiny neurons that coexpress NADPH-d and somatostatin are differentially resistant to NMDA mediated toxicity and are spared in Huntington's Disease. Here we report on the expression of SSTR1-5 proteins using subtype specific antipeptide antibodies and avidin biotin enhanced immunocytochemistry, and of SSTR mRNA by RT-PCR in striatal neuronal cultures of embryonic rat brain and in the striatum of adult rats.

% of Cultured Striatal Neurons Expressing SSTRs

	SSTR1	SSTR2	SSTR3	SSTR4	SSTR5
all striatal neurons	36 $\pm$ 10	34 $\pm$ 11	18 $\pm$ 4	50 $\pm$10	22 $\pm$ 5
NADPH-d neurons	50 $\pm$ 12	35 $\pm$ 6	34 $\pm$ 4	29 $\pm$ 9	16 $\pm$ 4

All 5 SSTRs were expressed in adult rat striatum as follows: SSTR1 (+++), SSTR2 (+++), SSTR3 (++), SSTR4 (++), and SSTR5 (+). The pattern of distribution was different in cultured neonatal striatal neurons, SSTR4 being the predominant species (Table). Both in cultured neurons (Table) and in rat striatum a subset of SSTR expressing neurons were also positive for NADPH-d. The NMDAR agonists, quinolinic acid (5 mM) and NMDA (1 mM), were without effect on SSTR1-4 mRNA expression in cultured striatal neurons but caused a 5-fold induction in SSTR5 mRNA levels. We conclude that adult rat striatum, cultured rat striatal neurons, and the subset of NADPH-d neurons display a differential pattern of expression of SSTR1-5. NMDAR activation induces SSTR5 but not SSTR1-4 gene expression.

NGF, BDNF AND bFGF TREATMENTS DECREASE GMAP-LI IN CULTURED DRG SENSORY NEURONS. N. Kerekes[1], M. Rydh-Rinder[1,2], O. Johansson[1]*, T. Hökfelt[1], [1]Department of Neuroscience, Karolinska Institute, S-171 77 Stockholm and [2]Astra Pain Control, S-141 57 Huddinge, Sweden.

Peripheral nerve injury causes dramatic changes in expression of neuropeptides in the corresponding dorsal root ganglion (DRG) neurons. Neurotrophins may play a role in this regulation of neuropeptide expression, especially with regard to substance P and calcitonin gene-related peptide (CGRP). In the present study we have used DRG cell cultures to study the effect of several growth factors on the expression of galanin message-associated peptide (GMAP) in DRG cultures. GMAP is in the rat a 60 amino acid peptide which is part of the galanin precursor polypeptide. In untreated cell cultures around one third of all neurons expressed GMAP-LI, a finding suggesting that the situation in cultured DRG neurons is similar to the axotomized state. After three days of administration of nerve growth factor (NGF) (100 ng/ml), brain derived neurotrophic factor (BDNF) (10 ng/ml) or basic fibroblast growth factor (bFGF) (10 ng/ml) to adult rat DRG cultures, there was a significant decrease in the number of GMAP-positive neurons. The strongest effect was seen for bFGF (down by 50%), whereas the effect of BDNF (down by 40%) and NGF (down by 30%) was less pronounced. These findings suggest that all three growth factors counteract the axotomy induced upregulation of GMAP/galanin synthesis.

791.1

ADRENALECTOMY (ADX) DECREASES GABA-BENZODIAZEPINE RECEPTOR (BZR) AFFINITY IN THE FRONTAL CORTEX (FC): NORMALIZATION BY SALMON CALCITONIN (sCT). F. Boujrad[1], F. Dauphin[2]* and R. de Beaurepaire[1]. [1] INSERM U320, Laboratoire de Pharmacologie, CHRU de Caen; [2] URA 1829 CNRS, Cyceron, Caen, France.

We have previously proposed an animal model of depression using calcitonin in which low doses of sCT may have antidepressant properties. In this model, we have shown that chronic treatment with sCT in ADX rats produces a normalization of the ADX-induced increases of ß-adrenergic receptor density in the FC (*Soc Neurosci Abs 21: 257.20, 1995*). In the present work, we explored the effect of sCT on GABA/BZD receptors with the rationale that 1) anxiety is a major symptom of depression, and 2) calcitonin has anticonvulsivant properties. We investigated the effect of chronic sCT treatment (2.5IU twice daily for 9 days, n=5-6) on GABA/BZD receptors in control and ADX female Sprague-Dawley rats through the use of [^{3}H]-flunitrazepam saturation binding experiments performed on crude membranes from FC and hippocampus (Hpc). Chronic sCT treatment in control rats did not modify GABA/BZD receptor density (Bmax, means± SEM; 1390±57 vs 1440±58 fmol/mg prot in FC; 691±89 vs 638±92 fmol/mg prot in Hpc, for control and sCT rats, respectively) nor the affinity (Kd; 1.26±0.17 vs 3.2±0.8 nM in FC; 1.28±0.09 vs 2.45±0.7 nM in HPc). After ADX, we found a significant increase in GABA/BZD receptor density in FC (1870±166 fmol/mg prot, +34%, $p<0.01$ ANOVA) associated with a ten-fold decrease in affinity (13.1±2.8 nM, $p<0.001$), and, in Hpc, a significant increase in density (1280±49 fmol/mg prot, +85%, $p<0.001$) without any change in affinity. In ADX rats, sCT treatment did not modify binding characteristics in Hpc nor receptor density in FC, but reversed the decrease in affinity in FC (3.1±0.6 nM, -76%, $p<0.01$). These results show that sCT can normalize the ADX-induced decrease in affinity of BZR. Further work is however necessary to determine if such an effect has a role in the anticonvulsivant effects of sCT and/or is implicated in anxiety. *Supported by grants from INSERM, CNRS, University of Caen and l' Association de Recherche en Neurobiologie.*

791.2

Cocaethylene stimulates the secretion of ACTH and corticosterone and the transcriptional activation of hypothalamic NGFI-B. **German Torres*[1], Judith Horowitz[1], Soon Lee[2] and Catherine Rivier.[2] Behavioral Neuroscience Program. Department of Psychology. State University of New York at Buffalo[1]. Buffalo, NY 14260. The Clayton Foundation Laboratories for Peptide Biology. The Salk Institute[2]. La Jolla, CA 92037.**

Cocaethylene is a cocaine metabolite formed by hepatic carboxylesterases in the presence of alcohol. The effects of cocaethylene of the hypothalamic-pituitary-adrenal (HPA) axis were investigated using ACTH and corticosterone secretion as indices of peripheral stimulation. To ascertain the central effects of cocaethylene on neurons of the paraventricular nucleus (PVN) of the hypothalamus, a specific cRNA probe was used to follow changes in the transcriptional activation of nerve growth factor I-B (NGFI-B), a member of the family of immediate-early genes. Intravenous injection of cocaethylene (5 mg/kg) to rats produced a marked but transient increase in plasma levels of ACTH and corticosterone within 10 min of drug exposure. Secretion of these hormones was accompanied by elevated levels of NGFI-B mRNA detected 30 min after IV or IP cocaethylene administration (20 mg/kg). The transcriptional stimulation of this immediate-early gene within parvocellular secretory neurons was relatively brief in duration, returning to basal levels by 180 min after drug exposure. Taken together, these findings indicate that cocaethylene has neuroendocrine properties on its own, targeting a critical region of the brain that regulates stressful events in the body. This, combined with other neurochemical properties, points to the possibility of cocaethylene augmenting the effects of a drug-dependent state. This research was supported in part by a Term Faculty Development Award and a Research Foundation Award of the State University of New York to GT, by NIAAA grant #06420 and by the Foundation for Research to SL and CR.

RESPONSES OF PLASMA ACTH AND FOS mRNA IN THE PARABRACHIAL NUCLEUS TO BACTERIAL INFECTION MAY VARY WITH THE SITE OF INOCULATION. D. E. Carlson*. Dept. of Surg., Univ. of Maryland Sch. Med., Baltimore, MD 21201.

Recent evidence that implicates vagal input in the responses to endotoxin and interleukin-1 suggests that the effects of a bacterial infection may vary with the site of inoculation. Male rats were prepared chronically with either iv or ip catheters under pentobarbital. Four days later they were inoculated with ~10^7 E. coli. ACTH increased in both iv and ip rats at 1 h ($P<0.01$). However, ACTH at 1 h in the iv group (621±71 pg/ml) was greater than it was in the ip group (289±119 pg/ml, $P<0.01$). This difference paralleled the response in plasma endotoxin at 1 h that measured 13.2±2.6 EU/ml in the iv group and 2.56±0.42 EU/ml in the ip group (difference is significant, $P<0.01$). Brainstems from similarly treated rats were examined for FOS mRNA at 60-90 min after inoculation. Of the areas examined, the lateral parabrachial region was most often positive for the FOS mRNA. This staining was present in 5 of 5 iv rats and in 3 of 4 ip rats but not in saline-treated rats. These results were consistent with the hypothesis that the response of ACTH is dependent on the circulating concentration of endotoxin which also induces FOS expression in the lateral parabrachial region. More rats were inoculated ip with a 30-fold greater dose of E. coli that increased the plasma endotoxin to 12.9±3.8 EU/ml, a value equivalent to iv dose of E. coli. This ip dose elicited an increase in ACTH that was more rapid and greater than that for the iv dose ($P<0.01$). This latter finding suggests that the response to the larger ip dose is mediated by at least some pathways that are independent of the circulation. Supported in part by NIH grant GM52796.

INVOLVEMENT OF CENTRAL EPINEPHRINE AND SEROTONIN IN THE ENDOTOXIN-STIMULATED ACTH SECRETION. A. Giovambattista[1], A. N. Chisari[1], R.C. Gaillard[2] and E. Spinedi[1]*. 1. Neuroendocrine Unit, IMBICE and School of Exact Sciences, UNLP, 1900 La Plata, Argentina; and 2. Div. of Endocrinology and Metabolism, CHUV, CH 1011 Lausanne, Switzerland.

The aim of the present work was to elucidate the role of the central epinephrinergic and serotoninergic pathways on ACTH released in plasma during the acute phase of the endotoxic shock. For this purpose, plasma glucose (G, enzymatic assay) and ACTH (IRMA) levels were measured 2 h after ip administration of 0.5 ml of vehicle (VEH) alone or containing 50 ug of bacterial lipopolysaccharide (LPS) in adult male Fischer rats (n=8-10 rats per group) without any previous treatment and in those having received either a central active inhibitor of phenyl-ethanolamine-N-methyltransferase (SKF 64139; 100 mg/Kg BW, ip, 12 h before LPS) or a central active inhibitor of tryptophan hydroxilase (p-chlorophenylalanine, PCPA; 50 mg/Kg BW, ip, 26 h before LPS). The results (mean ± SEM) indicate that both pre-treatments, SKF 64139 and PCPA, did not modify basal plasma G (1.30 ± 0.10 and 1.20 ± 0.03 g/l, respectively) and ACTH (75 ± 7.1 and 55 ± 2.3 pg/ml, respectively) levels with respect to those found in controls (G: 1.20 ± 0.02 g/l and ACTH: 46 ± 4.7 pg/ml). LPS administration was able to induce a significant ($P<0.05$) hypoglycemia in all groups studied (1.00 ± 0.03, 1.19 ± 0.03 and 0.90 ± 0.03 g/l in control, SKF 64139 and PCPA respectively). On the other hand, the LPS-induced ACTH release was abolished in SKF 64139 (108 ± 9.2 pg/ml)-injected rats and it was significantly ($P<0.05$) decreased in PCPA (430 ± 39 pg/ml)-treated animals vs. values obtained in control rats (660 ± 38 pg/ml). Our results suggest that central epinephrine and serotonin neuronal systems are involved in the regulation of corticotrope function under endotoxaemia and that this regulation appears to be of a stimulatory nature. It remains to be determined whether the LPS-induced cytokines release could be altered by these pharmacological treatments. (Supported by CIC-CONICET)

CNS EXPRESSION OF HIV-1 ENVELOPE PROTEIN GP120 ACTIVATES HYPOTHALAMIC-PITUITARY-ADRENAL (HPA) AXIS. J. Raber*¶#, S. M. Toggas¶, S. Lee¶, F. E. Bloom¶, C. J. Epstein‡, and L. Mucke¶# ¶Department of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037; #New affiliations: Gladstone Molecular Neurobiology Program and Department of Neurology, University of California, San Francisco (UCSF), CA 94141; ‡Department of Pediatrics, UCSF, CA 94143.

The impact of HIV-1 expression in brain on the development of AIDS is unknown. Previously, we developed a transgenic model in which expression of the HIV-1 envelope glycoprotein gp120 induced CNS damage similar to that seen in HIV-1 infected patients (Toggas et al., 1994). The HPA axis in gp120 transgenic mice was investigated and superfused brain slices were used to assess the effect of gp120 on the release of adrenocorticotrophic hormone (ACTH) secretagogues from the hypothalamus. Gp120 transgenic mice showed significant increases in plasma corticosterone and ACTH levels, and in pituitary ACTH content, compared with non-transgenic littermate controls or transgenic controls expressing other proteins from the same promoter. Recombinant gp120 induced release of the ACTH secretagogue arginine vasopressin (AVP) from superfused non-transgenic hypothalamic slices *in vitro* in a calcium-dependent fashion, suggesting a role for hypothalamic AVP release in the HPA axis activation in gp120 transgenic mice. This effect was inhibited by antagonists of nitric oxide synthase (NOS) or N-methyl-D-aspartate (NMDA) receptors, suggesting involvement of NMDA receptor stimulation and NOS activation. A role of free radicals in gp120-induced HPA axis activation was further supported by the finding that bigenic mice co-expressing gp120 and the free radical scavenger human copper/zinc superoxide dismutase (SOD) had normal corticosterone levels. This might relate to interference by SOD with the formation of peroxynitrite from NO generated by gp120-activated NOS. Thus, CNS expression of an HIV-1 coat protein can result in HPA axis activation. Overproduction of corticosteroids in HIV-infected patients could induce immunolgical and neurological alterations and increase pathology in steroid-responsive regions of the CNS. GLUCOCORTICOID REGULATION OF GLUCOCORTICOID RECEPTOR (GR) LEVELS IN RAT BRAIN DETERMINED BY WHOLE-CELL WESTERN BLOT PROCEDURE. B.A. Kalman*, M.S. Chi, M.A. Cole, P.J. Kim, R.L. Spencer. Behavioral Neuroscience Division, Department of Psychology, University of Colorado, Boulder, CO 80309.

Prior *in vivo* research showing steroid-induced regulation of GR has depended upon measurement of only the cytosolic fraction of tissue homogenates. In these instances, the investigator must remove the source of steroid at some point prior to sacrifice in order to allow complete clearance of steroid. Steroid removal may not be the best option, however, as this may result in some reversal in steroid-induced change in GR. We report here the effects of several steroids on GR protein levels utilizing the Western blot procedure on whole-cell hippocampus homogenates from male Sprague-Dawley rats. We observed an upregulation of GR in 5-day ADX animals given no steroid replacement and a downregulation in ADX animals receiving 5 days of high-dose corticosterone (CORT; 200 mg pellet) as compared to adrenal-intact controls. In animals receiving RU 28362 (RU; 10μg/hr), or aldosterone + RU (10μg/hr each), no downregulation was observed. This lack of downregulation was observed with a dose of RU that resulted in a decrease in spleen and thymus weight (~ 50%) identical to that produced by the high-dose CORT. In contrast, preliminary data suggest that 5 days of dexamethasone (DEX; 10μg/hr) treatment produced greater downregulation than high-dose CORT. We conclude that long-term treatment with CORT, DEX, or RU produces different profiles of GR changes (supported by grants, MH54742 & DK49143).

DIFFERENTIAL STRUCTURAL REQUIREMENTS FOR THE SIGNALLING PATHWAY OF THE TWO CORTICOSTEROID RECEPTORS. C.A. Caamaño*, M.I. Morano, M.T. Hoversten, S.J. Watson and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

The genomic effects of corticosteroids in the brain are mediated by their binding to two types of intracellular receptors, the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR). We have recently used a point mutational approach to identify key amino acids in the 90-kDa heat-shock protein (hsp90) binding region of the rat GR. Our results showed that a proline located in a conserved hydrophobic stretch of the predicted contact region with hsp90 is required for both *in vitro* hsp90 stabilization and normal signal transduction. Provided the substantial degree of structural homology between GR and MR, we decided to study and compare the effects of the mutation of the homologue proline in the MR. At the level of steroid binding, both mutated receptors retained the wild-type specificity and bound ligands at physiological concentrations. However, the GR mutant showed a moderate decrease in the K_d (4°C) and in the steroid-binding capacity. Although the proline mutation did not prevent hsp90 association with either receptor, it reduced the stability of the GR heterocomplexes, without significantly affecting the MR ones. Finally, our transcriptional activation results indicate that, under conditions in which the GR mutant exhibits less than 30% of the wild-type hormonal response, the MR counterpart is not appreciably affected. HSP27 SYNTHESIS IS ALTERED IN RESPONSE TO GLUCOCORTICOIDS AND HEAT SHOCK IN RAT BRAIN SLICES. C.S. Barr * and L.A. Dokas. Departments of Medicine and Biochemistry/ Molecular Biology, Medical College of Ohio, Toledo, OH, 43699.

Corticosteroids are hormones which are released from the adrenal gland as part of the endocrine response to stress. Because of their ability to bind specific nuclear receptors, they are able to produce pleiotropic effects by regulating the transcription of genes that contain a GRE sequence. Acute secretion of glucocorticoids can aid in the adaptation of neurons to cellular stressors, although chronic or repeated exposures to elevated titers of corticosteroids are maladaptive. Using [35S]-cysteine-methionine in rat brain slices to measure protein synthesis at 39°C, we have found the synthesis of a 28kDa protein to be elevated when animals are sacrificed 4 h following a single corticosterone or RU-28362 injection. When animals are sacrificed 24 h following an injection, however, the synthesis of the 28 kDa protein decreases. These effects are observed in hippocampal, cortical, and, cerebellar slices; the heat-inducible synthesis of the 28kDa protein is most marked in the cerebellum. Immunoblotting of proteins subsequent to separation by 2-dimensional gel electrophoresis has identified this glucocorticoid-sensitive, heat-inducible protein to be one of the small molecular weight heat shock proteins, HSP27. Such an increase in the synthesis of HSP27 following an acute exposure to corticosterone would be consistent with the known ability of glucocorticoids to produce short-term adaptive responses in neuronal tissue. Supported by NIH grant NS 30792

MECHANISM OF ACTION OF THE GLUCOCORTICOID RECEPTOR ANTAGONIST, RU40555. B.D. Pearce*, C.M. Pariante, T.L. Pisell, A.H. Miller. Emory Univ. Sch. of Med., Atlanta, GA 30322.

Glucocorticoid receptors (GRs) are found in virtually every nucleated cell in the body and are important mediators of the effects of adrenal steroids on target tissues. Recently, RU40555 has been introduced as a selective antagonist of the GR, joining the already available GR antagonist, RU38486. We have investigated the mechanism(s) by which RU40555 exerts its antihormone activity and have compared its effects to RU38486. Mouse fibroblasts (L929 cells) were incubated with RU40555 or RU38486, alone or in combination with the synthetic glucocorticoid, dexamethasone (DEX). In a competitive binding assay, RU40555, RU38486 and DEX had comparable affinities for the GR. In addition, both RU40555 and RU38486 proved to be potent antagonists of DEX-mediated gene transcription, as measured in L929 cells stably transfected with a CAT reporter gene behind a glucocorticoid response element (GRE); neither drug alone consistently exhibited agonist activity, even at high doses (40 µM). A radioligand binding assay and immunofluorescent staining of the GR demonstrated that RU40555 and RU38486, alone and in combination with DEX, induced translocation of the GR from cytoplasm to nucleus. Using an immunoprecipitation/western blot assay of cytoplasmic and nuclear extracts of L929 cells, both drugs induced a partial translocation of the GR from the cytosolic to the nuclear fraction in the presence or absence of DEX. However, DEX alone induced greater GR translocation than either RU40555 or RU38486 alone. In summary, the GR antagonists, RU40555 and RU38486, appear to act in a similar fashion by binding to the GR and leading to nuclear translocation of the receptor without subsequent activation of the GRE. ANTERIOR PITUITARY PROOPIOMELANOCORTIN (POMC) MESSENGER RIBONUCLEIC ACID LEVELS ARE MAINTAINED FOLLOWING ABLATION OF THE PARAVENTRICULAR NUCLEUS IN FETAL SHEEP. M.E. Bell*[1], T.J. McDonald[2], and D.A. Myers[1]. Dept. Physiology, Univ. Oklahoma HSC, Okla. City, OK[1] & Dept. Physiology, Coll. Vet. Med., Cornell Univ., Ithaca, NY[2].

In sheep, fetal maturation and parturition are dependent upon activation of the fetal hypothalamo-pituitary-adrenal axis and subsequent preterm rise in fetal cortisol concentrations. Lesions of the fetal paraventricular nucleus (PVN) in late gestation prevents the preterm cortisol rise and prolongs gestation (Am. J. Obstet. Gynecol. 165:764). The purpose of this study was to examine the effect of lesioning the fetal PVN on expression of POMC in the fetal anterior pituitary (AP). Fetal AP levels of POMC mRNA are maintained during the final weeks of gestation in spite of increasing levels of fetal plasma cortisol. Stereotaxic radiofrequency lesions (n=5 fetuses) or sham lesions (n=4 fetuses) of the fetal PVN were placed at 118-122 days gestation (DG; term=148DG). Fetal AP and hypothalami were collected at 138-142DG. Integrity of PVN lesions were confirmed histologically by examining the PVN for AVP expression. *In situ* hybridization was performed on fetal AP and neurointermediate lobe (NIL) for determining levels of POMC mRNA. Quantification of POMC hybridization was performed utilizing NIH Image analysis software. There were no significant differences in AP POMC mRNA levels between sham and PVN lesioned fetuses. No differences were observed in NIL levels of POMC mRNA between the two groups. In conclusion, basal mRNA levels and expression pattern of POMC in the fetal pituitary are maintained in the absence of a functional PVN. Thus, in fetal sheep, factors other than PVN neuropeptides must play an important role in basal expression of the POMC gene in the AP during development. NIH HD33147[1] & HD21350[2]

791.11

REVERSIBLE INHIBITION OF THE HYPOTHALAMIC VENTROMEDIAL NUCLEI (VMN) DEMONSTRATES A POTENT INVESTIGATIVE TOOL SuJean Choi*, C. Horsley, S. Aguila, and M.F. Dallman, Dept. of Physiology, UCSF San Francisco, CA 94143-0444

Historically termed "satiety centers", the VMN regulate many aspects of energy acquisition and storage. Permanent (electrolytic and chemical) VMN lesions increase food intake, body weight gain, insulin, and glucocorticoid levels in plasma. However, reversible inhibition of the VMN invites the use of additional approaches to studies of function.

In these studies, we have confirmed the work of Avrith and Mogenson (1978) on changes in food intake and body weight, and extended the validity of using bilateral injections of colchicine into the VMN to provide transient inhibition of VMN activity. Bilateral microinjections of colchicine, a microtubule transport inhibitor, temporarily inhibited VMN function without increasing gliosis (GFAP staining) compared to vehicle, and significantly less gliosis than observed after ibotenic acid. Demarcation of the effective spread was observed using fluorescein colchicine; there was no fluorescence in the 3rd ventricle, injection sites had discrete borders and at 24 hr averaged 0.14± 0.01mm^2.

During colchicine inhibition (8-10 d), food intake, body weight, plasma insulin and corticosterone increased significantly above controls; all returned to normal by d 15 post-injection.

We conclude that the physiological, behavioral, and anatomical sequelae of colchicine injections into VMN are identical to those of permanent lesions, with the exception of neuronal loss. The drug causes minimal cell damage and is confined within a discrete distance of the injection site. In addition to the obvious benefits of having each animal serve as its own control, the use of a reversible lesion in combination with permanent lesions or other manipulations provides a powerful tool for defining circuitry and other functional effects of neural structures. The time course of inhibition after a single, restricted injection makes this an extremely useful tool for studies of neuroendocrine regulation in systems which respond to surgical perturbation. *Supported by DK28172.*

THE HYPOTHALAMIC VENTROMEDIAL NUCLEI (VMN) EXERT MULTIPLE REGULATORY EFFECTS ON ACTIVITY OF THE HYPOTHALAMO-PITUITARY-ADRENAL (HPA) AXIS
C. Horsley, S. Choi, S. Bhatnagar, E.S. Hanson, and M.F. Dallman*, Dept. of Physiology, UCSF, San Francisco, CA 94143-0444.

The VMN are essential for normal regulation of energy balance. The effects of colchicine, a microtubule axoplasmic transport inhibitor, in the VMN on food intake and body weight were initially described by Avrith and Mogenson (1978). We have found that inhibition of the VMN with bilateral injections of colchicine produces transient effects identical to those of electrolytic or neurotoxin lesions; increases occur in food intake, body weight, insulin and HPA hormone levels. Colchicine-induced inhibition of VMN persists for 8-10 d, after which all measured variables return to values observed in vehicle-treated rats.

During the period of colchicine-induced inhibition, food intake increases primarily during the light cycle, but not during the dark, when rats normally eat 80-90% of their daily food. To determine the effects of colchicine on the HPA axis, male rats were bilaterally injected with 1 of 3 doses of colchicine into the VMN (0-0.2 µg/0.1 µl aCSF/side). Corticotropin (ACTH) and corticosterone (B) were measured 2, 5, and 15 d later under basal conditions and after restraint [the responses to a 24 h fast and insulin-induced hypoglycemia (1U/kg/ip) were also measured at 5 d.] During colchicine-inhibition, basal ACTH and B were elevated; by contrast, HPA responses to restraint and insulin were markedly reduced, suggesting that these stressor-induced neural inputs pass through or originate in the VMN. Basal and restraint-induced ACTH and B returned to normal by d 15.

The effects of VMN inhibition on HPA regulation resemble those observed in the AM after an overnight fast and those in the PM, prior to the first large meal of the day. We speculate that VMN activity, i.e. satiation, inhibits basal, and potentiates stress-induced HPA activity. This neural activity may provide a basis for HPA regulation normally observed in fed and fasted rats in the AM and PM. *Supported in part by DK28172.*

791.13

THE EFFECTS OF NOREPINEPHRINE ON THE ELECTRICAL PROPERTIES OF IDENTIFIED NEURONS OF THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS. **S.S. Daftary*, K. Szabó and J.G. Tasker**, Molecular & Cellular Biology Graduate Program and Dept. of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118.

The paraventricular nucleus (PVN), which is made up of magnocellular and parvocellular neurons, is richly innervated by catecholaminergic nerve terminals. Noradrenergic innervation of the PVN is involved in the regulation of the hypothalamic-pituitary-adrenal and hypothalamo-neurohypophysial axes. To determine how norepinephrine regulates the activity of PVN neurosecretory neurons, we studied the effects of norepinephrine and norepinephrine analogs on the membrane electrical properties of identified PVN neurons in slices of rat hypothalamus using conventional intracellular and patch-clamp recordings. PVN cells were identified as parvocellular or magnocellular neurons during recordings based on electrophysiological criteria, and were immunohistochemically labeled with antisera to oxytocin, vasopressin or neurophysin following biocytin injection. Bath application of norepinephrine (30-300µM) caused a reversible hyperpolarization (4-8mV) in 15% (2/14), and a depolarization (4-6mV) in 15% (2/14) of putative parvocellular neurons. Seventy percent (10/14) of the parvocellular neurons tested did not respond to norepinephrine. Sixty percent (9/15) of the magnocellular neurons tested depolarized (4-10mV) in response to norepinephrine. Norepinephrine-induced changes in membrane potential in magnocellular and parvocellular neurons were accompanied by a 10-20% decrease in input resistance in 45% (6/13) of the cells. These results indicate that norepinephrine has direct membrane effects on subsets of parvocellular neurons and magnocellular neurons of the hypothalamic PVN.

This work was supported by the Louisiana American Heart Association, Tulane Molecular and Cellular Biology Program and the NINDS.

NEUROENDOCRINE EFFECTS INDUCED BY 5-HT$_{1A}$ RECEPTOR AGONISTS ARE MEDIATED BY CENTRALLY LOCATED, POSTSYNAPTIC 5-HT$_{1A}$ RECEPTORS. L.Groenink, J.v.d.Gugten, S.K.Long[1] and B.Olivier*, Dept. Psychopharmacology, Fac. Pharmacy, Utrecht University, Utrecht and [1]CNS-Pharmacology, Solvay Duphar B.V., Weesp, The Netherlands.

5-HT receptor agonists like flesinoxan enhance plasma ACTH, corticosterone (CS) and prolactin levels. We investigated whether peripheral effects play a role in these neuroendocrine effects. Male Wistar rats were injected with the peripherally acting, potent and selective 5-HT$_{1A}$ agonist, N-N-di-propyl-5-carboxamidotryptamine (DP-5-CT) and plasma levels of ACTH, CS, prolactin and glucose were measured. Low doses of DP-5-CT (0.02 and 0.2 mg/kg SC) had no effect on plasma ACTH, CS and glucose levels. Only the highest dose of DP-5-CT (2.0 mg/kg SC) induced significant rises in plasma ACTH, CS and glucose levels, whereas prolactin was not affected. Neuronal activation, visualized by Fos immunoreactivity (Fos-IR) was found in the paraventricular nucleus of the hypothalamus (PVN), the central amygdala (CeA) and the dorsal lateral part of the bed nucleus of the stria terminalis (BNSTdl) after 2 mg/kg SC DP-5-CT. Surprisingly, 0.2 mg/kg DP-5-CT also induced Fos-IR in the CeA and BNSTdl, but not in the PVN. Microdialysis experiments in guinea pigs, showed that systemic (i.p.) injection of 2 mg/kg DP-5-CT did not decrease 5-HT levels in the hippocampus, whereas flesinoxan in a comparable dose (3 mg/kg, i.p.) did. Finally, depletion of the 5-HT system with PCPA did not reduce the flesinoxan-enhancing effects on plasma ACTH, CS, prolactin and glucose levels. These findings indicate that the neuroendocrine effects of 5-HT$_{1A}$ agonists are mediated via centrally located, postsynaptic 5-HT$_{1A}$ receptors.

EFFECTS OF ACUTE ADMINISTRATION OF BENZODIAZZPINE AGONISTS AND PARTIAL INVERSE AGONISTS ON HPA AXIS FUNCTION. K.M. Hartline*, M.J. Owens, S.J. Plott, J.C. Ritchie, C.B. Nemeroff Lab. Of Neuropsychopharmacology, Dept. Of Psychiatry and Behavioral Science. Emory Univ. Sch. Med., Atlanta, GA 30322

Corticotropin-releasing factor (CRF) is the major regulator of the hypothalamic-pituitary-adrenal (HPA) axis, and much evidence has accumulated consistent with the hypothesis that it plays a role in coordinating the endocrine, as well as autonomic and behavioral responses of an organism to stress. Furthermore, CRF has been shown to have anxiogenic effects in animal models. Benzodiazepines have been demonstrated to have many effects that are opposite to those of CRF. Thus, benzodiazepines suppress stress-induced HPA axis activation and are potent anxiolytics. In order to characterize the dose-response effects of drugs which are active at the benzodiazepine receptor for their actions on CRF neurons after acute administration, two benzodiazepine agonists, alprazolam and lorazepam, and one partial inverse agonist, FG7142, were administered subcutaneously to adult male Sprague-Dawley rats, in doses ranging from 0.1 mg/kg to 10 mg/kg, 90 minutes prior to decapitation. Plasma ACTH and corticosterone concentrations, as well as CRF concentrations in various brain regions were measured. In addition, serum drug concentrations were measured by HPLC. All three drugs were found to activate the HPA axis at the highest dose level, as demonstrated by elevated ACTH and corticosterone concentrations. Administration of the benzodiazepine agonist, alprazolam, caused a trend to dose-dependently decrease CRF concentrations in the locus ceruleus. Furthermore, a correlation was found between dose administered and serum drug concentrations for both alprazolam and lorazepam. (NIDA-08705)

791.16

EXPOSURE OF RATS TO CARBON DIOXIDE OR HALOTHANE PRIOR TO SACRIFICE INCREASES PLASMA ACTH AND BETA-ENDORPHIN CONCENTRATIONS. P. T. Lawson & C. W. Wilkinson*, VA Puget Sound Health Care System, American Lake Division, Tacoma, WA 98493, & University of Washington, Seattle, WA 98195.

In experiments requiring terminal blood or tissue samples from rats, it has become increasingly common to render the animals unconscious with carbon dioxide or halothane prior to decapitation. In order to determine whether the use of carbon dioxide or halothane prior to sacrifice results in elevation of stress-related hormones and neuropeptides, adult female Sprague-Dawley rats were divided into 3 groups of 15-16. Rats were handled 3 times weekly during the 2 weeks before the experiment. QD rats were removed from their cages and quickly decapitated within 15 sec. CO_2 rats were removed from their cages and placed in a chamber fully-charged with carbon dioxide until unconscious (45-60 sec) and then decapitated. HAL rats were placed in a bell jar containing halothane vapor until unconscious (30-45 sec) and then decapitated. ACTH, β-endorphin (β-E), and corticosterone were measured in plasma by radioimmunoassay. ACTH, α-melanotropin (α-MSH), and β-E concentrations were determined in pituitary extracts; and α-MSH, β-E, and corticotropin-releasing factor (CRF) were assayed in hypothalamic extracts. Mean ($\pm$ SEM) ACTH concentrations were 31.7 $\pm$ 5.2 pg/ml in the QD group, 85.4 $\pm$ 11.7 in the CO_2 group, and 69.4 $\pm$ 7.5 in the HAL group ($F_{2,43} = 10.82$, $p < 0.001$). Plasma β-E concentrations were similarly elevated in the CO_2 (218.5 $\pm$ 29.4) and HAL rats (228.3 $\pm$ 24.5) when compared to the QD rats (105.4 $\pm$ 18.9) ($F_{2,42} = 7.67$, $p < 0.005$). As expected, plasma corticosterone concentrations and ACTH and β-E content of the pituitary did not differ among experimental groups. Investigators wishing to obtain basal levels of hormones or neuropeptides should be aware that the use of carbon dioxide or halothane prior to sacrifice results in marked hormonal stress responses. Supported by the Dept. of Veterans Affairs.

S 15535 A SELECTIVE AGONIST AT 5-HT1A AUTORECEPTORS AND ANTAGONIST AT POSTSYNAPTIC 5-HT1A RECEPTORS : EFFECTS ON ACTH, CORTICOSTERONE AND PROLACTINE RELEASE IN THE RAT.
F. Héry ; E. Mocaër(1) ; P. Siaud ; M. Héry ; O. Bosler* and C. Oliver. INSERM U297, Institut Jean Roche, UER de Médecine Nord, Bd P. Dramard, 13916 Marseille Cedex 20. (1) Institut Recherches Internationales Servier, 6 place des Pléïades, 92415 Courbevoie, Cedex, France.

Previous studies showed that S 15535, which acts as a selective agonist at 5-HT1A autoreceptors and as an antagonist at postsynaptic 5-HT1A receptors has anxiolytic and antidepressant properties in rodents. According to the relationships between stress, anxiety and depression, we evaluated its action on the hypothalamo-pituitary-adrenal axis (HPA) under basal conditions and in rats exposed to a 60 min immobilization stress. S 15535 was administered s.c. at doses 0.4; 2 or 10 mg/kg and another group of rats was treated with 8-OH-DPAT (0.5 mg/kg). All rats were killed 60 mn later. ACTH, corticosterone (B) and prolactine (PRL) levels were measured in blood samples. In basal conditions, 8-OH-DPAT markedly increases ACTH (+285%) and B (+235%) and decreased PRL (-58%) levels. At the highest dose (10mg), S 15535 stimulated the release of ACTH, B and PRL (+37; +122 and +49% respectively). The lowest dose (0.4mg) decreased the release of ACTH and B (-51 and -30%). No significant effects were observed with the dose of 2mg. Immobilization stress markedly enhanced all of the 3 hormones : ACTH, +171; B, + 244; PRL, +84%. 8-OH-DPAT overstimulated ACTH and B release (+352 and +71%). Similar, but lower effects were induced by S 15535 at the dose of 10 mg/kg (ACTH, + 82%; B, +45%; PRL, +79%). At the lowest dose, S 15535 decreased (-22%) the stress-induced release of B and no ACTH overstimulation was observed. It is well known that 5-HT stimulates the HPA axis via 5-HT1A postsynaptic receptors. Our data suggest that S 15535 at highest dose acts as an agonist at 5-HT1A postsynaptic receptors. At the lowest dose, S 15535 decreases both basal and stress-induced activity of the HPA axis. In conclusion, as far as hormonal parameters are concerned S 15535 seems to act as a partial antagonist at postsynaptic 5-HT1A receptors.

791.18

LONG-TERM EFFECTS OF FLUTAMIDE ON THE HYPOTHALAMIC-PITUITARY-ADRENAL & GONADAL SYSTEMS OF MALE RATS.
E.M. Mahoney & C.M. McCormick*, Department of Psychology, Bates College, Lewiston ME 04240 USA.

Circulating levels of sex hormones influence hypothalamic-pituitary-adrenal axis (HPA) function (e.g., Viau & Meaney, 1991). Recent research suggests that sex hormones in early development may cause relatively permanent differentiation of aspects of the HPA (e.g., Patchev et al., 1995). To explore the role of androgens, we administered flutamide (FLUT) or vehicle either: (1) to dams on embryonic days 15-20; (2) to neonates on days 0-5; or (3) to adults on days 55-60. At 70 days, HPA function was assessed by determining plasma corticosterone (CORT) levels prior to, and at intervals following, 20 min of restraint stress. Plasma testosterone (T) and corticosterone binding globulin (CBG) levels also were measured in the basal samples. FLUT treatment resulted in higher levels of CORT compared to vehicle treatment in all three treatment-age groups. Further, prenatally-treated males tended to have higher CORT levels than neonatally and adult-treated males, who did not differ. The only interaction that approached significance was that of stress-test timepoint and treatment: The largest difference between FLUT and oil groups was at the stress timepoint. There was no effect of treatment or of age at treatment on plasma CBG levels in the basal samples. FLUT-treated animals had *higher* plasma T levels than oil-treated animals; This was unexpected as T is known to decrease stress-CORT levels. Age at treatment effects were found for morphological measures: Rats treated with FLUT prenatally had shorter anogenital distances at 12 days of age compared to all other groups. They also were the only ones to have splayed penises (examined as adults). The results suggest that, in males, FLUT treatment has a long-lasting effect on HPA function at all ages. Possible mechanisms for these effects are discussed and it is noted that the mechanism may not be the same perinatally as in adulthood.

ALTERATIONS IN KAPPA OPIOID RECEPTOR mRNA LEVELS IN THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS BY STRESS AND SEX STEROIDS.
Rustam Y. Yukhananov* and Robert J. Handa
Department of Cell Biology, Neurobiology and Anatomy, Loyola University Medical Center, Maywood, IL 60153

High levels of kappa-opioid receptor (kOR) have been observed in the paraventricular nucleus of the hypothalamus (PVN), a region which integrates neuronal and endocrine responses to stress. Certain behavioral responses to stress are mediated *via* the activation of kOR, however there are no data indicating whether stress can alter kOR in the brain. Since gonadal steroids can be important regulators of the endocrine responses to stress, in this study the levels kOR mRNA were determined in the rat brain using *in situ* hybridization following two types of stress (intraperitoneal injection of hypertonic saline or novelty) in the presence or absence of gonadal steroids. Gonadectomized (GDX) male rats were treated with estrogen or dihydrotestosterone and sacrificed 45 min after spending 15 min in a novel open field, or 60 min following hypertonic saline injection. Two-way ANOVA revealed that estrogen and novelty increased the levels of κOR mRNA in the ventral zone of the medial parvocellular part of the PVN but not in the lateral parvocellular part of the PVN, claustrum, nucleus accumbens or the nucleus of the lateral olfactory tract. Furthermore, novelty increased kOR mRNA in GDX and GDX rats treated with dihydrotestosterone, but not in sham-operated or GDX estrogen-treated animals. Taken together, these data indicate that kOR mRNA levels are under estrogenic control and up-regulated in a stressor specific fashion. Supported by NSF BNS 9408890.

GENDER DIFFERENCE IN STIMULATION OF THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS BY ALCOHOL IN RATS: ACTIVATIONAL ROLE OF GONADAL STEROIDS.
K.M. Ogilvie*, T. Sagrado and C. Rivier. Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Jolla, CA 92037

Alcohol (EtOH) administration evokes secretion of the hypothalamic-pitiutary-adrenal (HPA) hormones adrenocorticotropin (ACTH) and corticosterone (B). In both humans and rats, the extent of HPA activation is greater in females than males. Two actions of gonadal steroids are ascribed to the development of sex differences: Organizational effects occur perinatally and persist for life, whereas activational effects rely on circulating steroids and can be reversed by gonadectomy (GDX). Our previous work shows that the gender difference in HPA response to EtOH arises at puberty and is independent of the organizational actions of steroids. The present work determined the activational role of steroids in the HPA response to EtOH. Rats were surgically manipulated and implanted with steroids at 47 days of age to form the following groups: 1) intact females, 2) intact males, 3) GDX males, 4) GDX males given estradiol (E_2), 5) GDX males given dihydrotestosterone (DHT), and 6) GDX males given testosterone (T). Ten days later, animals were fitted with intravenous and intraperitoneal (ip) cannulae; after another 3 days, animals were injected with EtOH (3g/kg BW, ip) or vehicle and bled 0, 15, 30, 60, 120, and 180 min. later. Plasma was assayed for ACTH, EtOH (BAL), and B. Area under the curve data was analyzed by 2-way ANOVA. Steroid manipulation did not effect BAL ($p = 0.496$). However, the ACTH response to EtOH was greater in females and GDX E_2 males than in intact males ($p = 0.038$), suggesting that the presence of E_2 sensitizes the HPA axis response to EtOH. There was also a trend ($p = 0.066$) for levels of B to be modulated by steroidal manipulation, with females secreting more in response to EtOH than intact males. GDX males, GDX males implanted with DHT and GDX males implanted with T, did not differ from either intact males or females in their HPA response to EtOH. Therefore, our data indicate an activational role of E_2 in the gender difference in HPA response to EtOH, but we find no evidence that circulating T is the important testicular factor that suppresses EtOH-evoked ACTH and B secretion in adult animals.

PHOTOPERIODIC REGULATION OF AGONISTIC BEHAVIOR AND THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS.
C. Morgan and H. Akil*. Mental Health Res. Inst., Univ. of Michigan, Ann Arbor, MI 48109

Male golden hamsters were exposed to either short photoperiods (SP) (10 h. of daily light) or long photoperiods (LP) (14 h. of daily light) and then subjected to agonistic encounters (social isolation, followed by fighting) to test the following hypotheses: 1) SP and agonistic encounters stimulate the HPA response and 2) the light-dark rhythms of agonistic behavior and HPA activity are similar during SP. Since the HPA axis is an important regulator of agonistic behavior in general, it may also play a key role in the photoperiodic regulation of agonistic behavior. Our results show that SP increase agonistic behavior, as assessed by the attack frequency, and elevate HPA activity twenty-two hours after fighting, as assessed by radioimmunoassays for plasma cortisol, corticosterone, and adrenocorticotropic hormone (ACTH). Furthermore, agonistic behavior and HPA hormone levels were highest during the dark phase. It is unlikely that the plasma levels of HPA hormones remained elevated 22 h. after the fighting. Moreover, since adrenal weights were higher after SP and agonistic encounters, suggesting long-term activation of the HPA axis, we interpret these data to mean that the combination of SP and agonistic encounters increase both the sensitivity of the HPA response and the capacity of the HPA axis to respond.

EFFECTS OF DIABETES MELLITUS ON THE SEROTONIN AND BENZODIAZEPINE MECHANISMS OF THE RAT HYPOTHALAMIC-PITUITARY-ADRENAL AXIS (HPA).
G.K. Matheson*, D. Weinzapfel, D. Fuqua and K.Ries. Laboratory of Neurobiology, Indiana Univ. Sch. of Med., Evansville, IN 47712.

Diabetes mellitus is known to alter the number of receptors and the concentrations of serotonin and GABA in many areas of the brain. This study evaluated the effects of diabetes on the action of serotonin and benzodiazepine agents on the HPA axis. Diabetes was induced with streptozotocin (45 mg/kg, *i.v.*) and blood glucose levels were determined two months later, at the time of euthanasia. Glucose levels were 76 mg/dl $\pm$ 9.32 S.E.M. (#52) in the non-diabetic control animals and 286 mg/dl $\pm$ 16.3 (45) in the diabetic rats. Ten mg/kg (*i.p.*) of buspirone, a serotonin$_{1A}$ agonist, increased plasma corticosterone levels by 47.9 µg/dl in the control animal and 35.8 µg/dl in the diabetic animal. These values are significantly different at $P \leq 0.05$. The buspirone ED_{50} values were 3.6 mg/kg for the control and 6.3 mg/kg for the diabetic group. Ten mg/kg (*i.p.*) of chlordiazepoxide, a benzodiazepine agonist acting at the GABA receptor complex, increased plasma corticosterone levels by 37.2 µg/dl in the control animal and 22.7 µg/dl in the diabetic animal. The ED_{50} values for chlordiazepoxide were 8.0 mg/kg for the control and 6.3 mg/kg for the diabetic group. Diabetes mellitus reduced the responsiveness of the HPA axis to these agents. REALISTIC ADIABATIC MODEL FOR LASER INDUCED BUBBLE FORMATION J.S. Allard[2]*, A. Thrope Jr.[2], K. Sentrayan,[1,2] and C.O. Trouth[2] 1. Depts. of Physics, 2. Physiology and Biophysics, College of Medicine, Howard University, Washington, D.C. 20059.

The widespread use of laser procedures in many fields of medicine has lead to a possible increase in the risk of ocular injury. We have developed a theoretical model using real gas equations of state involving virial coefficients in the adiabatic expansion of bubbles induced by a laser as a possible physical damage mechanism to the retina. In this model, the melanosomes in the retinal pigment epithelium (RPE) are assumed to be the main absorbers of the laser and are surrounded by a homogeneous non-absorbing cellular medium[1]. The damage due to the bubble formation occurs when the laser pulse is in the submicro to nano second range. The size of the bubble increases in a non-linear fashion with laser energy fluence and absorption coefficient of melanosomes. The present model using real gas equations of state involving virial coefficients in the adiabatic expansion of the bubbles as well as in the calculation of absorbed laser energy in the melanosomes will more accurately predict the damage caused by the bubble formation. This model will not address the mechanical shockwave formation in the sub-nano second time scale of the laser pulse.

IN VIVO VERTEBRATE PHOTORECEPTOR ALTERATION ASSOCIATED WITH ACUTE LASER EXPOSURE. H. Zwick*, R. Elliott, J.D. Lund, P.A. Edsall S.T. Schuschereba U.S. Army Medical Research Detachment, Walter Reed Army Institute of Research, San Antonio, TX 78235

The small eye of the snake (*Thamnophis m. marcianus*; *Elaphe guttata emoryi*) was used in combination with confocal scanning laser ophthalmoscopy (SLO) to evaluate acute laser retinal damage effects at the *in vivo* cellular level. Because of the snake eye's high optical power and good ocular transmission, confocal scanning laser ophthalmoscopy provided tangential *in vivo* cellular resolution of the photoreceptor matrix and blood cell flow anterior to the photoreceptor matrix. At high exposure doses, Argon laser irradiation (80 mw, 10 msec) induced acute photoreceptor loss at the exposure site within 60 seconds and alteration in epiretinal vascular blood cell flow, blood cell "sticking", anterior to the the photoreceptor layer lesion. At the periphery of high dose lesions and at lower doses down to 5 mw, 10 -15 msec, swollen and "whitened" photoreceptors appeared, lasting 3 to 5 weeks and then disappearing, leaving retinal spaces devoid of photoreceptors. Histopathology through "whitened photoreceptors" revealed a change in the inner segment oil droplet color from slightly yellow to "whitish", indicating an induced shift in photoreceptor internal reflective optics that might account for the "whitening" of irradiated photoreceptors. However, at exposure levels of 5 or <5 mwatts, "whitened" photoreceptors were only visible with the near IR (780 nm) SLO laser imaging source, suggestive of spectroscopic as well as a physical component to such photoreceptor change. This type of inner segement photoreceptor change may be mediated by an induced alteration in metabolic transport of interphotoreceptor metabolites into inner segment structures resulting in increased internal reflection especially in the near IR.

TRANSDUCTION EFFICIENCY OF DIFFERENT TYPES OF VIRAL VECTORS FOR MOUSE RETINAL CELLS IN EXPLANT CULTURE
M. Kido[1], K.A. Rich[1], E. Barrón[1], D.B. Kohn[2], J.-K. Yee[3], M.D. Trousdale[1], and J.C. Blanks[1]* [1]Doheny Eye Inst. and Depts. Ophthalmol. and [2]Pediatrics, USC Sch. of Med., Los Angeles, CA; [3]Dept. Pediatrics, City of Hope, Duarte, CA.

The retina offers a model system for studying viral-mediated gene transfer since it is well-characterized both morphologically and biochemically and more experimentally accessible than other parts of the central nervous system (CNS). We have been studying the utility of retroviral vectors for gene transfer to the retina. Retroviral vectors require actively dividing cells for infection, and thus they may not be feasible for human gene therapy to the retina. Adenoviral and HSV vectors offer the advantage of the ability to infect post-mitotic neurons. Therefore, we have compared three types of recombinant viral vectors containing the lacZ reporter gene [retroviral (MoMLV-LTR), adenoviral (Ad5.CMV), and HSV (8117/43; Dobson *et al.*, 1990) vectors] for their ability to transduce retinal explants from neonatal and adult mice. In addition, retroviral vectors with two types of envelope proteins (native MoMLV and Vesicular stomatitis virus (VSV) G envelope) were compared, since VSV-G protein allows concentration of virus to high titers (Burns *et al.*, 1993). Mouse retinal explants were infected with viral vectors for 6 hours to overnight, and then cultured for additional 3-7 days *in vitro* (DIV). Numbers of lacZ positive cells were determined by X-Gal staining. Our preliminary results suggest that the transduction efficiency of each vector was proportional to the total viral titer applied. Thus far, the percentage of infected cells for each vector was as follows: 0-3 % for VSV-G retroviral, 3-20 % for HSV, and 5-30 % for adenoviral vector. In conclusion, retroviral vectors had a lower transduction efficiency than adenoviral and HSV vectors. While a higher efficiency of transduction by adenoviral and HSV vectors were achieved, potential cytotoxicity and stability issues must be evaluated. OCULAR LESIONS & ALTERED EXPRESSION OF Bcl-2 IN THE SIV-INFECTED MACAQUE RETINA: AN ANIMAL MODEL OF AIDS.
JK Johnson*, KA Warren[2], EB Stevens[3], O Narayan[3], PD Cheney[4], NE Engelbrecht[1], and NEJ Berman[1]. Depts. [1]Anat. & Cell Biol., [2]Ophthalmol., [3]Microbiol., & [4]Physiol. KUMC, Kansas City, KS 66160.

A variety of ocular pathologies can occur in AIDS patients that may result in apoptosis. Bcl-2, plays a significant role in preventing apoptotsis in many cell types. We investigated role of this protein in the retina of macaque monkeys challenged with AIDS-inducing viral strains. Adult rhesus and pig-tailed macaques were inoculated with simian or simian/human immunodeficiency viral strains, SIV or SHIV. The general health of the retina was evaluated by fundus examination prior to necropsy. Virus was detected by PCR amplification of viral DNA sequences, and Bcl-2 expression by traditional immunocytochemical protocols at necropsy. Fundus examination and photography revealed some inoculated animals to have choroidal lesions. Overall retinal morphology in inoculated animals appeared similar to controls. Immunocytochemistry of both control and experimental retinas showed that Müller cells expressed Bcl-2 with increasing intensity from central to periphery. The first clear staining was of Müller cell villar processes within the OPL followed by Müller staining that extended from the ILM to the OPL, with the OLM visible in the extreme peripheral retina. Bcl-2 staining was increased in ganglion, amacrine and horizontal cells of some inoculated macaques. Photoreceptor nuclei were not stained. These preliminary data suggest that the level of viral burden in experimental animals was sufficient to directly or indirectly induce chroidal lesions and to increase the expression of Bcl-2. Additionally, normal Bcl-2 expression by Müller cells may be integral to maintaining the overall health of the retina.

IN VITRO DEGENERATION OF ROD PHOTORECEPTORS FROM TRANSGENIC MICE WITH A RHODOPSIN MUTATION.
L.C. Streichert* and T.A. Reh. Department of Biological Structure, University of Washington, Seattle, WA 98195-7420.

Transgenic mice with a missense rhodopsin mutation (Pro23His) provide a useful animal model for studying human autosomal dominant retinitis pigmentosa (Olsson *et al.*, *Neuron*. **9**, 815, 1992). Retinas from these mice begin to demonstrate rod degeneration in the second postnatal week. We have developed an *in vitro* assay for rod photoreceptor degeneration in retinas from Pro23His transgenic mice. Retinas from normal and transgenic littermates are removed and dissociated on postnatal day 7 (P7) and placed in high density cultures. At this age the majority of rods have differentiated and can be cultured successfully. The retinas are cultured for 0-12 days, fixed, processed for immunocytochemistry using anti-opsin antibody rho 4D2, and then labelled rod photoreceptors are counted. On day P7, approximately 40% of the neurons in both transgenic and normal retinas are rods and the transgenic retinas show no overt signs of degeneration. After 6 days *in vitro*, the percentage of rods in the transgenic cultures is significantly smaller than in the normal cultures. Therefore, the death of the transgenic rods is significantly accelerated when compared to that of normal wild-type rods. This *in vitro* assay system will be useful for screening for factors that delay, prevent, or accelerate rod degeneration in the mutant retinas. Preliminary evidence indicates that adding 9-*cis* retinoic acid to the culture medium significantly increases the degeneration of rods in the transgenic retinal cultures, but has no effect on normal rod survival. (This work supported by the Foundation Fighting Blindness).

EFFECTS OF LIGHT AND TEMPERATURE ON THE GRADIENTS OF AGE AND RESPONSIVENESS OF ROD PHOTORECEPTORS IN XENOPUS LAEVIS.
K.N.Leibovic*, J.Bandarchi, Dept. of Biophysics., Sch. of Med. SUNY/B, NY, 14214.

A rod photoreceptor outer segment (OS) renews itself from base to tip. Thus the tip is older than the base. This is hypothesized to be the reason for the gradient of responsiveness along the OS. The rate of renewal is known to depend on light exposure and on temperature. Our objective was to determine the response gradient as a function of temperature and light exposure.

Xenopus laevis were divided into two groups, "L" and "T", controlled with respect to light and temperature,respectively, and kept for 2 -3 months,during which time the OS are completely renewed. "L"contained two sub-groups: Ld, kept in continuous darkness,.and Ll exposed to a 20 hr.light/4hr. dark cycle. "T"contained a sub-group Tc kept at 15 C. and another Tw at 28 C. In addition there were control groups Ln and Tn kept in diurnal lighting at room temperature. We determined the response gradients by recording from varying lengths of OS with the suction electrode.

Effects of Light: In the "L" group the differences between base and tip were in the following order: Ll<Ln<Ld. The light sensitivities of these subgroups paralleled their differences in responsiveness, with Ll being the most and Ld the least sensitive. We observed no differences in the OS dimensions of the "L" subgroups.

Effects of Temperature:In the "T" group the differences between base and tip were in the order: Tw<Tn<Tc. In addition the OS were shorter and thicker in the Tc than in the other two subgroups in which the OS were of comparable dimensions.

We conclude that increased light exposure and elevated temperature decrease the response gradient between the base and tip of the OS, and we ascribe this to the increased OS renewal rate under these conditions. The response gradient then parallels the cellular age gradient between base and tip.

RETINAL CHANGES IN CATS AFTER 40 WEEKS TREATMENT WITH ß-ALANINE, H. Imaki*, J.M. Messing and J.A. Sturman. New York State Institute for Basic Research in Devevelopmental Disabilities, 1050 Forest Hill Road, Staten Island, NY 10314.

When cats are deprived of dietary source of taurine they become depleted of this sulfur-containing amino acid and develop a number of neurological disorders including retinal degeneration. We reported previously that the progression of such condition was greatly accelerated when cats were given 5% ß-alanine, an analog which utilizes the same uptake system as taurine, in drinking water, which in 20 weeks resulted in drastic reductions in tissue taurine concentrations and changes in retinal morphology, greater than ever documented in cats deprived of dietary taurine. In the current study we extended the period of ß-alanine treatment to 40 weeks to examine the effect of more extreme taurine depletion in adult female cats fed a completely defined, taurine-free synthetic diet alone or supplemented with 0.05% taurine. Taurine concentrations were further reduced in tissues from both dietary groups compared to those from cats treated for 20 weeks. Light and electron microscopy of retinas from these cats revealed obvious reductions in number and organization of photoreceptor cells in mildly affected areas, and complete disappearance in more severely affected areas. The cells in the inner retina appeared relatively intact, except for hypertrophied Muller cell processes filled with intermediate filaments, while the retinal epithelial cells often were vacuolated, or attenuated. As noted in cats given ß-alanine for 20 weeks, the severity of degeneration was invariably proportional to the reductions in retinal taurine concentration and dependent on the retinal regions, in the order of nasal, temporal, superior and inferior. (Funded by New York State Office of Mental Retardation and Developmental Disabilities).

EFFECTS OF PAF AND PAF ANTAGONISTS ON CALCIUM DYNAMICS IN MAMMALIAN RETINAL SLICES. D.M Linn*, M.A. DeCoster and N.G. Bazan. LSU Eye Center and Neuroscience Center of Excellence, LSU Medical Center, New Orleans, LA 70112.

Recent studies have indicated that the neuronal damage associated with glaucoma may be due to neurotoxic levels of glutamate and not necessarily due to intraocular pressure. Platelet-activating factor (PAF) has been demonstrated to increase glutamate release in other regions of the CNS and thought to play a role in neuronal injury. Therefore, we examined the effects of PAF and PAF antagonists on the calcium dynamics of neurons labeled with a fluorescent calcium dye indicator in rabbit and rat retinal slices. Retinal slices from adult white rabbits and rats were prepared using conventional methods. Slices were loaded with fluo-3 AM for 1-2 hr. in the dark and then examined with a scanning confocal microscope in real time. In control exp., responses to increasing doses of KCl resulted in "step"-like increases in fluorescence. In contrast, responses from slices incubated in MC-PAF, were slower to respond and showed some decay resulting in a "scalloped" response curve. Responses from slices incubated in the selective PAF antagonist BN-52021 differed in that each dose resulted in a gradual increase leading to a "ramp"-like response curve. In addition, responses from slices exposed to the glutamate agonist, kainate, were more comparable to responses from slices in PAF; while slices exposed to the glutamate receptor desensitization blocker cyclothiazide were more comparable to responses in the presence of BN-52021. Preliminary results from transgenic rats targeted for the degradative enzyme of PAF, PAF-acetyl hydroxylase, were more comparable to incubation with MC-PAF. In conclusion, the effects of PAF and PAF antagonists appear to involve the modulation of glutamate release possibly in a manner analogous to other parts of the CNS. These results indicate that PAF antagonists may offer some promise as a neuroprotectant against the effects of glaucoma. (NIH NEI EY05121)

792.9

IMMUNOCYTOCHEMICAL LOCALIZATION OF VASCULAR ENDOTHELIAL GROWTH FACTOR IN NEURONS AND GLIA OF HUMAN RETINA. E. Famiglietti[1]*, P. Song[1], E. McGookin, B. Streeten[2], V. Kuo-Leblanc[1], A. Baird[3], A-M. Gonzalez[3], and E. Stopa[1]. [1]Dept. of Pathology (Div. Neuropath.), Brown Univ. Sch. of Med/ R.I. Hosp., Providence, R.I., [2]Depts. of Pathology and Ophthalmology, SUNY-HSC, Syracuse, NY, and [3]Scripps Res. Inst., La Jolla, CA.

The cytokine, vascular endothelial growth factor (VEGF), declines in the brain after neural development and primary angiogenesis. In adult retina, VEGF increases in ischemia-associated retinal neovascular diseases such as proliferative diabetic retinopathy. VEGF has been identified in pigmented epithelial cells, and during development appears in retinal glia: astrocytes and Müller cells. Immature neurons of the ganglion cell layer (GCL) can be induced to express VEGF. Previously, we reported VEGF in the ganglion cell layer (GCL) of adult human retina. In the present study, eyes were obtained postmortem and were fixed in 4% buffered paraformaldehyde. Both free-floating retina and cryosections were incubated in a polyclonal antibody directed against the amino terminus of VEGF (#67), together with monoclonal antibodies (Biogenex) against vimentin (VM) or neuron specific enolase (NSE), coupled to Cy3 and FITC for dual-wavelength fluorescence microscopy. VEGF labelled blood vessels, and occasionally VM-positive Müller cells. VEGF (mainly nuclear) and cytoplasmic NSE co-localized in the cell bodies of GCs and amacrine cells (ACs), both in the GCL and the amacrine cell (sub)layer (ACL). Some ACs in both GCL and ACL were brightly labelled. These findings suggest that retinal neurons provide continuous trophic support for their retinal blood supply.

MECHANICAL INJURY TO THE MOUSE RETINA INCREASES bFGF AND CNTF EXPRESSION. W. Cao, R. Wen, F. Li, M.M. LaVail*, and R.H. Steinberg. Depts. of Physiology, Anatomy and Ophthalmology, UCSF, San Francisco, CA 94143.

Mechnical injury to rat retina protects photoreceptors from degeneration near the wound site, and this is attributed to a localized survival-factor response to injury (Wen et al., 1995). In mouse, however, such protection is absent. Differences in this response between mouse and rat could explain the species difference in protection. We therefore examined expression of bFGF, CNTF and the receptors, FGFR-1 and CNTFR-α, following mechanical injury to the normal mouse retina. Retinal injury was made by an incision through the choroid and RPE of BALB/c mice. Retinas were taken 1, 2, 4, 7, 10 and 16 days post-injury. Northern blot analysis showed marked increases in bFGF and CNTF mRNAs following injury. Expression of bFGF increased by 3-fold at 1 day post-injury; peaked at 2 days (more than 5-fold); and was still 2-fold at 16 days. Expression of CNTF increased more than 2-fold at 1 day post-injury; peaked at 4 days (3-fold); and declined to baseline level at 16 days. Injury did not change CNTF receptor expression. While these responses resembled those of rat, there were some differences in amplitude and time of expression. Importantly, however, FGFR-1 did not up-regulate in mouse retina, as it did in rat retina. These results suggest that differences from rat in the mouse survival-factor response to retinal injury, e.g. absence of FGFR-1 mRNA up-regulation, may, at least in part, underlie the absence of injury protection of photoreceptors in the mouse.

LIGHT AND A CIRCADIAN CLOCK INFLUENCE ARRESTIN mRNA LEVELS IN THE LATERAL EYE OF THE HORSESHOE CRAB *LIMULUS POLYPHEMUS*. C.D. Williams, J-L. Schremser, B-A. Battelle*. Whitney Lab and Dept. of Neuroscience, University of Florida, St. Augustine 32086.

We are examining the relative importance of light and a circadian clock on the levels of mRNAs that encode photoreceptor specific proteins. Diurnal rhythms in gene expression have been reported in several vertebrate species, but the role of a circadian clock in these rhythms is not clear because, in most vertebrates, the clock that regulates retinal functions is in the eye itself and is difficult to manipulate. The visual system of the horseshoe crab provides a unique system in which to examine in detail the role of the clock in vision. In this animal, the clock primarily responsible for regulating retinal functions is in the brain, and clock input to the lateral eyes can be eliminated by cutting the optic nerves.

Using a ribonuclease protection assay, we examined the combined effects of light and the clock on photoreceptor specific arrestin mRNA levels in *Limulus* lateral eye. We compared arrestin mRNA levels in eyes receiving both light and clock input with that in eyes deprived of both light and clock input. Results suggest that arrestin mRNA levels normally decline at night, and that this reduction is, at least in part, driven by a circadian clock. The change in arrestin mRNA level anticipates darkness. We are now testing the separate effects of light and the clock on arrestin mRNA levels.

MELATONIN ACTS AS A CIRCADIAN CLOCK REGULATOR OF ROD AND CONE PATHWAYS IN FISH RETINA. S. C. Mangel* and Y. Wang. Neurobiology Research Center, Univ. of Alabama Sch. of Med., Birmingham, AL 35294.

In the fish retina, cone horizontal cells (HCs) receive synaptic contact from cones and not from rods. A circadian clock regulates cone HC light responses so that cone input predominates during the day and rod input predominates during the night (Wang and Mangel, 1996). Moreover, the clock regulates rod and cone input to cone HCs in part via dopamine pathways (Mangel and Wang, 1995). That is, the clock increases dopamine levels during the day so that D4 receptors are activated. To determine whether melatonin, a neurohormone found in the fish retina (Iigo et al., 1994), also acts as a circadian clock effector, the effects of melatonin on L-type cone HC light responses were studied during the subjective day and night. Following 14 days of a 12/12 hr light/dark cycle, goldfish were maintained in constant darkness for 24-48 hrs. Surgery was performed under dim red or infrared light following which intact retinas were superfused with a bicarbonate-based Ringer's solution. HCs were impaled without the aid of any light flashes. Superfusion of melatonin (0.1-10 μM) during the late subjective day (CT 9) increased rod input and reduced cone input to the cells, a state typically observed during the subjective night. In contrast, melatonin application during the early subjective day (CT 3) or during the subjective night (CT 15, CT 21) had no effect. These findings suggest that melatonin acts as a circadian clock signal for the night, increasing rod input and decreasing cone input to fish L-type cone HCs, possibly by inhibiting dopamine synthesis and release (Boatright et al., 1994). Supported by grants from the NIH and NSF.

RETINAL CIRCADIAN RHYTHMICITY IN THE RING-BILLED GULL, *LARUS DELAWARENSIS*. M. Emond, R. McNeil, P. Lachapelle and T. Cabana*. Dép. de Sciences Biologiques, Université de Montréal, C.P. 6128, Succ. Centre-Ville, Montréal, Canada H3C 3J7, and Dept. of Ophthalmology, McGill University, Montréal, Canada H3H 1P3

Circadian rhythmicity is known to be an intrinsic property of the retinas of Vertebrates, including Birds. Using corneal electro-retinographic recording (ERG), we tried to determine if such rhythmicity is expressed at the level of the photoreceptors (a-wave), which are suspected to synthesize melatonin (Cahill & Besharse, Prog. Retinal Eye Res. 14(1995)267-291), or at the second order level (b-wave) of the retina, in a diurnal avian species, the ring-billed gull *Larus delawarensis*. Animals were kept indoors, next to a window, exposed to a natural light-dark (LD 14:10) cycle (August-September) prior to recording. ERGs were obtained at 4-hour intervals. Intensity-response curves were established, in scotopic condition, for both the a- and b-waves, and the curves were then fitted to the $R(I,t)=I/I+[Ka/r*(t)]Rmax$ and $V/Vmax=I^n/(I^n+\sigma^n)$ equations, respectively. The values of Ka and σ, which represent the stimulus intensity needed to evoke half the saturated response, were used as measurements of visual sensitivity. Results show that the value of Ka does not change over the course of the day, indicating that photoreceptor sensitivity does not vary. In contrast, the value of σ is lowest at 12h00 and highest at 4h00. This suggests that circadian rhythmicity in the retina of *L. delawarensis* is expressed at the post-receptor level, possibly at the inner plexiform layer, where receptors for melatonin have been identified in the chick (Laitinen & Saavedra, Brain Res. 528(1990)349-352). DIRECT AND INDIRECT PHOTIC INPUT TO THE MIDLINE AND ANTERIOR THALAMUS Z.-C. Peng[1]*, D. Campara[2], M. Bentivoglio[1], [1]Inst. Anat. Histol.; [2]Dept. of Neurol. Sci., Univ. of Verona, 37134 Verona, Italy.

Incidental anterograde tracing observations indicated that the thalamic midline, and in particular the thalamic paraventricular nucleus (PVT) receives some fibers from the retina and from the intergeniculate leaflet (IGL). Connections linking the PVT with the suprachiasmatic nucleus (SCN), which is the circadian pacemaker and main recipient of the retinohypothalamic tract, have been described. Retinal input to the anterior thalamic nuclei has also been detected by means of anterograde tracing. To clarify the origin and organization of these circuits, we injected fluorescent tracers, under deep anesthesia, in the rat anterior or posterior portions of PVT and anteroventral nucleus (AV). **In the retina**, injections in the anterior PVT resulted in retrograde labeling of ganglion cells in the peripheral quadrants; labeled ganglion cells prevailed, however, in the central sectors of the retina after tracer injections confined to the posterior PVT. Injections into AV resulted in the labeling of a few ganglion cells sparsely distributed in intermediate location between the retinal center and periphery. **In the IGL**, a few labeled neurons were detected after injections in the posterior PVT and AV, but not after injections in the anterior PVT. **In the SCN**, no labeled neurons were found after AV injections; numerous neurons were labeled after injections in the anterior PVT, whereas only isolated neurons were detected in the SCN after posterior PVT injections. The present data indicate that both the direct and indirect photic input to AV is very limited. The anterior PVT receives direct input from the retinal periphery and indirect photic input from the SCN; the posterior PVT receives direct input from the center of the retina, but very limited photic information through the SCN and IGL. Since the SCN and IGL are main relays of the circadian timing system, PVT could be involved, throughout its extent but with a differential organization of its anterior and posterior parts, in processing photic information for circadian entrainment.

Cloning, Expression, and Function of Catfish Retinal and Extraretinal Photopigments. Yonatan H. Grad , Seth Blackshaw, and Solomon H. Snyder*
Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205

Previously (Soc. Neuroscience Abstr. 1995), we reported the cloning of a novel, extraretinal opsin from channel catfish. This gene b7, which shows 40-45% identity with avian pinopsin and vertebrate long-wave opsin genes and shows a novel intron-exon structure and thus defines a new family of vertebrate photopigments. Recently, we have also cloned the catfish genes encoding rhodopsin and the red cone pigment -- the only two retinal opsins, on the basis of microspectroscopic analysis. These show very high levels of homology (>90% identity) to orthologous genes from other bony fish. We have studied the expression pattern of all three photopigments of the fish via digoxygenin *in situ* hybridization in the retina, pineal, skin, and diencephalon. In particular, we observe intense expression of b7 in a small subset of pineal photoreceptors, although no expression in the single cone retina. Given that b7 appears to be a blue-sensitive photopigment, and that the channel catfish retina expresses only rhodopsin and the red cone pigment, this clearly demonstrates a separation of spectral sensitivity range between the retina and pineal, with the pineal sensitivity reaching considerably further into the blue wavelengths, with implications for the regulation of phototaxis and circadian function.

This work was partially supported by a Howard Hughes Predoctoral Fellowship and grants from the NIH.

792.16

MOLECULAR CLONING AND CHARACTERIZATION OF VISUAL PIGMENTS IN THE BOTTLENOSE DOLPHIN, (*Tursiops truncatus*). **J. I. Fasick*, and P. R. Robinson.** Biological Sciences, University of Maryland Baltimore County, Baltimore, MD 21228.

It is believed that most mammals are dichromats and possess a short and middle wave photoreceptor class. Based on this current understanding of mammalian color vision, we hypothesize that *Tursiops* possesses multiple photoreceptor classes; a rhodopsin based rod class as well as short and middle wave sensitive cone classes. Dolphin opsin cDNAs have been cloned from a *Tursiops* retinal cDNA library and sequenced. Based on homology to known opsins, the clones were identified as dolphin rhodopsin and a middle wave cone pigment. In order to characterize the spectral properties of dolphin rhodopsin, cloned cDNA was expressed in COS cells and the apoprotein was reconstituted with 11-*cis* retinal. The absorption maximum of expressed dolphin rhodopsin is 486 nm, a value which is blue-shifted from typical terrestrial mammalian rhodopsins which absorb maximally near 500 nm. The expressed pigment is also capable of activating the bovine G-protein transducin.

OLFACTORY SYSTEMS: OLFACTORY BULB PHYSIOLOGY

793.1

NOREPINEPHRINE INCREASES OLFACTORY NERVE-EVOKED EXCITATION OF RAT MITRAL CELLS IN VITRO. K.J. Ciombor, M. Ennis, C.A. Ossebaard* and M.T. Shipley. Dept. Anat., Univ. Maryland Sch. Med., Baltimore, MD 21201.

A major modulatory input to the main olfactory bulb (MOB) is the noradrenergic (NE) system which arises exclusively from the pontine nucleus locus coeruleus (LC). LC afferents terminate densely in the internal plexiform layer (IPL) and granule cell layer (GCL) and to a lesser degree in the external plexiform layer (EPL). We recently showed that selective activation of LC enhances mitral cell responses to weak (i.e., perithreshold), but not strong (i.e., suprathreshold), olfactory epithelium stimulation *in vivo*. Here, we investigated the effects of exogenously-applied NE on mitral cell activity in rat olfactory bulb slices.

Horizontal rat olfactory bulb slices (500 µm-thick) were obtained from 75-100 g rats and a stimulation electrode was placed on the olfactory nerve (ON) layer. ON-evoked field potentials were recorded in the glomerular layer and extracellular recordings were obtained from single mitral cells. Bath application of NE (25 µM) had no consistent effect on mitral spontaneous discharge and did not affect the size of ON-evoked field potentials in the glomerular layer. However, NE increased mitral excitatory responses evoked by perithreshold intensity ON shocks in most cells examined.

These results indicate that NE increases mitral cell responses to weak ON inputs in vitro. The ON-evoked field potential in the glomerular layer was not altered, suggesting that the enhancement of mitral spiking is not due to NE actions in this layer. This is consistent with the findings by Trombley (1992) and Trombley and Shepherd (1992) that NE reduces mitral-granule dendrodendritic interactions. Additional experiments will determine: (1) Which class(es) of adrenergic receptors mediate NE's actions, and (2) if increased sensory-evoked mitral responses are mediated by NE actions on mitral-granule cell dendrodendritic transmission. *Support: NIH DC00347, NS29218 and NS29635.*

BIOPHYSICAL PROPERTIES OF RAT OLFACTORY BULB NEURONS: NYSTATIN-PERFORATED WHOLE CELL RECORDING IN AN IN VITRO SLICE PREPARATION. P.M. Heyward, M. Ennis, M.T. Shipley *. Department of Anatomy and Neuroscience Program, University of Maryland, Baltimore MD 21201.

Little is known about the biophysical properties of mammalian main olfactory bulb [MOB] neurons. We have recorded spontaneous and evoked activity in the glomerular and mitral cell body layers of 400 micron thick slices of rat OB using conventional and Nystatin-perforated whole-cell patch-clamp methods.

Spontaneous activity in each layer consists of continuous firing at 0.5 to 5 Hz, or bursting activity with intraburst frequencies of up to 100 Hz in mitral cells, and 200 Hz in the periglomerular region. Under current clamp conditions using Nystatin in the recording pipette, mitral cell resting membrane potential lay between -70 and -40 mV. Cells with relatively hyperpolarized membrane potential were not spontaneously active and responded to depolarizing current with continuous action potential generation. Such evoked trains of action potentials were not followed by a detectable long -lasting after-hyperpolarization [AHP]. Spontaneously active cells with relatively depolarized membrane potential, however, frequently generated bursts of action potentials that were followed by pronounced and sustained AHPs. Mitral cells exhibiting continuous low -frequency action potential generation also showed slow AHPs following bursts of action potentials elicited by stimulation with depolarizing current. In our previous studies slow AHPs were absent in all cells recorded using conventional whole cell patch-clamp recording, although these cells did not differ in membrane potential, and remained electrically excitable. We conclude that a slow AHP is generated in mitral cells after trains or bursts of action potentials. The current underlying this AHP is eliminated after intracellular dialysis with solutions containing calcium chelator, and therefore requires a soluble intracellular mediator, possibly elevated intracellular calcium. We are investigating the role of slow AHP in the regulation of bursting activity in mitral cells, and whether or not it is influenced by modulatory neurotransmitters present in centrifugal afferents to the MOB. LONG-TERM POTENTIATION (LTP) IN AFFERENT AND DENDRO-DENDRITIC SYNAPSES IN RAT OLFACTORY BULB, M. Ennis*, V. Aroniadou-Anderjaska and M.T. Shipley. Dept. Anatomy, Univ. Maryland School of Medicine, Baltimore, MD 21201.

In olfactory bulb slices (13-18d-old rats), field potentials (FP) evoked in the glomerular layer (GL) by olfactory nerve (ON) stimulation consisted of an early component (N1; peak 9-13 ms) mediated by kainate/AMPA receptors (blocked by CNQX) and a late component (N2; peak 50-150 ms) mediated by NMDA receptors (blocked by APV). Tetanic stimulation (50 Hz, 5 sec) in the ON layer induced LTP of N1. Simultaneous FP recordings in the GL and in the mitral cell layer (MCL) showed that LTP of N1 was accompanied by LTP of a negative component in the MCL. This negativity presumably reflects synaptic input of mitral/tufted cells to granule cells, and it may include mitral cell spiking activity. Thus, LTP of the synaptic response in the GL may result in LTP of the mitral/tufted cell output. NMDA receptor activation was not necessary for LTP induction, since APV and MK-801 did not prevent LTP. LTP of N1 was synapse-specific, as a control, glutamatergic (blocked by CNQX) response (n1) evoked in the GL by stimulation in the MCL did not express LTP. The n1 presumably reflects autoexcitation of mitral/tufted cells, and/or dendrodendritic synaptic interactions among mitral, tufted and periglomerular neurons. Subsequent tetanic stimulation in the MCL induced LTP of n1. When tetanus was applied first to the MCL, and ON stimulation was used as the control pathway, LTP of n1 was not accompanied by LTP of N1. Thus, LTP of n1 indicates plasticity in dendrodendritic synaptic interactions rather than a long-lasting enhancement in neuronal excitability. Together with our previous findings of an NMDA receptor-dependent LTP of the APV-sensitive mitral cell spiking activity, these results suggest that both NMDA receptor-dependent and independent forms of LTP are expressed in the primary sensory synapses of the rat olfactory system, and that both kainate/AMPA or NMDA receptor-mediated components can be potentiated. Furthermore, these results suggest for the first time that dendrodendritic synaptic interactions are capable of expressing LTP. *Support: NIH DC00347, NS29218 and NS29635.*

793.4

PHARMACOLOGICAL CHARACTERIZATION OF GLOMERULAR SYNAPTIC RESPONSES IN RAT OLFACTORY BULB, V. Aroniadou-Anderjaska*, M. Ennis, and M.T. Shipley. Dept. Anatomy, Univ. Maryland School of Medicine, Baltimore, MD 21201.

In slices from the olfactory bulb of 13-18d-old rats, the field potential (FP) evoked in the glomerular layer (GL) by olfactory nerve (ON) stimulation consists of two components. The early component (N1; peak 9-13 ms) is mediated by kainate/AMPA receptors, as it is blocked by CNQX. The late component (N2; peak 50-150 ms) is mediated by NMDA receptors, as it is blocked by APV. Simultaneous FP recordings in the GL and unit activity recordings in the mitral cell layer (MCL) showed that N2 triggers prolonged spiking of mitral cells, since the N2 and the late unit activity in the MCL have the same time course and they are both blocked by bath applied APV. The N2 can be isolated in 10 μM CNQX, where it is enhanced by reduction of Mg^{++} or by bath applied bicuculline methiodide (BMI). BMI applied to normal medium enhances selectively the N2, while it causes a small reduction of N1. This late effect of BMI suggests that BMI-sensitive GABA-A receptors are present only on lateral dendrites of mitral/tufted cells. Bath applied baclofen (5 μM) blocks both N1 and N2, while it does not affect a glutamatergic (blocked by CNQX) FP (n1) evoked in the GL by stimulation in the MCL. The n1 presumably reflects autoexcitation of mitral/tufted cells, and/or dendrodendritic synaptic interactions among mitral, tufted and periglomerular neurons. The lack of an effect of baclofen on n1, when N1 and N2 are blocked, suggests that GABA-B receptors are located exclusively on the presynaptic ON terminals. In support of this hypothesis, a stimulus pulse in the MCL suppresses the response evoked by ON stimulation (ISI 10-100 ms), presumably through activation of periglomerular GABAergic cells acting on ON terminals. This suppression may be mediated by GABA-B receptors, since it remains unaffected when GABA-A inhibition is reduced by bath applied BMI suggesting that it is not mediated by BMI-sensitive GABA-A receptors. *Support: NIH DC00347, NS29218 and NS29635.*

FIELD POTENTIAL OSCILLATIONS IN FROG AND SALAMANDER OLFACTORY BULB AND EPITHELIUM. K. M. Dorries*, and J. S. Kauer. Dept. of Neuroscience, Tufts Univ. Sch. of Med., Boston, MA 02111.

Odor-induced or -enhanced oscillations in field potential (FP) have been recorded in the olfactory bulb (OB) of virtually all vertebrate species examined, and in the olfactory processing areas of several invertebrate species. These oscillations are thought to arise as a result of the excitatory and inhibitory connections within the OB or antennal lobe. The ubiquitous nature of the FP oscillations suggests that they may be important in the neural coding of olfactory information. We have recorded odor-induced oscillations in the OB and in the olfactory epithelium (OE) electro-olfactogram (EOG) in two species of amphibians, *Rana pipiens* and *Ambystoma tigrinum*. While bulb FP and EOG oscillations are not always observed in the same preparation, the oscillations in the two areas do have several features in common: 1) EOG and FP oscillations have similar time courses, with approximately the same latency (with respect to stimulus onset) and duration; 2) oscillations that are recorded simultaneously in the OE and OB of one animal are of approximately the same frequency, in the range of 8 to 18 Hz for different individuals of both species; 3) oscillations in both areas are generally first observable in response to moderate to high odorant concentrations, and both increase in amplitude and duration with increasing stimulus concentration; and 4) odorant concentration does not affect the frequency of the oscillation in either area. These similarities indicate there might be a causal relationship between the OE and OB oscillations. Small amplitude oscillations of the same frequency as odor-induced oscillations are occasionally observable in the OB in the absence of odor stimulation. To test whether these background oscillations are driven by activity in the OE, we blocked transmission of activity from the OE to the OB with topical application of lidocaine to the OE. The anesthetic abolished both odor-induced and background oscillation in the OB. Taken together, these observations suggest that in amphibians, oscillations in the OB may in part be driven by oscillatory input from the OE, even in the absence of odor stimulation. Analysis of stimulus-evoked spiking patterns of individual OE and OB neurons relative to oscillatory activity may provide evidence for a role for FP oscillations in olfactory processing.

ELECTRICAL STIMULATION OF RABBIT OLFACTORY BULB ELICITS *IN VIVO* VOLTAGE-SENSITIVE DYE SIGNALS. J. Fang*, L.B. Cohen, and C. Hickie. Dept. of Physiology, Yale University School of Medicine, New Haven, CT 06520.

Optical recording of neuronal activity using voltage sensitive dyes in the mammalian olfactory bulb could be useful in examining the specificity of glomerular activity to individual odorants. As a first step, we used an *in vivo* preparation which allowed optical recording from an electrically stimulated olfactory bulb. The olfactory bulb in a urethane-anesthetized rabbit was exposed by removing the overlying bone and most of the dura. A chamber was expoxied to the bone surrounding the skull hole and the olfactory bulb was stained for 60-90 min with the flourescent voltage-sensitive styryl dye RH 795. Bipolar electrodes were placed on the rostral aspect of the bulb's dorsal surface. The chamber was then filled with silicone oil and sealed, which greatly reduced heartbeat and respiratory-induced motion of the bulb. Triggering of recording on the peak of the EKG allowed further suppression of heartbeat-induced motion by allowing subtraction optical signals during a nonstimulus period from those during a stimulus. An area of the olfactory bulb 1.8 mm in diameter was imaged onto a 464-element photodiode array. Data was acquired at a 1 KHz frame rate; 1-16 trials were averaged. Electrical stimulation (a 2-5 ms, 100 V pulse) resulted in a rapidly rising optical signal. The latency to peak of this signal was about 10 ms, its duration (FWHM) was 5-15 ms and its df/f was 0.1-0.5%. The signal propagated across the array at a velocity of 0.5-1 mm/msec. We plan trying to record odor-induced optical signals. Supported by NIH grant NS08437 and a Browne Coxe Fellowship.

EXCITATION OF OLFACTORY BULB INTERNEURONS BY STIMULATION OF PIRIFORM CORTEX ASSOCIATION FIBERS IS ENHANCED FOLLOWING LTP. J. L. Cauthron* and J. S. Stripling. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

Stimulation of association fibers in the piriform cortex (PC) evokes a late negative wave in the granule cell layer (GCL) of the olfactory bulb (OB) which appears to represent synaptic excitation of granule cells by PC association fibers. We have previously shown that high-frequency stimulation of PC association fibers produces a long-term potentiation (LTP) of this negative wave and enhanced inhibition of mitral cells by association fiber stimulation. The present study examined the role of granule cells in this effect. Following the induction of LTP in male Long-Evans rats by daily high-frequency stimulation of PC association fibers, extracellular recordings were made under urethane anesthesia (1.4 g/kg). Presumed granule cells were identified by their location within the GCL and their activation by either lateral olfactory tract (LOT) or association fiber stimulation at variable latencies of 5 ms or longer. The superficial half of the GCL contained cells that were driven by LOT stimulation at latencies of 5-10 ms. High-frequency stimulation of either the LOT or association fibers had relatively little effect on the response of these cells. The deep half of the GCL contained cells that were driven by association fiber stimulation at longer latencies (20-30 ms). Following reinstatement of LTP these cells responded to association fiber stimulation, but not LOT stimulation, with increased firing at a shorter latency. This increased granule cell response can be explained either by LTP at PC association fiber synapses on granule cells, or by reentrant activity in association fibers generated within the PC (which would explain the long latency of the granule cell response). In either case, these results provide a mechanism for our previous finding of increased mitral cell inhibition following LTP stimulation, and they emphasize the powerful influence that PC pyramidal cells have over olfactory bulb activity via their projections to granule cells. Supported by DC02271.

MULTI-SITE FIELD POTENTIAL RECORDINGS IN THE OLFACTORY BULB USING A NEW SILICON MICROPROBE DESIGN. [1]J. S. Stripling*, [2]B. K. Lim, [2]S. S. Ang, [1]J. L. Cauthron, and [3]D. J. Woodward. [1]Dept. of Psychology and [2]Dept. of Electrical Engineering, University of Arkansas, Fayetteville, AR 72701, and [3]Dept. of Physiol., Bowman Gray School of Medicine, Winston Salem, NC 27158.

The ability to record simultaneously from multiple brain sites is a long-standing goal in brain research, and a variety of electrode designs have been developed to provide this capability. The present study provides an initial analysis of field potentials recorded with a new silicon microprobe design. Different versions of the microprobe contain 4 or 16 gold recording sites ranging in size from 36 x 155 μm to 8 x 10 μm. Thin (3 μm) nitrite-insulated gold traces are used to lead recorded signals off the microprobe, which is 40 μm thick and tapers from 120 μm wide at the base to a few microns at the tip. The microprobe is fabricated using a novel process in which reactive ion etching is used to produce the thin gold traces while anisotropic etching of the silicon substrate is used to control the final thickness of the probe. Recordings using the microprobe were made in male Long-Evans rats under urethane anesthesia (1.4 g/kg). Potentials evoked by stimulation of the lateral olfactory tract and association fibers in olfactory cortex were recorded at intervals of 100 μm (16-channel probes) or 200 μm (4-channel probes) across the external plexiform, mitral, and granule cell layers in the olfactory bulb. The microprobes produced low-noise recordings that were comparable in waveform to potentials recorded using micropipettes. Recordings made simultaneously using a microprobe or sequentially by advancing a micropipette yielded comparable depth profiles in the olfactory bulb. The recording characteristics of this microprobe design make it well suited for current source-density analysis of rapidly changing events that must be recorded simultaneously at all sites, such as changes in olfactory potentials in behaving animals, or changes occurring during synaptic potentiation or seizure activity. Supported by DC02271 (JSS) and DA2338 and NSF 9110308 (DJW).

IMPLEMENTATION OF A NEW NEURAL NETWORK ARCHITECTURE IN AN ARTIFICIAL CHEMOSENSORY SYSTEM. J. White*[1], T.A. Dickinson[2], D.R. Walt[2], and J.S. Kauer[1]. [1]Neuroscience Dept., Tufts Medical School, Boston, MA, [2]Chemistry Dept., Tufts Univ., Medford, MA.

We previously reported on the development of an artificial chemosensory system incorporating principles of distributed processing derived from studies of the olfactory system (White et al., 1994, *Soc.Neurosci.Abstr.*, #144.8). In the present study, signals from an array of fiber-optic based chemosensors are used as the receptor input to our computational model of the olfactory bulb (OB; White et al., 1992, *J.Neurosci.*, **12**:1772). Given this artificial input, the computer model generates a spatio-temporal spiking pattern distributed across the simulated mitral cells that varies with vapor identity. To discriminate these spatio-temporal spike patterns, we have begun developing a "delay line neural network" (DLNN), based on ideas proposed by Hopfield (*Nature*, 1995, **376**:33). This biologically plausible neural network utilizes the spike timing differences among mitral cells as a basis for its discriminations. The network consists of a single layer of units receiving inputs from the OB mitral cells via lines assigned randomly determined delays (analogous to axons with various conduction velocities). Spikes thus arrive at DLNN units with latencies that are the sum of the mitral firing latency plus the line delay. Units receiving coincident input spikes are more strongly activated than those receiving non-coincident spikes. To train the DLNN, mitral spike patterns are applied and the connections carrying spikes contributing to the activity of the most active unit for each pattern are strengthened (i.e., "winner-take-all") using an unsupervised, Hebbian mechanism. After training, activity across the DLNN units encodes odorant identity - the spatio-temporal spiking patterns of the mitral cells have thus been converted to a simple spatial pattern across the DLNN units. The OB-DLNN combination is capable of recognizing test inputs not included in the training set and appears to be tolerant of variations in input pattern amplitude (i.e., odorant concentration).

A-LIKE CURRENT AND SYNAPTIC PROPERTIES OF MITRAL CELLS IN RODENT OLFACTORY BULB SLICES. Wei R. Chen* and Gordon M. Shepherd. Section of Neurobiology, Yale University School of Medicine, 333 Cedar Street, New Haven, CT 06510.

We are continuing to develop the rodent olfactory bulb slice preparation for analysis of membrane and synaptic properties underlying olfactory processing. In response to depolarizing current injection, mitral cells showed three distinct membrane properties: 1) delayed onset of firing action potentials; 2) subthreshold membrane potential oscillations; 3) repetitive firing of clustered action potentials during prolonged threshold stimulation. These properties were associated with an early transient hyperpolarization at the onset of membrane depolarization. This hyperpolarization was abolished by depolarizing the membrane potential to above -70 mV and by applying 100 uM 4-aminopyridine (4-AP), suggesting that it was caused by an A-like inactivating potassium current. 4-AP also shortened the spike-firing latency, abolished membrane potential oscillations and changed the firing mode from clustered discharge to continuous discharge. It thus appeared that the inactivating potassium current contributed to all three of the membrane properties of the mitral cells. Excitatory and inhibitory synaptic circuits have been analyzed in response to olfactory nerve (ON) input. In response to an ON shock, three different kinds of response pattern were recorded. Most mitral cells showed either a long-lasting EPSP or an EPSP followed by an IPSP, suggesting a direct excitatory input. Some cells responded only with a pure IPSP, indicating that they were not activated by the stimulated olfactory axons but received lateral inhibition from other excited mitral cells. The ON-evoked EPSPs were blocked by 20 uM CNQX plus 100 uM APV, and the IPSPs by 20 uM bicuculline methiodide. The action potentials of the mitral cells were sometimes followed by a long and prominent hyperpolarizing potential. This hyperpolarization was reduced by either 20 uM bicuculline methiodide or 20 uM CNQX plus 100 uM APV, suggesting that it was a recurrent IPSP mediated by reciprocal dendrodendritic synapses. Supported by grants from NIDCD, NIMH, NASA and NIDCD (Human Brain Project).

OLFACTORY SYSTEMS: OLFACTORY BULB PHARMACOLOGY

794.1

COLOCALIZATION OF GEPHYRIN AND $GABA_A$ RECEPTORS AT SYNAPSES OF THE RAT MAIN OLFACTORY BULB. M. Giustetto[1], M. Bonino[1], J. Kirsch[2], J.-M. Fritschy[3], D. Cantino[1] and M. Sassoè-Pognetto*[1]. [1]Dept. of Anatomy, Pharmacology and Forensic Medicine, University of Turin, I-10126 Turin, Italy; [2]Max-Planck-Institut für Hirnforschung, Frankfurt am Main, Germany; [3]Institute of Pharmacology, University of Zurich, Switzerland.

The tubulin-binding protein gephyrin copurifies with the glycine receptor (GlyR) of spinal cord and is essential for its postsynaptic localization (Kirsch et al., Nature 366:745-748). Gephyrin has a widespread distribution in the CNS and occurs in many brain regions which are devoid of the ligand-binding subunits of the GlyR. We have demonstrated recently that in the retina gephyrin is colocalized with $GABA_A$ receptors at synapses that lack GlyRs (Sassoè-Pognetto et al., J. Comp. Neurol. 357:1-14). Here, we used double immunofluorescence with specific antibodies to determine whether gephyrin and the $GABA_A$-receptor subunits α1, α3 and γ2 occur at the same synapses in the rat olfactory bulb.

The antibodies produced immunofluorescent puncta on sections of the olfactory bulb that had been briefly fixed with paraformaldehyde. No immunoreactivity was observed when an antibody specific for the α1 subunit of the GlyR was applied. Electron microscopy showed that each immunofluorescent punctum corresponds to an aggregation of receptors at a postsynaptic site. Both gephyrin and the α1 subunit of the $GABA_A$ receptor were present at synapses made by granule cells with mitral and tufted cells in the external plexiform layer. Double immunofluorescence showed that gephyrin and the $GABA_A$-receptor subunits α1, α3 and γ2 occur at the same synapses. In particular, most of the α1-immunopositive puncta that outline the cell bodies and major dendrites of mitral and tufted cells were also labelled by the antibody against gephyrin.

These results demonstrate that gephyrin is localized at GABAergic synapses in the main olfactory bulb and suggest that this polypeptide might be involved in clustering of $GABA_A$ receptors at postsynaptic sites. (MURST 40% ,60%; CNR).

THE DISTRIBUTION AND ACTIVATION OF Ca^{2+} STORES IN CULTURED OLFACTORY BULB NEURONS G.C. Carlson*, M. Slawecki and A. Keller. Dept. Anatomy, University of Maryland School of Medicine, Baltimore, MD 21201.

Changes in free intracellular calcium concentrations ($[Ca^{2+}]_i$) evoked by release from intracellular stores were studied with microfluorimetry of dissociated cultures of olfactory bulb neurons. Cultures were prepared from bulbs obtained from 1 to 3 day old rat pups and maintained *in vitro* for one to three weeks. Neurons developed morphologies characteristic of mitral/tufted (M/T) cells or of peri-glomerular/granule (P/G) neurons. The cells were bulk loaded with the fluorescent Ca^{2+} indicator fluo-3AM (20 μM) and changes in $[Ca^{2+}]_i$ were monitored with a 16-bit intensified charged-coupled device. In some neurons, Ca^{2+} release from intracellular stores is reported to occur through 2 mechanisms: a ryanodine-sensitive Ca^{2+}-induced Ca^{2+} release mechanism, and an IP_3 (inositol-1,4,5-triphosphate) mediated release pathway. In the present study, Ca^{2+} fluxes from ryanodine-sensitive stores were evoked by bath applied caffeine (10 to 20mM). Fluxes from IP_3 -sensitive stores were evoked by local pressure application of quisqualate, the metabotropic glutamate receptor (mGluR) agonist whose activation can stimulate IP_3 production. In nominally Ca^{2+}-free solution (zero Ca^{2+} , 100μM EGTA) both M/T and P/G cells responded to caffeine with an increase in $[Ca^{2+}]_i$ in both their somata and proximal dendrites. In contrast, quisqualate application evoked $[Ca^{2+}]_i$ fluxes in P/G cells, but not in M/T neurons. The quisqualate-evoked $[Ca^{2+}]_i$ fluxes occurred in the somata and in proximal and distal dendritic segments. In all P/G cells examined both IP_3-dependent and ryanodine-sensitive Ca^{2+} release could be evoked. These findings indicate that olfactory bulb neurons support at least two mechanisms of Ca^{2+} release from intracellular stores, and that these mechanisms may be differentially distributed in different classes of neurons.

794.3

DIFFERENTIAL DISTRIBUTION OF IP_3 RECEPTORS IN RAT OLFACTORY BULB M.L. Slawecki*, G.C. Carlson and A. Keller. Department of Anatomy, University of Maryland School of Medicine, Baltimore, MD 21201.

The inositol-1, 4, 5-triphosphate receptor (IP_3R) regulates the release of calcium from intracellular stores. The identification of IP_3R in particular types of neurons can provide information about the specific function of IP_3-induced calcium release in these neurons. In the present study, immunohistochemistry was used to determine the distribution of IP_3R in the rat main olfactory bulb (MOB). Immunocytochemistry for the IP_3R antibody was performed on slices of MOB as well as on dissociated MOB neuronal cultures. Immunoperoxidase reacted tissue was examined with transmitted light microscopy. Immunofluorescence was used to double-label for IP_3R and neuron-specific proteins; this tissue was examined with fluorescence confocal microscopy. Immunoreactivity was absent in the olfactory nerve layer. In the glomerular layer many peri-glomerular cells stained strongly for IP_3R. Scattered sparsely throughout the external plexiform layer were isolated immunoreactive neurons with granular morphology. The highest density of IP_3R-positive neurons were found in the granule cell layer. All immuno-positive neurons displayed a homogeneous distribution of IP_3R signal within their somata and proximal dendrites. Well-labeled granule cells were also found in the mitral cell body layer. However, none of the mitral cells or their processes were immunoreactive for IP_3R. These findings indicate that IP_3R are preferentially localized to intrinsic neurons of the olfactory bulb, and that they are absent in the MOB projection neurons.

DIFFERENTIAL EXPRESSION OF GLUTAMATE RECEPTOR SUBUNITS IN DEVELOPING RAT OLFACTORY BULB. Artis A. Montague*, Winnie Au and Charles A. Greer. Sec. of Neurosurgery and Neurobiology, Yale Univ. Sch. Med., New Haven, CT 06510.

Ionotropic glutamate receptor (GluR) subunits exhibit highly specific localization in the adult rat olfactory bulb (OB). To explore the potential role of GluRs in the developing OB, we studied immunoreactivity (IR) of antibodies (Abs) to several ionotropic GluRs in the OBs of rats at embryonic day 18 (E18) and postnatal days 1 (P1) and 6 (P6). We also studied GluR-IR 2 and 4 wks. after a naris occlusion or denervation. IR for all GluR subunits was present by E18, though regional variation was noted within the OB. IR for GluR4 (Chemicon) and GluR5/6/7 (Pharmingen) mirrored the adult pattern; GluR4 was in mitral cells (MCs) and large external plexiform layer (EPL) processes; GluR5/6/7 was in MCs, large EPL processes, and granule cells (GCs). GluR1 (Chemicon) and GluR2/3 (Chemicon) IR showed developmental patterns. At E18 - P6, GluR1 was noted transiently in MC somata in addition to the adult pattern of IR in periglomerular and short axon cells and large EPL processes. GluR2/3 IR showed transient expression in MCs and large EPL processes in addition to GC-IR as is seen in the adult OB. Naris occlusion or denervation did not significantly alter GluR-IR. The results support the hypothesis that subunits of GluRs may differentially participate in synaptic circuits within the developing as well as the adult OB. In addition, the appearance of GluR IR in the embryonic OB, coupled with the transient expression of GluR2/3 in subpopulations of cells, is consistent with the notion that glutamate may have an inductive or morphogenic role during development. OPIOID MODULATION IN THE OLFACTORY BULB AND CORTEX OF FROG B.J. Hall*, J.G. Davison and K.R. Delaney, Dept. of Biology, Simon Fraser U., Burnaby, BC, Canada, V5A 1S6

The olfactory bulb processes sensory stimuli from the nose and gates the transfer of this information to higher olfactory centres. Within the bulb synaptic inhibition is critical to determining the extent and phasing of mitral cell (output) activity. While opioid peptides are reported to be present in putative inhibitory interneurons, at both the glomerular and external plexiform layers (periglomerular and granule cells), their role in shaping odour-evoked bulbar output is unclear. We examined the effects of pro-enkephalin derived peptides on spontaneous (<20Hz), odour-evoked and electrically stimulated field potentials using an *in vitro*, nose-brain preparation. Both Leu and Met-enkephalin (10μM in bath) produce a dramatic, naloxone antagonized, suppression of spontaneous and evoked activity in cortical olfactory areas. Surgical isolation of the cortex from the bulb indicates that the spontaneous cortical activity is highly dependent upon input from the bulb. Selective staining of mitral cells with voltage sensitive dye reveals an opioid mediated diminution of the long-lasting ipsp resulting from olfactory nerve shock. This is consistent with the observation that opioids have a disinhibitory effect on these principal neurons, through suppression of granule cell inhibition (Nicoll R.A., Alger B.E. & Jahr C.E., Nature, 287:4, 1980). However, spontaneous, odor-evoked and electrically stimulated field potentials in the bulb show less dramatic modulation in response to the opiate application. Therefore the effects of opioids on the bulbar circuitry are unlikely to be completely responsible for the dramatic reduction in the evoked and spontaneous cortical EEG.

DYNAMICS OF ODOR-INDUCED Ca^{2+} CHANGES IN MITRAL CELL APICAL TUFTS K.R. Delaney*[1] and W. Denk[2], Biological Sciences, Simon Fraser Univ. Burnaby, B.C. CANADA V5A-1S6[1] and Bell Labs Lucent Technologies, Murray Hill, NJ 07974 USA[2]

Mitral cell dendrites are distinctly divided into apical portions, with tufts within the glomeruli that receive sensory and interneuronal inputs, and horizontal secondary dendrites, in the external plexiform layer, that are sites of interaction with granule cells. To address the question of local processing by mitral cell apical dendritic tufts, we measured $[Ca^{2+}]$ with high spatial and temporal resolution using 2-photon excited fluorescence microscopy. Cells were filled by application of 10,000 MW Ca^{2+}-Green dextran to localized areas of the posterior lateral portion of the olfactory bulb in an *in vitro* frog nose-brain preparation (Delaney, & Hall, J. NSci. Meth. in press, 1996). Individual apical dendrites and tufts were clearly resolved in the anterior portion of the bulb. Two distinct temporal components of the Ca^{2+} change were seen in reponse to brief application of odor to the nose. All responding cells showed a late onset, slowly rising $[Ca^{2+}]$, (peak ≈ 1 sec after odor puff), that was graded with stimulus strength. The time to onset of this component varied with changes in stimulation intensity and between tufts by > 100 msec. In some tufts an additional, early, fast-rising component could be evoked with greater stimulus intensities. Electrical stimulation of the olfactory nerve usually resulted in a fast rising, short latency component which at higher intensities was followed by a small, late-onset, long-lasting component in some cells. This late component, more prominent with odor stimulation, might represent a source of persistent drive within the apical tuft which sustains the odor-evoked bulbar field potential oscillations. TAURINE IN THE OLFACTORY BULB: IMMUNOCYTOCHEMICAL LOCALIZATION. I. L. Kratskin* and X. Yu. Smell and Taste Center, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104.

The amino acid taurine is extremely abundant in the brain and possesses actions on several basic neural processes. Despite the fact that the main olfactory bulb contains the highest level of taurine in the brain, cellular localization of taurine and its functional role(s) in this sensory center are still unknown. The aim of this study was to localize taurine in the frog, rat, and human olfactory bulb using immunocytochemical techniques. Two groups of taurine-immunopositive elements were found at the light microscopic level. In one group, strongly immunostained processes were concentrated in the olfactory nerve layer and glomerular layer and most likely were primary olfactory axons. This pool of taurine may be essential for continuously renewed olfactory receptor cells due to its influence on neuronal growth and differentiation. The other group consisted of cell bodies, which were located in the glomerular, external plexiform, and especially in the granule cell layer and might be small neurons and glial cells. Immunoelectron microscopy of the frog's granule cell layer showed that taurine immunoreactivity was localized in short-axon cells and oligodendrocytes. In addition, colocalization of immunoreactivities for taurine and GABA was found in short-axons cells, most of which are considered to be inhibitory interneurons in the olfactory bulb. According to recent findings, taurine, delivered from neuronal and glial sites of storage, may interact with presynaptic $GABA_B$ receptors and inhibit synaptic release of GABA.

NEUROANATOMICAL AND ELECTROPHYSIOLOGICAL EVIDENCES FOR DOPAMINE ACTION IN THE FROG OLFACTORY BULB. P. Duchamp-Viret, V. Coronas, E. Moyse*, J.C. Delaleu, A. Duchamp, Univ. Lyon I-CNRS, F-69622, Villeurbanne, France

Dopamine (DA) content of the Amphibian olfactory bulb is supplied by interneurons scattered in the mitral cell/external plexiform layer. Occurrence of intrinsic DA neurons is a general feature of Vertebrate olfactory bulb, although with sub-regional localization differing among classes. Physiological involvement of DA in olfactory processing, as documented in Mammals, include modulation of odor detection and memory; these effects would be mediated by the numerous D2 receptors characterized in the mammalian olfactory bulb.

In the present study, we assessed in the frog the existence and localization of D2 receptors by radioligand binding in parallel with the electrophysiological effect of exogenous DA upon mitral cell activity.

D2-like binding sites were labeled on sagittal sections of frozen frog brains with 125I-Iodosulpride and visualized by film autoradiography. Specific D2-like binding sites were densely and homogeneously localized in the mitral cell/external plexiform layer, other layers of olfactory bulb being devoid of specific labeling.

Unitary electrophysiological activity of mitral cells was recorded in vivo. Local injection of dopamine agonists (DA or apomorphine) drastically reduced the spontaneous activity of mitral cells without suppressing their odor responsiveness. In 40% of recorded cells (N=62), agonist treatment induced only slight modifications of their intensity coding performances: sensitivity loss and response discharge frequency decrease. Pre-treatment with the D2 receptor antagonist eticlopride blocked agonist-induced modifications of mitral cell activity.

Altogether, these data suggest that in the frog olfactory bulb DA would improve signal/noise ratio by acting directly on mitral cells through D2 receptors.

DISRUPTION OF CONDITIONED OLFACTORY LEARNING BY SEROTONERGIC DEPLETION OF THE OLFACTORY BULB IS PREVENTED BY A ß-ADRENERGIC AGONIST. P.E. Langdon*, A. Darby-King, C.M. Whitt, and J.H. McLean, Div. of Basic Med. Sci., Memorial Univ. of Newfoundland, St. John's, Nfld., Canada A1B 3V6.

Conditioned olfactory learning has been shown to be dependent on serotonergic and noradrenergic inputs, that is, the loss of either transmitter results in disrupted learning. The present study was conducted to investigate the hypothesis that the loss of serotonin can be compensated by the augmentation of noradrenaline. Serotonin was depleted in the olfactory bulb of rat pups on postnatal days (PND) 1 or 2 by bilateral injections of 5,7-dihydroxytryptamine into the anterior olfactory nucleus. The pups were then trained on PND 7 following an olfactory learning paradigm using peppermint as the conditioned stimulus (CS). Forty-five minutes before training, the pups were injected i.p. with either saline, or isoproterenol (2 mg/kg or 4 mg/kg). Isoproterenol is a ß-adrenergic receptor agonist that has been reported to induce a preference for an odour when injected into pups prior to exposure to that odour (Sullivan et al., 1991). Sham operated pups that received odor (CS) plus stroking with a brush (unconditioned stimulus) showed subsequent preference for the CS when tested on PND 8 which has been previously reported. Normally, O/S pups that receive serotonergic depletions do not express an odour preference, however, when these pups received isoproteronol they did express an odour preference. Sham animals subjected to a control learning treatment (odour only) did not learn unless given isoproteronol (previously reported by Sullivan et al., 1991). At this time it is unclear whether pups that were depleted of serotonin learn in an odour only treatment coupled with isoproteronol injections. These results show how two modulatory neurotransmitters may interact such that one may compensate for the loss of another. Supported by MRC Canada.

CASTRATION ALTERS NOREPINEPHRINE FUNCTION FROM SUPERFUSED OLFACTORY BULBS OF MALE RATS. D. E. Dluzen* and Y. Shang. Dept. of Anatomy, NEOUCOM, Rootstown, OH 44272.

Previously, we have reported that castration reduced potassium-stimulated norepinephrine (NE) output from superfused olfactory bulbs (OB) of male rats. To further understand the possible mechanisms of this phenomenon, we measured the NE output from OB in intact and castrated male rats with either amphetamine (AMPH-10^{-3} M) stimulation (Exp. 1) or using uptake blockers (Exp. 2). In Exp. 1, both conditions responded to AMPH stimulation. However, only castrated rats showed a significant increase over basal levels (n = 8 /condition). In Exp. 2, synaptic NE output was similarly maintained with nomifensine (10^{-3} M) in both intact (n = 6) and castrated (n = 6) rats. While, after duloxetine (10^{-3} M) infusion, the NE output in the synaptic cleft was significantly greater than that of basal values in the intact (n = 8) but not in the castrated rats (n = 9). These results may imply that castration alters the distribution of OB-NE in the presynaptic terminal and/or the affinity of NE transporters to the uptake inhibitors. NEOUCOM-Pioneer Research Award

AGE-RELATED CHANGES IN MONOAMINES WITHIN THE OLFACTORY BULBS (OB) OF THE F-344 MALE RAT,
J. L. McDermott* and D. E. Dluzen. Dept. of Medicine, Edwin Shaw Hospital, Akron, OH 44312 and Dept. of Anatomy, NEOUCOM, Rootstown, OH 44272.

The OB were removed from young (5-6 month, N=9), middle-aged (15-16 month, N=11) and old (25-26 month, N=11) F-344 rats and assayed for concentrations of monoamines and their metabolites using HPLC-EC. Concentrations (pg/mg) of norepinephrine were significantly greater in old (403 ± 13) and middle-aged (390 ± 12) compared to young (324 ± 14) rats. By contrast, the norepinephrine metabolite, MHPG, was significantly lower in old (33 ± 2) versus the middle-aged (46 ± 4) and young (53 ± 6) animals. While OB concentrations of dopamine and serotonin did not differ among the three age groups, their respective metabolites, DOPAC and 5-HIAA, were significantly reduced in the middle-aged and old compared to the young animals. The salient bi-directional changes observed between norepinephrine and its metabolite MHPG are intriguing since they reveal some of the mechanistic alterations that occur in the OB noradrenergic system which may underlie the age-related changes in olfactory related memory-recognition processes. NEOUCOM - Pioneer Research Award.

VAGINOCERVICAL STIMULATION AFFECTS NEURAL ACTIVITY IN THE RAT OLFACTORY BULB VIA THE LOCUS COERULEUS.
F. Okutani*, H. Kaba, T. Murata, S. Takahashi, C. O. Okere and T. Higuchi. Dept. of Physiology, Kochi Med. Sch., Nankoku, Kochi 783, Japan.

Vaginocervical stimulation (VCS) at parturition has a critical role in the induction of maternal behavior in the rats. Although mothers show a preparturition aversion to pup odors, their maternal behavior tend to increase suddenly at postparturition. We have already demonstrated that VCS influences the dendrodendritic inhibition from granule cells to mitral cells in the rat olfactory bulb (OB) through β-noradrenergic receptors. Now we want to further examine if the locus coeruleus (LC) from which most noradrenergic centrifugal innervation originate to OB is involved in this VCS effect. The LC activity was blocked through a direct infusion with 1.0 μl of 0.5 % lidocaine chloride in a glass micropipette just before VCS. VCS was carried out using a rubber balloon which was inserted into the vagina and was inflated to increase intravaginal pressure to about 100 mmHg for 2.5 min. After the block of LC activity the dendrodendritic inhibition during and after VCS was not found to change significantly, although it has been previously confirmed that VCS influenced dendrodendritic inhibition in the intact situation on the same animal. These results suggest that the somatosensory stimulation to the vagina modulates the dendrodendritic inhibition from the granule to mitral cells in OB via the LC.

THE IMPACT OF ON-GOING CORTICAL ACTIVITY ON EVOKED POTENTIALS AND BEHAVIORAL RESPONSES IN THE AWAKE BEHAVING MONKEY.
A. Arieli[1]*, O. Donchin[2], A. Aertsen[1], H. Bergman[2], A. Gribova[2], A. Grinvald[1] and E. Vaadia[2]. [1]Dept. of Neurobiol., The Weizmann Inst., Rehovot, and [2]Dept. of Physiol. Hebrew Univ. Jerusalem, Israel.

Spatio-temporal patterns of coherent on-going synaptic activity are often very large, and therefore they should play a major role in cortical function. Recently it has been shown that an evoked response in the visual cortex has a deterministic component, and that the large variability in evoked activity observed in repeated trials results from the on-going cortical activity (Arieli et al., J. Neurophys. 73:2072, 1995; NS Abs. 21:772, 1995). These results were observed in anesthetized cats. Are these merely a peculiarity of the anesthesia ?

Here we present evidence that on-going activity does also affect the behavior of the awake macaque monkey. We analyzed the LFPs and the multiple single-unit activity recorded by up to 8 microelectrodes in the motor cortex (MI) during performance of a visually guided arm reaching task. We found large variability of the cortical evoked activity in response to the onset of a given visual cue even in a monkey performing highly stereotypical movements. Furthermore, we found that the variable evoked response was well correlated with the instantaneous on-going activity preceding it. In addition, we found that variations of the reaction time from visual cue onset to the initiation of arm movement were correlated with the amplitude of this preceding on-going activity. We suggest that behavioral relevance of the on-going activity reflects its importance as the 'context ' in which neural processing takes place.

HOW DO THE TWO HEMISPHERES OF THE CORTEX COMMUNICATE IN COORDINATING THE ACTIONS OF THE ARMS: SINGLE UNIT STUDY IN A BEHAVING MONKEY.
Donchin O. Gribova A., Bergman H., Vaadia E*. Dept. Physiol. Hebrew Univ.-Hadassah Med Sch, Jerusalem, ISRAEL 91120

We adressed the question of interhemispheric interaction by recording multiple single-units in both hemispheres of a rehsus monkey during the performance of a bimanual reaching task. Neuronal activity was recorded by four microelectrodes in each hemisphere in forelimb motor areas of the frontal cortex. Most cells in the primary cortex (MI) have a broadly-tuned directional preference during movements of the contralateral arm. About a third of the task related cells were activated in relation to movements of the ipsilateral arm. Many of these cells showed a preferred direction during unimanual movements of both the contralateral and the ipsilateral arms. The supplementary motor area (SMA) was characterized by a much larger percentage of cells responding ipsilaterally or bilaterally to unimanual movements.

More than a third of the cells we recorded in MI demonstrated activity during bimanual movements which was different from any linear combination of their activity during unimanual movements. In the SMA, an even higher percentage of cells were 'sensitive' to bimanual trials. We are now investigating the relation of the interactions among the cells with their response properties.

SIMULTANEOUS POPULATIONS OF SINGLE-CELL ACTIVITY RECORDED BILATERALLY IN PRIMATE MOTOR CORTEX.
P.D. Perepelkin and A.B. Schwartz* Whitaker Center for Neuromechanical Control , Arizona State University, Tempe, AZ 85287 and *Neurosciences Inst., San Diego, CA 92121

Chronically implanted electrodes make it possible to simultaneously compare single-cell activity recorded at different sites. Arrays of 32 wires were implanted in the right and left primary motor cortices of a rhesus monkey trained to perform a 3D reaching task consisting of movements in eight different directions from a center start location. We have been able to record 27 units from our best array and are able to record unit activity (60-350 mv amplitudes) from these arrays for more than five months. This capability will allow us to measure the amount of correlation between different units in the same and in opposite hemispheres.

The electrodes were implanted in the proximal arm areas of each hemisphere, 1-2 mm rostral to the central sulcus. Responses in this area are generated with passive movement of the shoulder and/or elbow. During the task, cells in both hemispheres are modulated when only one arm is used. A given cell's activity will be modulated whether the contra- or ipsilateral arm is used in the task. Preliminary results from one hemisphere suggest that these cells are directionally tuned and that their preferred directions are similar (48.5 ± 11.5 deg) when either arm is used. This suggests that the direction the arm is to move through external space is an important factor modulating cell activity and is fairly independent of the effector actually used to perform the task. Supported by the Whitaker Foundation, Barrow Neurological Inst. and the Neurosciences Research Foundation.

795.4

TASK RELATED OSCILLATORY ACTIVITY AT 20-30 Hz IN THE MOTOR CORTEX OF THE MACAQUE MONKEY.
S.N. Baker, E. Olivier and R.N. Lemon*. Sobell Department of Neurophysiology, Institute of Neurology, Queen Square, London, WC1N 3BG.

Several recent reports have shown the presence of bursts of oscillatory activity in primate motor cortex (eg Murthy & Fetz, 1992, *PNAS* **89**, 5670). However, a consistent task relationship has not been demonstrated. In a macaque monkey trained to perform a precision grip task for food reward, we have recorded local field potentials (bandpass: 10-120 Hz) from the primary motor cortex using two platinum-iridium glass insulated microelectrodes separated by 1.5 mm. Oscillations in the local field potentials occurred in the frequency range 20-30 Hz. Spectral analysis revealed that they were coherent between the two cortical recordings. An increase in power in this band, and the coherence, was shown to occur predominantly during the hold phase of the precision grip task (mean duration 0.8 s).

Up to 7 hand and forearm EMG's were also recorded. The coherence between rectified EMG and cortical slow wave recordings showed similar task modulation to that seen between the two cortical recordings, with a mean frequency of 25.8 Hz. Such task related coherence could also be seen between two simultaneously recorded EMG's.

Discharges of identified pyramidal tract neurones (PTN's) recorded from the same electrodes as the slow wave potentials, but with different filter settings, were used to compile spike triggered averages of the potentials. Gabor functions were fitted to these averages and used to assess objectively the presence of damped oscillations. In 11/17 averages of the potential recorded on the same electrode as the triggering spike, and 11/17 of that recorded on the distant electrode, significant oscillations were seen, indicating partial phase locking of the spikes to the cortical oscillations.

It is concluded that oscillations at 20-30 Hz are a feature of motor system function. They encompass the pyramidal tract output neurones, and propagate to the EMG of contracting muscles. Such oscillations can be seen reliably during performance of a highly trained task involving precise digit movements.

Generation of fast cortical rhythm in local circuits of rat somatosensory cortex cultures. D. Plenz* and S.T. Kitai, Department of Anatomy and Neurobiology, University of Tennessee, College of Medicine, Memphis, TN 38163.

During arousal and in the awake state, neuronal activity in the neocortex shows a fast rhythm in the range of 25 - 60 Hz. The origin of this fast cortical rhythm (FCR) is, however, unclear. In particular it is not known whether local cortical circuits can generate and maintain an FCR.

We analyzed evoked cortical activity in 31 organotypic cortex cultures, which were co-cultured with striatal and nigral tissue for 42 ± 3 days *in vitro*. Intracellular responses of evoked activity were recorded from 42 regular spiking pyramidal cells and 15 interneurons using single and double intracellular recordings. Electrical stimulation in the uppermost cortical layer was used to mimic a synchronized excitatory input to supragranular layers. Brief stimulation evoked an early depolarization shift followed by a long-lasting depolarization during which a prominent FCR was revealed (n = 41). The dominant frequency of the FCR was 38 ± 2 Hz. Using time-frequency plots (n = 14), analysis revealed the FCR as a destinct band (duration: 1.0 ± 0.2 s) thereby traversing a relatively broad but continuous frequency range between 25 and 50 Hz (slope: 11.5 ± 2.7 Hz/s). The FCR was localized to supragranular layers. Crosscorrelation analysis revealed that neurons stay synchronized, while the FCR changes its dominant frequency. The reversal potential of the FCR was -57 ± 4 mV (n = 7).

Results have shown that supragranular cortical layers express a self-sustained localized FCR. We suggest that corticocortical and/or thalamocortical inputs to supragranular layers can trigger a self-sustained local FCR, thereby facilitating synchronization between distant cortical and thalamic regions.

'WRONG' CHOICE RESPONSES IN A VISUOMOTOR MEMORY SCANNING TASK. G. Pellizzer*, A. Carpenter and A.P. Georgopoulos. Brain Sciences Center, VAMC, Minneapolis, MN 55417.

We have reported previously the results for correct responses obtained from a monkey doing a visuomotor version of the context-recall task (Soc. Neurosci. Abstr. 20: 983, 1994). The task consisted of a sequential presentation of three visual stimuli, after which one of them changed color (test stimulus): the correct response was to move a cursor in the direction of the stimulus that followed the test stimulus during the initial presentation. The analysis of the activity of cells in the primary motor cortex during the response time (RT) of correct responses indicated that the monkey chose the second stimulus in the sequence as the default response. This choice was maintained throughout RT when the test stimulus was the first in the sequence; in contrast, when the test stimulus was the second in the sequence, cell activity changed abruptly about in the middle of RT reflecting the selection of response toward the third stimulus (Science 269: 702-705, 1995). The analyses of wrong choice responses (3.1% of trials) showed the following. The distribution of RT had multiple peaks, unlike the distribution of RT for correct responses, which suggests that incorrect choices happened for different reasons. In some cases (0.2% of trials) the response was toward the test stimulus. These trials had short RT (mean=173 ms), and occurred only when the test stimulus was the second in the sequence. The analysis of neural activity indicates that these errors were anticipated default responses. The patterns of neural activity for the remaining cases (2.9% of trials) indicate that either the wrong response was anticipated from the beginning of RT, or that a wrong selection occurred during RT. In the latter case, RT tended to be longer. Analyses of neural activity suggests that most errors were related to a confusion of the order of presentation of the stimuli. A MUSCLE-SPACE DESCRIPTION OF MOTOR CORTICAL DISCHARGE. L.E. Miller*, J.D. Nocher, J.S. Lee, R. Garg. Physiology Dept., Northwestern Univ. Med. School, Chicago, IL 60611

Since the work of Georgopoulos and colleagues (J. Neurosci. 2: 1527, 1982) the sinusoidal tuning of motor cortical neurons has been accepted as evidence that these cells explicitly encode the trajectory of hand movement. However, this tuning (also found in areas 2, 5, 6 and cerebellum) is not the unique result of a system controlling hand movement. Similar tuning may result from a control system organized in muscle space (Mussa-Ivaldi, Neurosci. Lett. 91: 106, 1988) such as that of the red nucleus, whose spinal projections largely overlap those of the primary motor cortex (Miller and Houk, J. Physiol. 488: 533, 1995). While the spatial properties of the motor cortex have been extensively studied, an equivalent examination of cortical discharge and muscle activation dynamics has not often been undertaken.

We used a single task to examine both dynamics and spatial tuning. A monkey faced a circular array of buttons arranged in a vertical plane, reached toward and pressed a central button, then one of eight outer buttons. We recorded 285 primary motor cortical units from two macaque monkeys, along with limb movement and muscle activity. These units fell into four main groups: Those with activity only during reach, only during button press, maintained throughout reach and press, and having distinct phases during both reach and press. Most units were sinusoidally tuned during the task, often during the button press period. Like the units, most muscles were tuned, even during press. Fewer than 20% of the units had discharge that preceded movement onset and had dynamics like that of hand speed. In most of these cases, the discharge also resembled that of one or more muscles. The remaining 80% of units lagged hand movement, or had relatively complex discharge patterns, generally like that of the distal muscles. These results support the hypothesis that the primary motor cortex fundamentally commands muscle activation rather than hand movement.

REORGANIZATION OF MUSCLE REPRESENTATIONS IN MOTOR CORTEX FOLLOWING A FOCAL ISCHEMIC INFARCT. J.A. Bertelson, E.J. Plautz and R.J. Nudo*. Dept. of Neurobiology & Anatomy, Univ. of Texas Medical School, Houston, TX 77030.

Representational maps of hand movements in primary motor cortex (M1) undergo substantial remodeling following ischemic infarct (Nudo and Milliken, 1996). To examine infarct-induced changes in more detail, we tracked individual muscle representations before and after a focal infarct in M1 of adult squirrel monkeys. Four to six forearm muscles were surgically implanted with chronic, epimysial patch electrodes. Electrode wires were tunneled subcutaneously to an external plug anchored to spinous processes. Intracortical microstimulation (ICMS) techniques were used in M1 contralateral to the implanted muscles to derive muscle and movement maps. Infarcts were created by electrocoagulation of a small vascular bed supplying a cortical region centered on one of the digit muscle representations. After infarct, monkeys displayed a moderate deficit in manual skill. Manual skill recovered spontaneously within a few weeks. Then ICMS mapping procedures were repeated. Short latency, high amplitude electromyographic (SLHA-EMG) responses could still be elicited by ICMS at several sites in the intact cortex adjacent to the infarct. However, the number of sites at which ICMS elicited SLHA-EMG responses in digit muscles was reduced; the number of sites at which ICMS elicited SLHA-EMG responses in wrist muscles was relatively unchanged. These results provide further evidence that following a focal ischemic infarct in the hand representation in M1, functional reorganization occurs throughout the adjacent, undamaged hand representation. We hypothesize that disruption of local intrinsic connections at least partially accounts for this reorganization.

PROGRESSIVE CHANGES IN DIGITAL AREA OF MAMMAL MOTOR CORTEX AFTER ULNAR NERVE LESION. A.Mori*[1], T.Yoshimoto[1], A.Kawai[1], H.Hiraba[2], T.Huwa[3], Y.Uchiyama[4], T.Minejima[4], College of Humanities and Sciences, Nihon University[1], Department of Physiology, School of Dentistry, Nihon University[2], Department of Neurology, Tokyo Metropolitan Institute for Neuroscience[3], Medical care-Welfare Engineering, Institute of Science, Nihon University, Tokyo, Japan

We examined the relationship between the digits before and after reorganization in the digital area of the motor cortex (MCx-digital area) in adult cats following denervation of the ulnar nerve. A single tungsten-in-glass microelectrode was inserted into the depths of the MCx-digital area for recording unitary spikes and intracortical microstimulation (ICMS). The receptive fields(RFs) of neurons were identified using natural stimulation. The ulnar nerve was denervated under nembutal anesthesia (40mg/kg,i.p.). At 1 week following denervation of the ulnar nerve, neurons within the MCx-digital area, with RFs on the III-V pads were lost. At 1 and 3 months following denervation, the number of neurons within the MCx-digital area increased and responded to touch on the I and/or II pads. A small number of neurons in the MCx-digital area responded to light touch of the metacarpal pad. In addition, a small number of neurons within the MCx-digital area responded to touch of the dorsal I and II digital skin. At 1 week following denervation, with ICMS into the MCx-digital area, a small number of neurons produced flexion on the contralateral side of the I and II digits. At 2 and 3 months ICMS into the MCx-digital area produced flexion on the contralateral side of I and/or II digits. In addition, ICMS into the MCx-digital area produced extension on the contralateral side of the I and II digits.

Our findings suggest, reorganization of input and output of neurons in the MCx-digital area following denervation of the ulnar nerve.

LONG-TERM SIMULTANEOUS RECORDINGS OF NEURONAL ENSEMBLES ACROSS MULTIPLE CORTICAL AREAS IN BEHAVING PRIMATES. M.A.L. Nicolelis[#], B. Carswell[1], L.M.O. Oliveira[1], A.A. Ghazanfar[1], J.K. Chapin[2], R.C.S. Lin[2], R. J. Nelson[3], and J.H. Kaas[4]. [1] Dept. Neurobiology, Duke Univ.;[2] Dept. Neurobiology and Anatomy, MCP-Hahnemann Univ.;[3]Dept. Anatomy, Univ. of Tennessee; [4] Dept. Psychology, Vanderbilt Univ.

The goal of this study was to investigate how large populations of neurons, distributed across multiple somatosensory and motor cortical fields, interact when primates use their hands to explore objects. Chronic and simultaneous recordings of the extracellular activity of large ensembles of single neurons were carried out in two awake owl monkeys (*Aotus trivirgatus*). Four 16-microwire arrays (NBlabs, TX) were implanted in the first monkey and six in the second. Implants were placed in subdivisions of the motor and somatosensory cortices. A 96 channel neuronal acquisition processor (Spectrum Scientific, Dallas, TX) was used to simultaneously record the activity of up to 130 cortical neurons. Animals were trained to perform a reaching task in which they use their hand to localize and grasp a fixed target for a juice/food reward. Ensemble activity was recorded throughout the training period, and as many as 80-90 neurons were simultaneously recorded over a period of eight months. Waveform analysis revealed that the same neurons could be recorded for several weeks. As a rule, we observed that reaching hand/arm movements modulated, in a variety of ways, the firing of somatosensory neurons across the parietal cortex. Moreover, during the training period we observed long-lasting changes in the patterns of activation of motor cortical ensembles. These experiments demonstrated that ensemble recordings can be used to characterize spatiotemporal interactions between cortical fields and the long-term changes that they undergo during learning paradigms. *Supported by the McDonnell-Pew Foundation.*

THE CONTRIBUTION OF ANTERIOR AND POSTERIOR SUBDIVISIONS OF SI TO THE CONTROL OF THE PRECISION GRIP. Thomas Brochier, Michel Paré, Iran Salimi and Allan M. Smith*, Centre de Recherche en Sciences Neurologiques, Université de Montréal, Québec, Canada, H3C 3J7

Recent anatomical and physiological studies in monkeys have suggested that each of the 4 subdivisions of area SI (3a, 3b, 1 and 2) constitute a separate representation of the body receiving input from a limited subset of subcortical and cortical areas. The complex interconnections between these sensory areas and the frontal motor structures raise the question of their specific contributions to the movement control processes.

The present study compared the discharge pattern of a rostral and caudal subdivision of SI in the control of the precision grip. The discharge of single cortical neurons was analysed in a monkey trained to grasp and lift an object between thumb and index finger and to hold it stationary in a position window for 2.5 seconds. A total of 144 neurons were recorded along 55 penetrations within a cortical zone exending from the caudal border of area MI to the rostral border of area 5. The majority of the receptive fields (RFs) were cutaneous on the thumb or index finger and were in contact with the object surface during performance of the task. Proprioceptive RFs were encountered infrequently.

All the cells showed a modulation of their activity related to the lifting task but their discharge properties differed depending on their cortical localization. In an arbitrarily defined anterior part of SI (up to 2 mm posterior to the central sulcus, depth < 2.0 mm), about 60% of the cells showed rapidly adapting responses during the dynamic lifting phase with weak or no activity during the holding phase, whereas 24% were slowly adapting. In contrast, in the more posterior SI area (from 2 to 4.5 mm posterior), the neurons were more frequently slowly adapting (SA: 39%; RA: 23%). Cells within this posterior region showed a greater sensitivity to changes in object texture and friction. These results suggest that the anterior and posterior subdivisions of SI would have distinct functions in the sensorimotor control of the precision grip. Research supported by the FCAR of Quebec and the MRC of Canada.

EFFECTS OF REVERSIBLE COLD BLOCK OF PRIMATE FACE PRIMARY SOMATOSENSORY CORTEX (SI) ON PERFORMANCE OF TRAINED MOTOR TASK AND FACE MOTOR CORTEX (MI) NEURONES. D.Y. Yao, N. Narita and B.J. Sessle*. Fac. of Dentistry, Univ. of Toronto, Toronto, Ont., M5G 1G6, Canada.

Our published data have revealed that many neurones in face SI as well as face MI of the awake monkey have an orofacial mechanoreceptive field and show activity related to trained tongue protrusion behaviour, and that bilateral reversible cold block of SI or MI interferes with successful performance of this motor task. Given these findings and the interconnections between SI and MI, our aim was to test if unilateral SI cold block interferes with task performance and to initiate studies to test if the MI neuronal task-related activity is dependent upon an intact SI. A cranial chamber was chronically implanted in the monkey (Macaca fascicularis) to allow for the placement of a thermode (2.5x7.5 mm) on the dura overlying the face SI (defined by microelectrode recordings of neuronal activity evoked by orofacial stimuli) and for microelectrode recordings of neuronal activity in the ipsilateral face MI (defined by intracortical microstimulation; $<30\mu A$) as well as SI. A hot or cold alcohol-water solution was pumped through the thermode while the monkey carried out the tongue protrusion task during pre-cool (thermode temperature 37°C), cool (0°C) or rewarm (37°C) conditions. Tongue protrusion force and the EMG activity of several orofacial muscles were also recorded. Success rates for task performance in different recording sessions averaged 80.7 % (n=145), 82.7 % (n=73) and 81.2 % (n=138) for pre-cool, cool, and rewarm trials, respectively; there was no significant difference ($p>0.05$, χ^2) between these success rates. To date, a total of 28 single neurones has been recorded in face MI, and 5 of these showed clear task-related activity. While cold block reduced the spontaneous activity of 14 neurones, 3 of the 5 task-related neurones retained task-related activity during cold block. These findings indicate that, in contrast to the significant effects on task performance of bilateral cold block of face SI (Lin et al, J. Neurophysiol. 70, 985, 1993), unilateral SI cold block does not interfere with tongue task performance, although our preliminary neuronal data raise the possibility that some features of face MI neuronal activity may be influenced by SI.

ROSTROCAUDAL DIFFERENTIATION OF DORSAL PREMOTOR CORTEX WITH PHYSIOLOGICAL CRITERIA. N. Fujii*, H. Mushiake, and J. Tanji Dept. Physiology, Tohoku Univ. Sch. Med. Sendai, 980-77, Japan

Previous studies on architectonic structure and anatomical connectivity of the frontal lobe of primates have suggested that the dorsal premotor cortex is to be divided into two subdivisions. The rostral part has been termed 6aβ, 6Dr, PMr, or F7, and the caudal part, 6aα, 6Dc, or F2. We now propose that the rostrocaudal subdivision is possible on the basis of a constellation of physiological properties. We used two monkeys (*Macaca fuscata*) to study motor responses to intracortical microstimulation (ICMS), and then to analyze neuronal activity during performance of trained motor behavior. We first applied ICMS systematically to the entire expanse of the dorsal premotor cortex (12-50 pulses of 200 μs at 300Hz). In the caudal part (PMDc in our terminology), proximal arm or axial body movements were evoked with relatively high currents. On the other hand, in the rostral part (PMDr), eye movements were frequently evoked with low currents ($<50\mu$A) without limb or body movements.

We then studied neuronal activity from the mapped area while monkeys were performing (1) saccade task without arm movements, (2) target-reach task with an arm without eye movements, and (3) target-reach task with simultaneous saccade and arm-reach. Each motor task, instructed with visual signals, was initiated after delay. We have recorded 478 task-related neurons in the dorsal premotor cortex, 129 from PMDr and 349 from PMDc. The following properties characterized neuronal activity in the PMDr. (1) Saccade related activity, (2) activity related to both eye and arm movements, (3) eye position-related activity, (4) anticipatory activity before the occurrence of instruction signals. By contrast, in the PMDc, a vast majority of neurons were related to arm movements, exhibiting motor-set related as well as movement related activity.

ANATOMICAL AND FUNCTIONAL SUBDIVISIONS OF INFERIOR AREA 6 IN MACAQUE MONKEY

M. Matelli*¤, G. Luppino¤, P. Govoni‡ and S. Geyer†
¤ Istituto di Fisiologia Umana; ‡ Istituto di Istologia ed Embriologia, Universita' di Parma, Via Gramsci 14, I-43100 Parma, Italy; † Brain Research Institute, University of Düsseldorf, PO Box 101007, D-40001 Düsseldorf, Germany.

The two chemoarchitectonic areas forming the inferior area 6 of the macaque (areas F4 and F5) differ also in terms of motor representation, anatomical connections, and neuronal properties. The extensive exploration of F5 with intracortical microstimulation as well as with single unit recording showed that distal movements are most frequently evoked from the cortex buried in the anterior bank of the arcuate sulcus. Furthermore, the neurons in the bank fired when the animal performed grasping movements, whereas neurons in the F5 convexity showed more complex responses ("mirror neurons"). Such functional segregation suggests that within F5 different anatomical regions could be identified.

In the present study we analyzed the cytoarchitectonic organization of this area in several monkey brains processed either for Nissl staining or for demonstration of SMI-32, calbindin and parvalbumin immunoreactivity. Further brains were also processed for in vitro receptor autoradiography. The results showed that three different fields can be identified within F5 as defined with cytochrome oxidase histochemistry. They will be referred to as F5 anterior (F5a), F5 posterior (F5p) and F5 ventral (F5v). F5p corresponds to the excitable sector of F5, whereas F5v is the field in which "mirror neurons" were mostly recorded.

Preliminary anatomical data showed that these different F5 fields receive a differential input from parietal areas, supporting the architectonic parcellation. F5p and F5a are targets of area AIP and of area PFG, whereas F5v receives a parietal input from area PF. Among the three F5 fields, F5p is the only one that has direct projections to the spinal cord and connections with F3 (SMA-proper) and F1 (area 4), whereas all of them are reciprocally connected with F6 (pre-SMA).

PREMOTOR CORTEX OF THE MACAQUE MONKEY: ONE CASE OF EPILEPTIC ATTACK. L. Bon*° and C. Lucchetti† Institute of Physiology, University of Trieste, I-34127; °Dept. of Biomedical Sciences, University of Modena I-41100; †Institute of Human Physiology, University of Ferrara I-44100 -Italy.

The superior premotor cortex (SPC) is known to be invoved in the preparation and execution of arm and eye movements. We observed a brief epileptick attack (EA), after few microelectrode penetrations in the right (SPC), of one macaque monkey trained for fixation and saccade tasks. At the beginning, the animal showed tilting neck movements, and then torsional and tilting movement of the trunk. The day after, oculomotor behavior resulted normal while contralateral arm presented an hypertonus of flexor muscles with reduced reaching movements. From 2nd to 10th day after the EA the monkey neglected only averse visual stimuli (gloves and pole), presented in the contralateral hemifield. On the contrary, pleasant stimuli (food) evoked orienting responses. The animal performed saccades and fixations correctly. Reaching movements returned normal 15 days after the EA. A lesion in SPC was confirmed after animal suppression. These signes indicate a neglect and suggest that SPC is involved in attentional-motivational selection of stimuli.

European Comunity rules for animal care were followed during experiments.

THE PRIMATE PREMOTOR CORTEX: NEURONAL ACTIVITY IN RELATION TO FOVEAL VS. PERIPHERAL REACHING. C. Jouffrais and D. Boussaoud* Vision et Motricité, INSERM U94, 16 Avenue du Doyen Lépine, 69500 Bron, France.

To test the functional implications of gaze signals reported in the dorsal premotor cortex (PMd; *Boussaoud, J. Neurophysiol., 73, '95, 886-890*), we trained two rhesus monkeys to point at visual targets presented on a touchscreen. Each monkey had to put its hand on a starting position, orient gaze to a fixation point (FP), and maintain fixation throughout the trial. Then, a peripheral target appeared at one of eight locations equidistant from the starting position. After a variable delay, the target dimmed and the monkey had to move its hand to the target location while fixating. The FP appeared either near the hand starting position, or at the locations of the targets. This design required the monkey to make limb movements in identical directions, but under two tasks: in the foveal reach, the target was foveated prior to the arm movement; in the peripheral reach, the target was not foveated.

We recorded 137 cells from the PMd/M1 region and analyzed the effect of the task on the mean discharge rate (ANOVA) shortly after target onset (signal), during the instructed delay period (set), and during the response time (movement). Strong task effects were observed on the activity of a majority of cells. In addition, we found that the proportion of cells whose discharge rate varied with the task decreased from signal (67%) to set (60%) to movement (47%) periods. These effects, together with the modulation of the directional tuning of cells by gaze angle, suggest that eye position signals might provide arm-related neurons with the angular deviation of gaze relative to the target of arm movement, a possible neuronal correlate of eye-hand coordination.

PREMOTOR CORTEX NEURONS RELATED TO MOVEMENT SELECTION AND SPATIAL MEMORY. I. Yamane*, T. Sawaguchi, K. Kubota, and A. Mikami. Dept. of Behavioral and Brain Sciences, Primate Res. Inst., Kyoto Univ., Inuyama, Aichi 484, Japan.

To investigate the role of the premotor cortex in memory-guided movement, single neuron activity was recorded from the dorsal premotor cortex (PMd) while a monkey performed a delayed spatial matching-to-sample task with GO/NO-GO performance. This enabled us to examine neuronal activity related to memory and movement process separately. A sample cue was presented at one of four locations for 0.5 s and then, after the 1st delay period (3 s), a matching cue was presented (0.5 s). After the end of the 2nd delay period (3 s), all cues at four locations appeared (go signal). If the location of the matching cue was different from that of the sample cue, the monkey released the lever within 1s (GO response). If the location of a matching cue was the same as that of a sample cue, the monkey continued to hold the lever for 2 s (NO-GO response). One hundred and sixty-four neurons showed a change in activity during the 2nd delay period and/or the response period associated with the GO/ NO-GO response. Among them, 64 neurons also showed sustained increase or decrease in activity throughout the 1st delay period. Their activity was modulated in magnitude with the spatial location of the sample cue. Of these 64 neurons, 49 neurons changed activity during GO response (27: increased, 22: decreased), and 15 neurons changed activity during NO-GO response (15: decreased). Thus, there were neurons which changed activity in both the 1st delay period and the 2nd delay and/or response period. These results suggest that neurons in the PMd are involved in the memory process and switching between GO/NO-GO responses. It is likely that the PMd plays a role in selecting motor response based on spatial memory.

INSTRUCTED-DELAY PERIOD ACTIVITY RECORDED IN PRIMATE PREMOTOR CORTEX PRIOR TO SEQUENTIAL REACHING MOVEMENTS. D. J. Crammond* Laboratory of Neurophysiology, NIMH, Poolesville, MD 20837.

A rhesus monkey was trained to perform reaching movements to two of eight targets arranged in a circle in one of two task designs which were interleaved in blocks of 80 trials: A Sequential Reaction task in which the monkey held a handle over a central LED (mean 6.75 sec) and then moved to a target when illuminated by a red LED, held at the target for 500 ms at which time a second target was illuminated by a red LED to which the monkey moved and remained for 500 ms. Target pairs were randomized but targets were selected such that there were always 5 replications of each of 8 possible target locations. In Instructed-Delay (ID) trials, while the monkey held over the central LED a green LED was illuminated over one target (IDP1, mean 2.25 sec) after which it was extinguished and a green LED was illuminated at a second target (IDP2, mean 2.25 sec) after which it was extinguished and the monkey remained holding at the center for a third delay period (mean 2.25 sec). The red LEDs at all 8 target LEDs were then illuminated as a GO signal and the monkey was rewarded for correctly moving to and holding at each target for 500 ms, according to the instructed sequence.

Preliminary recordings have been made from a total of 44 neurons in the dorsal premotor cortex. In ID trials, IDP activity was recorded in 91% of cells of which 90% of IDP modulation occurred in both IDPs. In 80% of these cases, the directionality of IDP modulation for IDP1 and IDP2 was in the same directional axis. Further, in 93% of cases, this preferred discharge axis corresponded to the axis of discharge modulation recorded during movements. Despite this instruction-to-movement correspondence of the axis of greatest neuronal discharge, the polarity of neuronal discharge modulation was similar in only 52% of cases and the polarity reversed in 48% of cases.

NEURONAL CORRELATES OF MOVEMENT SEQUENCING IN SMA AND PRE-SMA, **W.T.Clower*, G.E.Alexander**. Emory University School of Medicine, Atlanta, Ga.

The SMA has been strongly implicated in the performance of sequential movements. Less is known about the possible role of the pre-SMA in this type of motor behavior. The present study compared neuronal activity within these two regions, SMA and pre-SMA, during performance of a movement-sequencing paradigm that dissociated current target position, intended target position, movement direction, and component order. A monkey used the right arm to operate a joystick which moved a cursor on a display monitor. Beginning from one of four targets arranged in the form of a baseball diamond, the monkey received a single visual cue that indicated the direction (clockwise or counter-clockwise) of the required 3-component movement sequence, after which three non-directional trigger signals were used to control the variable times of onset of each component movement. Single cell recordings of task-related activity indicated that both SMA and pre-SMA contain activity related to each of the four categories of behavioral variables dissociated in this study. However, direction-specific neuronal activity was seen in a larger proportion of SMA neurons, while component order effects were more common among pre-SMA neurons. Responses related to target position (both current and intended) were also more common among pre-SMA neurons. There was a predominance of movement-related activity in the SMA, while the pre-SMA contained a larger proportion neurons with set-related activity. *Supported by Emory University.*

796.9

NEURAL ACTIVITY RELATED TO TARGET LOCATION OR DIRECTION OF CURSOR MOVEMENT IN THE SUPPLEMENTARY AND CINGULATE MOTOR AREAS OF THE MONKEY. M.D. Crutcher, D.A. Backus and S. Ye. Dept. of Neurology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

We previously described the activity of neurons in the supplementary motor area (SMA), motor cortex and putamen related to which target was captured with the cursor independent of both the direction of limb movement and the required pattern of muscle activity. The purpose of this study was to further characterize such 'target-dependent' activity in both the SMA and cingulate motor areas. Monkeys were trained to perform several indirect tracking tasks in which they captured targets presented on a monitor with the cursor representing joystick (and hand) position. These tasks systematically dissociated 1) the target captured by the cursor from the direction and endpoint of the limb movement and 2) the target captured and the endpoint of movement from the direction of cursor and limb movement. Together, these tasks allowed us to distinguish neural activity related to each of four variables independent of the others: 1) the capture of a particular target, 2) the direction of cursor movement, 3) the direction of limb movement, and 4) the endpoint of limb movement. The most frequently observed activity was related to the direction of limb movement (75%). The activity of the remaining neurons was related to the direction of cursor movement on the monitor screen (14%), to which target was captured (4%) or to the endpoint of limb movement (8%). These results suggest that much of the previously labeled 'target-dependent' activity was in fact related to movements of the cursor representing limb position rather than to capture of the target *per se*. This cursor-related activity could be viewed as a neural correlate of tool use that develops with extensive overtraining. (Funded by NINDS #NS30212)

COMPARISON OF 2DG UPTAKE IN MEDIAL WALL MOTOR AREAS DURING PERFORMANCE OF VISUALLY-GUIDED AND REMEMBERED SEQUENCES OF MOVEMENTS. N. Picard*[1] and P.L. Strick[1,2]. [1]VAMC and [2]Depts. of Neurosurgery and Physiology, SUNY-HSC, Syracuse, NY 13210.

The medial wall of the hemisphere contains at least five motor areas. The supplementary motor area (SMA) and three cingulate areas (CMAd, CMAv, CMAr) are each connected to the primary motor cortex. Each of these areas also projects directly to the spinal cord. An additional motor field, the pre-SMA, is not connected to either the spinal cord or the primary motor cortex. We have used the 2-deoxyglucose (2DG) method to determine whether these areas are differentially involved in specific aspects of voluntary movements. Two monkeys were injected with 2DG while performing remembered sequences of reaching movements for juice rewards (REM task: Mushiake and Strick, 1995). An additional animal was injected with 2DG while performing the same movement sequences, but under visual guidance (Track task: Mushiake and Strick, 1993). Using autoradiographs of serial sections spaced 90 μm apart, we generated flattened maps of 2DG uptake in cortex on the medial wall contralateral to the working arm. Two of the cingulate motor areas, the CMAr and CMAv, showed little, if any activation during either task. The other three motor areas, the SMA, CMAd and pre-SMA, were activated during the Track task, as well as during the REM task. These findings indicate that the motor areas of the medial wall are not equally involved in these two motor tasks. Furthermore, areas activated during simple tasks (e.g., Track task) also contribute to more complex forms of the same motor behavior (e.g., REM task), although the intensity of activation in individual areas may vary between tasks. ROLES OF PRIMARY (MI) AND SUPPLEMENTARY (SMA) MOTOR AREAS IN BIMANUAL MOTOR ACTION. I. Kermadi, A. Tempini, E. Calciati, and E.M. Rouiller*. Institute of Physiology, University of Fribourg, 1700 Fribourg, Switzerland.

In primates, daily motor acts often require bimanual coordination. Previous (lesion) studies have suggested the implication of the primary motor cortex (MI) and the supplementary motor area (SMA) in such coordination. However, whether each of these two areas plays a specific role in bimanual motor acts needs further investigation. Two monkeys (macaca fascicularis) were trained for a complex, natural, bimanual task. The animal pulled a drawer with the left hand and picked in it a piece of food with the right hand. For comparison, the monkey was also trained to perform the same task unimanually, with the left or the right hand. To initiate a trial, the monkey put each hand on a sensitive pad. 100 ms later, a left or a right LED, or both, were illuminated instructing the animal to perform the task with the left, the right or both hands, respectively. After 1200 ms, windows corresponding to the illuminated LEDs were opened (go signal), giving access to the drawer. Single unit recordings conducted in MI and SMA showed that both areas contain cells which are instruction-related, preparation-related and/or execution related but in different proportions (more cue and preparation-related cells in SMA than in MI). In both MI and SMA, a large proportion of neurons showed an activity related to more than one particular event (e.g. cue and preparation, preparation and various components of the movement). No MI or SMA cells were exclusively activated during the bimanual task and not during the unimanual tasks. However, the number of cells exhibiting ipsilaterally related activity was higher in SMA than in MI. Distinct deficits were observed when MI or SMA were transiently and reversibly inactivated with infusions of muscimol: MI inactivation induced a dramatic loss in the capability to reach the drawer as well as in the precision grip ability while SMA inactivation impaired mainly the initiation of the trials. Inactivation experiments support the notion of distinct functional roles for MI and SMA while, in contrast, single unit data do not clearly support a strict functional segregation between the two areas, which only differ in a probabilistic way.

TWO-DIMENSIONAL RECONSTRUCTED PATTERNS OF METABOLIC ACTIVITY IN THE PRIMATE NEOCORTEX DURING PERFORMANCE OF A VISUALLY GUIDED REACHING TASK. **H.E. Savaki*, V.C. Raos and Y. Dalezios. Dept. Basic Sciences, Div. Medicine, Univ. of Crete, and Inst. of Applied Mathematics, FORTH, PO Box1393, GR-71110 Iraklion, Crete, Greece.**

The 2-(^{14}C) deoxyglucose method was used to map the metabolic activity in *Macaca nemestrina* monkeys performing a visually guided reaching task with one forelimb. The quantitative, high resolution, 2-dimensional reconstructed maps of the detailed spatiointensive patterns of activity demonstrated the involvement of discrete neocortical regions. It is suggested that the activated direction-selective (i) 4th layer of visual area 1 (V1), (ii) thick stripes of V2, and (iii) area V5 (or MT) convey visuomotion information to the activated medial superior temporal (MST) cortex, which may encode the constantly updated position of the moving forelimb in the extrapersonal space. In parallel, the metabolically activated (i) dorsal intraparietal area 7 (7DIP), and (ii) ventral itraparietal area (VIP) may encode visuospatial information related to the localization of the visual target in the extrapersonal space. The involvement of area 5-DIP in proprioceptive guidance of the moving forelimb is suggested, based on the parallel metabolic effects estimated within this region and the forelimb representations in MI and SI cortices. The activated network including (i) the inferior postarcuate skeletomotor area 6v, (ii) the inferior prearcuate oculomotor area 8, and (iii) the caudal periprincipal region 46 is suggested to participate in sensory-to-motor transformation, in common with the medial and lateral IP cortices. (Supported by HCM Grant ERBCHRXCT 930266).

ARM MOVEMENT-RELATED NEURONS IN THE VISUAL AREA V6A OF MONKEY SUPERIOR PARIETAL LOBULE, C. Galletti*, P. Fattori, D.F. Kutz and P.P. Battaglini, Dip. di Fisiologia umana e generale, Univ. di Bologna, P.zza Porta S. Donato 2, 40127 Bologna, Italy.

Area V6A is a cortical visual area located in the posterior face of the superior parietal lobule in macaque monkey. It contains visual neurons together with neurons sensitive to changes in the direction of gaze and neurons which are neither activated by visual stimuli nor by oculomotor activities. The aim of this study was to look for possible features able to activate these last type of neurons. Extracellular recordings were carried out in two awake *Macaca fascicularis* performing a fixation task with the head restrained. Eye position was recorded with an infrared oculometer. Electromyographic (EMG) activity was monopolarly recorded with surface electrodes from 14 muscles of the arms, shoulders, neck and trunk.

Out of a total of 70 non-visual neurons recorded from area V6A, 43 showed a clear arm movement-related neural discharge. In many of these cases (N=21) somatic stimulations of one or both arms (joint rotations or light touch of the skin) were also effective. Arm movement-related neural discharge started before the onset of arm movement, often before the earliest electromyographic activity. Therefore, proprioceptive signals and tactile stimulations cannot fully explain cell's activation. Arm movement-related neurons of area V6A seem to be well equipped for comparing motor signals related to arm movements with sensory signals evoked by those movements. Taking into account also the visual characteristics of V6A neurons, it seems likely that area V6A as a whole is involved in the visual guiding of reaching.

BASAL GANGLIA: FUNCTION IV

797.1

SPONTANEOUS $GABA_B$ SYNAPTIC POTENTIALS IN NEONATAL RAT SUBSTANTIA NIGRA DOPAMINERGIC NEURONS. T. Koós & J. M. Tepper*, Center for Molecular and Behavioral Neuroscience and Program in Cellular and Molecular Biodynamics, Rutgers University, Newark, NJ 07102 USA.

Midbrain dopaminergic (DAergic) neurons are known to express both $GABA_A$ and $GABA_B$ receptors, and spontaneous or evoked $GABA_A$ as well as evoked $GABA_B$ responses have been shown in these neurons *in vitro*. Here we describe spontaneously occurring $GABA_B$ mediated synaptic potentials in DAergic neurons of the neonatal substantia nigra.

Whole cell current clamp recordings were obtained under direct visual control using IR-DIC from 350 µm thick coronal sections of 9-15 day old Sprague-Dawley rats at 25-32°C. The recording pipettes were filled with (in mM) K-Gluconate 120; KCl 30; HEPES-Na 10; EGTA 0.02; ATP 2; GTP 0.2; Leupeptin 0.12. E_{Cl^-} =-38 mV; E_{K^+}=-107 mV. Presumed DAergic neurons were recorded from pars compacta and identified on the basis of electrophysiological criteria including long duration action potentials (>2.5 ms) prominent spike afterhyperpolarization and a slowly developing sag in the voltage response to hyperpolarizing current injection.

The majority of these neurons showed spontaneously occurring long hyperpolarizing potentials at a rate of 1-2/sec (average duration = 376±20 ms; n=11). The mean amplitude varied among neurons and was usually less then 4 mV. The reversal potential was estimated to be between -90 and -100 mV (n=2). These potentials were blocked by 300 µM 2-OH-saclofen and were unaffected by 50 µM bicuculline. These data identify them as $GABA_B$ receptor mediated IPSPs. These IPSPs are unlikely to be artifacts of intracellular dialyzation induced by whole cell recording since they were present immediately after rupturing the membrane.

The reported absence of these potentials in conventional *in vitro* intracellular recording experiments may reflect age dependent differences in GABA receptor expression, differences in the input resistance of the DAergic neurons or other developmental changes related to the firing patterns or survival of afferent neurons in the two preparations. 797.2

ROLE OF GLOBUS PALLIDUS IN THE REGULATION OF THE ACTIVITY OF NIGRAL DOPAMINERGIC AND GABAERGIC NEURONS P. Celada*and J. M. Tepper, Center for Molecular and Behavioral Neuroscience, Rutgers, The State University of New Jersey, Newark, NJ USA 07102

It has been suggested that the firing pattern of dopaminergic (DA) neurons in substantia nigra (SN) *in vivo* is modulated differentially by $GABA_A$ inputs arising from the axon collaterals of pars reticulata projection neurons and $GABA_B$ inputs arising from globus pallidus (GP). Disinhibition of these inputs has been proposed to cause DA neurons to fire in bursty and pacemaker modes, respectively (Tepper et al., *J. Neurosci. 15*:3092, 1995). To test this hypothesis we examined the activity of SN DA neurons during pharmacologically induced inhibition and excitation of GP neurons.

Adult male Sprague Dawley rats were anesthetized with urethane and dual 32g cannulae were implanted in GP. Spontaneous activity of DA neurons was measured by extracellular recordings before and after infusion of muscimol (MUS, 0.8 mM 0.2µl) and bicuculline (BIC, 1 mM 0.2 µl) into GP. The pattern of activity was quantified by computing autocorrelograms, coefficients of variation (CV) and percentage of spikes fired in bursts. MUS-induced inhibition of GP produced a significant increase in the regularity of the firing pattern of DA neurons, measured as a decrease in the CV ($t=2.35$, $p<0.05$) and an increase in the number of peaks in the autocorrelogram ($p<0.02$ Wilcoxon t-test). GP inhibition also produced a slight but significant decrease in firing rate (86% of basal; $t=4.22$, $p<0.01$, $n=11$). BIC-induced excitation of GP produced a significant increase in the firing rate of DA neurons (129% of basal; $t=-2.27$, $p<0.05$, $n=8$) together with a significant increase in the number of spikes in bursts ($t=-3.27$, $p<0.02$,) and in the CV($t=4.00$, $p<0.01$).

In order to determine the role of pars reticulata GABAergic projection (PR-GABA) neurons in these effects, we examined the response of PR-GABA neurons to manipulation of GP activity. GP inhibition produced a dramatic increase in the firing rate of PR-GABA neurons (372% of basal; $t=-6.91$, $p<0.01$, $n=8$), while GP excitation significantly decreased PR-GABA firing rate (35% of basal; $t=2.96$, $p<0.05$, $n=4$). These data suggest that GP controls the firing rate and pattern of DA neurons through at least two pathways: 1) inhibition by direct input to DA neurons (probably mediated by $GABA_B$ receptors as previously suggested) and 2) indirect excitation mediated through disinhibition of the $GABA_A$ input from PR-GABA neurons. Supported by NS 30679 and MH 45286. P. Celada was supported through Spanish and Catalan Government Fellowships.

IN VITRO ELECTROPHYSIOLOGICAL ANALYSIS OF THE DORSAL AND VENTRAL TEIRS OF THE SUBSTANTIA NIGRA PARS COMPACTA IN THE GUINEA-PIG. L.R. Johnson* and S.A. Greenfield. University Department of Pharmacology, Mansfield Rd. Oxford. OX1 3QT UK.

Dopamine neurons of the Substantia Nigra pars compacta (SNpc), which project to the striatum, are known to exist in two layers. The dorsal tier of the SNpc projects to the matrix compartment of the striatum while the ventral tier projects to the patch (striasome) compartments. The tiers can also be distinguished by the presence or absence of the 28kDa calcium binding protein Calbindin (CaBP), identified immunocytochemically. The dorsal tier is positive while the ventral tier is negative (Gerfen et al, 1987). Pathological and pharmacological discrepancies have been reported between the two tiers but never physiological differences.

The aim of this study was to examine and compare the electrophysiological characteristics of the two tiers. *In vitro* current clamp intracellular recordings were made in coronal slices of guinea-pig midbrain, with electrodes containing 1% neurobiotin in 2M potassium acetate. Dopamine neurons were identified by spontaneous firing at 1-5 Hz, broad action potentials 2-4 ms and the inability to generate burst firing. After recording sections were fixed in 4% formaldehyde, resectioned to 80μm and incubated in mouse monoclonal anti CaBP (SWant) then in Texas Red antimouse (Vector Labs). Filled neurons were identified with Avidin-Fluorescene (Vector Labs). Sections were examined under fluorescence and previously recorded neurons were identified as either CaBP positive or negative. Evidence to date suggests that the neurons can be distinguished by action potential shape: preliminary analysis shows that the two populations may be bimodally distributed (n=21) with respect to action potential amplitude, firing frequency, 10-90% risetime, but not action potential duration.

NT 4/5 ENHANCES MORPHOLOGICAL PARAMETERS AND CALCIUM CURRENTS IN ENRICHED FETAL MESENCEPHALIC CULTURES. T.DeFazio*, B.Knusel, K.Pong, and J.Walsh. Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089.

Cultures of microdissected rat substantia nigra were grown for 3 days in serum-free medium. 20% of the cells in these cultures stained intensely for tyrosine hydroxylase (TH), a marker enzyme for dopaminergic (DA) neurons. Image analysis showed that DA neurons had significantly larger cell bodies and greater total fiber length than TH-negative neurons. Two day treatment with NT 4/5 further enhanced the morphological parameters of DA neurons, with no significant increases observed in non-DA neurons.

Whole cell recordings using a K^+-based internal solution revealed a class of neurons with electrophysiological properties similar to those described for the DA class of neurons using *in vitro* brain slice techniques. Pressure application of 10mM DA elicited a small outward current in a subset of neurons recorded with a Cs^+-based internal solution. This effect diminished with recording time indicating that the internal perfusion of Cs^+ could block this response. Whole cell calcium currents were recorded in the presence of extracellular TEA-Cl, 4-AP, CsCl, and TTX, and the absence of extracellular Na^+ and K^+. Most cells exhibited a prominent low voltage activated (LVA) current blocked by 50μM $NiCl_2$, and large transient and sustained HVA currents. NT 4/5 treatment had no effect on the amplitude of LVA currents, but the transient HVA current was significantly increased. After recording, plates were fixed and double labeled for biocytin and TH. Our results indicate that NT 4/5 enhances morphological parameters and HVA calcium currents in developing dopaminergic neurons. Supported by NIA grants AG10480 (B.K. & K.P.), AG09793 and AG00093 (J.W. & T.D.).

THE DOPAMINERGIC INDUCTION OF FOS IMMUNOREACTIVITY IN IDENTIFIED POPULATIONS OF GLOBUS PALLIDUS NEURONS. D.N. Ruskin* and J.F. Marshall, Dept. of Psychobiology, University of California, Irvine, 92717.

Dopamine (DA) agonists have been shown to increase the activity of globus pallidus (GP) neurons, as shown electrophysiologically and with immediate-early gene (IEG) expression. More recently it has been shown that decreased D2 receptor activity also causes GP IEG expression. Similar responses occur in the striatum, where both DA agonists and D2 blockade induce IEGs, although in separate neuronal populations (i.e. striato-nigral and -pallidal). These experiments investigate the possible differential DAergic regulation of IEGs in different GP neuronal populations. GP cells were classifed as parvalbumin (PV) -positive or PV-negative (with PV immunostaining), or as projecting to the subthalamic nucleus (STN), substantia nigra (SN), or striatum (with retrograde tracer injections into these nuclei). Rats with prior nigrostriatal lesions received saline, D1 agonist, or D2 agonist. Rats with no lesions received saline, combined D1/D2 agonists, or the D2 antagonist eticlopride. Two hr after injection, rats were perfused and their brains processed for double labeling: either Fos staining with PV staining, or Fos staining alone in retrograde tracer labeled sections. All DAergic treatments induced more Fos in PV-negative than PV-positive cells, perhaps because of calcium buffering by the PV itself. Notably, unlike DA agonists, eticlopride induced significant Fos *only* in the PV-negative cells. DA agonist-induced Fos was found in GP neurons projecting to the STN, SN, or striatum, in both normal and nigrostriatal lesioned rats. Eticlopride-induced Fos occurred only in GP neurons projecting to the striatum, providing functional evidence for pallidostriatal cells without axon collaterals to the STN or SN. These results demonstrate that GP cells respond differently to DAergic treatments based on projection target and expression of PV. Support: MH 11086 & NS 22698.

MICROPRESSURE EJECTION OF CANNABINOIDS INTO THE GLOBUS PALLIDUS. A.S. Miller* and J.M. Walker, Schrier Research Laboratory, Department of Psychology, Brown University, Providence, RI 02912.

The globus pallidus has been identified as a site of action for the motor effects of cannabinoids as cannabinoids microinjected into this region act synergistically with GABA agonists and benzodiazepines in the production of catalepsy. The globus pallidus also contains a high concentration of cannabinoid receptors. The absence of cannabinoid receptor mRNA in the globus pallidus coupled with the observation that striatal lesions greatly reduce pallidal cannabinoid receptor binding suggests that pallidal cannabinoid receptors are located primarily on striatopallidal terminals. Previous studies in this laboratory have demonstrated that neural firing in the globus pallidus is inhibited following systemic administration of the potent and selective cannabinoid WIN 55,212-2 but not its inactive enantiomer, WIN 55,212-3. Furthermore, systemic cannabinoid administration reversed the inhibition which was produced by electrical stimulation of the striatum. The current study investigated whether the effects of cannabinoids on spontaneous activity are due to stimulation of cannabinoid receptors in the globus pallidus. Both WIN 55,212-2 and CP 55,940 produced an inhibition of spontaneous activity in the globus pallidus. This effect was not demonstrated by vehicle or WIN 55,212-3. A current study is exploring whether micropressure ejection of cannabinoids into the globus pallidus modifies the inhibition produced by striatal stimulation.

THE EVOKED RELEASE OF ENDOGENOUS GABA AND TAURINE IN THE DIRECT AND INDIRECT PATHWAYS OF THE BASAL GANGLIA OF THE RAT. L. Bianchi, F. Galeffi, J. P. Bolam, A. D. Smith* & L. Della Corte Dipartimento di Farmacologia Preclinica e Clinica M. Aiazzi Mancini, V. le G.B. Morgagni 65, 50134 Firenze, Italy & MRC Unit, Dept of Pharmacol, Oxford, U.K.

Inhibition of neurons in the substantia nigra pars reticulata (SNr) following cortical stimulation is mediated by the so called direct pathway which includes the GABAergic striatonigral projection. Increased firing of SNr neurons following cortical stimulation is due to activation of several 'indirect pathways' one of which leads to dinhibition of SNr neurons and is mediated by the GABAergic projection from the globus pallidus (GP) to the SNr The aim of the present study was to examine the stimulated release of endogenous GABA in both the direct and indirect pathways, i.e. from striatonigral and pallidonigral neurons, and to compare this to the release of endogenous taurine which may be associated with striatonigral neurons.

Rats were implanted with microdialysis probes in the striatum (STR) or GP and in the SNr. After 24 h the probes were perfused with artificial CSF (1.2 μl/min). STR or GP were perfused with the excitatory amino acid receptor agonist kainic acid (KA, 100 μM) alone or in the presence of DNQX. Fractions (20 min) were collected and following derivatisation and separation (hplc) the amino acids were detected fluorometrically. The application of KA to STR enhanced the release of both GABA and taurine locally in the STR and distally in the SN. The distal release of both amino acids in the SN was sensitive to the administration of DNQX and tetrodotoxin to the STR but only the local release of GABA was similarly sensitive. KA administration to GP also caused a DNQX-sensitive increase in the release of both GABA and taurine in the GP but only an increased release of GABA in the SN.

These results indicate that following KA stimulation, GABA is released by neurons in both the GP and STR. This stimulation also leads to the release of GABA from their axon terminals in the SN. Taurine is also released in response to KA but the characteristics are different to those of the release of GABA.

CLOSE PRESSURE APPLICATION OF CANNABINOID ANTAGONIST SR 141716A SLOWS SUBSTANTIA NIGRA RETICULATA NEURONAL DISCHARGE AND ANTAGONIZES AGONIST ACTION. T. Tersigni and H.C. Rosenberg.* Dept. of Pharmacology, Medical College of Ohio, Toledo, Ohio 43699.

High densities of cannabinoid receptors are present on presynaptic terminals of striatal projection neurons. In a previous study, cannabinoids dissolved in 45% 3-hydroxypropyl-β-cyclodextrin were applied by pressure from a side barrel of a multi-barreled glass electrode assembly while recording the spontaneous discharge of substantia nigra reticulata (SNr) neurons. Cannabinoids increased the firing rate of SNr neurons without affecting the action of iontophoretically-applied GABA, consistent with a presynaptic cannabinoid action. The present study used these techniques to study the effect of a cannabinoid antagonist, SR 141716A. Male Sprague-Dawley rats were anesthetized with chloral hydrate. A glass multi-barrel electrode was used for extracellular recording of SNr neurons and to pressure eject SR 141716A and CP 55940, a cannabinoid agonist. Local pressure application of SR 141716A decreased the spontaneous firing rate of SNr cells 3-64%. When the SR 141716A application was stopped after three min and CP 55940 application immediately begun, SNr firing rate returned to near baseline during CP 55940 application. In other experiments, SR 141716A was given for 5 min, then co-administered along with CP 55940 for 10 min. The firing rate returned toward baseline during co-application of CP 55940 and SR 141716A. When CP 55940 was administered a second time, 45 min after the end of the initial application, it caused the expected increase in SNr firing rate. These findings support a receptor-mediated action of cannabinoids in these experiments, and suggest the presence of an endogenous cannabinoid acting to modulate striato-nigral transmission. MODULATION OF CALCIUM CURRENTS BY DOPAMINE D1 RECEPTORS IN ACUTELY DISSOCIATED RAT NUCLEUS ACCUMBENS NEURONS. X.-F. Zhang* and F.J. White, Neuropsychopharmacology Lab, Dept. Neuroscience, FUHS/Chicago Medical School, North Chicago, IL 60064-3095.

The nucleus accumbens (NAc) is a ventral striatal region which receives dopaminergic (DA) input from the VTA and which plays a critical role in motivated behaviors and drug addiction. Voltage-dependent calcium channels (VDCCs) are thought to mediate a variety of intracellular processes such as transmitter release, enzyme activation and gene expression. DA receptor modulation of VDCCs has recently been demonstrated in dorsal striatal neurons.The present investigation examined whether similar modulation exists within the rat NAc. Whole-cell voltage clamp recordings were used to investigate D_1R modulation of calcium current (I_{CA}). NAc neurons from adult (> 4 weeks old) rats were acutely dissociated. Only medium-sized neurons (diameter < 14 µm), were used. I_{CA} was isolated using TTX externally to suppress sodium current and CsCl internally to suppress potassium currents. ATP, phosphocreatine, and leupetin were used internally to reduce rundown of I_{CA}. Most NAc neurons expressed high voltage activated (HVA) I_{CA}. Experiments with channel blockers suggested at least four types of HVA channels in NAc neurons: (1) ω-conotoxin GVIA-sensitive N type, (2) ω-agatoxin TK-sensitive P type, (3) nifedipine-sensitive L type, and (4) a current that was insensitive to the combination of these blockers. All types of I_{CA} were blocked by 0.4 mM Cd^{2+}. Application of the D_1R agonist SKF 38393 (1 µM) reversibly inhibited I_{CA}, an effect which was completely blocked by the D_1R antagonist SCH 23390 (1 µM). The membrane permeable cAMP analogue 8-Br-cAMP (50 µM) mimicked the effect of SKF 38393 and blocked further suppression by the agonist. When cells were dialyzed with the protein kinase inhibitor PKI [4-25] (10 µM), the inhibition by either SKF 38393 or 8-Br-cAMP was prevented. Co-application of the protein phosphatase inhibitor okadaic acid (1 µM) with SKF 38393 or 8-Br-cAMP also blocked the reduction of I_{CA}. The results suggest that D_1R modulation of NAc I_{CA} is mediated by both the cAMP-PKA system and a phosphatase pathway. (Supported by DA 04093 and DA 00207 to FJW.)

CHARACTERIZATION AND DOPAMINERGIC MODULATION OF THE INWARD RECTIFIER IN ACUTELY ISOLATED WILD-TYPE AND DARPP-32 KNOCKOUT MOUSE NUCLEUS ACCUMBENS NEURONS.
P.G. Mermelstein*, A.A. Feinberg, P. Greengard and D.J. Surmeier
Department of Anatomy and Neurobiology, University of Tennessee College of Medicine, Memphis, TN and Department of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY.

In striatal neurons, inwardly rectifying K^+ currents play an important role in regulating synaptic integration and the transition between 'down' and 'up' states. In spite of its importance, this current has escaped detailed biophysical, pharmacological and molecular analysis. In addition, the channels underlying this current may be targeted by dopaminergic signaling pathways relying upon DARPP-32.

Inwardly rectifying K^+ currents were studied in acutely dissociated mouse nucleus accumbens neurons with whole cell patch clamp techniques. Currents attributable to IRK subunits were isolated using a combination of biophysical and pharmacological tools. The isolated currents responded as expected to alterations in the K^+ equilibrium potential. Moreover, the current was reduced with substitution of external K^+ with either Rb^+ or Na^+. Millimolar concentrations of extracellular Ba^{2+} or Cs^+ blocked the currents. Single cell RT-PCR was performed to determine channel subunit (IRK1-3) expression and to phenotype studied cells.

Dopamine receptor stimulation reduced peak inward currents. The impact of the DARPP-32 mutation on this modulation is under study.

BASAL GANGLIA: MODELS

798.1

A COMPUTATIONAL MODEL OF THE ROLE OF BASAL GANGLIA IN A RECIPROCAL AIMING TASK. A. Bischoff*, M.A. Arbib, and C.J. Winstein.
University of Southern California, Los Angeles, CA 90089-2520.

A rapid reciprocal aiming task was used to test performance of arm movement in control subjects and in Parkinson's disease patients (Winstein and Pohl, 1995; Winstein et al., 1995). Targets were 37 cm apart with a width of either 8 cm or 2 cm. Parkinson's patients demonstrated a slower movement time and exhibited less variance in movements than controls. A computational model of the basal ganglia demonstrated that a reduction in the disinhibition of the ventrolateral thalamus by the internal globus pallidus may produce the slower velocity by the lack of drive to the motor cortex and the supplementary motor area (SMA). A simulated three-jointed arm was used to study the arm movements, with the motor cortex providing velocity and positional information. The aiming task was treated as a sequence of movements, with the supplementary motor area responsible for the overall sequence. The basal ganglia, with its strong pallidothalamic projections to SMA-proper, is proposed to assist in the sequencing of movements by inhibiting other motor control programs while permitting the current movement of the sequence to be performed. The weaker disinhibition therefore causes a difficulty not only in performing the current movement, but in setting up the next movement of the sequence as well. As seen with the Parkinson's patients, the parkinsonian version of the model was more restricted in its tapping placement on the targets than when functioning as a control subject. The model also supports Fitts' Law, which states that task complexity increases with larger distances and smaller target widths.
Supported in part by a grant from the Human Frontier Science Program and by AASERT award N00014-93-1-0694 from the Office of Naval Research.

798.2

COMPUTER SIMULATION STUDY OF IONIC MECHANISMS UNDERLYING VOLTAGE TRACES RECORDED FROM DOPAMINERGIC NEURONS.
R. Kötter* and M. Feizelmeier. Inst. für Morphol. Endokrinologie + Histochemie, C. + O. Vogt-Inst. für Hirnforschung, H.-Heine-Universität, Postfach 101007, D-40001 Düsseldorf, Germany.

At least ten distinct membrane currents appear to contribute to the complex voltage traces recorded from dopaminergic neurons. Controversial roles of individual currents were further investigated by computer simulation of model neurons constructed according to morphological and voltage clamp data. Rhythmic firing and responses to current injection paradigms in simulated neurons were compared to experimental current clamp data.

Simulation of a slowly inactivating Ca^{++} current (I_p, Neurosci. Res. 18:209) in addition to a leak current produced spontaneous oscillations of membrane potential whose amplitude and frequency were influenced by current injection. Inclusion of Na^+/K^+ spikes, outward and inward rectification accounted for further typical features. Simulated rhythmic firing showed slow firing rates, depolarized thresholds, broad action potentials, and a two-component (BK and SK $I_{K(Ca)}$) afterhyperpolarisation. More than one set of model parameters was required to reproduce responses to various current injection paradigms (Neurosci. Res. 18:195) most likely because of variations in currents underlying low and high threshold spikes. In distinction to previous models (Neuroscience 71:397) burst firing was evoked by release of hyperpolarization in the absence of simulated apamin and NMDA actions. In conclusion, spontaneous rhythmic firing and responses to current injection of dopaminergic neurons could be explained by interaction of previously characterized currents.

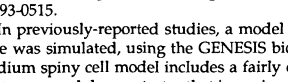

Fig. 1. Spontaneous rhythmic firing of simulated dopaminergic neuron. Abscissa: Ticks mark every 200 ms (left) and 10 ms (right). Ordinate is in mV.

798.3

A COMPUTATIONAL MODEL OF THE BASAL GANGLIA AND HOW PALLIDOTOMY ALLEVIATES SYMPTOMS OF PARKINSON'S DISEASE. G.S. Berns*[1] and T.J. Sejnowski[2]. [1]Western Psychiatric Institute & Clinic, Univ of Pittsburgh, Pittsburgh, PA 15213, [2]Howard Hughes Medical Institute, Salk Institute, La Jolla, CA 92186.

We propose a systems-level computational model of the basal ganglia based closely on known anatomy and physiology. First, we assume that the thalamic targets, which relay ascending information to cortical action and planning areas, are tonically inhibited by the basal ganglia. Second, we assume that the output stage of the basal ganglia, the internal segment of the globus pallidus, selects a single action from several competing actions via lateral interactions. Third, we propose that a form of local working memory exists in the form of reciprocal connections between the external globus pallidus and the subthalamic nucleus (STN), which could store information about sequences. The potential actions were represented as parallel processing streams of information, each competing for access to the cortical areas that implemented them. In the computational model, these actions were represented by units that corresponded to pools of neurons in each of the proposed processing streams. The model was comprised of three layers of units: a striatal layer (STR), a globus pallidus layer (GP), and a STN layer. Both the striatal layer and GP layer sent a convergent projection to a single dopamine unit, which computed the difference between these projections and represented an error signal, which was subsequently used to modulate connection strength changes between the STN and the GP layers. Low learning rates, which would be hypothesized to reflect low levels of dopamine, as in Parkinson's disease, led to slow sequence shifting when the model was trained first on one sequence and then switched to another sequence. However, this could be partially offset by modeling a lesion of the globus pallidus resulting in an increase in gain of the STN units. The gain increase is predicted based on a GP lesion narrowing the distribution of biases in the STN population.

798.4

A BIOPHYSICAL MODEL OF CORTICO-STRIATO-THALAMIC LOOPS AND ACTION/MOTOR CONTROL IN THE NORMAL AND PARKINSONIAN NEOSTRIATUM.
J. R. Gobbel*. Department of Cognitive Science, UC San Diego, La Jolla, CA 92093-0515.

In previously-reported studies, a model of the striatal medium spiny cell type was simulated, using the GENESIS biophysical simulation system. The medium spiny cell model includes a fairly complete set of K+ and Na+ conductances, and demonstrates that in conjunction with dopaminergic and cholinergic modulation of these conductances, intrinsic membrane properties of striatal medium spiny cells could allow them to be stable at either the "up" depolarized or "down" hyperpolarized membrane potential levels, given the same moderate level of excitatory input. This bistability can allow these cells to serve a working memory function, with each medium spiny cell acting essentially as a simple binary latch. Dopaminergic and cholinergic modulation can allow these cells to be cleared of a stored state and set into either an up or down state dependent on excitatory input levels.

The model reported on here uses the model of the striatal medium spiny cell and a relatively simple cholinergic cell to build a network model of the striatum. Other portions of the basal ganglia, thalamus, and cortex are represented schematically. The model demonstrates how, when connected in recurrent loops, the striatum and the basal ganglia as a whole can provide a mechanism for controlling the execution of motor or more general action sequences. "Lesioning" the model by lowering dopamine levels produces deficits in sequence execution which parallel some of those found in Parkinson's Disease patients.

798.5

A DISTRIBUTED MODEL OF A MIDBRAIN DOPAMINE NEURON SUPPORTS A ROLE FOR THE SODIUM PUMP IN NMDA-EVOKED BURST GENERATION. C. C. Canavier* Dept. of Neurobiology and Anatomy, The University of Texas Medical School, Houston, TX 77225.

A minimal model of NMDA-evoked burst generation was constructed using the simulation package NEURON. Midbrain dopaminergic neurons have been shown to fire in bursts in the presence of NMDA, and if TTX is also applied, a slow oscillation underlying the burst can be observed (Johnson *et al.*, 1992). A distributed model is required because membrane voltage and ionic concentrations vary significantly along the dendrites compared to that in the soma. The model, which includes a soma as well as four dendrites each 500 microns in length, was able to mimic this slow oscillation using physiologically realistic parameters. Published voltage-clamp data specific to this neuron was used to formulate a description for the NMDA-evoked current; a leakage current and an electrogenic sodium pump current were also incorporated into the model. A sodium balance was implemented in order to model the variation in internal sodium concentration. An oscillation in sodium concentration is produced by the interaction of the NMDA current and the sodium pump. In order for a compartment to oscillate, it must be biased in a negative slope conductance region of its I–V curve. Experimentally, a hyperpolarizing injected current is required to reveal bursting activity in the presence of NMDA. The model shows that this hyperpolarizing current is required to bias the dendritic compartments in the negative slope region; the depolarization induced by NMDA would otherwise mask the tendency to burst. Since the current is injected into the soma, the bias current varies along the dendrite. An oscillation in dendritic sodium concentration a few mM in amplitude is sufficient to produce the slow oscillation observed in the soma, although the sodium concentration in the relatively large somatic compartment remains essentially constant. The model is being expanded to include other currents expressed in this neuron, with the intention of using it as a tool to explain and predict the effects of pharmacological manipulations on the electrical activity of these neurons.

798.6

A NEURAL NETWORK MODEL OF REWARD-RELATED LEARNING, MOTIVATION AND ORIENTING BEHAVIOR. J.L. Contreras-Vidal* and W. Schultz. Motor Control Laboratory, Arizona State University, Tempe, AZ 85287-0404 USA and Department of Physiology, University of Fribourg, Rue du Musee 5, CH-1700 Fribourg, Switzerland.

The neural dynamics of basal ganglia-thalamo-cortical loops in relation to the learning of stimulus-reward associations are studied through neural network modeling. It is hypothesized that dopaminergic (DA) neurons are responsible for linking sensory-motivational representations in the ventral striatum (useful for goal selection) with sensory-motor representations in the dorsal striatum (associated with selection of movement parameters) effectively guiding the learning of approach behavior. Dopamine neurons, therefore, may engage motivational, orienting and learning processes that determine behavioral reactivity in response to environmental stimuli and the internal needs of the organism. In this mechanistic account, learning of stimulus-reward associations are marked by an adaptive (at striatum and prefrontal cortex) positive feedback loop between stimulus-driven motivational representations and learned expectancies during goal-directed behavior. Mismatch between stimulus-activated representations and learned motivational expectancies produce orienting reactions mediated by DA neurons that may lead to behavioral switching and new learning. This hypothesis is scrutinized via computer simulations of neural circuits and neurotransmitter subsystems underlying the learning and performance of approach behavior in relation to the free or contigent delivery of primary rewards.

798.7

AN INTEGRATED MODEL OF BASAL GANGLIA AND CEREBELLUM IN SEQUENTIAL CONTROL TASKS. K. Doya*. ATR Human Information Processing Research Labs., Seika-cho, Soraku-gun, Kyoto 619-02, Japan.

The basal ganglia and the cerebellum are known to play complementary roles in motor control (Thach et al., 1993). Here, a computational model of their functions in sequential control tasks is proposed based on a recent theory of reinforcement learning (Doya 1996).

The central idea in the theory of reinforcement learning is to identify the "value function" which predicts the future reward based on the past experience and the current sensory input. Once an appropriate value function is learned, there are two possible schemes for producing motor commands. The first scheme is to compute the desired direction of movement based on the gradient of the value function and then to convert it to a motor command using an internal model of the motor apparatus. The second scheme is to use the output of a task-specific controller which has been trained by the above motor command as the teacher. These schemes may correspond to short-term and long-term components, respectively, in sequence learning.

We propose that these computational processes can be mapped onto the brain structures including the basal ganglia and the cerebellum as follows. The patch compartment of the striatum computes the value function (Houk et al. 1995). The matrix compartment computes the gradient of the value function and its output to the direct and indirect pallidal pathways results in a selection of a desired movement in the thalamus and the motor cortices. It is then converted into a motor command in the lateral hemispheres of the cerebellum, where the model of the motor system was previously acquired. This motor command can be used both for immediate motor output (first scheme) and for training a task-specific controller in the intermediate hemispheres of the cerebellum (second scheme). THE THALAMUS TEMPORALLY GATES THE FLOW OF TACTILE INFORMATION TO SOMATOSENSORY CORTEX.
J.H. Thompson and J.M. Bower*. Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125

Tactilely-induced somatosensory information from perioral structures reaches the granule cell layer of the hemispheres of rat cerebellar cortex via two main pathways. A direct projection from the trigeminal sensory nuclei is responsible for a very short latency response (4-6 msec.). In addition, trigeminal input to primary somatosensory cortex (SI) via ventral posterior medial (VPM) nucleus of the thalamus is relayed, via the pontine nuclei, to spatially restricted regions in cerebellar cortex whose receptive fields are in register with those of the direct trigeminal input. The longer latency responses (12-18 msec.) induced by this pathway have greater variability in latency and amplitude. We have looked more closely at the timing of data acquisition with respect to thalamocortical oscillations by recording tactilely evoked responses simultaneously from VPM, layer IV of SI, and Crus IIa of the cerebellar cortex of an anesthetized rat. The pathway from SI yields a response in the cerebellum whose latency and amplitude depend on the phase relationship of the timing of the stimulus to the thalamocortical oscillations. Field potential recordings in VPM and SI reveal that the variability in the response latency occurs in SI, not VPM. Thus, VPM responds to tactile stimulation with the same latency in each trial.. This information then reaches SI with a delay determined by where in the phase of the thalamocortical oscillation a particular stimulus arrived. This data is discussed in the context of cerebral cortical modeling efforts ongoing in our laboratory. Supported by the Human Frontiers program.

INTERACTION BETWEEN NOXIOUS AND NON-NOXIOUS SOMATOSENSORY-EVOKED RESPONSES IN THE RETICULAR THALAMIC NUCLEUS. S.A. Eaton[1] and M.D. Bevan[2]*. [1]MRC Anatomical Neuropharmacology Unit, Oxford University, UK and [2]Department of Pharmacology, Oxford University, UK.

Inhibitory GABAergic input to the ventrobasal thalamus (VBT) from the thalamic reticular nucleus (TRN) plays a pivotal role in the integration and transfer of sensory information through the VBT. Noxious stimulation is known to inhibit an unidentified population of TRN neurones, but its effects on TRN neurones in the VBT-recipient compartment of the TRN has not been defined. Experiments were therefore performed to investigate the potential interactions between sensory responses evoked by noxious and non-noxious stimulation in the somatosensory TRN.

Single TRN neurones were recorded using extra- or juxtacellular recording techniques in urethane (1.2g/kg) anaesthetised rats. Non-noxious somatosensory responses, evoked by air jet stimulation of the vibrissal peripheral receptive field, were recorded before, during and after noxious mechanical stimulation applied to the ipsi- or contralateral hindpaw. TRN neurones displayed burst and/or tonic patterns of spontaneous activity. Non-noxious sensory responses consisted of a short latency burst of action potentials. Noxious stimulation could evoke a brief, relatively small action potential response at stimulus onset and offset, had little or no effect against sensory responses evoked by air jet stimulation (except facilitation when air jet responses were coincident with onset or offset noxious-evoked excitation) but produced a powerful inhibition of any ongoing tonic spontaneous activity.

These data suggest that inhibitory mechanisms within the TRN can mediate interactions between somatosensory submodalities and that noxious stimulation can increase the signal to noise ratio of low threshold, sensory-evoked inhibitory input to the somatosensory thalamic relay nuclei.

COMBINED LIGHT AND ELECTRON MICROSCOPIC EVIDENCE FOR THE LACK OF INTRINSIC AXON COLLATERALS AND THE EXISTENCE OF DENDRO-DENDRITIC SYNAPSES IN THE THALAMIC RETICULAR NUCLEUS OF THE RAT. D. Pinault*, Y. Smith and M. Deschênes *Centre Recherche Neurobiologie, Fac. Médecine, Univ. Laval, Québec, Canada*

Physiological and pharmacological studies suggest that neuronal interactions occur in the thalamic reticular nucleus (Rt) during thalamocortical operations. The anatomical substrate that underlies these intrinsic interactions still remains a matter of controversy. Dendro-dendritic synapses were found in cats, but few if any of such synapses were detected in both rat and monkey. In the rat and cat, light microscopic observations rather suggested the existence of intrinsic axon collaterals. In order to clarify this issue, we stained juxtacellularly Rt cells and examined their presumed intrinsic axonal segments at both light and electron microscopic levels.

The axon of 111 biocytin-filled Rt cells could be followed from its origin up to the thalamus. In 12 of them, 1-4 ramifying varicose fibres detached from the main axon before it leaves the Rt. Those axonal ramifications could not be distinguished from distal dendrites, raising the question as to whether their varicosities were presynaptic terminals. To verify this possibility, we examined the ultrastructural features of these intrinsic axon-like profiles in the electron microscope. The presumed axon collaterals were in fact post-synaptic structures that received dense asymmetric synaptic inputs from GABA-negative terminals. The axon hillock of Rt neurons was also found to form asymmetric synapses with numerous GABA-negative boutons. Examination of dendritic bundles cut in the horizontal plane revealed the existence of short symmetric dendro-dendritic synapses.

In conclusion, our data indicate: (1) that cell-cell functional interactions in the Rt of the adult rat might occur through dendro-dendritic synapses and (2) that the action potential initiation in Rt neurons might be strongly influenced by excitatory synaptic inputs on the axon hillock. *Supported by the Medical Research Council of Canada.*

INTRATHALAMIC MECHANISMS OF SHORT-TERM PLASTICITY PROCESSES DURING INCREMENTAL RESPONSES. M. Steriade* and I. Timofeev, Lab. Neurophysiol., Sch. Med., Laval Univ., Quebec, Canada G1S 7P4.

Cortical augmenting responses can be elicited by thalamic or white matter repetitive stimulation, incrementing from the second stimulus in a train at 7 to 14 Hz. These responses have been used to mimic the initially waxing pattern of sleep spindles. Although some studies have reported incremental cortical responses after thalamic lesions, thus suggesting that the cortex plays a major or even exclusive role in the process of augmentation, the complex mechanisms of these responses are largely unknown. Here we demonstrate that augmenting responses can be generated in the thalamus after decortication and we describe the intracellular mechanisms of these short-term plasticity processes. Intracellular recordings have been obtained *in vivo* from thalamocortical (TC) neurons in the ventrolateral (VL) nucleus and from thalamic reticular (RE) neurons in cats under ketamine-xylazine anesthesia, after ipsilateral decortication and transection of corpus callosum. Trains of 5 stimuli at 10 Hz were applied to the VL nucleus and produced augmenting responses in both TC and RE cells. **(1)** The responses of TC cells to a single stimulus consisted of an EPSP, followed by a long-lasting (0.15-0.3 s) biphasic IPSP, leading to a rebound low-threshold spike (LTS) crowned by a spike-burst. **(2)** Starting with the response to the 2nd stimulus in the 10-Hz train (falling during the IPSP elicited by the 1st stimulus), the initial EPSP of TC cells was immediately followed by an LTS which, through depolarization, *led to high-threshold spike-doublets or triplets, very different from postinhibitory spike-bursts.* **(3)** Further augmentation in TC cells in response to the last stimuli of the train was due to more depolarization, concomitant to a progressive diminution of successive IPSPs; this reduction in IPSPs is partially ascribed to intra-RE inhibitory processes (as, at given parameters of repetitive stimulation, RE cells displayed decremental responses), thus leading to disinhibition of TC neurons.

SPONTANEOUS AND CEREBELLAR-EVOKED FAST OSCILLATIONS IN THALAMIC VENTROLATERAL (VL) NEURONS AND THEIR SYNCHRONIZATION WITH CORTICAL POTENTIALS. E. LeBel*, I. Timofeev, M. Steriade., Lab. Neurophysiol., Sch. Med., Laval Univ., Quebec, Canada G1K 7P4.

Fast oscillations (20-40 Hz) appear in thalamocortical (TC) neurons during brain-activated states and during the late depolarizing phase of the slow sleep oscillation (*Neuroscience* 1993, 56:1; *J.Neurosci.* 1996, 16:2788). We investigated the electrophysiological features of these fast events, their origins in afferent pathways, and their synchronization with cortical potentials, by means of intracellular recordings of TC cells from VL nucleus in cats under ketamine-xylazine anesthesia. **(1)** The spontaneous fast waves were EPSPs that, at slightly depolarized levels, gave rise to all-or-none fast prepotentials (FPPs), occasionally leading to full spikes. The frequency of these events ranged from 20 to 120 Hz, mainly between 40 and 60 Hz; within epochs as short as 0.5 s, the frequency increased and thereafter decreased by a factor of 2 to 3. **(2)** Stimulation of brachium conjuctivum (BC) evoked EPSPs that were virtually identical to the spontaneous fast events. The BC-evoked EPSPs faithfully followed stimulation rates of 100 Hz or higher. **(3)** Cross-correlations and EPSPs-triggered averages obtained from *simultaneous intracellular recordings of VL cells and field potential recordings in motor cortical area 4 demonstrated synchronization of spontaneous and BC-evoked fast events in thalamocortical systems.* However, such periods of synchronization lasted for only short periods (usually less than 0.3-0.5 s), due to changing frequency in the thalamic or cortical lead. **(4)** The BC evoked and spontaneous fast EPSPs were drastically shortened and their amplitude decreased during the hyperpolarizing phase of spindle-related IPSPs in VL cells. These data demonstrate that some of synchronized thalamocortical fast oscillations originate in prethalamic relay stations.

IN VIVO INTRACELLULAR STUDY OF LOW-FREQUENCY SLEEP OSCILLATIONS IN THE THALAMUS OF DECORTICATED CATS. I. Timofeev* and M. Steriade Lab. Neurophysiol., Sch. Med., Laval Univ., Quebec, Canada G1S 7P4.

The aim of this study was to determine whether or not the slow sleep oscillation (less than 1 Hz) is present in the thalamus of decorticated animals and to investigate the shape and synchrony of thalamic-generated sleep rhythms [spindles (7-14 Hz) and clock-like delta oscillation (1-4 Hz)] after decortication. Intracellular recordings of rostrolateral thalamic reticular (RE) and ventrolateral (VL) thalamocortical (TC) cells (n=165), including simultaneous impalements of RE and TC cells or two TC cells (n=22), have been performed in cats under ketamine-xylazine anesthesia after ipsilateral decortication and callosal cut. **(1)** The slow oscillation is an emergent property of neocortical networks, but is reflected in RE and TC cells (*J. Neurosci.*, 1993, 13:3284; *ibid.* 1995, 15:604). In contrast to the presence of the slow oscillation in the intact-cortex (right) hemisphere, the slow oscillation was absent at the intracellular and field potential levels in the left thalamus after ipsilateral decortication. This result, together with previous data showing the presence of slow cortical oscillation in athalamic animals, clearly demonstrates that *the neocortex is necessary and sufficient for the generation of the slow oscillation.* **(2)** Spindle sequences mostly appeared as nearly synchronous events among simultaneously recorded TC and RE neurons or couples of TC cells within the VL nucleus. The difference between the decorticated and the intact-cortex thalamus mainly consisted in the waxing-and-waning shape of spindles in the former case, as opposed to the exclusively waning spindles in the thalamus with intact cortical connections. We ascribe this difference to the fact that the sharp depolarizing component of the slow oscillation represents a powerful corticothalamic drive, thus entraining the thalamic circuitry right from the start and preventing the waxing process (*J. Physiol.*, 1996, 490:159). **(3)** Clock-like delta rhythmicity was expressed as non-synchronous spike-bursts in TC cells recorded from multiple sites.

NUCLEUS RETICULARIS THALAMI CONTROLS THE QUIESCENCE OF THALAMOCORTICAL NEURONS DURING SEIZURES IN A COMPUTER NETWORK MODEL. W. W. Lytton*, D. Contreras, A. Destexhe and M. Steriade. Dept. Neurol., Univ. Wisconsin, Middleton VA Hosp., Madison, WI 53706, and Lab. Neurophysiol., Sch. Med., Laval Univ., Quebec, Canada G1K 7P4.

Intracellular recordings from thalamocortical (TC) neurons during spontaneous seizures in a cat model of spike-wave epilepsy indicate a surprising preponderence (60%) of quiescent cells (Steriade and Contreras, J. Neurosci. 1995, 15:623-642). During these seizures, thalamic reticular (RE) cells produced long (150-300 ms) spike-bursts simultaneous to the paroxysmal "spikes" in cortical EEG, whereas TC neurons either exhibited quiescence with continuous synaptic bombardement or occasionally displayed low-threshold spikes in synchrony. Several computer models of simple 2-neuron (RE-TC) models were assessed to explore factors contributing to the maintenance of quiescence and to the transition between quiescence and bursting in TC cells. Generally, small increases in $GABA_B$ strength tended to produce TC quiescence. We demonstrated that such changes could result from cooperative kinetics of $GABA_B$ activation via second messengers. Switching between quiescence and oscillatory mode in these models was shown to be related to the strength and to the precise timing of simulated cortical stimulation. In many cases, complex dynamics in the 2-neuron network gave extreme sensitivity to the precise phase of effective cortical inputs. The dynamics also permitted spontaneous switching between states. This study suggests that quiescent patterns of TC cells during spike-wave seizures can result from known intrinsic properties and synaptic interactions in the thalamic circuitry and emphasizes the important role of $GABA_B$ receptors.

RHYTHMICITY AT PRETHALAMIC LEVEL: DORSAL COLUMN NUCLEI-THALAMIC SYNCHRONIZATION IN THE CAT. J. Mariño*, L. Martinez and A. Canedo. Dep. de Fisiologia, Fac. de Medicina, Univ. de Santiago de Compostela, 15705, A Coruña, Spain.

Cortical and thalamic oscillations have been extensively studied, with the identification and characterization of three key sleep rhythms: slow (< 1 Hz), delta (1-4 Hz) and spindle (7-14 Hz) oscillations. In order to analyze the synaptic relations between the *nucleus cuneatus* (NC) and the thalamic *nucleus ventralis posterolateralis* (NVPL), we have simultaneously recorded cells in the NC (through tungsten electrodes) and in the NVPL (by using patch-like micropipettes containing neurobiotin) of anaesthetized (α-chloralose) and paralyzed (pavulon) cats. To record extracellularly cuneo-thalamic cells, a tungsten electrode was placed in the NC and relay cells were antidromically identified by electrical stimulation of the contralateral *lemniscus medialis* (LM) at A1. Records in the NVPL were made using the whole cell patch technique *in vivo*, so the recordings were relatively long lasting and stable. Cells within the NVPL were detected by electrical stimulation of the ipsilateral *capsula interna* and/or the primary somatosensory cortex and LM, as well as the receptive field in the contralateral forepaw. To reveal the relations between the cuneate and thalamic activities we used the spike triggered averaging method (STA) as well as cross-correlations. The results show the existence of a close relationship between the spontaneous activity of NC and NVPL neurons, with a high degree of synchronization. Auto-correlations revealed that 42 % of the studied cells in the NC exhibited <1 Hz and 1-6 Hz rhythms, similar to those existing in the cortico thalamo-cortical network. The STA technique showed in 23 % of cases that both, thalamic and cuneate rhythms, were highly coupled; nevertheless this synchronization seems not to be due to a cuneo-thalamic synaptic effect, rather the results point to an external source of synchronization, probably the cortex. Cross-correlations also revealed synchronization of NC and thalamic neurons within the range of slow (<1 Hz) and delta (1-4 Hz) oscillations. These results suggest that in our experimental conditions, the cortex could act synchronizing the activity of thalamic and cuneo-thalamic neurons. Furthermore, at least part of the spontaneous rhythmicity encountered in cuneate neurons has been demonstrated, in a different study, to be due to intrinsic membrane properties.

AFFERENT PROJECTIONS TO NUCLEUS REUNIENS OF THE THALAMUS IN THE RAT. R.P. Vertes* and A.M. Crane. Center for Complex Systems, Florida Atlantic University, Boca Raton, FL 33431.

The nucleus reuniens (RE) is the major source of thalamic afferents to the hippocampal formation (HF) and to the entorhinal cortex. We recently demonstrated that the supramammillary nucleus (SUM) and the posterior nucleus of the hypothalamus (PH) are directly involved in the control of the theta rhythm of the HF (Kocsis and Vertes, J. Neurosci. 14:7040, 1994), and further showed that SUM and PH project densely to RE (Vertes, J. Comp. Neurol. 326:595, 1992; Vertes et al., J. Comp. Neurol. 359:90, 1995). This suggests that the RE may also serve a modulatory role in the control of the hippocampal EEG. This report represents a comprehensive examination of afferents to RE.

Single injections of WGA-HRP were made into the RE of 15 rats. Patterns of retrograde cell labeling were as follows. Moderately to densely labeled sites (from caudal to rostral) included the locus coeruleus, the medial and lateral parabrachial nuclei, the Kolliker-Fuse nucleus, the laterodorsal and pedunculopontine tegmental nuclei, the dorsal raphe nucleus, the central gray, deep layers of the superior colliculus, the substantia nigra-pars compacta, peripeduncular nucleus, SUM, PH, zona incerta, reticular nucleus of thalamus, dorsal and ventral subiculum of HF, endopiriform nucleus, claustrum (CL), dorsal agranular insular cortex (InC), anterior cingulate cortex (CgC), medial and lateral agranular (frontal/prefrontal) cortex (AG_M, AG_L) and the infralimbic cortex (IlC). Projections from the rostral pole of the frontal cortex (CL, CgC, InC, AG_M, AG_L and IlC) to RE were massive.

We propose that the RE may act as a filter gating the flow of information from frontal cortex (FC) to HF and that "theta signals" conveyed from the SUM/PH to RE may be involved in controlling the types of information relayed from FC to the hippocampus via RE. FRONTAL LOBE PROJECTIONS OF THALAMOCORTICAL NEURONS WITH INPUT FROM THE RETICULAR PART OF SUBSTANTIA NIGRA IN MONKEYS. I. TANIBUCHI*, K. JINNAI[1] AND H. KITANO[2]. Dept. of Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510; [1]Dept. of Physiology & [2]Dept. of Neurosurgery, Siga Univ. of Med. Sciences, Ohtu 520-21, Japan.

We studied the topography and physiological characteristics of nigro-thalamo-cortical projections. Under pentobarbital anesthesia, stimulating electrodes were implanted in various cortical areas of the frontal lobe and the reticular part of substantia nigra (SNr) of two Japanese monkeys (Macaca fuscata). One month after the operations, unit activity of thalamic neurons was studied during performance of a go/nogo task. Thalamocortical neurons were identified by antidromic stimulation of the cortical areas, and subsequently the responses of the thalamocortical neurons to SNr stimulation were examined. 1) Thalamic neurons showing inhibitory responses with short latencies to SNr stimulation were located in the magnocellular part of VA (VAmc), the rostrolateral portion of MD and the medial portion of VL. 2) VAmc neurons with SNr input projected to wide areas of the prefrontal cortex (PFC). Most neurons projecting to the ventral area to principal sulcus (PSv) were located in the ventral portion of VAmc and were inhibited by stimulation of caudal SNr. The neurons projecting to other areas of PFC were found mainly in the dorsal portion of VAmc and inhibited mostly by rostral SNr stimulation. 3) Most MD neurons which were inhibited by stimulation of caudal SNr projected exclusively to PSv. This study indicates that nigro-thalamo-cortical projections have a topographical organization in monkeys. The pathways from caudal SNr through VAmc and MD to PSv may influence the cognitive functions of this cortical area.

SUPERIOR COLLICULUS PROJECTIONS TO MEDIODORSAL (MD) AND VENTRAL ANTERIOR (VAmc) THALAMIC NUCLEI IN THE MONKEY. Y. Tai, K. Kultas-Ilinsky and I.A.Ilinsky*. Dept. of Anatomy, Univ. of Iowa Coll. Med., Iowa City, IA 52242.

Pars reticularis of substantia nigra sends branching axons to VAmc and MD and to the deep layers of superior colliculus (SC). Projection from SC to these thalamic nuclei has also been suggested implying direct and indirect nigrothalamic pathways involved in the control of oculomotor function. The goal of this study was to verify the SC-thalamic pathway and determine the light and electron microscopic features of the fibers and boutons. Biotinylated dextran amine (BDA) and WGA-HRP were injected in SC in different experiments. The fine structure and postsynaptic targets of labeled terminals were analyzed and compared to those of nigrothalamic boutons labeled with BDA in a separate experiment. Two bouton populations were labeled in MD following SC injections. One consisted of large *en-passant* boutons containing pleomorphic vesicles and forming symmetric contacts. These were morphologically indistinguishable from nigrothalamic terminals and just as the latter formed synapses at proximal locations of thalamocortical projection neurons. Another population consisted of medium size boutons with round vesicles forming asymmetric contacts on distal dendrites. In the VAmc, only boutons of the first type were found labeled from SC. The results suggest that the pleomorphic vesicle containing labeled boutons in both nuclei are terminals of branching nigral axons back filled from SC injections. The second bouton population represents the terminals of SC afferents to the thalamus. The findings imply that of the two thalamic nuclei SC targets only MD and the overal density of this input is low. Supported by RO1 NS 24188.

PROJECTIONS OF THE THALAMIC PARAVENTRICULAR NUCLEUS TO THE LIMBIC FOREBRAIN OF THE RAT: NEUROANATOMICAL AND FUNCTIONAL CHARACTERIZATION. M. BUBSER*, C. D. YOUNG AND A. Y. DEUTCH. Depts. Psychiat. & Pharmacol., Yale Univ. Sch. of Med., New Haven, CT 06511, and VAMC, West Haven, CT 06516.

The thalamic paraventricular nucleus (PV) has been suggested to convey information from hypothalamic and brainstem nuclei to the limbic forebrain. In the present study we characterized PV projections to the ventral prefrontal cortex (PFC) and the shell of the nucleus accumbens (NAS) and investigated the role of PV projection neurons in stress-induced changes of forebrain dopamine (DA) utilization. Small deposits of the anterograde tracer biotinylated dextran amine into the PV showed that the dorsal and the ventral parts of the PV innervate both the shell and septal pole areas of the NAS while largely avoiding the core of the NAS. Retrograde labelling from the ventral PFC and the shell of the NAS to the PV was used to determine the degree of collateralization of PV projection neurons. About 10% of retrogradely-labelled PV cells were found to project both to the PFC and the NAS shell. These data suggest that a subpopulation of PV neurons may simultaneously influence PFC and NAS function. In order to determine whether PV neurons innervating the PFC or the NAS are activated by stress, we determined if footshock stress altered expression of *c-fos* in the PV. Our data suggest that stress increased Fos expression in neurons of the anterior but not posterior PV that project to the PFC. N-methyl-D-aspartate lesions of the PV tended to decrease basal and stress induced DA utilization in the ventral PFC, but not in the NAS. Taken together, these data imply that neurons in the anterior PV are involved in conveying stress-related information to the ventral PFC.

DOPAMINE D2 AND D3 RECEPTOR DISTRIBUTION IN THE HUMAN THALAMUS. R.W. Rieck*, W. Whetzell, and R.M. Kessler. Depts. of Radiology and Pathology, Vanderbilt Univ. Med. Cntr., Nashville, TN 37232.

The distribution of D2 and D3 receptor types was defined with selective radiolabeled ligands; ^{125}I-Epidepride and ^{125}I-Norepidepride, respectively. ^{125}I-Norepidepride is a D3 preferring antagonist ligand (K_D for D3 of approximately 90 pmolar). Three postmortem human brains were frozen, 30 um thick sections were obtained, and incubated with the respective ligands. Autoradiographs were obtained by exposing the sections to X-ray film for 2-6 days. The three brains were free of pathology, and the cause of death was unrelated to CNS disease.

There is a highly organized pattern of D2 receptor (D2-r) distribution within the thalamus. The intralaminar system, i.e., paracentral, centrolateral, and centromedian nuclei, contains a high density of D2-r. In addition there is a dense pattern of D2-r within the anterior aspect of the mediodorsal nucleus and the adjacent midline nuclei. The intralaminar system does not contain a elevated concentration of D3-r. The anterior nuclei, however, and particularly the principal anterior nucleus, do contain a dense concentration of D3-r. As anticipated, the D2-r distribution within the caudate and putamen is very heavy. The concentration within the external globus pallidus (GPe) is moderate to heavy, whereas the internal globus pallidus (GPi) contains a weak concentration of D2-r. The D3 receptor (D3-r) distribution in the basal ganglia is markedly different than D2 receptors. The D3-r concentrations within the striatum and the GPe are nearly equal, whereas there is dense D3-r in the inner portion of GPi, and the ventral pallidum.

There is a highly ordered pattern of D2 and D3 receptors distribution within the human thalamus. The nuclei giving rise to the thalamostriate projection contain a high concentration of D2 receptors. In addition, there are different patterns of distribution of D2-r and D3-r in the basal ganglia and basal forebrain.

EVIDENCE OF HARMONIC ENTRAINMENT OF TREMOR AND VOLUNTARY CONTROL PROCESSES. E.A. Franz*[1,2], K.A. Sigvardt[1,2], L.Tamas[3], H. Richard[3], C.M.Gray[1,2], Dept. of Neurology, UC Davis[1] andCenter for Neuroscience[2], UC Davis, CA 95616, and Pacific Neurosciences Institute, Lafayette, CA[3]

A subject with severe essential tremor in the right hand was tested on a repetitive tapping task performed at a rate of 2 Hz (for 20 consecutive taps per trial). Tapping was produced in single hand conditions and with concurrent movements of the left hand, right foot, left foot, or while counting aloud at the same pace. In single hand tapping conditions with the affected (right) hand, tremor-related rigidity resulted in abnormally long intertap intervals that tended toward harmonics of 250 ms (e.g., 750 ms, 1250 ms). Measures of variability indicate that tremor-related symptoms affect volitional movements of the opposite hand and ipsilateral foot to a larger degree than movements of the contralateral foot. Performing the speech task while tapping with the right hand resulted in normal tapping movements of the right hand!. The interlimb effects may shed light on the mechanisms of spread of tremor across effector systems. The speech-manual effects suggest that components of the volitional signal associated with speech interact with tremor.

SACCADIC REACTION TIMES ARE INFLUENCED BY THE METRICS OF PREVIOUS SACCADES IN MONKEY. M.C. Dorris*, D.P. Munoz, T. Taylor, R. Klein. MRC Group in Sensory-Motor Neuroscience, Queen's Univ., Kingston, Ont., CANADA. Dept. of Psychology, Dalhousie Univ., Halifax, N.S., CANADA.

Human subjects are slower to initiate saccades to targets presented at previously cued locations (inhibition of return, IOR). We sought to duplicate this effect in a multi-target saccade task in the monkey as a prelude to exploring its possible neurophysiological basis in the superior colliculus. A monkey was trained to make three successive saccades in response to a target light that stepped from a central location to a peripheral location, back to the central location, and ending in a final peripheral location. The reaction time of the final saccade was influenced by the metrics of the immediately preceding saccade. When successive saccades were made in opposite directions, the reaction time of the final saccade was faster, whereas, successive saccades which had the same metrics, resulted in final saccades with slower reaction times. Successive saccades made in orthogonal directions were intermediate in latency. When the metrics of successive saccades were systematically varied, the respective facilitation and inhibition of reaction times exhibited a gradient which was most pronounced when the saccades were the same amplitude and either the same or opposite in direction. Our findings appear to contradict what is found in human IOR studies. In those studies, however, subjects are required to suppress overt orienting (i.e., saccades) to the first stimulus. Although a saccade is not elicited to the initial peripheral cue, it has been proposed that the peripheral cue elicits an automatic shift of attention (covert orienting) to its location. In our paradigm, overt orienting was required to every stimulus. A model will be presented to show how these apparently conflicting results obtained with the overt and covert orienting paradigms are consistent with the physiology of the superior colliculus, a structure thought to underlie IOR. *Supported by National Science and Engineering Research Council of Canada.*

EFFECTS OF SIGNAL LIKELIHOOD ON GAZE SHIFT TIMING AND ACCURACY. L. Wang* and J.A. Stern. Dept. of Psychology, Washington Univ. St. Louis, MO 63130.

It has been shown that saccade latencies are affected by temporal cuing (Saslow, 1967) and spatial cuing (Posner, 1978). The current study examined effects of information other than stimulus physical features, specifically signal likelihood, on saccade latency and gaze shift accuracy.

Subjects participated in a signal detection task. A sequence of digits were presented on a display one at a time right or left of the fixation point at 10° eccentricity. The stimulus duration was 400 ms and interstimulus interval 2000 ms. The signal was an odd digit following another odd digit. The subject was instructed that an even digit always followed the signal. The subject's task was to make a manual response whenever he saw a signal. Eight subjects performed the task under one of the two conditions: random tracking where stimulus location was unpredictable and predictive tracking where stimulus location was predictable.

Signal likelihood was defined in terms of expectation to make a manual response. Three levels of signal likelihood were identified. At the NO level, subjects had least likelihood of requiring a response; at the LOW level, the likelihood was higher than the NO; and at the HIGH the likelihood was highest.

RESULTS In the random tracking condition, stimulus-elicited saccade latency decreased with increase in signal likelihood. In the predictive tracking condition, with higher signal likelihood, anticipatory saccades occurred earlier and gaze shifts accomplished by anticipatory saccades were more accurate.

CONCLUSIONS Signal likelihood influences gaze shift initiation as well as gaze shift accuracy, suggesting that signal likelihood plays a role in the allocation of attentional resources.

FOCAL ATTENTION LEVEL VARIATION WHILE TRACKING A SMOOTHLY MOVING TARGET BY INSTRUCTION INFLUENCES EYE MOVEMENT CHARACTERISTICS. Y. Ebisawa* and K. Suzu. Faculty of Engineering, Shizuoka Univ., Hamamatsu, Shizuoka, 423, Japan.

We have already indicated that the characteristics of eye tracking movements, e.g., amplitude of saccade (SC) and amplitude of smooth pursuit movement (SP) [eye movement angle caused by SP per cycle of target movement], change with the level of the focal attention concentrated on a sinusoidally moving target (horizontal, 1 Hz, ±10 deg). Moreover, we have indicated that the saccadic dynamics (peak velocity) change with the attention level (Proc of IEEE EMBS, 1995). To raise subjects' attention level, in the experiment, we gave them a visual feedback, i.e., whether the SP velocity was faster or slower than a sliding threshold was fed back in real time by whether the target was bright or dark, respectively. The subjects followed the target so that it would become as bright as possible. The eye movement characteristics were compared with those of non-feedback tasks. The experimental method, however, left a question that not focal attention level but the brightness transition of the target may have changed the eye movement characteristics.

In this study, to ascertain the results of the prior study, only the instruction to the subjects (six young men) was changed, i.e., whether they concentrated and tracked the moving constant brightness target or tracked it naturally. The heads of the subjects were immobilized. The horizontal eye movement of the viewing one eye was measured in the dark. Before the analysis of the SC and SP, the two components were precisely separated. The results were the same as the prior study, i.e., in the concentrated condition, the SC amplitude decreased and the SP amplitude increased compared with the normal condition. The peak velocity of saccade increased in the concentrated condition. Furthermore, the saccades in each condition were divided into two categories, respectively, by the amplitude of the SP where the saccade occurred. The peak velocity of the saccades in the higher SP amplitude category was larger than those of the lower SP amplitude category (4.5 %). These results strongly support the ones of the prior study, i.e., the variation of the focal attention level changes the saccadic dynamics as well as the SP and SC amplitude.

POST-TRIAL SACCADES AND EVOKED SINGLE-CELL ACTIVITY IN MACAQUE MONKEYS. D.D. Burman*. Institute for Scientific Research & Education, Oak Park, IL 60304.

In tasks commonly used to assess functional properties in the oculomotor system, subjects move their eyes on cue away from a central fixation target. In these tasks, the trial ends once the subject completes a saccade to the correct target location; saccades initiated after the trial ends are typically ignored. Post-trial saccades and single-unit activity related to these saccades were examined in macaque monkeys. Eye movements were recorded with the use of EOG electrodes or an implanted scleral eye coil. Almost always, the vector of the first post-trial saccade moved the eyes to a location somewhat above center; only when the eyes were already at this location did the vector of the post-trial saccade vary greatly. During standardized tasks where the task-related saccade was directed away from a central spot, the post-trial saccade thus moved the eyes in the opposite direction. These post-trial saccades were planned and purposive, as judged by the patterns of neuronal activity evoked in the lateral pulvinar and frontal eye field. Supported by NIH Grants EY2940 and E-04740.

THE INFLUENCE OF OPTICAL FLOW ON VISUAL ATTENTION. U. Schwarz* and J.-C. Javet. Neurology, University Hospital, CH-8091 Zürich, Switzerland.

It is known that the visual brain transforms a retinal optical image into neuronal signals by segregating visual objects into simple attributes, which are processed in parallel. In later stages, these signals are organized into a cohesive perception of the physical world using all or only a selected combination of these features. It is believed that final perception is achieved through a binding mechanism - invoked by **attention** - that temporarily associates groups of cells encoding these various properties. The goal of this study was to investigate the influence of motion of a visual target and/or its surroundings on attention by measuring latencies of initial saccades.

Eye position of 14 healthy naive subjects and one author (US) was measured using the magnetic search coil technique. The visual stimuli were backprojected onto a translucent tangent screen. Each trial started with a computer controlled fixation period of a small center target surrounded by a textured background (300 randomly distributed vertical line elements, 0.2 x 0.8 deg). The basic stimulus features consisted of the following attributes: The *target* jumped to the right or left after a gap (0, 100, 200, 300 ms) and remained stationary. The *background* either remained stationary, was extinguished immediately after the onset of the trial (control), or was shifted to the right or left after a fixed latency (100 ms for 300 or 700 ms) at a speed of 11 deg/s. All conditions were presented randomly interleaved. Saccadic latency was determined from splined and two-point differentiated eye position traces.

Our data show a strong, well established dependence of the saccadic latency on gap time. Surprisingly, however, additional motion of the visual surroundings did not alter the saccadic reaction time, although the **pop-out** was perceived more vigorously, as reported by all subjects. These results suggest that eye movements are elicited during **pre-attentive** processing which itself does not seem to use global features of the visual surroundings. *This study was not funded by a scientific or commercial grant.*

THE GAP EFFECT FOR SACCADIC EYE MOVEMENTS WITHOUT A FOVEAL FIXATION POINT. Robert Fendrich* & Shaban Demirel. Center for Neuroscience, Univ. of Ca. at Davis.

Turning off a fixation point prior to or coincident with the onset of a peripheral visual target reduces latencies to saccade to that target. This "gap effect" effect has been attributed to a quickened release from active fixation, possibly due to the facilitated shutdown of fixation related neurons in the rostral pole of the superior colliculus. We investigated whether a gap effect would occur if fixation was not maintained by an actual foveal target. Subjects either fixated a central point or at the center of a square defined by 4 points 5° eccentric from the fovea. In either case, the fixation stimulus was turned off either 200 msec prior to the onset of a saccadic target (the gap condition), coincident with the onset of that target (the no-gap condition), or was not turned off (the overlap condition). The saccadic target was presented randomly 6°to the left or right of the designated fixation location.

Saccadic latencies were reduced in the gap relative to no-gap condition. This reduction was not affected by the presence or absence of a foveal fixation point. However, a reduction in saccadic latency in the no-gap relative to the overlap condition occurred only when the foveal fixation point was present. This suggests that the offset of either a foveal or parafoveal stimulus can initiate fixation release, but that this release occurs more rapidly when no stimulus is present on the fovea.

CHARACTERISTICS OF CHAMELEON SACCADIC EYE MOVEMENTS P.S. Sandor, M.A. Frens, A.D. Van Beuzekom and V. Henn * Neurology Department, University Hospital, CH 8092 ZÜRICH, Switzerland.

Chameleons show patterns of oculomotor behaviour which are different from that known from primates. The timing of eye movements of left and right eye seem to be independent from each other and numerous questions arise about the characteristics as well as the organization of the oculomotor system. Binocular recordings in 2D were made using the magnetic search coil technique.

A first analysis suggests that chameleon's saccades are not generated completely independently in the two eyes under all conditions. Furthermore, the main sequence of saccades shows a linear relationship of amplitude and peak velocity as well as a saturating relationship of duration and amplitude. These characteristics, being different from primates, could be explained by the relatively high weight of the bulbi compared to the size of the ocular muscles. Further experiments shall investigate 3D properties of eye movements.

ADAPTABILITY AND VARIABILITY OF SACCADIC EYE MOVEMENTS. D.F. Scollan[1], B.K. Nakamoto[2], M. Shelhamer*[1]. [1]Johns Hopkins University, School of Medicine, Baltimore, MD 21287; [2]University of Hawaii, School of Medicine, Honolulu, HI 96822.

We are interested in predicting the adaptive capabilities of the human saccadic system by using measures of saccade variability and accuracy. Eight subjects were tested (1-4 times each, >1 month apart). Subjects made repeated saccades to targets at ±10°, then continued to make saccades to these remembered locations in the dark; saccade velocities and ending positions were measured to assess variability and accuracy. Then, saccade amplitudes were adaptively altered with a standard double-step paradigm, in which subjects were required to produce 10° saccades when presented with 15° targets. An exponential curve was fit to the sequence of primary saccades during adaptation, and the inverse of the time constant used as a measure of adaptation rate.

Saccade variability (standard deviations of amplitudes and velocities), saccade accuracy (average distance from target position), and adaptation rate (inverse of time constant) were computed. Amplitude variability to remembered targets was positively correlated with slower adaptation (R=0.65, P=0.003). Adaptation rate and saccade velocity (an indicator of fatigue) were uncorrelated.

Linear regression models were constructed to predict adaptation rate. Successful models predicted time constants for saccade adaptation by the use of linear combinations of saccade velocity and accuracy parameters. The coefficient of determination between the actual and predicted results (R^2, adjusted for number of variables) depended on the constraints placed on each model, and was as high as 0.97.

Our results indicate that those subjects with low variability in their saccades have a greater ability to alter adaptively the gain of their saccades. This is consistent with a view of the saccadic system as consisting of an adaptive process that is always in operation, constantly correcting for changes such as those due to aging.

SPATIAL PERCEPTION AND WORKING MEMORY SUGGESTED BY SELECTIVE AND DELAYED-CUE ADAPTATION OF HUMAN SACCADES. M. FUJITA[1,2]*, F. MINAKAWA[1], A. AMAGAI[2] Communications Research Laboratory, Koganei, Tokyo 184, Japan[1], Grad. Sch. Inf. Sys., Univ. Electro-Communications, Chohu, Tokyo 182, Japan[2].

Systematically induced intrasaccadic target stepback reduces the first saccade amplitude gradually by adaptation (Deubel, 1986, 1993). We found that saccades made to a jumping target (visually guided externally triggered saccade, VE-sacc), a stationary visible target (visually guided internally initiated saccade, VI-sacc) and a remembered target (memory-guided saccade, M-sacc) can have different gains due to adaptation (Fujita et al., 1994, 1995). This result suggests that at least three streams of spatial perception might exist for each type of target presentation. The gain reduction adaptation of one type of saccade transfers somewhat to another type of saccade. Such crosstalk in adaptation may suggest population coding in the adaptive neural mechanism. For adaptation, corrective saccades were always led by a target stepback, VE-saccades. This suggests that selective adaptation must have occurred during primary saccades, since saccade type-selective neural signals must have already disappeared during corrective saccades. Error perception associated with primary saccades, which is necessary for adaptation, may be the result of an immediately preceding primary saccade, or the result of further preceding saccades. Adaptation proceeded even when the target stepback was delayed consistently by 200 or 400 msec from the end of each saccade during each adaptation session. Adaptation under such conditions may require a spatial working memory with the motor performance evaluation retrieved in the following adaptation trials. These factors are summarized and implemented into a modified version of the local feedback model of D. A. Robinson (1975).

VISUAL TEST OF LISTING'S LAW DURING VERGENCE. Somani R, DeSouza JFX, Tweed D, Vilis* T. Dept of Physiology & Graduate Program in Neuroscience, University of Western Ontario. London ON Canada

While several labs have shown that Listing's plane (LP) rotates temporally when the eyes converge, they disagree as to how much, with estimates for the angle between the LPs of the two eyes ranging from 70% to 200% of the vergence angle. As all these estimates are based on eye position measurements done with the search coil technique, we sought an independent measure based on visual images. Eight subjects viewed two roughly horizontal, colored lines on a computer screen 50 cm away through filters, so that the right eye saw only the red line and the left eye only the green. Subjects rotated the green line until it looked to be parallel with the red. Then the actual angle between the lines on the screen revealed the relative torsion of the eyes and hence the angle between their LPs. We did this test with three eye elevations — center, 30° up and 30° down — under four conditions: *1.* Normal viewing (except for the colored filters); *2.* Viewing the screen through head-fixed prisms requiring an extra 10° vergence; *3.* With prisms that rotated vertically when the eyes did; *4.* Converged an extra 10° without prisms by fixating a near target but adjusting the images on the computer screen in the background. Different viewing conditions led to different angles between the lines on the screen, as predicted based on the optics, and all results were consistent with an inter-LP angle of 60% to 85% of the vergence angle, which agrees with the value of 70% reported by Mok et al. in *Vision Res* 1992. This visual method provides a simple test of the relative orientations of the LPs of the two eyes, and of the visual consequences of ocular torsion.

PRIMARY EYE POSITION AND THE ORIENTATION OF LISTING'S PLANE IS INDEPENDENT FROM STEREOTAXIC HEAD COORDINATES. E. Probst-Müller, D. Straumann, H. Scherberger, V. Henn. **(SPON: EUROPEAN NEUROSCIENCE ASSOCIATION)** Neurology Dept., Zurich University Hospital, Zurich, Switzerland.

The muscles of the eyes and the vestibular organ are closely related. We asked whether there exists a relationship between the physiological oculomotor and the anatomical vestibular coordinate system. Since the Reid stereotaxic horizontal forms a rather fixed angle with the horizontal semicircular canal (average and SD: 25 ± 6 degrees, Blanks et al. 1975), we used this anatomical landmark to compare its orientation with the primary position of the eye and the orientation of Listing's plane.

Under monocular conditions, the head stabilized on a bitebar, using afterimages, the eye's primary position and the orientation of Listing's plane were determined. We performed 1st order fits to calculate the pitch orientation of Listing's plane and 2nd order fits to look in addition at the twist of the surface, the curvature at the edges, and the concavity of the plane. The goodness of the 2nd order fit was tested with bootstrap methods.

In 10 normal subjects the individual pitch orientation showed a very small standard deviation, whereas the curvature and concavity varied much more. We found no correlation between primary position and Reid horizontal plane even if the uncertainty of ± 6 degrees about the exact orientation of the horizontal semicircular canals is taken into consideration. This suggests that intrinsically determined functional coordinates as defined by Listing's law cannot be deduced from anatomical coordinates.

OCULAR SELECTIVITY OF BURSTS IN HORIZONTAL BURST-TONIC UNITS DURING DISJUNCTIVE SACCADES. Wu Zhou* & W.M. King. Neuroscience Program,U. Rochester, Rochester, NY 14642 and Depts. of Neurology and Anatomy, U. Mississippi Med. Ctr., Jackson, MS 39216

Ocular selectivity analysis (Zhou & King, 1996, ANN. N.Y. ACAD. Sci.) is a new approach for studying the neural substrate of binocular coordination by relating the discharge patterns of units in oculomotor pathways to movements of each eye. In our previous studies, ocular selectivity for eye position and velocity were studied during monocular smooth pursuit in which monkeys track a target moving along the line of sight of one eye. In this study, we analyzed how the burst activity of horizontal burst-tonic units relates to the saccade in each eye during disjunctive saccades. 26 horizontal burst-tonic units were recorded in fastigial nucleus. For 90 percent of units in our population, the average firing rates of bursts during disjunctive saccade were monotonically correlated to the saccade amplitude of the ipsilateral eye alone. The discharge rates of these units were also only modulated by the position and velocity of the ipsilateral eye during monocular smooth pursuit. Ocular selectivity of bursts were also studied in two horizontal burst-tonic units, one in abducens nucleus and one in prepositus nucleus. During a monocular saccade paradigm in which the monkey made saccades to targets aligned with the line of sight of one eye, the burst of these two units occurred only in relation to saccades in the ipsilateral eye. During monocular smooth pursuit paradigms, their discharge patterns were only modulated by the position and velocity of the ipsilateral eye. These data are consistent with our hypothesis that the oculomotor system uses a left/right eye movement coordinate frame rather than a conjugate/vergence coordinate frame.(Supported by NIH EY04045 and NOR N00014 to Dr. W.M.King)

TRANSLATIONAL AND ROTATIONAL COMPONENTS OF HEAD MOVEMENTS CHARACTERIZED BY SPATIAL ROTATION VECTORS. J.A.M. Van Gisbergen*, B.J.M. Melis and C.C.A.M. Gielen. Medical Physics & Biophysics, University of Nijmegen, NL-6525 EZ Nijmegen, The Netherlands.

Passive head rotations cause compensatory eye movements which depend both on the orientation of the head-rotation axis and on its location in space. If the rotation axis is off-centre, the movement also involves head translation. Since most earlier studies on gaze control were performed with a translation-insensitive recording technique, little is known on the importance of these translational components during natural head movements. The present study was undertaken to express the complete movement in a format which gives equal consideration to its translation and rotation components.

An optical tracking system was used to record the natural head-orienting movements in four human subjects. On the basis of these raw data, each head posture was represented as a virtual rotation from a fixed reference position by a six-number mathematical entity termed spatial rotation vector. The latter can be regarded as a combination of a classical rotation vector, which describes the orientation of the rotation axis as well as the amount and direction of rotation, and of a location vector specifying the location of the axis in body coordinates.

The classical rotation vector behaviour was largely in line with earlier results obtained with the translation-insensitive coil technique. Our location vector data show that the location of the rotation axis for natural head movements varied over a limited range (~4 cm) along the anterior-posterior body-axis but more extensively (~10 cm) in the two orthogonal dimensions. In the latter, a strong correlation was found between axis location and target direction, such that head movements in opposite directions had similar axis locations.

NONLINEAR NETWORK MODELS OF THE OCULOMOTOR INTEGRATOR. D. D. Lee, B. Y. Reis, H. S. Seung* and D. W. Tank. Bell Laboratories, Lucent Technologies, Murray Hill, NJ 07974.

The velocity-to-position integrator of the oculomotor system is an example of a neural network in which the role of feedback appears crucial and yet incompletely understood. We examined integrator network models where the neurons possessed a threshold nonlinearity and sublinear behavior above threshold, as observed in brain slice measurements of oculomotor neurons. The recurrent connections in the network were tuned to minimize the spontaneous drift velocity of the eye. Even under optimal conditions, the drift velocity was still nonzero except at a discrete set of null positions. The positions corresponded to fixed points in the state space of the network dynamics and were limited by the number of neurons in the network. Similar fixed point structure was seen in networks tuned by an online gaze-holding learning algorithm, though the number of fixed points depended upon the learning rate. Our results suggest that in the dark, integrators with relatively few neurons may contain several null positions. This is in contrast to previous modeling studies with linear network models which can only have zero, one, or an infinite number of fixed points. (Supported by Bell Laboratories)

MODELING THE STEP RESPONSE OF THE SACCADIC FEEDBACK SYSTEM. B. Breznen* and J.W. Gnadt. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794

Prolonged stimulation in the monkey superior colliculus (SC) elicits a so-called staircase movement: a series of saccades immediately following each other in time. It has been shown experimentally that the kinetic profiles of the staircase movements depend on the stimulating current intensity and/or frequency. Here we present the results of a theoretical analysis and computational simulations of the saccadic control system using the paradigm of prolonged SC stimulation. We compared the performance of two popular models of the saccadic system: the Scudder model (Scudder, 1988) and the Jurgens model (Jurgens et al. 1981). We excluded the Scudder model since it was not capable of reproducing the staircase movements. By modifying the Jurgens model, we show that the staircase movements can be modeled as the step response of an underdamped second-order feedback system. To match the behavioral performance, we had to replace the originally proposed active reset of the feedback integrator by spontaneous discharge of a leaky integrator. Furthermore, we show that the stimulation-induced changes in kinetic profiles is the result of changes in the properties of the saccadic system itself. The stimulation changes the gains and time constant of the feedback. The change is proportional to the amount of stimulation: the higher the current intensity and/or frequency, the bigger the change. Thus, for high stimulation parameters, one can observe nearly smooth movement of the eyes (Breznen et al., 1996). However, this nearly smooth movement is, in fact, the limit case of a damped oscillatory response of the saccadic feedback to a step input.

ALTERNATIVES TO NEURAL NETWORKS. D. Tweed*, Depts. of Physiology and Applied Mathematics, Univ. of Western Ontario, London, N6A 5C1, Canada; Dept. of Neurology, Univ. of Tübingen, 72076 Tübingen, Germany

Neural networks are finding ever wider application in science, medicine and industry. Desirable features of such networks include fast learning, fast operation of the trained network on a PC, and manageable increases in learning time and network complexity with increases in task complexity, i.e. when the number of teaching patterns or input dimensions grows. Surprisingly, though, there is little evidence that the standard type of network now in use — three layers of logistic units, trained by back propagation — is optimal by any of these measures, so there may be room for improvement. I shall present two new "network" structures with associated learning algorithms. One algorithm learns extremely fast and scales well with the number of teaching patterns. The other also learns quickly, but scales better with input dimension and yields faster-running networks. I shall apply these techniques, alone and in combination, to a variety of tasks and compare their performance to that of classical neural network methods.

OCULOMOTOR SYSTEM: ACCOMODATION, VERGENCE, EYE BLINK, AND MUSCLE

801.1

SINGLE-UNIT ACTIVITY WITHIN THE POSTERIOR FASTIGIAL NUCLEUS DURING VERGENCE AND ACCOMMODATION IN THE ALERT PRIMATE. H.Y. Zhang* and P.D.R. Gamlin. Vision Science Research Center, University of Alabama at Birmingham, AL 35294.

It has been well documented that the fastigial nucleus is involved in the regulation of conjugate eye movements. However, very little is known about the role of this nucleus in the control of disconjugate eye movements and ocular accommodation. Since the fastigial nucleus has reciprocal connections with the midbrain near-response region, we decided to investigate the behavior of neurons within it during vergence and ocular accommodation.

Single-unit recording from the fastigial nucleus of three alert, trained Rhesus monkeys identified eighty-three cells that, on the basis of their responses during vergence and ocular accommodation, were related to the near-response. Following characterization during other eye movements, we found that 28% of cells were solely related to near-viewing and were thus near-response neurons, 63% responded during both saccades and near-viewing, and 29% increased their activity for near-viewing, saccades and blinks. The activity of none of these cells was modulated during smooth pursuit eye movements. Marking lesions confirmed that recording sites were in the posterior fastigial nucleus.

This study suggests that, in addition to playing a role in conjugate eye movements, a discrete region of the posterior fastigial nucleus is also involved in the control of vergence and ocular accommodation.

801.2

EFFECTS OF MUSCIMOL BLOCKADE OF THE POSTERIOR FASTIGIAL NUCLEUS ON VERGENCE AND OCULAR ACCOMMODATION IN THE PRIMATE. P.D.R. Gamlin* and H.Y. Zhang, Vision Science Research Center, University of Alabama at Birmingham, AL 35205

Recent studies in our laboratory have suggested that a region of the posterior fastigial nucleus is involved in the control of vergence and ocular accommodation in the primate. The functional role of this cerebellar region in these eye movements was evaluated using reversible muscimol blockade in one alert Rhesus monkey trained on a variety of oculomotor tasks.

Single-unit recording and microstimulation were used to localize the near-response region of the posterior fastigial nucleus prior to making unilateral injections of muscimol (0.5-1.0 μl; 4μg/μl). These injections resulted in consistent deficits in the ability of the animal to generate and maintain convergence and accommodation. In particular, convergence velocity was decreased and the animal displayed significant vergence insufficiency. Accommodative responses were almost eliminated over the tested range of accommodative demands. Also, consistent with previous reports, these injections significantly affected the metrics of both saccadic and smooth pursuit eye movements.

These results clearly indicate an important role for the posterior fastigial nucleus in the control of vergence and ocular accommodation. The precise role that this nucleus plays in these eye movements remains to be determined.

THE FREQUENCY CHARACTERISTICS OF ACCOMMODATION IN A PATIENT WITH AGENESIS OF THE POSTERIOR CEREBELLAR VERMIS.

S. Konno, K. Ohtsuka, and M. Sawa*. Dept. of Ophthalmology, Sapporo Medical Univ. Sch. of Med., Sapporo, Hokkaido 060, Japan.

To clarify the cerebellar control of accommodation in man, the frequency characteristics of accommodation were studied in a patient with agenesis of the cerebellar vermis and normal control subjects.

In a 29-year-old patient with agenesis of the posterior vermis and the paravermis and age-matched four normal control subjects, the gain and the phase lag of accommodative responses for predictable sinusoidal blur stimulus were calculated. The stimulus consisted of simple sinusoids of 2 ± 1.5 diopters in the frequency ranging from 0.05 to 1.0 cycles/s with seven steps. The accommodation target was shaped like an asterisk, with four black lines radiating in eight directions at the center of an illuminated field. Accommodation was monitored by an infrared high-speed optometer. This system has a resolution of 0.01 diopter. Accommodative responses were recorded on magnetic tapes for subsequent computer analysis, using a PCM data recorder. The data recorded on magnetic tapes were digitized by a computer at a sampling rate of 200 Hz.

The frequency characteristcs of the accommodation in the patient have larger phase lags and lower gains at higer frequencies than those in the four normal control subjects.

These findings suggest that the posterior vermis and the paravermis contribute to the predictable control of accommodation by improving the frequency characteristics at higher frequency.

NEW INSIGHT INTO THE ROLE OF THE BASAL GANGLIA IN REFLEX BLINK EXCITABILITY. V.M.Henriquez, E.J.Schicatano, and C.Evinger* Depts. of Neurobiology & Behavior and Ophthalmology, SUNY Stony Brook, NY 11794

Dopamine cell loss in the substantia nigra pars compacta, as occurs in Parkinson's disease, increases the inhibitory output of the substantia nigra pars reticulata (SNr), which leads to a dramatic elevation of trigeminal reflex blink excitability. Both in Parkinson's disease and in the rat 6-hydroxydopamine (6-OHDA) lesion model of Parkinson's disease, the increased SNr output to the superior colliculus reduces inhibition of the spinal trigeminal nucleus. Since Parkinson's disease is progressive and 6-OHDA lesions require 10 days to achieve full effectiveness, it is impossible to resolve whether increased blink reflex excitability is a short or long-term result of elevated SNr output.

The current study investigated the immediate effect of altering SNr output in normal, alert rats. Rats were prepared for chronic recording of the lid closing, orbicularis oculi, muscle EMG (OOemg) and stimulation of the supraorbital branch of the trigeminal nerve (SO). A guide cannula was implanted above the SNr for microinjections of either muscimol, bicuculline, or saline in the awake rat. Excitability was quantified by presenting pairs of identical SO stimuli and comparing the magnitudes of the OOemg activity evoked by the second stimulus relative to the first.

Enhancing SNr output with microinjections of bicuculline increased SO evoked blink magnitude. In contrast, reducing SNr output with muscimol microinjections decreased SO evoked blink magnitude. Neither of these microinjections, however, altered the excitability of the SO evoked reflex blinks. Our data suggested that changes in the spinal trigeminal complex induced by long-term increases in SNr output rather than an immediate effect of increased collicular inhibition by SNr, produced reflex blink hyperexcitability. Supported by EY07391 (CE) and IT32NSO7371(EJS).

MOTOR EFFECTS OF SEROTONIN INJECTIONS INTO THE FACIAL NUCLEUS OF AWAKE CATS. J.M. Smith[1], M.S. LeDoux[2], and J.F. Lorden*[1]. Dept. of Psychology[1], Univ. of Alabama at Birmingham, Birmingham, AL 35294. Dept. of Neurology[2], Univ. of Tennessee Coll. of Medicine, Memphis, TN 38163.

Facial motoneurons receive prominent serotonin (5-HT) input to both their somas and dendritic arbors. Although intracellular recordings from slice preparations show that 5-HT produces a slow depolarization of facial motoneurons, the effects of 5-HT injected into the facial nucleus of awake animals is not known. In four cats, chronic guide cannulae were placed above the facial nucleus to determine the effects of 5-HT on facial motoneurons. Injection of 5-HT (5 mM) into the facial nucleus by continuous infusion produced hemifacial spasm in all four cats. Injections of normal saline or the 5-HT_2/5-HT_{1C} antagonist ketanserin (10 mM) were not associated with hemifacial spasm. Histological analysis confirmed that all injections sites were within 200 μm of the facial nucleus. In addition, cannulae placement was confirmed by reversible inactivation of the blink reflex with infusion of 4% lidocaine. (Supported by the Dystonia Medical Research Foundation)

801.6

BLINK REFLEX CIRCUITS IN THE MACAQUE MONKEY: A DOUBLE LABEL STUDY. P.J. May[1-3], D.L. Andrew[1&4] and S. Warren[1*]. Departments of Anatomy[1], Ophthalmology[2], Neurology[3] and Occupational Therapy[4], University of Mississippi Medical Center, Jackson, MS 39216.

With each blink, the two muscles that control the eyelid must be coordinated. During the blink down-phase, the normally quiescent orbicularis oculi muscle is activated and the tonic activity of the levator palpebrae superioris muscle is silenced. Of the stimuli that evoke a reflex blink, trigeminal stimulation is the most thoroughly studied. Nevertheless, the circuits that subserve this reflex are incompletely described in primates. A double label approach was used to characterize premotor blink circuits in *M. fascicularis* monkeys. Muscle injections of WGA-HRP retrogradely labeled levator and orbicularis oculi motoneurons. Injections of biotinylated dextran amine (BDA) placed in each subdivision of the trigeminal sensory complex anterogradely labeled trigeminal axonal arbors. The primary afferents from the cornea and eyelid terminate heavily in pars caudalis of the spinal trigeminal nucleus. Injections in this region labeled a dense plexus of axons in the facial nucleus. These displayed *en passant* and terminal boutons in close proximity to labeled motoneurons. EM analysis showed that these terminals contain clear spherical vesicles and synapse directly onto orbicularis oculi motoneurons. The principal trigeminal nucleus receives little input from the cornea and eyelid, but BDA injections centered in this nucleus also labeled axon terminal arbors bilaterally in the facial nucleus, with boutons in close proximity to labeled orbicularis oculi motoneurons. Injection of retrograde tracers into the facial nucleus indicates that trigeminal neurons dorsolateral to the exiting facial nerve are the source of the commissural projection. The BDA injections in the principal nucleus also labeled terminal arbors bilaterally in the oculomotor nucleus that were closely associated with labeled levator motoneurons. In conclusion, the projection from pars caudalis presumably evokes the earliest (R_1) component of the blink reflex. Whether the principal nucleus projection supplies part of the R_1 or the later R_2 component remains to be determined. The projection to the levator motoneurons inhibits these cells during blink down-phase. **Supported by NIH Grant # EY09762 (PJM).**

UPPER EYELID PREMOTOR NEURONS IN THE ROSTRAL MESENCENCEPHALON OF THE PRIMATE. J.A.Büttner-Ennever*, and A.K.E.Horn. Dept. Anatomy and Inst. Neuropathology, University of Munich, Germany.

Premotor neurons for vertical saccadic eye movements lie in the mesencephalon in the rostral interstitial nucleus of the medial longitudinal fasciculus (rostral iMLF), in the primate. The activity of the upper eyelid (levator palpebrae, LP) is closely coordinated with the vertical eye position, acting in synchrony with the superior rectus muscle, except in blinking. However the source of the premotor saccade-like signals to LP motoneurons has not yet been demonstrated. After placing the non-toxic retrograde transsynaptic tracer, tetanus toxin BII_b fragment or fragment C, into LP (which always included vertical extraocular eye muscles), we found a small group of labelled premotor neurons lying separate from, and medial to, rostral iMLF, at caudal levels. Injections of tritiated-leucine into this medial area led to the labelling of afferent terminals over predominantly LP motoneurons in the oculomotor nucleus. The premotor neurons are round and weakly staining in Nissl sections. Double-labelling experiments revealed that the premotor cell group can be easily identified by its high parvalbumin content. We suggest that this cell group provides the upper eyelid motoneurons with a saccade-like premotor signal.

LID RESTRAINT IN NORMAL HUMANS MIMICS THE EFFECTS OF FACIAL NERVE PALSY E.J. Schicatano*, K.R. Peshori, V.M. Henriquez, and C. Evinger, Dept. of Neurobiology & Behavior, SUNY, Stony Brook, NY 11794-5230

Reflex blinking employs adaptive neural control mechanisms. For example, damage to the facial nerve weakens the orbicularis oculi (OO), the lid-closing muscle, and induces a compensatory increase in the drive onto blink circuits in the brainstem. With this increased reflex blink **gain**, a blink-evoking stimulus produces more OO activity than before OO weakness. The current study investigates whether adaptive processes also elevate reflex blink **excitability** in normal subjects with unilateral lid restraint and in a patient with facial nerve palsy.

We monitored OO EMG activity and upper eye lid position, and stimulated the supraorbital branch of the trigeminal nerve (SO) to evoke blinks. To quantify excitability, we presented pairs of identical SO stimuli and compared the magnitude of the blink evoked by the second stimulus to the magnitude of the blink evoked by the first stimulus. One upper eyelid was restrained in normal subjects by adding an upwardly directed weight to the eyelid. The patient presented with a right facial nerve palsy incurred during a surgical procedure.

Following lid restraint or facial nerve damage, reflex blink excitability increased and a single SO stimulus produced multiple blinks with a constant interblink interval - blink oscillations. In normal humans, reflex blink excitability increased within 60 min and blink oscillations were observed within 150 min of lid restraint. Increased excitability and blink oscillations remained for several minutes after removing the lid restraint, but returned to normal within 30 min. During 22 wks of recovery, the patient exhibited a similar pattern, such that reflex blink excitability returned to normal and blink oscillations vanished with the return of OO innervation. Thus, the compensatory processes initiated by lid restraint in normal humans simulated the increase in reflex blink gain and excitability caused by facial nerve damage in patients.

SUMMATION OF MOTOR UNIT TENSIONS IN CAT LATERAL RECTUS MUSCLE UNDER ISOMETRIC CONDITIONS. S. J. Goldberg* and M. S. Shall. Depts. of Anatomy and Physical Therapy, Virginia Commonwealth University, MCV, Richmond, VA 23298-0709.

Previous studies of skeletal muscle have noted that motor unit forces do not always add in a linear manner as individual units are recruited. Muscle fibers arranged in series might account for this and could have significant implications in precise motor control such as that for eye movements.

After antidromic activation and identification of a lateral rectus motoneuron (MN) through stimulation of the abducens nerve, the stimulation intensity delivered to the nerve was reduced so that a constant twitch tension of about 100 mg (~2 to 3 motor units) was obtained. The single MN was then directly stimulated in order to examine single muscle unit contractions and we also simultaneously activated the other muscle units using the low intensity nerve stimulation. If less than 80% of the single muscle unit's force was seen to add to the force of the nerve activated units (~100 mg, see above), then the unit was classified as "non-additive."

The contractile characteristics of 56 motor units were evaluated. The units showed an average twitch tension of 41.6 mg, maximum tetanic tension of 384.6 mg, twitch contraction time of 6.22 ms, fusion frequency of 170 Hz and a kt value (0.56). These values were consistent with previous studies.

Sixteen of the 56 units (29%) did not show a full addition (greater than 80%) of their twitch tension when added to the tension of the nerve activated units. In recent studies using addition of tetanic rather than twitch tensions, a higher proportion of units was seen to be "non-additive." Unit potentiation was not observed. (Supported in part by NEI grant EY-11249.)

OPTIMALITY OF OCULAR MOTONEURON SIGNALS FOR CONTROL OF FORCE IN HORIZONTAL EYE MUSCLES P. Dean*, J. Porrill & P.A. Warren. Dept. of Psychology and AIVRU, University of Sheffield, Sheffield S10 2TP, England.

Six muscles control movements of the eye, which have three degrees of freedom. Daunicht (*Biol. Cybern. 58(1988) 225*) proposed an optimisation rule for solving this redundancy problem, namely minimisation of effort, where effort was defined as the norm of the vector of motor commands required to produce a small change of eye position. Testing this hypothesis is complicated by the nonlinear relationships of muscle force to both innervation and length. The problem was therefore simplified to the one-dimensional case, for small changes in conjugate eye position in the horizontal plane.

Assuming these movements involve only the horizontal recti, Daunicht's hypothesis predicts reciprocal innervation, with the size of the small command matched to the strength of the recipient muscle at every starting position of the eye. The ratio of these commands to the two muscles should therefore vary as the square root of the muscle 'strengths' as these are usually estimated, because the measurements give only the product of actual muscle strength and control signal. Comparison of command size, measured as gradient of summed firing rate in primate oculomotor nerves (e.g. van Gisbergen & van Opstal 1989) with the 'strengths' of the horizontal recti in people (Robinson 1975) showed a good fit between data and prediction for the range ± 25 deg from the primary position.

The evidence is therefore consistent with the oculomotor system using the minimum effort optimisation rule, at least for control of conjugate horizontal eye position within the central 50 deg of the visual field. Use of this rule would have implications for (i) the adaptive adjustment of the integrator networks involved in converting velocity to position signals;. and (ii) if extendible to three dimensions, the generation of torsion commands.

EMG ACTIVITY IN DORSAL NECK MUSCLES OF THE RHESUS MONKEY DURING HEAD MOVEMENTS AND IN DIFFERENT HEAD POSITIONS B.D.Corneil*, G.E. Loeb, F.J. Richmond, D.P. Munoz. MRC Group in Sensory-Motor Neuroscience, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Recent work in monkeys on the co-ordination of eye and head movements in gaze shifts has examined the time of onset of the underlying movements of the eye and head. Little work has been done in the monkey on the timing and patterning of neck muscle activity that underlies the component movement of the head within a gaze shift. We have begun to investigate the activity of various monkey neck muscles in different head postures and in head movements of differing amplitudes. Bipolar hook or patch electrodes were implanted bilaterally in the following muscles: obliquus capitis inferior (OCI), obliquus capitis superior (OCS), splenius capitis (SP), complexus (CM) and longissimus capitis (LC). The horizontal and vertical position of the eye and head within space were monitored by search coils implanted subconjunctivally and mounted on the head when the monkey was placed within a magnetic field. During recording sessions, the head motion was completely unrestrained, and the monkey was free to look around the room as desired. The monkey's body position was limited to ± 90° and was monitored with a video camera. Preliminary results during horizontal head movements beginning at the center position indicate that the ipsilateral OCI is recruited about 10-30 ms sooner than ipsilateral OCS and SP. Tonic activity related to the horizontal position of the head was observed in ipsilateral OCI, OCS and SP, although the activity in OCS and SP decreased as the head was pitched forward. Activity in LC and CM was observed tonically in postures in which the head was pitched up, and phasically in vertical head movements and in fast horizontal head movements. This work was supported by the Medical Research Council of Canada.

801.12

OCCURRENCE OF MUSCLE SPINDLES AND TENDON ORGANS IN EXTRAOCULAR MUSCLES OF *CAMELUS DROMEDARIUS*. M. DeSantis*, A. A. Abuel-Atta and A. M. Wong. Dept. of Biological Sciences and WAMI Program, University of Idaho, Moscow, ID 83844.

Extraocular muscles of all artiodactyls so far studied have encapsulated receptors, but details as to their numbers and intramuscular configurations appear not to have been published for each receptor type in each of these muscles for any mammal.

The four rectus and two oblique muscles as well as the retractor bulbi and levator palpebrae superioris muscles from one orbit of an adult male Arabian camel were studied histologically for the presence of encapsulated sensory receptors, and the position of each receptor was charted.

Muscle spindles and tendon organs were the only encapsulated receptors observed; both were present in every muscle. Numbers of spindles and tendon organs per muscle ranged from 59 (retractor bulbi) to 181 (dorsal rectus) and from 16 (levator palpebrae) to 91 (lateral rectus), respectively. Spindles outnumbered tendon organs in every muscle; ratios ranged from 1.1 (lateral rectus) to 6.5 (levator (palpebrae). Total receptor number per gm of muscle was remarkably similar for averages of all recti (91/gm) versus obliques (93/gm). In rectus and oblique muscles spindles were most abundant in the half of the muscle near the origin. Tendon organs occurred throughout a muscle's length but were often most frequent on either side of the major concentration of spindles. Both types of receptor were located nearer the perimeter than the center in cross sections through the muscle. Often their position was at the part of the perimeter opposite the nerve entry zone.

Intraorbital skeletal muscles of the dromedary contain many encapsulated sensory receptors. There is a consistent pattern to the arrangement of muscle spindles and tendon organs along the length and through the thickness of rectus and oblique extraocular muscles.

DYNAMIC LOADING OF THE LOWER LIMB DURING SPONTANEOUS LEG KICKS IN HUMAN INFANTS: A NEW METHOD. S.M. Barlow*, D.S. Finan, R. Konopacki, A. Biswas, E. Thelen, and F.J. Diedrich. Dept. of Speech and Hearing Sciences, Program in Neural Science, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

The ability to sense limb movement and to respond to proprioceptive and haptic sensory information is critical for developing voluntary control. Yet little is known about these mechanisms in human infants due to the technical difficulties of delivering appropriate mechanical stimuli and measuring kinematic and neuromuscular responses. Here we report on a new servo-controlled mechanical stimulus generator, known as ROBOBABY, capable of delivering precisely timed load perturbations on infant limbs freely moving in 3 dimensions. The new system tracks the limb in real time through the balanced activation of two torque motors operating under force feedback. A high speed digital computer provides unanticipated loads at varying magnitudes and durations at specific phases of the leg kick cycle as determined by continuously monitored goniometers. Responses are measured by kinematic changes in joint angle displacements and EMG. These loads effectively displace or reverse the limb, which presumably activates muscle and joint afferents. Segmental responsiveness can be monitored as a function of stimulus intensity, movement phase or speed, or age of the infant. Developmental changes in mechanically evoked stretch reflexes are discussed in relation to the acquisition of locomotor skills. Supported by Training Grant NIH HD 07475 and NIH RO1 HDD830 and NIMH KO5 MH01102 to E.T.

DYNAMIC LOADING OF THE LOWER LIMB DURING SPONTANEOUS LEG KICKS IN HUMAN INFANTS: DATA. D.S. Finan, S.M. Barlow, F.J. Diedrich* and E. Thelen. Dept. of Speech and Hearing Sciences, Program in Neural Science, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

Human infants spontaneously kick their legs in smooth trajectories of flexion and extension. Previous work (Thelen, Kelso, & Fogel, 1987; Schneider, et al, 1990) has implicated spring-like control of the limb. Here we report for the first time the effects of unanticipated load perturbations on lower limb movements as a first step in understanding the development of adaptive mechanisms. Human infants aged 3 to 4 months participated in the study. We used the ROBOBABY apparatus to apply unexpected perturbations (load = 2-4 N, duration = 100 ms) to infants' ankles. Perturbations were triggered at a particular value of hip flexion. Kinematic data showed that perturbations at 4 N were effective in momentarily reversing the hip; perturbations below 4 N did not consistently evoke a detectable joint or muscle response. Surface EMG revealed widely dispersed responses in the monitored muscles (Quadriceps, Hamstrings, Tibialis Anterior, Gastrocnemius) at latencies (20-50 msec) that suggest segmental responses both at the onset and offset of the perturbation. Mechanisms for detecting and rapidly responding to mechanical perturbations are in place early in life. Further research will elucidate the contextual and developmental changes in these mechanisms. Supported by Training Grant NIH HD 07475 and NIH RO1 HDD830 and NIMH KO5 MH01102 to E.T.

802.3

AN UNLEARNED PRINCIPLE FOR CONTROLLING NATURAL MOVEMENTS. K. Daigle[1], F.T.J.M. Zaal[1], E. Thelen*[1] & G.L. Gottlieb[2]. [1]Department of Psychology, Indiana University, Bloomington, IN 47405 and [2]NeuroMuscular Research Center, Boston University, Boston, MA 02215.

Recently, Gottlieb and colleagues discovered a simple principle that acts to control the degrees of freedom in unconstrained, natural adult arm movements: a linear covariance of dynamic muscle torque across shoulder and elbow joints. Here we report that infants' early waving and reaching arm movements also adhere to the linear covariance principle. We examined 137 tokens from 4 infants followed weekly from age 3 to 52 weeks. Movements included both reaches to midline at shoulder height and spontaneous movements before reach onset. Hand path direction, amplitude, straightness, smoothness and speed, starting position, and joint angular rotations varied greatly within and between infants. In every case, however, the dynamic muscle torque (muscle torque-gravity torque) could be described by the equation: torque $(t)_{shoulder} = K_d$torque $(t)_{elbow}$, where $K_d = 2.62 \pm .44$ for reaching ($r^2 = .94$) and $2.68 \pm .70$ for pre-reaching ($r^2 = .94$). The similarity of the scaling constant across all movements at all ages suggests a powerful unlearned constraint to maintain proportional dynamic torques: motor patterns that violate this constraint were not seen in infants in this context. Natural reaching and grasping movements must appropriate this unlearned pattern. Independent joint torque control may be very difficult for the neuromotor system and require many years of practice. INFANTS USE DIFFERENT MUSCLES IN THE SAME SPATIAL REGIONS BEFORE VS. AFTER THEY LEARN TO REACH. J.P. Spencer* and E. Thelen, Dept. of Psychology, Indiana University, Bloomington, IN 47405

In studies of adult reaching, arm muscles show "preferred" pulling directions, yet contribute to force generation across many spatial directions. How do infants learn to coordinate directional forces? Previously, we showed that infants use different combinations of muscle activity after they learn to reach. Here we examined how these changes were related to where infants moved their hands in 3D space.

We observed 4 infants weekly from 3-30 wks and biweekly from 30-52 wks as they reached for toys at midline. We collected kinematics and computed the mean proportion of time infants' hands were in 11 spatial regions during PRE-reaching and REACH periods. We collected EMG data from the trapezius, deltoid, biceps, and triceps. EMG data for each muscle were transformed into an ON-OFF signal, and we computed 1) mean proportion of time each muscle was ON in each region, and 2) mean proportion of time each possible muscle combination was ON in each region.

Infants spent a proportional amount of time in 8 of 11 spatial regions PRE vs. REACH. There was an increase in the overall amount of muscle activity used in the HIGH front and front/side regions during the REACH period, and increases in DELT and TRAP activity with decreases in BI and TRI activity PRE vs. REACH in the MID and HIGH frontal and front/side regions. Decreases in BI and TRI activity were specific to when these muscles were active alone, while increases in DELT activity in the HIGH frontal regions were accompanied by increases in the activity of other muscles. These data indicate that the transition in muscle activity we observed in previous analyses was not solely a reflection of changes in where infants moved their hands. Instead, infants moved within very similar regions of space PRE vs. REACH yet used different muscles. This suggests that the coordination of directional forces in reaching via multi-muscle activity is learned during the first year.

DEVELOPMENT OF AUTOMATIC POSTURAL RESPONSES IN INFANTS H. Sveistrup & M.H. Woollacott*. Occupational Therapy, University of Ottawa, Ottawa ON Canada K1H 8M5 and Exercise & Movement Science, University of Oregon, Eugene OR 97405

In a series of experiments, we studied in infants aged 22 to 79 weeks the development of the automatic postural response (APR) elicited by either platform perturbation or by perturbation of the visual system using a moving room paradigm. Following platform perturbations, temporally disorganized activity was recorded in single or paired muscles in infants unable to stand without support . With development, postural leg and trunk muscles were activated: I) more frequently; ii) in a functional order; and iii) with decreased onset latencies. Consistent activation of postural muscles in functional synergies was not recorded until 51 weeks although the adult-like APR was recorded in one infant as early as 39 weeks. In contrast, APRs elicited by perturbation of the visual system elicited an adult-like postural response in one infant at 22 weeks. These data suggest that visual and somatosensory systems have varying access to postural synergies at different developmental periods. We then determined whether experience could facilitate emergence of APRs elicited by platform perturbations. The probability of activating postural muscles and probability of activating these muscles in groups increased in infants (mean age 43 weeks) given 300 trials of platform perturbation in comparison to control infants who received no practice.

THE DEVELOPMENT OF POSTURAL CONTROL AND THE ACQUISITION OF BIPEDAL INDEPENDENT LOCOMOTION IN INFANTS. J.A. Barela*[1,2], J.J. Jeka[1] & J.E. Clark[1]. [1]University of Maryland, College Park, MD 20742-2611; [2] State University of São Paulo, Rio Claro, SP 13506-900, Brazil.

Before infants achieve independent upright locomotion, they first demonstrate independent standing. This important motor milestone would seem to play an important precursor role in walking development. But what the nature of that role might be is not entirely clear. In the present experiment, we test the hypothesis that infants are learning to use sensory information to control body sway in upright stance before they attempt independent upright locomotion. Specifically, we investigate the relationship between body sway and force applied by the hand on a supportive surface while infants stand upright. The infants were studied longitudinally from the initiation of crawling to the onset of independent walking. Infants stood on a pedestal (10 cm deep x 20 cm long x 3.5 high) while touching one side of a rigid cube clamped to a force platform, permitting 3D measurement of the forces applied by the infants. A 3-D ultrasonic tracker device was affixed at the infant's waist to measure body sway. Our analyses focused on the absolute level of contact forces and the temporal relationship between these forces and body sway.

Preliminary results reveal that the amount of force applied to the surface decreased with increasing age. Cross-correlation and coherence values show that contact force and body sway were strongly correlated primarily in the anterior-posterior (AP) direction. Infants appear to perceive the least stable direction of sway (AP) and use force changes at the hand to modulate this sway even though the forces are of insufficient magnitude to provide the physical support necessary for standing. Overall these findings offer a view of postural development that suggests infants use touch surfaces initially for both biomechanical support and sensory information. As infants approach independent walking, they rely less on biomechanical support, suggesting that sensory information may be playing an important role.

CONTEXT EFFECTS ON NEUROMUSCULAR CONTROL OF STEPPING IN NEWLY-WALKING INFANTS. R. Angulo-Kinzler*, D. Chapman, B. Ulrich, and E. Thelen. Depts. of Kinesiology and Psychology, Indiana University, Bloomington IN 47405.

Recent research has emphasized the role of sensory input for maintaining pattern stability in adult human locomotion. Here we show that a similar context sensitivity is apparent at the first onset of independent locomotion in human infants. We examined the muscle activation patterns and torque profiles of 4 newly-walking infants as they stepped in 3 contexts: treadmill, supported and independent walking. Striking differences emerged across contexts. EMG patterns during treadmill were more stable and had fewer bursts of muscle activity than in the other two conditions. In contrast, considerable co-activation of all muscles occurred in the supported and independent conditions. Patterns were more complex and disorganized than on the treadmill. Across contexts, in swing, the dominant pattern of hip muscle torque was flexor-extensor-flexor; knee muscle torques were predominantly flexor throughout. Muscle activation patterns varied but the summed effect was consistent torque patterns across contexts, indicating similar global strategies were produced by many combinations of the available degrees of freedom. Pattern stability and regularity is an emergent property of the infant neuromotor system within its biomechanical context. Supported by NIH RO1 HD22830 and NIMH KO5 MH01102.

GAIT INITIATION IN 4-6 YEAR OLD CHILDREN. F.Malouin,*C.L.Richards, J.Trahan, C.Menier, F.Dumas and B.McFadyen. Department of Physiotherapy, Faculty of Medicine, Laval University, Quebec City, Qc, Canada, G1K 7P4.

The purpose of this work was to gain some insight into the development of preparatory adjustments (PAs) during gait initiation (GI), as well as into the factors associated with the expression of adult-like PAs. Muscle activity, ground reaction forces (GRFs) from each foot and body kinematics were recorded during GI in six children (4-6 years). Gait was initiated from both a natural stance and from a step position (swing foot placed behind stance foot) the latter increasing the antero-posterior base of support. When gait was initiated from the natural stance, all children displayed consistent PAs characterized by the anticipatory activation of the tibialis anterior (TA) of the swing limb. Two children showed consistent anticipatory activation of the gluteus medius (GM) of the swing limb as well. These anticipatory responses were also associated with backward and lateral displacement of the center of foot pressure towards the swing limb suggesting that the GI motor program, as seen in adults, was functional. Yet, the steady state velocity (SSV) was reached only after 3 to 4 steps, instead of one as in adults, indicating that the GI process may not be totally mature. Initiating gait from the step position promoted the anticipatory activation of the GM, increased the GRFs responsible for propelling the center of mass forward and towards the stance limb, increased the activity of the soleus at push-off and increased the rate of progression. The end result was that the SSV was reached one step earlier. These changes were associated with a longer duration of the GI process involving specifically the execution period (from heel-off to toe-off of the swing limb). These preliminary results on the effect of the base of support on the GI process support the idea that maturation of the musculo-skeletal system is the limiting factor in the expression of adult-like PAs during gait initiation in children. POSTURAL SWAY FREQUENCY AND CENTRE OF PRESSURE EXCURSION UNDER VARYING SENSORY CONDITIONS IN CHILDREN AND YOUNG ADULTS J. Drover, J. McGregor, L. Vallis, R. Thibeault & H. Sveistrup*. Occupational Therapy, University of Ottawa, Ottawa ON Canada K1H 8M5

We recorded ground reaction forces of children (aged 4 to 10 years) and young adults under six conditions of altered sensory input obtained by modifying the support surface (normal, foam) and visual cues (normal, eyes closed, sway referenced). Day-to-day reliability of the force measures ranged from 0.65 to 0.86. Anterior/posterior and lateral centre of pressure excursions and sway frequency were then determined. Centre of pressure excursions increased from baseline between 8% (visual information alone removed) and 400% (eyes closed, foam support surface). Relative increases in total power were similar for all ages. In young children (4- to 6-year-old) however, increasingly difficult sensory combinations were characterized by a shift towards higher median sway frequencies. Thus, in young children, the increased power was in the higher frequency range while in the older subjects the increase in power was distributed across the frequency range. This suggests that younger children rely more on fast high-frequency corrections to postural instability possibly functioning via a ballistic open-loop control. The lack of median frequency shift in the older children and adults may reflect a slower, sensory-monitored closed loop control mode.

802.10

GAIT ADAPTATION OF CHILDREN AND ADULTS WHILE STEPPING OVER OBSTACLES. S-H Law, A.M. Gentile and C.C. Bassile*. Teachers College, Columbia University , NYC, NY 10027.

Six-year old children have mastered a mature gait pattern (Berger 1984) and, probably, a general solution for stepping over obstacles while walking. However, they may lack consistency in regulating relevant parameters for adapting gait. Although the adaptation pattern for crossing obstacles was expected to be similar for children and adults, it was predicted that children would be more variable. Gait was analyzed for 4 children (6 yr olds) and 4 adults while stepping over obstacles varying in height (relative to leg length). The means and coefficients of variation (CV) of five kinematic measures were derived: foot clearance (elevation of the foot over the obstacle), peak step height, horizontal deviation of peak step height from obstacle location (HD), crossing velocity and stride length. Means for foot clearance and crossing velocity did not differ for children and adults (representing similar patterns); whereas peak step height, HD and crossing stride length did (simply representing morphological differences). As predicted, children were more variable than adults (significantly larger CVs). For children, the most notable finding was that CV for foot clearance was significantly higher than all other variability measures. We concluded that the general pattern for adapting gait was similar for children and adults. However, variability in foot clearance suggested that six-year-old children have not achieved a stable solution for optimizing two conflicting constraints in stepping over obstacles: minimizing energy expenditure and maximizing safety.

INSTABILITY OF ONE-LEG STANDING IN CHILDREN WITH DAMP SEEMS UNRELATED TO IMPAIRED POSTURAL CONTROL. H. Hirschfeld, G. Orlovsky*, Labs. of Motor Control, and Neurophysiology, Depts. of Phys. Ther. and Neuroscience, Karolinska Institute, S-171 77 Stockholm, Sweden.

Children with DAMP (Deficit, Attention, Motor Control and Perception) display qualitative differences in movement and balance persisting throughout their life span. One-leg standing is a commonly used balance test in motor assessment of children with DAMP. Performance of standing on one leg requiring an interaction between the voluntary movement control of lifting one leg and the postural control of anticipating the changing support surface conditions, is in children with DAMP below that expected given the child's chronological age and measured intelligence. To examine the relation between the voluntary control of initiating leg lifting and postural control of one-leg standing we tested eight children with DAMP and age matched controls standing on two force plates when performing one-leg standing. Body kinematics and ground reaction forces (GRFs) were recorded. Preliminary results suggest that the onset time of vertical loading as well as the increase of horizontal GRF beneath the lifting leg was significantly shorter with respect to lift off in children with DAMP than in the control group. The peak of the negative force rate drives of vertical and lateral forces was closer to lift off and three to five times higher in children with DAMP suggesting that the instability during one-leg standing with large oscillations of center of mass is an adequate response of postural control strategy for maintaining equilibrium during one-leg standing to compensate the inadequate programmed propulsive impulse beneath the lifting leg.

FUNCTIONAL NEURAL ACTIVATION IN NORMAL AND PARKINSONIAN SUBJECTS RELATED TO MOVEMENT FREQUENCY DURING PREDICTIVE VISUOMOTOR TRACKING USING PET. R.S. Turner*, J.M. Hoffman, S.T. Grafton and M.R. DeLong. Dept. of Neurology, Emory Univ. Sch. of Med., Atlanta, GA 30322

The goal of this project was to identify tracking- and frequency-related neural activations in normal and Parkinsonian (PD) subjects. PET activation techniques were used to study 6 normal and 8 PD subjects while they moved a joystick with the hand to follow sinusoidal movements of a visual target. Tracking at 0.1, 0.4, and 0.7 Hz using the same displacement amplitude was studied in a counterbalanced order during six movement scans (90 s). Two control scans required visual tracking of the target alone. Joystick displacement, integrated EMG, and EOG signals were acquired (250 Hz) together with the magnitude of relative regional cerebral blood flow (rCBF). Planned comparisons of mean rCBF were performed using linear contrasts with weights reflecting tracking (control vs. movement) and tracking frequency to detect brain regions with activity related to these two factors ($p<0.005$). Tracking-related activations appeared in areas associated previously with visuomotor tracking: motor, premotor and parietal cortices contralateral to the moving arm and in ipsilateral anterior cerebellum [Grafton '92]. Movement frequency-related activations in normals were observed in ipsilateral cerebellum, and contralateral motor cortex and medial pallidum. In contrast, PD subjects had significant movement frequency-related activations only in contralateral ventral cingulate motor area and rostral superior parietal cortices. In conclusion, the areas activated in relation to frequency of tracking in normals are not activated significantly in PD's.

COORDINATION AND PHASING IN A BILATERAL PREHENSION TASK: THE INFLUENCE OF PARKINSONISM J.L. Alberts, J.R. Tresilian, G.E. Stelmach, M. Saling* Motor Control Laboratory, Arizona State Univ. Tempe, AZ 85287.

Previous studies have examined Parkinson's disease (PD) patients' ability to perform two movement tasks simultaneously. Results from these studies indicated that PD subjects were differentially slower in conditions which required the concurrent performance of two movements as compared to independent performance of each, possibly due to the difficulty of superimposing two separate motor programs. The objective of this study was to investigate whether PD patients have difficulties with the independent control of multiple degrees of freedom (d.o.f.s). Subjects performed a bilateral prehension movement in which they reached for two objects that had different accuracy requirements. Degree of symmetry between limbs was assessed by comparing the absolute difference between the relative time to peak aperture and speed for each limb. Results indicated that control subjects produced an asymmetrical movement pattern (each limb produced kinematic patterns which were specific to target accuracy requirements). In contrast, PD patients displayed a higher degree of symmetry (similar kinematic pattern for each limb) than control subjects. Parkinson's subjects also demonstrated greater temporal asynchrony in bilateral movement initiation. Parkinsonian production of similar kinematic patterns for each limb, under asymmetrical accuracy conditions, suggests PD affects the optimal control of multiple d.o.f.s. The symmetrical pattern between limbs for PD subjects may be a strategy to reduce the number of d.o.f.s to be controlled by sending a general motor command to control both limbs.

FACILITATION OF UPPER LIMB MOVEMENTS IN ELDERLY AND PARKINSON'S DISEASE SUBJECTS USING RHYTHMIC AUDITORY CUEING. T. Liberzon* and S.H. Brown. Center for Human Motor Research, Division of Kinesiology, Univ. Michigan, Ann Arbor, MI. 48109-2214.

An inability to generate rapid sequential movements in Parkinson's Disease (PD) has been well documented. It has been shown, however, that external sensory stimuli may be used as pacing signals to enhance locomotion performance (Thaut et al., 1995). In the present study, the effects of rhythmic auditory cueing on the frequency of sequential arm movements was studied in five PD and six healthy elderly subjects. Subjects performed forward flexion and extension movements of the shoulder and elbow. Subjects held a pen in their dominant hand and were asked to perform alternating pointing movements between two vertically aligned targets (2 cm diameter, 10 cm apart). Elbow displacement was recorded using electrogoniometry. Subjects were asked to move as rapidly and accurately as possible between the two targets in the absence of auditory cueing. Following a brief period of practice, subjects were asked to move in time with a metronome tone, set at their maximum uncued frequency. The tone frequency was then gradually increased over several trials.

All subjects were able to increase movement frequency when movements were paced with an auditory tone. No consistent loss in end-point accuracy was observed. Furthermore, this increase in movement frequency persisted following removal of the tone. Qualitatively, in some subjects, auditory pacing was associated with a reduction in the number and magnitude of movement irregularities, particularly during reversal of movement direction. These preliminary findings provide further support for the use of sensory cueing to enhance motor performance in conditions characterized by movement slowing.

KINETIC TREMOR IN PATIENTS WITH MULTIPLE SCLEROSIS AND PARKINSON'S DISEASE: ASSESSED BY VISUALLY-GUIDED WRIST TRACKING TASKS. X. Liu, R. C. Miall, T. Aziz# and J. Stein (SPON: Brain Research Association). Univ. Lab. of Physiology, Oxford OX1 3PT; #Dept. of Neurosurgery, Radcliffe Infirmary, Oxford OX2 6HE, UK.

Visually-guided wrist tracking tasks have been applied to simultaneously assess kinetic tremor and dyskinetic tracking movement associated with multiple sclerosis (MS) and Parkinson's disease (PD) with approval of local ethic committee.

Subjects were instructed to pursue a displayed target by rotating a joystick. Amplitude and frequency of the kinetic tremor, in addition to accuracy in tracking velocity and effect of visual cue suppression on tracking movement, were assessed. With the same set up, visually-cued simple reaction time (RT) was also measured.

The kinetic tremor in MS did not correlate to either error in tracking velocity or delay of RT. Tremor and tracking accuracy reduced nearly 30% and more than 50%, respectively, with suppression of visual cues. In contrast, the kinetic tremor in PD correlated to the error in tracking velocity ($r=0.9602$, $p<0.01$, $n=7$). No significant increase in visual dependence of movement was found.

Unilateral thalamotomy or pallidotomy was carried out in some cases. In addition that the kinetic tremor in both conditions was abolished by the surgery, there was significant reduction in both tracking error (12.68±8.13% to 5.27±2.74%, mean±SD, $n=4$, $p<0.05$, paired t-test) and RT (0.28±0.07s to 0.23±0.07s) in PD but not MS.

Visually-guided tracking tasks have been proved to be an effective method for studying movement control. Deficits in sensory input, motor memory, or conversion of external input into motor command can effectively be detected and differentiated with these tasks. Clinical application of such tasks has significance in providing repeated, sensitive, and quantitative data for studying pathophysiological mechanisms and evaluating management of movement disorders.

DIFFERENTIAL INFLUENCE OF VISUAL FEEDBACK GAIN MODIFICATIONS IN PARKINSONIAN HANDWRITING. H.-L. Teulings*, J.L. Contreras-Vidal, and G.E. Stelmach. *Motor Control Laboratory, Arizona State University, Tempe, AZ 85287-0404, USA.*

Parkinson's disease (PD) and elderly control subjects performed sequences of handwriting loops ("lllllllll") on a digitizer overlaid by a display. In the first condition two horizontal lines were given indicating the target writing size, which varied between 0.5 and 2 cm. In the subsequent conditions only one horizontal line was given which served as the baseline. The visual feedback via the display was modified by compressing or expanding the vertical dimension to 70% or 140%, respectively. In the elderly control subjects, vertical stroke size and stroke duration, were not influenced by the modification of visual feedback, suggesting that they produced the movements in an open-loop fashion. In contrast, the PD subjects showed substantial size and duration effects, suggesting that they employ visual feedback to guide their movements. In the PD patients, the vertical expansion of visual feedback resulted in stronger effects than the vertical compression of visual feedback. It is hypothesized that the different effects in PD subjects originate from the overactivity of pallidal (GPi) neurons, the saturation of which prevents further reduction of thalamo-cortical activity required for small handwriting sizes.

EFFECTS OF ACCURACY CONSTRAINTS ON MULTI-JOINT ARM MOVEMENTS IN HUNTINGTON'S DISEASE. L. Quinn*, J.R. Flanagan and T.R. Kaminski. Department of Movement Sciences, Teachers College, Columbia University, New York, NY, 10027.

Individuals with Huntington's disease (HD) produce movements which are slow and multi-segmented. The purpose of this study was to investigate whether bradykinesia and the presence of submovements reflect a strategy by HD patients to maximize accuracy. Three-dimensional kinematic analysis was used to examine movement of the hand in twelve HD patients and six healthy control subjects performing reaching movements. Subjects reached to three targets of different diameters to determine the effect of accuracy constraints on motor performance. Although HD patients were able to move more quickly and produce fewer submovements as target size increased, they had lower maximum velocities, longer movement times and more submovements than healthy subjects.

A subset of subjects performed reaching movements: (1) with no external accuracy requirements; and (2) to a pillow target, which minimized the need for precise limb deceleration. Under both conditions, HD patients demonstrated smooth deceleration phases without submovements, and maximum velocities which were comparable to healthy subjects. However, HD patients continued to produce highly curved movements under all target conditions, which resulted in multiple velocity peaks during the acceleration phase. Healthy subjects produced curved hand paths only for movements to the pillow target; thus, curved hand paths may reflect the use of surface impact to stop movement. This study demonstrates that while HD patients are able under some conditions to produce the forces required to perform rapid movements, they have particular difficulty controlling and modulating these forces, especially for movements which have high accuracy constraints.

SPECIFICITY OF REACHING DEFICITS FROM DAMAGE TO DIFFERENT MOTOR STRUCTURES. A.J. Bastian*, J.W. Mink, A.W. Dromerick & W.T. Thach, Dept of Anatomy and Neuro, Prog in Physical Therapy, Dept of Neurology, Wash. U. Sch. of Med., St. Louis, Mo. 63110.

Classic abnormalities are supposed to characterize and distinguish certain movement disorders. People with Parkinson's disease are slow, with cerebellar disease are incoordinated, and with hemiplegia are weak with movements of small range. We examined this teaching by studying patients with Parkinson's disease (PD -Hoehn & Yahr stage 2 or 3, off meds), patients with cerebellar damage (CBL), patients with corticospinal tract damage (CST) and normal controls. All subjects reached in a parasagittal plane under three conditions: a "slow- accurate" condition where subjects made a self-paced reach to a 1 cm target on a 4 cm ball, a "fast-accurate" condition where subjects moved as fast as possible and touched any part of the 4 cm ball, and a "fast" condition where subjects moved as fast as possible towards the target, but were not required to stop on the target. Shoulder, elbow, wrist, and finger kinematics were videotaped. Anterior deltoid, posterior deltoid, biceps, and triceps EMGs were recorded. Elbow and shoulder torques were estimated using inverse dynamics.

All patient groups were slower than controls. The PD group had an EMG pattern with slight resting co-contraction and tonic activations, but were able to produce relatively normal kinematics and kinetics (except slowing). The CST and CBL groups both moved *more slowly* than the Parkinson's group and both produced curved wrist paths resulting from abnormal elbow-shoulder coordination. The CST group differed from the CBL group in showing agonist and antagonist co-contraction during the movement and predominantly target undershoot. The cerebellar group differed from the CST group in showing more phasic EMG activity, greater levels of elbow-shoulder decomposition, and target overshoot in the fast-accurate condition. For the cerebellar group, kinetic abnormalities consisted of muscle torques that did not appropriately compensate for interaction torques, which was also occasionally seen in the CST group.

These results support the idea that damage to different brain regions results in different movement deficits, although the relative magnitude of the deficits in this reaching paradigm is not always what would be expected from classic clinical generalizations

803.8

SINGLE AND DUAL TASK REACTION TIMES OF PATIENTS WITH PARKINSON'S DISEASE, WILSON'S DISEASE, CEREBELLAR LESIONS AND PARIETAL LESIONS

A.Roll[1], W.Wolf*[1] and H.Hefter[2].
[1]Bundeswehr Universität, Munich, Germany, [2]Neurologische Klinik, Heinrich-Heine-Universität, Düsseldorf, Germany.

Saccadic reaction times (SRT) and manual reaction times (MRT) were measured in single and dual task experiments. The target (LED) presented either 8° left or right from the fixation point appeared at the instant when the fixation point was switched off or 200 ms later. In the single task condition, subjects had to respond by either horizontal saccades or forefinger isometric reactions as fast as possible. In the dual task condition both reactions were required, in which the eye and finger reactions could be iso-directed (both reactions to target direction) or contra-directed (one reaction to and the other opposite to target direction). Patients with Parkinson's Disease, Wilson's Disease, cerebellar lesions and parietal lesions are compared with each other and with age-matched control groups. The aim of the study is to compare (i) the SRT and MRT and (ii) the number of saccades which are necessary to reach the target in single and in dual task conditions. We were interested in the ability to coordinate eye and finger reactions in iso- and contra-directed experiments.

The SRT of the four patient groups differ only little from those of control groups, but the number of saccades to reach the target indicates the tendency of multisaccades. The MRT show differences between patient groups and between patient and control groups in single and in dual task conditions. Patients reveal problems with motor coordination in contra-directed paradigms and, sometimes, a complete lack of correct responding. The longest MRT and the most frequently disturbed coordination of both reactions show patients with parietal lesions followed by patients with cerebellar lesions.

DEFICITS IN VISUALLY GUIDED STEPPING DURING A PHENYTOIN-INDUCED CEREBELLAR SYNDROME K.A.Crowdy, M.A.Hollands and D.E.Marple-Horvat (SPON: BRA). Dept. Physiology, University of Bristol, UK.

In a recent study the authors proposed that visually guided stepping is achieved predominantly via feedforward visuomotor control mechanisms and suggested that the oculomotor control system can provide the stepping motor controller with information that is useful for visual feedforward guidance of the limb. It is clear from clinical evidence that the ability to carry out visually guided tasks in general is dependent on the integrity of the cerebellum. To gain further insight into the cerebellar contribution we have studied a patient (JS) suffering from a Phenytoin-induced cerebellar syndrome. The difficulty JS experienced in visually guided stepping was investigated by monitoring her eye movements and stepping as she progressed along a series of 18 irregularly placed stepping stones positioned to demand precise foot placement at every step. Horizontal eye movements were measured using infra-red reflectometry and footfall was recorded via simple logic circuits connected to copper fabric soles stuck to the patient's footwear. Comparison of JS' performance with data obtained from healthy adults (n=8) carrying out the task has highlighted several deficits in JS' eye movements and stepping. JS was generally slower in her progression along the walkway and displayed a prolonged double support phase in her step cycle. Despite being made earlier in relation to footlift, rightwards saccades to the next target stone were similar in amplitude and nature to those made by normal subjects; but leftwards saccades were on average hypometric and additional small, corrective saccades were therefore necessary to gain a foveal image of the target. The close temporal relationship between these affected saccades and footlift supports the hypothesis that the oculomotor control system can provide the stepping motor controller with information that is useful for visual guidance of the limb and gives some indication of the extent to which ataxia is associated with or independent of the deficits in oculomotor control. It appears that patients suffering from a temporary Phenytoin induced "cerebellar syndrome" will provide a useful model of cerebellar dysfunction.

EEG ANALYSIS OF DEPTH ELECTRODE RECORDINGS FROM RED NUCLEUS IN A HAMSTER MODEL OF IDIOPATHIC DYSTONIA. M. Gernert, A. Richter, W. Löscher*. Dept. of Pharmacology, Toxicology, and Pharmacy, School of Veterinary Medicine, Bünteweg 17, D-30559 Hannover, Germany

The genetically dystonic (dt^{sz}) hamster is an animal model of paroxysmal dystonia that displays attacks of sustained abnormal movements and postures in response to mild stress. Although primary dystonia is a relatively frequent neurological disease in humans, little is known about its pathophysiology. Besides the presumption that an abnormal neural activity within the basal ganglia may be critically involved in the pathophysiology, some previous observations from autoradiographic studies pointed to a disturbance of the red nucleus (RN), which receives monosynaptic excitatory input from contralateral deep cerebellar nuclei and ipsilateral sensomotoric cortex, and monosynaptic inhibitory input from substantia nigra pars reticulata. In the present study we investigated depth EEG recordings from chronically implanted electrodes in the RN of freely moving hamsters. Changes of neural activity before and during dystonic attacks were compared to age-matched non-dystonic controls.

By means of computerized EEG spectral analysis using fast Fourier transformation in the range of 1.25 to 42.00 Hz a significant permanent decrease of total power was obtained in dt^{sz} hamsters, suggesting impaired interneural processing such as disturbed synchronization within the RN. Furthermore, the frequency at maximal power drifted to lower frequencies. Comparable to recent observations from caudate-putamen and globus pallidus, a frequency shift in the RN of dystonic hamsters could be shown: The delta activities (1.25 to 4.50 Hz) were increased and the alpha1, alpha2 and beta1 (7.00 to 18.50 Hz) were permanently decreased.

Even if these findings do not exclude that the alterations of neural activity within the RN may be secondary to disturbances of extrinsic structures connected to the RN, they indicate that abnormal changes of the RN are involved in the dystonic syndrome. It needs further investigations whether the obtained alterations may be secondary to disturbances of the substantia nigra, an output structure of the basal ganglia.

OCULO-MANUAL TRACKING WITH DELAYED VISUAL FEEDBACK IN CONTROLS AND CEREBELLAR PATIENTS. K.R. Kessler*, J. Salomon, P. Tass, H. Hefter, H.-J. Freund. Dept. of Neurology, HHU, 40225 Duesseldorf, F.R.G.

In previous studies we described characteristic delay-induced tracking patterns in the forearm movements of control subjects. These are fixed-point, oscillations, drifts and cycle slipping of the phase difference between tracking arm movement and target signal. The goals of the present study were to investigate whether a.) these different patterns are associated with typical visual control strategies, and b.) whether similar patterns can be observed in patients with cerebellar disease.

Five controls and four cerebellar (cb) patients were tested in a pursuit tracking task using a sinusoidal target signal presented on a screen. Subjects had to track the signal by performing flexion-extension movements of the forearm. Forearm position was displayed as a thin line on the screen. A delay was introduced between actual and displayed forearm position. Ten different delays between 0 and 100% of the target period were tested in pseudo-random order. The target frequency ranged between .5 and 1 Hz. Eye movements were recorded using an infrared reflection technique.

In cb patients fixed point behavior was generally less frequently observed than in controls, but the whole spectrum of delay induced movement patterns was present. Compared to controls, patients also showed a dramatically increased frequency of switches between visual tracking control strategies and were not capable of maintaining a stable correlation between eye movements and either target or arm position signals. This was associated with markedly impaired tracking ability.

Based on the disturbances of goal-directed movements in cerebellar pathology, the cerebellum has been proposed as the oculo-manual coordination control center. The results obtained in this study lend further support to this hypothesis. Furthermore, the presented approach provides new insights into the mutual interactions between oculomotor and skeletomotor control systems, and may help to clarify what it is exactly that the cerebellum controls during coordinated eye-arm tracking movements.

MOTION ANALYSIS OF RIGHT-HANDED SUBJECTS WITH CROSSED AND STANDARD PRESENTATION OF LIMB PRAXIS. M.Clark*, A.S. Merians, H. Poizner, J. Adair, A. Raymer, L.J.G. Rothi, K. M. Heilman. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102; VA Medical Center and University of Florida, Gainesville, FL 32610.

Reports of crossed apraxia (i.e. apraxia in a right-handed person subsequent to right hemisphere damage) offer the unique opportunity to study the relationship between skilled movement (limb praxis) and hand preference (handedness). To make the claim that skilled movement and hand preference dissociate in these cases, one has to prove that crossed apraxia is qualitatively the same as the apraxia seen in the standard presentation (the right-handed subjects with left hemisphere lesions). We used three dimensional movement analyses to study a right-handed subject with right fronto-parietal damage who exhibited both crossed apraxia and crossed aphasia. Trajectories of repetitive "slicing" movements made by the crossed apraxic subject were compared with the trajectories of four standard apraxic subjects and four normal controls in response to verbal command and with actual tool use. Movements of the ipsilesional arm/hand in the brain-lesioned subjects, and of both limbs for the normal subjects were digitized from neighboring views, reconstructed in 3D, and analyzed. Like the standard apraxic subject, the crossed apraxic subject was unable to maintain the normal linearity and planarity of individual or successive movement cycles; produced decoupled relationships between hand speed and trajectory shape; and showed interjoint coordination deficits by failing to properly apportion relative joint amplitudes. Also like the standard apraxic subject, the deficit in our crossed apraxic subject was most pronounced to verbal command, with the movement improving though remaining poorly performed when he actually used the tool and object. This case provides further evidence that handedness is not necessarily determined by cerebral dominance for skilled action. Supported by NIH Grant 2RO1NS28665

PRAXIS AND THE RIGHT HEMISPHERE. L.M. Maher, L.J.G. Rothi and K.M. Heilman* Center for Neuropsychological Studies, Univ. of Florida, Gainesville, FL 32606.

Liepmann (1920) proposed that in right handers it is the left hemisphere that contains the representations for learned skilled movements (praxis). However, recently, some investigators have proposed that the right hemisphere may also play an important role in mediating praxis. To learn if the right hemisphere does play an important role in praxis, we studied right handed patients with right (n=11) and left (n=11) hemisphere lesions as well as normal controls (n = 11) who were matched for age, education, and the interval between their cerebral infarction and testing. Two trained raters (inter-rater reliability = 87%) who were unfamiliar with the subjects or the hypotheses that were being tested scored the transitive gesture performance of the forelimb that was ipsilateral to the injured hemisphere. For the normal controls, the left and right hand performance were scored separately and used for statistical comparison (i.e. their right hand performance compared to the right hemisphere lesioned patient group and their left hand performance compared to the left hemisphere lesioned patient group). Independent comparisons were made on six dimensions that are important for accurate gesture performance: internal configuration (arm and hand posture), external configuration (orientation to the object that receives the action), movement (joint movement and joint coordination), amplitude, occurrence and sequencing. Based on these six dimensions subjects were also given an overall apraxia score.

When compared to normal control subjects the patients with left hemisphere lesions (LHD) did demonstrate an apraxia. However, those with right hemisphere lesions (RHD) did not. The one error of gesture performance noted in subjects with RHD was amplitude errors. In contrast, patients with LHD made more movement errors which were caused by the incorrect selection, activation and coordination of joint movements. 803.14

PROLONGED MUSCLE ACTIVITY VS. PREMATURE ONSET DURING PEDALING IN PERSONS WITH POST-STROKE HEMIPLEGIA D.A. Brown*, S.A. Kautz and C.A. Dairaghi. Rehabilitation R & D Center, VA Palo Alto Health Care System (153), Palo Alto, CA 94304

Studies in persons with post-stroke hemiplegia have investigated pathological mechanisms of muscle activity such as hyperactive stretch reflexes, improper muscle timing, and/or prolonged muscle activity, all thought to interfere with the execution of movement. This study investigated the timing and amplitudes of EMG activity in seven muscle groups as 15 subjects with hemiplegia and 12 healthy, elderly control subjects pedaled a modified bicycle ergometer at a constant velocity (40 rpm) and constant workload (120J). When compared to control subjects, subjects with hemiplegia, on average, demonstrated significant differences in timing of muscle activity so that muscles normally on during the power phase (soleus and vastus medialis) showed prolonged muscle activity and those muscles on during transition phases (medial gastrocnemius, rectus femoris, semimembranosus, and biceps femoris) showed premature onsets. Results indicate that locomotive movement deficits are caused by a combination of pathological mechanisms related to the biomechanical function of the muscle. ARM-TRUNK COORDINATION IN HEMIPARETIC PATIENTS DURING A POINTING TASK. P. Archambault*, P. Pigeon, M. Levin, A. G. Feldman, Institut de génie biomédical, University of Montreal, Montreal, QC H3C 3T5.

In neurologically normal subjects, trunk motion during a pointing task does not affect trajectory of the endpoint. In hemiparetic patients, arm trajectories during pointing movements are segmented and more variable than in healthy subjects, and arm coordination is affected by movement direction; however, arm-trunk coordination has not been studied in detail. In this study, measures of inter-segmental coordination obtained from ten right hemiparetic and ten age-matched healthy subjects were compared. Subjects were seated with their trunk 20 cm in front of the starting position and their arm flexed-abducted 70°. They performed ipsi- and contralateral pointing movements while either flexing (in phase movements) or extending (out of phase movements) the trunk, to a target 35 cm away using their right arm. Randomized blocks of ten trials to both targets (ipsi and contra) and for both conditions (in or out of phase) were performed. Each block was preceded by a series of ten control trials (arm movement only). Subjects were instructed to reach without touching the table, so that friction would not influence endpoint position. Values for endpoint precision and trajectory curvature were computed from 3D kinematic data, measured with a camera/active markers system. It was found that in healthy subjects, neither endpoint precision nor trajectory curvature were affected by trunk motion. Preliminary analyses show that in some hemiparetic patients, endpoint precision is preserved despite the inclusion of an additional degree of freedom in the movement. Results from this study could lead to a better understanding of the motor deficit in hemiparetics and the development of new treatment approaches. Supported by FRSQ-FCAR grant.

DEFICITS IN DISTAL MOVEMENTS IN THE LIMB IPSILATERAL TO A STROKE IN HEMIPARETIC SUBJECTS. C.A. Yarosh*, D.S. Hoffman and P.L. Strick, Research Service, VAMC and Depts. of Neurosurgery and Physiology, SUNY-HSC, Syracuse, NY 13210.

We tested the performance of 7 hemiparetic patients on a task that required step-tracking movements of the wrist. Subjects were asked to move as fast as possible to 8 peripheral targets (separated by 45 degrees) using combinations of flexion/extension and radial/ulnar deviation. All patients had unilateral ischemic lesions (4 left-sided, 3 right-sided) and had residual paresis in the arm contralateral to the lesion. For comparison, we also examined 7 age, sex and handedness matched control subjects. All patients displayed marked deficits in movements of the wrist *ipsilateral* to the lesion. Movement velocity was reduced by as much as 50% and the initial movement tended to undershoot the target. In some instances, patients used multiple small movements to reach a target. Movement trajectories of patients also were markedly altered. Diagonal movements tended to be spatially and temporally decomposed so that near vertical and horizontal components were performed sequentially. These results demonstrate that unilateral lesions of either the left or right hemisphere result in significant ***bilateral*** changes in the performance of ***distal*** limb movements. EVIDENCE FOR FEEDFORWARD PROCESSING IN THE CONTROL OF RAPID AIMING WHEN TIME TO PROGRAM IS CONSTRAINED. B.E. Fisher*, C.J. Winstein, and M.R. Velicki. Motor Behavior Laboratory, University of Southern California, Los Angeles, CA 90033.

Previous work using a modified timed-response paradigm (TRP) examined the extent to which healthy human subjects and those status post unilateral cerebral vascular accident (CVA) could specify amplitude and direction of targeted arm movements when programming time was constrained (Winstein et al., 1993). The time-course for parameter specification was similar for both groups; however, healthy subjects were more accurate than CVA subjects even though movement durations were shorter (Control MT $\leq$ 306 ms; CVA MT $\leq$ 377 ms). For the present project, detailed kinematic analyses of these aimed trajectories were done to determine the underlying strategy that enabled healthy subjects to optimize speed-accuracy tradeoffs. The majority of 2,048 trials/group were characterized as having a smooth, single-peaked velocity profile (Brooks et al., 1973) indicative of programmed movements. Of particular interest were those responses where obvious adjustments were embedded in the *initial* phase of the movement. First, for the CVA group, these responses comprised 4.7% compared to 14.5% of all responses for the Control group. Second, as time to prepare decreased from 400 to $<$ 100 ms, the frequency of these responses increased from 3.1% to 6.3% in the CVA group and from 3.5% to 21.3% in the Control group. These results suggest that healthy subjects compared to those post CVA can more effectively use internal feedback (Wolper et al., 1995) before sensory feedback is available. WORKSPACE DEFICITS AND ABNORMAL SYNERGIES DURING GUIDED REACHING AFTER STROKE

D.J. Reinkensmeyer*, J.A. Dewald, and W.Z. Rymer, Rehab. Inst. of Chicago, IL 60611

Workspace boundaries and constraint contact forces were measured during guided reaching by three hemiparetic stroke patients using a simple mechanical device (a "reaching guide"). The guide attaches to the wrist and constrains the hand to move radially outward from the shoulder in the parasagittal plane. To measure the workspace boundary, the guide was locked at a series of angles and the supine subject, starting with elbow flexed against a stop, reached out as far as possible. The boundary created by the maximum reach at each angle was recorded on a PC. In addition, the contact forces between the arm and guide during reaching were measured by a 6-axis load cell.

The workspace boundaries for the stroke patients' unimpaired arms and both arms of six unimpaired subjects were found to be roughly circular. In contrast, the boundaries for the stroke-impaired arms were shrunken, particularly in humeral flexion. The inaccessible area increased with increasing severity of motor impairment as gauged by a clinical scale (Fugl-Myer). Boundary shrinkage was attributable to a decrease in elbow passive range of motion (ROM) in the least impaired subject, but apparently arose from disturbances in voluntary force generation in the other two subjects.

Analysis of contact forces between the arm and guide elaborated the nature of the disturbances. While unimpaired subjects pushed laterally outward from the body during reaching thereby creating a small lateral force against the guide, all three stroke patients pushed toward the midline as they extended their impaired arms. This spatial pattern of contact force is consistent with the clinically reported extension synergy in which the shoulder is involuntarily adducted and internally rotated during efforts at elbow extension. Based on these results, it is hypothesized that an inability to selectively co-activate muscles, as well as decreased passive ROM and weakness, contribute to workspace shrinkage after stroke.

LINEAR AND NONLINEAR DYNAMICS IN HUMAN PHYSIOLOGICAL AND PATHOLOGICAL TREMOR. R. Edwards and A. Beuter*, Dept. of Kinanthropology, Univ. of Québec in Montréal, Montréal, QC, Canada H3C 3P8.

Although tremor is one of the most common neurological signs in neurodegenerative diseases there is too much overlap in its amplitude and frequency characteristics to associate specific neuropathologies with forms of tremor on this basis alone (Elble and Koller, 1990). There is growing evidence, however, that nonlinear analytic tools might provide a more sensitive and specific analysis of tremor able to detect subtler differences in time series which may have similar amplitude and frequency characteristics. In this study we examine several linear and nonlinear analytic approaches and use them to characterize tremor in subjects with various neurological conditions. These approaches include (1) amplitude; (2) measures of frequency concentration in tremor power spectra; (3) characteristics of the distribution of data points in the time series; (4) the morphology of the oscillations themselves (e.g. 'wobble' and positive/negative asymmetry, Edwards and Beuter, 1996); (5) characteristics of the autocorrelation function; (6) entropy; (7) measures of determinism, such as nonlinear prediction error; (8) statistical tests for rejection of a null hypothesis of linear dynamics driven by Gaussian white noise, using phase-randomized surrogate data sets and various statistics which characterize aspects of nonlinearity. All these techniques can be applied to real data as well as to simulated data generated from mathematical models of human tremor. We apply them to data collected in subjects with basal ganglia or cerebellar diseases and to simulated data from simple models and discuss the strengths and weaknesses of each of them in discriminating early signs of pathology. We find that on the basis of typical examples of tremor of various types, some of the techniques above appear to discriminate normal from pathological tremor, whereas others identify specific types of pathology. Funded by NSERC (Canada) and FCAR (Québec).

CONSTRAINT INDUCED (CI) MOVEMENT: A FAMILY OF PROCEDURES FOR INCREASING UPPER EXTREMITY USE AFTER CNS DAMAGE IN MONKEYS AND HUMANS, E. Taub*, R.D. Pidikiti, S.C.DeLuca, G. Uswatte, and J.E. Crago. Depts. of Psychology and Physical Therapy, University of Alabama at Birmingham, 35294 and Physical Medicine and Rehabilitation Service, Veterans Affairs Medical Center, Birmingham, AL 35233.

A new approach to the rehabilitation of movement after stroke, termed Constraint Induced (CI) Movement Therapy, has been derived directly from basic research with monkeys given somatosensory deafferentation. After unilateral forelimb deafferentation, monkeys do not use the affected limb in the free situation. However, they can be induced to use the deafferented extremity by either of two general techniques: 1) restricting movement of the intact limb for 7 or more days, 2) training the deafferented arm. A useless limb is thereby converted into a limb that can be used extensively.

The same techniques are effective for producing a substantial rehabilitation of movement after stroke in humans. CI consists of a family of therapies; their common element is that they induce stroke patients to greatly increase the use of an affected upper extremity for many hours a day over a period of 10-14 consecutive days. The signature intervention involves motor restriction of a contralateral upper extremity in a sling and training of the affected arm. The therapies result in large changes in amount of use of the affected arm in the activities of daily living outside the clinic that persist for at least the two years measured to date. Patients who will benefit from CI therapy can be identified before the beginning of treatment. Supported by Grant B93-629AP from the Rehabilitation Research and Development Service, U.S. Dept. of Veterans Affairs, and Grant 94-172 from the Retirement Research Foundation.

EFFECTS OF SECTION AND SPONTANEOUS REATTACHMENT OF THE SOLEUS MUSCLE ON THE GAIT OF THE ADULT RAT. R. A. Fox*, C. Moreno, and J. Knox. Department of Psychology, San José State University, San José, CA 95192-0120.

Biomechanical action of the soleus muscle was eliminated by sectioning the soleus muscle at the Achilles tendon in both hind legs of six adult male Sprague-Dawley rats. Gait of the rats was studied through analysis of movements of the hind legs during 7 days of recovery. Foot placement was assessed as the rats spontaneously walked across a 1-m walkway and limb kinematics were evaluated during locomotion on a treadmill in horizontal and inclined (10 deg) positions. Limb coordination was characterized in a swim test. All tests were administered prior to surgery to determine baseline performances and then at 4, 24, and 168 hr. after surgery.

At 4 hr. after surgery the rats walked in a slightly crouched posture with the ankle dorsiflexed and with normal limb coordination. Crouching and dorsiflexion of the ankle increased at 24 hr. post surgery. Normal ankle flexion returned by 168 hr. but the previously normal limb coordination was disrupted at this time. Post mortem examination indicated the soleus muscle had attached to the lateral gastrocnemius. These results suggest that the soleus muscle is not critical for typical, coordinated hind leg movement in the adult rat. The uncoordinated leg movements observed after the soleus attached to the gastrocnemius suggest that the CNS had not adapted sufficiently to produce smoothly controlled ankle movement.

THREE DIMENSIONAL KNEE TORQUES PRODUCED BY QUADRICEPS AND HAMSTRINGS MUSCLES IN THE CAT. T.A Abelew*, C.M.J.I. Huyghues-Despointes and T.R. Nichols.
Department of Physiology, Emory University, Atlanta, GA 30322

Predominant movements at the knee joint in cats consist of flexion and extension (sagittal) though some degree of axial rotation and abduction/adduction (nonsagittal) is likely used for adjustments during turning motions or during locomotion over uneven terrain. Bonasera et al.(Soc. Neurosci. Abstr., 21:1432, 1995) have reported three dimensional knee torques that were generated by the medial and lateral gastrocmemius muscles. In addition, the morphology of the feline thigh implies that the quadriceps and hamstrings muscles could be used to generate significant nonsagittal torques. Quadriceps and hamstrings muscles were stimulated individually and regionally in cats deeply anesthetized with Nembutal while the resulting isometric forces and torques were quantified using a multidimensional force/moment transducer. Nonsagittal torques were produced by both muscle groups with hamstrings producing more nonsagittal torque than quadriceps. While the proportion of peak nonsagittal to sagittal torques varied as different combinations of hamstrings were recruited, the quadriceps showed only slight changes in the proportion of these torques during individual muscle or regional recruitment. These data suggest that changes in nonsagittal position of the shank during movement are produced by the hamstrings muscles while the quadriceps provide relatively constant torque proportions. (Supported by NS 20855).

NON-UNIFORM DISTRIBUTION OF NEURAL FEEDBACK AMONG THE QUADRICEPS AND TRICEPS SURAE MUSCLES OF THE CAT. R.J.H. Wilmink, C.M.J.I. Huyghues-Despointes, T.A. Abelew and T.R. Nichols*. Department of Physiology, Emory University, Atlanta, GA 30322.

In order to test the hypothesis that length feedback primarily links muscles having synergistic actions at one joint while force-feedback links muscles acting across different joints (Nichols, T.R.(1994) Acta Anat. 151,1-13), we evaluated the distribution of stretch-evoked reflexes among triceps surae and quadriceps muscles. Muscles were activated using peripheral nerve stimulation, and responses were measured using separate myographs. Interactions among the single-joint vasti were characterized mainly by short-latency excitation, especially between vastus lateralis and medialis. Interactions between the biarticular rectus femoris and any of the three vasti were characterized by weak excitation and force-related inhibition. Reflexes between triceps surae and quadriceps muscles were inhibitory and increased with activation level. The inhibition was stronger from quadriceps to triceps than the reverse direction at low forces, but was approximately balanced in the two directions at higher forces. We conclude, in agreement with our hypothesis, that the pattern of neural feedback in these groups reflects the biomechanical specializations of each muscle. (Supported by NS 20855).

A COMPARISON OF CAT UP-SLOPE AND LEVEL GALLOPING. J. L. Smith*, P. Carlson-Kuhta., T.V. Trank, and S. Saywell.
Dept. Physiological Science, UCLA, Los Angeles, CA 90095-1568.

Members of our laboratory have studied level treadmill galloping (Wisleder et al. *Exp. Brain Res.* 79: 1990; Smith et al. *ibid.* 94: 1993), and here we contrast that behavior with gallops up an inclined walkway (45°). EMG of selected hindlimb muscles were recorded and synchronized with hindlimb kinematics obtained from digitizing high-speed ciné film.

The average cycle period for up-slope galloping was 395 ± 160 ms (22 steps); this is comparable to treadmill galloping at speeds of 2-2.5 m/s (Wisleder et al.). The percent of cycle devoted to stance was 58% for up-slope galloping but only 40% for treadmill galloping. Cats tended to use a half-bound gait in which the hindlimbs moved nearly synchronously to gallop up the steep inclined walkway, whereas rotatory and transverse gallops were typically used to gallop on the level treadmill.

During the stance phase of up-slope gallops, the yield (flexion) at the knee and ankle joints was ~18° compared to 45° for treadmill gallops. The range of extension (E3 phase) at both joints tended to be greater for up-slope than treadmill gallops (62° vs. 50°). At the hip joint, the range of flexion (swing) and extension (stance) was 15-20° greater for up-slope than treadmill gallops. Extensor muscles (hip - anterior biceps femoris, ABF; knee - vastus lateralis, VL; ankle - plantaris, PL) exhibited stance-related activity that was similar for both forms. The tibialis anterior (TA, ankle flexor) had similar activity under both conditions, whereas the ST (semitendinosus, knee flexor and hip extensor) had stance-related activity during the up-slope gallop (except for 1 cat) while the ST was inactive during stance of treadmill galloping.

Our data suggest the cycle period parameters for up-slope and level galloping are different and that hindlimb kinematics and motor patterns of some muscles are modified to meet the demands of the terrain.

A NEW QUANTITATIVE ANALYSIS OF QUADRUPEDAL GAIT. G. Bishop, C.D. Mah, M. Hulliger, A. Wojciechowski and U. Windhorst*. Dept. Clinical Neurosciences, University of Calgary, Alberta, Canada T2N 4N1.

Gait is often of interest in animal models, for example, in the evaluation of neurological deficits or models of osteoarthritis. However, the majority of the literature on quadrupedal gait, which analyzes joint angular displacement, neglects global features and does not emphasize inter-joint and inter-limb coordination. In fact, gait pattern analysis is better developed for bipeds than for quadrupeds. In humans, gait analysis has been employed to obtain clinically relevant information in patients with orthopaedic or neurological conditions (e.g. stroke, cerebral palsy). We have recently developed a method for the analysis of multivariate gait patterns (Mah et al., J. Motor Behavior 26, 83-102, 1994), based on principal component analysis, which is appropriate for quantification of global features of pathological gait patterns when univariate measures fail. In the work reported here, these methods are extended to quadrupedal gait.

This analysis was used to elucidate disturbances of gait patterns during ataxias resulting from manipulations such as deafferentation. Cats were trained to walk on a treadmill at slow (0.4 m/s), and fast (0.8 m/s), speeds. The positions of 10 reflective markers attached to major joints and vertebrae were digitized in 3 space dimensions during normal and ataxic walking. These data were used to calculate joint angles which formed the input to the pattern analysis.

During ataxic gaits we observed distributed changes in overall posture, and variability of limb movement, especially in the frontal plane relative to normal. In the quadrupedal analysis, data was segmented from hindlimb toe contact to forelimb toe contact for the following forelimb cycle. Analysis of the quadrupedal gait cycle separately revealed the global pattern of hindlimb and forelimb kinematics, and the correlation of hindlimb and forelimb patterns.

This analysis was useful in demonstrating the small changes in gait pattern associated with mild ataxia, and the statistical evaluation of inter-joint and forelimb / hindlimb coordination. As such, this modification of the principal component based analysis shows promise in evaluating the subtle features of pathological gaits in experimental animal models. EFFECTS OF LOAD ON MEAN EMG AND QUIPAZINE RESPONSE IN SPINALLY TRANSECTED STEPPING CATS. M. R. Recktenwald, R.D. de Leon, J.A. Hodgson, R.R. Roy, R.C. Weatherwax* and V.R. Edgerton. Department of Physiological Science and Brain Research Institute, UCLA, L.A., CA 90095.

EMG and video recordings were made from 5 step-trained spinal cats (transected T12-T13) during bipedal treadmill locomotion at a speed of 0.6 m/s. Cats trained to walk on a treadmill (30 min/day, 5 days/week, 0.2-1.0 m/s) exhibited full weight bearing stepping approximately one month after transection and continued to step for several months thereafter. Cats were tested on the treadmill during normal weight bearing locomotion, non-weight bearing cycling (i.e. hindlimb cycling induced by minimal contact with the moving treadmill belt) and greater than normal load stepping (i.e. the tail of the animal was pulled down to increase the weight supported by the hindlimbs). Lower mean EMG amplitudes in both flexor and to a greater extent extensor muscles were observed during non-weight bearing compared to normal weight bearing locomotion. Greater than normal load stepping resulted in increased extensor, but not flexor, mean EMG, relative to normal load bearing. Quipazine (2-3 mg/kg, i.p.), a 5-HT agonist, increased the cycle period, flexor and extensor EMG burst duration and the step length and step height in the swing phase during normal weight bearing locomotion and during non-weight bearing cycling when the foot still made contact with the treadmill surface. Cycling ceased when the paws no longer contacted the surface of the treadmill and quipazine had no effect on the inactive limbs. Under differing loads, quipazine increased EMG burst duration and cycle period, but had no consistent effect on the mean EMG amplitude. Thus we did not observe the increase in EMG amplitude following quipazine administration reported by others (Barbeau and Rossignol, *Brain Res.* 514:55, 1990) and suspect this increase may have been a result of improved weight support following quipazine administration. The present data, therefore, suggest that the EMG amplitude of hindlimb muscles are affected by the loading conditions, but not by quipazine during stepping in spinal cats. INTRACELLULAR KETAMINE REDUCES EXCITATION OF LUMBAR MOTONEURONS DURING FICTIVE LOCOMOTION IN THE CAT S. Krawitz*, R.M. Brownstone, L.M. Jordan Dept. of Physiology, University of Manitoba, Winnipeg MB Canada R3E 0W3

Voltage-dependent properties of lumbar motoneurons in decerebrate cats have been observed during fictive locomotion induced by stimulation of the mesencephalic locomotor region (MLR). Previous work has shown that the excitatory component of the locomotor drive potential (LDP) behaves in a voltage-dependent manner such that its amplitude increases with depolarization (1). Preliminary studies suggest a NMDA-mediated component to the LDP: the NMDA antagonist APV reduces locomotor output (2), perhaps by reducing voltage-dependent excitation in motoneurons (3). In light of suggestions that ketamine's lipid solubility might allow the latter to block NMDA receptors from within the cell (4), we elected to test the role of NMDA in producing LDPs by using intracellular ketamine.

In order first to determine that intracellular ketamine is effective in cat motoneurons we examined segmental EPSPs and demonstrated selective reductions in some but not all of the EPSPs. Once convinced that ketamine had a selective effect on some EPSPs (presumably on their NMDA components) we proceeded to examine its effects on the voltage-dependent increase in excitation of the LDPs. In most motoneurons examined there was no voltage-dependent increase.

These findings support the hypothesis that there is during locomotion a NMDA-mediated voltage-dependent increase in excitation in motoneurons, a mechanism which could at least in part account for the high frequency of motoneuron firing.

EFFECTS OF MICROINJECTIONS OF NMDA INTO THE PONTOMEDULLARY RETICULAR FORMATION ON VOLUNTARY GAIT MODIFICATIONS IN THE CAT. S.D.Prentice* and T.Drew. Dept. of Physiology, Univ. de Montréal, Montréal, Québec, Canada.

To investigate the role of reticulospinal neurons (RSNs) in the integration of posture and movement during voluntary gait modifications, microinjections of NMDA were made in the medial regions of the pontomedullary reticular formation (PMRF) in intact cats trained to step over an obstacle attached to a moving treadmill belt. NMDA (1μl; 10 mM) was injected into 10 loci within the PMRF in 2 cats in which the discharge characteristics of RSNs had been recorded during the same task, and the effects of these injections were monitored by recording electromyographic (EMG) and limb kinematics. In all cases, within 5 mins. of these injections the cats showed some inability to fully support their weight. This deficit was reflected during locomotion by decreased extensor activity in all four limbs and by increased flexion throughout the step cycle, primarily at the knee and ankle joints. There were also changes in the relative durations of the swing and stance phases. Nevertheless, the cats were always able to step over the obstacles without touching them and, in contrast to the unobstructed cycles, there was only a small reduction in the level of activity in the extensor muscles of the supporting limbs during the step over the obstacle. These results support the hypothesis that RSNs play an important role in the regulation of posture during locomotion but suggest differences in the postural control mechanisms used during normal locomotion and during the voluntary gait modifications. (Supported by the Canadian MRC, the FRSQ and the FCAR).

DISCHARGE CHARACTERISTICS OF VESTIBULO- AND RETICULOSPINAL NEURONES IN INTACT CATS DURING LOCOMOTION ON AN INCLINED PLANE. K. Matsuyama and T. Drew*. National Institute for Physiological Sciences, Okazaki, Japan, and Dept. of Physiology, University of Montreal, Canada.

We recorded the discharge characteristics of 45 vestibulo- and 51 reticulospinal (VSNs and RSNs respectively) from the left brainstem of 2 chronically implanted, intact cats during locomotion on an inclined plane. All VSNs and RSNs were identified by stimulation of their axon in the lumbar spinal cord (L2). RSNs were recorded between P4 and P12 and at lateralities between 0.5 and 2.0 from the midline; all VSNs were histologically verified to be confined to the lateral vestibular nucleus. The discharge characteristics of these neurones were recorded during normal treadmill locomotion, during treadmill tilt (from 20° up to 10° down) and during treadmill roll (between 20° left and right). During walking on a level surface, most VSNs increased their discharge frequency twice in each step cycle. Tilting the treadmill down, or rolling it to the left and/or right most frequently increased the depth of modulation without changing the peak rate. The discharge patterns of the RSNs were more variable, but the majority of neurones increased their discharge frequency when the treadmill was tilted up and/or rolled to the right. In addition, inclining the treadmill frequently modified the phase of the peak discharge in both VSNs and RSNs. The results suggest that these two descending pathways play a role in adjusting the level of EMG activity during locomotion on an inclined plane and might also play a role in modifying interlimb coordination. (Supported by the MRC and the FRSQ).

EFFECTS OF REVERSIBLE INACTIVATION OF THE INTERPOSITUS NUCLEUS ON LOCOMOTION IN INTACT CATS. J.-A. Rathelot, S. Lavoie, Y. Padel*, and T. Drew. Depts. of Physiology. U. Toulouse, France and U. Montréal, Canada.

As part of a study to examine the role of the different cerebellar nuclei in the control of locomotion, we injected small quantities of the GABA agonist muscimol (0.2 -0.4 μl: concentration 0.5μg/μl) into physiologically identified regions of the interpositus nucleus of 2 intact cats trained to walk on a treadmill and to step over obstacles attached to the treadmill belt. The effects of the injections were analyzed by recording electromyographic activity from selected fore- and hindlimb muscles and by measuring the joint angles of these limbs from simultaneously obtained video recordings. All injections that were histologically verified to be within the boundaries of the interpositus nucleus produced deficits in locomotion within ten to twenty minutes of the start of the injection. During normal treadmill locomotion the injections of muscimol into the rostral pole of the nucleus resulted in deficits that were restricted to the ipsilateral hindlimb which dragged along the treadmill belt during the swing phase. During the steps over the obstacle the trajectory of the hindlimb was modified such that the limb hit the obstacle instead of passing smoothly over the top as in the control sessions. Injections into the more caudal regions of the interpositus nucleus evoked similar deficits that were either localized to the forelimbs or that had effects on both the fore and hindlimbs. The results confirm and extend previous reports on the role of the interpositus nucleus in the control of locomotion. GABA AGONISTS INJECTED INTO THE MIDBRAIN ANTERIOR DORSAL TEGMENTUM BLOCK LOCOMOTION INITIATED BY STIMULATION OF THE HYPOTHALAMUS. M. Benaur and H.M. Sinnamon*. Neuroscience & Behavior Program, Wesleyan Univ., Middletown, CT 06459-0408.

We have shown that neural activity in the tegmentum of the anterior dorsal midbrain lateral to the central gray correlates in time with the onset of hindlimb stepping produced by hypothalamic stimulation. Because this region had not previously been implicated in locomotor initiation, we wanted to know if the locomotor correlates reflected a necessary relationship. We determined if inactivation of the region using GABA or muscimol injections would block the elicited stepping. Stimulation electrodes were implanted into locomotor sites of the hypothalamus of anesthetized rats (urethane, 800 mg/kg). Hindlimb stepping was elicited by 5-sec trains of electrical stimulation presented once per minute. A glass pipette (80-um tip) was inserted into the midbrain ipsilateral to the stimulation site, and injections of GABA or muscimol were made. The principal findings were drawn from the series of GABA studies because their short lasting effects allowed the testing of multiple sites along an injection track. In 48 injection sites in 18 rats, GABA injections (100-200 ug / 0.1-0.2 ul saline), blocked hindlimb stepping in 16 cases. Locomotor blocks occurred within 5 min of the injection, and typically recovered within 15-20 min. Postural effects were rare. The effective blocking sites concentrated around the interstitial nucleus of the medial longitudinal fasciculus at the level of the ventral tegmental area. Sites more dorsal and more anterior were not effective. Muscimol injections (200-500 ng) produced a similar distribution. The data are consistent with a role for the anterior dorsal tegmentum of the midbrain in the control of locomotor initiation.

VESTIBULAR AND NECK REFLEX ACTIVITY DURING CAT FORELIMB FICTIVE LOCOMOTION, Kazuhiko SEKI[1], Yumiko NAYA [1], and Takashi YAMAGUCHI* [1,2]. Inst Basic Med Sci, Tsukuba Univ[1], Tsukuba, Ibaraki 305; Inst Bio-Sens Tech, Yamagata Univ[2], Yonezawa, Yamagata 992, JAPAN

To understand neuronal mechanisms controlling dynamic postural adjustment during locomotion, we investigated reflex activity evoked by stimulation of vestibular and neck afferents during cat forelimb fictive locomotion. In immobilized, decerebrate cats with the lower thoracic spinal cord transected, fictive locomotion was induced by repetitive stimulation of the lateral funiculus at the upper cervical cord. Intracellular recordings were made from elbow extensor motoneurons.

In the resting state with no rhythmic motor activity, stimulation of the vestibular nerve on either side evoked oligosynaptic excitation of extensor motoneurons, while stimulation of the neck afferent, C2 dorsal root ganglion (DRG) induced polysynaptic excitation and/or inhibition of extensor motoneurons with predominance of the excitatory effect. During fictive locomotion, the uncrossed excitation from the ipsilateral vestibular nerve and DRG was abolished. In neck reflex, polysynaptic excitation was replaced by inhibition with the similar latencies. The crossed excitation from the contralateral side was preserved for both vestibular and neck reflexes. The results suggested that the uncrossed reflex is primarily responsible for static balancing, while the crossed reflex is important for maintaining dynamic balance during locomotion.

804.13

THE PROPRIOCEPTIVE REGULATION OF THE STEP CYCLE IN INTACT CATS IS STATE DEPENDENT. P.J. Whelan* & K.G. Pearson, Dept. of Physiol., Univ. of Alberta, Edmonton, Alberta, CANADA, T6G 2H7.
During locomotion many reflex pathways are modulated according to the phase of the movement or to the task. The aim of this study was to establish whether the influence of extensor group I afferents is altered when a cat walks under different conditions. The pathway we examined was an oligosynaptic pathway from group I extensor afferents to extensor motoneurons which is opened during locomotion. Previously we have shown that this pathway is involved in regulating the stance to swing transition (Whelan et al., 1995). In this study intact cats were trained to walk quadrupedally and bipedally on a treadmill. During the stance phase, the group I afferents in the LGS nerve were stimulated [trains: 800-1000 ms, 1.8 x T, 200 Hz]. When the cats were bipedally walking the stance phase was usually prolonged by stimulus trains. However, during quadrupedal stepping, the efficacy of LGS stimulation was significantly decreased (mean percentage effectiveness of the stimulus train in prolonging the cycle period: bipedal 30.70%; quadrupedal 15.57%; significantly different in 4/5 cats). When the speed of the treadmill was decreased from .5 m/s to .3 m/s the efficacy of LGS stimulation increased during both bipedal and quadrupedal stepping (1/1 cats). Moreover, when some of the intact cats were decerebrated, LGS stimulation via the chronically implanted cuff, powerfully extended stance often for the duration of the stimulus train (3/3 cats). The effects of LGS stimulation in the decerebrate state were similar to those observed previously (Whelan et al., 1995).We conclude that the efficacy of extensor group I stimulation on the duration of stance in the walking cat is variable and depends on the preparation and the locomotor task. Interaction between Deiter's nucleus and group I input from extensor muscles during fictive locomotion in the cat. H. Leblond* and J.-P. Gossard, Centre de Recherche en Sciences Neurologiques, Dép. Physiol., Univ. de Montréal, Montréal, Québec, Canada H3C 3J7.

The load signals from extensor muscles transmitted by the group I afferent fibres are able to reset the rhythm of fictive locomotion in the cat by stopping precociously the bursts of activity in flexor muscles and by initiating bursts of activity in extensor muscles. The stimulation of Deiter's nucleus was reported to have exactly the same effect on the locomotor rhythm in cats injected with L-DOPA (Russel and Zajac 1979) suggesting that Deiter's and group I input from extensors may converge on common spinal interneurones. This convergence was tested (N=52) with the spatial facilitation technique in lumbosacral motoneurones in spinal cats (Th13 ventral quadrant intact) injected with nialamide and L-DOPA to induce late DOPA reflexes or fictive locomotion. The stimulation of group I fibres from ankle extensors (3 pulses, 1.1-2.0T, 300Hz) and of Deiter's nucleus (3 pulses, 100-200μA, 300Hz) were coupled with several different intervals and evoked excitation in all extensor motoneurones studied (N=20). In all cases, there was no signs of spatial facilitation but a simple algebraic sum of the two EPSPs. This suggests that both input act through different interneuronal pathways and that rhythm generator(s) in the spinal cord may be controlled independently by sensory and supraspinal signals. (Supported by Rick Hansen Foundation, MRC and FCAR).

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CIRCUITRY AND PATTERN GENERATION VI

BUCCAL CEREBRAL INTERNEURONS B63 AND B34 PLAY DIFFERENT ROLES DURING THE PROTRACTION PHASE OF BUCCAL MOTOR PROGRAMS IN *APLYSIA*. A.J. Susswein, I. Kupfermann*, & I. Hurwitz. Cntr. Neurobiol. & Behav. Columbia U. NY, NY 10032 & Dept. Life Sci., Bar Ilan Univ., Ramat Gan 52 900, Israel.

Neurons B63 and B34 are elements of a central pattern generator. Both neurons are active during the protraction phase of buccal motor programs (BMPs), and excite the contralateral B31/B32. Each of them has an axon that travels to the cerebral ganglia via the contralateral cerebro-buccal connective. B63 fires readily, and is active during all of the various BMPs that occur in isolated ganglia. The bilateral B63 and B31/B32 neurons form a single functional unit due to synaptic coupling. B63 is electrically coupled to the ipsilateral and contralateral B31/B32. B63 also makes a chemical excitatory synaptic connection exclusively to the contralateral B31/B32. B31/32 depolarization excites both B63 neurons and causes them to fire. Activation of this complex appears to evoke a protraction-like phase regardless of whether the program is ingestion or egestion. During spontaneous BMPs, B34 shows phasic depolarizations, but unlike B63 it often does not fire. B34 firing produces facilitating EPSP's in the contralateral B31/B32, and strongly activates B61/B62 (motoneurons which, similar to B31/B32, innervate the protractor muscle I2). In addition, B34 excites the radula closer motoneuron B8, and shifts its activation phase from retraction to protraction. Thus, activity in B63 appears to be essential for any BMP, while activity of B34 leads to amplification of radula protraction that is coupled with radula closing, a pattern characteristic of egestion. Supported by US-Israel BSF grant 93-224 and NIMH grant MH35564.

PLATEAU GENERATING CEREBRAL-BUCCAL INTERNEURONS IN *APLYSIA*. Ray Perrins* and Klaudiusz R. Weiss. Dept. Physiology & Biophysics, Mount Sinai School of Medicine, New York, NY 10029.

Four identified cerebral-buccal interneurons (CBIs) have been implicated in the control of feeding-related buccal motor programs (BMPs) in *Aplysia*. We have now characterized a further pair of CBIs, CBI-5/6 which are electrically coupled to each other and are morphologically and physiologically indistinguishable. CBI-5/6 have soma in the ventral e-cluster, at the base of the cerebral-to-buccal connective, and have an axon which arborises in each buccal hemi-ganglion. CBI-5/6 are part of the feeding circuitry since they were excited by seaweed applied to the lips and were active during feeding-related buccal motor programs (BMPs). Input to CBI-5/6 during BMPs had three main phases, recorded from the soma. Firstly a barrage of fast chemical EPSPs, secondly a barrage of axon spikes (A-spikes) arriving from the buccal ganglion, and thirdly a plateau potential. The potentials during the second phase were shown to be A-spikes since (1) they were not blocked by $0Ca^{2+}$/10mM Co^{2+} applied to the cerebral ganglion (2) they were reduced in amplitude by hyperpolarization of CBI-5/6. Since the A-spikes were obtained in isolated cerebral/buccal ganglion preparations, they were presumably generated by input to the buccal processes of CBI-5/6. During the plateau potential truncated spikes were usually recorded in the soma, so this neuron spikes both orthodromically and antidromically during BMPs. Plateau potentials in CBI-5/6 could also be generated by brief depolarizing current injections or by EPSPs resulting from firing in presynaptic neurons (e.g. the buccal-cerebral interneuron B19 and the cerebral mechanoafferent C2) and could be terminated by brief hyperpolarization. The unique properties of CBI-5/6 lead to the possibility of two modes of action. In the first mode, the A-spikes allow it participate in both buccal and cerebral events. In the second mode, the plateau potential may allow it to act locally in the cerebral ganglion by exciting other neurons via electrical coupling. (Supported by HFSP).

805.3

TWO PAIRS OF THE CEREBRAL TO BUCCAL INTERNEURONS THAT MODULATE BUCCAL MOTOR PROGRAM IN *APLYSIA* ARE MYOMODULIN PEPTIDE CONTAINING CELLS. Y.Xin*, S. C. Rosen, R.Perrins, I.Hurwitz, K.R. Weiss and I.Kupfermann. Center for Neurobiol. and Behav., Columbia. Univ., New York, NY 10032. Dept. of Physiol. and Biophysics, Mt. Sinai Med. Center, New York, NY 10128.

To search for the myomodulin-containing cerebral neurons that project to the buccal ganglion (CBIs), we used biocytin backfills of cerebral-buccal connectives combined with immunocytochemistry for myomodulin. Three bilateral neurons were double-labeled. One was a newly identified variant of CBI-2 in the M cluster (see abstract by Hurwitz et al.) . The other two neurons were the near-identical pairs of E cluster cells, previously identified as CBI 8 and CBI 9 (Xin, et al, 1995). HPLC confirmed that CBI-8/9 contain authentic myomodulin. These cells exhibit strong electrical and dye coupling and are also electrically coupled to CBI-2. Intracellular recording showed that CBI-8/9 are normally silent with no spontaneous PSPs. They were excited by firing of C-PR and electrical stimulation of buccal nerves. During programs evoked by CBI-2, CBI-8/9 fired phasically at a moderate firing rate. Firing of CBI-8/9 excited unit activity in all buccal nerves, particularly buccal nerve 3. A large number of identified buccal motor neurons were found to receive either monosynaptic or polysynaptic inputs from CBI-8/9. Neurons involved in protraction were excited, whereas those involved in retraction were inhibited. The data suggest that CBI-8/9 may not act as pattern generating neurons, but rather act as premotor neurons that shape one phase of buccal movement. Supported by NIH grants: MH35564, 36730 and GM320099.

805.4

CHOLINERGIC INPUTS CONTRIBUTE TO INTEGRATIVE ACTIONS OF COMMAND-LIKE INTERNEURONS IN THE FEEDING SYSTEM OF *APLYSIA*. **S. C. Rosen*, S. Gapon, K. R. Weiss[1] and I. Kupfermann. Cntr. Neurobiol. & Behav., NYS Psychiat. Inst., New York, NY 10032; [1]Dept. Physiol. & Biophys., Mt. Sinai Sch. of Med., New York, NY 10027.**

Strong firing of cerebral-to-buccal interneuron 2 (CBI-2) initiates a buccal motor program (BMP) that produces biting-like responses of the buccal mass. To fire strongly, CBI-2 must integrate excitatory inputs from three behaviorally relevant sources: (1) the postural arousal system orchestrated by neuron C-PR; (2) chemosensory input from the perioral zone (lips); and (3) feedback from buccal CPG interneuron, B19, which conveys mechanosensory input from the food-grasping radula. Both C-PR and B19 produce voltage dependent EPSPs in CBI-2 that might enhance synaptic inputs from other sources. To further understand the integrative actions of CBI-2, we investigated transmitter properties of neurons with input to CBI-2. The cholinergic agonist, carbachol, excites CBI-2 and drives a BMP that produces biting-like behavior. The muscarinic agonist, pilocarpine, does not excite CBI-2, but initiates a slower BMP and buccal mass movements that resemble swallowing. CBI-2 was incorporated into the swallowing-like rhythm and could phase advance or delay the BMP if stimulated or depressed. Thus, in different contexts, CBI-2 acts either as a "command" or CPG neuron. Cholinergic antagonists had no effect on inputs from B19 or the C-PR circuit, but atropine blocked CBI-2 inputs from the periphery. The results suggest that cholinergic neurons transmit chemosensory information to multiple command-like neurons that differ in their response to ACh and in their ability to modify the neuronal network underlying ingestive feeding behaviors. CEREBRAL-PEDAL REGULATOR NEURON (C-PR) OF *APLYSIA* DIFFERENTIALLY MODULATES THE EXCITABILITY OF VARIOUS KNOWN, AS WELL AS NEWLY-IDENTIFIED CEREBRAL-BUCCAL INTERNEURONS. I. Hurwitz*, S. C. Rosen, R. Perrins, K. R. Weiss, Y. Xin and I. Kupfermann . Columbia U. NY, NY 10032

Food stimuli produce excitation of neuron C-PR which evokes a complex of responses that represent the appetitive central motive state that precedes consummatory feeding movements. Consummatory feeding movements are evoked when food contacts the lips and excites cerebral-buccal interneurons (CBIs) that drive buccal motor programs or components of the programs. Previous evidence indicated that firing of C-PR produces excitatory input to CBI-2 (Teyke et al., 1989) We found that there is one other neuron in the cerebral M cluster that resembles CBI-2. Both cells drive robust buccal programs. Nevertheless, the two cells show opposite-changes in excitability when C-PR is fired: one cell receives voltage dependent EPSPs; the other, receives inhibition. Furthermore, one of the cells exhibits myomodulin immunoreactivity, and the connections of the cells to buccal CPG elements is not identical. The excitability of many of the other CBIs are also affected by firing of C-PR. Some of the neurons are affected only during the time that C-PR is active; other neurons become affected only after C-PR stops firing, and some show mixed effects. The data are consistent with the hypothesis that the CBIs comprise a small set of interneurons that are differentially activated and contribute to the variations of the numerous buccal programs that are known to exist. Supported by NIH grants: MH35564, 36730 and GM320099.

MODULATION OF THE PERIPHERAL ACTIVATION OF THE B21/B22 NEURONS IN *APLYSIA* . E.C. Cropper*[1,2], V. Alexeeva[1], C. G. Evans[2], S. C. Rosen[3], and M.W. Miller[4]. [1]Mt. Sinai Med. Schl., NY, NY 10029; [3]Columbia Univ., NY, NY 10032; [4]Univ Puerto Rico, San Juan, PR 00901.

Recent data has suggested that the feeding motor program in *Aplysia* is modified by the activity of a cluster of neurons in the buccal ganglion. This cluster, which includes the cells B21 and B22, innervates the subradula tissue. It is likely that effects of the B21/B22 cluster on the feeding motor program will depend on how these neurons are activated. Neurons B21 and B22 synthesize SCPa and SCPb, and it is commonly observed that peptide release is preferentially associated with particular patterns of neuronal activity.

Previous data has indicated that the B21/B22 neurons are sensory neurons. They are activated by two types of peripheral stimuli; by changes in the contractile state of the subradula tissue, and by mechanical stimuli applied to the food grasping portion of the radula. In this study we demonstrate that B21/B22 responsiveness to peripheral stimulation can be altered by physiologically relevant modulatory neurotransmitters; 5-HT and the SCPs. Serotonergic input to the subradula tissue originates from the MCCs; the SCPs appear to be released peripherally from the B21/B22 neurons themselves. 5-HT and the SCPs exert effects both on the contractile state of the subradula tissue and on B21/B22 responsiveness. In conclusion, it has commonly been observed that activity in sensorimotor pathways is gated to insure that responses to changes in the external environment occur in an appropriate manner. Much previous work has, however, concentrated on gating mechanisms operative in the CNS. In contrast our experiments focus on peripheral factors that influence the activation of the B21/B22 neurons.

THE PERIPHERAL ACTIVATION OF BUCCAL NEURONS IN *APLYSIA* BY CONTRACTION OF BUCCAL MASS MUSCULATURE. C.G. Evans*, S.C. Rosen and E.C. Cropper. Mt. Sinai Schl. Med. N.Y., N.Y. 10029; Ctr. Neurobio., Columbia Univ., N.Y., N.Y. 10032.

Data suggests that sensory input plays an important role in shaping feeding motor programs in gastropod molluscs. It is particularly important in controlling transitions from one phase of a movement to another and/or reinforcing ongoing motor activity. We are investigating mechanosensory feedback loops that may play this type of behavioral role in feeding in *Aplysia*. Other studies have concentrated on radula mechanoafferent neurons B21/B22.

These experiments demonstrate two things. First we show that B51, a characterised premotor neuron thought to be important in generating the buccal motor program (Plummer,Kirk 1990), additionally can function as a sensory neuron. It can be activated by contractions of muscles associated with the closing/retraction phase of feeding (eg. I4and I6). Second, we identify a new cluster of sensory neurons that can be activated in a similar manner. This cluster consists of 6-8 cells with axons in the radula nerve. Neurons of the newly identifed cluster are electrically coupled to each other, to neuron B51, and to the radula mechanoafferents B21 and B22. Like B51 and the radula mechanoafferents, newly identified sensory neurons appear to receive input from the feeding central pattern generator. Rhythmic activity is observed in isolated ganglia.

In summary, we have now characterised several types of neurons likely to provide sensory feedback to the feeding central pattern generator. Some of this feedback is likely to signal changes in the external environment. Other feedback is likely to reflect changes in the contractile state of the buccal musculature.

TEMPORAL DYNAMICS OF GRADED SYNAPTIC TRANSMISSION IN THE LOBSTER PYLORIC NETWORK, F. Nadim*, Y. Manor, L. Abbott, and E. Marder, Volen Center, Brandeis University, Waltham, MA 02254.

Graded synaptic transmission plays a critical role in the generation of the pyloric rhythm of the lobster *Panulirus interruptus*.

We studied the temporal dynamics of graded synaptic transmission in pairs of pyloric cells by voltage-clamping the presynaptic cell with a variety of waveforms applied at different frequencies. These waveforms included square pulses, sine waves, and realistic waveforms that were recorded from individual oscillatory cells and "played back" into the cells. The graded postsynaptic potentials (GPSPs) were measured in saline containing TTX, which blocks action potentials and abolishes the pyloric rhythm. We find that the amplitude and shape of pyloric GPSPs is dependent on the presynaptic waveform, baseline, amplitude, frequency, as well as the history of activity of the synapse. In response to a sequence of identical stimuli in the presynaptic cell, the amplitude of the first GPSP was larger than the subsequent ones. In one example this depression was 4 times larger for a set of stimuli applied at 1.5 Hz, in comparison to 0.75 Hz. The recovery from depression followed an exponential course with a slow (~ 500 ms) time-constant.

When we played back a realistic waveform in the presynaptic cell, and rapidly changed the frequency of oscillation, the GPSP changed rapidly, and in a nonlinear fashion. The nonlinearity is not nearly as prominent for electrical synapses, therefore it cannot be solely attributed to cable attenuation of the signal. Our observations indicate that the dynamic behavior of GPSPs is sensitive to the presynaptic waveform. In particular, the standard square-pulse paradigm does not capture the true nature of the synaptic waveform during normal oscillations.

DECODING GRADED SYNAPTIC TRANSMISSION IN THE LOBSTER PYLORIC NETWORK, K. Sen*, Y. Manor, F. Nadim, L. Abbott, and E. Marder, Volen Center, Brandeis University, Waltham, MA 02254.

Graded synaptic transmission is an essential component of the pyloric rhythm in the stomatogastric ganglion of the spiny lobster. Using traditional techniques, it is difficult to predict the postsynaptic response to an arbitrary presynaptic waveform, because the response of these synapses may be history-dependent. For example, we have found depression and other complex behaviors in some pyloric synapses. Sen et al. (1996) developed a method to specify the transfer function of a synapse, allowing the prediction of the postsynaptic response to any presynaptic spike train. We have extended this method to graded synaptic transmission by describing the input waveform as a sequence of short pulses of different amplitudes. We describe the postsynaptic response as a product of two time-dependent functions. The first function is the response to a single short pulse, scaled by a factor that depends on the amplitude of the presynaptic waveform. The second function is constructed using a learning algorithm based on input-output data, and accounts for history-dependent effects like depression.

We use a training set of short pulses of various amplitudes, separated by randomly chosen intervals, to construct the two time-dependent functions and then use these functions to predict the responses to novel presynaptic waveforms. The results reveal that at low frequencies, the postsynaptic response is well characterized by the first function, scaled by the presynaptic amplitude. At higher frequencies, for some synapses, we see the onset of depression which is characterized by the second function.

CHARACTERIZATION OF CONVERGENT MODULATION USING SYNAPTIC DECODING. J.C. Jorge-Rivera*, K.Sen, L.F.Abbott and E. Marder. Volen Center, Brandeis Univ. Waltham, MA 02254.

Modulation of muscles contributes to behavioral flexibility in invertebrates. Ten substances are known to modulate functionally antagonistic muscles (gm1 and gm4) in the stomatogastric musculature of *Cancer borealis*. We have applied the newly developed synaptic decoding method (Sen et al, 1996) which characterizes synaptic transfer to the problem of convergent modulation by multiple substances. This method yields two time-dependent functions: one describes the response to isolated spikes and the other describes changes in the response due to the history of presynaptic firing. By comparing these functions under control and modulatory conditions we quantitatively characterize the physiological effects of these modulators. We find that modulators can alter one or both time-dependent functions. For example, octopamine does not appreciably alter the response to an isolated spike, but modifies the temporal development of facilitation. In contrast, TNRNFLRFamide modifies the response to an isolated spike appreciably while having a smaller effect on facilitation. As a result, TNRNFLRFamide enhances the response to low frequency stimulation while octopamine enhances high frequency responses. In general, the effect of these modulators depends on the frequency of presynaptic spiking and multiple modulators may be required to modify responses over the entire frequency range.

A PERSISTENT SODIUM CONDUCTANCE ASSISTS PROLONGED BURST FIRING IN NEURONS OF A CHEWING RHYTHM GENERATOR IN THE LOBSTER STOMATOGASTRIC GANGLION. R.C. Elson* and A.I. Selverston Department of Biology, UCSD, La Jolla CA 92093.

Identified stomatogastric motor neurons that control tooth movements in the gastric mill of the spiny lobster, *Panulirus interruptus*, produce a burst of spikes in each cycle of the chewing rhythm. During their burst, they fire continuously throughout a prolonged depolarization (2 - 10+ s). When the circuit is quiescent, they fire tonically or are silent (but can be driven to fire repetitively by current injection). In this state, addition of 5 - 20 mM TEA to the superfusate induces regenerative, short plateau potentials (SPPs), 10 - 30 mV in amplitude and100 -1000 ms in duration. Each SPP seems to arise at, or near to, the spike-initiating zone, from an action potential that fails to repolarize fully. It drives a pattern of continuous (c. 50 Hz) or inactivating spiking in the motor axon.

SPPs persist in reduced extracellular [Ca] and in Mn or Cd, but are blocked by low extracellular [Na] and 100 nM TTX. Inward rectification, observed during depolarization to membrane potentials subthreshold for spike or SPP generation, shows the same pharmacology. We conclude that a persistent Na conductance underlies both the inward rectification and the generation of SPPs. The conductance was studied in current-camp because it is unlikely to be under good spatial control in these extended neurons (however, it can be clamped in cultured stomatogastric neurons: cf. Turrigiano et al., J. Neurosci. 15: 3640, 1995).

Low doses (1 - 40 nM) of TTX do not abolish spikes but reduce repetitive firing during imposed depolarization. They can also impair the long (2 - 10+ s) plateau potentials that sustain burst firing during rhythm generation. This suggests that the persistent Na current is important in supporting both the prolonged depolarizations and repetitive firing that characterize spontaneous rhythmical activity in these chewing motor neurons.

THE IONIC BASIS OF DOPAMINE INHIBITION OF PD NEURONS IN THE PYLORIC NETWORK OF THE LOBSTER STOMATOGASTRIC GANGLION Robert M. Levini, Jack H. Peck*, and Ronald M. Harris-Warrick, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853 and Department of Psychology, Ithaca College, Ithaca, NY 14850.

The 14 neuron pyloric network of the stomatogastric ganglion produces a triphasic rhythmic output that is the product of the synaptic connections between the members of the network and the intrinsic properties of the neurons. Dopamine (DA) alters the rhythmic output of the central pattern generator by selectively strengthening or weakening synapses and exciting or inhibiting different neurons in the network. The two PD neurons, along with the AB neuron, form the pacemaker group of the pyloric network. DA inhibits PD by hyperpolarizing it and reducing its rate of firing action potentials, which lead to a phase delay of PD relative to the AB neuron and a reduction in the pyloric cycle frequency. The hyperpolarization of PD is accompanied by a decrease in input resistance. When a brief (1sec) puff of 10^{-3}M DA is applied to an isolated, voltage clamped PD neuron a small voltage dependent outward current is evoked, accompanied by an increase in membrane conductance (33.4±10%@-40mV). The DA evoked outward current and conductance increase are occluded by the combined presence of the potassium channel blockers 4AP and TEA. These results suggest that DA modulates at least the transient potassium current, I_A, and a TEA sensitive outward current. Complete characterization of I_A in voltage clamp shows that DA causes a 3mV hyperpolarizing shift in the $V_{1/2}$ of the voltage activation curve, as well as an 8% increase in I_A maximal conductance. Since the voltage dependence of inactivation does not shift in the presence of DA, the area of overlap between the activation and inactivation curves is larger, leading to a larger tonic I_A in the region of the resting potential. We are currently analyzing the effect of DA on the TEA sensitive outward current. Supported by NIH grant NS 17323 and the Human Frontiers Science Program.

MODULATION OF THE PYLORIC RHYTHM IN THE SPINY LOBSTER: COMBINED EFFECTS OF AMINE MODULATION AND INPUTS FROM THE CARDIAC SAC NETWORK. A. Avali and R.M. Harris-Warrick*, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

The crustacean stomatogastric nervous system serves as a model for studying the mechanisms of network modulation. A number of modulatory pathways are known to affect the pyloric network in the stomatogastric ganglion of the spiny lobster. We studied the combined effect of dopamine modulation and descending inputs from another stomatogastric network, the cardiac sac network, on the pyloric rhythm. Inputs to the stomatogastric ganglion from the esophageal and commissural ganglia were kept intact. Bath application of dopamine directly and markedly changed the firing patterns of all the neurons of the pyloric circuit. The cardiac sac network activity also had a dramatic effect on all the pyloric cells, acting directly on some cells and indirectly on others. Dopamine did not affect the activity of CD_2, a cardiac sac neuron, but cardiac sac bursts markedly altered the effect of dopamine on pyloric neurons. Dopamine caused VD to switch from bifunctional, pyloric and cardiac sac, to unifunctional, cardiac sac activity only. While dopamine directly inhibited VD, VD's firing activity during the cardiac sac burst was unaffected by dopamine. Dopamine directly excited IC, but VD inhibition of IC during a cardiac sac burst caused IC to be silent both with and without dopamine. Cardiac sac inputs restored normal pyloric activity to the PD, temporarily eliminating the inhibitory effects of dopamine on these neurons. The same effect was demonstrated, indirectly, in the LP neuron.

The combination of different modulatory effects reveals another layer of complexity and plasticity in the pyloric network motor patterns, and another source of variability of small neural circuit's motor output.

MOTOR PATTERNS OF CARDIAC, GASTRIC AND PYLORIC NEURONS IN THE STOMATOGASTRIC GANGLION OF THE SHRIMP *PENAEUS*. K. Tazaki.* Biol. Lab., Nara Univ. Educ., Takabatake, Nara 630, Japan

Motor patterns of the stomatogastric ganglion neurons of the shrimp *Penaeus* were studied from a comparative perspective. This genus belongs to the most primitive decapod suborder, relative to lobsters and crabs employed extensively in the stomatogastric research. Spontaneous activity was recorded intracellularly from the neuronal somata and extracellularly from the motor nerves in semi-isolated preparations of the complete stomatogastric nervous system (STG, OG, CoGs). The pyloric pattern is most commonly active, whereas the gastric pattern, the cardiac sac pattern and the oesophageal pattern are sometimes active. All these patterns repeat with different periods, and are flexible under the influence of modulatory inputs. The pyloric and gastric motor patterns are variable also due to interactions between these networks. Some pyloric motor neurons can be active in time with the gastric rhythm or the cardiac rhythm. Many gastric motor neurons can be active in time with the pyloric rhythm. Some pyloric and gastric neurons can switch from one pattern to another. The basic principles that the pattern generator circuits are reconfigured under different conditions can apply to the stomatogastric system of the shrimp *Penaeus* despite considerable differences in the foregut structure. Since the most variable feature of the nervous system among different decapod species appears to be the neuromodulatory inputs, phylogenetic differences might occur in types of configurations. INPUTS FROM THE HEAD TO THE STOMATOGASTRIC NERVOUS SYSTEM IN THE CRAYFISH CHERAX DESTRUCTOR. H.-G. Heinzel*and D.C. Sandeman. Inst. of Zool., Univ. Bonn, D - 53115 Bonn, Germany and Biol. Sciences. Univ. New South Wales, Sydney 2052, Australia

The neural networks of the crustacean stomatogastric nervous system (STNS) and their modulation by many inputs are well studied in isolated preparations. The inputs from the brain, however, are almost completely unknown, mainly because the lack of a preparation which includes the head and the STNS.

We have developed such a preparation which includes the head capsule with its sensory organs, the brain, the esophagus with the two attached commissural and the esophageal ganglia, as well as the stomatogastric ganglion (STG) which was isolated from the stomach. Perfusing the brain with saline via the dorsal artery can keep this preparation functioning. This is demonstrated by antennal and eyestalk reflexes, rhythmic movement of the esophagus, as well as rhythmic pyloric and often gastric motor output of the STG.

Extracellular recordings from two sites of the only direct nerve connecting the brain to the STNS, the inferior ventricular nerve (ivn), revealed the activity of eight axons. Their actionpotentials can be distinguished by size, shape, and by velocity as well as by direction of their conduction. Six axons are ascending towards the brain, whereas maximally two axons descend from the brain towards the STNS. They respond to mechanical stimulation of both pairs of antennae after latencies of only 4ms. The ivn does not react to increased levels of light, which can strongly accelerate slow pyloric rhythms by lowering their period duration from values between 4 and 10 s down to 2 s. This long lasting effect is reversible and often occurs within the next pyloric cycle after the change of light.

The head-STNS preparation opens the way for an exploration, at the level of identified neurons, of behaviourally demonstrated interactions between the brain and stomatogastric system. Supported by HFSP.

DIFFERENCES IN MORPHOLOGY ARE CORRELATED WITH FUNCTION OF AGONISTIC NEURONS IN THE STOMATOGASTRIC GANGLION OF CRAYFISH. P. Eitner, H. Böhm*, H.-G. Heinzel. Inst. of Zool., Univ. Bonn, Poppelsdorfer Schloss, D - 53115 Bonn, Germany.

We investigated the activity and morphology of selected neurons in isolated preparations of the stomatogastric ganglion of crayfish, *Orconectes limosus* and *Astacus astacus*. Stainings with Lucifer Yellow revealed typical morphological features of each neuron with respect to the branching pattern of the primary neurite and the preferred location of the somata. Substantial variation was found in the insertion and arborisation of the secondary and tertiary neurites.

By projecting the neuron onto a horizontal plane, the characteristic form of the primary neurite is elucidated: The Anterior Burster neuron is W-shaped, the Lateral Pyloric neuron is U-shaped, the Ventral Dilator neuron is H-shaped,the Inferior Cardia neuron is Y-shaped, the Anterior Median neuron is X-shaped, and Cardia Dilator 2 neuron only intrudes the periphery of the neuropil. Even agonistic cells differ in morphology. The two Pyloric Dilator neurons (PD) e.g. can be clearly divided into two individuals. PD1 has a straight form, whereas the primary neurite of PD2 meanders within the neuropil. Moreover, intracellular recordings of these cells in a rhythmically active *in vitro* preparation of *Astacus astacus* have shown, that PD1 always fires more action-potentials than PD2 and preceds its electrically coupled partner during their synchronous bursts at the beginning of the pyloric cycle.

These studies indicate that probably all neurons of the stomatogastric system of crayfish are individuals with unique morphological features. Even agonistic neurons, which are often treated as undistinguishable multiples of one cell-type, are indeed individuals with distinct morphological and physiological differences, which can play a role in the fine-tuning of the networks.

DEVELOPMENTAL CHANGES IN THORACIC LEG MOTOR PATTERNS IN ISOLATED NERVE CORDS OF *MANDUCA* . R. M. Johnston* and R. B. Levine. Division of Neurobiology, University of Arizona, Tucson, AZ 85721

During metamorphosis the coordination pattern for locomotory behavior involving the prothoracic legs changes from left-right synchrony in larvae to left-right alternation in adults. Previously, we showed that pilocarpine-induced prothoracic leg motor activity in the isolated larval nerve cord displayed left-right synchrony. To determine the extent to which changes in bilateral coordination were associated with metamorphic changes in the CNS as opposed to sensory feedback, we examined the thoracic leg motor activity produced by adult isolated nerve cords. Motor activity was monitored in isolated adult nerve cords from specific nerve branches that supply the femoral levator (cx_2) and the femoral depressor (cx_1, cx_4, st_2) muscles of the prothoracic legs. In saline, bursting activity was absent. However, in the presence of the muscarinic agonist pilocarpine (2.5 x 10^{-4}M), prothoracic leg motor neurons showed patterned, rhythmical bursting activity, such that ipsilateral femoral levator activity alternated with femoral depressor activity. Furthermore, left and right sides were active in antiphase, such that left femoral levator activity alternated with right femoral levator activity. Left-right alternating activity displayed cycle-to-cycle frequency coupling between both sides of the prothoracic ganglion, with an average cycle period of 718 ± 19.6 ms, similar to walking in intact, freely moving adults. In saline or pilocarpine, ascending inputs from the pterothoracic and abdominal ganglia or descending inputs from the brain and subesophageal ganglion did not influence prothoracic leg motor activity. The pilocarpine-evoked activity was abolished reversibly by the muscarinic-receptor antagonist atropine. Thus, left-right alternating pattern of motor activity characteristic of adult behaviors, such as walking and airstepping, and never observed in larvae, can be produced by the isolated adult CNS. These data indicate that the CNS is modified during metamorphosis to accommodate changes in bilateral coordination from left-right synchrony in larvae to left-right alternation in adults. CIRCUIT MODIFICATIONS ASSOCIATED WITH RECONFIGURATION OF THE *TRITONIA* ESCAPE SWIM NETWORK BY SUBTHRESHOLD STIMULI. W.N. Frost* and P.S. Katz. Department of Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77030.

In the marine mollusc *Tritonia diomedea*, strong salt stimuli cause the transient reconfiguration of a resting neural network into a central pattern generator (CPG) circuit that drives the animal's rhythmic escape swim behavior. Previous work showed that CPG interneuron C2 displays enhanced excitability and synaptic strength for several minutes following the motor program. These effects coincide with a period of post-swim sensitization, during which swims are easier to elicit in the intact animal (lower threshold and shorter onset latency). These results raise the possibility that these changes in C2 properties are associated with the re-configuration of the resting network from its non-oscillatory to its oscillatory mode.

To further evaluate this possibility, we determined whether subthreshold stimuli might also reduce the threshold for subsequent stimuli to reconfigure the network into the swim mode, and if so, whether this would still be accompanied by an enhancement of C2 excitability. In behavioral experiments we found that an initially subthreshold salt stimulus can sensitize swim threshold. We next replicated this in the isolated brain preparation. We found that an initial weak nerve stimulus both lowered swim motor program threshold, and enhanced C2 excitability. These effects were accompanied by a long-lasting elevation in tonic firing of another CPG element, the serotonergic dorsal swim interneuron (DSI). Previous work has shown that DSI stimulation itself produces a modulatory enhancement of C2 excitability.

The fact that the enhancement of C2 excitability parallels the reduction of swim motor program threshold, irrespective of the actual occurrence of the motor program itself, supports the hypothesis that this circuit modification is associated with the reconfiguration of the *Tritonia* swim network from its resting to its CPG state.

THE DORSAL SWIM INTERNEURONS OF THE *TRITONIA* ESCAPE SWIM CPG SIGNIFICANTLY REDUCE SPIKE FREQUENCY ADAPTATION IN CPG NEURON C2: POSSIBLE ROLE IN NETWORK RECONFIGURATION. P.S. Katz* and W.N. Frost. Department of Neurobiology and Anatomy, University of Texas Medical School, Houston TX 77030.

We are examining the physiological mechanisms underlying the reconfiguration of a motor network in the nudibranch mollusc, *Tritonia diomedea*, from a non-oscillatory state into a functional central pattern generator (CPG) for the animal's escape swim response. In rested preparations, one component of the CPG, interneuron C2, exhibits strong spike frequency adaptation (SFA) that significantly reduces its ability to fire repeated bursts of action potentials in response to successive depolarizing current pulses. However, throughout the course of a swim motor program, C2 and the other CPG neurons fire repetitive bursts of action potentials at high instantaneous spike frequencies. We hypothesized that removal of SFA in C2 might be a necessary prelude to evoking a swim motor program.

Previously, we showed that, in addition to their synaptic actions, a set of serotonergic neurons intrinsic to this CPG, the dorsal swim interneurons (DSIs), cause a neuromodulatory enhancement of all synaptic connections made by C2. Here, we find an additional DSI modulatory effect: stimulation of a single DSI significantly reduces SFA in C2, thereby enhancing C2 excitability and allowing C2 to fire without a progressive decrease in frequency to successive depolarizations. DSI-induced removal of SFA also increases the slope of the sigmoidal frequency/current relationship for C2, allowing it to spike faster in response to all levels of injected current.

By essentially disabling SFA, DSI transforms C2 into a neuron more capable of firing repetitive bursts. Because repeated activation of C2 is crucial for motor pattern generation, this modulatory action may enable production of the behavior while also ensuring that the swim CPG is not activated by inputs to C2 other than the DSIs. *Supported by NIH grants NS35371 to PSK and MH48536 to WNF.*

EFFECTS OF PHOTOINACTIVATION OF GIANT NEUROPIL GLIAL CELLS ON THE ACTIVITY IN AN OSCILLATORY NETWORK IN THE LEECH. J.Schmidt* and J.W. Deitmer. Dept. of Zoology, Univ. of Kaiserslautern, D-67653 Kaiserslautern, Germany.

Each segmental ganglion of the leech contains two electrically coupled giant neuropil glial cells (NG) that arborize in the anterior and posterior part of the ganglion. The 3rd and 4th segmental ganglion (G3 and G4) respectively contain a pair of heart interneurons (HN(3) and HN(4)), each of which makes reciprocal inhibitory synapses across the ganglion, thereby forming oscillators that pace the heartbeat rhythm. HN(3) and HN(4) cells form inhibitory synapses with ipsilateral heart motor neurons (HE). Ipsilateral HN(3) and HN(4) cells fire nearly in phase through reciprocal inhibitory connections with ipsilateral HN(1) and HN(2) cells in G3 and G4 (Calabrese and Peterson, Symp Soc Exp Biol 37;195, 1983). The objective here was to study the effects of inactivation of the NGs in G3 on synapses and activity in the HN network. Intracellular recordings were made from cell bodies of neurons and NGs in G3 and G4. For inactivation an NG was filled with the dye Lucifer Yellow (LY) and irradiated (442 nm). As a result both NGs of a ganglion, which are dye coupled, depolarized irreversibly. Photoinactivation of the NGs in G3 caused disruption of the synaptic connection between HN(3) cells and between HN(3) and HE(3) cells. In isolated G3 this effect led to tonic spike discharge in HN(3) cells or silenced them. When chains of G3 and G4 were used we still observed alternate bursting of the two HN(3) cells in most preparations, although reciprocal inhibition between HN(3) cells was disrupted. However, when one connective between G3 and G4 was severed the HN(3) on that side was tonically active or silent. Thus, the coordinated rhythmic activity of HN(3) cells if interrupted in G3 by inactivation of the NGs, appears to result from their connectivity pattern with the other HN cells in G4. Indeed, the spikes recorded in the cell bodies of the HN(3) cells originated in G4. Supported by the DFG (SFB 256, TP C7).

LESIONS OF SEPTAL AREA AND THE SALIVARY SECRETION INDUCED BY PERIPHERAL INJECTION OF PILOCARPINE IN RATS. A.F. Miranda, A. Renzi, W.A. Saad*, L.A.A. Camargo and J.E.N. Silveira. Departamento de Ciências Fisiológicas, Faculdade de Odontologia, UNESP, Araraquara, SP, 14801-903, Brazil.

In the present study we compared the effect of electrolytic lesion of the septal area (SA) with the effect of the lesion restricted in the medial septal area (MSA) in the increase of the salivary secretion induced by intraperitoneal (IP) injection of pilocarpine (PIL). Rats were submitted a SA lesion (2 mA x 20 s) or a MSA lesion (2 mA x 10 s). One day, five and fifteen days after the sham (S) or electrolytic lesions (L) rats were anesthetized with uretane and the salivary fluxe was measured by pre-weighed cotton balls inserted in the mouth. Salivary secretion after IP injection of pilocarpine is presented in the table.

Days after lesion	SHAM-SA	L-SA	SHAM-MSA	L-MSA

EVOKED SYNAPTIC RESPONSES OF RAT MEDIAL SEPTUM/ DIAGONAL BAND NEURONS. S.K. Norris, Z. Henderson and K. Appenteng (SPON: Brain Research Association). Dept. of Physiology, University of Leeds, Leeds LS2 9NQ, U.K.

To study local interactions between cholinergic and non-cholinergic neurons in the medial septum/diagonal band complex (MS/DB) we have used whole-cell recordings from MS/DB neurons together with fornical stimulation to characterize evoked synaptic responses *in vitro*. Recordings were made at 25°C from 500 μm thick longitudinal brain slices from 21 day old rats. A concentric bipolar electrode for extracellular stimulation was placed in the dorsal fornix 3–5 mm from the recording position.

Application of a single shock (0.2 ms, 10–60 V) to the fornix evoked graded postsynaptic potentials (53% of neurons; latency 4–20 ms) or all-or-nothing antidromic spikes (41% of neurons; latency <1.5 ms) in recorded MS/DB neurons. EPSPs were characterized by their sensitivity to blockade by CNQX (1–10 μM) and their greater amplitude at hyperpolarised membrane potentials. IPSP amplitudes were reduced by bicuculline (1–10 μM), and were reduced or reversed polarity at hyperpolarised membrane potentials. Frequently EPSP/IPSP complexes and polysynaptic EPSPs were observed. Large EPSPs could reach threshold for action potential generation. Failures of either the EPSP or IPSP were seen in most cells.

These results suggest that glutamate or GABA can be released in the MS/DB following activation of (i) axons projecting from the hippocampus, (ii) septohippocampal axon collaterals or (iii) MS/DB interneurons.

MORPHOLOGY AND EVOKED RESPONSES OF ELECTROPHYSIOLOGICALLY IDENTIFIED MEDIAL SEPTAL NEURONS *IN VITRO*. E. Brazhnik*, M. Stewart and S.E. Fox SUNY Health Sci. Ctr., Brooklyn, NY, 11203.

Rhythmic bursting activity in the medial septal nucleus and nucleus of diagonal band of Broca (MS/DB), that paces the hippocampal theta rhythm, is highly dependent on brainstem and diencephalic ascending influences. Cholinergic and GABAergic septohippocampal neurons (SHNs) were found *in vitro* to have distinct electrophysiological properties (Matthews & Griffith, 1986; Griffith 1988). Cholinergic SHNs have prolonged spikes and slow afterhyperpolarizations (AHPs). GABAergic SHNs have brief spikes followed by fast AHPs.

Intracellular recordings were taken from MS/DB neurons in 400 μm coronal slices, using microelectrodes filled with 2% biocytin in 2 mM potassium acetate. We studied the electrophysiological and morphological properties of MS/DB neurons, including their responses to stimulation of the base of the septum (0.1 ms square pulses, intensity 20-900 μA).

We found that the population of long-spike, slow-AHP cells (n = 18) consisted of at least two subtypes: large multipolar neurons (25-35 μm in dia., heavily stained, with thick dendritic branches, n = 3) and small oval or fusiform cells (10-15 μm in dia., usually bipolar with a few long, thin branched dendrites, n = 4). The large subtype are likely cholinergic SHNs; the small may be interneurons. The brief-spike, fast-AHP cells (n = 7), were medium in size (15-20 μm) and triangular or multipolar in shape with irregular branching thin dendrites. This morphology is consistent with that of GABAergic SHNs. Neurons of both types responded to stimulation of the base of the septum (10 of 12), usually with a short-latency EPSP evoking a single spike at the higher intensities (n = 8).

The results suggest that both cholinergic (long-spike, slow-AHP) and GABAergic (brief-spike, fast-AHP) MS/DB cells receive powerful synaptic inputs that may originate in the brainstem reticular formation. *Supported by NIH grant NS17095.*

IDENTIFICATION AND RECONSTRUCTION OF SUBFIELDS IN THE RAT MEDIAL AND LATERAL HABENULAR NUCLEI. K.-H. Andres[1], and R.W. Veh*[2]. [1]Inst. für Anatomie, Ruhr-Universität, D-46045 Bochum and [2]Inst. für Anatomie der Charité, D-10098 Berlin

The habenular complex is a phylogenetically constant structure in the diencephalon of all vertebrates. Apparently it is engaged in a variety of physiological mechanisms such as central pain processing, reproductive behaviors, nutrition, sleep-waking-cycles, stress responses, and learning. Based on Nissl-stained sections in the rat one medial and two lateral nuclei have been recognized. A considerably more complex subnuclear structure is suggested from cytochemical, hodological, and functional studies.

To gain further insight into the subcomposition of the habenular nuclei, we have systematically investigated the fine and ultrastructure of this area in the rat. Predominantly based on the morphological analysis of the neurpil at the semithin section level, criteria were developed to identify five subfields in the medial and nine in the lateral habenular nucleus. With the aid of complete series of semithin sections through the rat diencephalon and mesencephalon, all 16 subnuclei were reconstructed, their dimensions determined, and their topographical relationships with respect to the different habenular subnuclei as well as to the neighboring thalamic nuclei identified and demonstrated. The new understanding of the subnuclear organization of the habenular complex may facilitate further functional investigations.

THE CONNECTIONS OF THE PERIRHINAL CORTEX IN THE RAT: A BIOTINYLATED DEXTRAN AMINE (BDA) STUDY. D.-H. Wang[1] O. Isacson[2*] and T. Deacon[2,3] Biological Anthropology, Harvard University, Cambridge, MA 02138[1] Neuroregeneration Lab, McLean Hospital, Belmont, MA 02178[2] Biological Anthropology, Boston University, Boston, MA 02115[3]

In the mammalian brain, the rhinal sulcus (RS) is consistently located between isocortex and allocortex and is distinguishable from surrounding cortex by its cytoarchitecture and low myelin content. It has been argued that this area functions as a bridge in the information flow from the neocortex to the entorhinal cortex, which is the major source of afferents to the dentate gyrus and other parts of the hippocampus. Recently, it was reported that the perirhinal region provides direct projections to the dentate gyrus. These data suggested that the perirhinal cortex may simply be part of the lateral entorhinal cortex. In order to more precisely characterize this cortical region we have traced connections to and from the perirhinal region using iontophoretically injected BDA (biotinylated dextran amine) in Long Evans Rats. When tracer injections included the fundus and ventral bank of the RS, dense axonal labeling was found in layer I of the dentate gyrus, the subiculum, and the CA fields. When tracer injection was limited to the dorsal bank of the posterior RS, however, labeling was found to include CA and subicular fields but not the dentate gyrus. The major route of these projections was through the forceps major of the posterior corpus callosum. When BDA was placed in a number of major areas of the neocortex, labeling in the perirhinal region seldom extended beyond the ventral bank of RS into the entorhinal cortex. These distinctive connectional patterns distinguish it from the classic entorhinal cortex and argue for retaining this terminological distinction. INTERACTION BETWEEN GABA AND EXCITATORY AMINO ACID RECEPTORS IN THE REGULATION OF ANXIETY BY THE BASOLATERAL AMYGDALA. T.J. Sajdyk* and A. Shekhar, Department of Psychiatry, Indiana University Medical Center, Indianapolis, IN 46202.

Blockade of $GABA_A$ receptors in the region of the anterior basolateral amygdala (BLA) with bicuclline methiodide (BMI) results in an increase in heart rate (HR), blood pressure (BP) and 'anxiety' in male Wistar rats. The purpose of this study was to investigate the interaction between GABAergic inhibition and glutamatergic excitation in the BLA. All rats were anesthetized with pentobarbitol and then implanted with femoral arterial catheters and chronic microinjection cannulae bilaterally into the BLA. Animals were injected with either artificial cerebrospinal fluid (a-CSF, 100 nl), BMI (20 pmol/100 nl), or BMI+one dose of an excitatory amino acid antagonist. Antagonists of both the N-methyl-d-aspartate (NMDA) receptor (AP5 and MK-801) or the non-NMDA receptor (CNQX and GYKI52466) were utilized. After 3 days of recovery, intracranial injections were given on experimental days 1, 3 and 5, with all animals receiving the three injections in a balanced design. The increases in HR, BP and 'anxiety' observed in rats after BMI injections into the BLA were blocked in a dose dependent manner with the concurrent injection of either NMDA or non-NMDA antagonists. These results suggest that there may exist a balance between GABAergic inhibition and glutamatergic excitation within the BLA that plays an important role in the regulation of physiological and behavioral components of anxiety in rats (Supported by MH52619, AAMHRE and IUMC Biomedical grants).

PROJECTIONS FROM THE LATERAL PART OF THE CENTRAL NUCLEUS OF THE AMYGDALA: A PHAL STUDY IN THE RAT G. D. Petrovich* and L.W. Swanson NIBS Program and Dept. of Biol. Sci., USC, Los Angeles, CA 90089-2520

A long history of anatomical, physiological, and behavioral studies provides strong evidence that the central amygdalar nucleus is involved in visceral functions important for the expression of affect (e.g., fear).

The central nucleus has at least three anatomically distinct parts (medial, lateral and capsular) that most likely differentially contribute to its functions. The lateral part of the central amygdalar nucleus (CEAl) receives a direct input from the insular cortex and its neurons are distinct from the rest of the central nucleus, and the amygdala, because they express a large variety of neuropeptides including CRH, NT, ENK, and SS. CRH has been implicated in stress, anxiety and the expression of conditioned fear, and neurons in the CEAl were shown to respond to stress and increased corticosterone levels by increases in CRH peptide and CRH mRNA, respectively. Thus, we decided to examine the projections from this cell group in the rat using PHAL as an anterograde tracer.

Our results suggest a uniquely simple pattern of axonal projections from the CEAl. Within the amygdala the CEAl heavily innervates the medial part and lightly the capsular part of the central nucleus, and densely the rest of the CEAl itself. Other parts of the amygdala are completely avoided by the axons from the CEAl.

Extraamygdalar projections from the CEAl can be divided into ascending and descending components. The former end in the substantia innominata and bed nuclei of the stria terminalis, where the CEAl heavily innervates specifically the oval and fusiform nuclei. Descending projections from the CEAl end mainly in the parabrachial nucleus, where they heavily innervate the lateral region--including the external lateral, central lateral, and to a lesser extent external medial and ventral lateral parts. Considerably fewer axons from the CEAl reach the medial region of the parabrachial nucleus, especially the dorsocaudal ("the waist") area.

The results of our study will be discussed in terms of anatomical circuitry involving the CEAl. Furthermore, the place of the CEAl in the organization of the central nucleus, and the amygdala as a whole, will be suggested.

EFFERENT PROJECTIONS OF THE CENTRAL NUCLEUS OF THE AMYGDALA (CNA) TO DENDRITES IN THE PERI-LOCUS COERULEUS (LC) AREA. E. Veznedaroglu*, E.J. Van Bockstaele, R.J. Valentino#, and V.M. Pickel Dept. of Neurol. and Neurosci., Cornell Univ. Med. Coll., NY, NY, 10021; # Dept. of Psychiatry, Hahnemann Univ., Phila., PA., 19102.

Light microscopic tract-tracing studies indicate that CNA neurons project to a region of the dorsal pontine tegmentum which contains noradrenergic dendrites of the LC. To determine whether CNA efferent terminals target LC dendrites in this region, we combined peroxidase labeling of biotinylated dextran amine (BDA) from the CNA with gold-silver labeling of tyrosine hydroxylase (TH) in adult rats. By light microscopy, BDA-labeled processes were dense in the dorsal pons within the parabrachial nuclei and in the peri-LC where they overlapped with TH-labeled processes. By electron microscopy, anterogradely labeled axon terminals contained small, clear as well as some large dense core vesicles and were commonly apposed to astrocytic processes. BDA-labeled axon terminals often formed symmetric type synapses characteristic of inhibitory transmitters with unlabeled dendrites. Of 250 BDA-labeled axon terminals, 19% contacted TH-labeled dendrites. CNA efferents were also often apposed to other unlabeled axon terminals suggesting sites for presynaptic modulation of other afferents. Retrograde tracing combined with corticotropin releasing factor (CRF) immunocytochemistry revealed that many CRF/CNA neurons were retrogradely labeled from the peri-LC. These results demonstrate that amygdaloid efferents may directly modulate the activity of LC dendrites as well as non-catecholaminergic neurons in the peri-LC area. Furthermore, these data suggest that CRF is a potential neuromodulator in this pathway. Amygdaloid regulation of noradrenergic activity may integrate behavioral and visceral responses to threatening stimuli by influencing the widespread noradrenergic projections from the LC. SYNAPTIC ORGANIZATION OF PARVALBUMIN-IMMUNOREACTIVE NEURONES IN THE LATERAL AND BASOLATERAL AMYGDALOID NUCLEI IN THE CAT. J.-F. Paré[1], Y. Smith[1], D. Paré[2] and M. Filion[1]*. [1]Ctr. Recherche Neurobiol. and [2]Dept. de Physiol., Univ. Laval, Québec, Canada.

Parvalbumin (PV) has been localized in different types of aspiny interneurones in the amygdaloid complex. In order to understand better the organization of the intrinsic inhibitory circuitry of the amygdala, we analysed the synaptic organization of PV-positive neurones in the lateral (L) and basolateral (BL) in the cat.

In the light microscope, large- and small-sized PV-immunoreactive neurones lay in a rich network of immunoreactive fibres and terminals in the L and the BL. At the electron microscopic level, the immunoreactivity was confined to perikarya, dendrites and terminals. Overall, the distribution and ultrastructural features of boutons in contact with PV-immunoreactive neurones was quite similar in both amygdaloid nuclei. The majority were small-sized (0.5-1.5 µm), and formed asymmetric synapses mainly with the distal dendrites, but also with the perikarya and proximal dendrites of PV-immunoreactive neurones. A few symmetric axo-somatic and axo-dendritic synapses were also encountered. In the L, the initial axonal segment of small-sized neurones received asymmetric synaptic inputs. Dendro-dendritic synapses were also found on the same type of neurones. In both nuclei, most of the PV-immunoreactive boutons formed symmetric synapses with the proximal part of the neurones, though the proportion of axo-somatic synapses was significantly higher in the L than in the BL (37% vs 16%). The reverse was true for the contacts with proximal dendrites (36% in L vs 53% in BL). The remaining terminals formed synapses with distal dendrites (15-20%) and spines (5-8%). In a few cases, the post-synaptic targets were immunoreactive for PV.

In conclusion, our findings show: (1) that the PV-immunoreactive interneurones are the targets of massive excitatory synaptic inputs and (2) that the PV-immunoreactive terminals are strategically located to subserve a powerful inhibitory control on amygdaloid neurones. *Supported by the MRC and FRSQ*

AMYGDALOID CENTRAL NUCLEUS NEURONAL ACTIVITY: CORRELATIONS WITH EEG AROUSAL. B.S. Kapp*, A. J. Silvestri and F. A. Guarraci. Dept. of Psychology, University of Vermont, Burlington, VT 05405.

We have reported that the activity of putative cholinergic neurons within the substantia innominata (SI) correlates with the level of arousal as reflected in the EEG (Whalen, Kapp and Pascoe, 1994). Of significance was the finding that a subpopulation of these neurons demonstrated firing characteristics similar to neurons within the amygdaloid central nucleus (ACe; Pascoe and Kapp, 1986); that is, low spontaneous rates (<1Hz) and sensory responsiveness. The present research was conducted to determine if the activity of ACe neurons also correlates with the state of EEG arousal.

New Zealand rabbits were prepared for the recording of single neurons from the ACe and frontal cortex EEG. Neurons with low spontaneous rates were isolated and their response to novel auditory stimuli was assessed. The results demonstrated that the spontaneous activity of a population of ACe neurons was negatively correlated with the power of delta (1-4Hz) in the EEG; the greater the delta, the less the activity. Spontaneous rates ranged from 0.1 Hz during periods of delta to 3.4Hz during periods of low voltage fast activity (LVFA). These neurons responded with a short latency (< 100 msec) excitation to auditory stimuli which outlasted the duration of the stimulus. Lower rates of spontaneous discharge returned as the LVFA elicited by the stimulus gradually yielded to higher amplitude delta following the stimulus.

In conclusion, the activity of ACe neurons correlates with the degree of arousal as reflected in the EEG. Further, the results suggest that a population of neurons with characteristics similar to ACe neurons is located within the SI and represents neurons of the extended ACe which are distributed rostromedially through the SI. COMPARISON OF GRANULAR ARGYROPHILIC NEURONS AND VARIOUS NEUROTRANSMITTERS IN THE EXTENDED AMYGDALA OF OLD AND NEW WORLD MONKEYS J.S. de Olmos[1], G.F. Alheid[2], H. Ferreyra Moyano*[1],J. Marksteiner[3] and L. Heimer[4] Ferreyra Institute (INIMEC)[1],Cordoba, Argentina[1], Depts. Psychiat. Med.[2], Otolaryngology[4], and Neurosurgery[4], Univ. Va., Charlottesville, Va.22908, Neurochem. Unit, Psychiatry, Innsbruck, Austria[3].

Specific homologous areas of normal brains of several vertebrate species (toad, turtle, rat, rabbit, cat etc.) are characterized by nervous elements with particular morphological and staining qualities: Knoche's (1958 Z. Zellforsch.,48:602) granular argyrophilic neurons (ARGN) and neuropil. These terms derive from a heavy, black granular deposition of reduced silver into their cell bodies and processes, which sharply contrasts with "unstained" perikarya and processes of ordinary neurons. This is readily demonstrated by the cupric silver method (e.g de Olmos et al., 1994) applied to appropriately fixed frozen brain sections. The main structure identified by this procedure is the central division of extended amygdala (e.g. de Olmos et al, 1985; Alheid et al., 1995; Rat Nervous System, Paxinos, ed).

By applying this procedure to brains of old world (Macaque) and new world monkeys (squirrel and marmoset), it has been possible to confirm previous findings on the distribution of perikarya and axons terminals of ARGN in the extended amygdala of lower mammalian forms and compare them with the distributions pattern of perikarya and neuropil generated by neurons displaying immunoreactivity for substance P, met-enkephalin, angiotensin II, secretoneurin and GAD. None of these or other known markers coincides entirely with the silver neronal labeling. Additional species differences in the organization of these elements within the extended amygdala, as well as in the circumventricular organs (subfornical and lamina terminalis organs), hypothalamus, median eminence and other brain regions are evident and discussed. Supported by CONICET (Argentina), SFB F 00206 (Austria), and USPHS grants NS-17743 (LH), GM27739 (RRM).

AFFERENTS TO THE INTERSTITIAL NUCLEUS OF THE POSTERIOR LIMB OF THE ANTERIOR COMMISSURE: EVIDENCE FOR A NOVEL COMPONENT OF THE EXTENDED AMYGDALA. S. J. Shammah-Lagnado*[1], G. F. Alheid[2], C. A. Beltramino[3] and L. Heimer[2]. *[1]Univ. of São Paulo, Inst. Biomed. Sci., São Paulo, Brazil, [2]Univ. of VA Sch. of Med., Charlottesville, VA 22908, [3]Instituto de Investigación Medica M.Y.M. Ferreyra, Córdoba, Argentina.

The interstitial nucleus of the posterior limb of the anterior commissure (IPAC) is, like the striatum, rich in tyrosine hydroxylase, but also displays features that are typical of the extended amygdala. Caudally, it merges with the amygdalostriatal transition areas (AStr). Iontophoretic deposits of cholera toxin subunit b (CTb) were placed in IPAC, central amygdaloid nucleus (CeA), AStr and adjacent striatopallidal area. IPAC receives afferents from the central extended amygdala and from several other structures that send major projections to the CeA, including the insular and amygdalopiriform transition areas, posterior basolateral, basomedial and anterior cortical amygdaloid nuclei, midline thalamus, lateral hypothalamus, nigral complex and parabrachial area. Other substantial inputs to IPAC arise from the prelimbic, infralimbic, perirhinal and entorhinal areas, ventral subiculum, anterior basolateral and intercalated cells of the amygdala. After CTb injections in the ventrocaudal globus pallidus, retrograde labeling is observed in the AStr but not in IPAC. Our data also indicate that the AStr shares many of the caudate-putamen input sources. However, while amygdaloid afferents to the caudate-putamen originate primarily from the basolateral amygdaloid nucleus, amygdaloid inputs to the AStr arise from the basolateral, lateral, basomedial and medial (anteroventral part) nuclei. Taken together, our results reinforce the different nature of IPAC and AStr; the former is intimately associated to the central division of the extended amygdala and the latter to the striatal system. Supported by FAPESP 94/0387-0, CNPq 303265/84 and USPHS grant NS-17743.

806.13

EFFERENT PROJECTIONS OF A DOPAMINE-RICH LATERAL WING OF THE RAT EXTENDED AMYGDALA. G.F. Alheid[1], S.J. Shammah-Lagnado[2], C.A. Beltramino[3], M. Yang[4], R.R. Miselis[5], J.S. de Olmos[5], and Lennart Heimer*[6]. Depts. Psychiatric Med.[1], Otolaryngology[6], and Neurosurgery[6], Univ. Virginia Health Sciences Center,. Charlottesville, Va. 22908. Dept. Physiology[2], Univ. Sao Paulo, Brazil, Dept. Psychology[3], University of Cordoba, and Ferreyra Institute (INIMEC)[3,5], Cordoba, Argentina; and Dept. Animal Biology[4], Univ. Pennsylvania, Phil. Pa. 19104.

The term, "interstitial nucleus of the posterior limb of the anterior commissure " (IPAC) describes a zone along the posterior limb that is very rich in both tyrosine hydroxylase and acetylcholinesterase, but on the basis of most other histochemical and retrograde labeling data appears to be related to the central division of extended amygdala (e.g. Alheid et al., 1995 in Paxinos, The Rat Nervous System.). Small PHA-L injections targeted for IPAC were made to compare the efferents of this structure with striatum or with elements of the extended amygdala. PHA-L deposits in IPAC result in anterograde labeling very similar to that seen after PHA-L injections in the central nucleus of the amygdala, including prominent associative connections to other portions of IPAC. In short, IPAC targets the bed nucleus of the stria terminalis, sublenticular extended amygdala, central nucleus of the amygdala, lateral hypothalamus, retrorubral area, mesopontine tegmentum, central gray, parabrachial nucleus, nucleus of the solitary tract, dorsal vagal nucleus and adjacent parvocellular reticular formation. Injections of retrograde tracers in efferent targets of IPAC retrogradely label cells in IPAC and not in the adjacent striatum, and this observation is reinforced by retrograde transynaptic viral labeling of IPAC by pseudorabies viral injections in the stomach and esophagus that labels the extended amygdala, including IPAC, but not the striatum. Injections just dorsal or lateral to IPAC project in a manner typical for striatum. Supported by FAPESP 94/0387-0, CNPq 303265/84 (Brazil), CONICET (Argentina), and USPHS grants NS-17743 (LH), GM27739 (RRM).

PERIPALLIDAL PORTIONS OF THE EXTENDED AMYGDALA IN THE RAT: THE SUPRACAPSULAR AND MARGINAL ZONES. Gore, P[1]., G.F. Alheid*[2], S.J. Shammah-Lagnado[3], C.A. Beltramino[4], M. Yang[5], J. Marksteiner[6], R.R. Miselis[5], J.S. de Olmos[7], and Lennart Heimer[8]. Depts. Otolaryngology[1,8], and Neurosurgery[8], Psychiatric Med.[2], Univ. Virginia Health Sciences Center,. Charlottesville, Va. 22908. Dept. Physiology[3], Univ. São Paulo, Brazil, Dept. Psychology[4], University of Cordoba, and Ferreyra Institute (INIMEC)[4,7], Cordoba, Argentina, Dept. Animal Biology[5], Univ. Pennsylvania, Phil. Pa. 19104, and University of Innsbruck, Austria.

The extended amygdala designates a continuous territory encompassing the bed nucleus of the stria terminalis, central and medial amygdaloid nuclei, as well as interconnecting cell columns that traverse the area below the dorsal pallidum. Also included are path neurons accompanying the stria terminalis referred to as the supracapsular bed nucleus of the stria terminalis (BSTS). Histochemical features in boundary areas adjacent to the rat dorsal pallidum, that distinguish the "marginal zone" (Mz) from striatum (Shu et al., 1988), generally seem to be similar to the histochemical features identifying extended amygdala. Immunohistochemical labeling for MAP2 indicates that the lateral pocket of BSTS is a nearly continuous column of cells, that is interrupted only briefly at the caudal portion of the stria terminalis. Immunohistochemistry for angiotensin II or secretoneurin densely labels BSTS as well as Mz. Retrograde labeling from the area of the pedunculopontine tegmental nucleus labels neurons in lateral BSTS and in Mz; the lateral BSTS and caudal Mz may also be retrogradely labeled with viral transsynaptic labeling from the stomach. Retrograde labeling from the medial hypothalamus labels scattered neurons in the medial portions of BSTS but does not label Mz. These data suggest that Mz, like BSTS, may represent path neurons of the central division of extended amygdala. Supported by FAPESP 94/0387-0, CNPq 303265/84 (Brazil), CONICET (Argentina), SFB F 00206 (Austria), and USPHS grants NS-17743 (LH), GM27739 (RRM).

806.15

INTRINSIC CONNECTIONS OF THE RAT AMYGDALOID COMPLEX: PROJECTIONS ORIGINATING IN THE CENTRAL NUCLEUS. E. Jolkkonen*[1,2] and A. Pitkänen[2]. [1]Department of Neurology and [2]A.I.Virtanen Institute, University of Kuopio, P.O.Box 1627, FIN- 70211 Kuopio, Finland.

The central nucleus of the amygdala receives inputs from the deep amygdaloid nuclei and conveys information to the brainstem and hypothalamus to elicit the autonomic responses associated, for example, with fear or stress behaviours. The inputs to the central nucleus are topographically organized and terminate in its different divisions. In order to study, how the central nucleus may integrate information entering its various portions, we iontophoretically injected anterograde tracer PHA-L (*Phaseolus vulgaris* leucoagglutin) into all divisions of the central nucleus of 20 rats. After immunohistochemical processing, the distribution of labeled fibers and terminals in the central nucleus as well as in the other amygdaloid nuclei was analyzed. Our cytoarchitectonic, chemoarchitectonic and connectional observations suggest that the central nucleus has four subdivisions: capsular, lateral, intermediate and medial. The capsular division has moderate reciprocal connections with the medial division. The lateral division projects to the capsular and medial divisions. The intermediate division does not project the other divisions of the central nucleus. The capsular and medial divisions also project lightly to the parvicellular division of the basal nucleus. Our findings suggest that (1) the central nucleus has very few intra-amygdaloid connections and (2) the central nucleus can integrate the information entering its various portions via topographically organized intranuclear connections.

806.16

PROJECTIONS FROM THE LATERAL NUCLEUS OF THE AMYGDALA TO THE ENTORHINAL CORTEX IN RAT. M. Miettinen*, V. Savander[1,2], and A. Pitkänen.[1] A.I. Virtanen Institute[1] and Department of Neurology[2], University of Kuopio, P.O. Box 1627, FIN-70 211 Kuopio, Finland.

The amygdala and hippocampal formation are part of the temporal lobe circuitries involved in seizure generation in temporal lobe epilepsy. It is known that the amygdala sends many more projections to the hippocampal formation than *vice versa*. However, relatively little is known about the topography of these connections. In this study, the anterograde tracer, *Phaseolus-vulgaris* leucoagglutinin, was injected into the medial, dorsolateral or ventrolateral divisions of the lateral nucleus of 17 rats. After immunohistochemical processing, the distribution of labeled terminals was analyzed in different subfields of the entorhinal cortex. The heaviest projections originated in the medial and ventrolateral divisions of the lateral nucleus. In the entorhinal cortex, the highest density of labeled terminals was found in the ventral intermediate and dorsal intermediate entorhinal subfields. A substantially lighter projection was found in the medial entorhinal subfield and in the amygdalo-entorhinal transitional field. Most of the labeled terminals were located in layer III. Our data suggest that (1) only selective regions of the lateral nucleus send projections to the entorhinal cortex and (2) the projections from the lateral nucleus to the entorhinal cortex are topographically organized. Via these connections the amygdala may modulate the entorhinal outputs to the hippocampus as well as to the other cortical and subcortical regions.

806.17

PROJECTION FROM THE LATERAL NUCLEUS TO THE BASAL NUCLEUS MAKES SYNAPTIC CONTACTS WITH SOMATOSTATIN IMMUNOREACTIVE NEURONS IN THE RAT AMYGDALA. [1,2]Vesa Savander*, [2]Riitta Miettinen and [1]Asla Pitkänen, [1]A. I. Virtanen Institute and [2]Department of Neurology, University of Kuopio, P.O.Box 1627, FIN-70211 Kuopio, Finland.

Recent connectional studies have shown that each of the amygdaloid nuclei have topographically organized intra-amygdaloid connections. As a part of our ongoing efforts aimed at further elucidating these circuits and their neuronal targets we examined whether the projection from the lateral nucleus to the basal nucleus terminates on somatostatin immunoreactive (ir) neurons, a subpopulation of inhibitory GABAergic neurons in the rat amygdala. To address this issue we injected *Phaseolus vulgaris* leucoagglutinin (PHA-L), an anterograde axonal tracer, into the lateral nucleus and peformed double-labeling with antibodies against PHA-L and somatostatin. We found that the projection from the lateral nucleus to the basal nucleus made contacts on somatostatin-ir neuronal profiles. The electron microscopic analysis revealed that the synaptic contacts were symmetric, and formed mainly on somata of the somatostatin-ir neurons. These findings suggest that the projection on the somatostatin-ir neurons is inhibitory. Consequently, the lateral nucleus may be able to pursue disinhibitory control over the neuronal activity in the basal nucleus.

INHIBITORY SYNAPSES IN THE HUMAN AMYGDALA: CALRETININ-IMMUNOREACTIVE CELLS MAKE SYNAPSES ON CALBINDIN-D28K-IMMUNOREACTIVE CELLS. A. Pitkänen[1], H. Sorvari[2], R. Miettinen[2]*, and H. Soininen[3]. [1]A.I. Virtanen Institute and [2]Department of Neurology, University of Kuopio, PO Box 1627, and [3]Department of Neurology, University Hospital, PO Box 1777, FIN-70 211 Kuopio, Finland.

The amygdala is known to be essential in mediating the somatic and autonomic responses to sensory stimuli. The lateral nucleus is the first relay station of sensory input in the amygdala. However, the processing of the information in the lateral nucleus is still largely unknown. Three calcium-binding proteins, calbindin-D28k (calbindin), calretinin and parvalbumin are shown to localize in different subpopulations of amygdaloid inhibitory neurons. In the present study, we investigated electron microscopically calbindin- and calretinin-immunoreactive (ir) neurons in the lateral nucleus of the human amygdala. We found that calretinin-ir neurons make symmetric synapses on the somata and proximal dendrites of calbindin-ir neurons. This suggests that calretinin-ir neurons possess disinhibitory control over the calbindin-ir neurons. As a result, calretinin-ir neurons may participate in the synchronization of the electrical activity of calbindin-ir neurons. This, in turn, may have a significant effect on the processing of incoming sensory information in the human amygdala.

INHIBITORY SYNAPSES IN THE HUMAN AMYGDALA: PARVALBUMIN-IMMUNOREACTIVE CHANDELIER AND BASKET CELLS MAKE SYNAPSES ON PYRAMIDAL CELLS. H. Sorvari[1]*, R. Miettinen[1], H. Soininen[2] and A. Pitkänen[3]. [1]Department of Neurology and [3]A.I. Virtanen Institute, University of Kuopio, PO Box 1627, and [2]Department of Neurology, University Hospital, PO Box 1777, FIN-70 211 Kuopio, Finland.

The amygdala is involved in the generation of behavioral responses to sensory stimuli. Sensory input first activates the neurons in the lateral nucleus of the amygdala. The information is then conveyed to the basal nucleus and other amygdaloid regions. We investigated the inhibitory circuitries that regulate the neuronal activity in the early phases of information processing in the human amygdala. We examined the postsynaptic targets of parvalbumin-immunoreactive (ir) axon terminals in the lateral and basal nuclei of the human amygdala with correlated light and electron microscopy. Parvalbumin-ir terminals made two typical axonal formations: cartridges and baskets. The cartridges made symmetric synaptic contacts on the axon initial segments of the pyramidal cells, which suggests that cartridges are the terminals of GABAergic inhibitory chandelier cells. Over 90% of the cartridges counted were located in the lateral division of the lateral nucleus. The baskets established symmetric synaptic contacts on the pyramidal cell somata and proximal dendrites, which suggests that they are axon terminals of GABAergic inhibitory basket cells. Over 80% of the baskets counted were located in the magnocellular and intermediate divisions of the basal nucleus. Our data suggest that parvalbumin-ir chandelier and basket cells have a crucial role in the control of pyramidal cell responses to sensory stimuli in the human amygdala. Consequently, impaired function of parvalbumin-ir neurons may result in uncontrolled firing of pyramidal cells which facilitates the generation of abnormal behavioral responses to external stimuli in pathological conditions, such as human anxiety disorders or epilepsy.

CHANGES IN ADULT BRAIN AND BEHAVIOR CAUSED BY NEONATAL AMYGDALA DAMAGE: IMPLICATIONS FOR THE ETIOLOGY IN SCHIZOPHRENIA. F. M. Barrington*, M. P. Weisend, and R. J. Sutherland. Depts. of Psych. & Physiol., Univ. of New Mexico, Albuquerque NM 87131.

Schizophrenia may result from early specific brain damage which adversely affects maturation in other structures. There is a recent MRI study done with very young schizophrenics that found abnormalities only in the amygdala (Hendren et al., 1996). Our study addresses the possibility that an early amygdala lesion represents the specific damage causing abnormal maturation of anatomically related structures. Structures affected in schizophrenia include the hippocampus, prefrontal cortex, and forebrain dopamine systems. We addressed these issues by assessing adult brain morphology, drug response, and specific cognitive processes in rats that received stereotaxic, electrolytic lesions of amygdala 48 hr after birth. A variety of well-established, morphologically-based behavioral tasks that depend upon the integrity of the hippocampus, amygdala, or prefrontal cortex, and a dopamine-sensitive task were administered. The tasks include place navigation, contextual fear conditioning, gustatory neophobia, delayed-nonmatching-to-sample, and apomorphine-induced locomotion. This study contributes to our understanding of the pathogenesis of schizophrenia by determining if early amygdala damage produces behavioral, morphological, and neurochemical symptoms similar to those seen in adult schizophrenics. CHANGES IN SEPTUM/DIAGONAL BAND CHOLINERGIC AND GABAERGIC CELL POPULATIONS FOLLOWING INTRASEPTAL ADMINISTRATION OF 192 IgG SAPORIN. K.D. Dougherty* and T.J. Walsh, Rutgers University, New Brunswick, NJ, 08903.

Changes in cholinergic and GABAergic medial septum/diagonal band (MSDB) cell populations were analyzed following intraseptal injection of the immunotoxin 192 IgG saporin (SAP). Subjects received either 0 (aCSF), 100 or 375 ng of SAP into the septum in 0.46 ul. Twenty one days following surgery, they were perfused through the heart and slices were subsequently taken from both the MSDB and hippocampus (HPC). MSDB slices were stained for choline acetyltransferase- and parvalbumin-immunoreactivity (ChAT-IR, PV-IR). Both MSDB and HPC slices were stained for acetylcholinesterase (AChE) positive fibers. Intraseptal SAP led to dose dependent decreases in the number of ChAT-IR cells in the dorsal, intermediate and ventral MSDB cholinergic cell groups and dose dependent decreases in AChE positive fiber density in cingulate cortex, dendate gyrus, CA1 and CA3. Size of remaining ChAT-IR cells was comparable to that in controls. While number of PV-IR cells remained comparable to that of controls, such cells were significiantly (10-20%) smaller in SAP subjects. Our findings provide the first quantitative analysis of MSDB cholinergic cells and fibers and GABAergic projection neurons following SAP treatment. Contrary to previous reports, these findings suggest functional changes in GABAergic as well as cholinergic neurons following intraseptal injection of SAP. Supported by NSFIBN 9514557 to TJW.

BIOLOGICAL RHYTHMS AND SLEEP: CIRCADIAN RHYTHMS IV

ESSENTIAL ROLE OF VIP-NEURONS OF THE SUPRACHIASMATIC NUCLEUS IN THE HYPERGLYCEMIA CAUSED BY INTRACRANIAL INJECTION OF 2-DEOXY-D-GLUCOSE IN RATS. S. Chun, A. Niijima, N. Nagai, K. Shimizu, H. Ide and K. Nagai*. Inst. Protein Res., Osaka Univ., Suita, Osaka 565, Japan

Previously, we found that the neurons of the suprachiasmatic nucleus (SCN) which receive retinal neural inputs are involved in the mechanism of glucose homeostasis through the control of the autonomic nervous system. In this experiment we examined the role of vasoactive intestinal peptide (VIP)-neurons of the SCN in this mechanism, since the VIP-neurons receive retinal inputs. A heart and brain catheters were implanted into male Wistar rats under pentobarbital anesthesia 3 days before the experiment. Effects of an additional injection of VIP to that of 2-deoxy-D-glucose (2DG) into the lateral cerebral ventricle on the blood glucose and sympathetic activity were examined in control and SCN-lesioned rats. It was observed that intracranial injection of VIP stimulated both the hyperglycemia and the excitation of the sympathetic adrenal nerve caused by 2DG in control rats, and that the VIP injection restored these responses to 2DG which disappeared after SCN-lesions. Considering the lack of VIP-neurons in the vicinity of the SCN without the SCN, these findings suggest that VIP-neurons of the SCN are essential for the hyperglycemia and sympathetic excitation due to intracranial injection of 2DG. NEONATAL CLOMIPRAMINE TREATMENT ALTERS CIRCADIAN RHYTHMS AND ALCOHOL INTAKE IN ADULTHOOD. A.M. Rosenwasser*, S.M. Dwyer and M.J. Hayes, Dep't of Psychol., Univ. of Maine, Orono, ME 04469.

Treatment of neonatal rats with antidepressant monoamine uptake inhibitors results in a constellation of behavioral and neurochemical changes in adulthood that resemble aspects of human depression. Since depressed patients show characteristic alterations in circadian rhythmicity, we have examined free-running circadian drinking rhythms in this putative animal depression model. In a previous study (Psychopharmacol 115, 237, 1994), neonatal desipramine treatment lengthened circadian period, increased rhythm amplitude, and increased voluntary alcohol intake (10% v/v) in male Wistar rats, relative to saline controls. The present study extends these observations by examining the effects of neonatal clomipramine treatment (2 x 15 mg/kg sc, postnatal days 8-21) in both males and females. Preliminary results (N = 6/group) indicate that neonatal clomipramine -- like neonatal desipramine -- increases both rhythm amplitude and alcohol intake. However, in contrast to the effects of neonatal desipramine treatment, neonatal clomipramine appears to shorten free-running circadian period. This discrepancy could be related to the different relative selectivities of desipramine and clomipramine for noradrenergic and serotonergic uptake mechanisms, respectively. In addition, males appeared more sensitive to treatment effects on circadian period, but females appeared more sensitive to treatment effects on rhythm amplitude and alcohol intake. These findings support the hypothesis that alterations in monoamine neurotransmission may underlie relationships between circadian rhythmicity and affective behavior in both humans and animals. Circadian rhythms, baseline rest activity and recovery rest activity after acute sleep loss in IL-1ß-deficient mice. S.C. Veasey*, M. Mackiewicz, H. Zheng, M. Trambauer, M. Ogilvie and A.I. Pack, University of Pennsylvania, Philadelphia, PA 19104 and Merck Research Laboratories, Rahway, NJ 07065.

That interleukin-1ß (IL-1ß) is somnogenic and that acute blockade of IL-1ß receptors reduces recovery sleep after sleep loss, suggest that IL-1ß may play an important role in sleep regulation. To begin to describe the complete role(s) of IL-1ß in circadian rhythm, sleep-wake activity and recovery sleep after acute sleep loss, we are studying mice homozygous for the deleted IL-1ß gene (IL-1ß KO's), using their wild type litter mates as controls. Circadian rhythms of wheel-running activity were recorded for differences in the endogenous period of the circadian pacemaker. There were no differences in τ_{DD} between controls (23.61±0.13 hrs, n=6) and IL-1ß KO's (23.62±0.44 hrs, n=6). Thereafter, a photobeam activity analyzer was used as an estimate of total activity, measured as numbers of beam breaks. There were no differences in the diurnal ratios of activity for the two groups (sampling period 21 days). We found an increase in activity by 27.3% in the IL-1ß KO's during the subjective day, $p<0.05$. There were no significant differences in activity counts during either the 12 hr light period or the total 24 hour period. The same activity monitor was used to determine all one minute epochs of zero activity. These data were used as an indirect measure of rest/sleep activity. Baseline total rest/sleep activity for 24 hours was not different for controls and IL-1ß KO's (737.25±68.01 min. vs. 821.75±41.36 min., NS). Similarly, the amounts of rest/sleep activity for both the subjective day and night periods were indistinguishable for the two groups. In control litter mates, six hours of total sleep deprivation during the subjective day resulted in a significant rebound in rest/sleep activity in the first 12 hour recovery subjective day (30.2±4.7% increase, $p<0.05$). In contrast, the IL-1ß KO's did not demonstrate a rebound in rest/sleep activity in the recovery subjective day (7.3±7.1%, NS). This suggests that response to sleep loss may be impaired in the IL-1ß KO's. EEG studies in these mice are now underway to more fully characterize sleep/wake differences and differences in recovery sleep. Supported in part by NIH grants HL02838, HL42236, HL07713.

EFFECTS OF $GABA_B$ AGONISTS AND ANTAGONISTS ON THE PHASE-ADVANCING EFFECTS OF LIGHT FOLLOWING THEIR INJECTION INTO THE SUPRACHIASMATIC NUCLEUS (SCN). C.F. Gillespie*, E.M. Mintz, C.L. Marvel, K.L. Huhman, and H.E. Albers, Lab of Neuroendocrinol. & Behav., Depts. of Biol. & Psychol., Georgia State Univ., Atlanta, GA 30303.

Exposure to light during the late portion of subjective night produces phase advances in circadian rhythms. Since GABA is found in most, if not all, neurons of the SCN, the present study examined whether central administration of a $GABA_B$ agonist (Baclofen, Sigma) or antagonist (CGP-35348, Ciba-Geigy, Basel, Switzerland) alters phase advances produced by light. Hamsters were implanted with guide cannulae aimed at the SCN region and housed in constant darkness. After stable free-running activity rhythms were established, hamsters were microinjected with either baclofen (0.5 µg in 200nl saline; pH 2.14), CGP-35348 (20 µg in 200nl 2% DMSO), or vehicle (200nl saline pH 2.14 or 200nl 2% DMSO) at circadian time 19 in counterbalanced order. Immediately following microinjection, the hamsters were exposed to 15 minutes of light at an intensity of 290 lux. Microinjection of baclofen prior to a pulse of light resulted in very small phase delays (-0.01 ± 0.09hr) that were significantly smaller than the phase advances induced by pretreatment with vehicle (1.30 ± 0.16hr). Microinjection of CGP-35348 prior to a pulse of light resulted in phase advances (1.05 ± 0.13hr) that were not significantly ($p>0.05$) different from the phase advances induced by pretreatment with vehicle (1.30 ± 0.16hr). Phase advances produced by control injections (without light exposure) of baclofen (0.093 ± 0.11hr) or CGP-35348 (0.012 ± 0.13hr) were not significantly ($p>0.05$) different from the phase shifts produced by injection of vehicle (0.003 ± 0.27hr). These data suggest that $GABA_B$ activity within the SCN plays an important role in modulating the phase-advancing effects of light.

MICROINJECTION OF 8-OH-DPAT INTO THE DORSAL AND MEDIAN RAPHE PHASE SHIFTS CIRCADIAN RHYTHMS. H. E. Albers*, E. M. Mintz, C. F. Gillespie, C. L. Marvel, and K. L. Huhman. Laboratory of Neuroendocrinology and Behavior, Departments of Biology and Psychology, Georgia State University, Atlanta, GA 30303.

The raphe nuclei of the midbrain are thought to be involved in the regulation of circadian rhythms, although the exact nature of their role has not yet been established. The suprachiasmatic nucleus (SCN), which appears to functions as a circadian clock in hamsters, receives a direct projection from the median raphe nucleus (MR), approximately half of which is serotonergic. The dorsal raphe nucleus (DR) is also thought to be involved in the regulation of circadian rhythms and is linked to the circadian system by a projection to the intergeniculate leaflet (IGL), which in turn projects to the SCN. This series of experiments was designed to determine how serotonergic activity in the DR, MR, and IGL might alter the phase of circadian rhythms, and thereby establish a possible site for the action of systemically injected serotonergic drugs on the circadian system. A total of 31 Syrian hamsters were surgically implanted with guide cannula aimed at the DR (n=10), MR (n=10), and IGL (n=11), and placed in constant darkness in cages equipped with running wheels. After a 10 day recovery period, hamsters were microinjected with 100nl of either 8-OH-DPAT (500 ng) or vehicle (0.9% saline) through a 32-gauge needle. Each hamster received both injections with a 10-day period in between, and the order of injection was counter balanced across all animals. All injections were made at circadian time 7. 8-OH-DPAT caused phase advances that were significantly different from saline when injected into the DR and MR, but not the IGL. In the DR, the mean phase shift was 26.4±7.9 min vs. 4.9±6.5 for saline ($p<.05$). In the MR, 8-OH-DPAT induced a 32.7±6.2 min advance vs. 14.9±2.4 for saline ($p<.05$). In the IGL, however, 8-OH-DPAT induced only a 12.0±3.9 min advance vs. -4.6±6.1 for saline ($p>.05$). Injections into the median raphe resulted in damage to the dorsal raphe as a result of the needle passing through that area, and it is also possible that some of the 8-OH-DPAT leaked into the dorsal raphe during the injection. These results demonstrate that the DR is capable of playing a role in the regulation of circadian rhythms, most likely via a projection to the IGL.

TETRODOTOXIN-RESISTANT COMPONENT OF CIRCADIAN RHYTHM FROM RAT SUPRACHIASMATIC NUCLEUS SLICE DETECTED BY BIOCHEMILUMINESCENCE.

Y. Isojima*[1] and T. Isoshima[2]. [1] Photodynamics Res. Cent., The Inst. of Physical and Chemical Res. (RIKEN), Sendai 980, Japan, [2]Frontier Research Program, RIKEN.

The suprachiasmatic nucleus (SCN) *in vitro* as well as *in vivo* presents circadian change in electrical and metabolic activity. However, it was reported that tetrodotoxin (TTX) did not affect either the phase of the rhythm in firing rate or that of the rhythm in glucose metabolism.

In the previous work, we reported measurement of ultraweak biochemiluminescence as a new, non-invasive, long-term detection method of the circadian rhythm from an SCN slice. We also presented that the circadian pattern of the biochemiluminescence was quite different from that of firing rate or metabolic activity in the SCN.

In the present work, we report that the intensity of the ultraweak biochemiluminescence from the SCN presents circadian change even under TTX existence. This result suggests that the emission mechanism of ultraweak biochemiluminescence is related with the circadian pacemaker more closely than firing rate or glucose utilizaion in the SCN. CIRCADIAN CHANGES IN THE EXPRESSION OF THE mRNA FOR THE ISOFORMS OF PROTEIN KINASE C IN THE RAT SUPRACHIASMATIC NUCLEI. F.R.A. Cagampang, M. Rattray[1], I. C. Campbell[2], J.F. Powell[2] & C. W. Coen*. Biomedical Sciences, King's College, London WC2R 2LS; [1]Biochemistry & Molecular Biology, UMDS Guy's Hospital, London SE1 9RT; [2]Department of Neuroscience, Institute of Psychiatry, London SE5 8AF, U.K.

The molecular basis of the circadian pacemaker in the mammalian suprachiasmatic nuclei (SCN) and its entrainment mechanisms remain unclear. Nevertheless, various neurotransmitter systems have been implicated in the regulation of these nuclei; several of these function by signal transduction processes which activate protein kinase C (PKC) and hence initiate phosphorylation cascades. PKC exists as a family of isoenzymes linked to various extracellular signalling events in the brain. Since these enzymes play crucial roles in cell function, we have examined the expression of their mRNAs in the SCN throughout the circadian cycle. Male Wistar rats, previously kept in a 12:12h light-dark (LD) cycle, were used. To establish whether the mRNAs for these isoenzymes change in the absence of LD entrainment cues, lights were not turned on at the usual time of transition from dark to light (designated as CT 0). Animals were sacrificed over the following 24h of dim red light at CT 0, 2, 6, 10, 12, 14, 18 and 22. Coronal sections containing the SCN were obtained; *in situ* hybridization was carried out using ^{35}S-labelled oligonucleotides for PKC α, β1, β2, γ and ε. Quantitative analysis indicates significant variation ($p<0.0001$, ANOVA; n=28-30 at each time point) in the expression of the mRNA for PKC α, β1, β2 and γ, but not ε, within the SCN during the circadian cycle. There is a monophasic rhythm of PKC α mRNA with a peak at CT 14. In contrast, there is a biphasic variation in PKC β1, β2 and γ mRNA with one peak at CT 0 and another at either CT 12 or 14. Comparable patterns of mRNA expression were observed for PKC β1 and γ, but not for α or β2, within the cingulate cortex; no variation in PKC ε mRNA was found at this site. These results suggest that particular isoforms of PKC subserve specific temporal functions at the site of the circadian pacemaker and also within the cingulate cortex.

DIRECT APPLICATION OF NMDA TO THE SCN IN VIVO MIMICS THE PHASE SHIFTING EFFECTS OF LIGHT AT CIRCADIAN TIME 13.5 AND 19. E. M. Mintz* and H. E. Albers. Laboratory of Neuroendocrinology and Behavior, Departments of Biology and Psychology, Georgia State University, Atlanta, GA 30303.

There is a considerable body of evidence that photic information is transmitted to the circadian clock in the mammalian suprachiasmatic nucleus (SCN) via a glutamatergic pathway. n-Methyl-d-aspartate (NMDA) antagonists applied directly to the SCN block the phase shifting effects of light both *in vitro* and *in vivo*. Although it has been demonstrated *in vitro* that glutamate and NMDA can produce both phase advances and delays of the SCN neuronal firing rhythm in a pattern similar to the phase shifts produced by light, a light type phase response curve has yet to be produced by a glutamatergic agonist *in vivo*.

To determine whether NMDA can mimic the phase shifting effect of light, 20 Syrian hamsters were surgically implanted with guide cannula aimed at the SCN, and placed in constant darkness in cages equipped with running wheels. After a 10 day recovery period, hamsters received microinjections (volume: 200nl) of either 10mM NMDA or vehicle (0.9% saline) through a 32-gauge needle inserted into the guide cannula. Each hamster received both injections with a 10-day period in between, and the order of injection was counter balanced across all animals. Nine animals received the treatment at circadian time (CT) 13.5, and 11 at CT 19.

At both time points, NMDA induced phase shifts that were significantly different from those induced by saline alone. At CT 13.5, NMDA induced an average phase delay of 72.9±8.9 minutes vs. 14.1±4.1 minutes from saline ($t=5.27$, $p<0.001$). At CT 19, NMDA induced a phase advance of 27.3±5.7 minutes vs. a delay of 9.5±5.4 minutes from saline ($t=5.11$, $p<0.001$). These results provide evidence that NMDA receptors have an important role in the transmission of photic information to the SCN.

GLUTAMATERGIC ANTAGONISTS DO NOT ATTENUATE LIGHT-INDUCED FOS PROTEIN IN RAT INTERGENICULATE LEAFLET NEURONS. Kim Edelstein* and Shimon Amir. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Canada H3G 1M8.

Photic information is transmitted to the suprachiasmatic nucleus (SCN) via a direct, excitatory retinal projection and an indirect projection originating in retinorecipient intergeniculate leaflet (IGL) neurons. The transmitter involved in relaying photic information to the IGL is not known; however, because bifurcating retinal ganglion cell axons innervate both the SCN and IGL, it seems likely that the retinogeniculate projection is glutamatergic as well. Expression of Fos protein in SCN neurons is a molecular correlate of photic entrainment. Light pulses that induce phase shifts also induce Fos; treatments with NMDA receptor antagonists that prevent phase shifts in hamster activity rhythms attenuate light-induced Fos expression in SCN neurons. In the present study we demonstrate that treatments with the NMDA receptor antagonists MK-801 (5mg/kg, i.p.) or CPP (4 nmoles, i.c.v.), 10-15 min. prior to a 30 min. light pulse at CT16 have no significant effect on light-induced Fos immunoreactivity (Fos-IR) in IGL neurons despite attenuating Fos-IR in the SCN. Similarly, pretreatment with the non-NMDA receptor antagonist DNQX (40 nmoles i.c.v.) did not alter light-induced Fos-IR in the IGL, suggesting that, in contrast with light-induced Fos in the SCN, light-induced Fos in the IGL may not be mediated by glutamate receptor activation. Transmission of photic information along retinogeniculate and retinohypothalamic pathways may be mediated by different mechanisms.

EFFECTS OF PHOTOPERIOD AND PINEALECTOMY ON THE EXPRESSION OF NEUROPEPTIDE MESSENGER RNAS IN THE SIBERIAN HAMSTER SUPRACHIASMATIC NUCLEI. M.J. Duncan*. Dept. of Anatomy and Neurobiology, University of Kentucky Medical School, Lexington, KY 40536.

The suprachiasmatic nuclei (SCN) receive and transmit photoperiodic information which profoundly affects reproduction and metabolism in many mammalian species. Our recent studies of the Siberian hamster SCN have shown that two types of neuropeptide-containing neurons, vasopressin (AVP) and vasoactive intestinal peptide (VIP) neurons, respond to short photoperiod (SP, 10 h light/day) by decreasing mRNA expression. To investigate whether the pineal mediates SP inhibition of AVP and VIP mRNA expression, male hamsters were pinealectomized or sham-operated on the day of weaning, exposed to long photoperiod (LP, 16 h light/day) or SP for 2 weeks, and sacrificed in the morning. Coronal sections through the SCN were prepared and processed for in situ hybridization. SP inhibited the expression of AVP or VIP mRNA in the SCN; these effects of SP were not prevented by pinealectomy. Surprisingly, pinealectomy decreased AVP mRNA in the SCN of LP- and SP-exposed hamsters, but increased VIP mRNA in the SCN of LP hamsters. A second study tested whether photoperiod alters somatostatin (SS) mRNA expression. Siberian hamsters were sacrificed at 4-h intervals after 2 weeks of exposure to LP or SP. Neither photoperiod nor time of day affected SS mRNA expression in the SCN. In conclusion, SP decreases expression of AVP and VIP, but not SS, mRNA in the SCN. The pineal differentially modulates AVP and VIP mRNA expression in the SCN but does not mediate the effect of SP. (Supported by USPHS DK-42056 and the UKMC Research Fund.)

ATTACHMENT SITE OF GRAFTED SCN INFLUENCES PRECISION OF RESTORED CIRCADIAN RHYTHM.

J. LeSauter*, P. Romero, M. Cascio and R. Silver. Dept. of Psychology, Barnard College and Columbia University, New York, NY 10027.

The quality of rhythms restored by hypothalamic grafts of the SCN is variable. The present study explored which features of the graft predict the quality of the recovered rhythm. The results indicate a significant positive correlation between precision of activity onset and the proximity of the closest SCN cluster to the site of the lesioned host SCN. Proximity of the graft in the dorsal and caudal directions, but not the rostral direction, was positively correlated with the precision of the recovered rhythm, with rostral grafts producing a more precise rhythm than equidistant dorsal or caudal grafts. Other anatomical or behavioral indices were not significant. (Anatomical measures used: number of SCN clusters, size of the cluster closest to the SCN lesion site, total size of all the clusters, distance between the transplant and other hypothalamic nuclei. Behavioral measures used: amount of activity, period and robustness of the recovered rhythm). Comparison of the distribution of NP- and VIP-immunoreactive fibers indicates that the extent of innervation of the normal target areas does not predict either the occurrence or the precision of the recovered rhythm. Taken together, the results suggest that the target(s) of SCN pacemakers regulating locomotor rhythmicity lie near or rostral to the SCN.

PHASE DEPENDENT DIFFERENTIAL DISTRIBUTION AND CO-LOCALIZATION OF LIGHT-INDUCED C-FOS EXPRESSION WITHIN VIP AND / OR GRP SUPRACHIASMATIC NUCLEUS (SCN) NEURONS

J. C. Speh* and R.Y. Moore. Depts. of Psychiatry and The Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA

Circadian rhythmicity is controlled by a light-entrainable oscillator in the suprachiasmatic nucleus (SCN). Brief light exposure during subjective night causes phase shifts in the free running activity rhythm as well as induction of c-fos related proteins (FOS) in SCN neurons. Light exposure during early subjective night (CT14) causes phase delays while during the late subjective night (CT19) they cause phase advances. Recent studies report light-induced FOS expression (FOS+) in different populations of neurons in the SCN of hamster in conjunction with phase advances or delays (Rea,'92), and co-localization of phase advancing FOS+ within gastrin releasing peptide (GRP) but not vasoactive intestinal polypeptide (VIP) neurons of the rat SCN (Earnest et al.,'93).

The present study utilized a highly sensitive fluoresecent immuno-cytochemical technique and phase delaying or advancing light-induced FOS+ to determine the pattern and extent of co-localization within GRP and VIP neurons. Animals in constant conditions were given 15 minute light pulses at either CT 14 or 19 or 3 hour light pulses from CT 12 - 15 or CT 18 - 21. Control animals received no light pulse at the same timepoints. There is a significantly larger number of FOS+ cells at phase advance (FOS+ cells = 2523±108) than phase delay (FOS+ cells = 1235±203) timepoints. Phase advance FOS+ is primarily localized within the ventrolateral subdivsion with some extension into the dorso-medial and dorso-lateral areas . Phase delay FOS+ is more scattered throughout the entire SCN with a majority of the FOS+ cells localized to the dorso-lateral SCN. Phase advance FOS+ is found colocalized within both GRP and VIP neurons while phase delay FOS+ is found only within VIP neurons. Supported by NS 16304.

807.13

EXPRESSION OF NMDAR1 SPLICE VARIANTS IN THE DEVELOPING SUPRACHIASMATIC NUCLEUS (SCN) OF THE SIBERIAN HAMSTER (PHODOPUS SUNGORUS).

Giles E Duffield, Anna S Cronin and Francis J P Ebling* Department of Anatomy, University of Cambridge, UK.

Glutamate is present in the retinohypothalamic tract (RHT) and is implicated in mediating the entraining effects of light on the circadian clock (SCN) in adult rodents. Glutamate may also play a role in innervation by the RHT and synaptogenesis, developmental events that occur during the early postnatal period in the rodent SCN. Previous studies have revealed the presence of NMDAR1 mRNA in adult rodent SCN. The common subunit gene for NMDAR1 can be alternatively spliced in three regions to generate functionally different products. Thus the aim of the current study was to investigate which NMDAR1 mRNA splice variants are present in the SCN through development. RHT innervation was studied using intraocular injections of cholera toxin B to trace innervation of the SCN. This revealed that the RHT begins to grow into the ventrolateral SCN between postnatal day (PD) 3 and PD4 and having an adult-like pattern by PD6. Therefore, receptor expression in PD2 (pre-innervation), PD6 (post-innervation) and adult (post-synaptogenesis) animals was studied. *In situ* hybridization was carried out on coronal sections at these ages, using ^{35}S-labelled oligonucleotide probes complementary to common and variable regions of the rat gene (*J Comp Neurol* 1994, 313:1-6). Hybridization of the common probe occurred ubiquitously in the brain, including the SCN at PD2 and at all subsequent ages. A probe complementary to deletion II/exon 22 was also abundant in the SCN at all ages. In contrast, no hybridization of probes complementary to insertion I/exon 5 or to deletion I/exon 21 were detected in the SCN at any age. These observations suggest that NMDAR1 is present in the SCN early in development, prior to RHT innervation and synaptogenesis, and before the age at which light can induce cellular changes (*c-fos* expression) within the SCN (*Eur J Neurosci* 1995, 7:1089-1096). These data suggest that a predominant isoform in the SCN at all postnatal ages is $NR1_{001}$ and thus provide no evidence that postnatal developmental events are regulated by an alteration of NMDAR1 isoform. *Supported by the MRC and The Wellcome Trust 037667/Z/93.*

MODIFICATIONS OF VIGILANCE STATES BY ACETYLCHOLINESTERASE INHIBITOR IN RATS.

B. Hars, S. Deurveilher, J.C. Bizot and E. Hennevin*. NAM, URA 1491, Univ. Paris-Sud. 91405 Orsay , FRANCE.

Cholinergic mechanisms are involved in the control of sleep-wake cycle and in the generation of paradoxical sleep (PS) in particular. Therefore administration of "irreversible" cholinesterase inhibitor, which durably facilitates cholinergic activity, should affect sleep-wake cycle and increase PS. To our knowledge, no studies have investigated the kinetics of the effects of cholinesterase inhibitor chronic administration on vigilance states in rat. In this experiment rats were treated chronically with low doses of Diisopropylfluorophosphate (DFP) and their vigilance states were recorded daily.

Twenty-four adult male Wistar rats were instrumented for polygraphic detection of vigilance states which were recorded daily for 6 hours. After a baseline recording day with no injection, rats were assigned to two control groups which received either saline or oil (vehicle) and to an experimental group which received DFP (0.2 mg/kg, subcutaneously). Injections were made daily for 9 consecutive days (D1 to D9), 30 min before recording. Three recording days were also conducted after the end of the treatments, on Days 11, 13 and 28.

Compared to baseline values as well as to control groups, DFP treated rats spent more time in wakefulness and PS, and less time in slow-wave sleep (SWS).These modifications began to appear on D3 and developed during the following days until D9. They disappeared after the end of DFP treatment. Biological assays are still under process to compare the kinetics of the DFP effects on sleep and on cholinesterase activity.

These results suggest that cholinergic activation promotes EEG desynchronized states and/or decreases EEG synchronized states. In either case, this could account for the strongly enhanced PS/SWS ratio observed in DFP treated rats.

REGULATION OF LOCOMOTOR BEHAVIOR BY VASOPRESSIN AND THE CIRCADIAN SYSTEM IN HAMSTERS.

H. Cormier, M. Tran, A. J. Lança and M. R. Ralph*. Department of Psychology, Zoology and Pharmacology, University of Toronto, Toronto, M5S 1A1, Canada.

Subcutaneous injections of vasopressin (AVP) have been shown previously to induce c-fos expression in the suprachiasmatic nucleus of the rat; however, a role for AVP in the regulation of circadian rhythms produced in the SCN has not been described. To investigate this issue further, we hypothesized that the activation of SCN cells by AVP indicates a regulatory influence of this peptide on pacemaker output. To test this general hypothesis, we have examined (1) the effect of AVP on locomotor behavior; (2) the involvement of V_1 vs. V_2 mechanisms; and (3) the site of action.

We have found that in golden hamsters, s.c. AVP (20μg) produces a long lasting (3 hour) inhibition of locomotor behavior when the animals are most active. There is no phase shift of the rhythm, but FOS is induced in a subset of cells in the medial SCN where calbindin-ir is also found. The action of 8-Arg-AVP is mimicked by a V_2 agonist, but not by a V_1 agonist. Experiments are underway to determine whether the FOS positive cells in the SCN are directly or indirectly involved in the behavioral response.

2. The Netherlands Institute for Brain Research, 1105 AZ Amsterdam ZO, The Netherlands.

The rat suprachiasmatic nucleus (SCN) provides a monosynaptic innervation to neurons in the hypothalamic paraventricular nucleus (PVN) that uses GABA and glutamate as rapid neurotransmitters. SCN somata and outgoing axons also show immunoreactivity to various peptidergic transmitters, such as vasopressin (VP). To investigate the role of VP in synaptic transmission from SCN to PVN, the present study employed whole-cell patch-clamp recording techniques in rat hypothalamic slices to evaluate the electrical response of PVN neurons to bath application of VP. The majority of magnocellular (type I) and parvocellular (type II and III) PVN neurons responded to VP application (concentration range 100-500 nM) with an increase in the frequency of spontaneous, $GABA_A$ receptor-mediated, inhibitory postsynaptic potentials or currents (IPSPs resp. IPSCs). The influence of VP persisted in the presence of non-NMDA and NMDA receptor antagonists NBQX and D-CPP, but was abolished by the specific VP V1 receptor antagonist Manning compound. Cells that responded to VP were unaffected by the structurally related peptide oxytocin. Application of VP did not visibly change the amplitude of evoked $GABA_A$ receptor-mediated IPSPs or responses to bath applied GABA (100 μM).

These data suggest that VP activates a set of GABAergic neurons that innervate magno- as well as parvocellular PVN neurons, resulting in an increase in the frequency of spontaneous IPSPs (IPSCs), leading to a reduction of their excitability.

AN IMMUNOHISTOCHEMICAL STUDY OF THE EXPRESSION OF THE TRANSCRIPTION FACTORS CCAA/T ENHANCER BINDING PROTEIN C/EBPβ and δ IN THE CIRCADIAN CLOCK OF THE SYRIAN HAMSTER. J. Servière*(1) M. Lavialle (1), J-R. Cardinaux (2), P. Magistretti (2). (1) INRA Paris, FR, (2) Institut de Physiologie, Lausanne, CH.

The central circadian clock of mammals, located in the suprachiasmatic nucleus (SCN) of hypothalamus exhibits cellular nycthemeral and circadian rhythms such as multi-unit activity, energy metabolism, astrocytic activity (glial fibrillary acidic protein or GFAP distribution), immediate early gene expression (c-fos) and peptidergic synthesis (including VIP). Astrocytes play an important role in regulation of the energetic environment of activated neurons.

The transcription factor family CCAAT/EBPs is involved in the expression of genes implicated in energy metabolism in peripheral tissues. Recently we have found that 2 members of this family, C/EBPβ and δ, are induced in cultured astrocytes by VIP. In these cells C/EBPβ and δ behave as cAMP-inducible immediate early genes and regulate glycogen metabolism through the induction of the gene encoding for glycogen synsthesis (Cardinaux and Magistretti, J. Neurosci., 16: 919-929. 1996). In view of daily fluctuations in glucose utilization, GFAP distribution and VIP content within SCN, we monitored the variations of the level of expression of C/EBPβ and δ over the 12h light-12h dark cycle (LD 12:12). Using C/EBP antibodies (Santa Cruz, 1/1000) we observed by immuno-histochemistry a rhythm in C/EBPs expression within adult male hamster SCN with a decrease in the number of cells-ir and intensity of staining around the L/D transition (time 12 to 14) and the peak of expression in the middle of the dark period (time 18). Double staining experiments revealed only a partial colocalization of C/EBPβ with GFAP-ir positive cells. This pattern of daily fluctuations is in register with that of glucose utilization and VIP content. These data suggest that C/EBP is an other marker of circadian clock activity.

EXPRESSION AND CELLULAR LOCALIZATION OF preproTRH AND TRH RECEPTOR mRNAs IN RAT RETINA . N.Lexow*, M.Mackiewicz, C.Lane, M.Parekh, & A.Winokur. Depts. of Psychiatry & Pharmacology, U. of PA School of Medicine, Philadelphia, PA 19104.

There is evidence to support a compelling relationship between activity of neuronal systems containing TRH and photoperiodic modulation of CNS activation. As the retina is the primary neural structure responsible for transduction photic information to the organism, knowledge regarding the discrete localization of TRH and TRH receptors within distinct retinal microcircuits will provide a critical link in our understanding of how circadian periodicity determines distinct biological events.

The presence of ppTRH and TRH-R mRNAs in retina throughout the light-dark cycle was evaluated using RT-PCR. Total RNA from whole retina was reverse transcribed (RT) to the first strand of cDNA, RT products were then amplified by PCR using primers for target sequences in TRH and TRH-R genes. Our data indicate that TRH-R mRNA is consistently present in retina at all time points measured. In contrast, diurnal variations occur in ppTRH mRNA.s.

In-situ hybridization hystochemistry was used to identify cellular sites of synthesis for ppTRH and TRH-R in transverse sections of rat and cat retina. Radioloabeled riboprobes detect preproTRH transcripts within nearly all somata in the ganglion cell layer; in addition, a strong hybridization signal extends across the entire inner nuclear layer. In contrast, moderate labeling for TRH-R mRNA distributes evenly over the IPL, GCL, and NFL, however, the GCL is significant for a distinct absence of grains over most soma.

These data will be compared to the cellular localization of TRH and TRH-R in retina as determined by immunocytochemistry and autoradiography carried out in our laboratory.

EFFECTS OF DIFFERENT ENVIRONMENTAL LIGHTING CONDITIONS ON REGIONAL THYROTROPIN-RELEASING HORMONE (TRH) CONCENTRATIONS AND TRH RECEPTOR DISTRIBUTION IN THE GOLDEN HAMSTER. K.A. Gary* and A. Winokur. Department of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104.

TRH (100 nM) injected into the suprachiasmatic nucleus (SCN) produces phase advances in the circadian rhythm of wheel running activity in the hamster (*Mesocricetus auratus*). The golden hamster is the predominant species employed in circadian rhythms studies due to precise timing of circadian wheel running activity. TRH neuronal systems, however, have not been characterized in the hamster. This study examined regional TRH concentrations in the hamster by radioimmunoassay and TRH receptor distribution by [^{3}H]MeTRH binding and quantitative autoradiography. The impact of lighting conditions on TRH or its receptors was evaluated by maintaining animals in either 14:10 LD or constant dim red (DD) lighting conditions prior to sacrifice.

Hamsters were entrained in 14:10 light/dark conditions for seven days, then one half of the group transferred to DD conditions. Wheel running activity was monitored/recorded by computer for 14 days. Animals were sacrificed at CTs 3, 6, 9, 12, 15, 18, 21, and 24. In DD animals, CT 12 was defined as the onset of wheel running activity. For radioimmunoassay, brains were removed and microdissected on ice into cerebellum, medulla, hypothalamus, striatum, hippocampus, midbrain, and cortex. For autoradiographic studies, brains were frozen on dry ice and cryostat sectioned at 20 μm. TRH levels were significantly increased in hypothalamus (28%) and medulla (21%) at CT 6 in DD animals. TRH levels in hippocampus and striatum, however, decreased 39% and 14% at CT 6, respectively, although decreases in striatum were not statistically significant. No change in TRH receptor density was noted at any time examined.

CLONING AND LOCALIZATION OF mRNA ENCODING RHESUS MONKEY SEROTONIN *N*-ACETYLTRANSFERASE. S.L. Coon, E. del Olmo, W.S. Young III, P.H. Roseboom* and D.C. Klein. Lab. of Developmental Neurobiology, NICHD and Lab. of Cell Biology, NIMH, National Institues of Health, Bethesda, MD 20892.

The pineal hormone, melatonin, plays a prominant role in regulating vertebrate circadian and seasonal physiology. Large changes in the activity of the penultimate enzyme in melatonin synthesis, serotonin *N*-acetyltransferase (arylalkylamine *N*-acetyltransferase, AANAT; E.C. 2.3.1.87), control the large circadian changes in melatonin production in vertebrates. In this study the Rhesus monkey was studied because of its usefulness as a human model. The sequence of Rhesus AANAT cDNA is 95% identical to that of human; the amino acid sequences are 93% identical and 96% similar. Northern blot analysis demonstrates that AANAT mRNA is present as a single 1.0 kb band. It is detected in the pineal gland and retina at similar levels. In both tissues, AANAT mRNA is high during the day, with only a small increase during the night. AANAT was not detected in the brain, but was detected in the pituitary and testis at about 1% pineal levels. *In situ* hybridization histochemistry indicates that the AANAT transcript can be detected in the pineal gland in pinealocytes and in the retina in photoreceptor cells. In addition, it appears that the transcript is present in the outer region of the inner nuclear layer. The high level of AANAT mRNA in the Rhesus retina suggests this tissue might be useful for analysis of the role this enzyme plays in retinal physiology in primates, and could provide some insight into the role it plays in the human retina.

CLONING OF FULL-LENGTH PINEAL-SPECIFIC cDNAs IN RAT BY DDPCR AND RACE. X. Wang, A. L. Iacangelo, K F. Malik*, M. J. Brownstein and W. S. Young, III. Laboratory of Cell Biology, NIMH, NIH, Bethesda, MD 20892

Synthesis of melatonin in the mammalian pineal gland is regulated by the rhythmic expression of acetyl-CoA: serotonin N-acetyltransferase (SNAT) and other factors. To screen for pineal-specific mRNAs potentially involved in melatonin synthesis and/or regulation, differential display PCR (DDPCR) was employed. Eighty primer pairs have been used. Forty bands of interest were isolated in our initial studies. Using *in situ* hybridization histochemistry, two of these clones (designated PG23 and PG25) were found to be pineal-specific. Another clone PG10.2 is expressed specifically in both pineal gland and the outer nuclear layer of the retina. The restricted local expression of these clones were further confirmed by northern blot analysis. In addition, the sizes of corresponding mRNA for PG10.2 and PG25 were determined to be 8 kb and 2.4 kb, respectively. Two mRNAs (2.0 and 2.5 kb in size) were found to correspond to PG23. Full-length cDNAs for PG10.2 (7.5 kb), PG25 (2.0 kb) and PG23 (1.3 and 2.0 kb) were then obtained using a long template PCR-based RACE technique. Our studies demonstrate a fast integrated PCR-based cloning method that should be useful for cloning genes with restricted expression in anatomically complex regions of the brain and genes that have altered expression because of pathology or experimental manipulation, including genes expressed at a low level with a very limited tissue distribution. (Support NIMH Intramural Research Programs).

A RANDOM MUTAGENESIS SCREEN FOR BEHAVIORAL MUTATIONS IN THE MOUSE. M. Bucan*[1,2,3], G.E. Pickard[1,3] and P. Nolan [1,3], Departments of Psychiatry[1], and Genetics[2], and Center for Sleep and Respiratory Neurobiology[3], Univerity of Pennsylvania, Philadelphia, PA 19104.

As a first step in the identification of genes underlying behavioral processes, we search for chemically induced mouse mutations with altered behavior. The main goal of this project is to identify (semi) dominant mutations that affect circadian behavior and entrainment to light, while a subset of mice are being tested in additional behavioral paradigms to identify mice with abnormal sleep patterns, aggressive or depression-like behavior, and an abnormal startle response. To date, 1000 progeny of ENU mutagenized mice have been screened by monitoring their wheel-running activity in constant darkness, to identify mice with an abnormal circadian period, a primary characteristics of the biological clock.

Two independently identified mutations with a strikingly similar phenotype have been identified and each has been shown to be caused by a single gene mutation. Both mutant lines exhibit an early onset of activity in light:dark conditions, as well as a shortened circadian period. Phenotypic and genetic analysis of progeny carrying mutations in the homozygous state, as well as compound heterozygotes harboring both mutations, will provide further insight into the nature of these mutations and the component of the circadian system that they affect.

CIRCADIAN VARIATION IN A BARIUM-SENSITIVE CONDUCTANCE IN NEURONS OF THE RAT SUPRACHIASMATIC NUCLEUS. M.T.G. De Jeu, A.M.S. Geurtsen, R.M. Buijs* and C.M.A. Pennartz Netherlands Inst. Brain Res., Grad. Sch. Neurosciences Amsterdam, Amsterdam, The Netherlands.

In mammals, the suprachiasmatic nucleus (SCN) of the hypothalamus is the site of the circadian pacemaker. Neurons of this nucleus exhibit a circadian rhythm in spontaneous firing. As a working hypothesis, we have considered the possibility that a tonically active K^+ current (inward rectifier, KIR) may be subjected to circadian modulation and thereby causes a circadian rhythm in spontaneous firing rate. We have tested this hypothesis by applying Ba^{2+}, a blocker of the KIR, to neurons recorded either in the subjective day or night period. Brain slices (250 μm) were prepared on two different circadian time points (CT 4h and CT 11h). Whole-cell patch-clamp recordings were made at least 1h later. Application of Ba^{2+} (500 μM) revealed the existence of a Ba^{2+}-sensitive conductance in SCN neurons. Current clamp studies showed that this conductance causes a hyperpolarization of the resting membrane potential. The magnitude of this contribution was shown to be dependent on circadian time. Its hyperpolarizing contribution was small (2.3 ± 0.5 mV; $n=9$) during the day and much higher (7.5 ± 1.5 mV; $n=10$; $p<0.005$) during the night. Furthermore, voltage clamp studies showed that the Ba^{2+}-sensitive conductance exhibits characteristics consistent with a classical KIR, such as instantaneous activation. In agreement with the current clamp results, the Ba^{2+}-sensitive current revealed a dependence on circadian time. Its slope conductance, as assessed between -100 and -70 mV, was low during the day (0.03 ± 0.02 nSi; $n=4$) and high during the night (0.33 ± 0.04 nSi; $n=6$; $p<0.005$). For the first time, these results reveal a clear day-night difference in an intrinsic membrane current of SCN neurons. The effect of the Ba^{2+}-sensitive current on the resting membrane potential varies across the circadian cycle and therefore is likely to constitute an important element of the ionic mechanism underlying the circadian rhythm in spontaneous firing rate of SCN neurons.

NEUROPEPTIDE Y ACTIVATES LARGE CONDUCTANCE CHANNELS IN SUPRACHIASMATIC NUCLEI (SCN) NEURONS. A.C. Hall* and M.E. Harrington, Departments of Psychology and Biology, Smith College, Northampton, MA 01063.

Neuropeptide Y (NPY) is a critical neurochemical signal for non-photic phase-shifts of the mammalian circadian clock. NPY-induced phase shifts of the rhythm in neural activity of the mammalian pacemaker, the suprachiasmatic nuclei (SCN), can be measured *in vitro*. Phase shifts by NPY are mediated by Y2 receptors, but little is known of the intracellular effects of NPY application on SCN neurons. Mechanisms of Y_2 receptor activation vary, depending on cell type, including effects on high threshold calcium currents[1] and receptor-operated channels[2].

Using the standard cell-attached configuration of the patch clamp technique, we investigated the effects of NPY on acutely dissociated SCN neurons from 5-14 day old hamsters on a 14:10 LD cycle. Cell-attached patches were held at -80 mV with 140 mM K^+ in the recording pipette. Outward currents with unit conductances of *ca.* 40, 90 and 160-190 pS were frequently observed (n=8 cells). In the presence of NPY (300 nM) after a brief delay (10-40 s) there was a pronounced increase in the probability of opening (*Popen*) of the 160-190 pS channels (n=4). These channel currents reversed at +10 mV close to an estimated K^+ reversal potential.

To establish whether the increased *Popen* was attributable to the activation of Ca^{2+}-dependent K^+ channels (BK_{Ca}), we recorded voltage-gated Ca^{2+} currents from SCN neurons using standard whole-cell and perforated -patch techniques. High threshold and total Ca^{2+} currents, reversibly blocked (>90 %) by a solution containing 20 μM Cd^{2+} and 100 μM Ni^{2+}, were not affected by 300 nM NPY (n=10). In conclusion, NPY activates large conductance channels in some SCN neurons. These channels are possibly BK_{Ca} channels responding to a rise in intracellular Ca^{2+} that does not depend on Ca^{2+} influx through voltage-gated channels.

PHASE SHIFTS TO NEUROPEPTIDE Y ARE BLOCKED BY BICUCULLINE BUT NOT TETRODOTOXIN. S.M.Biello, D.Golombek and M.E.Harrington*, Depts. of Psychology and Biology, Smith College, Northampton, Ma., 01063.

Circadian rhythms of the suprachiasmatic nuclei (SCN) can be recorded *in vitro* for several days. Coronal hypothalamic slices containing the SCN were prepared from Syrian hamsters housed under a 14L:10D light:dark cycle. Tissue was bathed in artificial cerebrospinal fluid (ACSF), and 3-min recordings of the firing rate of individual cells were performed on the second day *in vitro*. Control slices receiving either no application or application of ACSF to the SCN at ZT6 on the first day *in vitro* showed a consistent daily peak in their rhythms (n= 13, mean peak = ZT 6.6, SEM 0.8). Significance of phase shifts were determined using Mann Whitney U tests to compare peak times in control slices with those receiving a treatment.

Neuropeptide Y (NPY) phase shifts the circadian clock at ZT 6 (n= 4, mean peak=3.3, SEM=0.3; $p < 0.016$). Tetrodotoxin (TTX; 1μM or 10μM) was used to block sodium dependent action potentials. Treatment with TTX did not significantly affect the phase of the slice when administered with ACSF (n=3, mean peak=6.8, SEM=0.2). Advances induced by NPY were unaltered by pretreatment with TTX (n=5, mean peak=3.7, SEM= 0.2). This confirms previous *in vitro* work[2] and may indicate that classical synaptic transmission is not necessary for NPYphase advances.

Bicuculline, the selective GABAa receptor antagonist, has been shown to block phase shifts to NPY *in vivo*[1]. We have found that pretreatment with bicuculline also blocks phase shifts to NPY *in vitro*. Bicuculline in combination with ACSF administered at ZT 6 has no significant effect on peak firing rate (n=2, peak = 6.7, SEM = 0.02). The peak in slices treated with bicuculline followed by NPY were significantly different from slices that received NPY alone ($p< 0.02$). This indicates that GABAa activity within the suprachiasmatic nucleus may be necessary for the phase shifting effects of NPY.

Neuropeptide Y Phase-Shifts the *In Vitro* Multi-Unit Activity Rhythm in the Suprachiasmatic Nucleus of the Male Sprague-Dawley Rat. Timothy G. Youngstrom* & Rebecca A. Prosser, Dept. of Biochem. & Cell. & Molec. Biol., University of Tennessee, Knoxville, TN. 37996.

The suprachiasmatic nucleus of the hypothalamus (SCN) contains a circadian clock that is entrained to the prevailing light-dark cycle. Two afferent systems provide photic input to the SCN, a direct input through the retino-hypothalamic tract and an indirect input through the geniculo-hypothalamic tract (GHT). The neurotransmitters γ-amino-butyric acid and neuropeptide Y (NPY) have been associated with the GHT. Previous *in vitro* studies have reported that the rhythm of SCN single-unit activity (SUA) is maximally phase-shifted by NPY when applied at zeitgeber time 8 (ZT8; with ZT0 = lights on). We examined the effect of NPY on the time of peak multi-unit activity (MUA) in the SCN. Coronal brain slices (500 μm) containing the SCN of adult male Sprague-Dawley rats were prepared and maintained as reported previously. At selected times, perfusion of the tissue was stopped and the medium in the bath was replaced with medium containing NPY (10^{-6}M). After 1h, NPY-free medium was reintroduced and perfusion of the tissue reinstated. We recorded MUA *in vitro* prior to and following application of NPY. The time of peak MUA on day 2 was compared to that of untreated slices. Phase advances (3.04h ± 0.31h; $\bar{x} \pm$ sem) occurred when NPY was applied at ZT10, while NPY application at ZT8 did not alter the time of peak of MUA (0.40h ± 0.97h). The differences between these results and those of previous studies could be due to the method of recording neuronal activity or the strain of rat used in these experiments. The effect of NPY on the phase of SCN SUA is currently being investigated in the laboratory. Supported in part by NIH Grant MH-53317 to RAP.

PARALLELS BETWEEN CABP-IR CELLS AND BEHAVIORAL PHASE SHIFTS IN THE HAMSTER SCN. R. Silver* and J. LeSauter. Dept. Psychol. Barnard College and Columbia Univ. New York, N.Y. 10027.

Calbindin-D28K (CaBP)-ir cells form a discrete subnucleus in the hamster SCN. These cells receive direct retinal input (Romero et al., Soc. Neurosci. Abstr., 1996). About 80% of CaBP cells express fos-ir following a light flash (Silver et al., Neuroreport, 7: in press, 1996). Partial lesions of the SCN that destroy the CaBP cells disrupt locomotor rhythmicity. SCN transplants restore rhythmicity only when CaBP cells are present. Finally, homozygous tau mutant hamsters have more CaBP-ir cells than do wild type hamsters (LeSauter & Silver, Soc. Neurosci. Abstr. #76.3, 1995).

Since the phase delays to light at CT 14 increase in homozygous tau mutant hamsters after 7 weeks in constant dark (Shimomura & Menaker, JBR , 2:97,1994), we examined the influence of such housing on CaBP-ir. The results indicate that the number of CaBP-ir cells in the CaBP subnuclei increases more in tau mutant than in wild type hamsters, paralleling the behavioral phase delays. The results suggest an important role for the CaBP subnucleus in circadian organization.

No CaBP-ir cells (X±SEM)

	1 Week DD	7 Weeks DD
Wild Type	532 ± 17 (N=18)	682 ± 41 (N=14)

PACAP RESETS THE CIRCADIAN RHYTHM IN THE SUPRACHIASMATIC NUCLEUS VIA A cAMP-DEPENDENT PATHWAY. J. M. Ding*, D. Chen, J. Hannibal#, J. Fahrenkrug#, P. Larsen$, J. D. Mikkelsen$, and M. U. Gillette. Depts. of Cell & Structural Biology, Physiology, and Neurosci. Program, Univ. of Illinois, Urbana, IL 61801; #Dept. of Clinical Biochem., Bispebjerg Hospital, and $the Institute of Medical Anatomy, Univ. of Copenhagen, Denmark.

The suprachiasmatic nucleus (SCN) of the hypothalamus is the endogenous circadian clock in the mammalian brain. Pituitary adenylate cyclase activating peptide (PACAP) is localized in rat retinal ganglion cells projecting to the SCN via the retinohypothalamic tract (RHT). Using a brain slice preparation, the effect of PACAP on the phasing of the SCN rhythm of neuronal activity was assessed. In contrast to the nocturnal phase resetting effect of the glutamatergic neurotransmission of the RHT, PACAP adjusts the phase of the SCN neuronal activity rhythm in the daytime, but not at night. Application of PACAP-38 in a microdrop directly to the SCN at CT 6, the mid-subjective day, advanced the SCN activity rhythm by 3.5 ±0.4 hr. This PACAP-induced phase shift was fully blocked by a specific peptide antagonist, PACAP 6-38. The phase shifting effect was dose dependent, with a half-maximal shift occurring in response to a microdrop of 3 x 10^{-9} M of PACAP-38. VIP applied in the same way over a range of concentrations was 1000 fold less potent than PACAP suggesting that it acts through a type 1 receptor. This finding is consistent with the *in situ* hybridization of PACAP-R1 mRNA in the retinorecipient area of the SCN. The circadian sensitivity of the SCN to PACAP is in antiphase to SCN sensitivity to light, NMDA receptor activation, NO donors and transcriptional activation by CREB and Fos. However, it is overlapping with SCN sensitivity to cAMP, serotonin, and NPY. The phase shift elicited by PACAP-38 was blocked by preincubation of the cAMP antagonist Rp-cAMPS, supporting the involvement of a cAMP-dependent pathway. (Supported by NIH NS22155).

PITUITARY ADENYLATE CYCLASE ACTIVATING POLYPEPTIDE (PACAP) IN THE RETINOHYPOTHALAMIC TRACT. J.Hannibal§,J.Fahrenkrug§,P.J.Larsen*, J.M.Ding‡, D.Chen‡, M.U. Gillette‡, and J.D.Mikkelsen#*§ Dept. Clinical Biochemistry, Bispebjerg Hospital,*Inst. Med. Anatomy, Univ. of Copenhagen, ‡Dept. Cell. and Struct. Biol., Univ. of Illinois, and #Dept. Neurobiol., H. Lundbeck A/S, Copenhagen, Denmark.

The retinohypothalamic tract (RHT) relays photic information from the eyes to the suprachiasmatic nucleus (SCN). Activation of this anatomical pathway plays a role in adjusting circadian timing to light exposure at night. So far, the only transmitters shown in this pathway are glutamate and substance P. Light and glutamate stimulate a signalling pathway, which involves nitric oxide, CREB, c-fos, and cyclic GMP. Here we report that PACAP, a member of the VIP/secretin/glucagon family of peptides and a potent stimulator of cAMP, is present in the RHT. Using dualimmunocytochemistry for PACAP and the in vivo tracer Cholera toxin subunit B (ChB) intense PACAP-immunoreactivity (IR) was observed in the retinal afferents of the rat SCN as well as in the intergeniculate leaflet (IGL) of the thalamus. This PACAP-IR was lost upon bilateral eye enucleation though few positive fibers inside and outside the retinorecipient area of the SCN remained. PACAP afferents originating from retinal ganglion cells, which were distributed throughout the retina. The retinal ganglion cells expressing PACAP-IR were frequent and comprised a population of small neurons with a few branching processes likely belonging to the W-type. The position of PACAP positive terminals varied along the rostro-caudal axis of the SCN, but overlapped extensively with the retinorecipient area and with the SCN zones occupied by VIP-IR cell bodies and NPY-IR nerve terminals. In the rostral SCN, PACAP positive fiber plexus was located in the extreme ventral part of the nucleus, whereas in the middle and the caudal SCN, its position changed to a more lateral and dorsal position. Using a ^{35}S-cRNA probe PACAP-R1 receptor mRNA was demonstrated in the retinorecipient area of the SCN. The PACAP-R1 receptor is coupled to activation of a cAMP signalling pathway. This suggests that PACAP is a transmitter of the RHT mediating its effect via a signalling pathway different from glutamate.

CONDITIONED STIMULUS CONTROL OF LIGHT-INDUCED FOS EXPRESSION IN THE SUPRACHIASMATIC NUCLEUS. S. Amir* and J. Stewart. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Quebec, Canada.

In rodents light pulses given in the early or late subjective night stimulate the expression of Fos protein in the SCN and induce phase shifts in free running rhythms. We have shown recently that these effects can be induced, in the absence of light, by a conditioned stimulus (CS), previously paired with light (US). We hypothesized that once conditioning had occurred the CS might serve to optimize the response of the system to light, and that in the absence of the CS the response to light would be attenuated. To test this idea, rats were given 10 explicit pairing of a neutral non-photic stimulus (20 min of air flow, CS) and light (15 min, US) as previously described (Nature, 1996, 379, 542-545). Conditioning and testing took place during the second hour of the dark phase of the cycle. On the test day animals were presented with either the CS followed by the US, or the US only. Their response to the US was compared to that of a group of animals that had prior presentations of the US only. Animals were killed 45 min after the termination of the US presentation. Animals in the conditioning group that received both the CS and the US on test day showed robust Fos expression in the SCN which was comparable to that seen in response to light alone in animals without prior conditioning experience. Fos expression in the SCN in response to the US alone was significantly attenuated in animals in the conditioning group. These findings are consistent with the idea that stimuli that reliably precede light onset contribute importantly to the phase resetting function of light. Supported by FCAR, Quebec.

ENTRAINMENT OF CIRCADIAN RHYTHMS BY A CONDITIONED STIMULUS. B. Robinson*, J. Stewart and S. Amir. Center for Studies in Behavioral Neurobiology, Psychology Department, Concordia University, Montreal, Canada.

We have shown that the mechanism responsible for circadian pacemaker phase resetting by light can be brought under conditioned stimulus control. We found that a neutral non-photic stimulus (air flow) paired with light in Pavlovian conditioning trials was capable of eliciting in rats cellular and behavioral effects characteristic of light-induced pacemaker phase resetting, the expression of the transcription factor Fos in SCN cells, and phase shifts in free running activity and temperature rhythms. To determine whether light-mediated entrainment of circadian rhythms can, likewise, be brought under conditioned stimulus control, a group of rats was housed under a skeleton photoperiod consisting of two 1-h light pulses (8-9 am, and 8-9 pm), the US. Each light pulse was preceded by a 20-min air flow, the CS, that overlapped with the light for 5 min. Body temperature was recorded continuously using telemetry. This skeleton photoperiod effectively entrained temperature rhythms to the 24-h day. On tests for conditioning, the CS was presented alone twice daily at the same times. Entrainment persisted under these conditions, indicating that the CS had acquired through pairings with light the ability to substitute for the entraining effect of light. Removal of the CS resulted in free running rhythms with a period longer than 24 h. Reinstatement of the CS restored 24-h rhythmicity. These results show that a stimulus that comes to predict the onset of light can entrain circadian rhythms to the 24-h day. Supported by FCAR, Quebec.

PHASE RELATIONSHIPS IN ULTRADIAN AND CIRCADIAN RHYTHMS BETWEEN THE SUPRACHIASMATIC NUCLEUS AND OTHER BRAIN REGIONS. S. Yamazaki*, M.C. Kerbeshian, C.G. Hocker, G.D. Block and M. Menaker. NSF Center for Biological Timing, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22903.

We recorded multiple unit neural activity (MUA) inside and outside of the suprachiasmatic nucleus (SCN) from freely-moving male golden hamsters housed in running wheel cages under constant darkness. The circadian period of MUA in the SCN matched the period of locomotor activity: it was 24.1 h ±0.15 SE in wild type (n=4) and 19.9 h ± 0.15 in *tau* mutant (n=4) hamsters. The peak of MUA in the SCN was always observed in the middle of the subjective day. There were circadian rhythms of MUA outside of the SCN (thalamus, caudate putamen or septal nucleus). These rhythms were in phase with the rhythm of locomotor activity, peaking during the subjective night. In addition to the circadian rhythm, there were significant ultradian rhythms present: one, of about 80 min, was in anti-phase between the SCN and other brain areas; another, of about 14 min, was in phase between the SCN and other brain areas. The period of these ultradian rhythms were not significantly different between wild type and *tau* mutant hamsters. We also observed that the MUA of the nucleus proprius of the stria terminalis (n=2) showed the same phase of oscillation as the SCN in both circadian and many ultradian components. This suggests that the stria terminalis is strongly coupled to the SCN and may be one of its output pathways. This research was supported by NSF Center for Biological Timing along with NIH AG10870 (M.M.), NIH NS09329 (C.G.H.), NSF fellowship in Biosciences Related to the Environment (M.C.K.).

ROLE OF MATERNAL LIGHT PERCEPTION IN THE CIRCADIAN RHYTHM OF FOS IN THE MATERNAL AND FETAL SUPRACHIASMATIC NUCLEUS (SCN) IN SHEEP. L. Constandil*, V.H. Parraguez†, F. Torrealba,* M. Serón-Ferré. F. Cs. Biológicas, Pontificia Universidad Católica de Chile and †F. Cs. Veterinarias, Universidad de Chile; Santiago. Chile.

The SCN presents day-night changes in Fos protein in adult mammals and in fetal sheep. Since light exposure during darkness induces Fos in the adult SCN, daily Fos changes may not be endogenous. To assess this, we measured SCN Fos at 1200 and 2400 in 12 pregnant sheep and their fetuses at 93% of gestation. Six mothers had the eyes covered by an opaque black patch and six were controls. Sheep were kept 2 weeks 12:12 light:dark cycle; lights on 0800. Afterwards they were deeply anesthetized, and fetuses were delivered by hysterotomy at 1200 and 2400. Maternal and fetal heads were perfused with fixative. Brains were removed, cut in 40μm frozen sections and alternate sections were stained with cresyl violet or anti-Fos antibody. Density of Fos positive neurons (Fos+) in the SCN (number/mm^2) was calculated in each animal.

	Maternal SCN		Fetal SCN	
Hour	2400	1200	2400	1200
Control	91±8,6*	202±42	132±20*	768±73
Covered eyes	228±46*	41±20	485±59*	163±23

Means ±SE. * = P<0.05 vs. 1200 (Student t test).

In control sheep and fetuses the density of Fos+ neurons in the SCN was highest at 1200, while this was inverted in the maternal and fetal SCN when the mothers had the eyes covered. These data support the presence of an endogenous rhythm of Fos in the maternal SCN entrained by light. In addition the data suggest that the fetal SCN Fos rhythm is entrained by maternal signals. TRYPANOSOMA BRUCEI DYSREGULATES THE CIRCADIAN PACEMAKER IN THE RAT SUPRACHIASMATIC NUCLEUS *IN VITRO* J. Christenson*[1,2], G. Lundkvist[1], R. A. K. el Tayeb[1], Z-C Peng[3], M. Bentivoglio[3] and K.Kristensson[1]. [1]Dept. of Neuroscience, Karolinska Institute & [2]Astra Pain Control AB; Stockholm; Sweden [3]Institute of Anatomy and Histology, Univ, of Verona, Italy.

The extracellular parasite *Trypanosoma brucei* is the cause of African sleeping sickness, hallmarked by fragmentation of the sleep pattern. The suprachiasmatic nucleus (SCN) is a circadian pacemaker in the mammalian brain involved in regulation of endogenous rhythms including sleep-wake rhythms. It is entrained by input from retina via glutamate. Adult male Sprague Dawley rats were kept on a 12:12 hour light-dark cycle. Rats were infected with *Trypanosoma brucei* and sacrificed after 40-50 days. The endogenous electrical activity in slices containing the SCN region was recorded extracellularly and the slices were fixed and analyzed microscopically. In slices from control rats a peak of activity could be observed at circadian time (CT) 6-8. Slices from infected animals, however, had a peak of activity at CT 4. The mean firing frequency was significantly lower in infected animals as compared to the control population. A moderate astrocytic reaction and a marked microglia activation were detected in the SCN. Anterograde tracing *in vivo* with HRP-labelled cholera toxin did not display structural changes of the retinal terminals in the SCN. However, immunoreactivity to subsets of glutamate receptors was reduced during daytime in the SCN of infected rats as compared to the controls. Thus, trypanosome infection causes a dysregulation of brain neurons that entrain biological rhythms. Mechanisms of the dysregulation can be analyzed in an *in vitro* brain slice model of the SCN. SUPRACHIASMATIC NUCLEUS TRANSPLANTS IN NEONATAL RATS. F.J. Yang*, M.-T. Romero. Dept. of Psychology, State University of New York at Binghamton, Binghamton, NY 13902.

It is widely accepted that the suprachiasmatic nucleus (SCN) is responsible for the generation of circadian rhythms and that fetal SCN transplansts are capable of reversing behavioral arrythmicity produced by SCN lesions. Moreover, the grafted fetal SCN implanted into the adult brain survives and contains all the cell groups characteristic of this structure, including vasoactive intestinal polypeptide (VIP). Althought it is known that various types of fetal grafts survive in the neonatal brain, there are no studies which use hypothalamic tissue and in particular SCN tissue.

In the present study, we examined the survival, integration and VIP-ir expression in fetal SCN transplanted into neonatal hosts. Intact postnatal day 3 pups ware anesthetized by hypothermia, and received two pieces of fetal hypothalamic tissue containing the SCN, or cortex from embryonic day 20 fetuses into the 3rd ventricle. Animals were sacrificed 9,12,15, 20, 40 and 60 days after transplantation, brains were removed and serial (50um) sections were processed for VIP immunoreactivity through the area which contained the transplanted hypothalamic tissue. Preliminary data from cresyl violet and VIP labels indicate that both SCN and cortical tissue survived and expressed VIP through the period examined. Unlike most transplants in the adult animal, the graft-host interfase was not clearly delineated. In some hosts, grafting of the fetal transplant resulted in enlarged ventricles as well as in damage to intrinsic architecture. Further studies are underway to examine the behavioral effects of neonatal SCN grafts.

CORRELATION BETWEEN SUPRACHIASMATIC NUCLEUS NEURONAL ACTIVITY AND LOCOMOTOR ACTIVITY IN HAMSTERS M.C. Kerbeshian*, S.Yamazaki, C.G. Hocker, M. Straume, M. Menaker, and G.D. Block NSF Center for Biological Timing, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22903

Multi-unit neuronal recordings from the suprachiasmatic nucleus (SCN) reflect the circadian oscillation of the mammalian biological clock: activity is high during the subjective day and low during the subjective night. During an experiment in which we recorded locomotor and neuronal activity from the SCN and other brain regions (around the caudate nucleus) in male golden hamsters, we noted that bursts of locomotor activity corresponded with decreased activity in the SCN and increased activity in the other brain regions. To test the significance of this observation, week-long records of neuronal activity from 5 hamsters were compared to their records of locomotor activity. First, the cross-correlation between neuronal activity and locomotor activity was calculated with time lags ranging from 0 to $\pm$ 360 min. Significance was estimated using randomization of the data to calculate multiple-measure Z scores for each time lag. All but one animal showed a highly negative correlation between SCN activity and locomotor activity with a time lag around 0 min. This animal had such a strong circadian component to its neuronal activity that any smaller variations in the data may have been difficult to detect; thus, a second examination of the data used singular-spectrum analysis to remove long-term trends and circadian periodicities from the neuronal data. Visual inspection of the de-trended data revealed that SCN neuronal activity decreased within each continuous bout of activity for all animals. Both analyses revealed a positive connection between locomotor activity and neuronal activity in other brain regions, although the strength of this correlation varied among animals. Further analysis and additional experiments are needed to identify the causal link between locomotor and SCN neuronal activity.

STRAIN DIFFERENCES IN PHASE RESPONSE BETWEEN C57BL/6J AND DBA/2J INBRED MICE. JR Hofstetter, AR Mayeda, JI Nurnberger, Jr.* Indiana University School of Medicine and Richard L. Roudebush Veteran Affairs Medical Center, Indianapolis, IN 46202

There were significant differences in phase-response to light between C57BL/6J (B6) and DBA/2J (D2) inbred strains of mice at circadian time (CT) 15. B6 and D2 mice were housed individually, given running wheels and maintained in DD. Each mouse received 10 min pulses of 10 lux white light at various CT to generate phase response curves. Phase shifts ($\Delta\phi$) at each CT were calculated by fitting a line through activity onsets of the last 10 days prior to light exposure and 7-10 days after. The 5 days immediately after exposure were excluded to avoid transients. The strain difference may be amenable to genetic studies aimed at hypothesizing quantitative trait loci contributing to the genetic component of the variance in $\Delta\phi$ using the BXD recombinant inbred panel or BXD F_2 mice.

MOUSE RUNNING ACTIVITY IS LOWER AFTER BRUCELLAS ABORTUS TREATMENT, PROVIDING A POTENTIAL MODEL TO STUDY CHRONIC FATIGUE. J.E. Ottenweller, B.H. Natelson, W.L. Gause, K.K. Carroll, C. Goldstein, D. Beldowicz, S.D. Cook* and J.J. LaManca. Department of Neuroscience, New Jersey Medical School-UMDNJ, Newark NJ and Neurobehavioral Unit (127A), VA Med Center, East Orange NJ 07018-1095.

Chronic Fatigue Syndrome is characterized by severe and persistent fatigue which can occur after acute infection and last for years. Others have reported decreases in mouse running activity following infection and have suggested this may provide an animal model for studying chronic fatigue. Voluntary running is a highly motivated activity in mice, which in our lab will often run 5-7 miles/day. We treated female BALB/c mice with Brucellas Abortus (BA; 0.2 ml 1:6 dilution of packed washed BA, fixed killed whole BA ring test antigen from USDA) or vehicle and observed its effect on voluntary running. 60 day old mice were acclimated to running wheels for 2 weeks under LD 12h:12h with food and water available ad libitum, and then tail vein injections were made. Mice were maintained in wheels for 2 months after injections during which grooming was assessed periodically. Injection of BA caused an immediate large decrease in running for 1-3 days and lack of grooming. Vehicle injections produced no change in behavior. After the initial phase, normal levels of running and grooming returned slowly over the next 2-4 weeks with substantial individual differences in the rate of recovery. The pattern of running during recovery was intriguing in that BA mice first ran at normal levels just after the lights went out, but they stopped after only 1-2 hours. As recovery proceeded, they gradually increased the duration of the running bout during the night. Because this model uses voluntary exertion and the ability to run for longer periods of time characterizes recovery, it may provide a good model for studying the biological underpinning of chronic fatigue. ENVIRONMENTAL MANIPULATIONS ALTER NEURAL RESPONSE TO LORDOSIS-INDUCING STIMULI IN SYRIAN HAMSTERS. R.A. Mangels*, A.P. Auger, J.D. Blaustein and J.B. Powers. Dept. of Psychology and Neuroscience and Behavior Program, University of Massachusetts, Amherst, MA 01003-7710.

Sexual behavior in female Syrian hamsters is dependent on the sequential release of estradiol and progesterone from the ovaries. While appropriate hormonal conditions are important for sexual receptivity, environmental factors such as photoperiod and food availability have a profound influence on reproductive behavior. Long term exposure to a short photoperiod or short term exposure to food deprivation inhibits sex behavior in ovariectomized Syrian hamsters treated with estradiol and progesterone. These environmental manipulations may alter behavioral responses to steroid hormones, in part by reducing estrogen and/or progestin receptor levels in relevant brain sites. Neural response to sexually relevant social stimuli, such as somatosensory and chemosensory cues, could also be reduced by these treatments. Using Fos-immunoreactivity (Fos-ir) as a marker of neural responsiveness, we have begun to explore if and in which brain regions environmental manipulations alter neuronal responses to specific hormonal and sociosexual cues. In an initial study, Syrian hamsters were ovariectomized and housed in a long (14L:10D) or short (8L:16D) photoperiod for ten weeks with food and water available ad lib. All hamsters were treated with estradiol benzoate and progesterone and tested for lordosis 3.5h later. One hour after this test, hamsters were killed and their brains processed for Fos-ir. Short photoperiod exposure significantly decreased Fos-ir in the medial preoptic nucleus but had no effect on Fos-ir in the bed nucleus of the stria terminalis. A more complete analysis of relevant brain sites will be presented. Additional work will investigate whether these changes reflect an altered response to hormonal, chemosensory, or somatosensory stimulation, and will compare the influence of photoperiod and food deprivation. Supported by HD30372 to JBP and NS19327 to JDB.

EFFECTS OF CHRONIC RESTRAINT STRESS ON DOPAMINE RELEASE IN THE MEDIAL PREFRONTAL CORTEX OF THE RAT, K. D. Beck*, L. Sterbank, V. N. Luine. Department of Psychology, Hunter College of the City University of New York, New York, NY 10021.

Both acute stress and short-duration chronic stress increase dopaminergic activity in the prefrontal cortex. Longer-duration restraint stress increases monoamine levels in the hippocampus and decreases them in the prefrontal cortex, with accompanying memory deficits. In a continuing effort to assess the effects of chronic stress on neurochemistry and associated behavior, we examined the extracellular content of dopamine in the medial prefrontal cortex using in vivo microdialysis with electrochemical detection. Subjects were stressed by placement in a plexiglass tube for 6 hrs/day for 21 days. Subjects were tested by microdialysis from 3-21 days following the stress period. After establishing a steady level, basal release was monitored. No difference in basal release was found between control (.14 fmol/ul, +/- .005) and chronically stressed subjects (.167 fmol/ul, +/- .008). Following an injection of the dopamine reuptake anatagonist, nomifensine maleate (7mg/kg dose i.p.), an average 75% increase in extracellular dopamine was seen in both control and stressed subjects. The current results suggest that memory deficits associated with chronic restraint stress may not be associated with any imbalance in prefrontal cortex dopamine levels.

EFFECT OF PRENATAL STRESS ON 5-HT INDICES IN ADULT RAT FRONTAL CORTEX. J.R. Haigh, R.E. Poland and J.T. McCracken*. Neuropsychiatric Institute, UCLA School of Medicine, Los Angeles, CA 90024 and Harbor-UCLA Medical Center, Torrance, CA 90509.

The complex inter-relationship between 5-HT and the hypothalamic-pituitary-adrenal (HPA) axis has important implications for the understanding of the neuroendocrine response to stress. Prenatal stress has been reported to affect 5-HT neuron development, the adult offspring of stressed pregnant rats showing increased hypothalamic 5-HT content, for example. We have studied the effect of prenatal stress on 5-HT_2 receptor binding in frontal cortex using ^{3}H-ketanserin as a specific 5-HT_2 receptor ligand. Pregnant dams were restraint stressed for 1 h twice daily from days 14-21 of gestation with a control group composed of non-stressed dams. At 120 days of age, male offspring were sacrificed and ^{3}H-ketanserin binding performed with determination of B_{max} and K_D values by Scatchard analysis. We found a 14% increase in the B_{max} value and a 14% decrease in the K_D value in the stressed versus non-stressed offspring, as follows (means $\pm$ 1 S.D. n=5): B_{max} 506$\pm$130 fmol/mg protein and 439 $\pm$ 104 fmol/mg; K_D 0.84 nM and 0.98 nM, respectively. The serotonin content in frontal cortex, hypothalamus and hippocampus is also being investigated in these groups of animals. The implication of these data in light of long-term functional consequences of prenatal stress will be discussed.

MACROPHAGE ACTIVITY AND CELL PROLIFERATION FOLLOWING NATURALISTIC STRESSORS IN HIGH AND LOW SEIZURE SUSCEPTIBLE RATS. Z.W.Lu, C. Song, D. McIntyre, G.J. Remington* & H. Anisman. Institute of Neurosciences, Carleton University, Ottawa, Canada & Clarke Institute of Psychiatry, Toronto, Canada.

Stressors have been shown to influence various aspects of immune functioning. Inasmuch as marked interindividual differences exist in response to stressors, as well as with respect to immune functioning, we assessed the effects of stressors on immune activity in two strains of rats differentially reactive to stressors. Although these strains were selectively bred for vulnerability to induced seizures, we have observed that they also exhibit profound behavioral differences in their responses to stressors. In the present investigation we show that the strains differ in their corticosterone and ACTH responses to stressors, but that the magnitude of these changes are dependent on the nature of the stressor employed (i.e., restraint vs. exposure to a ferret). Additionally, in rats that develop seizures slowly, macrophage activity was greater than in the fast line, while cell proliferation in response to mitogens (Con A and LPS) was greater in the fast than in the slow line. Further, while stressors did not affect macrophage activity in the fast line, in the slow line stressor application, particularly exposure to a ferret, reduced macrophage activity. Cell proliferation, in contrast, was unaffected by the stressor in either strain. Evidently, while stressors may influence immune functioning, such effects are dependent on the strain of animal, the nature of the stressor used, and the aspect of the immune response examined.

BEHAVIORAL, ENDOCRINE AND CENTRAL NEUROCHEMICAL ALTERATIONS INDUCED BY INTERLEUKIN-1. S. Lacosta*, J. Kulczycki, Z. Merali, and H. Anisman. Institute of Neuroscience, Carleton University & University of Ottawa, Ottawa, Ontario, Canada.

Interleukin (IL)-1, may serve as a link between the immune system and the CNS. Specifically, IL-1 released from activated macrophages may gain access to the brain, influence central neurotransmitter functioning, and hence affect behavior. In the present investigation it was demonstrated that systemic administration of IL-1 (0.2 - 1.6 ug) dose-dependently increased plasma corticosterone and ACTH concentrations, and affected the turnover of norepinephrine (NE), dopamine (DA) and serotonin (5-HT) in several mesolimbic regions. These effects were independent of the pyrogenic consequences of IL-1 treatment, being evident at subpyrogenic doses. Interestingly, although hypothalamic-pituitary-adrenal functioning, and particularly release of CRH from the paraventricular nucleus may involve NE activity, IL-1 was actually more effective in modifying NE functioning in other brain regions, including the locus coeruleus and prefrontal cortex. Furthermore, the effects of the systemic IL-1 treatment were as marked following acute administration of the cytokine, as they were following a repeated treatment regimen. In addition to the endocrine and neurochemical consequences, IL-1 modified exploratory behavior in an open field test, and reduced open-arm entries on a plus-maze, suggesting that this treatment induced an anxiogenic response. Although IL-1 had effects similar to those elicited by stressors, the two treatments had neither synergistic nor additive effects with respect to either the endocrine, neurochemical or behavioral alterations.

INTERACTIONS OF MEPROBAMATE AND NALOXONE ON THE BEHAVIOUR OF MICE CONFRONTED WITH TWO UNCONDITIONED CONFLICT PROCEDURES C. BELZUNG and A. AGMO LEPCO UFR Sciences Parc Grandmont F-37200 TOURS (Spon: EBBS)

The present study was designed to study the interactions of various doses of the anti-anxiety compound meprobamate with the opiate antagonist naloxone in mice of different strains (Swiss, C57BL/6 and Balb/c) confronted to two animal models of anxiety : the elevated plus maze and the light/dark choice tests. In all strains, meprobamate (30, 60 and 120 mg/kg) dose-dependently increased the percent of open arm entries and the time spent in the lit box, an effect that can be interpreted as an anxiolytic one. This anti-conflict action of meprobamate is completely abolished by naloxone (10 mg/kg) in the Swiss and C57BL/6 strains. However, the same dose of naloxone was unable to block the anxiolytic action of meprobamate in the Balb/c strain. Moreover, when administered with a subeffective dose of meprobamate, the opiate antagonist strongly potentiates the anxiolytic action in all strains tested. It is concluded that the potentiating effect of naloxone does not depend upon the same underlying mechanims as its antagonizing properties.

IMMUNE ALTERATIONS ASSOCIATED WITH STRESSORS IN CONTROL AND DEPRESSIVE POPULATIONS. M.D. Zaharia*, A.V. Ravindran, Z. Merali, J. Griffiths, & H. Anisman. Institute of Neuroscience, Carleton University, and Dept of Psychiatry, Royal Ottawa Hospital, University of Ottawa, Ottawa, Canada.

Laboratory stressors provoke various immune alterations, which may be dependent upon the individual's stress history and emotionality. In the present investigation that a laboratory stressor (mental arithmetic challenge; psychiatric interview) influenced circulating lymphocytes, particularly NK cells, and that such effects were related to stress/coping factors and affective state. In contrast, irrespective of experiential factors, the stressor did not appreciably influence macrophage or neutrophil activity, mitogen-induced cell proliferation, or IL-1β and IL-2 production. However, a potent naturalistic stressor (anticipation of an academic examination), was associated with more pronounced variations of circulating lymphocytes, including not only NK cells, but also CD3, CD4 and CD8 cells. Additionally, mitogen-provoked cell proliferation was appreciably modified by this stressor. Finally, the effects of laboratory stressors on immune functioning were no greater in clinically depressed than in nondepressed subjects. While depressed subjects reported increased stress perception concerning day-to-day events, and exhibited alterations in circulating NK cells and mitogen-induced cell proliferation, the response to a laboratory stressor was comparable to that seen in nondepressed subjects. The data are discussed in terms of the efficacy of employing laboratory stressors to examine factors associated with vulnerability to immune alterations in patients with mood disorders.

AN OPIOID CONTRIBUTION TO THE EFFECTS OF INESCAPABLE SHOCK ON ESCAPE RESPONDING AND CONDITIONED FEAR IN RATS. R.E. Grahn*, M.B. McQueen, S. Maswood, L.R. Watkins, and S.F. Maier. Behavioral Neuroscience Program, Department of Psychology, University of Colorado, Boulder, Colorado, 80309.

Prior exposure to inescapable tailshocks (IS), but not indentical escapable tailshocks, induces an escape deficit and enhances conditioned fear 24 hr later. Recent investigations have revealed that the dorsal raphe nucleus (DRN) is critically important in mediating these learned helplessness effects. Converging lines of evidence support the idea that IS produces DRN hyperexcitability 24 hr later. At this time, DRN activation is proposed to result in exaggerated release of serotonin in projection regions, thereby producing the various behavioral consequences of IS.

The present study examines the role of DRN opioid receptor activation in learned helplessness. The opiate antagonist naltrexone (2µg/µl/rat) administered through preimplanted stainless steel cannulae into the region of the DRN immediately prior to IS prevented the escape deficit and enhanced conditioned fear measured 24 hr later. The same dose of naltrexone administered at the time of testing partially attenuated these effects of IS. Conversely, intra-DRN administration of morphine (10µg/µl/rat) in combination with 20 IS trials (1.0 mA, 5 s, 5 min variable ITI) induced an escape deficit and enhanced conditioned fear 24 hr later, thereby mimicking the effects of 100 IS trials. Neither 20 IS trials nor 10_{0}g morphine into the DRN was sufficient to produce these phenomena. Taken together, these data suggest that endogenous opiates provide an excitatory influence in the DRN at the time of IS, leading to a transient hyperexcitable state that can account for behavioral consequences of IS. Support provided by NIH grants #MH-50479, #MH-00314 and #MH-14617.

809.8

INHIBITION OF NITRIC OXIDE SYNTHESIS IN THE DORSAL RAPHE NUCLEUS PREVENTS POOR ESCAPE RESPONDING AND ENHANCED CONDITIONED FEAR IN RATS EXPOSED TO INESCAPABLE SHOCK. M.B. McQueen*, R.E. Grahn, L.R. Watkins, and S.F. Maier. Behavioral Neuroscience Program, Department of Psychology, University of Colorado, Boulder, Colorado, 80309.

Exposure to inescapable tailshocks (IS), but not identical escapable shocks, leads to learned helplessness effects including enhanced conditioned fear and poor escape responding 24 hr later. Accumulating pharmacological evidence supports the idea that IS leads to a transient state of hyperexcitability in the DRN. This hyperexcitable state is believed to be responsible for the poor escape responding and enhanced conditioned fear observed 24 hr later.

Since nitric oxide (NO) is known to produce neuronal hyperexcitability, the present study examined whether NO production in the DRN mediates the enhanced conditioned fear and poor escape learning observed 24 hr after IS. Nω-nitro L-arginine methyl ester (L-NAME; 5µg/µl/rat, in sterile saline) was administered into the DRN through preimplanted stainless steel cannulae either before IS (100 5s shocks, 1.0 mA, 1min variable ITI) or before behavioral testing 24 hr after IS. Both treatments attenuated the escape deficit and enhanced conditioned fear observed in the vehicle control groups. L-NAME was in fact more effective when delivered before testing than before IS. These results suggest that NO mediates increased excitability of the DRN, providing a possible mechanism by which IS leads to learned helplessness effects. Ongoing studies are addressing the role of NMDA receptors as inducers of NO. Support provided by NIH grant #MH-50479 and #MH-14617.

CHRONIC NEONATAL OPIOID BLOCKADE MODULATES BEHAVIOR AND BRAIN DOPAMINE RESPONSE TO STRESS IN DAY 10 RATS. P. Kehoe* & L. Triano. Neuroscience Program, Trinity College, Hartford, CT 06106 USA.

Our previous study has shown that neonatal handling and/or isolation experience significantly enhances locomotor response to amphetamine (AMPH) and brain dopamine (DA) turnover 24 hrs after the last isolation treatment in a sex-specific manner. To further assess this phenomenon, the present study utilized daily opioid blockade with naltrexone prior to handling or isolation. During PND 2-9, pups within each litter were individually isolated for 1 hr or handled and returned to the nest. All pups received a daily ip injection of saline (SAL) or NAX (1.0 mg/kg). Following SAL or AMPH (0.5 mg/kg) on PND 10, pups were placed in a novel environment for a 15 min test session, and behavioral activity was recorded. Brain DA turnover was assessed using HPLC. NAX blocked the enhanced locomotor response of previously isolated females to AMPH. All handled males had an exaggerated response to AMPH, with no evidence of NAX blockade. Locomotor activity of all NAX-treated male and female pups in response to novelty was significantly decreased compared to controls. Enhanced septal and hypothalamic DA turnover in females with prior isolation experience was blocked by NAX. These results suggest that chronic opioid blockade in the neonate differentially modulates male and female behavioral and brain DA responses to environmental or pharmacological challenge.

EFFECTS OF NEONATAL ISOLATION ON LTP MEASURES OBTAINED FROM MALE AND FEMALE RATS IN ADULTHOOD. R.J. Austin-LaFrance,* C. FitzSimons, R. McGill, J.D. Bronzino and P. Kehoe. Neuroscience Program, Trinity College, Hartford, CT 06106, USA.

We have previously reported that neonatal isolation results in sex-dependent differences in hippocampal long-term potentiation (LTP) recorded from freely moving juvenile (30-day old) male and female rats. Specifically, we found that neonatal isolation resulted in a greater magnitude of initial LTP enhancement in isolated males and a greater duration of enhancement in isolated females. The present study examined whether the effects of neonatal isolation on LTP endured into adulthood. Twenty-four hours after birth, litters were culled to 6 male and 6 female pups. On PND 2 all pups were weighed, and 3 male and 3 female pups were randomly assigned to one of two treatment groups: isolated or non-isolated. Isolated animals were individually separated from the nest, dam, and siblings for a period of 1hr per day over PNDs 2-9. At 70-90 days of age, animals were tested for their ability to establish and maintain LTP. Measures of population EPSP slope and population spike amplitude (PSA) were used to assess the magnitude and duration of LTP in these adults. Estrous cycle was monitored in adult females and baseline input/output (I/O) response and tetanization were carried out during the estrous phase. No differences in I/O measures were obtained as a function of either sex or treatment. However, the duration of tetanization-induced enhancement of PSA was significantly longer in females than males, with isolated females having the longest duration of any group. The data indicate that neonatal isolation results in enduring, sex-dependent differences in specific LTP measures.

AVAILABILITY OF ETHANOL DIFFERENTIALLY AFFECTS STRESS-INDUCED AND BASAL PLASMA CORTICOSTERONE LEVELS IN INDIVIDUALLY VERSUS TRIAD-HOUSED RATS. L.A. Pohorecky,* M.H. Baumann and D. Benjamin. Div. of Neuropharmacol., Center of Alcohol Studies, Rutgers Univ. Piscataway, NJ, 08855, and Clin. Psychopharmacol. Sec., NIDA, Baltimore, MD 21224.

Singly and triad-housed male Long Evans rats were used to determine the effect of rank status on basal and stress-induced blood corticosterone (CS) levels. Subjects were triad- and singly-housed rats, half of which had a choice of drinking a 6% solution of ethanol (ET) or water in the home cage. Dominance status was ascertained by monitoring behavior during the initial 30 minutes of triad formation, and by monitoring body weight and subsequent behavioral assessments. Sixty days after triad formation, animals were stressed by restraining them for 30 min in a cylindrical wire mesh. Blood was collected from tail cuts just before and after restraint. Singly housed water-consuming rats had lower basal CS than did triad-housed rats, and of these the alpha rat had highest levels. While singly-housed rats consuming ET had higher CS levels, ET did not alter CS levels of triad-housed rats, and if anything, lowered levels of the alpha rats. After 30 min of immobilization, CS levels were comparably high in triad and singly housed rats irrespective of ET consumption. The immobilization-induced increase in CS levels appeared to be lower in ET consuming-gamma rats. Analysis of trunk blood collected at the end of the study showed that beta and gamma rats, but not alpha rats consuming ET had lower CS levels than did the water consuming rats. These results indicate that housing conditions influence blood CS levels, and the consumption of low levels of ET (about 2 g/kg/day) can modulate blood CS levels in stressed rats. Thus, the stress of rank status, housing conditions and consumption of ET interact differentially to affect blood CS levels. (Supported by NIAAA grant AA05306).

EFFECT OF HANDLING AND MIXING STRESS ON CANNABINOID RECEPTOR mRNA LEVELS IN THE PIG HYPOTHALAMUS. G.D. Weesner[1] and P.V. Malven*[2]. [1]USDA-ARS and [2]Purdue University, W. Lafayette, IN 47907.

Pigs possess cannabinoid receptors in their brain. They also synthesize anandamide, an endogenous ligand for this receptor. We have previously demonstrated that pharmacological activation of this receptor with cannabinoid compounds results in behavioral hypomotility in pigs. We hypothesized that the cannabinoid pathway may be involved with stress-coping mechanisms in the pig. Tame, mature boars (n=10) were obtained. Five were quickly rendered unconscious with sodium pentobarbital, and hypothalamic tissue was collected and frozen (Control). The other five pigs (Trt) were hurriedly walked through a series of gates and pens for 15 min. Then, for an additional 15 min, each Trt boar was put into a pen with a strange boar where aggressive behavior was displayed. Hypothalamic tissue was then collected as above. Total RNA was extracted and quantitative RT-PCR was performed to reflect relative amounts of cannabinoid receptor mRNA in each sample. Pigs experiencing the handling and mixing stress had 42% more ($P<.05$) cannabinoid receptor mRNA (RT-PCR product) when compared to controls. Differences in the abundance of LHRH mRNA were not observed between the two groups. These results demonstrate that certain stressors can induce changes in the cannabinoid pathway. STRESSOR-INDUCED *IN VIVO* MONOAMINE VARIATIONS: ENHANCEMENT BY OLFACTORY BULBECTOMY IN RATS.

T.J. Connor [1], C. Song [3], Z. Merali [2], B.E. Leonard [1], and H. Anisman*[,3].
[1]Dept. of Pharmacol., Univ. Coll. Galway, Ireland. [2]Sch. of Psychol. & Dept. of Pharmacol., Univ. of Ottawa, [3]Dept. of Psychol. Carleton Univ., Ottawa, On. Canada.

Olfactory bulbectomized (OB) rat has been developed as an animal model of depression. The OB rat exhibits many behavioral, neurochemical, endocrine and immune alterations that are qualitatively similar to those observed in clinically depressed patients. This study examined the effects of two stressors on the interstitial levels of monoamines and their metabolites at the nucleus accumbens (nAcb) of OB rats and sham operated controls. The first stressor consisted of air puffs (5 x 5sec.), and the second (and more severe stressor) was 10 min of physical restraint. Administration of air puff stress caused a significant increase in HVA (26%), 5-HIAA (42%) in the OB rats. In the sham operated group this stressor failed to significantly alter the same parameters. Restraint stress caused significant increases in HVA (62%), 5-HIAA (55%) and DOPAC (31%) in the OB group. Sham operated controls displayed a significant increase in HVA (30%). In addition, OB rats displayed significantly lower basal levels of 5-HIAA. In conclusion, this study demonstrates that OB rats exhibit more robust and longer lasting accumbal neurochemical responses to both stressors examined. In addition the reduced basal levels of 5-HIAA observed in the OB rats is consistent with previous reports of the OB rat being a model of hyposerotonergic depression.

ATTENUATION OF RESTRAINT STRESS-INDUCED *c-jun* mRNA EXPRESSION IN THE HIPPOCAMPUS BY MIDAZOLAM AND N-METHYL-D-ASPARTATE (NMDA) ANTAGONIST

E. A. Del Bel, C. Lino de Oliveira and F. S. Guimarães. SPON: Brain Research Association. Dept. of Pharmacology, School of Medicine, and Dept. of Physiology, School of Odontology, Campus USP, Ribeirão Preto, SP, 14049-900, Brazil.

The effect of restraint stress on *c-jun* mRNA expression in the hippocampal formation was investigated by *in situ* hybridization, dot blot and northern blot. Rats were forced immobilized for 0, 15, 30, 60 or 120 *min, before being sacrificed by decapitation. The three techniques* showed that, after 60 *min* of restraint, *c-jun* mRNA expression increased in the dentate gyrus, CA1 and CA3 regions of the hippocampal formation. This restraint-induced increase in *c-jun* mRNA in the hippocampus was attenuated by pre-stress, *i.c.v.* injection of the anxiolytic benzodiazepine midazolam (20 nmol/2 µl) or the glutamate NMDA receptor antagonist 2-amino-7-phosphonoheptanoic acid (AP-7, 5 nmol/2 µl), but not by the 5-HT1A agonist, (±) 8-hydroxy-dipropylaminotetralin (8-OH-DPAT, 20 nmol/2 µl). These results suggest that the hippocampal formation is activated during restraint stress, and that this activation can be modulated by benzodiazepine/GABA-A or NMDA receptors.

MOLECULAR CORRELATES OF A CHRONIC MILD STRESS MODEL OF DEPRESSION.

A. Charkrabarti, S. P. Rossby, D. H. Manier,C. Perrin, E. S. Onaivi and F. Sulser* Dept of Pharmacology, Meharry Medical College, Nashville, TN 37208 and Depts of Psychiatry and Pharmacology Vanderbilt University, Nashville, TN 37232.

Chronic mild stress-induced anhedonia has been described as a model of depression with disease validity (Willner et al, Neurosc. Biobehav. Rev., 16: 525-534, 1992). Therefore, previous studies have shown that chronic exposure of rats to a variety of mild stress causes a decrease in the consumption of weak sucrose solutions. In this on-going project we have set up the rat CMS model to study the molecular correlates of depression which is poorly understood. Two groups of male Wistar rats were habituated to the consumption of 1% sucrose solution as a reward. The control non stressed group was kept in a different room on a 12:12hr light:dark cycle while the sequential application of mild stressors were applied daily to the experimental animals and repeated every week. Once every week the sucrose test was carried out following 12hrs of food and water deprivation for both groups. The CMS-induced hedonic deficit was characterized by a significant decrease in sucrose consumption in the stressed but not in the non stressed animals. By week 7, the activity, and stereotyped behavior were determined in both groups. There was no difference in the expression of motor activities and the weights of the animals in the control and stressed groups were indistinguishable. The molecular correlates of the CMS-hedonic deficit are being evaluated to test the serotonin/norepinephrine/glucocorticoid link hypothesis of affective disorders.

IMMOBILIZATION STRESS ELEVATES GTP CYCLOHYDROLASE I mRNA LEVELS IN RAT ADRENALS PREDOMINANTLY BY HORMONALLY MEDIATED MECHANISMS.

L.I. Serova[1], B. Nanková[1], R. Kvetnansky[2] and E.L. Sabban[1]. [1]Dept. of Biochem. and Mol. Biol., New York Medical Coll., Valhalla, NY 10595. [2]Inst. of Exp. Endocrinol. Slovak Acad. of Sciences, Bratislava, Slovakia.

GTP cyclohydrolase I (GTPCH) is the rate-limiting enzyme in the biosynthesis of tetrahydrobiopterin, the cofactor for catecholamine, indolamine and nitric oxide biosynthesis. To study the effect of immobilization stress (IMO) on GTPCH mRNA levels in rat adrenal medulla (AM), a rat GTPCH cDNA was cloned by rPCR. Northern analysis revealed two species of GTPCH mRNA (about 3.6 and 1.2 kb) in AM, adrenal cortex and PC12 cells. The levels of both forms of GTPCH mRNA were increased 3-6 fold in AM by single and repeated IMO. Unilateral splanchnectomy did not affect induction of the 3.6 kb GTPCH mRNA by IMO. While hypophysectomy had no effect on the basal levels, it prevented the IMO elicited rise in both GTPCH mRNAs, suggesting involvement of hormone regulation, possibly of glucocorticoids (GC). The effect of GC on GTPCH mRNA levels was examined in rat AM and in PC12 cell cultures. Cortisol administration increased rat AM GTPCH mRNA levels. Treatment of PC12 cells with dexamethasone for 12-48 hrs led to a 4-6 fold increase in both GTPCH mRNAs. The results reveal that GTPCH gene expression is activated by IMO, requires an intact pituitary-adrenocortical axis and may be directly modulated by GC.

LEARNED HELPLESSNESS AND GABA: IN VIVO MICRODIALYSIS STUDIES OF MEDIAL PREFRONTAL CORTEX AND HIPPOCAMPUS.

F. Petty,* G. L. Kramer, J. H. Wu, VAMC and Univ. Texas Southwestern Med. School, Dallas, TX 75216

Learned helplessness (LH) is an animal model of stress induced behavioral depression. As in human depression, a role for GABA is well documented in the development and reversal of LH. We have now applied the technique of in vivo microdialysis to study GABA release in medial prefrontal cortex (mPFC) and hippocampus (HPC) of conscious, freely moving rats. Rats received inescapable tailshock stress and were tested for LH in a shuttlebox one day later. After testing, microdialysis probes were implanted, with perfusion on the subsequent day. In HPC, K^+-stimulated GABA levels in perfusate were comparable in rats developing LH, in stressed rats not developing LH (non-helpless, NH), and in non-stressed tested controls (TC). However, all three groups were lower than naive, non-tested control rats, suggesting a nonspecific lowering in intracellular GABA from shuttlebox testing. In mPFC, there were no significant differences in K^+-stimulated GABA release among the four experimental groups. Perfusion with Ca^{++}-free medium resulted in a decrease in K^+-stimulated GABA efflux of about 50%, and no further decrease was noted after addition of TTX to the perfusing medium, suggesting a partly glial origin for the GABA in perfusate. These experiments confirm regional differences in GABA response to stress.

CHRONIC SOCIAL STRESS DECREASES BINDING TO 5HT TRANSPORTER SITES AND REDUCES DENDRITIC ARBORS IN CA3 OF HIPPOCAMPUS.

C.R. McKittrick*, A.M. Magariños, †D.C. Blanchard, †R.J. Blanchard, B.S. McEwen and ¶R.R. Sakai. Rockefeller Univ., New York, NY 10021, †Univ. of Hawaii, Honolulu, HI, 96822 and ¶Univ. of Pennsylvania, Philadelphia, PA, 19104.

Male rats housed in mixed-sex groups in a visible burrow system quickly form dominance hierarchies. Both dominants and subordinates show physiological signs of being stressed, compared to control males housed in male-female pairs. Dominants and subordinates had decreased [^{3}H]paroxetine binding to 5HT transporters (5HTt) throughout hippocampus compared to controls, with the most pronounced effects in dominant animals. 5HTt binding was lower in dominants than controls by 31% in CA1 and by 21% in CA2, CA3 and CA4. Binding in dominants was also lower than subordinates in CA1 (-15%) and CA4 (-13%). In subordinates compared to controls, 5HTt binding was reduced by 18% in CA1 and by 14% in CA2 and CA3. Dominant animals also exhibited a larger stress-induced shrinkage in the apical dendritic tree of CA3c pyramidal neurons. Compared to controls, total apical dendritic length and branch points were decreased by 19% and 18%, respectively. Smaller decreases were observed in subordinates with only the decrease in branch points significantly lower than controls (-10%). Since the decrease in 5HTt binding is greater in the dominants, increased extracellular 5HT may be involved in mediating the shrinkage of the apical dendritic arbors. This hypothesis is supported by a related study in which the 5HT uptake facilitator, tianeptine, effectively prevented the dendritic shrinkage induced by chronic restraint.

DEHYDROEPIANDOSTERONE (DHEA) & DEHYDROEPIANDOSTERONE SULFATE (DHEA-S) IN THE RAT: CONVERGING EVIDENCE OF ANTI-GLUCOCORTICOID PROPERTIES. J. Love*[1], R. Pugh[1], D. Tremblay[1], J. W. Rudy[1], G. Rose[3], D. Diamond[3], R. S. Mazzeo[2], L. R. Watkins[1], S. F. Maier[1], & M. Fleshner[1], Dept Psych[1], Dept Kines[2], U CO, Boulder, CO 80309. Dept Pharm[3], U. CO. HSC, Denver, CO.

The adrenal steroid hormone DHEA influences many biological systems. It is the most abundant adrenal hormone produced in young & middle-aged people & declines rapidly with age. Interest in this hormone has recently increased because it antagonizes many effects of glucocorticoids. Although readily measurable in humans & primates, little work has been done assessing this hormone in the rat. Thus the first goal was to characterize DHEA & DHEA-S levels in the rat. Serum levels of DHEA & DHEA-S were assessed in young (7mos; n= 21), middle-aged (15mos; n=23) & old (25mos; n=14) Fischer 344 rats using RIA. DHEA/DHEA-S levels declined with age in the rat. The second goal was to test the anti-glucocorticoid properties of DHEA in two different sytems which are modulated by glucocorticoid levels, i.e., the immune system & hippocampal-dependent learning systems. High doses of glucocorticoids can reduce the anti-KLH*in vivo* antibody response. Rats treated with DHEA-S (n=12) in the drinking water for 2 days prior to KLH immunization showed elevated anti-KLH Ig levels compared to controls (n=12). Removal of GCs (via ADX or RU486) inhibits contextual fear conditioning (a hippocampal dependent memory task) but not tone fear conditioning. Administration of DHEA in the drinking water 2 days prior to conditioning disrupted contextual but not tone conditioning. Thus DHEA is measurable in the rat, shows age-related decline, & functions as an anti-GC hormone. NIH-MH45045.

CHRONIC EXPOSURE TO STRESS LEVELS OF CORTICOSTERONE INCREASES GAD_{65} mRNA LEVELS IN HIPPOCAMPAL NEURONS. M. Orchinik*, N.G. Weiland and B.S. McEwen. Laboratory of Neuroendocrinology, Rockefeller University, New York, NY 10021.

Prolonged exposure to stress or elevated levels of corticosterone (CORT) alters neurophysiological and morphological characteristics of hippocampal neurons, possibly related to changes in the major neurotransmitter systems. In previous studies, chronic CORT exposure increased radioligand binding to the NMDA subtype of glutamate receptor, increased NMDA receptor subunit mRNA levels, and produced complex changes in $GABA_A$ receptor subunit mRNA levels and binding sites. We hypothesized that chronic stress or CORT exposure increases hippocampal excitability by shifting the balance between excitatory and inhibitory transmission, and predicted that GABA activity would be down-regulated. The mRNA levels of glutamate decarboxylase (GAD), the rate-limiting enzyme in GABA synthesis, were quantified as a measure of GABA activity in hippocampal neurons. Adult male rats received subcutaneous CORT implants that produced circulating CORT levels of approx. 33 ug/dl. Animals were sacrificed after 10 days, and brain sections were hybridized using a [^{35}S]-labeled probe specific for GAD_{65}. CORT did not alter the number of GAD_{65}-containing neurons in the hippocampus. However, CORT increased mean GAD_{65} mRNA levels per neuron in CA1 strata radiatum and pyramidale, CA3C stratum oriens, and dentate gyrus molecular layer. These data are not consistent with our prediction. A neuron-specific increase in GABA synthesis might contribute to enhanced hippocampal excitability through disinhibition or, alternatively, CORT-induced GABA synthesis may be a homeostatic mechanism for modulating the potentially deleterious effects of enhanced excitatory transmission. Supported by a fellowship from the Pharmaceutical Manufacturer's Association Foundation (M.O.), NIH grants NS30105 (N.G.W.), MH41256 and NS07080 (B.S.M.).

809.21

RAPID EYE MOVEMENT SLEEP DEPRIVATION (REMd) PLUS A L-LEUCINE SUPPLEMENTED DIET IMPAIRS SPATIAL REFERENCE AND WORKING MEMORY IN RATS B.D. Youngblood*, G.N. Smagin, J. Zhou, D.H. Ryan, and R.B.S. Harris Neuroscience Department, Pennington Biomedical Research Center, Baton Rouge, LA 70808.

REMd induced by the "flower pot" technique is a continuous stressor that impairs spatial reference memory. REMd is also associated with increased hippocampal, prefrontal cortex, and hypothalamic 5-HT metabolism in rats. It has been reported that a 3% l-leucine excess diet (LEU) will reduce the availability of the 5-HT precursor amino acid l-tryptophan (TRP) to the carrier transporter across the blood-brain-barrier and lower brain TRP and 5-HT turnover. Therefore, we investigated whether LEU would prevent the increase in 5-HT metabolism and attenuate the spatial reference memory deficit in REMd rats. Six groups of 8 male Wistar rats were assigned to: REMd housed on a 6.5 cm pedestal over water, large pedestal controls (LP) housed over water, or home cage controls (CC) and fed either LEU or control liquid diets for 4 days. Spatial reference and working memory were tested on days 2, 3, and 4 of REMd using a variation of the learning-set task protocol in the Morris water maze. The procedure involved 6 starting locations with duplicate 2-min trials with the submerged platform in a different location each consecutive day. Latency, distance swum to find the hidden platform, and swim speed were measured. Day 4 reference memory (trial 1) in both dietary groups of REMd rats was significantly impaired. Regional brain TRP was the same for all groups and 5-HT turnover were increased in all REMd rats compared with LP or CC. Day 4 working memory (trial 2) in the REMd-LEU group was significantly impaired compared with REMd controls. Striatal dopamine turnover was increased significantly in all REMd rats.

These results suggest (1) LEU had no effect on central 5-HT metabolism or reference memory. (2) REMd-LEU induced a working memory deficit independent of 5-HT metabolism.

GLUCOCORTICOID (GC), BUT NOT MINERALOCORTICOID (MC), RECEPTOR AGONIST AND ANTAGONIST BLOCK SPATIAL MEMORY PERFORMANCE ON THE Y-MAZE. C.D. Conrad*, S.J. Lupien, B.S. McEwen. The Laboratory of Neuroendocrinology, The Rockefeller University, 1230 York Avenue, New York, NY, 10021.

The purpose of this study was to determine whether the GC and MC receptors contribute differentially to performance of rats on a spatial Y-Maze task. To address this issue, adrenalectomized (ADX; n=71) and intact rats (n=55) were injected with either stress levels of corticosterone (ADX; n=15; CORT), a GC receptor agonist (ADX; n=14; RU362), a MC receptor agonist (ADX; n=14; Aldosterone); a GC receptor antagonist (intact; n=10; RU555), or a MC receptor antagonist (intact; n=12; RU318). Adrenalectomized rats injected with sesame oil were used as controls for the ADX groups, while intact rats injected with sesame oil, or not injected at all served as controls for the intact groups. Each group received the injection 2 hrs before their first trial in the Y-Maze, at which time one arm was blocked ("novel" arm), and rats were allowed to investigate the other two arms ("start" and "other" arms) for 15 minutes. After a delay of 4 hrs, rats were placed in the Y-Maze again and all arms were now available for investigation. The first arm chosen (FC), the number (NV) and duration (DV) of visits in each arm on Trial 2 constituted the dependent variables. The analyses showed that on Trial 2, all groups except the GC agonist, the GC antagonist and the high CORT group entered the novel arm more often than the other arms [G X A; $F(8,108)=2.57$; $p<0.02$]. We have previously shown using the Y-Maze task that this measure of spatial learning is sensitive to hippocampal lesions and stress (Conrad et al., submitted). The results of this study suggest that the GC receptor may contribute to spatial memory abilities in a non-linear fashion whereby the occupation of GC receptors at extremely low or high levels can impair spatial memory. This research was supported by MH10804 to CDC and MH41256 to BSM.

EFFECTS OF HIPPOCAMPAL MINERALOCORTICOID AND GLUCOCORTICOID RECEPTOR BLOCKADE ON ANXIETY. C. Timothy* ,D. Murphy, B. Costall and J.W. Smythe Dept. of Pharmacology, Univ. of Bradford, Bradford, U.K., BD7 1DP

Corticosterone (CORT) modulates anxiety-like behaviour (ALB) in rats but the brain region and mechanism remains unknown. The hippocampus has the highest density of mineralocorticoid receptors (MR) and glucocorticoid receptors (GR) where CORT is known to act. In the present study we investigated the effects of intrahippocampal infusions of MR and GR antagonists on ALB as measured by the black-white box and social interaction tests. Adult male, Lister hooded rats were implanted bilaterally with hippocampal cannulae 3 weeks prior to testing. On the test day, rats were infused with 3µl vehicle (VEH; artificial CSF with 5% ethanol), 150 ng of spironolactone (MR antagonist), or 150 ng RU38486 (GR) antagonist), either 10 min or 3 hr prior to being placed into the white chamber of the Black-White box (n=9-11/group). Rats were scored for time spent in the white chamber and intercompartmental crosses. A separate group of rats was injected with VEH or spironolactone (n=10-12) as above, and placed in a social interaction test. Rats were placed into an open field and scored for time spent engaged in interactive behaviours (sniffing, following, physical contact). Data were assessed by ANOVA and *post hoc* testing was performed using Bonferroni corrected t-tests. ANOVA on the black-white box data revealed a significant drug effect on time spent in the white chamber at 10 min ($P<.04$), but not at 3 hr. Spironolactone significantly increased time in the white area ($P<.05$). ANOVA on crossing behaviour similarly showed a drug effect, at 10 min ($P<.01$), where spironolactone increased crossing behaviour ($P<.01$), and an effect at 3 hr ($P<.04$), where spironolactone decreased crossing behaviour ($P<.01$). There were no obvious effects of RU38486 on any behaviors, nor any effects of spironolactone on social interaction. These data show that CORT affects ALB via hippocampal MR, on some tests but not others. *(supported by U. of Bradford)*

EFFECTS OF CORTICOSTERONE AND NIMODIPINE ON MORPHOLOGY OF CA1 & CA2 HIPPOCAMPAL AREAS. G. H. Beagley,* Alma College, Alma. MI 48801, USA, S. Dachir and A. Levy, Israel Institute for Biological Research, Ness-Ziona 70450, Israel.

Prolonged corticosterone administration has detrimental effects on cognitive performance and hippocampal morphology in rats. Nimodipine improves cognitive functions and protects brain cells from effects of corticosteroids. Brains from rats treated with corticosterone and nimodipine at the Israel Institute for Biological Research were examined at the electron microscope laboratory in Alma, MI to investigate morphology of affected hippocampal pyramidal cells. 15 male Fischer 344 rats, aged 4.5 mo were divided into 3 treatment groups. Group I was implanted 4 times with corticosterone sustained release pellets (CSR)(200 mg over 3 weeks), plus nimodipine sustained release pellets (NSR) (20 mg over 21 days). Group II was implanted with CSR pellets, and placebo for nimodipine. Group III was implanted with placebo pellets for corticosterone and nimodipine. 45 days after treatment, rats were decapitated, brains removed, washed with saline and shipped to Alma in fixative of buffered aldehydes. Coronal slices 500 µm thick were cut though the anterior-posterior extent of the hippocampus from bregma -2.2 mm through bregma -2.9 mm. Tissue was examined at 3000 to 14000 X magnification. Rats who received CSR without nimodipine showed substantial damage to both CA1 and CA2 areas There was deterioration of pyramidal cell bodies; many cells were missing. Rats with placebos had normal pyramidal cells in these areas. In rats that received both CSR and NSR, CA1 cells were protected from damage, CA2 cells showed only slight damage. Data extend findings that nimodipine protects cells in the CA1 area from effects of corticosterone. They also suggest differential vulnerability in areas CA1 and CA2. Supported by IIBR and Alma College.

CHOLINERGIC CHANGES FOLLOWING PROLONGED CORTICOSTERONE TREATMENT. S. DACHIR, M. LEVY and A. LEVY*, Israel Institute for Biological Research, Ness Ziona, 74048, ISRAEL.

Prolonged high levels of corticosterone, as well as extended periods of stress, have been shown to cause in laboratory animals morphological hippocampal changes and cognitive impairments, resembling those found in aging subjects. The septo-hippocampal cholinergic system, which was established as playing a major role in cognitive functions, was found to deteriorate during aging. The interactions between stress and the cholinergic system were investigated in numerous studies with conflicting and controversial results.

Recently we have developed a rat animal model, in which continuous corticosterone administration produced the above hippocampal and behavioral changes. The cholinergic effects of this treatment were examined in the present study. Using the microdialysis technique, the extracellular levels of acetylcholine (ACh) within the CA1 / dentate gyrus areas of the hippocampus were monitored in young Fischer 344 rats. Following three months of corticosterone treatment (plasma levels in the range of 15-25 µg/dl), the scopolamine-induced ACh release was significantly reduced. Nevertheless, spatial memory tests such as the Morris water maze and the 8-arm radial maze, failed to exhibit any change under these conditions. The cholinergic activity was also tested against the hypothermic effect of the cholinergic agonist oxotremorine, and the amnesic effect of the cholinergic antagonist scopolamine, using the passive-avoidance behavioral paradigm.

The results confirmed that prolonged corticosterone treatment induced hippocampal cholinergic hypofunction, although some behavioral tests seem not sensitive enough to be affected by the change.

YOHIMBINE AND SEXUAL BEHAVIOR IN MALE RATS: EFFECTS OF REPEATED TREATMENTS AND PHYSIOLOGICAL STATE. J.T. Clark*, J.N. Gudger and P.D. Epperson. Dept. Physiology, Meharry Medical College, Nashville, TN 37208.

In our continuing evaluation of *α*-adrenergic influences on copulatory behavior we have presently addressed some unanswered questions. [1] What are the effects of long-term treatment? We evaluated the effects of daily injections of 2 mg/kg yohimbine on mounting behavior after genital desensitization, and tested different groups of rats 20 minutes after 1, 10 and 21 injections. We observed a decrease in the effectiveness of yohimbine with the increasing number of daily treatments. [2] What are the most effective doses of yohimbine, and are similar dose-relations seen with rauwolscine? The effects of rauwolscine and yohimbine on mounting behavior following genital desensitization are dose-dependent. [3] Is yohimbine effective in aging rats? The effects of 0.5 or 2 mg/kg yohimbine on copulatory behavior and penile reflexes were evaluated. Either dose significantly increased the proportion of middle-aged (18 months of age) copulating to ejaculation, but only the 2 mg/kg dose was associated with reductions in ML and IL, and with increases (towards young values) in IF. In reflex tests, yohimbine suppressed erection in young and middle-aged males. [4] Is yohimbine effective in streptozotocin-diabetic rats exhibiting sexual dysfunction? In this study, yohimbine (20 min pretesting) partially restored copulatory behavior in diabetic rats. These data provide further evidence for *α*-2-adrenergic modulation of sexual function, and suggest a possible therapeutic use in reversing sexual dysfunction in aging and diabetes. NORADRENERGIC ROLE IN STRESS-INDUCED HYPERTHERMIA. X. Páez*, E. Briese and L. Hernández. Lab. of Behavioral Physiology, Universidad de los Andes, Mérida 5101, Venezuela.

Since blood norepinephrine (NE) in rats increases simultaneously with stress-induced hyperthermia (SIH), we investigated if NE had a direct influence on SIH. In demedullated and adrenalectomized rats, plasma catecholamines were measured by alumina extraction and HPLC-EC. Plasma epinephrine was 60 times lower than controls, while plasma NE was not affected. However, both demedullated and adrenalectomized rats exhibited SIH with an increment of more than 0.5° C of rectal temperature in the first 15 min. The blockade of sympathetic activity by 10 and 20 mg/k i.p of hexametonium significantly diminished or abolished SIH [$F=29.716$, $p< 0.001$]. The β adrenergic blockade with 10 mg/k i.p of propranolol prevented the SIH, and with 20 mg/k produced a significant decrease of body temperature [$F=56.711$, $p<0.001$]. Prazosin, an α_1 adrenergic blocker at doses 2 and 10 mg/k did not block the SHI while 20 mg/k diminished the body temperature 30 and 45 min after being injected. In conclusion, it seems that SIH depends on the sympathetic activity through the NE. The adrenal gland or epinephrine were not necessary in generating the SIH. Moreover, since propranolol blocked the SIH in a dose-response manner, while SIH was not affected by prazosin, SIH may be specifically dependent on a β adrenergic action.

ATIPAMEZOLE, AN α2-ADRENOCEPTOR ANTAGONIST, INCREASES THE SEXUAL BEHAVIOR OF VERY OLD AND SEXUALLY SLUGGISH MALE RATS. T. Viitamaa, A. Haapalinna*. Neuropharmacological Lab., Orion-Farmos, Orion Corporation, P.O. BOX 425, FIN-20101 Turku, Finland.

It has been shown that α2-adrenoceptor antagonists increase male sexual activity. Yohimbine has been used for the treatment of impotence in clinical medicine. The stimulatory action of yohimbine and idazoxan on sexual activity have also been demonstrated in some animal studies but also opposite effects have been reported. Atipamezole (ATI) is a selective and potent α2-adrenoceptor antagonist, which in our previous study increased the sexual behavior of middle aged, sexually sluggish, male rats significantly, whereas yohimbine did not[1]. In this study, the effect of ATI (0.1 and 0.3 mg/kg s.c.) on sexually sluggish, very old (27 months), male rat sexual activity was studied. 11 old male Spraque-Dawley rats were tested with receptive females to see if they would show sexual activity. Tests were done with a counterbalanced crossover design. ATI decreased the mount latency at the dose 0.3 mg/kg (48% of control, p=0.02). Mount frequency increased at doses 0.1 (444%, p=0.04) and 0.3 mg/kg (778%, p=0.02).

These results show that atipamezole increases the sexual activity not only in adult but also in sexually sluggish, normally almost inactive, very old male rats. The stimulatory effect was most pronounced in the mount latency and mount frequency. This stimulatory effect of atipamezole on mating behavior is thought to reflect increased sexual arousal and might have beneficial effects in male impotence, especially of central origin.

TWO METHODS OF ENHANCING LOCUS COERULEUS-NOREPINEPHRINE FUNCTION DIFFERENTIALLY AFFECT CURIOSITY AND OPEN FIELD BEHAVIOR IN THE RAT. C.W. Harley* and A.A.H. Mansour. Psychology Dept., Memorial Univ., St.John's, NF A1B 3X9; Fac.of Veterinary Med., Cairo Univ., Giza, Egypt

Idazoxan preferentially increases phasic activity of the locus coeruleus-norepinephrine (LC-NE) system (Simson and Weiss, 1987). Increased LC-NE innervation of neocortex, as measured by an electrophysiological index, has been reported following 10 min of warm water immersion daily for two weeks (Nakamura et al, 1989).

In the present study, the hole board curiosity test, a behavior sensitive to LC-NE function (Sara et al, 1994), was used to assess both idazoxan (2 mg/kg ip) and the warm water treatment in male Long-Evans rats. Response to novelty was tested in a 5 min trial after two habituation days.

All groups showed curiosity, with more nose poke activity in holes containing novel objects. Only the idazoxan group showed greater than normal curiosity (see also Devauges and Sara, 1990). Rearing was reduced by idazoxan, but enhanced by warm water treatment. Center entries were elevated in the warm water group relative to its control, but well-handled controls made similar center entries.

These data suggest increased LC-NE innervation produces different behavioral sequelae than increased LC-NE phasic activation. Interestingly, tonic infusion of NE in hippocampus increased both rearing and center entries in a similar hole board (Flicker and Geyer, 1982).

LC NEURONS IN MONKEY ARE SELECTIVELY ACTIVATED BY THE EARLIEST PREDICTORS OF REWARD. J. Rajkowski*, P. Kubiak, S. Ivanova and G. Aston-Jones, Dept. Psychiatry, Med Coll PA & Hahnemann Univ., Phila., PA 19102

LC neurons were recorded in Cynomolgus monkeys during performance of a visual discrimination task which required lever release after presentation of a target cue (10-20% of trials) to receive a drop of juice reward, but no response after nontarget cues (80-90% of trials). As previously reported (Aston-Jones et al., 1994; Rajkowski et al., 1994), LC neurons were phasically activated by target stimuli, but not by juice reward presentation in this task. However, LC neurons were phasically activated by "free" juice delivered by the experimenter; these free juice trials were delivered in blocks of 10-30, and were not preceded by target cues and did not require lever release (n = 26 cells). Closer analysis indicated that these LC responses to free rewards were produced by other conditioned stimuli associated with juice delivery (solenoid click or sight of juice), rather than by juice ingestion. In particular, responses persisted for solenoid activation after juice delivery was occluded. The response to juice-associated stimuli habituated with frequent presentation of free rewards (sec apart), and was re-established when free rewards were presented less frequently (min apart). In addition, these responses gradually extinguished after removal of the juice reward. The dynamics of the process of LC conditioning were studied during task contingency reversal. Immediately after reversal, the new target (old nontarget stimulus) was ineffective in activating LC responses, but LC neurons responded to other stimuli preceding the reward (e.g., solenoid click). With repeated presentation of the new task contingency, the response to the new target gradually emerged (within ~50 target trials), while response to the other reward-related stimuli disappeared. These findings indicate that LC neurons are phasically activated by the earliest conditioned stimuli that predict reward availability. These results may indicate a role for phasic LC activation in preparing for adaptive responses to significant events. 810.6

ENHANCEMENT OF MONKEY LOCUS COERULEUS (LC) NEURONAL RESPONSES TO VISUAL TARGETS BY PRECEDING AUDITORY DISTRACTORS. G. Aston-Jones, P. Kubiak, J. Rajkowski, S. Ivanova and J. Cohen*, Dept. Psychiatry, Med Coll PA & Hahnemann Univ., Phila, PA 19102; *Dept. Psychology, Carnegie Mellon Univ., Pittsburgh, PA 15213.

We previously reported that LC neurons are selectively activated by target stimuli in a visual discrimination task (Aston-Jones et al., J. Neurosci., 1994), and that the magnitude of this response decreases with higher frequency of targets (Rajkowski et al, Soc. Neurosci Abstr., 1994). We now report that LC neuronal responses to visual target stimuli are enhanced by preceding auditory distractors. LC neurons were recorded from a Cynomolgus monkey performing a visual discrimination task requiring pedal release after infrequent (20%) target cues but no response for frequent (80%) nontarget cues. Auditory distractor stimuli (70 msec, 78 db) were presented throughout the experimental session at a rate of 1 per 5 or 8 sec. These auditory stimuli were presented independently of the task and randomly in relation to target and nontarget stimuli. As we previously found, LC neurons were phasically activated by target cues (~120 msec onset latency) but not by nontarget cues. LC neurons were also phasically activated by the auditory distractors but at shorter latencies (~50 msec onset). Presentation of distractors did not substantially affect task performance. However, auditory distractor stimuli that occurred within 200 msec prior to target presentation enhanced LC responses to these target cues. These results indicate that unexpected strong stimuli sensitize LC neurons to subsequent attended stimuli, and may thereby facilitate LC's role in modulation of cognitive processes related to the attended stimulus. 810.7

RESPONSE OF MONKEY LOCUS COERULEUS (LC) NEURONS TO TARGET STIMULI IN A VISUAL DISCRIMINATION TASK VARIES WITH DISCRIMINATION DIFFICULTY. P. Kubiak*, J. Rajkowski, S. Ivanova & G. Aston-Jones. Dept. Psychiatry, Medical College of PA & Hahnemann Univ., Philadelphia, PA 19102.

We reported previously that LC neurons are selectively activated by target stimuli in a visual discrimination task (Aston-Jones et al, 1994). The present results reveal that the latency and magnitude of this response vary with task difficulty as determined by the similarity of target and nontarget stimuli. LC neurons were recorded from a Cynomolgus monkey performing a visual discrimination task requiring pedal release after infrequent (20%) target stimuli but no response to frequent (80%) nontarget stimuli. Target vs. nontarget stimuli were vertical vs. horizontal rectangles on the video screen. Three pairs of stimuli were used which varied in length-width difference (length X width, in cm: 1.0 X 0.2, 0.55 X 0.25, 0.5 X 0.3). All stimuli had similar absolute areas (in sq. cm) on the monitor. LC neurons were phasically activated by target stimuli in all cases; however, the latency of this activation varied with discrimination difficulty, being shortest for targets in the pair of stimuli with the largest length-width difference. The magnitudes of LC responses changed in parallel with these latency differences, being strongest for target stimuli in pairs with the largest length-width difference. The latencies and magnitudes of LC target responses also correlated with the latencies of pedal release to target stimuli, which were shortest for targets of the stimulus pair with the largest length-width difference. These results indicate that phasic LC responses to conditioned stimuli are sensitive to discrimination difficulty. The close correlation between behavioral responding, and the latency and magnitude of LC responses, suggest a role for LC in performance in this attentional task. Supported by AFOSR grant F49620-93-1-0099, PHS grant MH 55309, and the Human Frontiers Science Program.

LOCUS COERULEUS NEURON AND EYE MOVEMENT. K. Yamamoto, N. Ozawa and T. Shinba. Department of Neurophysiology, Tokyo Institute of Psychiatry, Tokyo, 156, Japan.

There is growing evidence that the locus coeruleus is a system which sustains vigilance of the brain. If this assumption is correct, neuronal activity of the nucleus should be related with eye movement as well because eye movement can be an indicator of attention.

Three monkeys(Macaca Fuscata) were trained to watch a small moving target on CRT placed 57cm in front of the animals. The monkey's head was set to a monkey chair (Narishige, MH-50) stereotaxically. The eye position was recorded with a magnetic search coil. The target moved sinusoidally in the horizontal direction. The visual angle of the sinusoidal movement was 20° and one cycle of the movement took 3s. The target size was 0.05°.

The neuronal activity of the locus coeruleus was identified as follows. 1. Individual variation of the stereotaxic coordinate was adjusted by finding the position of the abducens nucleus and the trigeminal motor nucleus with unit recording. 2. Elicitation of the antidromic spike by stimulation of the dorsal noradrenergic bundle. 3. Suppression of the activity with clonidine (i.m.) and activation with yohimbine (i.m.). 4. Electrical lesion and histological identification after completion of the recording.

The locus coeruleus neuron(n=11) thus identified showed a marked firing increase associated with eye movement during accurate tracking of the target.

NORADRENERGIC α-2 AGONISTS DIMINISH BEHAVIORAL AND DOPAMINERGIC RESPONSES TO CONDITIONED FEAR, B.A. Morrow*, T.P. George, E.J.K. Lee and R.H. Roth, Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06520

In order to test the involvement of the noradrenergic system in the stress-activation of the mesocorticolimbic dopamine (DA) neurons, rats were subjected to a conditioned fear paradigm. Briefly, rats underwent 3 sessions lasting 30 min on 3 consecutive days: habituation, acquisition, and extinction. The day following the habituation session, rats were returned to the test chambers and exposed to 10 x 5 sec tones each of which terminated with a 0.4 mA x 0.5 sec footshock. On the extinction day, rats were given clonidine (CLON, 0.1 mg/kg i.p.), guanfacine (GFC, 0.1 mg/kg i.p.), or saline and, after 30 min, were returned to the test chambers and exposed to 10 tones without footshock. Immediately after extinction, rats were killed and several brain regions were dissected out for monoamine determination by HPLC-ED.

GFC blunted the fear-induced immobility on the extinction day. CLON caused sedation, thus limiting the interpretation. As expected, fear conditioning increased DA metabolism in the medial prefrontal cortex (mPFC) and the nucleus accumbens (NAS). Treatment with CLON or GFC blocked the stress-induced increase in DA metabolism in both the NAS and mPFC. A second group of rats was prepared for central injection by implanting a guide cannula. In this experiment, on the extinction day, rats were given local injections of CLON (1 μg/0.5 μL), GFC (1 μg/0.5 μL), or saline into the ventral tegmental area (VTA), the region containing the dopamine cell bodies of the discreet NAS and mPFC projections. Intra-VTA treatment with CLON or GFC failed to prevent fear-induced immobility. Additionally, in a preliminary experiment, GFC failed to prevent the activation of the immediate early gene, *fos*, by the conditioning footshock in DA neurons in the VTA. These data indicate that it is unlikely that the anxiolytic actions of α-2 agonists noted above are mediated at the level of the VTA. *Supported by US PHS MH-14092*

EFFECTS OF MONONAMINE OXIDASE BLOCKADE ON RAT BEHAVIOR AND BRAIN BIOCHEMISTRY. H.-M. Hwang* and S.-J. Weng. Department of Anatomy, Chang Gung College of Medicine and Technology, Taoyuan, Taiwan 33333, Republic of China.

Human studies had indicated that isolated complete monoamine oxidase (MAO) deficiency was associated with a recognizable phenotype including disturbed regulation of impulsive aggression. An animal model of long-term MAO suppression was used to simulate functional changes of brain biochemistry in the case of MAO deficiency. Adult male Long-Evans hooded rats were injected with either clorgyline or deprenyl in a dosage of 2 mg/kg in 0.5 ml of saline i.p. daily for a month. Locomotive activity tasks performed 24 hours after the last injection indicated that clorgyline treatment caused increased locomotion in terms of counts of crossing-over, rearing and poking in a designed chamber. MAO assay, using [^{3}H]5-HT and [^{3}H]PEA as enzyme substrates of MAO-A and MAO-B respectively, showed a dramatic decrease of MAO-A activity in cerebrum, hippocampus and cerebellum but no change in MAO-B. Binding assay of membrane fractions from brain tissue, using [^{3}H]DHA as a ligand, indicated a decrease of β-adrenergic receptor activity in the cerebrum but not other brain regions. These results implied the possibility that stress-irritated emotional outburst in human MAO deficiency case may also involve receptor changes. (supported by NSC-85-2331-B-182-131-Y)

ELEVATED LOCOMOTOR ACTIVITY FOLLOWING EXCITATORY AMINO ACID MICROINFUSION INTO THE VENTRAL HIPPOCAMPUS: RECEPTOR-SUBTYPE SPECIFICITY. M. E. Bardgett* & D. M. Brenner Department of Psychiatry, Box 8134, Washington University School of Medicine, St. Louis, MO 63110.

The mammalian hippocampus contains a high density of ionotropic (NMDA, AMPA, and KA) and metabotropic receptors for the excitatory amino acid neurotransmitter, glutamate. Previous studies have suggested that stimulation of NMDA receptors in the ventral hippocampus (VH) selectively increases locomotor behavior, while stimulation of AMPA and KA receptors produce seizures. The effects of metabotropic receptor stimulation are unknown. The purpose of this study was to microinfuse subtype-specific ligands into the VH and compare the effects on locomotor activity. Adult male rats (100 days of age) had bilateral cannulae surgically implanted over the VH. Locomotor testing began one week later and each animal was tested five times over a two week period. Locomotor activity was increased by VH microinfusion of NMDA (1 and 10 nmol per side), KA (50 pmol) and the metabotropic receptor agonist, ACPD (100 nmol). However, clonic seizures were observed in animals treated with AMPA (1 nmol) or KA (50 pmol). These studies indicate that NMDA and metabotropic glutamate receptors in the VH may play a specific role in the expression of locomotor behavior, while KA and AMPA receptors are primarily involved in the expression of seizures. EFFECTS OF NEONATAL BLOCKADE OF NMDA RECEPTORS ON THE RAT BEHAVIOR IN MODELS OF PSYCHOSIS AND ON THE DENSITY OF DOPAMINERGIC D-2 RECEPTORS. *K. Wędzony*, K. Fijał, M. Maćkowiak and A. Czyrak. Institute of Pharmacology, PAN, 31-343 Krakow, 12 Smetna street, Poland.*

Recently it has been suggested that a neurodevelopmental deficits may lead to psychosis in adult life. Therefore, in order to model the above neurodevelopmental deficits and to examine a possible involvement of NMDA receptors, the present study investigated the impact of neonatal administration of a competitive NMDA receptor antagonist CGP 40116 on functional parameters characteristic of the dopaminergic neurotransmission, i.e. sensitivity of rats to amphetamine and quinpirole, and the density of dopamine D-2 receptors, as measured by an autoradiographic and saturation binding studies ([^{3}H]spiperone as a ligand). We found that neonatal chronic administration of CGP 40116 enhanced exploratory activity of rats and enhanced the locomotor stimulant effects of amphetamine and quinpirole. Such supersensitivity was also observed at a receptor level, as an increase in the number of D-2 dopamine receptors. Finally, it was found that neonatal administration of CGP 40116 attenuated the prepulse-induced inhibition of acoustic startle response and induced alterations in the latent inhibition measured by a taste aversion conditioning test. It is concluded that alterations in neurodevelopment, evoked by the blockade of NMDA receptors in neonatal period, may induce supersensitivity of dopaminergic systems and cause behavioral deficits typical of schizophrenia.

EFFECTS OF THE D3-PREFERRING AGONISTS 7-OH-PIPAT AND PD-128,907 ON MOTOR BEHAVIORS AND PLACE CONDITIONING. T. V. Khroyan *, R.A. Fuchs, D. A. Baker, and J. L. Neisewander. Department of Psychology, Arizona State University, Box 871104,Tempe, AZ 85287-1104.

Dose-dependent effects of 7-OH-PIPAT and PD-128,907 on motor behaviors and place conditioning were examined in rats. Four two-day conditioning trials were conducted over eight consecutive days. On one day of the trial, animals received an injection of either saline, one of five doses of 7-OH-PIPAT (0.01-3.0 mg/kg), or one of five doses of PD-128,907 (0.01-1.0 mg/kg), and were placed into a distinct compartment for 40 min. On the other day, animals received an injection of saline and were placed into a different compartment for 40 min. Locomotion, sniffing, and yawning were measured following the first and last drug injections. Place conditioning was assessed the day following the last trial. None of the doses of 7-OH-PIPAT nor the 0-0.3 mg/kg doses of PD-128,907 produced place conditioning. However, the 1 mg/kg dose of PD-128,907 produced conditioned place preference. Across doses, both 7-OH-PIPAT and PD-128,907 produced a U-shaped change in sniffing and locomotion, and an inverted U-shaped change in yawning. Across time, lower doses produced decreases in locomotion and sniffing and increases in yawning that was evident immediately, whereas higher doses produced biphasic changes in that there was an initial decrease in locomotion and sniffing followed by an increase. Behaviors produced by both low and high doses were sensitized following repeated administration. In general, PD-128,907 was more potent than 7-OH-PIPAT. (Supported by DA07730).

REPEATED LOW-LEVEL FORMALDEHYDE EXPOSURE PRODUCES LONG-TERM CROSS-SENSITIZATION TO COCAINE : RELEVANCE TO AN ANIMAL MODEL FOR MULTIPLE CHEMICAL SENSITIVITY. B.A. Sorg[1], J.R. Willis[2], R.E. See[2], C.D. Barnes[1]*, B.Hopkins[3] and H.H. Westberg[3]. [1]Dept. of VCAPP, [2]Dept. Psychology and [3]Dept. Civil and Environmental Engineering, Washington State University, Pullman, WA 99164.

Multiple chemical sensitivity (MCS) is a disorder in humans attributed to exposure to many volatile organic compounds. Amplification of symptoms in individuals with MCS resembles the phenomenon of psychostimulant sensitization in rodents. In ongoing studies to develop an animal model for MCS, female Sprague-Dawley rats were placed into chambers in which they were exposed to either air or formaldehyde (FORM, approximately 1 ppm) for 1 hr/day for 7 days or for 20 days (5 days/week x 4 weeks). Two days after the last exposure, rats were given a cocaine challenge (= early withdrawal). Four to six weeks later, an additional cocaine challenge was given (= late withdrawal). No differences in cocaine-induced locomotor activity were noted between groups after 7 daily exposures. However, after the 20-day exposure, vertical activity was elevated at both early and late withdrawal times in FORM rats. Since not all animals maintained the sensitized response to cocaine after late withdrawal, we determined if differences existed in the response to a novel aversive odor between rats that maintained sensitization vs. those that did not. Control and FORM groups were each divided into the highest (responders, R) or lowest (nonresponders, NR) groups of 8 rats according to their response to cocaine comparing across early to late withdrawal times. Odor aversion was measured by placing rats in a box with a cotton swab saturated with distilled water on one side or 7% xylene on the opposite side, and time spent on each half of the box over 4 min was recorded. In the FORM-pretreated group, R spent a significantly less amount of time than NR on the xylene side, opposite to what was found for the control group. These results suggest that animals which maintain long-term FORM-induced sensitivity to cocaine demonstrate greater avoidance to subsequent aversive odor presentation compared to controls, supporting the hypothesis that MCS may in part be induced by limbic system sensitization. Supported by the Wallace Genetic Foundation.

CISPLATIN INCREASES LEVEL OF OXIDIZED GLUTATHIONE AND AUGMENTS SUBSEQUENT CISPLATIN-INDUCED EMESIS IN *SUNCUS MURINUS*. H. Hagiwara*, H. Saito and N. Matsuki. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo 113, Japan.

Cisplatin and pyrogallol release serotonin from the enterochromaffin cells via the production of free radicals, which subsequently stimulates 5-HT_3 receptors on the vagal afferents and causes emesis. A dose of 500 mg/kg (s.c.) of reduced glutathione completely inhibited 130 mg/kg (i.p.) pyrogallol-induced emesis, and reduced glutathione up to 1000 mg/kg decreased dose-dependently the number of vomiting episodes and increased the latency to the first vomiting caused by 20 mg/kg (i.p.) cisplatin. These results suggest that glutathione scavenged the free radicals produced by pyrogallol or cisplatin to inhibit the emesis. Our previous studies showed that 20 mg/kg cisplatin-induced emesis is augmented by pretreatment of 10 mg/kg cisplatin 3 days before, and the anti-emetic effect of 5-HT_3 receptor antagonists on the augmented emesis is less effective. We measured the reduced and oxidized glutathione contents of the intestine. Administration of 10 mg/kg cisplatin tended to increase oxidized glutathione contents and GSSG/GSH ratio in the intestine analyzed after 3 days. These results suggest that cisplatin may consume glutathione for the detoxication and cause the highly oxidized condition, that may account for the augmentation of subsequent cisplatin-induced emesis. REDUCED AGGRESSIVENESS AND IMPAIRED EXPLORATORY BEHAVIOR IN MICE LACKING HISTAMINE H1 RECEPTORS. KAZUHIKO YANAI, TAKEHIKO WATANABE*, ISAO INOUE[1], AND TAKESHI WATANABE[1]. Dept. of Pharmacology I, Tohoku Univ. Sch. of Med. Sendai 980-77 and [1]Dept. of Molecular Immunology, Medical Inst. of Bioregulation, Kyushu Univ., Fukuoka 812, Japan

To define the contribution of the histamine H1 receptors (H1R) to behavior, mutant mice lacking the H1R were generated by homologous recombination. Mutant mice appeared to develop normally and be healthy and were fertile. The bindings of [^{3}H]pyrilamine and [^{3}H]doxepin were examined in brains of wild type, heterozygous, and homozygous mutant mice. In wild type mice, the binding was observed in the hypothalamus, cerebral cortex, amygdala, thalamus, hippocampus and cerebellum, while no specific binding was seen in homozygous mutant mice. The amounts of H1R protein in hetrozygotes were found to be about half as much as that of wild type mice. The exploratory behavior in a new environment was examined to clarify whether the absence of H1R in mice affects actions relating to their emotions. Although motor coordination test and passive avoidance test were normal in H1R null mice, they showed significant decreases in ambulation and time of rearing for the first 30 minutes in a new place. Moreover, when confronted with an intruder, mutant mice attacked the intruder slower and more infrequently than did wild-type mice. These results indicate that through H1R, histamine modulates various physiological functions such as locomotor activity, emotion, and aggressive behavior.

CLONING OF AN AMINE RECEPTOR FROM THE AMERICAN LOBSTER. H. Schneider*, C.A. Couture, P. Budhiraja, & E.A. Kravitz, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Serotonin (5HT) and octopamine (OCT) participate in the regulation of agonistic behavior in the American lobster, *Homarus americanus.* Injections of amines triggers postures resembling those observed in dominant (5HT-injection) and subordinate (OCT-injection) lobsters (Livingstone et al. 1980, Harris-Warrick & Kravitz 1984). In addition: 5HT and OCT-containing neuron systems have been mapped in the lobster cns (Beltz & Kravitz 1983, Schneider et al 1993); the functions of certain of the 5HT-cells have been defined (Ma et al 1992); and the behavior of subordinate animals during agonistic encounters can be reversed by 5HT injections (Huber et al 1996). Most recently Yeh et al (1996) have shown that slow changes in 5HT receptor distribution at specific synapses accompany changes in social status in crayfish. To understand 5HT signaling mechanisms in greater detail and to identify key neurons in 5HT-modulated circuitries we have begun to clone lobster serotonin receptors.

Towards that goal, we designed degenerate primers from the conserved transmembrane regions of Drosophila 5HT receptor cDNAs. Using genomic lobster DNA and PCR techniques, we cloned a 206 bp fragment that was 75% identical at the nucleotide level to the Drosophila 5HT2A receptor. Specific primers designed from that fragment were used to screen cDNA and genomic libraries using a PCR-based technique. A single clone was isolated from a genomic library and subsequently sequenced. That clone, which was 2375 bp in length, contained an 1834 bp open reading frame. The open reading frame includes all seven transmembrane regions and the amino acid sequence is 35% identical to that of the Drosophila 5HT1 receptor. The percent identity is highest in presumed transmembrane regions 2, 3, 6, and 7, and lowest in a loop connecting transmembrane regions 5 and 6. The amino acid sequence also resembles Drosophila OCT receptor clones. Transfection and binding assays will be used to further characterize this amine receptor. *Supported by NINDS.*

EXCITATORY INPUT FROM LATERAL (LG) AND MEDIAL (MG) GIANT INTERNEURONS TO AN IDENTIFIED 5HT-CONTAINING NEURON IN THE AMERICAN LOBSTER. M. Hörner[1] D.H. Edwards[2] and E.A. Kravitz*. 1. Zool. Inst., Dept. Cell Biol., Univ. of Göttingen, FRG; 2. Dept. Biology, Georgia State University; *Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

Our previous studies suggest that 5HT functions as an important modulator of agonistic behavior in lobsters. A pair of large 5HT-containing neurons found in the first abdominal ganglion (A1) are believed to be regulators of the postural components of this behavior. These cells, which serve as "gain-setters", have sets of peripheral endings that supply 5HT to the haemolymph, and central endings that regulate postural circuitries. The present study focusses on identifying presynaptic inputs to the A1-5HT cells. Among the candidates are the MG and LG fibers used in the tail-flipping seen during escape and agonistic behavior.

Ventral nerve cords were dissected from adult lobsters of both sexes. After removing the ganglionic sheath, A1-5HT cells were identified as in previous studies for intracellular recordings, and LG and MG axons were identified by their locations, by the presence of large extracellular spikes, and ultimately by intracellular recording, stimulation and dye injection. The results showed that both LG and MG stimulation elicited short-latency, short rise time, long lasting (100-150ms) EPSPs in A1-5HT cells in all preparations (n=12). The LG EPSPs were larger (2-5mv) than the MG responses. Inputs from both sources elicited spikes in 5HT cells, reset their spontaneous firing rhythms, and were followed at high frequencies. The results suggest that during tail flips mediated by MG or LG, firing of A1-5HT cells should increase. This should enhance the release of 5HT into the circulation and ventral nerve cord, thereby possibly reinforcing agonistic behavior in these animals.

AGGRESSIVE BEHAVIOR AND STRESS RESPONSE IN 5-HT1B RECEPTOR "KNOCK OUT" MICE. S. Ramboz, N. Castanon, [1]M.C. Buhot* and R. Hen. Columbia University, New York, NY 10032. [1]CNRS-URA 339, Talence, France.

To study the function of 5-HT1B receptors, we generated by gene targeting knock out mice (129/Sv strain) lacking the gene encoding this receptor. Mutant males displayed increased aggressive behavior. This finding may relate to the observation that certain 5-HT1A/1B agonists, such as eltoprazine, have anti-aggressive properties. As a result, those drugs were termed serenics. In order to determine whether 5-HT1B receptors are the main target of the serenics, we studied their effect in the mutant mice. In the resident-intruder aggression test, eltoprazine (1 and 2.5 mg/kg) decreased aggressive behavior not only in wild-type but also in mutant mice suggesting that the 5-HT1B receptor is not the only receptor mediating the anti-aggressive properties of this serenic. Pretreatment of mutant mice with the 5-HT1A antagonist WAY 100635 (0.5 and 1 mg/kg) abolished the effect of eltoprazine indicating the participation of 5-HT1A receptors in the modulation of aggressive behavior. We also compared the aggressiveness of mutant and wild-type females during the lactation period. After introduction of an adult male in a cage with a female and her pups, we observed, in both groups, a progressive increase in maternal aggression until postpartum day 10, followed by a decrease until weaning. During this period, mutant females were more aggressive than wild-type females, and aggressive behavior disappeared after weaning.

In order to evaluate the reactivity of mutant mice in another situation, we studied their behavioral response to a novel environment (open-field). In this test, both female and male mutant mice were more active both in the periphery and in the center of the open-field. However, after a period of habituation to the open-field (90 minutes), the basal levels of locomotor activity were similar in wild-types and mutants suggesting that the initial difference was due to a differential reactivity to the novel environment rather than a difference in locomotor activity. We are currently measuring the neuroendocrine changes occuring during this test in order to evaluate whether mutants display a difference response to stress than wild-types.

DIMINISHED ANXIETY-LIKE RESPONSES IN 5-HT$_{2C}$ RECEPTOR MUTANT MICE. S. Das* and L. Tecott. Dept. of Psychiatry, University of California, San Francisco, CA 94143-0984.

5-HT$_{2C}$ receptors have been implicated in the serotonergic regulation of anxiety. Nonspecific 5-HT receptor agonists like m-chlorophenylpiperazine (mCPP) are known to produce anxiogenic effects in humans and in rodent models. To further examine the contributions of this receptor subtype to the serotonergic regulation of anxiety, we examined anxiety-like behaviors in a mutant mouse strain lacking 5-HT$_{2C}$ receptors (Tecott et al *Nature* 372: 542 '95). Mutant (n=10) and wild type (n=10) mice were exposed for 10 minutes to an open field for 3 consecutive days. The measures observed included numbers of line crossings in the outer, intermediate, and the central zones of the open field enclosure and frequencies of stretch attend postures (SAPs). Whereas SAP frequencies are considered to correlate with anxiety state, central zone activity is believed to inversely correlate with anxiety state (thigmotaxis). Mutants displayed 33% higher overall activity levels and 50% lower SAPs during the initial open field exposure. Repeated exposure produced marked increases in central square activity and decreases in SAPs in the wild type mice, indicating habituation to the anxiogenic properties of the open field. In contrast, overall activity and SAPs did not change during repeated exposure of mutants to the open field. Consistent with prior studies, mCPP decreased overall activity and increased SAPs in wild type mice. In contrast, mutants displayed a paradoxical increase in overall activity and diminished SAPs. This indicates that 5-HT$_{2C}$ receptors contribute to the hypolocomotor effects of mCPP and that the absence of 5-HT$_{2C}$ receptors may unmask actions of mCPP at other receptor subtypes. Overall, the results indicate diminished trait anxiety and altered processes of habituation to spatial novelty in 5-HT$_{2C}$ receptor mutant mice. *Supported by the EJLB Foundation and DA00282.*

LOW DOPAMINE (DA) AND SEROTONIN (5HT) LEVELS IN VMN OF OBESE ZUCKER RAT AND ITS RELATIONSHIP TO FOOD INTAKE. V. Blaha, Z-Y Yang, J-K Chai, and M.M. Meguid*. Neuroscience Program, Surgical Metabolism and Nutrition Lab, Department of Surgery, University Hospital, Syracuse, NY 13210.

A reciprocal activity in food intake control between lateral hypothalamic area (LHA) and ventromedial nucleus (VMN) is well established. We recently reported high DA activity in LHA of obese Zucker rats. Whether monoamine activity in VMN is lower in obese vs lean Zucker rats was examined by using in vivo microdialysis. **Methods**: A guide cannula was placed stereotaxically into VMN of 8 obese and 8 lean Zucker rats. 14 days after recovery from surgery, microdialysis was performed. DA and 5HT were measured pre-, during, and post-eating. Data were compared using Student's t-test.

Results:	Pre-Eating		During Eating		Post-Eating	
	Obese	Lean	Obese	Lean	Obese	Lean
DA	9.2±1.1*	13.4±1.5	6.1±0.6^{+}	10.4±1.2	5.7±0.4^{*+}	12.7±1.8
5-HT	0.7±0.1*	1.2±0.1	1.1±0.2^{o+}	1.5±0.2	1.0±0.2	1.3±0.2

(M±SE, pg/10µl, *p<0.05, °p=0.05 obese vs lean; $^{+}$p<0.05 vs baseline)

i) Pre-eating, VMN-5HT and VMN-DA were low in obese vs lean rats. ii) Food intake during microdialysis was higher in obese vs lean rats (6.8±0.4 g vs 5.2±0.6 g, p<0.05). iii) During eating, VMN-DA decreased and VMN-5HT increased both in obese and lean rats, but were still lower in obese vs lean rats. iv) Post-eating, VMN-5HT decreased towards baseline while VMN-DA remained depressed in obese Zucker rats. **Conclusion**: Enhanced LHA-DA activity and attenuated VMN-DA and 5HT activity is associated with enlarged meal size of obese Zucker rats.

SYNAPTIC INTERACTIONS THAT MEDIATE THE SENSORY INPUT ONTO THE SEROTONERGIC NEURONS IN THE LEECH. L. Szczupak*, A. Kleinhaus and W. B. Kristan Jr. Dto. de Fisiol., Fac. de Medicina (UBA); Paraguay 2155, 1121 Bs.As., Argentina. Dept. of Cell Biol. and Anat., NY Medical College; Valhalla, NY 10595. Biology Dept; UCSD; La Jolla, CA 92093-0357.

Retzius (Rz) neurons are the main source of serotonin in the leech nervous system. They receive excitatory input from the pressure (P) mechanosensory cells via an interneuronal pathway (INP) that spans the nerve cord. Thus, stimulation of P cells can excite Rz neurons in a series of segments, depending on the strength of the stimulus (Szczupak & Kristan, 1995). We have investigated the synaptic interactions that link P and Rz neurons with the INP, using a recording chamber with two compartments. This enabled the stimulation of P cells and the recording of Rz neurons of the same chain of ganglia as they were bathed in different external solutions: normal and high Mg^{++} salines. Recordings performed in different configurations showed that: **1.** P cells excite the INP through chemical transmission. **2.** P neurons excite the INP at three sites: in the ganglion of origin and in the two adjacent ganglia. **3.** The INP excites the Rz neurons through a mixture of chemical and electrical junctions. Morphological studies confirmed that P cells extend a branch through each ipsilateral connective nerve that end in the adjacent ganglia where it arborizes. These branches are, probably, the ones that carry the excitatory signal to the INP in adjacent ganglia. The identity of the chemical transmitters is being investigated.

The results show that P cells convey excitatory input onto the Rz neurons through a pathway with a robust connectivity, suggesting that the mechanosensory neurons are an important drive of the serotonergic neurons in the leech.

EFFECTS OF RU24969, 8-OH-DPAT, AND GR127935 ON PREPULSE INHIBITION IN WILD TYPE AND SEROTONIN 1B MINUS MICE. S.C. Dulawa*[1], R. Hen[3], K. Scearce[3], and M.A. Geyer[1,2]. Depts of Neuroscience[1] and Psychiatry[2], University of California San Diego, La Jolla, CA 92093. Center for Neurobiology and Behavior[3], Columbia University, New York, NY 10032.

The attenuation of the startle response termed "prepulse inhibition" (PPI) occurs when an abrupt startling stimulus is preceded 30-500 msec by a barely detectable prestimulus or "prepulse". PPI provides a reliable behavioral measure of sensorimotor gating, and is defined as the percent decrease in startle amplitude when a weak prepulse precedes a startling pulse. In rats, the 5HT-1A/1B direct agonist RU24969, and the direct 5HT-1A agonist 8-hydroxy-2(di-n-propylamino)tetralin (8-OH-DPAT) is capable of reducing PPI. We compared PPI in wild-type and homozygous 5HT-1B-minus 129sV mice in a startle response paradigm in which some 120 dB acoustic pulses were preceded by 4 or 8 dB prepulses above a 65 dB background. Animals received 0 and 10 mg/kg BW intraperitoneal injections of RU24969, and 0 and 5 mg/kg BW subcutaneous injections of 8-OH-DPAT in a within subjects design. 5HT-1B-minus mice showed significantly more PPI than wild-type mice at the 0 mg/kg BW dose, suggesting that activation of 5HT-1B receptors by endogenous serotonin may decrease PPI. The 10 mg/kg BW dose of RU24969 diminished PPI in wild-type mice but not in 5HT-1B-minus mice (reported previously); 8-OH-DPAT induced significant increases in PPI in both groups of mice. In a second experiment, 0, 0.5, and 3.0 mg/kg BW GR127935, a selective 5HT-1B antagonist, was administered to explore whether the phenotypic difference in PPI in 5HT-1B minus-mice results from lack of the receptor in the adult mouse, or from changes in development due to gene knock out. GR127935 increased PPI in wild-type mice to levels comparable to those seen in 5HT-1B-minus mice. GR127935 did not alter PPI in 5HT-1B-minus mice. Thus, the increase in PPI observed in 5HT-1B-minus mice may result largely from lack of the receptor in the adult mouse. Supported by NIDA (R02DA02925), NARSAD, and NIMH (K05MH01223).

DEPLETION OF SEROTONIN INCREASES PREFERENCE FOR UNCERTAIN REWARDS IN RATS. J.B. Richards*, L.S. Seiden. University of Chicago, Department of Pharm/Phys Sci., Chicago, Il. 60637.

Previous researchers have hypothesized that low 5HT (As indicated by low levels of 5HIAA in CSF.) may be associated with risk taking in non-human primates (Mehlman, Am J Psychiatry, 151, 1485-1491). The present study examined the effects of 5HT depletion on choice between uncertain rewards (Rewards presented with a probability of less then 1.0.) and certain rewards. Rats received 5HT lesions (LES) induced by intraventricular injection of the neurotoxin 5,7-DHT (100 ug/side, pre treatment with 30 mg/kg desipramine) (N = 19) or intraventricular injection of vehicle (CNT)(N = 15). Previously we have found that 5,7-DHT causes depletion of 5HT to less than 15% of control levels in all of the areas assayed (nucleus accumbens/olfactory tubercle, striatum, somatosensory cortex, amygdala, hypothalamus, and hippocampus). Dopamine and norepinephrine levels were not affected. Thirsty rats were given a choice between a 200 ul of uncertain water reward or a smaller amount certain water reward. The amount of the certain water reward was adjusted until each rat chose the certain reward and the uncertain large reward with equal frequency (i.e. indifference point). We found the indifference points for five probabilities of the large water reward (1.0, 0.7, 0.4, 0.2, and 0.1) in LES and CNT rats. At a probability of 1.0 there was no significant difference between the LES and CNT groups. At probabilities of 0.7, 0.4, 0.2, 0.1 s the LES rats chose larger certain amounts of water reward then the CNT rats. The results show that rats with 5HT lesions had a greater preference for the uncertain large rewards then control rats. This result is consistent with the hypothesis that low serotonin is associated with increased risk taking. (Supported by: MH-11191; RSA-10562, L. Seiden).

Effects of Serotonergic modulation on Pemoline-Induced self-injury in the rat. Elise Witte, Howard C. Cromwell, and Bryan H. King*. Mental Retardation Research Center., UCLA, School of Medicine, Los Angeles, CA., 90024.

Pemoline is an indirect agonist which reliably produces self-injurious behavior following systemic injection of high doses in the rat. It has been hypothesized that serotonergic systems play a role in the expression of this behavior. The following experiments were aimed at assessing the effects of serotonergic agents on the development of pemoline-induced stereotyped movements and self-injury. The effects of clomipramine (CMI), paroxetine, buspirone, 8-hydroxy-2-dipropylaminotetralin (8-OH-DPAT), ketanserin, and propranolol were examined. Each drug was administered immediately prior to the pemoline injection. Several doses of each drug were tested to establish a dose-response relationship. Animals were videotaped at specific intervals following the pemoline injection (between 2 and 32 hours after injection), and stereotyped movements and self-injurious behaviors were scored by raters blind to drug conditions. The re-uptake blocker, paroxetine, exerted a modest protective effect against subsequent pemoline-induced self-injury as did the 5-HT_{1A} partial agonists 8-OH-DPAT and propranolol. Buspirone, CMI and the 5-$HT_{2A/2C}$ antagonist ketanserin were either devoid of effects or inconsistent across trials and doses. On balance, serotonergic agents had little effect on the expression of self-injurious behavior in this paradigm. Supported by NIMH Grant No. K20 MH 00917 to BHK.

FLUOXETINE-INDUCED INCREASE IN TARGET BITING BUT NOT RESIDENT-INTRUDER ATTACK. J. Matray-DeVoti*, D. Widmer, C. Cornille and G.C. Wagner. Psychology Dept., Rutgers Univ., New Brunswick, NJ 08903

Reports that fluoxetine increases human suicidal tendencies and aggression were investigated using two murine defensive aggression paradigms, single-subject target biting and resident-intruder attack wherein intruders were injected. Mice bit an inanimate target at three distinct rates: a high rate (42 bites/15 s) following a 2 mA, 0.15 s tail shock; an intermediate rate (26 bites/15 s) during a 2-min inter-shock interval; and a low rate (8 bites/ 15 s during a tone CS). Acute fluoxetine (IP 30 min presession) did not alter target biting behavior. However, the same mice showed increased biting (up to approx. 75, 52 and 20 bites/ 15 s, respectively) 24 h after the 8.0 mg/ kg dose. Under baseline conditions, intruder mice counter-attacked residents 14.1 times/10 min session with a 264 s latency to the first attack. Fluoxetine reduced this defensive attack 24 h later (ED-50 = approx. 8.0 mg/kg). Fluoxetine also caused a long-term (24 %) decrease in brain 5-HIAA. Taken together, these observations indicate defensive aggression may appear following fluoxetine in humans.

TRYPTOPHAN DEPLETION: PREDICTION OF FUTURE DEPRESSION. **F.A. Moreno, P.L. Delgado*, K. McKnight, A.J. Gelenberg, G.R. Heninger, K. Bachar A. Buonopane, R. Potter, Department of Psychiatry, Univ. of Arizona College of Medicine, 1501 N. Campbell Avenue, Tucson, AZ 85724**

Tryptophan (TRP) depletion lowers brain serotonin and causes depressive symptoms in some healthy subjects and depressed patients. This presentation describes the sensitivity, specificity, positive and negative predictive value (PPV and NPV, respectively) of TRP depletion in prediction of major depressive episodes (MDE). **METHOD:** Results from two separate studies are presented. Study #1 included 12 medication-free (≥3 months) subjects with a past history of major depression but now in remission and 12 age- and gender-matched controls. Study #2 included 17 depressed patients having responded to 6-12 weeks of fluoxetine treatment. TRP depletion included two tests one week apart. Each test included a TRP-free, 15 amino acid drink day and a follow-up day. Hamilton Depression Scale (HAM-D) ratings and plasma for TRP levels were obtained prior to, during, and after testing. Follow up assessments were at weekly intervals x4, then 6 and 12 months after testing. **RESULTS:** Study #1: 9/12 patients and 1/12 controls had ≥6 pt. increase in HAM-D during TRP depletion (depletion-positive). 6/9 patients and 1/1 controls who were depletion-positive developed a new MDE during follow-up. 2/14 depletion-negative subjects developed a new MDE. In regard to prediction of future episodes, these data show a sensitivity of 78%, specificity of 80%, PPV of 70% and NPV of 86%. Study #2: 9/17 subjects became depressed during depletion. 7/9 depletion-positive subjects, and 1/8 depletion-negative subjects went on to develop a depressive episode during follow-up. In regard to prediction of long-term course, TRP depletion has a sensitivity of 88%, specificity of 78%, PPV of 78% and NPV of 88%. **IMPLICATIONS:** TRP depletion may be a useful in identifying individuals at risk for future MDEs, regardless of previous history or treatment intervention.

CORRELATES OF DEPRESSIVE RELAPSE IN MEDICATED DEPRESSED SUBJECTS UNDERGOING ACUTE TRYPTOPHAN DEPLETION. R.M. Berman, P. L. Delgado, H. L. Miller, L. H. Price, G. R. Heninger, D. S. Charney* Affective Disorders Program of West Haven VA Medical Center, Yale University School of Med, West Haven, CT 06516.

Acute dietary depletion of tryptophan (ADT), an amino acid precursor of serotonin, has been shown to reverse antidepressant response in medicated, formerly-depressed subjects, a phenomenon more closely associated with the use of selective serotonin reuptake inhibitors (SSRI) than other antidepressant classes.

Previously obtained data, from five studies over the past 8 years, were pooled and re-analyzed in order to determine the clinical correlates of depressive relapse in SSRI-medicated, formerly-depressed subjects when undergoing ADT. Of forty-four such subjects, 8 (18%) demonstrated a full relapse; and, 15 (34%), partial relapse. Criteria for full relapse included an increase in the Hamilton depression rating scale (HDRS) score by at least 50% and minimum score of 17, reached on the depletion day. Criteria for partial relapse included the above criteria or an increase in HDRS score by at least 9 points. Predictor variables that correlated with full-relapse included: weeks medicated prior to depletion (i.e. greater vs. less than 13.7 weeks medicated; 2-tailed fisher exact, p=0.047), shorter medication half-life (i.e. paroxetine and fluvoxamine vs. fluoxetine; p=0.0004), previous inpatient admissions (p=0.023), prior antidepressant trials (p=0.002), melancholia (p=0.0005), and absence of a remote substance abuse history (p=0.037). A logistic regression model revealed that partial relapse was associated with fewer weeks on medication (odds ratio 0.2) and shorter medication half-life (odds ratio 0.1).

811.11

AMINES AND AGGRESSION IN THE CRICKET H. Hofmann, P.A. Stevenson and K. Schildberger*. Institut für Zoologie, Universität Leipzig, Talstr. 33, D-04103, Leipzig, Germany.

We investigate the effects of local brain injections of amines and amine-depletion on aggression in crickets. Three behavioral aspects were examined where amines may be expected to exert different influences. 1: Level of aggressiveness (cricket fights are highly stereotyped, and can be quantified by a simple scale reflecting the occurrence and duration of its various motor elements). 2: Recall of established aggressive states (winners exhibit offensive, and losers defensive behavior on contacting a conspecific for hours after a fight). 3: Resetting of aggressive state by the activity of specific motor programs (e.g. submissive males become highly aggressive after flying).

Pressure injections of octopamine, dopamine and serotonin (0.3-1.0 nl; 0.01 evoked various different and reproducible behavioral effects that could last for minutes (e.g. octopamine enhanced the escape responses to wind stimulation). However, none of these treatments had any influence on aggressive behavior.

Reserpine depletes the crickets nervous system of octopamine, dopamine and serotonin, and the animals become very lethargic (e.g. highly reduced escape response). Despite this, reserpinized animals exhibited all motor aspects of normal aggression, post-fight recall of agonistic behavior was unaffected, and flight motor activity reset the aggressive readiness of losers as in controls.

Although it is evident that amines can influence many aspects of motor activity, we conclude, contrary to that expected from other arthropod studies, that amines are not essential for the expression, maintenance and modulation of the behavioral states which characterize normal aggression in crickets.

INCREASED MONOAMINE LEVELS IN THE LIMBIC SYSTEM OF FLINDERS SENSITIVE LINE RATS, A GENETIC MODEL OF DEPRESSION. Abraham Zangen, #David H. Overstreet Sanford S. Sampson*and Gal Yadid. *Dept. of Life Science, Bar-Ilan University, ISRAEL and #Dept. of Psychiatry, University of North Carolina, Chapel Hill.*

Depressive disorder is associated with alterations in monoamines transmission, but the etiology of the disease is not yet understood. Recently, a new genetic rat model of depression was established named Flinders sensitive line (FSL). We used this model to asses alterations in monoamine levels in specific brain regions in comparison to a control matched group - the Flinders resistant line (FRL) rats. Tissue punches from nucleus accumbens (N.AC), hypothalamus (HYPT), hippocampus (HIPC), cingulate cortex (C.C), dorsal raphe nucleus (RAPHE) and striatum (STR) were removed and homogenized in iced buffer. Levels of dopamine (DA), its main two metabolites, dihydroxyphenylacetic acid (DOPAC) and homovalinic acid (HVA); serotonin (5-HT), its precursor, 5-hydroxytriptophan (5-HTP), and metabolite, 5-hydroxyindolacetic acid (5-HIAA) were determined by a high pressure liquid chromatography (HPLC) apparatus coupled to an electrochemical detector. Our results show a 2 - 8 fold increase in levels of DA, DOPAC and HVA in FSL's HYPT, N.AC, HIPC and RAPHE compared to FRL's but no significant differences were observed in the C.C and STR. 5-HTP levels were not altered between the two animal lines in all regions although 5-HT and 5-HIAA levels were 2 - 6 fold higher in FSL's HYPT, N.AC, C.C, HIPC and RAPHE. In the striatum, no significant differences were observed between the two animal lines. These results indicate that monoamine levels are specifically elevated in the limbic system of a rat model of depression and might indicate the relevance of serotonin-dopamine interaction to the behavioral deficit in depression .

INDIVIDUAL DIFFERENCES IN SUGAR CONSUMPTION, DOPAMINE RELEASE AND HYPERLOCOMOTION INDUCED BY DOPAMINERGIC AGONISTS. T.L. Sills*, A. Onalaja and J.N. Crawley, Section on Behavioral Neuropharmacology, NIMH, Bethesda, MD 20892

Rats exhibit significant individual differences in their consumption of sugar and other rewarding substances such as cocaine and amphetamine (AMP). Intrinsic variation in the functioning of the mesolimbic dopamine (DA) system is one potential mechanism underlying the expression of these individual differences. The present study examined the locomotor activating effects of dopaminergic drugs in LOW and HIGH sugar feeders. As well, the effect of AMP treatment on DA overflow in the nucleus accumbens (Acb) in LOW and HIGH sugar feeders was investigated. HIGH sugar feeders exhibited significantly higher levels of locomotor activity in response to AMP (0.25-1.0 mg/kg) than LOW sugar feeders. AMP (0.5 mg/kg) treatment produced significantly higher DA overflow in the Acb of HIGH as compared to LOW sugar feeders. Preliminary evidence indicate that the D_2 agonist quinpirole (0.5-4.0 mg/kg) and the D_1 agonist SKF-38393 differentially affected locomotor activity in LOW and HIGH sugar feeders. The findings of this study indicate that LOW and HIGH feeders exhibit differences in DA transmission, possibly through D_1 and D_2 receptor mechanisms.

DOPAMINE RECEPTOR DYSFUNCTION AND CRAVING IN ALCOHOLICS WITH POOR TREATMENT OUTCOME. A. Heinz*, J. Podschus, S. Kuhn, P. Dufeu, H. Rommelspacher, L.G. Schmidt. Dept. Psychiat. of the FU Berlin, 14050, FRG.

It has been hypothesized that dysfunction of central dopaminergic receptors is associated with craving and poor treatment outcome in alcoholism. Therefore, 42 alcohol-dependent patients were assessed according to their sensitivity of central dopamine receptors (apomorphine-induced secretion of Growth Hormone), self-rated craving and clinical outcome during a six-month observation period. Subsequent relapsers displayed reduced sensitivity of dopamine receptors during early withdrawal. Significantly more subsequent relapsers than abstainers reported craving when they left the ward after three weeks of detoxification treatment. However, the intensity of craving was not correlated with dopamine receptor dysfunction. During biweekly follow-up examinations, relapsers and abstainers did not differ in the reported intensity of craving. Thus, while both dopamine receptor dysfunction and craving are associated with poor treatment outcome, we found no evidence that craving is caused by reduced dopaminergic transmission.

GENETIC LINKAGE AND ASSOCIATION OF DRD2 SER311CYS IN ALCOHOLISM AND SUBSTANCE ABUSE, D. Goldman*, M.Urbanek, D. Guenther, R. Robin, J. Long Lab. of Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

Ser311Cys is the most abundant of three naturally occurring DRD2 amino acid substitutions and the only DRD2 polymorphism thought to affect receptor function (coupling) [Cravchik et al, AJHG, 57: A189, 1995]. Using an allele-specific assay, we observed that Cys311 is surprisingly frequent in a Southwestern American Indian population: 0.16 as compared to 0.03 in Caucasians. Association studies have implicated DRD2 in alcoholism and in "Reward Deficiency Syndrome." However, a substantial volume of evidence is not only contradictory but provides alternative explanations including 2-4 fold population differences in Taq1A "A1" allele frequencies. The abundance of Cys311 in this particular population enabled us to test the hypothesis that functional DRD2 polymorphisms are associated with alcoholism or "Reward Deficiency Syndrome." We studied 447 psychiatrically interviewed subjects all of whom were members of three interrelated superpedigrees. Cys311, the Taq1A polymorphism, and the intron-2 STR were genotyped. Preliminary analyses reveal no linkage (by SIBPAL) or association (by chisquare analysis) of Cys311 to DSMIIIR alcoholism or substance abuse. As shown, the proportion of alleles identical by descent (i.b.d.) did not differ in sibpairs that were unaffected, discordant or concordant for alcoholism or for substance abuse. Also, frequencies of alcoholism and substance abuse in the fourteen Cys311/Cys311 homozygotes were equivalent to population prevalences for these disorders.

Sibpair Type	# of Pairs-EtOH	Alleles i.b.d.	# of Pairs-Drug	Alleles i.b.d.
Unaffected	40	0.510	141	0.491
Discordant	134	0.482	153	0.498
Affected	179	0.487	59	0.456

CENTRAL EFFECTS OF VASOTOCIN ON APPETITIVE AND CONSUMMATORY SEXUAL BEHAVIOR IN MALE QUAIL. C. Castagna*, P. Absil & J. Balthazart, University of Liège, Laboratory of Biochemistry, 17 place Delcour, B-4020 Liège, Belgium.

We previously demonstrated that intramuscular injections of [Arg8]-vasotocin (VT; Sigma V0130) inhibit appetitive and consummatory aspects of male sexual behavior as well as crowing in male Japanese quail. A dense testosterone-sensitive vasotocinergic innervation is present in several steroid-sensitive areas of the quail brain such as the medial preoptic nucleus, the bed nucleus striae terminalis and the ventromedial hypothalamic nucleus suggesting that the behavioral effects of VT may be centrally mediated. This idea was tested by injecting various doses of either VT (2 to 200 ng) or the potent V1 receptor antagonist ([Deamino-Pen1, Tyr(Me)2,Arg8]-Vasopressin or dPTyr(Me)AVP, 500 ng; Bachem H-5340) in the third ventricle of castrated male quail that were chronically treated with exogenous testosterone. On each experimental day, one part of the birds were injected with the drug while another part received the solvent (1 µl saline) as control. Treatments were reversed on successive days so that birds could be used as their own control. Appetitive male sexual behavior was measured by the time spend in front of, and looking through, a small window that provides a view of a female that will subsequently be released into the cage allowing to evaluate copulatory behavior per se (mount attempt and cloacal contact movements). VT inhibited both appetitive and consummatory components of male sexual behavior but the former were more affected than the latter by these treatments so that at low doses, appetitive aspects only were inhibited. The i.c.v. injection of dPTyr(Me)AVP increased most aspects of sexual behavior but the effect only reached statistical significance for the frequency of looks through the window and the frequency of mount attempts. The central injection of this V1 receptor antagonist (500 ng) was also able to completely block all behavioral effects of a systemic injection of 20 µg VT. Finally, the highest of the VT dose (200 ng) that produced strong behavioral effects when injected i.c.v. had no effect when injected systemically which agrees with previous data showing that the smallest effective dose affecting male sexual behavior is 10 to 100 times larger. These data indicate that VT acts centrally to inhibit male sexual behavior even after systemic injection. The stimulatory effects of the receptor antagonist also suggest that endogenous VT inhibits this behavior.

THE CENTRAL CONTROL OF COURTSHIP AND AGGRESSION IN MALE ZEBRA FINCHES (*Taeniopygia guttata*): EFFECT OF VASOTOCIN INFUSIONS. Goodson, J. L., Greenwood, V. R. and Adkins-Regan, E.* Department of Psychology, Cornell University, Ithaca, NY 14853.

The present investigation was designed to determine if arginine-vasotocin (AVT), the non-mammalian homologue of arginine-vasopressin (AVP), functions in the central control of courtship and aggression in male zebra finches (*Taeniopygia guttata*). Subjects (n=10) were implanted with cannulae aimed at the septum, a region known to regulate reproductive and agonistic behaviors. Birds were housed individually. Treatments consisted of infusion of .1µg AVT/.5µl saline or .5µl saline control delivered in a within-subjects design with two days between tests. Following infusion, a stimulus male was introduced to the subject's cage and behavior was recorded for 2 min. A female was then exposed in an adjacent cage and behavior observed for 5 min. The stimulus male was then removed and the stimulus female was placed in the subject's cage, followed by 5 min of observation. Preliminary results suggest that courtship may be facilitated by AVT, with more directed songs sung following AVT infusions than in the control condition (p=.065, paired t-test). Central AVT may regulate aggression as well. Subjects pecked significantly more following AVT treatment (p<.03, paired t-test). A similar non-significant trend was observed for beak-fencing. Eight subjects chased the stimulus male following AVT infusions and 3 subjects chased in the control condition (p<.04, sign test). These results suggest that AVT may function in avian reproductive behavior in a manner similar to AVP in mammals. Funding provided by Cornell University.

STIMULATION OF THE AMYGDALA DECREASES FREQUENT SEXUAL BEHAVIORS. Timothy K. Smock, Patrick Stark, Harry Wimbish, and Herbert Alpern*. Behavioral Neuroscience Program, Department of Psychology, University of Colorado, Boulder, CO 80309.

A vasopressin-like peptide mediates sexual attraction and arousal in male rats. Cells in the amygdala synthesize the peptide and project fibers to other limbic targets where the substance is released. In the hippocampus, release of the peptide causes suppression of one of the two major outputs of the structure. This inhibition is completely blocked by a vasopressin antagonist, which also inhibits sexual behavior when applied to the awake animal. Similar inhibition of hippocampal output is seen upon sexual behavior, but generally not other social and non-social behavior. Stimulation of the peptidergic cells elicits proximate sexual behaviors, but recording from the cells shows that they are active earlier, during the behaviors ultimately responsible for coitus such as investigation and recognition of a suitable mate (see Exp. Brain Res., 97: 444-450, 1994, for details and references).

Here we show that electrical activation of the system prevents sexual behavior that would otherwise occur. **Estrus females** were introduced to five sexually experienced males with bilateral stimulating electrodes in the medial amygdala. A 7 v. train of stimuli elicited 13 mounts in a 30 minute session while 48 mounts were seen following sham stimulation. Scores for three other sexual behaviors also decreased upon electrical stimulation, and in each case the difference was significant (ANOVA, $p<0.01$). We interpret these data to mean that the system, once activated, becomes refractory to further activation by stimuli that would normally elicit sexual behavior.

812.4

STIMULATION OF THE AMYGDALA INCREASES INFREQUENT SEXUAL BEHAVIORS. Patrick Stark, Herbert Alpern, John Fuhrer, Marnie Trowbridge, Harry Wimbish, and Timothy K. Smock*. Behavioral Neuroscience Program, Department of Psychology, University of Colorado, Boulder, CO 80309

In these studies we show that electrical stimulation of vasopressin-containing cells of the amygdala elicits sexual attraction in male rats when it otherwise does not often occur.

Non-estrus females were introduced to seven sexually experienced males with bilateral stimulating electrodes in the medial amygdala. A 7 v. train of stimuli elicited 12 mounting episodes while only one mount was observed following sham stimulation. Scores for three other sexual behaviors also increased upon electrical stimulation, and in each case the difference was significant (ANOVA, $p<0.01$).

Other males were introduced to four sexually experienced males with bilateral stimulating electrodes in the medial amygdala. A 7 v. train of stimuli elicited 39 mounting episodes while only 6 mounts were observed following sham stimulation. Scores for three other sexual behaviors also increased upon electrical stimulation, and in each case the difference was significant (ANOVA, $p<0.01$).

We interpret these results to mean that the medial amygdala mediates some aspect of appetitive sexual behavior.

ADOLESCENT ANABOLIC STEROIDS, VASOPRESSIN, AND AGGRESSION IN GOLDEN HAMSTERS. R.H. Melloni, Jr.*, R.J. Harrison, D.F. Connor, and C.F. Ferris, Neuropsychiatric Sciences Program, Department of Psychiatry, University of Massachusetts Medical Center, Worcester, MA 01655

Anabolic androgenic steroid (AAS) abuse by adolescents represents a significant health care risk due to the potential for long term negative physical and psychological sequelae, including increased aggressive behavior. This study examines the effects of AAS treatment on aggression and anterior hypothalamic-arginine vasopressin (AH-AVP), (i.e., the neural system implicated in the regulation of offensive aggression) in male adolescent hamsters (*Mesocricetus auratus*). We hypothesized that AAS exposure during adolescence predisposes hamsters to heightened levels of offensive aggression, correlated with changes in AH-AVP expression. To test these hypotheses adolescent male hamsters were administered high doses of synthetic AAS throughout their adolescent period (P27-P45). Immediately following the exposure, hamsters were tested for offensive aggression using a resident-intruder model. Hamsters treated with high dose AAS during adolescence show heightened measures of offensive aggression (i.e., decreased latencies to bite and increased total number of attacks and bites), while measures of total activity (total contact time) remained unchanged. Next, to determine if these behavioral alterations correlate with changes in hypothalamic AVP, AVP gene expression was examined in the AH of AAS-treated hamsters. Hamsters exposed to AAS during adolescent development show marked increases in AH-AVP, suggesting a possible causal role for AH-AVP in AAS-stimulated aggression. Studies are currently underway to examine the expression of AVP mRNA in these same brain regions.

MOLECULAR CLONING AND BINDING CHARACTERISTICS OF THE VASOPRESSIN V1A RECEPTOR IN GOLDEN HAMSTERS. C.F. Ferris*, R.J. Harrison, and R.H. Melloni, Jr., Neuropsychiatric Sciences Program, Department of Psychiatry, University of Massachusetts Medical Center, Worcester, MA 01655

Arginine vasopressin (AVP) has been implicated in numerous brain functions, including fluid homeostasis, learning and memory, arousal, and neuroendocrine response to stress. In addition, in golden hamsters (*Mesocricetus auratus*), AVP has been implicated in the modulation of agonistic behavior. In the hamster, the primary isoform of receptor which mediates the action of AVP on agonistic behavior is the AVP V1A receptor subtype. To more fully characterize the molecular mechanism of action of this receptor, and the role it may play in regulating agonistic behavior in this species, we have cloned and sequenced the hamster AVP V1A receptor subtype, and studied its expression patterns and binding characteristics. Sequence analysis of these clones reveal that the hamster cDNA exhibits significant homology to both the human and rat V1A receptor genes, with notable exceptions. Gene expression studies show that the receptor is tissue-specific, being expressed at high levels in the liver and low-to-moderate levels in few other tissues, including brain. Analysis of the competition binding of the endogenous receptor in hamster liver membranes support a two site model for ligand binding. To determine if there are both high and low affinity components to the same hamster AVP V1A receptor, or two separate AVP V1A receptors subtypes, studies are currently underway examining the binding characteristics of exogenously expressed AVP V1A receptor cDNAs in tissue culture cell lines.

EARLY STRESS ALTERS THE TEMPORAL ONSET OF AGONISTIC BEHAVIOR IN GOLDEN HAMSTERS. R.J. Harrison*, R.H. Melloni, Jr., and C.F. Ferris, Neuropsychiatric Sciences Program, Department of Psychiatry, University of Massachusetts Medical Center, Worcester, MA 01655

Early life stress has been demonstrated to alter both later responsiveness to stress, and behavior. In golden hamsters, flank marking behavior is part of the ethogram of offensive aggression. This behavior has been shown to be regulated by arginine vasopressin(AVP) signaling in the anterior hypothalamus (AH). AVP is a neurochemical signal affecting numerous functions, however it is best known for its role in fluid homeostasis. Recently, we have shown that the temporal onset of flank marking behavior occurs between P18 and P22, and is correlated with an increase in AVP in the AH. In the wild, juvenile hamsters first display flank marking behavior at the time of weaning and independence from the nest. We hypothesized that this period of development may present several significant stressors, including dehydration. Thus, we sought to examine whether dehydration stress would alter the temporal onset of normal AVP-mediated behaviors, namely flank marking. To test this hypothesis, P17 hamsters were injected once with either isotonic saline or a dehydrating colloid suspension. Animals injected with the colloid demonstrated an earlier onset of flank marking relative to saline-treated or naive controls. This data suggests that early dehydration stress alters AVP signaling in the AH to bring about a change in AVP-mediated behaviors. These behavioral alterations are being correlated with changes in the AVP neural system implicated in the regulation of agonistic behavior in golden hamsters. Supported by NIMH #MH52280 to C.F.F.

812.8

Heterogeneity of Vasopressin Efficacy within the Periaqueductal Gray to Stimulate Flank Marking in Syrian Hamsters (*Mesocricetus auratus*). J.M. Bird & A.C. Hennessey*, Clark Science Center, Dept. of Psychology, Smith College, Northampton, MA 01063

Flank marking is one form of scent marking used by Syrian hamsters to communicate social information. Microinjection of vasopressin (AVP) into the caudal periaqueductal gray (PAG) elicits flank marking in hamsters. The PAG is an anatomically and functionally heterogeneous region. The intent of the present study was to determine whether anatomical specificity of AVP efficacy to stimulate flank marking after microinjection into each of three contiguous rostrocaudal subregions of the PAG exists. Each adult hamster was implanted stereotaxically with a unilateral cannula directed at one of three rostrocaudal PAG subregions (rostral, mid or caudal). Each hamster (n=5-8/subregion) received a 100 nl injection of AVP (9.0 μM) or saline on two consecutive test days using a counterbalanced design. Hamsters exhibited significantly higher levels of flank marking following injection of AVP into the caudal PAG (mean=37.8) compared to levels observed after injection into the mid or rostral PAG (mean=1.25, mean=0.0, respectively;$p < 0.01$). Thus, AVP injection into the caudal PAG and not more rostral PAG stimulates flank marking in hamsters.

LATERAL SEPTAL VASOPRESSIN IN RATS: ROLE IN SOCIAL AND OBJECT RECOGNITION H.G.J. Everts, J.M. Koolhaas and P.G.M. Luiten*. Centre for Behavioural and Cognitive Neurosciences, Dep. of Animal Physiology, Univ. of Groningen, P.O. Box 14, 9750 AA Haren, The Netherlands.

The capacity of male rats to remember previously met individuals is called social recognition. It is a form of short term memory (lasting ± 1 hr) shown to be modulated by lateral septal (LS) vasopressin (VP). The specificity of this phenomenon was studied by examining the question whether recognition of previously investigated *objects* is also under control of lateral septal VP.

For social recognition mature male wistar rats were confronted with juveniles for 5 minutes. Re-exposure to the same juvenile took place after 30 or 120 min, or with a different juvenile after 30 min. This procedure was duplicated for object recognition, but instead of a juvenile a small plastic food cup or a 50 ml erlenmeyer flask was used. After these initial tests osmotic minipumps and brain canulas were implanted which delivered a VP receptor antagonist into the LS (dPTyr(Et)AVP, bilateral, 1ng/0.5µl/hr). After recovery animals were retested for social and object recognition using 30 min re-test interval (same juvenile or object).

We reproduced known results concerning social recognition; animals recognized juveniles after 30 min, not after 120 min and VP antagonist treatment blocked recognition. Testing for object recognition revealed a reduction in investigation time at the 30 min interval (same and different object), but not after 120 min. VP antagonist treatment blocked this reduction.

The data suggest that, in contrast to social recognition, object recognition is more a process of habituation. However, it does seem to be under control of LS VP. (supported by BCN and University of Groningen)

HYPOTHALAMIC AND LIMBIC PROJECTIONS TO THE MPOA-AH ARE INVOLVED IN REGULATION OF VASOPRESSIN-INDUCED SCENT MARKING IN SYRIAN HAMSTERS. M. Bamshad* and H. Elliott Albers. Lab. of Neuroendocrinology and Behavior, Depts. of Biology & Psychology, Georgia State Univ., Atlanta, GA 30303.

Vasopressin (AVP) regulates scent marking in Syrian hamsters. Microinjection of AVP in specific sites of the brain, including the medial preoptic-anterior hypothalamus (MPOA-AH), stimulates scent marking. Previously we showed that scent marking in response to microinjection of AVP into the MPOA-AH increases Fos-immunoreactivity (Fos-ir) in the bed nucleus of stria terminalis (BNST), periaqueductal gray (PAG) and central amygdala (Ce) suggesting the involvement of these sites in scent marking. In the present study, we investigated the projections to the MPOA-AH that are involved in regulation of scent marking. Hamsters were microinjected with fluorogold (FG), a retrograde tracer substance, into the MPOA-AH. After 4 days, they were tested for scent marking following microinjection of either saline or 9μM of AVP into the MPOA-AH or without any microinjections. FG containing neurons were found in limbic, hypothalamic and midbrain regions. Neurons co-expressing Fos-ir and FG were found in the BNST, amygdala and hypothalamic regions. Microinjection of AVP increased double labeling in the BNST, and several hypothalamic regions. The data suggest that projections from the BNST and areas within the hypothalamus are important in the regulation of scent marking. (Supported by NSF IBN 9222099).

CENTRAL OXYTOCIN MODULATES ORAL BEHAVIORS OF PREWEANLING RAT PUPS. Eric E. Nelson * & Jeffrey R. Alberts. Department of Psychology, IndianaUniversity, Bloomngton IN. 47405

Suckling provides infant mammals with nutritive and hydrational sustenence as well as important forms of social contact and interaction. In other behavioral contexts, central oxytocin has been implicated in both ingestive and affiliative behaviors of rats. Here we report that central oxytocin manipulations alter the oral behaviors of preweanling rat pups. Oxytocin administration potentiated and oxytocin antagonism inhibited mouthing and paw sucking behavior in young rat pups. Furthermore, preliminary measures of intramammary pressure during suckling suggest that oxytocin may also affect the motoric patterns of suckling. The roles of oxytocin in the infants' oral and social behaviors will be discussed as a potential substrate for the emergence of social affiliation.

COMPARISON OF OXYTOCIN RECEPTOR TRANSCRIPTS IN THE RAT HYPOTHALAMUS AND AMYGDALA. L.H. Calizo,* J.L. King and L.M. Flanagan-Cato. Dept. Psychology and Inst. Neurological Sciences, Univ. of Pennsylvania, Philadelphia, PA.

Oxytocin receptors (OTRs) have been identified by autoradiographic receptor binding in the ventromedial nucleus of the hypothalamus and the central nucleus of the amygdala. Recently, antisera directed against the putative third intracellular loop of the OTR localized immunostaining in the ventromedial hypothalamus but not in the central nucleus of the amygdala, raising uncertainty as to whether these brain areas express identical proteins. In the present study, we directly determined the mRNA sequence of OTR expressed in the ventral hypothalamus and the amygdala using homology-based polymerase chain reaction (PCR). The forward and reverse primers corresponded to the coding region for the second and sixth transmembrane domains, respectively. Both the ventromedial hypothalamus and the amygdala generated a PCR product of approximately 600 bp. The sequences of these products were 99-100% identical to each other and to the previously cloned rat OTR gene. Thus, although OTRs in the hypothalamus and the amygdala are differentially detected by peptide-directed antibodies, partial transcripts from these brain areas are virtually identical. A possible explanation for this apparent incongruity would be post-translational modifications of the third intracellular loop. Alternatively, detection by PCR is likely to be more sensitive than immunocytochemistry. Supported by the University of Pennsylvania Research Foundation.

SOCIAL RELATIONSHIPS ALTER THE ABILITY OF OXYTOCIN (OXT) TO STIMULATE FLANK MARKING IN FEMALE SYRIAN HAMSTERS. A.C. Harmon*, K.L.Huhman, K.N.Lee and H.E.Albers. Lab. Neuroendocrinol. & Behav., Depts. Biol. And Psychol., Georgia State Univ., Atlanta, GA 30303.

Flank marking is a behavior used by hamsters to communicate a variety of information, including female mate choice and social status. Vasopressin but not OXT, injected into the medial preoptic-anterior hypothalamus (MPOA-AH) stimulates flank marking in hamsters tested in social isolation. Since OXT has been implicated in regulating social interactions in several species, we examined if OXT alters flank marking in female hamsters tested in different social conditions. In the first group, female Syrian hamsters were paired for 7 days (7 min/test in a neutral arena), and allowed to establish a stable dominant/subordinate relationship after being singly housed for two weeks. Dominant females were implanted with a guide cannula aimed at the MPOA-AH and injected with OXT (300ng in 300nl saline) or vehicle in a counterbalanced order. In the second group, naive hamsters were paired with novel opponents and injected with vehicle or OXT in a counterbalanced order. Following injection with OXT and re-pairing with their partner, dominant females in the domiant/subordinate group showed a significant increase in the number of flank marks as compared to naive females exposed to a novel opponent (OXT[dominant]: 25.6±5.0; OXT[naive]: 4.0 ±2.2; $p<0.05$). There were no significant differnces between the groups when saline was given (saline[dominant]: 1.875 ±0.7; saline [naive]: 0.0±0.0; $p<0.05$). These data suggest that OXT stimulates flank marking in social conditions in which a dominant/subordinate relationship has been established.

EFFECTS OF INJECTIONS OF PROLACTIN INTO THE VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS (VMH) ON FOOD INTAKE IN FREE FEEDING, VIRGIN FEMALE RATS. D. Sauvé* and B.C. Woodside. *Centre for Studies in Behavioral Neurobiology, Concordia University, Montreal, Canada.*

Significant increases in feeding behavior and levels of Prolactin (PRL) are behavioral and hormonal hallmarks of lactation. A series of studies in our laboratory has provided support for a causal relationship between PRL and the hyperphagia of lactation. Early data showed that PRL injected intracerebroventricularly (icv) twice daily for ten days to virgin females rats produced a dose-dependent increase in food intake without disrupting vaginal cyclicity. In light of the relatively recent report on the location of PRL receptors in various hypothalamic nuclei of the rat brain, the anatomical specificity of the hyperphagic effect of central administration of PRL was undertaken. It was hypothesized that doses that were ineffective in elevating feeding behavior when introduced icv might produce a hyperphagic effect when injected directly into nuclei that are known to have both PRL receptors and a role in feeding. The first two of a series of studies designed to address this question revealed that administration of PRL (800 ng) in the paraventricular nucleus produced a hyperphagic effect but the same dose failed to increase food intake when injected into the VMH. These results confirm that it is highly likely that the hyperphagic effect of PRL is mediated, at least in part, by the PVN. To our knowledge, these are the first attempts at investigating the anatomical mapping of the effect of PRL on food intake in female rats. (Supported by grants from NSERC (#7938) & FCAR to B.C.W.)

TIME OF DAY MODIFIES PVN OXYTOCINERGIC BUT NOT PROLACTIN RESPONSES TO MATING IN THE FEMALE RAT. E.K. Polston, K.M. Centorino, J.A. Willan, and M.S. Erskine*, Dept. of Biology, Boston University, Boston MA, 02215

Oxytocinergic (OT) activity in the PVN peaks at times of day which correlate to prolactin (PRL) secretion in pregnant animals, and OT has been shown to be a PRL releasing factor. We hypothesized that mating-induced PRL secretion also may be influenced by OT activity. We examined *c-fos* expression in PVN OT neurons and acute PRL responses to mating at different times of day. Ovariectomized female rats were treated with estrogen and progesterone and given 15 intromissions (15I) from males, mounts-without-intromission (MO), or remained in their home cage (HC). One hr after mating at 0600 and 1200h, females were anesthetized and perfused. Brain sections (60µm) were processed immunocytochemically for FOS and OT and positively labelled cells were quantified throughout the PVN. Additional animals were mated at 0600, 1200, and 1800h and blood samples were obtained for PRL RIA via indwelling jugular catheters 5 min before and 5, 15, 30 and 60 min after mating. Numbers of PVN FOS-IR cells were increased at both 0600 and 1200h in 15I and MO females compared to HC females ($p\leq.05$). Mating treatment also increased numbers of OT-IR cells in the mid-PVN; 15I but not MO induced significantly more OT-IR cells than HC treatment ($p\leq.05$). Furthermore, animals sacrificed at 0600h had more OT-IR cells than those sacrificed at 1200h ($p\leq.05$). This response was also seen in sampled animals whose brains were processed 6-7 days after mating. Significant increases in numbers, but not percent, of FOS labelled OT cells were seen in 15I females mated at 0600h compared to all other groups ($p\leq.05$). However, similar plasma PRL levels were observed after 15I regardless of mating time. These results show that differences in OT labelling occur in the PVN in response to mating and time of day; these changes are not associated with mating-induced changes in PRL secretion. Supported by HD21802 to MSE.

MATERNAL BEHAVIOR AND BRAIN OXYTOCIN RECEPTORS UNAFFECTED IN OXYTOCIN KNOCKOUT MICE. L.J. Young*[1], Z. Wang[1], K. Nishimori[2], Q. Guo[2], M. Matzuk[2], and T.R. Insel[1]. [1]Dept. of Psychiatry and Behavioral Sciences, Emory University, Atlanta GA. 30322. [2] Dept. of Pathology, Baylor College of Medicine, Houston TX 77030.

Oxytocin (OT) has been implicated in the control of parturition, milk ejection, maternal behavior, and sexual behavior in rodents. To determine if oxytocin is essential for any of these physiologic and behavioral functions, we used a transgenic mouse with a knockout of the oxytocin gene. Homozygous OT knockout mice show no evidence of OT mRNA in either the PVN or the SON by in situ hybridization and absent OT gene expression by Southern blot. Vasopressin mRNA expression in the PVN and SON is unaffected. Surprisingly, OT knockout mice mate and deliver pups normally, but they fail to show milk ejection. In tests of pup-induced maternal behavior, nest building and pup retrieval behaviors appear identical in knockout and control (heterozygous) mice. In anatomic studies, the pattern and concentration of both OT receptor and vasopressin receptor binding is identical in knockout and control mice. These results demonstrate that OT is not necessary for parturition or maternal behavior in mice. It remains possible that OT may be an important modulator of sexual behavior, parturition and maternal behavior in other species, as there are marked species differences in OT receptor distribution. Furthermore, the absence of OT innervation does not alter the distribution of OT receptors in the brain. By extrapolation, the pattern of OT innervation is unlikely to contribute to the species diversity of OT receptor expression. Supported by: P51-RR00165

SEX DIFFERENCES IN THE NUMBER OF GALANIN AND CGRP IMMUNOREACTIVE CELLS IN THE SEXUALLY DIMORPHIC AREA OF THE HYPOTHALAMUS OF MONGOLIAN GERBILS. C. Ulibarri* and N. Rust. Dept of Veterinary & Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University, Pullman WA 99164.

The sexually dimorphic area of the gerbil hypothalamus (SDA) is a complex of cell groups found between the preoptic area and anterior hypothalamus. The SDA has a demonstrated role in the control of sociosexual behavior. Evidence from other species suggests that the neuropeptides galanin and calcitonin gene-related peptide (CGRP) are distributed in a sexually dimorphic pattern in the hypothalamus and are involved in expression of copulatory behavior. This study examined the SDAs of male and female Mongolian gerbils (*Meriones unguiculatus*) to determine if galanin and CGRP were found within the SDA, and if so, whether they were distributed dimorphically. Adult gerbils were treated intraventricularly with colchicine, allowed to survive for three days, and transcardially perfused with normal saline followed by 4% paraformaldehyde. Brains were removed, cryoprotected, frozen, and sectioned coronally. Sections were then processed for immunohistochemical visualization of either galanin or CGRP using the avidin-biotin staining technique. After immunohistochemistry, sections were mounted onto gelatinized slides, air dried, and stained with thionin to allow visualization of the SDA. The number of immunoreactive (ir) cells were counted in each division of the SDA by observers unaware of the sex of the gerbil or neuropeptide visualized. Males had significantly more galanin-ir cells within all areas of the SDA than did females (total number of galanin-ir cells; ♂ = 303.9 ± 46.4 vs ♀ = 172.8 ± 27.5). In contrast, females had significantly more CGRP-ir cells within the SDA than did males (total number of CGRP-ir cells; ♂ = 35.0 ± 13.1 vs ♀ = 78.9 ± 5.1). This research was supported by a WSU grant to CU.

POSSIBLE INVOLVEMENT OF VENTRAL TEGMENTAL GALANIN IN DEPRESSION: DOSE RESPONSE EFFECTS AND ANTAGONISM BY GALANTIDE. M.K. Demetrikopoulos*, J.H. Kreiss, A.J. Turner, P.A. Koski, R.W. Bonsall, & J.M. Weiss. Dept. of Psychiatry & Behavioral Sciences, Emory University, Atlanta GA 30306

It is hypothesized that galanin (GAL) released by the locus coeruleus during burst firing mediates depressive symptomatology by inhibiting activity of ventral tegmental (VTA) dopaminergic neurons. Results from our laboratory have demonstrated changes in spontaneous locomotor activity and swim test activity following bilateral VTA GAL infusion in male Sprague-Dawley rats. The present study examined this phenomena further. Experiment 1 utilized 3 doses of GAL (0.003, 0.3, & 3.0 µg/side) and demonstrated that VTA GAL infusion increased the amount of floating behavior during the swim test in a dose-dependent manner ($p<.005$). Experiment 2 utilized the 0.3 mg dose and examined the neurochemical specificity of the phenomena by attempting to block GAL effects with the GAL receptor antagonist, galantide. A two by two design was employed such that subjects were bilaterally infused with either galantide (0.3 µg) or vehicle followed by either GAL (0.3 µg) or vehicle. The increased floating behavior produced by VTA GAL infusion was blocked by pretreatment with galantide ($p<.02$). Furthermore, galantide alone (i.e., galantide followed by vehicle) reduced floating behavior relative to animals receiving vehicle-only infusions ($p<.05$), suggesting that galantide may have blocked the effects of endogenously-released GAL.

Glucagon-Like Peptide-1 in models of abnormal feeding and effect on behaviour. I. Gunn(1), T. Humby(3), J. Herbert(3), J.M. Polak*(2), S.R. Bloom(1) and D. O'Shea(1). Department of (1)Endocrinology and (2)Histochemistry, Hammersmith Hospital, London, U.K., and (3)MRC Cambridge Centre for Brain Repair, University of Cambridge, Cambridge, UK.

Glucagon-Like Peptide-1 (GLP-1) is naturally present in both rat and man. We have recently shown that GLP-1 is a powerful physiological inhibitor of appetite in rats, when administred intracerebroventricularly (ICV). Here we show that ICV GLP-1 is effective in two models of abnormal feeding and has an effect on locomotor activity and acoustic startle reflex (ASR). Central administration of GLP-1 (10μg) caused a decrease in feeding in both the diabetic (dexamethosone induced) and genetically obese Zucker rat. Blockade of endogenous GLP-1 by the specific GLP-1 antagonist, exendin (9-39) (100μg), caused an increase in feeding, (0.6±0.2 vs 1.8±0.2g/2 hrs, $p<0.05$, diabetic model), (1.1±0.32 vs 3.1±0.37/2hr, $p<0.002$, zucker). We have assessed the effect of administration of GLP-1 on locomotor activity and ASR in the rat. Both intraperitoneal (IP)(300μg) and ICV(3 or 10μg) administered GLP-1 caused a total reduction in the number of beam breaks in the activity cages compared with control, (IP, $p=0.003$, ICV, $p=0.002$). ASR was measured in an SR-LAB test station. The animal was subject to background noise, pre-pulse stimuli and startle stimuli. Responses were recorded as 100 1-millisecond readings. ICV(3 or 10μg) infusion of GLP-1 reduced ASR compared to controls ($p<0.02$). However, IP administration of GLP-1 (300μg) caused an increase in ASR, ($p=0.0035$). Different prepulse intensities produce a significant reduction in prepulse inhibition ($p<0.0001$). Infusion of GLP-1 had no effect on this response.

These results confirm that central GLP-1 potently inhibits feeding and has an effect on behaviour in animal models.

Angiotensin II interacts with nitric oxide-cGMP pathway in the central control of drinking behaviour but not *c-fos* expression. B. Zhu and J Herbert*, Department of Anatomy and MRC Cambridge Centre for Brain Repair, University of Cambridge, Cambridge CB2 3DY, U.K.

We have shown previously that NMDA receptors mediate dipsogenic responses and *c-fos* expression induced by intracerebroventricular (icv) infusion of angiotensin II (Ang II). Since these receptors are known to be linked to the nitric oxide (NO)-cGMP pathway, we explored the contribution of this path to the behavioral and cellular effects of icv Ang II. NG-nitro-L-arginine methyl ester (L-NAME, 125 and 250 ug, icv), an inhibitor of nitric oxide synthase, and methylene blue (100ug icv), an inhibitor of guanylate cyclase, antagonised the water intake induced by icv injection of 25 pmol Ang II. The effects of L-NAME were reversible by co-injection of L-arginine, the natural substrate for nitric oxide synthase (NOS). However, L-NAME could not alter the pattern of Ang II-induced *c-fos* expression in the OVLT, median preoptic nucleus (MPN), or paraventricular and supraoptic nuclei. Extensive co-distribution of NADPH-diaphorase stained cells and those expressing Fos in response to icv injection of Ang II was found, especially in the MPN, implying that NO might participate in the mechanism of Ang-II-induced drinking behavior. However, a low rate of co-localisation of the two markers within individual cells suggests that Ang II stimulated the production of NO in an indirect way - for example, by acting on glutamate-NMDA dependent synaptic transmission - rather than directly on nitric oxide synthesis in the neurons responsive to Ang II. ALCOHOL EFFECTS ON HUMAN TEMPORAL FACTORS IN VISUAL PERCEPTION. J.M. Ordy*, Neuroscience Research, Pittsford, NY 14534; M.B. Jones, The Pennsylvania State University College of Medicine, Hershey, PA 17033; R.S. Kennedy, Essex Corporation, Orlando, FL 32803; and W.P. Dunlap, Tulane University, New Orleans, LA 70118.

Visual perception of motion, depth, form and color is mediated by parallel occipitotemporal, or ventral, and occipitoparietal, or dorsal pathways, that provide different streams of spatial and temporal visual information. Ethyl alcohol (ETOH) is the most widely used and legally sanctioned psychoactive drug. Studies have suggested that ETOH may have very rapid dose-response effects on the highly vascular retina and the striate cortex resulting in adverse outcomes on high spatial and temporal resolution. In this study, the acute effects of ETOH-BAC doses of 0.11, 0.09, 0.07, and 0.05 were evaluated in 16 young adult males and 12 females in a temporal visual factors (TVF) test battery, administered on a PC, comprising: 1) Critical Flicker, 2) Phi-Apparent Movement, 3) Simultaneity, 4) Masking, 5) Group\Element Movement, and 6) Saccadic Accuracy. BAC was monitored with a gas chromatograph. At 0.11 BAC of ETOH, all but the CF were significantly affected ($P=.001$). At 0.09 BAC, ETOH produced lesser dose effects, reflected in the lower statistical levels of confidence ($P=0.01$). At the 0.07 BAC of ETOH, Simultaneity and Masking were still affected significantly ($P=0.02$). These effects contrasted with alcohol induced changes on tests of cognitive, psychomotor, and visual contrast sensitivity given to the same 28 subjects. At BAC .11, the temporal visual factors tests showed an average loss of 44% when compared to baseline. The cognitive tests (19% loss) and psychomotor tests (16% loss) showed less change. Contrast sensitivity changes were small and not statistically significant. These findings indicate significant dose-response ETOH-BAC effects on specific human temporal visual factors critically involved in such dynamic psychomotor tasks as driving and flying.

STARTLE AND FEAR-POTENTIATED STARTLE RESPONDING IN THE ALCOHOL-PREFERRING (P) AND NON-PREFERRING (NP) RAT. D.L. McKinzie, T.J. Sajdyk, J.M. Murphy*, W.J. McBride, L. Lumeng, T.-K. Li & A. Shekhar. Depts Psych. & Med., Indiana Sch. Med. and VAMC, and Dept. Psychology, Purdue Sch. Science, IUPUI, Indianapolis, IN 46202.

Previous reports have provided mixed results on the association between alcohol preference and innate levels of anxiety. The objective of the present study was to determine whether selectively-bred P and NP rats differ in magnitude and resistance to extinction of the acoustic startle and fear-potentiated startle response. In experiment 1, rats received two training sessions separated by 3-4 hrs. Each training session consisted of 10 light-footshock pairings (25 W light; 0.2-0.4 mA footshock). Testing consisted of ten startle (acoustic stimulus; 115 dB) and fear-potentiated startle (acoustic stimulus + light) presentations administered every 24 hrs for nine consecutive days. Results indicated that both startle and potentiated startle responding was greater in P than NP rats for the first six test days ($p < 0.01$). In experiment 2, P and NP rats received a single training session followed by a single test session 24 hrs later (50 startle alone and 50 potentiated startle trials). Analysis again revealed that P rats exhibited consistently higher startle and potentiated startle responses than did NP rats and only P rats expressed significant fear conditioning ($p < 0.04$). Taken together, these data indicate that P rats: (1) exhibit higher baseline levels of arousal following training as measured by startle responding alone and (2) express fear-potentiated startle responding under conditions which NP rats do not. (AA07611, AA07462, AA10717, AA10256, MH45362)

THE EFFECTS OF ALPHAXALONE, ALLOPREGNANOLONE AND ALCOHOL ON INTRAMALE AGGRESSION IN MICE. J.F. DeBold*, G. Casadesus, L. Sakoda, J. Schaffhausen, S. Hussain, and K.A. Miczek. Dept. Psychology, Tufts University, Medford, MA 02155.

Ethanol, benzodiazepines and some steroids have similar modulatory actions on the $GABA_A$ receptor complex within the brain. These actions may be the basis for their shared behavioral effects, such as sedation and anxiolysis. In addition, benzodiazepines and ethanol can have stimulatory effects on aggression. However, the extent to which $GABA_A$-active steroids can influence aggressive behavior or alter alcohol effects on aggression are unknown. The following experiment was designed to determine if $GABA_A$-active steroids 5α-pregnan-3α-ol-11,20-dione (alphaxalone) or 5α-pregnan-3α-ol-20-one (allopregnanolone) alter aggressive behavior in male mice and how alcohol administration interacts with the effect of these steroids. Adult male CFW mice were pair-housed with a female as and three weeks later were observed for their behavioral response to an unfamiliar group-housed male mouse introduced into their home cage. After establishing the baseline levels of aggression, the effects of alphaxalone (3-30mg/kg, ip) on aggressive behavior were measured. Mice treated with 17 mg/kg alphaxalone showed an enhancement of aggressive behavior toward intruders and a suppression of attack bites, and locomotion, at the 30 mg/kg dose. Alcohol has a similar biphasic dose response effect on aggressive behavior, although it is far less potent. Additional mice given ethanol (0.3, 0.6 or 1.0mg/kg, po) plus treatment with alphaxalone or allopregnanolone are currently being examined for the possible interactive effects of these compounds on aggressive behavior. Preliminary results with low doses of each compound have not yet demonstrated any interactive potentiating effects on aggression.

ETHANOL ADMINISTRATION BLOCKS THE SUPPRESSIVE EFFECTS OF THE CENTRAL NUCLEUS OF AMYGDALA UPON DEFENSIVE RAGE BEHAVIOR IN THE CAT. A. Siegel*, K. Schubert-Reilly, and M.B. Shaikh. Lab. of Limbic System & Behavior, Depts. of Neurosciences & Psychiatry, NJ Medical School, UMDNJ, Newark, NJ 07103 and Dept. of Biology, Kean College, Union, NJ.

Ethanol administration powerfully facilitates defensive rage behavior (DR) in the cat by acting on the pathway from the medial hypothalamus (MH) to the periaqueductal gray (PAG). The present study asked whether the potentiating effects of ethanol upon DR could also be attributed to a blockade of a pathway from the central nucleus of amygdala (CE) to the PAG that suppresses DR. Stimulating electrodes were implanted into: (1) the PAG for elicitation of DR, and (2) CE from which modulation of DR could be tested by comparing paired trials of single (PAG) and dual stimulation (PAG + CE) upon DR. Initially, dual stimulation involving the CE significantly suppressed the occurrence of PAG elicited DR ($p<.001$). Then, ethanol administration at a dose of 1.0 g/kg, i.p. totally blocked the suppressive effects of CE stimulation upon DR, while a lower dose of 0.5 g/kg was ineffective. This finding suggests that ethanol's potentiating effects upon DR are mediated by its inhibitory effects upon the pathway from the CE to the PAG that normally suppresses DR as well as it excitatory actions upon a facilitatory pathway from MH to the PAG.

A NOVEL PARADIGM FOR ASSESSING THE DEPRESSANT EFFECTS OF ALCOHOL USING THE ACOUSTIC STARTLE RESPONSE IN RATS. T.R. Efferen, L.R. Ewing, J.R. Schoonmaker, and J.V. Cassella*, Behavioral Biology Department, Neurogen Corporation, Branford, CT, 06405.

A serious problem with sedative/hypnotic drugs is their potentiation of the depressant effects of alcohol. The efficient development of novel hypnotic drugs depends on the ability to accurately predict efficacy and to identify potential side effects, including alcohol interaction. The acoustic startle response of rats is sensitive to the depressant effects of drugs. This paradigm can be used to quantify the potentiation of the startle-depressing effects of alcohol by a test compound. Male rats were dosed with either zolpidem (2.0-24 mg/kg, PO) or lorazepam (0.07-0.3 mg/kg, PO) 45 minutes prior to an injection of ethanol (1.0 mg/kg, IP) or H_2O (1 ml/kg). Both of these hypnotic compounds depressed startle amplitude when given alone and also increased the depressant effects produced by alcohol. Lorazepam and zolpidem were also tested in the Loss of Righting Reflex model and these data are presented for comparison. Thus, potential alcohol- interaction effects of novel test compounds can be assessed using this acoustic startle paradigm.

ETHANOL ENHANCES AUTOSHAPING OF LEVER-PRESSING IN RATS: AUTOSHAPING PREDICTS WITHIN-SESSION INCREASES IN PLASMA CORTICOSTERONE LEVELS. A. Tomie, E.M. Mosakowski, N. Quartarolo, C. Cunha, E.I. Saiff*, D. Benjamin, and L.A. Pohorecky. Division of Neuropharmacology, Center of Alcohol Studies, Rutgers University, Piscataway, NJ, 08855-0969.

The effects of ethanol (ET) on the acquisition of autoshaping conditioned responses (CRs) and on within-session changes in plasma corticosterone levels was investigated in Long-Evans male rats (N = 46). Rats receiving daily presession injections of 0.5 g/kg ET (Group ET-PAIRED) required fewer Pavlovian lever (CS) -food (US) pairings to acquire the autoshaping CR than did saline-injected controls (SAL-PAIRED). Pseudoconditioning controls experienced insertion of the lever randomly with respect to food, and rats injected presession with 0.5 g/kg ET (ET-RANDOM) exhibited little lever-pressing. Plasma corticosterone levels measured from tail blood samples obtained before and after the 20th autoshaping session revealed that the rats that had acquired the autoshaping CR in fewer than 300 trials in the ET-PAIRED (n = 11) and the SAL-PAIRED (n = 5) groups, showed large within-session increases in plasma corticosterone levels, an effect not observed in the remaining (i.e., non-autoshaping) rats. These data suggest that autoshaping, the reflexive expression of consummatory-like responding directed at small objectives predictive of rewarding substances, may provide an animal model of vulnerability to excessive and compulsive responding, as suggested by the recently developed CAM model of drug abuse (Tomie, *Neurosci. Biobehav. Rev.*, 1996). (Partial support from NIAAA #08499 and NIAAA #10124).

GENETIC DIFFERENCES IN ENDOGENOUS NEUROACTIVE STEROIDS DURING ACUTE ETHANOL WITHDRAWAL. D.A. Finn* and J.C. Crabbe. Dept. Behav. Neuroscience, OHSU and VAMC Research, Portland, OR 97201.

We are testing the hypothesis that genetic differences in ethanol withdrawal severity is due, in part, to modulatory effects of GABA-agonist neuroactive steroids. A recent time course study in genetically heterogeneous male mice found that plasma 3α-hydroxy-5α-pregnan-20-one (3α,5α-P) was significantly decreased at 7 hrs post injection of ethanol (4 g/kg) and unchanged at 0.5, 2, 10 & 24 hrs post injection. The decrease in plasma 3α,5α-P at the 7 hr time point corresponded to peak acute ethanol withdrawal. The present studies were conducted in standard inbred strains of mice to determine whether endogenous 3α,5α-P changed in a manner that was consistent with their genetic differences in acute ethanol withdrawal severity. Male C57BL/6J, DBA/2J, A/HeJ, PL/J, CBA/J, 129/J, C57L/J and SJL/J were injected with 4 g/kg ethanol (20% v/v) or saline and euthanized at 7 hrs post-injection for plasma 3α,5α-P and corticosterone (CORT) determinations. Plasma 3α,5α-P and CORT were significantly influenced by genotype and treatment. CORT was increased in the ethanol injected mice, but this increase was significant in only DBA/2 mice. Plasma 3α,5α-P was significantly decreased in ethanol injected C57BL/6, DBA/2, CBA and 129 animals, non-significantly decreased in A/He and C57L mice and unchanged in PL and SJL animals. These results indicate that there are genetic differences in the effect of acute ethanol administration on plasma 3α,5α -P. Correlations between withdrawal severity (assessed in an earlier study) and plasma CORT and 3α,5α-P (present study) suggest that withdrawal severity was not correlated with 3α,5α-P, but was positively correlated with CORT, mainly due to the values in DBA/2 mice. Future studies will investigate the influence of chronic ethanol on plasma 3α,5α-P. Supported by grants AA08261 and AA10760 from NIAAA and a grant from the Dept. of Veterans Affairs.

REPEATED ETHANOL WITHDRAWAL EXPERIENCE INFLUENCES PLASMA CORTICOSTERONE LEVELS IN MICE DURING A SUBSEQUENT WITHDRAWAL EPISODE. H.C. Becker*, J.L. Diaz-Granados, K.G. Fernandes, and R.R. Reich, Medical University of South Carolina and VAMC, Charleston, SC 29425.

Repeated experience with ethanol (EtOH) withdrawal has been shown to exacerbate the severity of subsequent withdrawal-related seizures. In addition to heightened neural excitability, withdrawal from chronic EtOH exposure has been shown to increase plasma corticosterone (CS) levels, and glucocorticoids are thought to play a modulatory role in EtOH withdrawal seizure intensity. This study was designed to examine whether repeated EtOH withdrawal experience, which results in an exacerbation of withdrawal seizures, alters CS levels during a subsequent withdrawal episode. C3H mice were divided into three treatment groups: a multiple withdrawal (MW) group received 4 cycles of 16 hr EtOH vapor separated by 8 hr periods of abstinence; a single withdrawal (SW) group received a single 16 hr bout of EtOH; and controls (C) received no EtOH. At final withdrawal, plasma samples were collected from separate groups of animals at 0, 8, 16, and 24 hrs post-withdrawal and CS measured by RIA. Upon removal from the inhalation chamber (0 hr), blood EtOH levels did not differ between MW and SW groups (190.1 mg%, 191.4 mg%, respectively). Further, as expected, CS levels were significantly elevated at this time point in both EtOH-exposed groups as compared to the C group. However, whereas CS levels sharply decreased close to control levels at 8 and 16 hrs in SW mice, MW animals still evidenced significantly higher CS levels than both SW and C groups. By the 24 hr timepoint, both EtOH-treated groups had higher CS levels than controls but did not differ from each other. These results suggest that multiple EtOH withdrawal experience exacerbates subsequent exposure/withdrawal-related activation of the hypothalamic-pituitary-adrenal axis. Supported by NIAAA and VAMC.

RAPID ACUTE NEURONAL TOLERANCE TO ETHANOL IN LAS RATS MAY INVOLVE A RAPID DESENSITIZATION OF β-ADRENERGIC MECHANISMS. **B.J. Pearson, R.K. Freund,* and M.R. Palmer. Dept. of Pharmacology, Univ. of Colorado Health Sci. Ctr., Denver, CO 80262.**

We previously reported that cerebellar Purkinje neurons of low alcohol sensitive (LAS) and high alcohol sensitive (HAS) rats are differentially sensitive to the depressant effects of locally applied ethanol (EtOH). The neuronal insensitivity of LAS rats is partially due to low initial sensitivity of these neurons to the depressant effects of EtOH, and partially due to a further desensitization to these effects which occurs over the first few minutes of EtOH (rapid acute tolerance). Using electrophysiological methods to record extracellular action potentials from single Purkinje neurons while applying EtOH by pressure ejection from multibarrel micropipettes, we find that approximately half of LAS Purkinje neurons show this phenomena under the conditions of our experiments. We have also found that isoproterenol, a β-adrenergic agonist, potentiates the depressant effects of EtOH in the cerebellum, and that EtOH-induced depressions on a similar proportion of LAS Purkinje neurons can be antagonized by timolol, a β-adrenergic antagonist. These latter data suggest an influence of endogenous catecholamine synapses on the EtOH responses of those cells. Furthermore, we do not observe rapid acute tolerance to EtOH effects following the timolol-induced antagonism of EtOH depressions. The present data characterize the relationship between β-adrenergic modulation of GABA-induced depressions and the development of rapid acute tolerance to EtOH.

USE OF THE CONFLICT PARADIGM TO STUDY DIAZEPAM WITHDRAWAL. R.L. Smith*, B.H. Calabro, and R.J. Barrett. John F. Kennedy Center, Depart. of Psychiatry and Psychology and V.A. Medical Center, Nashville, TN 37203.

The effects of a single administration of diazepam (DZ) (5 mg/kg) on conflict behavior using a modification of the Geller-Seifter paradigm that is sensitive to both increases and decreases in anxiety were studied. Rats were trained on a multiple schedule using food reward. Sessions consisted of three, 5-m periods under a VI 60-s schedule alternated with three, tone-signaled, 2-m periods under a CRF schedule. In addition to reinforcement, each response during the tone period was punished using an incremental shock procedure whereby each lever press incremented the shock intensity. Animals made an average of 14.8 punished responses/conflict period under non-drug conditions. Following training, rats were assigned to one of four matched groups. Two groups were pretreated with 5 mg/kg DZ and two with saline. Four hours later one group from each pretreatment condition was injected with either 32 mg/kg flumazenil or saline. Five minutes later they were tested in the conflict paradigm. Animals in the DZ-Sal group showed a significant increase in punished responding while animals in the DZ-Flu group showed a significant decrease in punished and unpunished responding relative to saline controls. The Sal-Flu group did not differ from control. This procedure was replicated at 8, 12, 16 and 20 hr post-DZ to determine if spontaneous withdrawal could also be measured. Results from 10 and 20 mg/kg DZ will also be presented. NICHD grant no. HD15052, Veterans Administration.

813.11

PERMANENT EFFECTS OF PRENATAL EXPOSURE TO DIAZEPAM ON SEXUAL BEHAVIOR OF MALE MICE. L.A.I. Hernández-Alvarez*, A. Martínez-Vargas, B. Victoria-Romero, A. Márquez-Orozco and M.C. Márquez-Orozco. Unit for Research in Reproduction. School of Medicine, BUAP and Dept. of Embryology. School of Medicine, UNAM, México 04510 D.F., México.

We have shown in forgoing works, effects of prenatal exposure to diazepam (DZ) on sexually dimorphic reproductive behaviors of adult mice. The aim of this work was to compare the alterations of sexual behavior of CD-1 strain male mice exposed *in uterus* to DZ, during their reproductive span. One group of female mice was s.c. treated with DZ (2.5 mg/kg/d) from 6th to 17th days of gestation and a control group received saline sol. The spontaneous offspring male sexual activity to receptive females was tested in 3 sessions (1/week) twice, once on the 6th month of age and later on the 27th. Tests were performed during the dark stage of the photoperiod and videorecorded under red light. Precopulating and copulating activities were evaluated. No difference was found in precopulating behaviors from both groups. During copulating stage adult DZ-treated males showed greater incidence of interruptions of intravaginal penetration into mount series with ejaculation, while senile DZ-treated males had lower latencies of mount series and greater proportion of ejaculations. Both adult and senile DZ-treated males exhibited a significant larger incidence of falls and pauses during mount series with intromission. Results show a permanent effect of prenatal exposure of DZ on sexual behavior.

813.12

EFFECTS IN THE RETINAL ULTRASTRUCTURE OF MOUSE FETUSES EXPOSED IN UTERO TO DIAZEPAM A. Márquez-Orozco*, M.C. Márquez-Orozco, M.V. Gazca-Ramírez and G. de la Fuente-Juárez. Embryol Dept. School of Medicine UNAM, POB 70-553 México 04510 D.F. México.

Diazepam (DZ) accumulation during gestation in the retina of mouse fetuses delays cellular differentiation. We investigated if DZ 1.0 mg/kg doses produces similar ultrastructural changes in the fetal mouse retina with 2.5 mg/kg doses. Three gestating CD-1 strain mice groups were injected daily sc from day 6 to 17, the first group with single daily DZ doses (2.7 mg/kg), the second group with single daily DZ doses (1.0 mg/kg), the third group received saline solution (S). A fourth group was non-treated (NT). All were killed in a CO_2 atmosphere the 18th day, and the fetus removed. Their eyes were fixed with 2.5% glutaraldehyde, post-fixed in OsO_4 and embedded in epoxy resin. The fine sections were contrasted with uranyl acetate and lead citrate and observed under a transmission microscope. The fetal retina in both DZ groups nuclear density per area was greater than the S and NT fetuses ($p<0.05$). Heterochromatin was atypically distributed in the nuclei, the Golgi Complex, the polyribosomes and the mitochondrias were more abundant. The cisterns of the rough endoplasmic reticulum were distended. The great nuclear density and the alterations of the cytoplamic organelles could reveal disruptions in cell multiplication. Results give evidence that both DZ doses produces ultrastructural changes in the fetal retina.

813.13

ULTRASTRUCTURAL ALTERATIONS IN CEREBELLAR CORTEX OF ADULT MICE EXPOSED PRENATALLY TO DIAZEPAM. M.C. Márquez-Orozco*, A. Márquez-Orozco, M.V. Gazca-Ramírez and G. de la Fuente-Juárez. Embryol. Dept. School of Medicine UNAM, POB 70-553 México 04510 D.F. México.

We investigated if diazepam (DZ) 2.7 mg/kg induced long-term, ultrastructural alterations in the cerebellar cortex in adult mice prenatally exposed to DZ. Two gestating CD-1 strain mice group were injected daily sc from day 6 to 17, the first group with single daily DZ doses (2.7 mg/kg) and the second group received saline solution (S). A third group was non-treated (NT). The offspring's were wet-nursed by non-treated mice weaned and kept for 60 days. All mice were killed in a CO_2 atmosphere, the cerebellum fixed in 2.5% glutaraldehyde, post-fixed in OsO_4 and embedded in epoxy resin. The fine sections were contrasted with uranyl acetate and lead citrate and observed under a transmission microscope. In the cerebellar cortex DZ group was demonstrated the presence of abundant neuroblasts in the external granular layer, decreases in neuron density of the internal granular layer paucity of parallel fibers in the molecular layer, as were compared with S and NT group ($p<0.05$). The Purkinje cells and granular layers cells the nuclei showed clumps of heterochromatin adhering to the membrane, poor dendrite tree and a decrease, in the neuropile extension. The rough endoplasmic reticulum was frequently dilated and disorganized. The Golgi Complex was abundant. Results show a long-term effect of prenatal exposure of DZ on cerebellar cortex.

813.14

POTENTIATION OF GABA RECEPTORS MAY PARTIALLY MEDIATE ETHANOL'S BLOCKADE OF LONG-TERM POTENTIATION. J. Schummers, M.D. Browning* Dept of Pharmacology, Univ.Colorado H.S.C., Denver, CO, 80262.

We have attempted to elucidate the mechanisms by which ethanol inhibits the induction of long-term potentiation (LTP) in area CA1 of the adult rat hippocampus. In our hands, 100mM EtOH completely abolished the induction of LTP by high frequency stimulation (HFS), as measured 30 minutes after delivery of tetanus. We found that 100mM EtOH reduced the initial slope of NMDA fieldEPSP's, isolated pharmacologically by blocking AMPA/Kainate, GABAa and GABAb receptor activity (with NBQX, picrotoxin and CGP35348, respectively), by 19.6 ±3.5%. However, we determined that a 20% suppression of the NMDA EPSP, produced by other competitive and non-competitive NMDA antagonists, could not alone account for ethanol's ability to block LTP. We therefore postulated that an EtOH-mediated potentiation of the GABA system might also contribute to ethanol's inhibition of LTP induction. When measured in the presence of picrotoxin and CGP35348, any effect of ethanol on GABA receptors would be masked. We therefore examined the effects of 100mM EtOH on NMDA fEPSP's elicited in the presence and absence of GABA antagonists. We found that ethanol suppressed NMDA responses to a significantly greater degree when GABA blockers were not present. (36 ±7% in the presence of NBQX alone, 16 ±5% in the presence of NBQX, picrotoxin and CGP35348; P=.013). This indicates that ethanol may potentiate basal levels of GABA activity, thus suppressing the NMDA response even further. Thus, it seems likely that, under more physiological conditions (with functional GABA circuitry intact), EtOH inhibits NMDA activity by both a direct action on the NMDA receptor molecule, and indirectly, by potentiating GABA receptor activity. Both actions would contribute to a decrease in Ca^{++} entry into the postsynaptic terminal, which is thought to be necessary for LTP induction. Thus, ethanol's blockade of LTP may involve effects at both NMDA and GABA receptors. Supported by PHS AA09765.

FOCAL ADMINISTRATION OF FLUMAZENIL (FLU) INTO CEREBRAL CORTEX (CCX) IN DIAZEPAM (DZ) DEPENDENT RATS. X. Jing, E.P. Wala, J.W. Sloan and Joseph R. Holtman, Jr.*. Dept. of Anesthesiology, College of Medicine, University of Kentucky, Lexington, Kentucky 40536.

The ability of FLU to precipitate (ppt) abstinence syndrome in frontal (FCx) and occipital (OCx) cortices, the brain areas rich in central benzodiazepine receptors (CBR) was determined. Rats (F, 250g) were implanted with indwelling cannulas on the surface of frontal (sFCx) (n=5) [AP=10.7; L=2; V=9.8] and occipital (sOCx) (n=5) [AP=-0.16; LL3.0; V=8.6] cortices. The rats were subcutaneously implanted with silastic capsules containing DZ [3x180 mg/cap/wk]. After 3 wk exposure to DZ 1µl [25mg/ml] of FLU followed 3 days later by 1µl of DMSO-vehicle were injected once/wk into either sFCx [V=9.8] and FCx [V=9] or sOCx [V=8.6] and OCx [V=7]. Dependence on DZ was confirmed by seizures and other abstinence signs ppt by systemic FLU (40 mg/kg, IV). The rats were observed 10 min prior to and 40 min after focal injections for signs of ppt abstinence (PA) and behavioral states. The PA Score (PAS) and Behavioral Score (BS) were calculated. FLU did not produce significant PAS and BS in any cortical loci. However, in sFCx FLU evoked clonic convulsions (CL) (1 rat) tachypnea, and decrease in head bobbing, blinking, walking, exploring and digging. In FCx twitches and jerks occurred within 5 min after FLU. No PA signs were ppt from sOCx. In OCx FLU produced CL convulsions (1 rat) and blinking. FLU-evoked PA seems not to be directly related to population of CBR (highest in lamina IV of FCx and OCx) since as reported from our laboratory more severe PAs were evoked from other brain loci (hippocampus, cerebellum or substantia nigra) where the density of CBR is lower than in CCX. Chronic DZ treatment results in decreased GABA function as reflected by decreased GABA-stimulated CL influx, mRNA α-1 levels and ability of GABA to enhance BZ binding in the CCx but not in cerebellum or hippocampus [rev. Gallager and Primus 1993]. The data confirm regional brain heterogeneity in response to chronic DZ. Supported by NIDA DA02195.

ENHANCEMENT BY FLUMAZENIL OF DOPAMINE AND ACETYLCHOLINE RELEASE IN THE BRAIN OF RATS REPEATEDLY EXPOSED TO DIAZEPAM, IMIDAZENIL AND ABECARNIL. L. Dazzi , M.L. Porceddu, A. Sanna, C. Motzo and G. Biggio*. Dept. of Experimental Biology, Chair of Pharmacology, University of Cagliari, 09123 Cagliari, Italy.

The effect of long-term treatment with pharmacologically active doses of the benzodiazepine (BDZ) receptor partial agonist imidazenil (IMZ) (0.5 mg/kg, i.p.) on basal dopamine (DA) and acetylcholine (ACh) release in the nucleus accumbens and hippocampus of freely moving rats, was compared with that of diazepam (DZ) (3 mg/kg, i.p.) a BDZ receptor full agonist, using brain microdialysis. Moreover, the effect of long-term treatment with the selective agonist abecarnil (AB) (0.5 mg/kg, i.p.) on basal hippocampal ACh release was also studied. Challenge doses of these drugs decreased the extracellular hippocampal ACh release as well as the DA output from the nucleus accumbens by approximately the same extent in animals repeatedly exposed to vehicle or to the respective drug. Moreover, the abrupt discontinuation of long term-treatment with DZ or IMZ failed to affect basal ACh and DA release during the first 5 days of withdrawal. The acute administration of the BDZ receptor antagonist flumazenil elicited a marked increase in DA release in the nucleus accumbens 6h after withdrawal of IMZ or DZ, respectively. Flumazenil induced the same effect 5 days after DZ but had no discontinuation effect 5 days after IMZ withdrawal. Flumazenil increased hippocampal ACh release 2 days after discontinuation of long-term treatment with DZ but failed to induce the same effect 5 days after DZ withdrawal and 2 and 5 days after discontinuation of long-term treatment with IMZ or AB. Our data support an important contribution of mesolimbic DA and septohippocampal ACh in the behavioural effects that are associated with the withdrawal syndrome in benzodiazepine dependence. Moreover, these results further differentiate the pharmacology of BDZ receptor full and partial agonists.

ETHANOL INHIBITION OF NMDA RESPONSES INVOLVES PRESYNAPTIC $GABA_B$ RECEPTORS Z. Nie, S.C. Steffensen*, J.R. Criado, S.J. Henriksen and G.R. Siggins. Department of Neuropharmacology, Scripps Research Institute, La Jolla, CA 92037

Numerous studies have demonstrated that ethanol has a dose-dependent inhibitory effect on NMDA receptor-mediated neurotransmission. As $GABA_B$ receptors have been shown to modulate NMDA EPSPs, and ethanol increases GABA receptor-mediated IPSPs in some brain regions, we evaluated in vivo and in vitro the role of $GABA_B$ receptors in ethanol-induced inhibition of NMDA responses in the hippocampus (HC) and nucleus accumbens (NAcc). In situ microelectrophoretic application of the $GABA_B$ antagonist CGP35348 dose-dependently blocked baclofen- and ethanol-, but not APV-induced reduction of NMDA enhancement of hilar and oriens/alveus interneuron firing, as well as NMDA enhancement of afferent-evoked population spikes in the dentate gyrus and CA1 HC subfields in vivo. Similarly, in the NAcc, ethanol inhibition of amygdala-driven NAcc unit activity was blocked by CGP35348 in vivo. We performed in vitro studies in NAcc slices to better evaluate the role of $GABA_B$ receptors in mediating ethanol effects on NMDA responses. Superfusion of CGP35348 (0.5 mM) or the more potent CGP55845 (2 μM) blocked ethanol (66 mM) inhibition of local stimulus-evoked NMDA-mediated EPSP amplitudes in NAcc slices. However, neither CGP compound had any effect on ethanol inhibition of NMDA currents evoked by pressure application of NMDA in the presence of CNQX (10 μm), bicuculline (30 μM) and TTX (1μM). As we and others have found no evidence for postsynaptic $GABA_B$ receptors in the NAcc, these findings suggest that ethanol acts through presynaptic $GABA_B$ receptors to inhibit NMDA receptor-mediated glutamate release, perhaps via a second messenger-mediated system. REWARDING PROPERTIES OF GAMMA HYDROXYBUTYRIC ACID IN DRUG-NAIVE MICE, M.C. Martellotta, G. Cossu, L. Fattore and W.Fratta* Department of Neuroscience, University of Cagliari, Italy.

Gamma hydroxybutyric acid (GHB) is a putative neurotransmitter or neuromodulator found in the mammalian brain. In the clinical practice it has been successfully used to alleviate both alcohol and opiate withdrawal symptoms. Recent data have demonstrated the establishment of GHB preference over water in rats. We have investigated on the possibility that GHB, like drugs of abuse, might be intravenously self-administered in drug naive mice. Mice were tested in pairs of identical test cage, the "active" mouse was placed in one cage, the "yoked passive" mouse confined to the other. Each test cage presented an infrared detector that activated a cumulative recorder and a syringe pump to deliver solution,(1 μl) in the lateral tail vein, contingent on a nose-poke response (NPR). When GHB injection were made contingent upon NPR by naive mice, they increased their rate of nose-poking with respect to animals receiving contingent saline injection or yoked control animals, receiving non contingent GHB injection. As a measure of the rewarding effect of the drug the ratio "R" between the cumulative NPRs of the active and passive mouse during 30-min session was used. The effect of the drug was onsidered rewarding, neutral or aversive when R was respectively higher, equal or smaller than 1. Our results show that GHB is intravenously self administered in drug naive mice in a dose related manner, according to a bell-shaped curve. Furthermore, pretreatment with the GHB antagonist, NCS-382 antagonizes GHB self administration.

It is noteworthy to underline that GHB, other than a drug used in clinical practice, is being sold unlawfully as warned by FDA. Our findings indicate that particular attention should be addressed to its addictive properties.

MODULATION OF GABA RECEPTOR FUNCTION IN RAT BRAIN BY CHRONIC DIAZEPAM ADMINISTRATION AND WITHDRAWAL

S. Toki[1]*, A. Nabeshima[1], T. Saito[1], S. Hatta[1], M. Watanabe[1], H. Ozawa[1] and N. Takahata[1]. [1]Dept. of Neuropsychiatry and [2]Dept. of Pharmacology*, Sapporo Medical University, Sapporo, 060, Japan

Changes in $GABA_A$ receptor function in diazepam (DZP) -dependent rats and their relation to withdrawal signs were studied. Physical dependence on DZP was induced in male Fischer rats by using the drug-admixed food method. Immediately after the final DZP treatment (non-withdrawn rats), GABA-stimulated ^{36}Cl influx into cerebral cortical synaptoneurosomes was significantly decreased compared with that in control rats. Furthermore, flunitrazepam (FZ) induced potentiation and an antagonistic effect of Ro15-1788 on GABA-stimulated ^{36}Cl influx were not observed in non-withdrawn rats. On the other hand, 42 hr after the DZP treatment, withdrawal scores reached maximum point and GABA-stimulated ^{36}Cl influx was significantly increased compared with that in control rats. Whereas FZ significantly potentiated the GABA-stimulated ^{36}Cl influx, it was not effectively suppressed by the addition of Ro 15-1788 in 42 hr after the DZP treated rats. Seven days after the DZP treatment, withdrawal signs were almost disappeared and GABA-stimulated ^{36}Cl influx was reversed as same as the control value. Furthermore, an agonistic effect of FZ and an antagonistic effect of Ro15-1788 was recognized. The present study indicates that the functional changes in GABA/benzodiazepine/Cl channel complex may be possibly involved in manifestation of the withdrawal symptoms.

813.20

LOSARTAN BLOCKS THE EFFECTS OF DIAZEPAM ON THE AERIAL RIGHTING REFLEX IN RATS. H.A. Tracy, Jr., M.J. Wayner* and D.L. Armstrong. Division of Life Sciences, The University of Texas at San Antonio, San Antonio, TX 78249-0662, USA.

Previously, we discovered that angiotensin II (AII) inhibited long term potentiation (LTP) induction in medial perforant path-dentate granule cell synapses and the inhibition was mediated by the AII AT_1 receptor because the inhibition was blocked by losartan, an AII AT_1 specific antagonist. Inhibition of LTP in these synapses by ethanol and diazepam (DZ) is mediated by the AII AT_1 receptor because the inhibition can also be blocked by losartan. Since the intoxicating effect of ethanol on the aerial righting reflex can be blocked in a dose dependent way by losartan, the purpose of the present study was to determine the effectiveness of losartan in reducing the effects of DZ on the righting reflex in rats. Losartan, 20 mg/kg i.p. 2 hours prior to the administration of DZ, 1 mg/kg i.p., significantly reduced the effect of DZ on the aerial righting reflex, $p<0.008$ df 1,18. These results support our earlier findings that the AII inhibition of dentate granule cell LTP induction is associated with impaired physiological functions and behavioral effects.

DRUGS OF ABUSE: ETHANOL, BARBITURATES, AND BENZODIAZEPINES V

814.1

INCREASED EXPRESSION OF α4 SUBUNIT mRNA AND INCREASED STEROID MODULATION OF BENZODIAZEPINE BINDING TO $GABA_A$ RECEPTORS IN HIPPOCAMPUS OF RATS TREATED WITH CHRONIC INTERMITTENT ETHANOL. M.H. Kang*, M. Mahmoudi, N. Tillakaratne, A.J. Tobin and R.W. Olsen. Depts. of Pharmacology and Physiological Sciences, UCLA, Los Angeles, CA 90095.

Alterations in pharmacological binding properties and subunit mRNA expression of $GABA_A$ receptors (GABAR) were observed in brain sections of rats treated with chronic intermittent ethanol (CIE). Rats given 60 doses of ethanol under an intermittent regime of repeated withdrawals show a persistent increase in withdrawal severity assessed by various behavioral signs including reduced threshold for seizures induced by the GABAR channel antagonist PTZ (Kokka et al., 1993), reduced GABAR-mediated inhibition in hippocampus, and increased sensitivity of hippocampal GABAR to inhibition by benzodiazepine inverse agonists like DMCM (Kang et al., 1996). *In situ* hybridization histochemistry revealed significant increases in the levels of mRNA for the GABAR α4 subunit in all regions of hippocampus, parietotemporal cortex, and thalamus of CIE rats, but no changes in α5 subunit or GAD67 mRNAs in these regions. Radioligand autoradiography binding to sections showed significant increases in neuroactive steroid (10 μM alphaxalone) modulation of [^{3}H]flunitrazepam binding in all regions of hippocampus, but no changes of basal binding or zolpidem-insensitive binding, a measure of the α5 subunit. The increased levels of α4 subunit and increased steroid modulation of binding are suggested to be related to the hypoactive GABAR function and possibly the seizure susceptibility of this ethanol withdrawal-kindled rat model of alcohol dependence. Supported by AA07680 and NS22256.

814.2

EFFECTS OF ACUTE ETHANOL AND A STEROID ANESTHETIC ALPHAXALONE ON $GABA_A$-MEDIATED SYNAPTIC RESPONSES IN CA1 PYRAMIDAL CELLS FROM CHRONIC INTERMITTENT ETHANOL-TREATED RATS. R.W. Olsen[1], M.H. Kang[1], Z. Li[2]*, and I. Spigelman[2]. [1]Department of Pharmacology, UCLA School of Medicine, [2] Section of Oral Biology, UCLA School of Dentistry, Los Angeles, CA 90024

Chronic intermittent ethanol (CIE)-treated rats exhibit a kindling-like persistent decrease in the PTZ-induced seizure threshold (Kokka et al., Alcohol. Clinic. Exp. Res. 17, 525-531, 1993). As a possible underlying mechanism, an alteration of $GABA_A$ receptor function was suggested since muscimol-evoked $^{36}Cl^-$ efflux was decreased in the hippocampal slices from CIE rats and paired-pulse inhibition, predominantly due to $GABA_A$ receptor-mediated recurrent inhibition, was persistently decreased in the CA1 hippocampal area (Kang et al., Brain Res., 709, 221-228, 1996). To further characterize the functional alteration of $GABA_A$ receptors after CIE treatment, $GABA_A$ receptor sensitivity to neurosteroids was examined by studying the modulatory effect of alphaxalone on monosynaptically evoked $GABA_A$-mediated postsynaptic inhibitory potentials (IPSPs). Bath application of alphaxalone (1 μM) potentiated the area of $GABA_A$-IPSPs in control and CIE rats at 2 days withdrawal by 125 and 154 %, respectively. There was no significant difference between these groups ($p = 0.375$). Secondly, the acute ethanol effect on $GABA_A$-IPSPs was examined in the CIE rats to see if this response is altered after CIE treatment. Bath application of ethanol (60 mM) also enhanced the $GABA_A$-IPSPs, but the potentiation in CIE rats at 2 days withdrawal (98 %) was significantly ($p = 0.0266$) greater than in control rats (53 %). These data suggest that separate mechanisms underlie ethanol tolerance and withdrawal hyperexcitability.

814.3

MODULATION OF GABA-ACTIVATED CHLORIDE FLUX FOLLOWING BENZODIAZEPINE EXPOSURE IN MALE AND OVARIECTOMIZED RATS: INFLUENCES OF STRESS. M. A. Wilson*, R. Biscardi, S. Abulhawa, and H.S. Stock. Dept. Pharmacology, Univ. South Carolina School of Medicine, Columbia, SC 29208.

Acute stress induces sex-specific changes in corticosterone release, GABA/benzodiazepine (BZ) receptors, and adaptations to chronic benzodiazepine exposure in rats. In the present study, GABA responses in cortex and hippocampus were analyzed following BZ exposure in ovariectomized female (OVX) and sham-operated male rats. Following a 3 week treatment with either vehicle or diazepam-filled (DZ) silastic capsules, the ability of the neurosteroid tetrahydrodeoxy-corticosterone (THDOC, 200 nM) and the BZ midazolam (1 μM) to enhance GABA-activated ^{36}chloride influx (at 10 μM) were determined in groups of unstressed and restraint-stressed (15 min prior to sacrifice) rats. In hippocampus, male groups had significantly greater levels of GABA-stimulated chloride flux at 10 μM GABA than OVX groups, while OVX groups displayed greater increases with midazolam and THDOC than males. Acute stress increased BZ enhancement of GABA-activated $^{36}Cl^-$ flux in hippocampus, although this effect was significant in male but not OVX groups. In cortex, maximal GABA responses (at 100 μM) were decreased by stress and enhanced by chronic DZ exposure, although these changes were only observed in OVX groups. Midazolam enhancement of cortical GABA responses was also increased in OVX groups receiving an acute diazepam injection. Corticosterone levels were decreased by chronic DZ exposure in male and OVX groups. These results suggest that gender-related factors and stress can modify benzodiazepine and neurosteroid enhancement of GABA responses in hippocampus, but not cortex. BZ exposure appears to alter cortical GABA responses selectively in OVX rats. *Support: RO1 DA05932&K02 DA00249 to MAW*

EFFECTS OF REPEATED EXPOSURE TO FLUMAZENIL ON SCHEDULE-CONTROLLED BEHAVIOR IN CHLORDIAZEPOXIDE-TREATED RHESUS MONKEYS. L. R. Gerak and C. P. France*. Department of Pharmacology, Louisiana State University Medical Center, New Orleans, LA 70119.

Flumazenil (FLU) precipitates withdrawal in benzodiazepine-treated subjects; however, this effect can be attenuated on subsequent exposures to FLU. The purposes of the present study were to determine: whether FLU disrupts schedule-controlled responding in chlordiazepoxide (CDP)-treated monkeys; and whether effects of FLU diminish upon subsequent exposure. In 3 untreated monkeys, FLU (0.1-3.2 mg/kg) had no effect on rates of responding under a multiple (FR10, FR10) schedule of food presentation and stimulus-shock termination (SST). Chronic treatment with 32.0 mg/kg/day of CDP (s.c.) decreased mean response rates to 83% of control in the food component and to 74% of control in the SST component. After 2 weeks of CDP treatment, FLU dose-dependently decreased food-maintained responding with a dose of 3.2 mg/kg reducing the average rate to <10% of control; for 1 monkey, 0.1 mg/kg of FLU eliminated responding in the SST component whereas response rates for the other 2 monkeys were unchanged up to a dose of 3.2 mg/kg of FLU. When the interval between FLU exposures was shortened from 4 to 2 to 1 week then to 4 days, similar doses of FLU (1.0 or 3.2 mg/kg) decreased rates in the food component. To the extent that FLU-induced disruptions of food-maintained responding are indicative of withdrawal, these data suggest that dependence developed to 32.0 mg/kg/day of CDP. In contrast to previous studies that examined the effects of repeated exposure to a single dose of FLU, the current study determined complete dose-effect curves for FLU using progressively decreasing inter-test intervals. Collectively, these results fail to support the view that intermittent exposure to FLU attenuates the development of dependence on CDP; however, it is possible that more frequent exposure (<4 days) to FLU might cause a diminished response to its disruptive effects in CDP-treated monkeys. INVOLVEMENT OF AMPA/KAINATE RECEPTORS IN DIAZEPAM INDUCED CONDITIONED PLACE PREFERENCE IN RATS. J.A. Pratt* and A. Gray. Dept. of Physiology and Pharmacology, University of Strathclyde, Glasgow, G11XW, U.K.

The role of dopamine in the rewarding properties of benzodiazepines remains to be resolved. Since there is evidence that glutamate receptors may be a component of the rewarding properties of other psychotropic drugs, the aim of this study was to determine if the selective AMPA/kainate receptor antagonist, GYKI 52466 could block the acquisition of conditioned place preference (CPP) induced by diazepam.

CPP responses were measured in a three compartment apparatus with a small central compartment. Initial preference for individual rats was determined for each compartment on day 3 following 15 min daily exposures to the test chamber. Rats were subjected to four conditioning trials. On days 4,6,8, and 10 of training, injections of GYKI 52466 (4.8 mg kg^{-1} i.p.) or saline were made 5min prior to diazepam (2.5mg kg^{-1}i.p.) or vehicle, and rats were confined to the initially least preferred side for 30 min. On the intervening days all groups were injected with vehicle and confined to the preferred side. Rats were retested for their place preference on day 13. Diazepam significantly increased the time spent in the initially least preferred side from 196±20sec before conditioning to 530±20sec after conditioning. In contrast, vehicle treated rats showed no change in their preference (149±19sec and 157±22sec respectively, in the non-preferred side prior to and after conditioning). CPP was no longer apparent in the group pretreated with GYKI 52466. Thus 109±34sec was spent in the initially least preferred side before conditioning compared to 203±91sec after conditioning. These data suggest an involvement of AMPA/kainate receptors in CPP induced by diazepam, and support a view that these receptors may be involved in psychotropic drug-induced reward. Supported by the University of Strathclyde and SHERT.

COMPARISON OF THE WITHDRAWAL SYNDROMES PRECIPITATED BY THE CENTRAL AND PERIPHERAL BENZODIAZEPINE ANTAGONISTS IN DIAZEPAM-DEPENDENT FEMALE RATS. E.P. Wala*, J.W. Sloan, and X. Jing College of Medicine, University of Kentucky, Lexington, Kentucky 40536.

These studies were conducted to determine the involvement of central (CBR) and peripheral (PBR) benzodiazepine receptors in physical dependence on diazepam (DZ). Two groups of rats (female; 250g; n=6/group) were chronically exposed to DZ which was slowly released from subcutaneously implanted silastic capsules (1x90 mg/cap/wk). The rats were stabilized on DZ for 5 weeks prior to precipitation with either graded doses of the CBR or PBR antagonists, flumazenil (FLU) and PK 11195 (PK), respectively. FLU [10, 20, 40 mg/kg], PK [5, 10, 20 mg/kg] and DMSO-vehicle were administered at weekly intervals as bolus IV injections (Latin square). The rats were observed in 5 minute epochs for signs of abstinence and behavioral states 10 minutes prior to and 20 minutes after IV injections. The Precipitated Abstinence Score (PAS) was calculated. The peak PAS which was observed within 5 minutes after IV injections had a significant regression on dose of FLU but not on dose of PK. Occurrences of clonic (CL) and tonic-clonic (T-CL) seizures increased with increasing dose of FLU whereas PK (10 mg/kg) evoked CL and T-CL convulsions in only one rat. Several signs of abstinence tended to increase (twitches and jerks, writhing, jumping) or to decrease (backing, blinking) with increasing dose of FLU. Rearing significantly decreased with increasing dose of PK. FLU (10 and 20 mg/kg) produced tachypnea and head bobbing which were significantly different from DMSO-vehicle. PK (20 mg/kg) produced significantly more tachypnea in comparison to DMSO-vehicle. It can be concluded that both CBR and PBR are involved in dependence on DZ. FLU and PK produce several common abstinence signs; however, there are noticeable differences between these two antagonists, particularly in their ability to precipitate seizures. Overall, in DZ-dependent rats, FLU precipitates a more severe abstinence syndrome in comparison to PK. Supported by NIDA grant DA02195.

814.7

EFFECT OF GENDER ON PHYSICAL DEPENDENCE ON DIAZEPAM (DZ) IN RATS. J.W. Sloan*, E.P. Wala, X. Jing and P.H. Holtman. Dept. of Anesthesiology, Coll of Med, University of KY, Lexington, KY 40536.

Sprague-Dawley male (♂) [350.5 ± 1.6 g] and female (♀) [229.8 ± 3.4 g] rats, 85-90 days old, were implanted once/week with DZ contained in 3 silastic capsules (180 mg/capsule). After 5 weeks of exposure to DZ, the rats were precipitated weekly via the tail vein with bolus injections of the benzodiazepine central antagonist, flumazenil (FLU) [40 mg/kg]; the peripheral antagonist, PK 11195 (PK), and the vehicle, DMSO. The rats were observed for signs of precipitated abstinence (PA) for 10 min prior to and 20 min after IV injections (in 5 min epochs). Weight gain was greater in ♂ rats during the course of the experiment (43.1 ± 4.6 g) than in ♀ rats (26.3 ±3.3g), $p < 0.025$. Chronic DZ resulted in the death of 4/10 ♂ rats but none of 6 ♀ rats. During PK-evoked PA 2/7 ♂ and 1/6 ♀ rats died whereas none died after FLU. FLU produced a significant PA score (PAS) in ♂ but not in ♀ rats and significant behavioral depression in both ♂ and ♀ rats. PK produced neither a significant PAS nor behavioral score in either sex. More ♂ rats had clonic convulsions (CL) [6/7] and tonic-clonic convulsions (T-CL) [5/7] after FLU than ♀ rats where 2/6 had CL and T-CL. After PK, 2/7 ♂ rats had CL and T-CL whereas 3/6 ♀ rats had CL and 2/6 had T-CL . FLU, but not PK, produced significant tachypnea in both ♂ and ♀ rats. Several other FLU and PK-evoked abstinence signs differed in ♂ and ♀ rats. Mean total plasma levels of DZ plus its metabolites were equal to 7.6 ± 0.55 and 8.2 ± 0.76 μg/ml in ♀ and ♂ rats, respectively. The data suggest that ♂ rats developed a higher level of dependence; were more sensitive to the toxic effects of a high chronic dose of DZ than ♀ rats; that gender differences were not due to pharmacokinetics, and that both central and peripheral receptors are involved in the dependence-producing properties of DZ in both sexes. Supported by NIDA grant DA02195.

CPP-INDUCED BEHAVIORS DIFFER BETWEEN LONG- AND SHORT-SLEEP MICE. M.J. Velardo* and N.R. Zahniser. Neurosci. Prog. and Dept. Pharmacol., Univ. Colo. Hlth. Sci. Ctr., Denver, CO 80262.

Glutamate neurotransmission appears to be involved in acute ethanol responsiveness. Long-sleep (LS) and Short-sleep (SS) mice were selectively bred for differential sensitivity to the acute hypnotic effects of ethanol, with LS mice exhibiting loss of righting reflex (LORR) at doses > 3g/kg,(i.p.). However, at doses of ethanol < 5g/kg, SS mice do not exhibit LORR but do show greater locomotor activation. Similarly, doses of the NMDA receptor channel blocker MK801 ≥ 1.5 mg/kg (i.p.) induce LORR in LS, but not SS mice; and all doses ≥ 0.1mg/kg produce greater locomotor activation in SS mice. To further examine these behavioral observations, open field activity tests were performed using the competitive NMDA receptor antagonist CPP. Behavioral effects of CPP were measured over a range of doses (10, 20, 40, 80 mg/kg, i.p.) at 5-min intervals for three hours. At efficacious doses (≥ 20 mg/kg), SS mice exhibited a monotonic increase in locomotor activation similar to that seen with MK801. In contrast, LS mice exhibited minimal increases in locomotor activity at lower doses but significant decreases at higher doses. We excluded the possibility that these behavioral differences resulted from differences between the lines in absorption of the drug into the brain by measuring levels of [^{3}H]CPP/CPP. Our observations that both competitive and non-competitive NMDA receptor antagonists induce greater locomotor activity and less sedation in SS than LS mice suggest that NMDA receptor-mediated neurotransmission differs between these two lines and may contribute to their differential ethanol sensitivity. MOUSE CORTICAL KAINATE AND NMDA RECEPTOR CHANGES MAY INTERACT TO PRODUCE WILD-RUN AND TONIC-CLONIC SEIZURES DURING PHENOBARBITAL WITHDRAWAL.

K. R. Short* and B. Tabakoff Dept. of Pharmacology, UCHSC, Denver, CO 80262, *Dept. of Psychology, Creighton Univ., Omaha, NE 68178.

We have reported decreased kainate (KA) receptor and increased NMDA receptor numbers in mouse cortex during chronic phenobarbital (PhB) treatment. To further characterize potential mechanisms for withdrawal (W/D) seizures, we now report the duration of KA receptor reduction and of NMDA receptor elevation following PhB W/D, and the corresponding rates of both wild-run (W-R) and tonic-clonic (T-C) W/D seizures and levels of serum PhB.

C57BL/6 mice (N=85) ate normal diet or diet containing 2.0 g PhB/kg food (increased to 2.5 g/kg after 5 days) for 7 days, then drug was removed. Mice were tested for auditory seizures at 0, 8, 12, 24, 36, 48, & 72 hrs W/D, & sacrificed at 0, 12, 24, 36, or 72 hrs W/D. Trunk blood was assayed for serum PhB and cortical tissue was prepared for KA and NMDA receptor quantification ([^{3}H]KA (1-64 nM) and [^{3}H]MK-801 (0.25-25 nM) binding to crude synaptic membranes via centrifugation & filtration, respectively).

At 12 hrs W/D only 25% of the seizures were T-C, while at 24 & 36 hrs 75-80% of seizures were T-C. Serum PhB returned to normal by 12 hrs W/D. MK-801 B_{max} remained elevated (24-49%) until 24 hrs W/D, but dropped to control levels at 36 hrs, while KA B_{max} (~ 61-69%) returned to control levels by 24 hrs W/D. These results suggest that PhB W/D W-R seizures are associated with increased NMDA receptor number, reduced KA receptor number and low serum PhB, while PhB W/D T-C seizures occur only after KA receptor numbers have returned to normal and NMDA receptors remain elevated. (AA-09014, AA-09005, AA-07464)

CHRONIC PENTOBARBITAL ADMINISTRATION INCREASES [^{3}H]FORSKOLIN BINDING IN THE RAT BRAIN: AN AUTORADIO-GRAPHIC STUDY, T. Ito[1]*, T. Suzuki[2], S.E. Wellman[1], and I.K. Ho[1]. [1]Dept. of Pharmacology and Toxicology, Univ. of Mississippi Med. Ctr., Jackson, MS 39216. [2]Dept. of Psychiatry, Univ. of Tsukuba, Tsukuba, 305, Japan.

Chronic pentobarbital administration renders rats tolerant to and dependent on pentobarbital. Our previous studies show that the tolerance/dependence leads to alterations in $GABA_A$ receptor-related ligand binding as well as changes in the levels of the receptor subunit mRNA. In order to investigate the possible mechanism of these changes, we have studied alterations in cAMP-dependent protein kinase in rats tolerant to and dependent on pentobarbital. Rats received continuous intracerebroventricular infusion of pentobarbital (300 µg/10 µl/h) for six days. [^{3}H]Forskolin binding was carried out in the frozen brain sections of the brain of these rats. Increases in binding were observed in the thalamus, superior and inferior colliculi, hippocampus, substantia nigra, and molecular layer of the cerebellum of pentobarbital-tolerant rats. The regions that showed significant increases in the binding matched the regions in which we have found decrease in α1 and/or γ2 subunit mRNA expression. These results suggest that chronic pentobarbital administration affects cAMP-dependent kinase, and that such an effect might be at least partly responsible for the regulation of expression of $GABA_A$ receptor genes. Moreover, because the direction of the changes in the binding was opposite to those that have been reported in ethanol-tolerant animals, the mechanism through which pentobarbital down-regulates $GABA_A$ receptors might be different from those involved in ethanol tolerance. (supported by NIDA 04480)

814.11

CHANGES IN [^{3}H]PHORBOL DIBUTYRATE BINDING TO PROTEIN KINASE C BY TOLERANCE TO AND DEPENDENCE ON PENTOBARBITAL. S. Oh*, T. Ma and I. K. Ho, Dept. Pharmacol. & Toxicol., University of Mississippi Med. Ctr., Jackson, MS 39216

These studies were designed to examine the effects of chronic administration of pentobarbital on activity of protein kinase C (PKC) in the rat brain by autoradiography. Recently it was noticed that phosphorylation of specific proteins may be involved in the production of various physiological functions, especially in the development of physical dependence, and consensus sites for phosphorylation were found within the large intracellular domains of many $GABA_A$ receptor subunits. It has been found that a number of barbiturates competitively displace diacylglycerol and inhibit PKC acutely (Deshmukh et al., 1989). These results opened up the possibility that the inhibitory effects of barbiturates on PKC are linked to their pharmacological actions. An experimental model of barbiturate tolerance and dependence was developed using i.c.v. infusion of pentobarbital (300 µg/ 10 µl/ hr for 7 days) by osmotic minipumps and abruptly withdrawn from pentobarbital. The levels of [^{3}H]phorbol dibutyrate binding were highly elevated in rats 24-hr after withdrawal from pentobarbital; elevated in the region of cortex, caudate putaman, septum, thalamus, dentate gyrus, and cerebellum but not in hippocampal CA1 and CA3. However it was only slightly elevated in striatum and thalamus of pentobarbital tolerant rats. In the present study, it was shown that the activity of PKC was significantly elevated in pentobarbital withdrawal but not in tolerant rats. These results suggest that the activity of PKC could be modulated by pentobarbital withdrawal in a region specific manner. (Supported by NIDA-04480)

PRESSURE-ENHANCED DELIVERY OF SOLUTES VIA MICRODIALYSIS

P.M. Bungay[1]* and R.A. Gonzales[2] Biomed. Eng. & Instr. Prog., NCRR/NIH[1], Bethesda, MD 20892, and Inst. of Neuroscience, Univ. of Texas[2], Austin, TX 78712

Driving microdialysis perfusate across the probe membrane provides a mechanism for augmenting the rate of delivery of a solute dissolved in the inflowing perfusate. In microdialysis experiments with cellulosic membrane probes implanted in rat striatum, we measured effluent dialysate flow rates, Q_d^{out}, that averaged 14% less than the inflow perfusate pump setting of Q_d^{in} = 2 µl/min. The measured steady-state fractional reduction in perfusate ethanol concentration from inflow to outflow was $E_d = 1 - \left(C_d^{out} / C_d^{in}\right) = 0.22 \pm 0.04$. By contrast, the rate of ethanol delivered to the tissue expressed as a fraction of the calculated rate of ethanol flowing into the probe was $F_d = 1 - \left(Q_d^{out} \cdot C_d^{out}\right) / \left(Q_d^{in} \cdot C_d^{in}\right) = 0.33 \pm 0.08$. Thus, perfusate pressures (estimated to be greater than 1 atm above ambient) appeared to cause ultrafiltration of perfusate across the membrane that elevated the rate of delivery of ethanol to the tissue by about 50% above that resulting from diffusion alone.

With the aid of a mathematical model, we predict that increases in the perfusate ultrafiltration fraction over practicable ranges will produce substantial increases in the rate-based fractional delivery of the solute, F_d, while causing only minor decreases in the concentration-based extraction fraction of the solute, E_d. We envision potential applications for pressure-enhanced delivery of solutes via microdialysis probes, particularly with respect to molecules of the size of neuropeptides and larger. These applications could exploit the currently available membranes of higher fluid permeability and higher molecular weight cutoffs than those of the cellulosic membranes conventionally employed in microdialysis.

DRUGS OF ABUSE: AMPHETAMINE—NEUROTOXICITY

815.1

METHAMPHETAMINE WITH OR WITHOUT 2-DEOXYGLUCOSE DOES NOT CAUSE LOSS OF DOPAMINE NEURONS IN THE SUBSTANTIA NIGRA AS EVALUATED WITH AN UNBIASED STEREOLOGICAL METHOD. P. Chan*, M. Zhao+, D.A. Di Monte and J.W. Langston, A.M. Janson+, Parkinson's Institute, Sunnyvale, CA 94089; + Dept. of Neuroscience, Karolinska Institute, S-17177, Stockholm, Sweden.

Although methamphetamine (METH) has been shown to cause a long-lasting decrease in striatal levels of dopamine, its effect on the dopaminergic cell bodies in the substantia nigra remains controversial. We recently reported that METH-induced decrease in striatal dopamine levels was greatly enhanced by prior administration of 2-deoxyglucose (2-DG), an inhibitor of glucose transportation and utilization. The purpose of the study is to determine whether or not this enhancement of striatal toxicity was accompanied by neuronal loss in the substantia nigra. Six to seven month old Swiss-Webster mice were divided into four groups: (1) saline; (2) METH (10mg/kg i.p. x 4 doses at 2 hrs-intervals); (3) 2-DG; and (4) METH and 2-DG (1mg/kg, i.p. 30 min before each injection of METH). One week later, the animals were given an overdose of sodium phenobarbital and perfused transcardially with physiological saline and 4% paraformaldehyde. Brains were fixed and sectioned systematically throughout the entire substantia nigra. Dopamine neurons were identified by double-staining with tyrosine hydroxylase and cresyl violet and counted with a computer-assisted stereological system. The estimates of the total number of dopamine neurons in the substantia nigra were not different between METH and saline treated animals. Furthermore, 2-DG did not cause a loss of dopamine neurons in the nigra by itself nor in animals treated with METH. These results suggest that METH does not cause a loss of nigral dopamine neurons even in the presence of 2-DG. The relationship between cell counts and biochemical changes (e.g. levels of ATP and dopamine) in the striatum and substantia nigra will also be discussed. This work was supported by the Parkinson's Institute, grants from the Parkinson's Institute Auxiliary Group (PC) and the Swedish Medical Research Council (#10816 for AMJ).

IN VIVO CHANGES IN STRIATAL DOPAMINE RELEASE AND CLEARANCE IN METHAMPHETAMINE TREATED RATS. W. A. Cass* and M. T. Dugan. Department of Anatomy and Neurobiology, University of Kentucky, Lexington, KY 40536.

The repeated administration of methamphetamine (METH) to animals can result in long-lasting decreases in dopamine (DA) levels, tyrosine hydroxylase activity and DA uptake sites in the striatum. However, whether or not these changes lead to functional alterations in the dynamics of DA release and/or uptake has not been extensively examined. The present study used in vivo electrochemistry and microdialysis to examine potassium and amphetamine-evoked release of DA in the striatum and nucleus accumbens (NAc) of METH treated rats. Male Fischer-344 rats were administered METH (5 mg/kg, s.c.) or saline 4 times in one day at 2 hour intervals. One week later the animals were anesthetized with urethane and prepared for in vivo electrochemistry recordings. The METH treatment resulted in dramatic decreases in potassium-evoked release of DA and DA clearance in the striatum, while the NAc was affected to a lesser degree. In vivo microdialysis studies demonstrated significant decreases in basal DA levels and in potassium and amphetamine-evoked overflow of DA in the striatum of METH treated animals. Basal and evoked DA levels in the NAc were not significantly altered. Post-mortem levels of tissue DA were decreased by 41-65% in the striatum and 25-32% in the NAc. These results indicate that the striatum is more sensitive than the NAc to the neurotoxic effects of METH, both in measures of functional dynamics of DA signaling and in tissue levels of DA. It remains to be determined whether these functional changes in DA release and uptake are permanent or tend to recover over time. Supported by the University of Kentucky Medical Center Research Fund.

815.3

EFFECTS OF AGE ON METHAMPHETAMINE-INDUCED DOPAMINE DEPLETION AND RECOVERY. K. B. Burrows* and C. K. Meshul, Depts. of Behav. Neurosci. and Pathology, Oregon Health Sciences University, and VA Medical Center, Portland OR 97201.

Methamphetamine (METH) treatment results in long-lasting depletion of dopamine (DA) in the caudate (CD). Recent evidence suggests that older animals may be more susceptible to the neurotoxic effects of METH (Bowyer *et al.*, 1993). To further explore the hypothesis that METH toxicity is age-dependent, rats of different ages (3, 6, 9, and 12 months old) were treated with 4 doses of 5 mg/kg METH (freebase) repeated at 2 hr intervals. Hyperthermia was monitored by rectal thermometer and animals were killed 1 or 4 weeks after drug administration. Peak body temperature (41.2°C) was not influenced by age, but lethality was greater in older animals (30% of 3 m.o. rats compared to 55% of 6-12 m.o. rats). DA content in the dorsal CD (DCD) was depleted in all animals 1 week after METH administration. At this 1 week time period, older animals (6-12 m.o.) appear to have a greater degree of depletion compared to 3 m.o. rats. Four weeks following METH treatment, DA content in DCD was 80% of control levels in 3 m.o. rats, 70% of control levels in 6 m.o. rats, 35% of control levels in 9 m.o. rats, and 50% of control levels in 12 m.o. rats. This suggests that recovery from METH-induced DA depletion may be influenced by age. There is also an indication that for a given peak body temperature, DA depletion appears to be greater in older animals. Further analysis of METH-induced DA depletion in the ventral CD and NAc is underway. (Supported by Dept. of Veterans Affairs and NIDA training grant 5T32DA07262)

815.4

EFFECTS OF PERIODIC HIGH-DOSE METHAMPHETAMINE (METH) ON DRL 72-s SCHEDULE PERFORMANCE IN RATS. K.E. Sabol*, J.B. Richards, A. Ainsworth, and L.S. Seiden. Dept. Psych., Univ. of Mississippi, University, MS 38677 and Dept. Pharm./Phys. Sci., Univ. of Chicago, Chicago, IL 60637.

High doses of METH deplete the brain's dopamine and serotonin systems. In the present study, rats were treated with 3 METH regimens at 7 week intervals; DRL 72-s schedule performance was evaluated (Gp 1). Each METH regimen consisted of 4 injections of 15mg/kg (salt) at 2 hr intervals. During METH treatment, if core temperature rose above 39.5 degrees C, the animals were cooled until the temperature dropped below 39.5 degrees. Otherwise, the chamber temperature was held at 24 degrees C. A 2nd gp of rats received only 1 METH regimen (Gp 2).

Prior to METH treatment, DRL 72-s training (water reinforcer) began at age 10 weeks. Twelve weeks later, the 1st regimen was administered. Testing resumed 3 weeks after METH, and continued for an additional 3 weeks. Ad lib access to water preceded the next regimen by 1 week. Peak Area (area of the IRT distribution) was significantly decreased after the 1st METH regimen in gps 1 and 2. Peak area recovered after regimens 2 and 3; or, after the equivalent training in Gp 2. Three other measures (response rate, reinforcers earned, and peak location) were not affected by METH treatment. The rats in this study are part of a longer term experiment and monoamines levels are not presently available.

These results suggest the following: when the behavior is evaluated 3-6 weeks post METH, 3 high-dose METH regimens administered at 7 week intervals cause no additional DRL 72-s schedule impairment than is observed with 1 METH regimen. Support: NIDA08588-02.

EFFECTS OF REACTIVE OXYGEN SPECIES ON DOPAMINE TRANSPORTER FUNCTION IN RAT STRIATUM: IMPLICATIONS FOR METHAMPHETAMINE TOXICITY R.R. Metzger*, A.E. Fleckenstein, M.L. Beyeler, J.W. Gibb and G.R. Hanson, Department of Pharmacol. and Toxicol., Univ. of Utah, Salt Lake City. UT 84112.

Methamphetamine (METH)-induced dopaminergic toxicity is purportedly mediated by reactive oxygen species. This hypothesis is supported by findings of the present study that METH administration increased oxygen radical formation in striatal tissue, as assessed by measuring 2-3 dihydroxybenzoic acid formation after coadministration of salicylate with METH. Because of this observation and the finding that repeated METH administration decreases acutely [^{3}H]dopamine uptake into striatal synaptosomes prepared from METH-treated rats, effects of oxygen radicals on dopamine transporter function were investigated. Preincubation of striatal synaptosomes prepared from non-treated rats with the oxygen radical generator, xanthine oxidase, caused a concentration-dependent decrease in synaptosomal [^{3}H]dopamine uptake: an effect blocked by concurrent preincubation with the superoxide radical scavenger, superoxide dismutase. Antioxidants or scavengers of other reactive oxygen species such as catalase, ascorbate, mannitol, histidine and melatonin did not prevent the decrease in [^{3}H]dopamine transport caused by xanthine oxidase. Xanthine oxidase preincubation did not affect striatal synaptosomal lactate dehydrogenase content. Taken together, these data demonstrate that METH can cause the formation of oxygen radicals which, in turn, have the capacity to impair dopamine transporter function. (Supported by USPHS grants DA 00869 and DA 04222)

815.6

AMPHETAMINE INDUCES HYDROXYL RADICAL FORMATION IN THE STRIATUM OF RATS. **N.-K. Huang, S.-H Chaung, H.-Y. Lee*#, C.-S. Tung. Graduate Institute of Life Sciences, #Academia Sinica and National Defense Medical Center, Taipei, Taiwan, ROC**

Evidences suggested that free radicals may be involved in amphetamine (AMPH) analog-induced striatal toxicity, since AMPH analogs induced the formation of 6-hydroxyl-dopamine (OHDA) and antioxidants attenuated AMPH analog-induced neurodegeneration. Furthermore, the neurotoxicity can also be attenuated by DA transporter blockers and DA synthesis inhibitors. Thus, it was concluded that the release of DA is important for the induction of toxicity. On the other hand, the autoxidaton of DA and its consequent generation of free radicals such as hydroxyl radical (·OH) have been reported to occur especially in the iron and oxygen containing rich area, nigrostriatal system. Therefore, because of the etiologic factor of ·OH in neurodegenerations and the possible way of DA autoxidation in the striatum, we planned to study if AMPH can induce the formation of ·OH in the striatum. Male SD rats pretreated with saline or desipramine (10 mg/kg i.p.) and then received AMPH sulfate (10 mg/kg i.p.) were performed in this study. During AMPH treatment, salicylate (5mM/μl/min) dissolved in the Ringer's solution was continuously prefused through the microdialysis probe within the striatum. The contents of perfusate such as DA and dihydroxybenzoic (DHBA) were then collected and monitored by HPLC-ECD. Our results revealed that the amounts of DA and DHBA were both significantly increased in the striatum during AMPH treatment no mater in the groups pretreated with saline or desipramine. Comparing these groups, the release of DA, the amounts of DHBA and even the stereotyped behaviors enhanced more in the desipramine-pretreated group. As a whole, we demonstrated AMPH-induced ·OH formation in the striatum and suggested this formation of ·OH might correlate with the AMPH-induced neurotoxicity. (NSC85-2331-b-016-115 M27)

815.7

ACUTE EFFECTS OF METHAMPHETAMINE ON TRYPTOPHAN HYDROXYLASE ACTIVITY AND OXYGEN RADICAL FORMATION IN RAT BRAIN: ROLE OF HYPERTHERMIA A.E. Fleckenstein*, J.W. Gibb and G.R. Hanson, Department of Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84112

Methamphetamine (METH)-induced decreases in tryptophan hydroxylase (TPH) activity are purportedly effected by reactive oxygen species whose generation might be promoted by the hyperthermia which results from METH administration. This hypothesis is based, in part, on findings that: 1) METH administration increases central oxygen radical formation; 2) TPH is susceptible to oxidative damage *in vitro*; and 3) hyperthermia can promote oxygen radical formation. This hypothesis is supported by findings of this study that prevention of METH-induced hyperthermia in male rats attenuated both increased oxygen radical production and decreased TPH activity 1 h after METH administration. In this study, salicylate was coadministered with METH and the concentration of the metabolite of salicylate, 2-3 dihydroxybenzoic acid, was measured in brain tissue as an index of oxygen radical generation. Neither METH administration nor elevated body temperature alone affected brain salicylate concentrations. These data suggest that hyperthermia contributes to both the oxygen radical generation and the TPH impairment which result from METH administration. However, since prevention of hyperthermia attenuated but did not prevent, METH-induced decreases in TPH activity, factors other than hyperthermia must also be important for effecting METH-induced decreases in TPH activity. (Supported by USPHS grants DA 00869 and 04221)

815.8

ACUTE EFFECTS OF METHAMPHETAMINE ON TRYPTOPHAN HYDROXYLASE ACTIVITY IN RAT BRAIN: ROLE OF 5HT TRANSPORTERS G.R. Hanson, A.E. Fleckenstein, M.L. Beyeler, J.C. Jackson, D.G. Wilkins and J.W. Gibb* Dept. of Pharmacology and Toxicology, and Center for Human Toxicology, University of Utah, Salt Lake City, UT 84112

Methamphetamine (METH)-induced 5-hydroxytryptaminergic neuronal damage purportedly involves transport of newly released dopamine (DA) from extracellular spaces into 5-hydroxytryptaminergic terminals. This hypothesis is based, in part, on past and present findings that: 1) DA is required for, whereas 5HT uptake inhibitors prevent, METH-induced deficits in 5-hydroxytryptaminergic neuronal function; and 2) DA, per se, has an inhibitory effect on the activity of tryptophan hydroxylase (TPH), an indicator of 5-hydroxytryptaminergic neuronal function. This hypothesis is not, however, supported by findings of the present study that 5-hydroxytryptaminergic neuronal damage, induced by p-chloroamphetamine, does not decrease [^{3}H]DA uptake into rat synaptosomes prepared from 5HT-transporter-containing tissue. Moreover, despite having greater affinity for the 5-HT transporter, citalopram has an IC_{50} for [^{3}H]DA transport into these synaptosomal preparations that is greater than that of fluoxetine. These data suggest that 5HT transporters may not facilitate 5-hydroxytryptaminergic neuronal damage by effecting DA uptake. Other mechanisms related to 5HT uptake inhibitor attenuation of METH-induced deficits were investigated. Fluoxetine pretreatment prevented the METH-induced decrease in TPH activity despite permitting hyperthermia and increasing central METH concentrations. The significance of these findings will be discussed. (Supported by USPHS grants DA 00869 and 04221)

815.9

SEROTONIN CONCENTRATION IS REDUCED IN PREFRONTAL CORTEX OF HUMAN METHAMPHETAMINE USERS. J.M. Wilson*, K. Shannak and S.J. Kish. Clarke Institute of Psychiatry, Toronto, Ontario, Canada.

Repeated administration of methamphetamine (MA) produces degeneration of serotonergic neurones in brain of experimental animals. However, the neurotoxic nature of this psychostimulant drug on serotonergic neurones in the human brain remains unclear. Brain material was obtained at autopsy from chronic MA users (n=12, age 33 ± 3 years) who died during drug intoxication, and matched controls (n=9, age 28 ± 4 years). All drug users had a history of MA use and tested positive for MA (negative for all other drugs of abuse) in blood, brain and, where available, hair (n=7) samples. Levels of serotonin (5-HT) and its metabolite, 5-HIAA, were measured using HPLC with electrochemical detection. 5-HT levels were significantly ($p<0.05$) reduced in prefrontal cortex, Brodmann areas 11 (-56%) and 12 (-61%), but were normal in other frontal, occipital, temporal and cingulate cortical regions. 5-HIAA levels were significantly reduced in Brodmann areas 6 (frontal cortex, -45%, $p<0.05$) and 12 (-45%, $p<0.05$), with a non-significant reduction in area 11 (-34%, $p>0.05$). 5-HT and 5-HIAA levels were distinctly normal in all examined subcortical regions: caudate, putamen, nucleus accumbens, hypothalamus and medial olfactory area. The reduced cortical 5-HT levels could reflect a transient depletion of neurotransmitter stores or permanent loss of serotonergic nerve endings; this finding could be related to the preliminary report of reduced 5-HT transporter concentration in Brodmann area 12 of aggressive and impulsive patients (Kuikka, et al., J Nucl Med, Abstract, 1995), two-traits considered to be involved in the pathophysiology of drug abuse. (Supported by US NIDA DA 7182)

EXTRACELLULAR LEVELS OF D-FENFLURAMINE IN THE FRONTAL CORTEX OF RATS P. Clausing*, and J.F. Bowyer, National Center for Toxicological Research/FDA, Jefferson, AR 72079-9502.

In an effort to better characterize the neurochemical and possible neurotoxic effects caused by d-fenfluramine (FEN) and its major metabolite d-norfenfluramine (N-FEN) in the rat, an HPLC method has been developed to quantitate the levels of these two compounds in brain microdialysate. They were separated on a C18 reversed phase column and quantified by fluorescent detection after precolumn derivatization with dansyl chloride and sample cleanup with Macro-Prep 50 Q resin. The minimum quantifiable amounts in microdialysate were 0.05 pmoles/μl for FEN and 0.01 pmoles/μl for N-FEN. Animals implanted with CMA/12 microdialysis probes in the frontal cortex (3.5mm AP, 1.3mm L, 3.6mm V) received 3 doses of FEN sc, spaced two hours apart. Peak levels (pmoles/μl) for FEN in the microdialysate were 0.4 , 0.6, and 0.9 after the first, second and third dose, respectively. Likewise, peak levels (pmoles/μl) for N-FEN were 0.1, 0.25, and 0.35 after the first, second and third dose, respectively. In comparison to earlier studies with d-amphetamine (JPET 274:614-621, 1995) using the same dose and dosing schedule, peak levels of FEN were about the same but occurred at later time points. Studies are under way to correlate the time course of FEN and N-FEN levels with that of serotonin and its metabolite 5-HIAA in the frontal cortex. Supported by Experiment 6903.01 NCTR/FDA. P.C. was supported through an appointment to the Oak Ridge Inst. f. Science & Education.

LONG-TERM EFFECTS OF AMPHETAMINE (AMPH) NEUROTOXICITY ON TYROSINE HYDROXYLASE (TH) mRNA AND IMMUNOREACTIVITY IN AGED RATS. [1]J.F. Bowyer*, [1]P. Clausing, [2]K. Nagamoto and [2]A.W. Tank. [1]Div. of Neurotoxicol., NCTR/FDA, Jefferson, AR 72079-9502, [2]Dept. of Pharmacol., Univ. of Rochester, Rochester, NY 14642.

The long-term effects of 4 doses of 3 mg/kg AMPH i.p. (2 hrs apart, ambient temp.=24°C) that produced pronounced hyperthermia and sustained depletions of striatal dopamine (DA) (20%, 18% and 42% of control at 3 days, 14 days and 4 months, respectively, post AMPH) were examined in 15 month old male rats. Although pronounced DA depletions occurred in striatum, substantia nigra TH mRNA(34±5 attamoles TH mRNA/μg RNA) levels did not significantly differ between control and AMPH treated rats at 3 days, 14 days or 4 months as determined by the ribonuclease protection assay or RtPCR. Although TH immunoreactivity did not reveal a prominent decrease in the number of TH positive cells in the substantia nigra at 4 months post AMPH, changes in the caudate/putamen were present. The number of TH positive axons was decreased with many of the remaining axons having pronounced swelling. Interestingly, in some animals TH immunopositive cells appeared 4 months post AMPH in the dorsal caudate/putamen. Studies are underway to determine if neurotrophic factors are involved in generating TH positive neurons in caudate/putamen and to explain the lack of effect AMPH treatment on TH mRNA in substantia nigra.

MDL 101,002 ATTENUATES DAMAGE TO DOPAMINE NERVE TERMINALS PRODUCED BY INTRASTRIATAL 6-HYDROXYDOPAMINE. P.K. Sonsalla*, L.Y. Moy and D.S. Albers. Dept. of Neurology, UMDNJ-RWJ Med. Sch., Piscataway, NJ 08854.

Previous studies have demonstrated that the neurotoxic effects of methamphetamine (METH) in the rat may be associated with oxidative stress. In mice, we have obtained conflicting data regarding the neuroprotective effects of the nitrone spin-trapping agents, α-phenyl-tert-butylnitrone (PBN, 150-300 mg/kg) or MDL 101,002 (25-100 mg/kg; gift of Hoechst Marion Roussel Research Institute), against METH-induced damage to DA nerve terminals. The purpose of the present study was to determine the ability of MDL 101,002 to protect against damage to striatal DA nerve terminals produced by an intrastriatal infusion of 6-hydroxydopamine (6-OHDA), a compound which is known to generate free radicals. MDL 101,002 (25 mg/kg i.p.) was administered 1 h before, 15 min before and 1 h after the striatal infusion of 6-OHDA (10μg/2μl). In 6-OHDA-treated mice, striatal DA was reduced to 14 ± 13% of control (contralateral striatum as control, 12.6 ± 1.3 μg/g, n = 3). In MDL 101,002/6-OHDA-treated mice, DA was reduced to only 51 ± 11% of control (n = 4, $p<.05$ vs 6-OHDA alone). These data indicate that systemically administered MDL 101,002 can attenuate intracellular toxicity produced by a known free radical generating system. The conflicting data obtained with the spin-trapping agents in the METH-treated animals may indicate that oxidative stress does not play a pivotal role in the toxicity produced by the amphetamines in mice or alternatively, the METH-treated mice may not have been exposed for a sufficient duration of time to the spin-trapping agents. Studies are in progress to determine if larger doses or more frequent dosing of the spin-trapping agents will provide protection. This work was supported by a grant from the National Institute of Drug Abuse (DA06236).

815.13

EFFECTS OF VARIOUS PHARMACOLOGICAL AGENTS IN THE REVERSAL OF METHAMPHETAMINE-INDUCED HYPERTHERMIA IN MICE. R.G.W. Staal*, D.S. Albers and P.K. Sonsalla. UMDNJ-Robert Wood Johnson Medical School, Dept. of Neurology, Piscataway, N.J. 08854

Overdoses with amphetamines in humans can lead to life-threatening complications including hyperthermia. Emergency room treatment for hyperthermia includes administration of drugs such as dantrolene and/or cooling the patient (e.g. ice packs). The purpose of the present study was to determine the efficacy of various drugs in reversing the hyperthermia induced by methamphetamine (METH) in mice, an animal model useful for the study of the hyperthermic effects of the amphetamines. Subcutaneous treatment of mice with METH significantly elevated core temperatures by ≥2°C for >2 hours. At 90 minutes after METH treatment, mice were injected with a drug or placed in an ice bath. The hyperthermic effect was rapidly and significantly reversed by haloperidol (0.5 mg/kg), dizocilpine (0.5 mg/kg) or cooling with ice but not by dilantin (50 mg/kg) or propranolol (10 mg/kg). Although treatment of mice with dantrolene (20-100 mg/kg) or diazepam (20 mg/kg) alone reduced core temperatures by >4°C, neither drug reversed the METH induced hyperthermia. The rapidity with which haloperidol acted suggests that the hyperthermia is mediated centrally by dopamine's actions on its receptors. Furthermore, the lack of effect of dantrolene, which is a useful treatment of neuroleptic malignant syndrome, in reversing the stimulant-induced hyperthermia provides further evidence that it is the central action of the amphetamines which is most critical to the disruption of temperature regulation. This work was supported by a grant from the National Institutes on Drug Abuse.

815.14

DAMAGE TO DOPAMINERGIC NERVE TERMINALS BY METHAMPHETAMINE IS ENHANCED BY CONCURRENT INHIBITION OF Na^+/K^+-ATPase ACTIVITY. D.S. Albers* and P.K. Sonsalla. Dept. of Neurology, UMDNJ-RWJ Med. Sch., Piscataway, NJ 08854.

The administration of methamphetamine (METH) to experimental animals produces damage to nigrostriatal dopaminergic neurons. There is growing evidence that the neurotoxic effects of METH may partially result from perturbations of energy metabolism in dopaminergic neurons. That is, decreased ATP levels in dopaminergic neurons may impair Na^+/K^+-ATPase activity and lead to partial neuronal depolarization and NMDA receptor overactivation. Therefore, the purpose of the present study was to determine if reduced Na^+/K^+-ATPase activity would potentiate the neurotoxic actions of systemically administered METH. Mice received an infusion of saline or ouabain, a specific inhibitor of the Na^+/K^+-ATPase, into the left striatum prior to treatment with METH at doses which produced no significant loss in striatal DA content or TH activity. Ouabain (0.3 or 1.0 nmol), by itself, produced dose-dependent decreases in DA content and TH activity as compared to the contralateral side in animals sacrificed 5-7 days after treatment. However, in combination with METH, more significant reductions in DA content and TH activity were observed in the infused side as compared to the ipsilateral side of mice which received either ouabain or METH alone. Moreover, significant decreases in striatal GABA content were observed only in mice treated with METH and 1.0 nmol ouabain indicating the dopaminergic system is more sensitive to the effects of ouabain/METH. These data suggest that impairment of Na^+/K^+-ATPase activity via METH-induced perturbations of energy metabolism may ultimately contribute to the neurodegenerative effects of METH. This work was supported by a grant from the National Institute of Drug Abuse.

MK-801 PRETREATMENT DOES NOT BLOCK METHAMPHETAMINE-INDUCED STRIATAL DOPAMINE DEPLETION IN THE VERVET MONKEY. W.P. Melega*, M.J. Raleigh, G. Lacan, D.C. Harvey, D.B. Stout, S-C. Huang and M.E. Phelps. Molecular and Medical Pharmacology, UCLA Sch. of Med. Los Angeles, CA 90095

Adult male vervet monkeys (Cercopithecus aethiops sabaeus) were administered methamphetamine (MeAmp) (2 mg/kg, i.m; 2 injections - 4 h apart). This drug protocol effected significant decrements in presynaptic striatal dopamine system function as indexed by biochemical and positron emission tomography (PET) studies. At one and three weeks post-drug, PET studies with 6-[18F]fluoro-L-DOPA (FDOPA) and [11C] WIN 35,428 (WIN) showed that relative to each subject's pre-drug scan, the FDOPA uptake rate constant (Ki) was reduced by 75% while WIN binding (striatum/cerebellum - 1) was reduced by 60-80%. Post-mortem biochemical analysis showed decreases in striatal dopamine levels of ~80% and [3H]WIN binding of 75%. These long term alterations in striatal dopamine levels, aromatic amino acid decarboxylase enzymatic activity and dopamine transporter binding indicate that decrements in endogenous dopamine synthesis capacity and dopamine terminal function were associated with a presumptive "neurotoxic" effect of MeAmp rather than with its pharmacokinetic/acute-pharmacodynamic actions. In the rodent, MK-801 and drug/environment induced hypothermia provide "neuroprotection" from the "neurotoxic" MeAmp effects at the dopamine terminal. However, the vervet monkey appeared to be insensitive to the "neuroprotective" effects of both MK-801 and drug/environment induced hypothermia. Monkeys were pretreated with MK-801 (1 mg/kg; i.m) 30 min prior to the MeAmp protocol.. Concomitantly, a reduction in core temperature (2 - 3.5°C) was observed for 4 - 6 h after MK-801. However, both FDOPA and WIN binding decreases were similar to those observed after MeAmp only. These results suggest that primate and rodent striatal dopamine function may be differentially regulated. Supported by the Dana Foundation and the Department of Energy.

ATTENUATION OF METHAMPHETAMINE-INDUCED NEUROTOXICITY IN VIVO BY INHIBITION OF BRAIN NITRIC OXIDE SYNTHASE. S.F. Ali* and Y. Itzhak[1]. Neurochemistry Laboratory, Division of Neurotoxicology, NCTR, Jefferson, AR 72079 and [1]Department of Biochemistry and Molecular Biology, University of Miami School of Medicine, Miami, FL 33101.

Amphetamine-induced neurotoxicity is associated with depletion of dopamine (DA) and its metabolites, and decreased of DA uptake binding sites in the striatum. The present study was undertaken to determine whether inhibition of the neuronal isoform of nitric oxide synthase (NOS) by 7-nitroindazole (7-NI) protects against methamphetamine (METH)-induced neurotoxicity in vivo. Adult male Swiss-Webster mice were administered (ip) either (I) vehicle/saline, (II) vehicle/METH (10 mg/kg q 2h x 4), (III) 7-NI (25 mg/kg q 2h x 4) 30 min before METH or 7-NI (25 mg/kg q 2h x 4) 30 min before saline. Animals were sacrificed 24 h after the last injection and the striatum was dissected for biochemical analysis. In the vehicle/METH group, DA levels determined by HPLC were reduced to 60-80% of controls. The number of DA uptake binding sites labeled by [^{3}H]-mazindol was reduced to 40 % of control. In the 7-NI/METH group DA levels were 30-35% lower than controls, while the number of DA uptake binding sites was only 10% lower than the control values. 7-NI alone had no effect on either DA levels or [^{3}H]-mazindol binding. Since 7-NI is considered a relatively selective inhibitor of the neuronal NOS isoform, the present study suggests that blockade of brain NOS provides protection against METH-induced neurotoxicity. Supported in part by R55DA08584 from NIDA.

DELTA OPIOID PEPTIDE [D-ALA^2, D-LEU^5]-ENKEPHALIN (DADLE) ATTENUATES METHAMPHETAMINE (METH)-INDUCED NEUROTOXIC DAMAGE TO DOPAMINERGIC NEURONS IN MICE. L-I Tsao*, B. Ladenheim, J. L. Cadet and T.-P. Su. Molecular Neuropsychiatry Section, Neuroscience Branch, Division of Intramural Research, National Institute on Drug Abuse, NIH, Baltimore, MD 21224.

Previous studies have demonstrated certain novel actions of the *delta* opioid peptide DADLE. For example, DADLE can induce hibernation in summer-active ground squirrels (Oeltgen *et al.*, *Life Sci.* 43:1565, 1988) and prolongs tissue survival time in an organ preservation preparation (Chien *et al.*, *J. Thorac. Cardiovasc. Surg.* 107:964, 1994). Although the exact mechanism(s) underlying these effects of DADLE remains to be elucidated, these studies apparently demonstrated a tissue-protective property of DADLE. In this study, we were interested in testing if DADLE might have a protective effect against METH-induced neurotoxic damage to dopaminergic (DA) terminals in mice. Male CD1 mice (8 wk old; n = 5) were given an *i.p.* injection of 5 mg/kg of METH every 2 hr for four injections. Test animals (n = 5 per group) received, *in lieu* of saline, 1 mg/kg, 2 mg/kg, 4 mg/kg of DADLE (*i.p.*) 30 min before each METH injection. Animals were sacrificed 14 days later. Brains were quickly removed, frozen, cut into 20 μm coronal sections, and processed for *in vitro* quantitative autoradiography using a DA uptake site marker [^{125}I]RTI-121 with nonspecific binding defined by 1 μM GBR 12909. METH caused about a 50% and a 25% reduction of DA uptake sites in the striatum and in the nucleus accumbens, respectively. These deleterious effects of the drug were dose-dependently attenuated by DADLE. DADLE at 4 mg/kg completely blocked the effects of METH. The mechanism by which DADLE protects against METH-induced neurotoxicity is being investigated.

REPEATED STRESS AND METHAMPHETAMINE NEUROTOXICITY. S. Novotney and B. K. Yamamoto*. Dept. of Psychiatry, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

Methamphetamine (METH) and acute restraint stress increase extracellular dopamine (DA and glutamate (GLU). Pre-exposure to repeated stress augments the behavioral and biochemical responses to an acute psychostimulant challenge. The present study examined whether prior exposure to repeated restraint stress augments the acute changes in extracellular DA and GLU produced by challenges with high doses of METH and its subsequent long term depletion of DA and 5HT. Male rats were subjected to daily 1 hr periods of restraint stress for 7 consecutive days. After a 2 wk withdrawal from restraint stress, rats were injected with 4 doses of METH or saline, each injection given 2 hr apart. In some rats, changes in extracellular DA and GLU in striatum (STR) and prefrontal cortex (PFC) were measured by microdialysis. All rats were sacrificed 7 days later and DA and 5HT tissue content were assayed.

Prior restraint stress attenuated METH-induced increases in extracellular DA in STR but not in PFC. There were no differences between stressed and non-stressed rats with respect to METH-induced increases in extracellular GLU. In rats previously exposed to restraint stress, the long-term depletions in the content of DA and 5HT in STR were attenuated by 65% and 97%, respectively. The attenuations in DA release and the subsequent depletions of tissue DA and 5HT are probably not due to the altered bioavailability of METH since the extracellular concentrations of METH in STR of stressed and non-stressed rats were not different during and after METH. These results indicate that pre-exposure to stress produces tolerance and not a sensitization to the pharmacological and toxicological effects of METH. Supported by DA07606

INDUCTION OF Bcl_{xS} AND Bcl_{xL} BY METHAMPHETAMINE IN IMMORTALIZED NEURAL CELLS. M. T. McCoy* and J. L. Cadet, Molecular Neuropsychiatry Section, NIH/NIDA, IRP, Baltimore, MD 21224.

Methamphetamine (METH) is a drug of abuse that destroys monoaminergic terminals in vivo and causes cell death in vitro. We have shown recently that the cell death caused by METH occurs through the production of oxygen-based radicals and is apoptotic. Moreover, METH-induced cell death is attenuated by the over expression of the proto-oncogene antioxidant Bcl_2. It was just of interest to assess the effects of the drug on the expression of cell death related genes in vitro. A cell line immortalized from rat mesencephalon was used in this study. We thus assessed the effects of METH on the expression of Bcl_{xS} (pro-death), Bcl_{xL} (anti-death), and of the immediate early gene, c-fos and zif-268. Exposure of the cells to METH caused increases in zif-268, Bcl_{xS}, and Bcl_{xL}, but no observable changes in c-fos. The changes in zif-268 occur by 60 min of exposure and returned to normal by 120 minutes. The changes in Bcl_{xS} and Bcl_{xL} were much more delayed, appearing at 180 minutes and staying elevated up to 300 minutes.

These results suggest that METH-induced cell death might occur through the activation of cell-death related genes. The effects of manipulation that protect against METH-induced cell death will be presented.

815.20

MULTIDRUG RESISTANT (mdrla) KNOCKOUT MICE ARE DIFFERENTIALLY AFFECTED BY METHAMPHETAMINE (METH) AND METHYLENEDIOXY-METHAMPHETAMINE (MDMA). H. Mann , H. Hirata, B. Ladenheim, T.H. Moran# and J.L. Cadet* Molecular Neuropsychiatry Section, DIR, NIH/NIDA IRP, Baltimore, MD 21224, #Department of Psychiatry and Behavioral Sciences, JHU, School of Medicine, Baltimore, MD 21205

Cellular resistance to drugs with different chemical structures and mechanisms of action is caused by phosphoglycoproteins (Pgps) which are encoded by multidrug resistant genes. We have used mdrla knockout mice, which do not have detectable P-glycoprotein in the blood brain barrier in order to test the role of this protein in the entry of amphetamine analogs in the brain. The toxic effects of METH (2.5, 5 and 10 mg/kg) and MDMA (5,10 and 20 mg/kg) on dopaminergic systems were thus assessed in the striatum and nucleus accumbens of both wild-type and knockout mice using autoradiography and HPLC methods. The lowest doses of METH (2.5 mg/kg) caused only small changes in the wild-type mice, but marked decreases in the mdrla knockouts. The two higher doses (5 mg/kg and 10 mg/kg) caused similar changes in both strains of mice. Unlike METH, all the doses of MDMA caused similar changes in the dopamine systems of both wild-type and knockout mice. These results suggest that METH and MDMA are handled differentially by P-glycoproteins and document a role for these proteins in the uptake of METH into the brain via the blood brain barrier.

CONTINUOUSLY GROWING NEURONAL CELL LINES DERIVED FROM NORMAL AND TRISOMY 16 FETAL MICE, AN ANIMAL MODEL FOR HUMAN DOWN SYNDROME. P. Caviedes*[1,3], N. Araya[1], X. Rocca[1], S. Berríos[2], R. Fernández - Donoso[2], S. Rapoport[4] and R. Caviedes[1]. [1]Dept. Physiol. & Biophys. and [2]Dept. of Biol. & Genet., Fac. Medicine, Univ. of Chile, Casilla 70005, Santiago, Chile; [3]Centro de Estudios Científicos de Stgo.; and [4]LNS/NIA/NIH, Bethesda, MD 20892.

Cell lines derived from cerebral cortex (CC), spinal cord and dorsal root ganglia were established from normal and trisomy 16 fetal mice. Another line derived from the hippocampus of a normal fetus. Primary cultures were established from tissues carefully dissected under a microscope, plated in plastic culture dishes and fed medium consisting of DMEM/Ham-F_{12} (1:1) supplemented with 10% adult bovine serum, 2.5% fetal bovine serum, and 10% media conditioned by the rat thyroid cell line, UCHT1, procedure which reportedly induces transformation *in vitro*. After 6 - 8 months, transformation foci become evident in the cultures. The cell lines so established present doubling times of 12 - 14 hrs, plating efficiencies of 30 - 50%, saturation densities of 12 - 20 x 10^3 cells/mm^2, and have undergone at least 10 passages. Karyotype analysis of one CC trisomy 16 cell line (CTh1) showed the presence of two metacentric chromosomes (Robertsonian translocations 11.16 and 16.17), which confirmed the trisomic condition. The chromosome mode was 2n=43, and the presence of 1 - 2 microchromosomes was evident. Less than 10% of the cells presented a tetraploid karyotype. Immunohistochemical staining for neuron specific enolase was positive, while glial markers GFAP and S100 were negative, suggesting a neuronal origin. The cell lines established in our laboratory could represent interesting and accessible *in vitro* models to study the neurobiology of Down syndrome and Alzheimer's disease.

TRISOMY 16 MICE DEMONSTRATE DIFFERENCES IN METABOLITE AND PHOSPHOLIPID LEVELS RELATIVE TO THEIR EUPLOID LITTERMATES. F.S. Yao[3], M.T. Caserta[1], M.A. Segraves[3*], A.M. Wyrwicz[2]. [1]Dept. Psych., Northwestern Univ. Med. Sch., Chicago, IL 60611 and [2]Ctr. for M.R. Rsrch., Evanston Hosp., and [3]Northwestern Univ. Inst. for Neuroscience, Evanston, IL 60201

Murine trisomy 16 (ts16) is a genetic and developmental model for human trisomy 21 (Down Syndrome) and Alzheimer's Disease (AD). In humans, triplication of chromosome 21, on which the Alzheimer Precursor Protein (APP) is located, results in the pathological hallmarks of AD that include intracellular neurofibrillary tangles and extracellular amyloid plaques. Triplication of murine chromosome 16 produces an animal that also shows neuronal abnormalities characteristic of AD including dysregulation of somatostatin and NPY neuronal expression and differentiation.

Analysis of brain tissue from AD patients shows decreases in membrane phospholipid components as well as other metabolites. To determine if there are changes in membrane phospholipid components between ts16 fetal brain and their euploid controls, the brains from 15-day-old fetal ts 16 mice were removed, homogenized, and extracted with a 2:1 chloroform-methanol solution. Euploid littermates served as a control. The phases were separated and washed so that the organic phase, consisting of various phospholipid membrane components, was prepared for analysis using ^{31}P NMR spectroscopy on a Bruker 400 MHz spectrometer. The aqueous phase, consisting of various metabolites, was prepared for analysis using ^{1}H spectroscopy on a GE 500 MHz spectrometer.

Phosphorus NMR results show that levels of phosphatidylserine and phophatidylcholine are lower in ts 16 mice. Furthermore, proton NMR results show a trend towards decreased levels of taurine, choline, and creatine in ts 16 mice relative to their controls. These preliminary results suggest that there are membrane phospholipid differences in trisomy 16 mouse brain which may underlie the delayed development of trisomic neurons in culture and lead to possible early neuronal death or increased susceptibility to Alzheimer's associated pathology. DEVELOPMENTAL ABNORMALITIES AND ACCELERATED BRAIN AGING IN A MOUSE MODEL OF DOWN SYNDROME. J. Chua-Couzens 1, J. Kilbridge 1, D.M. Holtzman 2, Y. Sun 2, D. Santucci 1, C.J. Epstein 1, W.C. Mobley 1*. 1 *University of California, San Francisco, Depts. of Neurology & Pediatrics, San Francisco, CA 94143.* 2 *Washington University, Dept. of Neurology & Center for Study of Nervous System Injury, St. Louis, MO 63110.*

All humans with Down syndrome (DS) or trisomy 21 develop the neuropathology of Alzheimer disease (AD). To study the pathogenesis of CNS abnormalities in both DS and AD, we have analyzed a new genetic model of DS, the partial trisomy 16 (Ts65Dn) mouse. Ts65Dn mice have an extra copy of the distal aspect of mouse chromosome 16 which is homologous to the region on human chromosome 21 just centromeric to APP to a region just telomeric to ETS-2. We have found that these animals demonstrate abnormal behavior during post-natal development and in the adult period. Though the size of many brain regions are normal, Ts65Dn mice have evidence of astrocytic hypertrophy and increased glial gene expression. The septohippocampal cholinergic system which is severely affected in both DS and AD developed normally in Ts65Dn mice but showed evidence of accelerated neuronal loss during aging. These findings suggest that Ts65Dn mice may be a useful model to study the pathogenesis of neurodegeneration in DS and AD.

A CHROMOSOME 19 INVERSION MAY BE THE CAUSE OF DEAFNESS IN MICE. M. DeAngelis , S. Premkumar, N. Nouri, D. Kass, A. Rao, M. Batzer, R.P. Bobbin*, P. Deininger, B.J. Keats. Louisiana State University Medical Center, New Orleans, Louisiana, U.S.A.

The deafness locus (dn) has been mapped to mouse chromosome 19 by linkage analysis in intersubspecific backcross offspring using Mus musculus molossinus (Keats et al., Mammalian Genome 6:8-10, 1995). The deafness gene is autosomally recessive and homozygotes never hear, although there are no other apparent physical or behavioral anomalies. By 10 days of birth, the organ of Corti, stria vascularis, and, occasionally, the saccular macula, are markedly degenerated. Backcross offspring (236) were phenotyped by recording auditory brainstem responses (ABRs). Genotypes of DNA microsatellite markers on chromosome 19 showed no recombination with D19Mit14, D19Mit60, and D19Mit41, while 7 were observed with D19Mit 28 and 6 with D19Mit96, the closest flanking markers. An independent genetic map of this region suggested that the order and recombination fractions are D19Mit28-(0.2) D19Mit41-(.01) D19Mit60-(.03) D19Mit14/ D19Mit96. The lack of recombination between dn and three markers which are about 4 map units apart is consistent with the presence of an inversion that may be several megabases long on the chromosome with the mutant allele. Moreover, a 500 kb YAC is positive for both D19Mit14 and D19Mit96. The inversion may have caused the mutation in the curly-tail stock, although the it could be present in both the chromosome with the mutant allele and that with the normal allele. However, this is unlikely because, within the inversion, the allele size in the normal chromosomes is different from the mutant. Our present data suggest that an inversion causing the mutant allele arose in the curly-tail mice before maintenance of the inbred stock began. The YAC and BAC clones together with our cDNA libraries from the cochlea of both hearing and deaf mice provide essential resources to isolate the deafness gene. **PHS DC00379**

INCREASED AGGRESSION BUT NOT SELF INJURIOUS BEHAVIOR IN HYPOXANTHINE PHOSPHORIBOSYL-TRANSFERASE DEFICIENT MICE TREATED WITH AN ADENINE PHOSPHORIBOSYLTRANSFERASE INHIBITOR. A. Bosch, J.L. Pemberton, T.J. Plumb and B.L. Davidson*. Department of Internal Medicine, University of Iowa, Iowa City, IA.

Lesch-Nyhan syndrome (LNS) is a severe genetic disease characterized by hyperuricemia, mental retardation, choreoathetosis and a compulsion to self-mutilate. LNS is caused by deficiency of hypoxanthine phosphoribosyltransferase (HPRT), an enzyme critical in purine salvage. HPRT deficient mice, however, do not show the self injurious behavior (SIB) seen in humans probably due to the ability of murine adenine phosphoribosyltransferase (APRT) to salvage adenine and maintain purine pools.

We have treated HPRT deficient mice from birth with 9-ethyladenine (9-EA), an APRT inhibitor. After one year of treatment, analysis of the brains of these mice shows that caudate adenine pools are depleted between 25 to 40% and behavioral tests demonstrate increased aggression in 75% of the treated male mice. None of them has developed the SIB reported by another laboratory. Normal mice with the same background and treated with 9EA for the same period of time do not show any changes in behavior or nucleotide pools.

Studies to correlate aggression and purine pools, with neurotransmitter levels may give us insights into the pathophysiology of LNS. Gene transfer to CNS using an adenovirus coding for the rat HPRT gene may ameliorate the acquired behavioral disorder and altered purine pools.

DIFFERENTIAL EXPRESSION OF CA^{2+}/CALMODULIN-DEPENDENT PROTEIN KINASE II AND TRANSCRIPTION FACTORS IN THE ACCUMBAL CORE AND SHELL OF AN ANIMAL MODEL OF ATTENTION-DEFICIT HYPERACTIVITY DISORDER.
M.Papa*, T.Sagvolden[2], J.A.Sergeant[3], and A.G.Sadile[1]. [1]Lab. Neurophysiol. Behav. & Neural Networks, and Inst. Human Anat., SUN, Naples, I; [2]Dept. Neurophysiol., Univ. Oslo, N; [3]Inst. Clin.Psychol., UVA, Amsterdam, NL.

The Spontaneously Hypertensive Rat (SHR) is a suitable model for studying some aspects of Attention-Deficit Hyperactivity Disorder (ADHD) in children. This project aims at investigating the neural substrates of ADHD in this genetic model by using Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and transcription regulators such as immediate-early genes (IEGs) as markers. The nucleus accumbens complex (ACB), which is thought to be an interface between motivational and motor systems, is our site of interest. Six-wk old male SHR and Wistar-Kyoto (WKY) control rats were used. The brains were perfused and processed for CaMKII or a member of the *FOS*, *JUN-B* and *ZIF-268* families using immunocytochemistry. CaMKII: (i) in both groups there was a higher level of positive elements in the shell than in the core of the ACB, and (ii) a lower level of positive elements in the shell of the ACB in SHR than in WKY rats. IEGs: in the shell of the ACB there was a lower expression of peptide products of the *FOS* family (*c-FOS*, in particular) and *zif-268*. In addition, SHR demonstrated a lower expression of *c-FOS* and *zif-268* in the core of the ACB than WKY rats. In contrast, there was an increased basal level of *JUN-B* in the core of the ACB of SHR. The differential basal expression of CaMKII and IEGs in the ACB pole, core and shell of SHR correlates with a lower dopamine release, a higher number of D-1/D-5 dopamine receptor binding sites, and eventually to a higher number of "standing-by" medium spiny GABAergic neurons in the SHR. Thus, transcription regulation could be set at a lower level in the ACB of the SHR, and this in turn might be crucial to the understanding of some aspects of ADHD in children. **(Supported by EC grant ERBCHRXCT930303).**

STIMULANT-RESPONDERS AND STIMULANT NON-RESPONDERS IN AN ANIMAL MODEL OF ATTENTION-DEFICIT HYPERACTIVITY DISORDER.

R.Aspide , U.A.Gironi Carnevale, T.Sagvolden[1], J.A.Sergeant[2], and A.G. Sadile (SPONSORED BY THE EUROPEAN BRAIN AND BEHAVIOR SOCIETY). Lab. Neurophysiol. Behav. & Neural Networks, SUN, Naples, I; [1]Dept. Neurophysiol., Univ. Oslo, N; [2]Inst. Clin. Psychol., Univ. Amsterdam, Amsterdam, NL.

The frequency and duration of two theta-related activity components in a novelty situation have been monitored to index attention at low motivational levels in an animal model of Attention-Deficit Hyperactivity Disorder (ADHD), the Spontaneously Hypertensive Rat (SHR). Six-wk old male SHR and Wistar-Kyoto control rats were given the DA re-uptake blocker methylphenidate (MP; 3 mg/kg, i.p.), or vehicle, daily during a 15-day period. Twenty-four hours after the last injection, rats were exposed to a spatial novelty (a Làt-maze) for three 10-min periods separated by a 24-h interval. The behavior was monitored by a CCD videocamera and stored for off-line analysis of frequency of corner-crossings and rearings on hindlimbs, and duration of rearing episodes per 30-sec blocks. Vehicle-treated SHR showed rearing episodes of shorter duration which were not modified by time of testing neither within-trial nor across-trial, as compared to WKY rats. In contrast, MP-treated SHR increased the average duration of rearing episodes over time. However, SHR showed a dichotomy with two subpopulations, one of which increased (stimulant responders) and the other decreased (stimulant non-responders) the duration of rearing episodes. Since SHR appear also to model stimulant-responders and non-responders in humans, they might be used also to test drugs for specific aspects of ADHD in children. **(Supported by EC grant ERBCHRXCT930303).**

DEVELOPMENT OF ADENOVIRUS VECTORS FOR USE WITHIN THE CNS WHICH ELICIT MINIMAL IMMUNE RESPONSES.

G.H. Clayton♦*, J. Schaack#, K.J. Staley♦, C.L. Wilcox+, R.L. Smith♦

(♦Depts. of Neurology and Pediatrics, and the #Dept. of Microbiology, Univ. of Colo. Health Sci. Center, Denver, Colorado; +Dept. of Microbiology, Colo. State Univ., Fort Collins, Colorado)

The use of adenovirus has become prevalent in the neuroscience community for use as an investigative tool and putative gene therapy vector in the central nervous system (CNS). While many reports suggest that adenovirus will have great utility in both areas the pathology associated with adenovirus infection has been insufficiently described and attempts to redesign adenovirus vectors to minimize pathogenic responses have to date been only mildly successful. In order for adenovirus to become a successful tool and/or long term therapy delivery agent an attempt must be made to understand the mechanisms by which the CNS responds to infection and what elements of the viral genome, and therefore its physiology, are responsible for inducing these responses. Here we describe in-vivo and ex-vivo experiments designed to discover the mechanisms behind cell death associated with adenovirus infection. Although the CNS is considered to be isolated to some degree with respect to immune responses, neuronal death associated with adenovirus infection occurs very early (≤ 24 hrs post infection in-vivo). The early destruction of neurons suggests that non-specific cytokine mediated early responses rather than targeted CTL or antigen-antibody mediated immunity is involved. In these experiments the effects that different promoter elements, adenoviral genome deletions, and acute non-dissociated slice culture have on the efficiency and stability of expression of marker proteins are evaluated as well as the extent of neuronal cell death associated with each. *[Supported by NS01741, Epilepsy Found. of America and CU-Cancer Center*

CYCLOSPORIN TREATMENT ATTENUATES THE CNS IMMUNE RESPONSE FOLLOWING TRANSFECTION OF HYPOTHALAMIC NEURONES WITH ADENOVIRUS. B.J. Geddes*, T.C. Harding, D. Hughes, S.L. Lightman, A. Byrnes and J.B. Uney. Dept. of Medicine Laboratories, Univ. of Bristol, Bristol UK, BS2 8HW.

A number of investigators have shown that post-mitotic neuronal cells can be transfected with very high efficiency using adenoviral (Ad) vectors and have therefore suggested that Ad may be used as gene therapy agents in the CNS. However, studies on peripheral tissues have shown that administration of Ad elicits an inflammatory response which could interfere with the therapeutic effects of the gene therapy. In this study we have therefore assessed the immune response generated following the stereotaxic injection of Ad (expressing β-gal) into the CNS and investigated the ability of the immunosuppressive agent cyclosporin to attenuate this response.

β-gal expression was observed 1, 2, 5, 7, 14, 21, 28 and 56 days after unilateral Ad injection into the rat paraventricular nucleus (PVN). Immunohistochemical analysis of cryostat sections through the PVN showed a biphasic immune response to adenovirus injection. T-cells and macrophages could be seen to infiltrate the injection region within one day of treatment. In the second phase of the response, which peaks approximately 7-10 days after Ad treatment, activated cytotoxic T-cells were recruited to the area. However, in rats treated systemically with cyclosporin, beginning 2 days prior to and continuing daily for 7 days subsequent to Ad injection, the presence of all immune markers tested [day 7] was substantially attenuated. Therefore, cyclosporin treatment may provide a means of attenuating the immune response stimulated by delivery of Ad vectors to the CNS. Based on this data our lab is conducting further experiments using adenoviral vectors in both gene therapeutic and basic neuroendocronological investigations of the rat hypothalamus.

TREATMENT OF SANDHOFF DISEASE MICE BY BONE MARROW TRANSPLANTATION. F.N. Norflus[1]*, C.J. Tifft[2], M.P. McDonald[3], J.N. Crawley[3], K. Suzuki[4], and R.L. Proia[1]. [1]GBB, NIDDK, NIH, Bethesda, MD 20892; [2]Department of Medical Genetics, Children's National Medical Center, Washington, D.C. 20010; [3]ETB, NIMH; NIH, Bethesda, MD 20892; [4]Department of Pathology, The University of North Carolina, Chapel Hill, NC 27599.

A mouse model for the lysosomal storage disorder, Sandhoff disease, has been constructed (*Nature Genetics* 11: 170-176, 1995). These mice lack β-hexosaminidase A and B activity and accumulate G_{M2} and G_{A2} ganglioside in the central nervous system (CNS). Motor deficits develop at about 3-1/2 months and death ensues between 4-5 months of age from severe neurologic disease. Bone marrow transplantation (BMT) as a treatment for lysosomal storage disorders remains controversial, especially for those with CNS involvement. BMT was evaluated as a treatment of the Sandhoff disease model mice. 129/Sv *Hexb* -/- mice (9-16 days of age) were irradiated and transplanted the following day with bone marrow cells from wild type 129/Sv mice. This procedure resulted in transplanted mice that had serum hexosaminidase activities increased to approximately one-third of the wild type level. The transplanted mice had decreased excretion of urinary oligosaccharides as compared to their untransplanted littermates. Significantly, the life span of the transplanted mice has been increased to at least 7 months suggesting that functional enzyme was introduced into the CNS. (supported in part by U.S.P.H.S. grants NS-24453 and HD-03110)

MAPPING MURINE LOCI FOR SEIZURE RESPONSE TO PENTYLENETETRAZOLE. T.N. Ferraro, G.T. Golden, G.S. Smith, C. Ballas, N. Mulholland, H. Choi, T.A. Hare*, W.H. Berrettini. Thomas Jefferson University, Philadelphia, PA and DVAMC, Coatesville, PA.

DBA/6J (D2) and C57BL/6J (B6) mice exhibit differential sensitivity to seizures induced by various chemical and physical methods with D2 mice being relatively sensitive and B6 mice relatively resistant. Mature D2, B6, B6D2F1/J (F1) and F2 intercross mice were used to investigate behavioral seizure responses to pentylenetetrazole (PTZ) and to map genetic loci influencing strain differences. Mice were injected with PTZ (60, 70, 80 or 90 mg/kg, ip) and observed for 1 hour. Seizure parameters included latencies to focal clonus, generalized clonus and tonic hindlimb extension (THE). Dose-response experiments showed that D2 mice have significantly shorter latencies to both the first partial and generalized seizure. Also, significantly more D2 mice exhibited THE. Sensitivity of F1 mice was intermediate between the parental strains. F2 mice (n = 511) exhibited a wide range of latencies with two-thirds of the group expressing THE. There were no gender effects noted in parental or F2 mice and the response to PTZ was 70% heritable. Mapping data derived from contingency analysis of allele distributions and the presence/absence of THE documented a locus of significant influence on chromosome 1 ($p < 10^{-8}$) near marker D1Mit30. We also detected this locus in a previous seizure study of D2 and B6 mice where F2 offspring were tested with kainic acid. It is likely that this locus represents a gene(s) of general importance in mediating the difference in seizure sensitivity between D2 and B6 mice. This work was supported by NINDS grant RO1-NS33243.

ANOXIA RESISTANCE IN *DROSOPHILA MELANOGASTER*: GENE REGULATION AS MOLECULAR BASIS. E. Ma, and G.G. Haddad*, Department of Pediatrics, Section of Respiratory Medicine, Yale University School of Medicine, New Haven, CT 06520

Previous studies from our laboratory have demonstrated that *Drosophila melanogaster* is very resistant to anoxia. These fruitflies can recover fully even after 4 hours of a complete anoxia. Our data have also indicated that certain genes such as heat shock protein 70 were up-regulated by this stress. To understand the cellular and molecular basis of the tolerance to anoxia, we utilized differential display and molecular techniques to determine the differentially expressed genes during anoxia (1 or 4 hours). Several mRNAs were differentially expressed and one of them was very highly up-regulated (termed *Fau*). Our results from Northern blotting and sequencing analysis further indicated that a cDNA for this highly expressed mRNA is 987 base-long with an open reading frame of 390 bases. Computer-aided analysis indicated that this cDNA contained 7 ATTT motifs at its 3'-untranslated region and its deduced amino acid sequence contained three 5-amino acids-long motifs of heterogeneous ribonucleoprotein. *In situ* hybridization of fly head sections (10 μm) showed that the mRNA was located in the neurons of the lamina and cortex. Co-transfection of this cDNA with a marker (Flag) sequence into CHO cell line showed that the protein from this mRNA was located in the nucleus. We conclude that: a) anoxia differentially regulates the expression of genes; and b) *Fau* is a gene that may participate or contribute to anoxia tolerance in the *Drosophila melanogaster*. (Supported by NIH grants PO-HD 32573, P20-NS 32578 and T32-HL 07778).

PLAQUE FORMATION AND ßA4 IMMUNOREACTIVITY IN RAT BRAIN TRANSPLANTS EXPOSED TO HUMAN APP, T.A. Bayer*, S. Weggen, C. Czech, N. Ida, K. Beyreuther and O.D. Wiestler Institute for Neuropathology, Medical Center Bonn, Sigmund-Freud-Strasse 25, 53105 Bonn and ZMBH, Im Neuenheimer Feld 282, 69120 Heidelberg, FRG.

We have established an *in vivo* model of ß-amyloid precrusor protein (APP)-associated pathology in a transplantation based model. Recombinant retroviral vectors harboring normal and mutant (670/671 double mutation) cDNAs for human APP were introduced into fetal rat brain transplants. At six months post-transplantation, grafts exposed to human APP695 developed neuropil deposits with morphological features of neuritic plaques. The plaques strongly immunoreacted with antibodies against ubiquitin, ApoE and human APP, but showed no evidence for ß-amyloid. No difference was observed between wild-type and mutant APP695. However using two antibodies to ßA4 peptide, we were able to observe modest ßA4 staining in the plaques. More evidently ßA4 immunoreactivity was detected in recombinant neurons within the grafts. The number of ßA4 positive neurons increased within the first six months. Preliminary observations suggest that ßA4 formation occurs predominantly in those transplants harboring mutant APP695. We are currently analysing transplants exposed to APP770.

GENETIC ASSAY FOR MULTIMERIZATION OF WILD-TYPE AND MUTANT TRANSTHYRETIN. J. Herbert*, X. Chen, S-D. Yan and J. Fu Department of Neurology, New York University Medical Center, New York, NY 10016.

TTR is a tetrameric plasma transport protein. The most common form of familial amyloid polyneuropathy (FAP) is caused by TTR Met30 mutation. However, the mechanisms for TTR-amyloid fibril formation are still poorly understood. Recent biochemical studies suggest that Met30 mutation reduces stability of the TTR tetramer. We established a genetic assay based on the two-hybrid system to study TTR intermolecular interactions. Two functional domains of the *GAL4* transcriptional activator were cloned into two different expression vectors. TTR monomeric sequences were fused with either of these two domains and co-expressed in yeast. Expression of the *lacZ* gene is an indicator of the TTR-TTR interaction. An intense intermolecular binding between wild-type TTR monomers was detected in the yeast. When one of the normal TTR was replaced with Met30 mutant TTR, the binding strength was reduced by more than 57%. When both fusion proteins contained Met30 mutant, the binding strength was reduced by 84%. This result suggests that the presence of Met30 mutation markedly reduces TTR multimerization in this two-hybrid system. Accumulation of a monomeric intermediate resulting from this diminished multimerization may be a prerequisite for TTR-amyloid fibrillogenesis.

THE HEREDITABILITY OF LATENT INHIBITION: TOWARDS AN ANIMAL BEHAVIORAL MODEL OF SCHIZOPHRENIA. R.E. Gross, T.D. Ely, P.D. Lambert, and C.D. Kilts Department of Psychiatry and Behavioral Sciences, Emory Univ. Sch. of Med., Atlanta, GA 30322

Latent Inhibition (LI) paradigms assess the influence of experience on stimulus salience, a key psychophysiological construct of schizophrenia. We have applied selection pressure to LI to develop an animal behavioral model of the defect cognitive state of schizophrenia. Selective breeding was initiated using a genetically heterogeneous foundation stock of rats (N/Nih). The derived S_0 demonstrated marked interindividual variability in the conditioned suppression of drinking behavior and the effect of stimulus (house light) preexposures (PE) on response suppression. A standardized off-baseline LI paradigm (ie., 25 PE, 4 CS-US pairings) was used to assess the response of LI to bidirectional selection (closed matings without common grandparents). Rats exhibiting a negligible vs. maximal effect of PE on conditioned suppression to the CS were chosen as progenitors of the Low vs. High lines, respectively. Divergence between selected lines was observed by the S_4, suggesting a high hereditability of LI. PE-induced LI of conditioned suppression in the S_6 for the Low line was less than half that seen in the High line; intermediate, stable LI effects were seen for the randomly selected Control line. Compared to the High line, the Low line in the S_5 also exhibited a diminished acoustic startle response and prepulse inhibition of startle. Behavioral genetic techniques thus can be used to generate animal behavioral models of stimulus filtering deficits common to schizophrenia, without presumption of their neuroanatomical or neurochemical bases.

SEX DIFFERENCES: DISTINGUISHING BETWEEN GENOTYPE AND PHENOTYPE. **A.J. Seaman and V. H. Denenberg*. Biobehavioral Sciences Graduate Degree Program, University of Connectucut, Storrs, CT 06226.**

The *Mus domesticus poschiavinus* Y-chromosome has been transferred onto the C57Bl/6J genome. Female offspring are either XX or XY genotypes, and XY male offspring are hermaphrodites. When compared to offspring of regular C57Bl/6J matings, it is possible to dissociate genotypic and phenotypic factors affecting behavior. C57Bl/6J females were bred to C57Bl/6J males (Reg) or C57Bl/6J-Ypos hermaphrodites (Ypos). As adults, these offspring were given a set of behavioral tests known to differentiate the sexes. PCR analyses were run to determine the genotype of the Ypos females. The table below lists the behavioral test means and N for the five experimental groups.

	C57Bl/6J♀ x C57Bl/6J♂		C57Bl/6J♀ x C57Bl/6J♂		
	XX♀	XY♂	XX♀	XY♀	XY♂
Water Escape-sec [N]	56.9 [31]	44.2 [40]	35.9 [17]	43.7 [23]	27.0 [10]
Open Field-inches	1621.7 [31]	1478.9 [31]	1866.1 [17]	1807.9 [23]	1505.1 [9]
Active Avoidance-# A	23.1 [13]	17.4 [19]	29.5 [12]	25.7 [11]	21.4 [7]
Morris Maze-inches	432.9 [18]	367.5 [18]	432.9 [5]	311.3 [11]	

The Reg males and females differ significantly on all behavioral measures. On the first three measures, the Ypos phenotypic males (hermaphrodites) differ significantly from at least one of the Ypos phenotypic female groups. The differences are in the same direction as those seen for the Reg animals. Thus, these differences may be interpreted as being due to phenotypic effects based upon male or female body form and physiology. The last test in the table is a test of spatial learning. Here, the Ypos female phenotypes differ as a function of their genotype, again in the same direction as the Reg sex difference (hermaphrodites are not included, as only 2 were tested). Thus, spatial learning appears to be affected more by genotype than phenotype.

On the first three measures, the two XX female groups differ significantly. Two of the possible explanations for this are a substrain genetic difference due to a mutation or the androgen level in utero.

We thank Dr. Eva Eicher for the mice and Paul Betts for his technical assistance with PCR.

IMPAIRED VESICULAR STORAGE OF DOPAMINE IN AN ANIMAL MODEL FOR ATTENTION-DEFICIT HYPERACTIVITY DISORDER - THE SPONTANEOUSLY HYPERTENSIVE RAT. V.A. Russell*, A.S. de Villiers, T. Sagvolden, M.C.L. Lamm, and J.J.F. Taljaard. Department of Chemical Pathology, University of Stellenbosch, P O Box 19113, Tygerberg 7505, South Africa.

Stimulants are the drugs of choice in the treatment of Attention-Deficit Hyperactivity Disorder (*ADHD*). Both methylphenidate (ritalin) and d-amphetamine released [^{3}H]DA from prefrontal cortex, nucleus accumbens and caudate-putamen slices of spontaneously hypertensive rats (SHR) and their normotensive Wistar-Kyoto controls (WKY), but methylphenidate was between 7 and 17 times less potent than d-amphetamine and released less [^{3}H]DA from nucleus accumbens slices of SHR than WKY, while d-amphetamine released more [^{3}H]DA from SHR than from WKY tissue. Since methylphenidate releases DA from vesicular stores only and is less potent than d-amphetamine, it may allow more precise control of the effect on DA function than is possible with d-amphetamine.

Depolarization-induced release of [^{3}H]DA from vesicular stores, effected by either electrical stimulation of the slices, exposure to high K^+ concentration or methylphenidate, was lower in prefrontal cortex, nucleus accumbens and caudate-putamen of SHR compared to WKY. In contrast, d-amphetamine-induced transporter-mediated release of [^{3}H]DA was significantly greater in SHR tissue compared to WKY. These results suggest that vesicular storage of DA, and possibly the vesicle transporter, is impaired in SHR. (Sponsored by the South African MRC and EU project no. ERBCHRXT930303)

HERITABILITY OF PLANUM TEMPORALE ASYMMETRY IN MONOZYGOTIC AND DIZYGOTIC TWINS, L. F. Luevano*, D. W. Jones, D. R. Weinberger. Clinical Brain Disorders Branch, DIRP, NIMH, NIH, Neuroscience Center at St Elizabeth's, Washington, DC 20032

This study investigated the genetic component in the development of the well-documented asymmetry of the planum temporale (*PT*), a structure associated with language processing. We measured PT area in 9 strongly right-handed normal dizygotic (DZ) twins pairs and 9 strongly right-handed normal monozygotic (MZ) twin pairs using three-dimensional surface renderings of the supratemporal cortex from magnetic resonance imaging (MRI) scans. Results confirmed normal PT asymmetry in both sets of twins. Within-twin comparisons of PT asymmetry showed a strong association for MZ, but not DZ, twin pairs, indicating a strong heritability for PT asymmetry.

816.19

ROLE OF DM20 PROTEOLIPID PROTEIN IN EMBRYONIC CNS DEVELOPMENT. N. L. Nadon*. Oklahoma Medical Research Foundation, Oklahoma City OK 73104

The myelin proteolipid protein DM20 is expressed as early as embryonic day 10 in mouse CNS. Mutations in the X-linked PLP gene encoding DM20 have serious consequences for postnatal oligodendrocyte development and myelination, but do not affect embryonic development in a noticeable manner. However, we recently demonstrated that expression of a mutant form of DM20 from a transgene in the same cells as the wild-type form (from the endogenous, X-linked gene) creates an embryonic lethal condition. These results suggest that DM20 is involved in protein:protein interactions critical to its function in embryonic CNS development. A yeast two-hybrid system is being used to investigate these interactions. Immunoprecipitation of DM20 from embryonic CNS will also be used to identify proteins that DM20 may interact with.

INFLUENCE OF ACTIVITY IN NUCLEUS TRACTUS SOLITARIUS (NTS) ON SEIZURE MANIFESTATIONS

Amy Easton*, Ben Walker, and Karen Gale. Department of Pharmacology, Georgetown University Medical Center, Washington DC, 20007.

Afferent vagal nerve stimulation has been demonstrated to have anticonvulsant effects in several experimental seizure models. The NTS is a primary site at which vagal afferents terminate, but the role of neurotransmitters in NTS for modulating seizures has not yet been investigated. In this study, we examined the influence of GABA transmission in NTS on seizures evoked by systemic bicuculline. Bicuculline methiodide (117 pmol), a $GABA_A$-receptor antagonist, or muscimol (438 pmol), a $GABA_A$-receptor agonist, was microinjected bilaterally into caudomedial NTS. 5 min later, seizure activity was induced by an intravenous bicuculline injection. Bicuculline infusions into NTS resulted in increased seizure severity, with the appearance of tonic extension at doses of iv bicuculline which induced only myoclonic seizures in controls. Muscimol infusions into NTS suppressed several seizure components, especially myoclonic manifestations. These results suggest that focal manipulation of NTS can affect the intensity and topography of experimental seizures. This is consistent with the hypothesis that the anticonvulsant effects of afferent vagal nerve stimulation are mediated by NTS. In addition to $GABA_A$ transmission, $GABA_B$ and glutamate-mediated transmission in NTS are also likely to contribute to seizure modulation.

A MODEL OF COMPLEX-PARTIAL SEIZURES AND STATUS EPILEPTICUS IN THE INFANT MONKEY

V. Gunderson, K. Gale and M. Dubach*. Infant Primate Research Laboratory, University of Washington, Seattle, WA 98195.

This project entailed the establishment of a nonhuman primate model to study the effects of seizures during infancy on long-term developmental outcome. Subjects were 4 infant pigtailed macaques (18 to 145 days of age). Microinjections of bicuculline methiodide (4 - 20nmol in 0.5ul) were made via stereotaxically-positioned cranial platforms into awake animals. Localization of injection sites was confirmed by MRI. The microinjection of bicuculline methiodide into area tempestas induced complex-partial seizures that were episodic or continuous, depending upon the dose. In some animals, at least 2 episodes of prolonged complex-partial status epilepticus (> 1 hr) were evoked 1-week apart. The effects of the microinjections were highly site specific. EEG verification of seizures was obtained. All animals are presently undergoing a battery of tests indexing cognitive, emotional, and social functioning. Results indicate that complex-partial seizures can be evoked from area tempestas in infant monkeys. This model can be used to study the effects of status epilepticus on neuropsychological development in otherwise normal infants

METABOLIC ACTIVITY IN THE RAT BRAIN IN TETANUS TOXIN INDUCED CHRONIC EPILEPSY.

M. Lutzenburg, C. Bruehl, O.W. Witte*. Neurologische Klinik, Heinrich-Heine-Universität, Moorenstr. 5, D-40225 Düsseldorf

In contrast to patients who show a focal hypometabolism in the interictal state, animals with induced epilepsy usually show a hypermetabolism in the focus. Here we investigated the alterations of brain metabolism in a chronic model of epilepsy.

Epileptiform activity was induced in the brain of adult male Wistar rats by injection of 0.5 ml tetanus toxin solution containing 4 ng toxin (~ 40 MLDs). Injection sites were the motor cortex (Fr2) or the somatosensory cortex (Par1), in each case 1.0 mm beneath the pial surface. In additional animals stainless-steal skullscrews were implanted chronically in order to record the electrocorticograms. After recovery from surgery for at least 3 days the ECoGs of awake freely mooving animals were recorded via a comutator apparatus. Tetanus toxin caused long lasting epileptiform activity. Brain metabolism was measured 7, 14 or 30 days after injection by quantitative [^{14}C]-deoxyglucose autoradiography.

In the area of toxin injection the brain metabolism was reduced. This reduction was limited to the functional brain area where the toxin was applied: an injection into the motor cortex did not cause alterations of metabolism in the sensory cortical areas, and vice versa. However, the metabolic alterations were more widespread with an epileptic focus in the parietal area than in the motor area, in accordance with the size of these functional brains areas.

The data show that chronic epileptiform activity causes a reduction of brain metabolism also in animal experiments. Furthermore, the metabolically disturbed areas are limited to the bounderies of functional cytoarchitectonic areas, and obviously are more widespread than the diffusion of the drug itself.

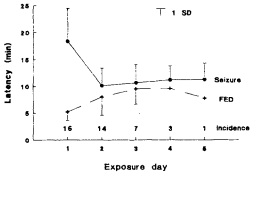
REPEATED EXPOSURE TO HYPERBARIC OXYGEN DECREASES LATENCY TO SEIZURES.

J.C. Braisted, M. Chavko, D.F. Forcino, M. Saraswati*, and A.L. Harabin. Naval Medical Research Institute, Bethesda, MD 20889-5607.

Hyperbaric O_2 is used in clinical and diving applications and can produce seizures in animals and humans. We studied the effect of daily exposures on latency to seizure. Rats (♂, 450 g; n=17) were surgically implanted with stainless-steel screw electrodes over the cerebral cortex for recording electroencephalogram (EEG). Following 6-7 d recovery, awake, freely moving animals were exposed to 5 atmospheres (gauge) O_2 until seizure on 5 consecutive days. On the first exposure, most animals exhibited a electrographic seizure first electrical discharge (FED) after 5.2±.6 (SD) min that consisted of brief (.25±.05 min) 3-5/s sharp spikes with no or minor motor components. Generalized seizures occurred after 18±6 min, and consisted of .45±.1 min high-amplitude, high-frequency spikes, .43±.2 min quiet EEG, followed by .56±.2 min of high amplitude polyspikes. There were clonic movements of upper body, often with bilateral forelimb extension. The animals' behavior and EEG returned to normal within minutes after seizure, with continued weight gain on subsequent days.



Following the first exposure, latency to seizure decreased and time to FED increased (ANOVA, $p<0.001$); incidence of FEDs decreased. These results suggest that one O_2-induced seizure has long-lasting effects that precipitate earlier seizures on subsequent exposures. HYPERBARIC OXYGEN-INDUCED SEIZURE: HIPPOCAMPAL CELL SPARING COMPARED TO KAINIC ACID SEIZURES, L.S.Jones*, P.Kirby, S.Y.Grooms, J.H.Hamilton, and R.Coffman Dev Bio & Anat, Univ So Carolina, Sch of Med, Columbia, SC 29208.

Hyperbaric oxygen (HBO) induced seizures occur in a subpopulation of patients receiving HBO treatment, but long term CNS effects are not known. One possibility is tissue damage and cell death as seen in other seizure models (e.g., excitotoxic drugs, kindling). We examined the effects of a single HBO-induced seizure on rat brain and compared the results to negative controls (no seizure) and positive controls that had a seizure provoked by kainic acid (KA). Male, Sprague-Dawley rats (3-4 weeks) were divided into 3 groups (16/group); HBO-treated rats were exposed to 6 ATM HBO until seizure onset ($\approx$20 min). Seizures were usually Class 5 (Racine scale). KA rats received an i.p. injection (8 mg/kg); Class 3-5 seizures usually occurred within 20 min. Rats in either group not exhibiting at least Class 3 seizures were rejected. Controls were placed in the HBO chamber at ambient pressure for 30 min. Rats were observed until recovery and then returned to the Animal Care Facility until sacrifice. The groups were further divided into 4 groups of 4 for these time points: 1 day, 1 wk, 2 wks, or 4 wks. Subjects were perfused and the fixed brains sample-sectioned at 10 μm and processed for Nissl and silver degeneration staining. Sections were examined blindly and only sections from KA-treated rats contained visible damage. Cell counts performed blindly in CA3 and CA1 regions of hippocampus indicated that the HBO-seizure rats were not different from controls in either region at any time point; cell loss in the CA3 region of KA-seizure rats approached significance in CA3 at the 4 week time point.

KETOGENIC DIET TRANSIENTLY ELEVATES AFTERDISCHARGE THRESHOLD IN KINDLED ADULT RATS. C.E. Stafstrom*, A. Hori, P. Tandon, G.L. Holmes. Dept. Neurology, Children's Hospital, Harvard Medical School, Boston, MA 02115.

The ketogenic diet (KD) is a high fat, low protein/carbohydrate diet which has been used as an alternative antiepileptic therapy for refractory seizures for more than seven decades. Nevertheless, the experimental literature about the KD is scant and the mechanism of KD action is unknown.

We designed an experimental KD for rats which approximates that used in humans. Calories are provided as follows: 88% from fat, 10% from protein and 2% from carbohydrate. When provided ad libitum, rats ingest the KD and gain weight similarly to rat chow-fed controls. As shown by an enzymatic assay for serum β-hydroxybutyrate (β-OHB), rats receiving the KD become ketotic within two days of KD initiation and stay ketotic throughout the six week period of KD treatment (mean β-OHB increase: 5x baseline).

Adult (P60) rats (n=20) were kindled using standard parameters, then randomly divided into KD or control groups (n=10 each). Afterdischarge (AD) threshold, stage 5 seizure threshold, AD duration and seizure duration were determined: a) before, b) weekly during the six week experimental diet period and c) one week after the KD rats were returned to the standard diet. Compared to controls, rats fed the KD had a significantly elevated AD threshold for the first three weeks only ($p<0.05$), indicating a transient antiepileptic effect. Throughout the study period, there was no difference in AD duration or in stage 5 seizure threshold or duration.

These results suggest that the KD confers a transient protective effect against seizures, as indicated by the increase in kindled AD threshold. Furthermore, the KD is well tolerated by adult rats and produces a ketotic state which persists for the duration of treatment. Therefore, this is a promising model system for future investigations into mechanisms of KD anticonvulsant action.

SEIZURE DURATION AND NEURONAL INJURY IN HYPERTHERMIC SEIZURES IN RATS. W. Jiang*, T. Duong and N.C. de Lanerolle, Yale Univ.Sch. of Med., New Haven, Connecticut 06520.

Neuronal injury and the development of temporal lobe epilepsy are reported to be correlated with the occurrence of early childhood febrile seizures. To determine the relationship between febrile seizures and neuronal injury, seizures were induced by hyperthermia [Klauenberg & Sparber, Epilepsia, 25: 292-301 (1994)] in young rats (beginning at 22 days) and the degree of neuronal injury after varying numbers of seizure episodes was examined 24 hr later using a silver degeneration stain [Nadler & Evenson, Methods in Enzymol., 103: 393-400 91983)]. Rats experiencing short duration (< 6 -10 min) tonic-clonic seizures repeatedly (12 to 24 times) showed no significant neuronal injury. However, in two rats after the 6 and 12 seizure respectively, the tonic-clonic seizure developed into status epilepticus. In a group of rats left for six months after 12 tonic-clonic seizures and then restimulated once, several (8/30) developed status epilepticus (SE), which lasted from 2 to 6 hr. In all rats that showed status epilepticus, compared to those that only experienced tonic-clonic seizures, there were degenerating neurons in the hippocampus (hilus, CA3, CA2 and CA1 but not dentate granule cells). Additionally degenerating neurons were observed in the amygdala, parts of the thalamus, and layers IV and VI of some cortical areas. Immunocytochemistry reveals upregulation of neuropeptide Y in dentate granule cells and pyramidal neurons only in SE rats. The hippocampal injury seen in these rats resembles the pattern of injury in human hippocampi of patients that experienced febrile seizures. However, in rats this injury is correlated only with long periods of seizure such as status epilepticus. [Supported by NS 27081 & 30619 from NIH]

Suppression of Seizure-Like Activity Using DC Electric Fields.

T.I. Netoff*†, B.J.Gluckman§, E.J. Neel‡, S.J. Schiff†‡.
†Institute for Neurobiology, George Washington University, Washington D.C.
‡Dept. Neurosurgery, Children's National Medical Center, Washington D.C.
§Naval Surface Warefare Center, White Oak, Maryland

Electric fields have long been known to influence cellular activity. We demonstrate that seizure-like activity can be reversibly turned off and on using electric fields. Hippocampal slices cut transversely or longitudinally were placed in an interface chamber and perfused with high potassium artificial cerebral spinal fluid (ACSF) to produce interictal- and ictal-like behavior. The electric field was applied by creating a potential difference across two Ag/AgCl plates submerged in the ACSF on either side of the hippocampal slice. Seizure like activity was suppressed when an electric field was applied along the dendritic-somatic axis so as to hyperpolarize the pyramidal cells, and the activity was facilitated when the field was reversed. Fields applied perpendicularly to the apical dendrites had very little effect. A time dependence of this effect was observed; this may be due to the polarization of the electrode plates and/or may be due to cellular adaptation.

817.9

EFFECTS OF RADIOSURGERY ON KINDLING EPILEPSY MODEL. A.A.F.De Salles, B. Sun, P.M. Medin, B. Hoebel, M.J.Felder-Allen, T.D.Solberg, C.W. Xie, R. Ackermann*. UCLA School of Medicine. Los Angeles, CA 90095

Ionizing radiation is known to affect neuronal excitability. We studied single dose irradiation (radiosurgery) induced electrophysiological changes in 33 kindled rats. Kindling was accomplished by daily stimulation of 1 sec. 400 mA in the right hippocampus via bipolar electrodes. Once rats were kindled, the duration and threshold of afterdischarges were recorded. Radiosurgery was given by a 10MV linear accelerator fitted with a 5 mm collimator. Doses of 10 Gy or 40 Gy (at the 80% isodose line) were given to kindled and control rats. Kindled hippocampal slices were also studied in vitro regarding synaptic transmission changes after radiosurgery. Forty Gy decrease seizure threshold ($p<0.04$) within 5 days while 10 Gy did not ($p<0.17$). No significant change in seizure duration was found with either dose of radiation ($p<0.20$ and $p<0.10$, respectively). After the acute decrease in seizure threshold, 2 of 4 animals in the 40 Gy group had a persistent increase in seizure threshold lasting up to 3 months. The in vitro study showed that 60 Gy can suppress EPSP in the CA3 of the hippocampus. This study shows that radiosurgery has a significant effect on kindled hippocampal excitability, possibly by changing synaptic transmission. These findings are important for further understanding of the influence of ionizing radiation on neuronal excitability. This may have implications in the treatment of focal epilepsy.

817.10

VAGUS NERVE STIMULATION IN FREELY-MOVING CATS: EFFECTS ON CIRCADIAN SLEEP ORGANIZATION AND KINDLING DEVELOPMENT. A. Fernández-Guardiola*, A. Martínez-Cervantes, A Valdés-Cruz, V.M. Magdaleno-Madrigal, and R. Fernández-Mas. Div. de Invest. en Neurociencias, Inst. Mex. Psiquiatría and Fac. Psicología-UNAM. México, 14370 D.F.

The effects of chronic vagus nerve (VN) stimulation on sleep organization and daily amygdaloid kindling (AK) were analyzed in freely-moving cats. Eight adult male cats were implanted for conventional sleep recordings including left and right temporal lobe amygdalae. A bipolar hook (5 mm separation) stainless steel electrode was implanted in the unsectioned left VN. Cats were recorded in three experimental conditions: A) Control recordings of circadian sleep organization under L-D (12:12 hours), B) VN stimulation alone, C) VN plus amygdaloid stimulation, in this case VN was daily stimulated during one minute (1.2 mA, 0.5 ms pulses, 30 Hz) followed by AK, (1 s train, 1 ms pulses, 60 Hz). The 23 hours sleep control recording showed a polyphasic distribution of sleep stages with a major W tendency and a low REM total time in the D period. VN stimulation was done five times between 10:00-14:00 hours. The behavioral changes were: left miosis, blinking, licking, abdominal contractions, swallowing, and eventually yawning, meow and upwards gaze. Outstanding polygraphic changes were: an increasing of SPOL (Sommeil phasique à des ondes lentes) and PGO waves and rapid eyes movements. The SWS latency was significantly diminished as well as the REM sleep latency. PGO density was also significantly augmented. A peculiar fact was the PGO waves apparition being the animal awake and quiet, with a pseudo hallucinatory behavior and moderate muscle tonus. AK was completed (stage 6) in one animal in 33 days. In other animals kindling was significantly delayed. Despite AK, VN stimulations induced always the same polygraphic and behavioral changes. Supported by CONACYT 3605-N, DGAPA-UNAM IN-202894 and PUIS-UNAM.

LOCAL CEREBRAL GLUCOSE UTILIZATION DURING ELECTRICAL AND PENTYLENETETRAZOL-INDUCED SEIZURES IN THE NAIVE AND KINDLED GUINEA-PIG. P. A. Valentine*, E. J. Thiessen, T. H. Gilbert, C. Peyton, R. M. Cooper and G. C. Teskey. Behav. Neurosci. Res. Grp., Dept. of Psychology, Univ. of Calgary, Calgary, AB, Canada T2N 1N4.

Our laboratory has previously demonstrated that while amygdaloid kindling in the guinea-pig resulted in a progressive increase in the duration, amplitude and frequency of the afterdischarge (AD), and in the severity of convulsive behaviours, 250 stimulations failed to elicit fully generalized seizures. However, the guinea-pig is capable of expressing fully generalized seizures following administration of high doses of chemical convulsants such as pentylenetetrazol (PTZ). The purpose of this study was to determine those structures involved in the development of kindling in the guinea-pig using the [14C] 2-deoxyglucose (2-DG) autoradiographic technique.

Animals were electrically kindled with either daily stimulation to one amygdala or stimulation was alternated between amygdala sites. Immediately following 2-DG injection via a jugular catheter, a total of five ADs were elicited in the electrically kindled animals over the 50 minute 2-DG uptake period. The PTZ-induced seizure group was administered PTZ i.p. to induce a minimum of two seizures during the 2-DG uptake period. The brains were perfused, frozen, sectioned, and processed for deoxyglucose autoradiography. The sections were subsequently stained with thionin to aid in histological assessment.

Enhanced deoxyglucose utilization was associated with increased seizure severity in many of the limbic structures. During partial electrical kindling (stage 1-2), the greatest increase in 2-DG uptake was observed in the ipsilateral amygdala and piriform cortex, while further behavioural progression to stage 3 was associated with an additional increase in bilateral hippocampal activity. PTZ-induced seizures resulted in increased 2-DG uptake in thalamic nuclei, and neocortex. Supported by NSERC.

SPONTANEOUS EPILEPTIFORM ACTIVITY IN ORGANOTYPIC TISSUE CULTURES OF RAT BRAIN SLICES MEASURED WITH VOLTAGE SENSITIVE DYES. T.S. Donta*. Division of Neurological Sciences, University of Connecticut Health Center, Farmington, CT. 06030.

Spontaneous, synchronous neural activity in organotypic tissue cultures made from hemispheres of rat brain slices was recorded using voltage sensitive dyes and a photodiode array. The objectives were to examine in which neocortical layers spontaneous synchronous activity originated, and to measure the extent of spread from the site(s) of origin. Tranverse brain slices from the neocortex of post-natal day six Long-Evans hooded rat pups were taken for organotypic tissue cultures using the membrane support method. Tissue cultures between one week and two months *in vitro* were used for experiments. Fluorescent naphthyl styryl dyes and a 124-element photodiode array were used for optical recordings. Recorded tissue cultures were sectioned and Nissl stained. To relate the locations and spread of activity to tissue culture cytoarchitecture, activity images generated from the optical recordings were overlayed with photographs from the stained cultures. It was found that the majority of bursts detected optically spread to involve the entire culture under examination. The smallest bursts detected spread approximately 1-2 mm. Most activity was detected spreading in deeper cortical layers before upper layers. The path of activity spread was dependent on an individual tissue culture.

TEMPORAL ALTERATIONS IN DISTRIBUTION OF CRF-EXPRESSING NEURONS IN RAT BRAIN FOLLOWING KAINIC ACID-INDUCED SEIZURES. D.T. Piekut* and B. Phipps. Dept. of Neurobiology and Anatomy, University of Rochester, Rochester, NY 14642.

The induction of corticotropin-releasing factor (CRF) in extrahypothalamic brain sites following generalized clonic seizures induced by kainic acid (KA) was examined. The time course and spatial distribution pattern of CRF-like labeling was followed in rats allowed to survive from 2 to 48h following seizure onset. Male Sprague-Dawley rats were administered KA (18 mg/kg, ip), and animals typically responded with a fully generalized seizure syndrome. Controls were injected with saline. Animals were perfused and brains were processed for CRF immunocytochemistry. At 2h following onset of seizures, no alterations were observed in CRF distribution patterns following KA administration. However, by 5h after seizure onset, CRF-like immunoreactivity began to appear in extrahypothalamic sites that typically demonstrated little or no CRF in controls. By 24h, there was a marked increase in these same areas both in intensity and number of neuronal perikarya and processes positively labeled for CRF when compared to controls. Substantial CRF-like labeling was observed in olfactory structures such as the main olfactory bulb (internal granular layer), anterior olfactory nucleus, and deep layers of piriform cortex. Other sites of increased CRF-like immunoreactivity included the tenia tecta, inner layers of cingulate cortex, lateral septum, endopiriform nucleus, nucleus accumbens, fundus striatum, and nucleus of the lateral olfactory tract. Additionally, CRF-like labeling was atypically increased in the amygdala (lateral and basolateral amygdaloid nuclei) and hippocampal formation (pyramidal cells of regions CA1/CA3 and polymorph cells within the hilus). By 48h following seizure onset, CRF-like immunoreactivity was greatly reduced in many of the aforementioned brain sites.

CRF-like immunoreactivity appeared increased in many of the same areas known to exhibit degenerative changes following kainate elicited seizures. Although it is not entirely clear what function CRF may play at these extrahypothalamic sites, its presence in vulnerable areas suggests a neuroprotective or neurodegenerative role. PERIODIC ORBITS IN NEURONAL ENSEMBLE ACTIVITY

J. T. Francis*, P. So and S. J. Schiff. The George Washington University Neuroscience program and the Children's National Medical 111 Michigan Ave. Washington D C 20010.

Recent work has suggested that neuronal ensemble behavior may at times be deterministic, and unstable periodic behavior may be exploited in an attempt to control such ensembles. The purpose of the work presented here is to establish whether unstable periodic behavior (UPB) is present in neuronal ensembles, study its time evolution, and characterize changes in dynamics as a function of extracellular potassium.

Four hundred μm thick slices were cut from the hippocampus of 125-150 gm Sprague-Dawley rats and perfused in artificial cerebrospinal fluid containing 3.5 mM [K+] for 90 min. The perfusate was then switched to one containing 7.5-10.5 mM [K+], and extracellular burst discharges in CA3 recorded with saline filled glass micropipettes.

A new technique is presented for the detection of UPB in dynamical systems. This method attempts to define UPB within experimental data, using randomized surrogate data to serve as a null hypothesis that no unstable periodicities exist, and to place statistical confidence limits on our results.

Thirty -five experiments were performed on 14 slices from 12 rats. UPB was identified in a majority of our experiments. The period of time spent within these UPBs decreases with increasing potassium level. Furthermore, we found that these UPBs change in time, indicating that the dynamics is nonstationary.

These experiments suggest that UPB can be observed in the activity of small neuronal ensembles. Characterizing UPB provides a way to deal with the nonstationarity of such systems, and a means for control.

STRUCTURAL BRAIN ABNORMALITIES IN METHYLAZOXY METHANOL TREATED RATS: AN ANIMAL MODEL FOR HUMAN DEVELOPMENTAL DYSGENESES . G. Battaglia*, C. Colacitti, M. Di Luca, A. Caputi, C. Frassoni, E. Cattabeni, and R. Spreafico. Neurological Institute "C. Besta", and Dept. of Pharmacological Sciences, Univ. of Milano, Italy.

The prenatal exposure to methylazoxymethanol (MAM), an antiproliferative agent selective for actively dividing neuroblasts, induces a dose- and time-dependent hypoplasia of selected brain areas. The MAM treatment was employed in the present study to induce selective cortical malformations in rats. Pregnant rats were administred a double MAM intraperitoneal injection (15 mg/Kg) on gestational day 15, corresponding in rodents to the neurogenetic peak for the cerebral cortex. The cytoarchitectural features of neo- and archi-cortical areas were investigated in the young adult offsprings, by means of neuronal and glial immunocytochemical markers. Different cortical and subcortical structural abnormalities were found: 1. distruption of the normal neocortical layering; 2. a thick band of subpial heterotopic neurons, divided by a thin layer of white matter from the underlying cortex; 3. nodules of heterotopic neurons close to the lateral ventricles, and extending in both the neocortex and the hippocampal formation; 4. clusters of heterotopic neurons in the hippocampal CA2 region. The heterotopic cortical and subcortical structures were characterized by the presence of neurons with atypical morphology and altered expression of neuronal markers, and by the persistence of embryonic glial markers..

The present results demonstrate that MAM might negatively interfere with the normal development of anatomical structures involved in the neuronal migration during embryogenesis. Moreover, given the similarities between the brain malformations here reported and those described in the human neuropathology (i.e., band heterotopia and periventricular nodular heterotopia), MAM-treated rats can be proposed as a useful animal model for human migrational disorders. Neurophysiological experiments are now in progress to ascertain whether the ectopic neurons are characterized by intrinsic hyperexcitability.

AXON REORGANIZATION IN THE HIPPOCAMPUS OF CATS INFECTED WITH THE FELINE IMMUNODEFICIENCY VIRUS (FIV). T.W. Mitchell *, P.S. Buckmaster, E.A. Hoover, L.R. Whalen, and F.E. Dudek. Colorado State University, Fort Collins, CO 80523

Patients infected with the human immunodeficiency virus (HIV) suffer from neurological impairments with memory loss and seizures occurring in 10-20% of HIV-positive patients. An hypothesis of temporal lobe epileptogenesis states that following loss of hilar neurons, dentate gyrus granule cell axons sprout new collaterals that form an abnormal positive-feedback circuit which generates seizures. Because lentiviruses have been shown to kill neurons, we hypothesized that lentivirus-associated seizures could be produced by a similar epileptogenic mechanism -- hilar neuron loss and subsequent granule cell axon reorganization. To address this hypothesis we examined the dentate gyrus of FIV-infected cats (virus subtypes B or A&B). Hippocampal fixation was by perfusion (0.37% sulfide & 4% paraformaldehyde (PF); n=11 FIV-positive cats; n=1 FIV-negative cat) or by immersion (0.37% sulfide & 1% PF / 1.25% glutaraldehyde; n=15 FIV-negative cats). Hippocampal sections (40 μm) were taken from systematically random points along the entire septotemporal axis. To reveal the zinc-rich axon terminals of granule cells, sections were developed according to the Timm's method. All cats showed normal Timm's staining in the hilus. Abnormal Timm's staining in the inner-third of the molecular layer was not found (0 of 16, ages 1-6 yrs) in FIV-negative control cats, but was seen in 45% (5 of 11, ages 0.2-5 yrs) of FIV-positive cats. The degree of axonal sprouting in FIV-positive cats was variable: in 3 cats sprouting was intense, in 2 cats it was mild, and in 6 cats no evidence of sprouting was found. The factors underlying this variability in axon reorganization are unclear. Durations of infection varied from 2-32 months but did not appear to correlate with the degree of axonal sprouting. Our results indicate that some FIV-infected cats show reorganization of hippocampal dentate gyrus granule cell axons, consistent with a proposed mechanism of temporal lobe epilepsy. Because seizures are a common clinical manifestation in people infected with HIV, these preliminary findings suggest a mechanism by which lentivirus-infected individuals develop seizure disorders.

AUDIOGENIC SEIZURES IN 5-HT_{2C} RECEPTOR MUTANT MICE. T.J. Brennan, M. Kilgard[1] and L. Tecott*. Depts. of Psychiatry and [1]Physiology, University of California, San Francisco, CA 94143.

The 5-HT_{2C} receptor is an abundant serotonin receptor subtype for which there are no selective agonists and antagonists. To examine the functional roles of this receptor, a 5-HT_{2C} receptor mutant mouse strain was generated (Tecott et al *Nature* 372: 542 '95). These animals display spontaneous seizures that are infrequent and sporadic. The rarity of spontaneous seizures in these animals has hindered studies of the mechanisms underlying their enhanced neuronal network excitability. We therefore sought to determine the sensitivity of mutants to a noninvasive audiogenic stimulus. Mutant and age-matched wild type mice were exposed to a complex 110 dB acoustic stimulus with predominant frequencies within the 12-16 kHz range. Whereas no wild type animals displayed behavioral evidence of seizure activity, audiogenic seizures (AS) were apparent in 100% of the mutants. At 2-3 seconds following tone onset, all of the mutants exhibited the sudden onset of wild running and erratic leaping. This response persisted for 1-2 seconds, followed immediately by a period of extensor rigidity leading to apparent respiratory arrest and death. Mice could be resuscitated by artificial ventilation, provided by repeated blowing into a plastic tube covering the nose and mouth of the animal. The susceptibility of 5-HT_{2C} receptor mutant mice to AS is consistent with previous reports of serotonergic abnormalities in AS-susceptible rodent strains and the anticonvulsant actions of serotonin reuptake blockers in these models. The AS model provided by the 5-HT_{2C} receptor mutant strain may therefore prove useful for examining serotonergic determinants of seizure susceptibility. *Supported by T32 MH19552 (TJB) and DA00282 (LT).*

GLOBAL CHANGES IN SEIZURE SUSCEPTIBILITY IN MICE LACKING 5HT_{2C} SEROTONIN RECEPTORS. C.D. Applegate* and L. Tecott[1]. Program in Neuroscience, University of Rochester School of Medicine and Dentistry, Rochester, NY, 14642 and [1]Department of Psychiatry, UCSF, San Francisco, CA, 94143.

Previous research has indicated that 5HT_{2c} receptor knockout mice are prone to develop spontaneous seizures and exhibit increased susceptibility to the convulsant pentylenetetrazol (Tecott, et al., Nature, 374(6522):542-6,1995). In this study, we evaluated the susceptibility of these mice to olfactory bulb kindling and corneal electroshock. Separate groups of mice were either implanted with bipolar stimulating electrodes into the olfactory bulb for kindling or exposed to corneal ECS (10 mA). In comparison with wild-type controls, mutant mice exhibited significant increases in susceptibility in both seizure models. For kindling, mutant mice (N=8) exhibited significantly lower thresholds for afterdischarge (AD; 181 vs 288uA), longer AD durations at all stages of kindling and faster kindling rates (3.0 vs 6.3 trials) compared to controls (N=8). In addition, 6/8 mutants exhibited a stage 4 or 5 seizure on the first kindling trial compared to 0/8 for controls. Corneal ECS resulted in tonic hindlimb extension (THE) in 6/7 mutants as compared to 0/8 controls, and carbamazepine was found to block THE in both mutants and wild-types following ECS at 40 mA. Together these data indicate that deletion of the 5HT_{2c} receptor gene results in both a lowered seizure threshold and facilitated seizure propagation in the nervous system. SUSCEPTIBILITY TO DRUG-INDUCED SEIZURES OF FYN TYROSINE KINASE DEFICIENT MICE. **H. NIKI[1]*, T. MIYAKAWA[1] and T. YAGI[2] [1]Dept. of Psychol., Fac. of Lett., University of Tokyo, Tokyo, 113, Japan, [2]Dept. of Neurobiol. Behav. Genet., National Inst. of Physiol. Sci., Okazaki, 444, Japan.**

We have recently reported that Fyn-deficient mice were more fearful and were more likely to show acoustically primed audiogenic seizures (Miyakawa et al: Mol. Brain Res., 1994, 1995). In the present study Fyn-deficient mice were examined for their susceptibility to seizures induced by various convulsive drugs (pentylenetetrazol, picrotoxin, and bicuculline, kainic acid, N-methyl-D-aspartate (NMDA), and strychnine). Homozygous Fyn deficient mice were significantly more likely to show myoclonic convulsions when they were injected with pentylenetetrazol, picrotoxin, bicuculline, kainic acid and NMDA. On the other hand, no difference in seizure susceptibility was found between homozygous and heterozygous mutants when strychnine was administered. The observed enhanced seizure susceptibility of Fyn-deficient mice (along with the increased fearfulness of these mice in our previous study) may be attributable to the decrease in density of benzodiazepine receptors reported in our separate poster. **Supported by Grant-in-Aid for Scientific Research 07451018.**

OVEREXPRESSION OF A SHAKER-TYPE K^+ CHANNEL IN A TRANSGENIC MOUSE LEADS TO A PARADOXICAL HYPEREXCITABLE PHENOTYPE. S.H. Williams*[1,2], R. Abedi,[1] J.L. Noebels[1,2], P. Pfaffinger[2], P. Overbeek[3], and M.L. Sutherland[1,2]. [1]Department of Neurology, [2]Division of Neuroscience, [3]Department of Molecular and Cellular Biology, Baylor College of Medicine, One Baylor Plaza, Houston TX, 77030.

We have created transgenic mouse lines expressing the *Aplysia* AKv1.1a K^+ channel, driven by the HPRT promoter (HypK mice). The transgene mRNA was expressed in the CNS and antibodies directed against an epitope tag added to the 3'-terminus of the AKv1.1a cDNA showed strong staining in the cerebral cortex and hippocampus. Two lines derived from separate founder mice were chosen for study: 836, a high phenocopy line, and 842 a lower phenocopy line. EEG recordings were made from control, 836 and 842 mouse lines. Both transgenic lines exhibited spontaneous spike and wave like discharges, but 836 had more frequent discharges (3-6 per hour). Following the *in vivo* recordings, hippocampal slices were prepared and recordings performed. We used the high K^+ model to test the excitability of the hippocampus. In control mice the threshold [K^+] for spontaneous epileptiform discharges was 8.5 mM. In contrast 836 mice frequently demonstrated epileptiform discharges at 7.5 mM [K^+] (80% of slices). The duration of discharges was also significantly prolonged (~20%) in the 836 line compared to control mice. At 8.5 and 10 mM [K^+] the frequency of discharges was identical in control mice and 836 and 842 lines. These data indicate that ectopic potassium channel expression can lead to a paradoxical hyperexcitable phenotype. In parallel studies we have seen alterations in endogenous potassium channel mRNA expression in HypK mice, which may explain these observations. Another possibilty is that developmental abnormalities underlie the phenotype. We are currently investigating these hypotheses. ADENOVIRUS ENCODING A VOLTAGE-GATED POTASSIUM CHANNEL ATTENUATES PICROTOXIN-INDUCED HIPPOCAMPAL EPILEPTIFORM DISCHARGE IN VIVO. **R.D. Kirkby*, D.C. Johns[1], E. Marban[1], J.H. Lawrence[1] and M.A. Rogawski. Epilepsy Research Branch, NINDS, NIH, Bethesda, MD 20892, and [1]Div. of Cardiology, Dept. of Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.**

As a strategy to reduce pathological excitability of central neurons *in vivo*, we utilized a recombinant adenovirus AdShK, which expresses an inactivation-deficient *Drosophila Shaker* K^+ channel. The Adβgal virus expressing β-galactosidase was used as a control. The engineered viruses were delivered to the right hippocampus (4×10^7 pfu/4.0 μl) of freely moving male NIH Swiss mice 2 d prior to the intrahippocampal administration of picrotoxin (0.67 nmol/0.2 μl). Within a few minutes of injection, picrotoxin reliably provoked high-amplitude epileptiform spiking (recorded from the injection site) that increased in frequency during the 45-min period after the injection. Mice receiving AdShK exhibited significantly slower growth in rates of spiking than did controls ($p < 0.05$). Thus, mean rates of spiking (spikes/min ± S.E.M.) 40 - 45 min following the administration of picrotoxin in mice treated with vehicle (PBS containing 10% glycerol and 1 mM $MgCl_2$, pH, 7.4; $n = 9$), Adβgal ($n = 11$) and AdShK ($n = 8$) were 433 ± 110, 406 ± 57 and 262 ± 73, respectively. The excitability-modulating properties of AdShK demonstrate the potential of ion channel-encoding viral vectors in the gene therapy of epilepsy and other functional neurological disorders.

ACTIVITY-DEPENDENT DECREASE IN GLUTAMATE TRANSPORTER mRNA EXPRESSION: A MECHANISM FOR EXCITOTOXIC CELL DEATH FOLLOWING SEIZURES. M.L. Sutherland*[a,b], T.A. Delaney[b], J.L. Noebels[a,b]. [a]Division of Neuroscience and [b]Department of Neurology, Developmental Neurogenetics Laboratory, Baylor College of Medicine, Houston TX 77030, USA.

Glutamate is the major excitatory neurotransmitter of the mammalian central nervous system (CNS) acting as a ligand for glutamate metabotropic, AMPA/KA and NMDA receptor subtypes. Transport through high-affinity, Na^+-dependent uptake proteins located in the plasma membrane of presynaptic terminals and surrounding glial cells is the mechanism that maintains glutamate below neurotoxic levels in the synaptic cleft.

We have used *in situ* hybridization analysis to study changes in the expression of glutamate transporter mRNAs in a systemic rat model of KA-induced status epilepticus. At time points four and six hours post-injection, a marked decrease in the expression of the rEAAT2 transcript was observed in a subpopulation of hippocampal hilar cells. Cells in molecular and granular layers of the dentate gyrus and the hippocampal pyramidal cell layer continued to express the rEAAT2 mRNA, and showed no decrease in the signal intensity per cell. In contrast, the mRNA level and distribution of a second rat glutamate transporter, rEAAT1 remained constant, indicating a subtype-specific transporter response to seizure activity.

Pentylenetetrazole (PTZ)-induced statue epilepticus had no affect on either rEAAT1 or rEAAT2 mRNA expression, while pilocarpine i.p. administration resulted in a similar subtype-specific decrease in the rEAAT2 transcript. Studies are currently in progress with subtype-specific antibodies to determine the effect on EAAT protein levels 7 to 21 hours after KA i.p. injection.

M.L. Sutherland is the recipient of an American Epilepsy Society Postdoctoral Fellowship. NIH NS29709 to JLN.

REGULATION OF GABA AND GLUTAMATE TRANSPORTER mRNAs IN THE SEVERE-SEIZURE GENETICALLY EPILEPSY-PRONE RAT (GEPR-9). M. T. Akbar[1], M. Rattray[3], N. W. S. Chong[2] and B. S. Meldrum[1]*. Depts. [1]Neurology and [2]Neuroscience, Inst. Psychiatry, London SE5 8AF UK and [3]Div. Biochemistry and Molecular Biology, Guy's Hospital, London SE1 9RT UK.

High affinity transporters for the amino acids L-glutamate and GABA are essential for the removal of these transmitters from the synaptic cleft and for regulating their extracellular concentration. Recent studies suggest a crucial role for these transporters in epileptogenesis and seizure propagation. The GEPR is an animal model of inherited generalised tonic-clonic epilepsy that shows abnormal susceptibility to audiogenic seizures (AGS). In addition to AGS, GEPRs show a lowered threshold to a variety of seizure-inducing stimuli. The present study examined the levels of expression of the mRNAs encoding the glial and neuronal glutamate transporters, GLT1 and EAAC1 respectively, and the neuronal GABA transporter, GAT1, in paired male GEPR-9 and Sprague-Dawley control rats using the technique of in situ hybridization. Animals were assessed for susceptibility to AGS on six occasions, and sacrificed 7 days following the last audiogenic stimulus exposure. Rat brains were processed for in situ hybridization with radioactive ^{35}S labelled oligonucleotide probes (EAAC1 and GAT1) and ^{35}S labelled riboprobes (GLT1). Semi-quantitative analyses were carried out on X-ray film autoradiograms in four brain regions (hippocampal subfields CA1-4, dentate gyrus; cortex, CTX; striatum, STR; and inferior colliculus, IC). Reductions in GAT-1 mRNA were found in GEPRs in all brain regions examined (-8 to -24% compared to control). Similar reductions in GLT-1 mRNA expression levels were seen in CTX, STR, IC and CA1 (-8 to -20%) of GEPRs. There was a tendency for a reduced expression of EAAC1 mRNA in most regions of the GEPR brain although this reached statistical significance only in the STR (-12%). These results show innate differences in the mRNA expression levels of three crucial amino acid transporters that possibly reflect altered homeostatic and epileptogenic phenomena in this genetically-determined animal seizure model. (M.T. Akbar is the holder of an MRC Studentship).

GLUTAMATE DECARBOXYLASE (GAD) ISOFORMS IN THALAMIC NUCLEI IN LETHARGIC (*LH/LH*) MOUSE MODEL OF ABSENCE SEIZURES. S. Lin, F-H. Lin*, D.A. Hosford. Duke & Durham V.A. Med. Cntrs., Durham, NC 27705.

NRT neurons are exclusively GABAergic, and they appear to regulate the synchronized thalamocortical burst-firing of absence seizures. Recurrent collaterals from these neurons may activate $GABA_A$ receptors on other NRT neurons, thereby decreasing output to thalamocortical relay neurons and suppressing absence seizures. Our previous studies using *lh/lh* mice demonstrated that microinjection of the $GABA_A$ receptor agonist muscimol into the nucleus reticularis thalami (NRT) significantly suppressed absence seizures. To begin to test the possibility that GABA synthesis within NRT neurons is involved in the regulation of absence seizures, we used Western blot and immunohistochemical techniques to examine thalami of *lh/lh* and matched nonepileptic (+/+) littermates for 2 GAD isoforms: GAD_{67} (primarily somatic) and GAD_{65} (primarily dendritic).

Western blot techniques demonstrated a strongly immunoreactive band corresponding to GAD_{67} (K2 antibody) in both strains. Immunohistochemical methods using this antibody demonstrated that all neuronal somata in NRT but virtually no other thalamic neurons exhibited strong labelling; the density of GAD_{67} immunoreactive NRT neurons was similar in the 2 strains. Quantitation of Western blots demonstrated significantly greater (40%; $p < .05$; rank-sum test) GAD_{67} in *lh/lh* compared to +/+ thalami ($n = 9$ pairs). In contrast, reverse transcriptase-PCR techniques using primers complementary to GAD_{65} mRNA showed no difference in GAD_{65} expression in the 2 strains.

These findings suggest that there may be differences in subcellular compartmentalization of GABA synthesis in NRT of *lh/lh* compared to +/+ mice. We are using in situ hybridization techniques to further localize and quantitate expression of GAD isoforms in thalamic nuclei. [NINDS & V.A. grants]

818.8

mRNA EXPRESSION OF $GABA_A$ RECEPTOR SUBUNITS (G_ARS) IN THALAMIC NUCLEI IN LETHARGIC (*LH/LH*) MOUSE MODEL OF ABSENCE SEIZURES. F-H. Lin, Y. Wang, D.A. Hosford*. Depts. of Medicine (Neurology) and Neurobiology, Duke & Durham V.A. Med. Cntrs., Durham, NC 27705.

$GABA_A$ receptors are pentameric isoforms composed of a variety of subunits: α_{1-6}, β_{1-4}, Γ_{1-3}, δ and rho_{1-2}. Each different isoform has unique pharmacological and biophysical properties. In previous studies using *lh/lh* mice we demonstrated: i) that activation of $GABA_A$ receptors in nucleus reticularis thalami (NRT) could regulate absence seizures; and ii) that regionally distinct $GABA_A$ receptor isoforms might underlie benzodiazepine insensitivity of anterior ventral lateral thalamic nucleus (VLa) compared to NRT. In this study we analyzed and compared mRNA expression of G_ARS in VLa and NRT of matched *lh/lh* and nonepileptic (+/+) mice.

We used northern blot techniques with RNA probes (complementary to rat $\alpha_{1,2}$, and β_1 G_ARS) or DNA probes (complementary to rat $\alpha_{3,4}$, β_2, $\Gamma_{1,2}$ and δ G_ARS) to validate that each probe hybridized to bands of appropriate size in mouse brain RNA. Within each strain, in situ hybridization techniques demonstrated a rank order of mRNA expression in VLa as follows: $\alpha_1 > \beta_2 > \delta > \Gamma_2 > \Gamma_1$, $\alpha_{2,3,4}$ and β_1. NRT expressed less signal compared to VLa, and a differing rank order of mRNA expression. We found no significant differences between *lh/lh* and +/+ mice in mRNA expression of $\alpha_{1,2}$ or β_1 G_ARS; comparisons of other subunits are proceeding.

These findings suggest that regional differences in G_ARS mRNA expression may underlie differential sensitivity to benzodiazepines in NRT compared to VLa. By suggesting a molecular basis for the regionally specific antiabsence effects of benzodiazepines, our findings underscore the need to develop agonists specific for $GABA_A$ receptor isoforms in NRT, in hopes that these compounds would possess antiabsence effects. [NINDS & V.A. grants]

818.9

DIFFERENTIAL INDUCTION OF PROTEIN KINASE GENE EXPRESSION BY KINDLING AND QUENCHING STIMULATION. G. Xing, S.R.B. Weiss, T. Heynen, X-L. Li, H. Li, S-Y. Kim *, R.M. Post, and M.A. Smith. Biological Psychiatry Branch, NIMH/NIH Bethesda, MD 20892-1272

A variety of protein kinases play important functions in modulating the response to extracellular signals and in neuronal plasticity. In an effort to identify novel protein kinases potentially relevant to CNS plasticity, we used differential display PCR to examine the transcriptional pattern of mRNAs belonging to several kinase gene families (PKC, CaM II, TRK) following electrical stimulation of the amygdala which caused kindling, a model of neural plasticity in which repeated stimulation eventually induces generalized seizures. The first group of rats were stimulated daily (60 Hz 1s) until they developed repeated seizures, and then sacrificed 1 wk after the last seizure. A second group received low frequency stimulation (1 Hz 15 min.), or "quenching", for 1 wk which suppresses the kindling process. A third group received kindling followed by a week-long quenching stimulation. The fourth group was not stimulated (sham control). Brains were pooled for each group and total RNA extracted for RT-PCR. First strand cDNAs were generated by reverse transcription using oligo-dT primers. Several sets of 3' end PCR primers designed according to the highly conserved region of protein kinase gene families were used as anchor primers in PCR reactions in combination with sets of 5' end arbitrary random primers. RT-PCR products were separated on a denaturing polyacrylamide gel, blotted and exposed to X-ray-film. Results showed that kindling and quenching stimulation differentially regulated multiple kinase-related cDNAs, thus raising the possibility that specific kinases are involved in the maintenance of kindling.

OXYGEN TOXICITY IN RAT BRAIN: ACTIVATION OF REDOX-SENSITIVE TRANSCRIPTION FACTORS. A.V. Prasad* S.T. Ahlers, and C. R. Auker. Naval Medical Research Institute, 8901 Wisconsin Ave, Bethesda, MD 20889-5607.

Introduction: Transcription factors (TFs), NF-κB and AP1 are sensitive to oxidative stress and have been proposed as intracellular oxidative stress specific response factors. Another transcription factor, Sp1, can act synergistically with NF-κB in some circumstances. Activation of these 3 redox-sensitive TFs has been demonstrated in certain seizure models. Hyperbaric Oxygen (HBO), a unique agent of oxidative stress, causes seizures. We hypothesized that exposure to HBO activates the TFs NF-κB, AP1, and Sp1.

Methods: Adult ♂ S-D rats were exposed to 5.5 atm absolute of 100% O_2 as follows: Group#1- until onset of motor seizures; Group#2- for 30 min without seizing; Group#3- for 20 min without seizing. At predetermined post-exposure intervals (30'-24 h), rats were euthanized and brains were quickly dissected and frozen. Nuclear extracts prepared from these brains were subjected to mobility shift assays. Controls were unexposed rats.

Results: Group #1: Induction of NF-κB and AP1 exhibited 3 peaks. The major peak for NF-κB was a 20-fold increase at 1 h and for AP1 it was a 10-fold increase at 2 h. Induction of Sp1 was linear with a peak (27-fold increase) at 24 h. Group #2: All 3 TFs had 2 peaks. NF-κB: 1.6- and 4-fold increase after 4 h and 24 h, respectively; AP1: 11- and 8-fold increase at 1 h and 8 h, respectively; Sp1: 10- and 11-fold increase at 2 h and 16 h, respectively. Group#3: NF-κB and Sp1 were activated earlier (2-fold at 30 min and 4 fold at 1 h, respectively). AP1 response was linear with a maximum 12-fold increase at 8 h.

Conclusion: Our data demonstrate that exposure to HBO activates the TFs NF-κB, AP1, and Sp1. The response of these TFs to HBO is dependent on the duration of exposure and the occurrence of seizures. *(Supported by NMRDC Work Unit 62233N MM33P30.005-1519)*

THE ENHANCED EXPRESSION OF SYNAPSIN I, NOT OF SYNAPSIN II, MESSENGER RNA IN THE KINDLING MODEL OF EPILEPSY. K. Sato[1,2*], K. Morimoto[3] and T. Hayabara[1]. [1]Clinical Research Institute, National Sanatorium Minamiokayama Hospital, Okayama 701-03, Japan. [2]Department of Neuropsychiatry Okayama University Medical School, Okayama 700, Japan. [3]Department of Neuropsychiatry, Kagawa Medical School, Kagawa 761-07, Japan.

Synapsin is a synaptic vesicle associated protein and is thought to be involved in the regulation of synaptogenesis and neurotransmitter release. We studied mRNA levels for the synapsin I and II, using the amygdaloid kindling model of epilepsy of rats. The inductions of mRNAs for synapsin I and II were evaluated just after (time 0) and at 30 min and, 1, 2, 4, 8, and 24 h after generalized stage 5 seizures induced by daily electrical stimulations. There were marked increases in the synapsin I mRNA in the bilateral dentate gyrus of hippocampus. Synapsin I mRNA increased significantly by 44 to 73 % in the ipsilateral dentate gyrus to the stimulation, 1 to 8 h after kindled seizures. In the contralateral side, the levels of synapsin I mRNA significantly elevated 2 h and 8 h after seizures. There were no significant changes up to 24 h after seizures in other brain regions, which included CA1, CA2, CA3, and the polymorphic layer of the hippocampus, the amygdala, and the temporal and perirhinal cortices. The mRNA for synapsin II, however, did not change in the areas examined up to 24 h after kindled seizures. Synapsin I and synapsin II are presumed to perform different functions. It was found that synapsin I regulated glutamate release from rat brain synaptosomes. The increases of synapsin I mRNA in this study suggest that synapsin I play a part in the presynaptic molecular mechanisms which underly the neuronal changes in kindling.

CHANGES IN SOMATOSTATIN (SRIF) RECEPTOR mRNAs AND BINDING SITES IN RAT BRAIN DURING KINDLING. A. Vezzani[1], C. Piwko, V. S. Thoss, R. Samanin[1] and D. Hoyer*. Preclinical Research, 360/604, SANDOZ Pharma Ltd, Basel CH-4002, Switzerland and [1]Lab. of Neuropharmacology, Mario Negri Inst. for Pharmacol. Res., Milano, Italy 20157.

We studied SRIF receptor mRNA and binding sites in the brain of adult rats electrically kindled in the dorsal hippocampus by *in situ* hybridization histochemistry using SRIF sst_1 - sst_5 receptor mRNA selective oligoprobes and quantitative receptor autoradiography. As compared to controls (implanted with electrodes but not stimulated), we found a bilateral significant 40% decrease of SRIF receptor binding in the molecular layer (ML) of the dentate gyrus (DG) using the $SRIF_1$ receptors selective ligand [^{125}I]Tyr^3-octreotide and the non subtype-selective ligands [^{125}I]LTT- SRIF-28 and [^{125}I]CGP 23996 (in Mg^{++}-buffer) at stage 2 (pre-convulsive stage) and one week but *not* one month after stage 5 (tonic-clonic seizures). No changes occurred in [^{125}I]CGP 23996 binding when assessed in Na^+-buffer, which facilitates binding to $SRIF_2$ sites. SRIF receptors did not change in other limbic and cortical areas during kindling. The mRNA levels for sst_1 - sst_5 receptors were unaffected during kindling as well as receptor binding or mRNA levels after one afterdischarge.

In view of the antiepileptogenic action of SRIF in kindling, the selective decrease of $SRIF_1$ receptor sites in the ML of the DG may contribute to the increased sensitivity for the induction of generalized seizures.

LONG-TERM INCREASE IN METABOTROPIC GLUTAMATE RECEPTOR mRNAs IN THE RAT SUPRAOPTIC NUCLEUS AFTER STAGE 5 AMYGDALA KINDLING. **Walid M. Al-Ghoul, Rick B. Meeker* and Robert S. Greenwood. Dept. of Neurology, Univ. of North Carolina, Chapel Hill, NC 27599.**

Metabotropic glutamate receptors (mGluRs) are thought to play an important role in different types of neuronal plasticity such as long-term potentiation and kindled seizures. We have previously shown that kindled seizures cause a sustained increase in plasma vasopressin (VP) and VP mRNA in the supraoptic nucleus (SON). We hypothesized that changes in mGluRs might mediate the plastic changes seen in VP regulation in the SON. Three mGluR subtypes are detected in the SON in the following relative levels: mGluR3 > mGluR1 > mGluR7. We examined the levels of mGluR1 and mGluR3 mRNAs in the SON and the cerebral cortex using *in situ* hybridization, one month after stage 5 amygdala kindling. mGluR3 mRNA showed the greatest increase in both the SON (55.5%, n=9, p = 0.001) and the cerebral cortex (37.6%, n=9, p= 0.003). mGluR1 mRNA also increased by 26.8% in the SON (n=8, p=0.05) and 28.5% in the cortex (n=8, p=0.02). These results show that sustained increases in mGluR mRNAs parallel the changes in VP expression in the SON. Thus, mGluR1 and mGluR3 may participate in the development of long-lasting plastic changes associated with seizure activity.

Phenidone, dual inhibitor of cyclooxygenase/lipoxygenase, blocked kainic acid (KA)-induced seizure and subsequent activation of nuclear factor kappa Beta(NFkB)-transcription factor in the rat hippocampus.

H. C. Kim, J. H. Suh, M. B. Wie, J. M. Suh, C. Kim and W. K. Jhoo College of Pharmacy, Kangwon National University, Chuncheon, 200-701, KOREA.

Escalating evidence suggests that KA promotes the generation of oxy-radicals not only *in vivo* but also *in vitro*. The purpose of this study was to understand alteration of NFkB, an oxidative stress-response transcription factor, to KA-induced lesions after modulation of arachidonic acid metabolic pathways. Pretreated phenidone, co-inhibitor of cyclooxygenase/ lipoxygenase, but neither esculetin, inhibitor of lipoxygenase nor aspirin, inhibitor of cyclooxygenase, reduced wet dog shake, seizure behavior following KA and subsequent neuronal cell death. Immunoreactivities of NFkB p50 and NFkB p65 were observed in neuronal elements of normal brain. After systemic KA injection, we found an increase in the immunoreactivity against the NFkB p50/p65 subunit, localized to activated glia, in hippocampal areas such as CA1 and CA3 regions. Cyclooxygenase inhibitor, aspirin and lipoxygenase inhibitor, esculetin showed no effect on KA-induced NFkB activation. While the cyclooxygenase/lipoxygenase inhibitor phenidone attenuated KA-initiated NFkB induction. Thus our results suggest that both cyclooxygenase/lipoxygenase pathways are essential to potentiate neurodegenerative process following KA (Supported by KOSEF 95-0403-19-01-3).

CYCLOOXYGENASE 2 IS INDUCED IN RAT BRAIN AFTER KAINATE INDUCED SEIZURES AND PROMOTES NEURONAL DEATH IN CA3 HIPPOCAMPUS. S.H. Graham*, K. Kawaguchi, L. Zhu, and J. Chen. Department of Neurology, University of Pittsburgh, Pittsburgh PA 15261.

Two forms of cyclooxygenase (COX), the enzyme that catalyzes the conversion of arachidonic acid (AA) into prostaglandins, have recently been cloned. The second form, COX2, is the predominant form expressed in brain and is an immediate early gene that is induced by synaptic activity. COX produces an oxygen free radical as a byproduct of its AA metabolism; therefore, COX2 expression could have a role in epileptic neuronal injury. To address this hypothesis, we studied COX2 mRNA and protein expression after kainate-induced limbic seizures in rats and determined the effects of inhibition of COX2 upon neuronal death in CA3 hippocampus. COX2 protein and mRNA expression was studied by Northern, in situ, Western and immunocytochemical techniques 24 hr after 10 mg/kg kainate s.c. 3 mg/kg of the highly selective COX2 inhibitor SC58125 was administered p.o. 30 min prior to and 24 and 48 h after an injection of 2μg/kg of kainate i.c.v. an additional dose of 3mg/kg of SC58125. After 60 min of type IV seizure activity, 6 mg/kg of lorazepam was given i.v. to terminate seizure activity. Neuronal death was assessed by counting surviving neurons in cresyl violet stained sections obtained at 7 d. COX2 mRNA expression was induced throughout limbic cortex at 8 and 24 hr after ischemia. COX2 protein expression was increased in CA3, dentate gyrus, and limbic cortex at 24 hr after ischemia. There was increased survival of CA3 neurons in drug treated rats at 7 d after ischemia. There was no effect of drug treatment on brain temperature. These results suggest that COX2 expression may play an important role in epileptic neuronal injury.

A POINT MUTATION (D79N) OF THE α_{2A} RECEPTOR ABOLISHES THE ANTIEPILEPTOGENIC ACTION OF NOREPINEPHRINE. S. Janumpalli[1], L. S. Butler[1], L. B. MacMillan[2], L. E. Limbird[2*] and J. O. McNamara[1]. [1]Epilepsy Research Laboratory, Depts. of Medicine, Neurology, and Neurobiology, Duke University Medical Center, Durham, NC 27710, and [2]Dept. of Pharmacology, Vanderbilt University Medical Center, Nashville, TN 37232.

The kindling model permits study of the mechanisms controlling epileptogenesis in the mammalian nervous system. Noradrenergic (NE) neurons residing in the locus coeruleus exert a powerful anti-epileptogenic action, mediated through α_2 subtype of NE receptor (Gellman *et al*, JPET, 1987, 241(3):891-898). Molecular cloning has identified multiple subtypes of α_2 receptors but the identity of the α_2 receptor subtype responsible for this anti-epileptogenic action is unknown. Also unknown is the mechanism by which the α_2 receptor mediates this action. To begin to address these questions, we examined the rate of kindling development in mice carrying a point mutation (D79N) in the α_{2A} receptor gene that perturbs receptor-effector interactions, created by gene targeting strategies. Both wild-type (WT) (n=21) and homozygous mutant (MT) (n=20) mice underwent stereotaxic implantation of an electrode in the amygdala. The rate of kindling development was measured by the number of stimulations required to trigger three consecutive clonic motor seizures. The mutation markedly accelerated the rate of kindling development (WT 15.6 ± 1.48 vs. MT 6.0 ± 0.52 stimulations, $p < 0.001$). Moreover, the effects of the mutation were sufficient to account for all of the effects of a systemically administered α_2 antagonist; that is, the rates of kindling development were equivalent in MT mice treated with saline (6.0 ± 0.52) and WT (6.9 ± 0.37) or MT (6.8 ± 0.47) mice treated with idazoxan (3 mg/kg IP). These findings demonstrate that the α_{2A} subtype of α_2 receptors mediates the anti-epileptogenic effects of endogenous NE. KNOCK-DOWN OFα SUBUNIT OF CALCIUM/CALMODULIN- DEPENDENT KINASE II REDUCED INHIBITORY POSTSYNAPTIC CURRENTS AND INCREASED EXCITABILITY IN CULTURED HIPPOCAMPAL NEURONS. S. Sombati*, E.M. Jakoi, L. Severt, S.B.Churn and R.J. DeLorenzo. Department of Neurology, Medical College of Virginia, Richmond, VA 23298.

Calcium/Calmodulin-dependent kinase II (CaM-KII) plays an important role in modulating synaptic receptor channels and neurotransmission. Alteration in the activity of this enzyme has been shown in various several animal seizure models. Since CaM-KII phosphorylation has been shown to increase GABA and inhibitory postsynaptic currents in CNS neurons (J.Neurophysiol, 1995:73;2099). This study was initiated to determine whether knock-down of CaM-KII would affect inhibitory postsynaptic and GABA receptor currents and cause hyperexcitability in cultured hippocampal neurons. Neonatal hippocampal neurons were cultured at high density and used for experiments after 2 weeks in culture. Antisense strategy was employed by applying antisense oligodeoxynucleotides (3 μM, ODN) daily for 3 days to the cultures. Control cultures (n=10 plates) were treated with matching missense oligodeoxynucleotides (n=10 plates). Western blot analysis showed approximately 40% reduction in CaM-KII immunoreactivity in treated neurons compared to those of the control (n=4 plates) The effects of α CaM-KII knock-down on miniature IPSC amplitudes were studied using whole-cell voltage clamp techniques. The treatment resulted in a 38.92±3.26% reduction in mIPSC amplitudes. Similar results were also observed with GABA receptor currents. Whole-cell intracellular recordings revealed that treated cells exhibited long duration epileptiform bursts (1-3sec). Each burst exhibited a large depolarization (30-40 mV) containing 10-20 spikes. This "seizure" activity of 3-8 Hz was consistently observed. Antisense-treated cells did not show this activity. The results indicate that knock-down of CaM-KII α subnit resulted in down regulation of the protein which in turn reduced IPSC and GABA current amplitudes. The reduction of CaM-KII- mediated GABA functions may underly an increase in the excitability of hippocampal neurons.

WIDESPREAD INCREASE OF BRAIN-DERIVED NEUROTROPHIC FACTOR PROTEIN IN THE RAT FOREBRAIN AFTER KINDLING-INDUCED SEIZURES. E. Elmér, Z. Kokaia, M. Kokaia, J. Carnahan[1], H. Nawa[2], J. Bengzon* and O. Lindvall. Section of Restorative Neurology, Department of Clinical Neuroscience, Wallenberg Neuroscience Center, S-221 85 Lund, Sweden; [1]Amgen Center, Thousand Oaks, California 91320, USA; [2]Brain Research Institute, Niigata University, Niigata 951, Japan.

Kindling is one of the most extensively studied animal models of epilepsy and neural plasticity. The mechanisms underlying the development and permanence of the increased excitability in kindling are presently poorly known. The neurotrophins have been implicated in the plastic responses occurring in kindling and, in addition, in the potentiation of synaptic transmission. The kindling-induced changes of brain-derived neurotrophic factor (BDNF) mRNA expression have been characterized in detail, while the tissue levels of the translated BDNF protein have not been assessed. Using a recently developed two-site enzyme immunoassay we have measured the basal and seizure-induced levels of BDNF protein in various forebrain areas in Sprague-Dawley rats at 2, 6, 24, 96 h and 1 and 4 weeks following 40 rapidly recurring seizures evoked by hippocampal kindling stimulations. The tissue content of BDNF in the dentate gyrus increased to 194 % of control values (maximum at 6-24 h) and remained elevated at 96 h after the last stimulation. In the CA1 and CA3 regions, the BDNF levels increased to 127 and 149 % of control, respectively (maximum at 6-24 h). In the piriform cortex, the response was more rapid with maximum increase at 2h (to 282 % of control) and return to basal values at 24 h. No significant changes of BDNF levels were found at 1 and 4 weeks. The results of this study show that the previously demonstrated increases of BDNF mRNA expression induced by hippocampal kindling lead to the presumed alterations of BDNF protein levels. The long-lasting increases of BDNF protein content after rapid hippocampal kindling are in good agreement with a role for BDNF in triggering plastic events and in modulating synaptic function.

DIFFERENTIAL DISPLAY SCREENING FOR CHANGES IN LONG TERM GENE EXPRESSION IN A HIPPOCAMPAL MODEL OF RECURRENT SPONTANEOUS SEIZURES. T. A. Morris[1]*, R. E. Blair[2], S. M. Taylor[3] and R. J. DeLorenzo[1], [1]Depts. of Neurology; [2]Pharmacology and Toxicology; and [3]Microbiology and Immunology, Medical College of Virginia, Richmond, VA 23298.

Epilepsy is the result of long term changes in neuronal plasticity. This change is likely derived from, or at least affected by, alterations in normal gene expression. We have developed an *in vitro* model of epilepsy in which cultured hippocampal neurons (HN) are exposed to Mg^{2+}-free media for 3 hours resulting in permanent recurrent spontaneous seizure activity [Sombati and DeLorenzo, *J. Neurophys.* (1995)73:1706]. We are using differential display PCR to identify any genes whose expression is altered at the mRNA level in the 'epileptic' HN model. Total RNA was isolated from control and 'epileptic' cells, reverse transcribed using $(T)_{12}XY$ primers and semi-quantitatively PCR amplified using the end-labeled $(T)_{12}XY$ primer and an array of arbitrary 10 bp primers. The amplified end-labeled cDNAs from treated and control HNs were compared by denaturing electrophoresis and autoradiography. As determined by this technique, the vast majority (>95%) of cDNAs resolved on the gels were expressed at the same levels in treated and control HN cultures. However, several primer sets reproducibly produced cDNA bands which were either increased or decreased in the 'epileptic' state. These cDNAs were excised from the gel, PCR reamplified, cloned, sequenced and used as probes in Northern blotting. Two of the cDNA probes specifically showed differential expression of RNAs on the Northern, matching the changes seen by differential display. These results suggest that epileptogenesis does not alter the expression of the majority of genes in hippocampal neurons. However, by using differential display we have found a few genes whose expression is altered in the epileptic state and whose products may play a role in the genesis and maintenance of epilepsy.

DIFFERENTIAL DISPLAY IDENTIFIES A NOVEL SEIZURE-INDUCED SYNAPTOTAGMIN GENE.

J.M. Babity, J.N. Armstrong, J.-C.L. Plumier, R.W. Currie and H.A. Robertson*.

Laboratory of Molecular Neurobiology, Faculty of Medicine, Dalhousie University, Halifax, N.S., Canada, B3H 4H7.

Differential display polymerase chain reaction was used to search for novel genes expressed in degenerating areas of the rat brain after kainic acid-induced status epilepticus. In this model, kainic acid-induced excitotoxicity leads to neuronal cell death at 24 hours in the dentate hilus and piriform cortex, but not in the parietal cortex. A novel cDNA fragment that is expressed after kainic acid-induced seizures in the hippocampus and the piriform cortex, but not in the parietal cortex was identified. This novel cDNA fragment was cloned, sequenced and found to be a new member of the synaptotagmin gene family. Northern analysis confirmed the differential expression of this synaptotagmin after kainic acid-induced seizures. *In situ* hybridization showed that this synaptotagmin gene was expressed in the dentate granule cells of the hippocampus and layer 2 of the piriform cortex, but not in the parietal cortex. This new synaptotagmin gene may be part of a direct link between depolarization-induced neuronal gene expression and excitotoxic neuronal degeneration.

EPILEPSY: BASIC MECHANISMS—MORPHOLOGICAL STUDIES

819.1

NEURITE ARBORIZATION OF FETAL LOCUS COERULEUS (LC) NEURONS IN VITRO: ANALYSES OF SUBSRATES, CYTOSINE-ARABINOFURANOSIDE AND CO-CULTURES IN PREPARATION FOR STUDIES ON EPILEPSY. R.W. Clough*, B.R. Peterson, J.B. Eells, R.A. Browning, J.L. Steenbergen, P.K. Mishra, P.C. Jobe. Dept. of Anat., Southern Il. Univ. Sch. of Med., Carbondale, IL 62901 and Dept. of Biomed. and Therapeutic Sci., Univ. of Il. Coll. of Med.-Peoria, Peoria, IL 61656.

Genetically epilepsy-prone rats (GEPRs) have a paucity of noradrenergic (NA) terminals in several target brain structures including the tectum. Moreover, GEPRs have distinctly fewer NA axons within select areas of the brain. It is unknown whether the reduced NA profiles result from 1) a primary deficiency of LC neurons or 2) the microenvironment to which they grow. The present studies are designed to investigate the capacity of fetal NA neurons obtained from GEPRs or control rats to develop terminal aborizations of noradrenergic neurons within co-cultured explants or dispersed cell cultures obtained from epileptic or control hosts. Several culture techniques were investigated with control tissues to ascertain the appropriate culture conditions, substrate type, age of donor tissues, effects of glial inhibition and other factors. Experiments were performed on organotypic explants or dispersed cell cultures obtained on fetal days 14 through 17 of gestation. Substrates analyzed for the ability to support neuritogenesis included Matrigel, Cell-Tak, poly-d lysine, and Fibronectin F. The effect of cytosine-arabinofuranoside (ARA-c) inhibition of glial-like cell growth was assessed using variant concentrations of ARA-c. Neurite arborization of noradrenergic neurons was assessed by immunocytochemical identification of tyrosine hydroxylase. We found the most favorable combination of culture parameters to include either dispersed cell or organotypic cultures, Fibronectin F or Cell-Tak substrate, day 14 gestation tissues, no use of ARA-c and the presence of co-cultured tectal tissue. Comparative cultures of epileptic tissues are in progress. Supported by SIUSM and UICOM-P.

EFFECTS OF SPROUTING OF MOSSY FIBERS ON THE NEURONAL ACTIVITY OF DENTATE GRANULE CELLS ANALYZED BY OPTICAL RECORDINGS. Y.Otsu[1], T. Iijima[2], H. Ohata[1], M. Ichikawa*[2], E. Maru[1]

(1) Nippon Medical School, Japan, (2) Electrotechnical Lab., Japan

In the kainate-treated (KA) rat, an animal model of temporal lobe epilepsy, mossy fibers have been known to sprout and project into the supragranular layer of the hippocampal dentate gyrus. It is proposed that the sprouted mossy fibers form excitatory recurrent circuits resulting in the hyperexcitability of granule cells. To test this hypothesis, we studied the neural responses of granule cells in KA-treated rats with an optical recording technique, which allowed the analyses of changes in spatio-temporal pattern of neural activities of granule cells by the sproutings. In 14 slices out of 24, prepared from KA rats (n=6), an electrical stimulation to the hilar region caused optical signals in the molecular layer, near the cell bodies of granule cells, each of which was consisted of an initial spike-like component and a following slow and large upward deflection of signal which lasted about 100 msec. The second phase of the optical signal was obviously smaller in the outer portion of the molecular layer. In those slices, dense sproutings were detected anatomically in the supragranular layer. By removing extracellular Ca^{2+}, the latter component, probably reflecting slow membrane depolarizations, was diminished, although the initial fast component remained. In the presence of bicuculline (10μM), the size and duration of the slow depolarizations, but not the initial ones, increased. Therefore it was concluded that the initial fast depolarizations and the following slow depolarizations corresponded to antidromic spikes and excitatory synaptic responses, respectively. In the other 10 slices the latter phases were generally smaller and shorter, and the sproutings were also weaker. Compared with those slices of KA rats, in the slices of intact rats (control) the optical signals in the molecular layer did not exhibit the slow depolarizations. These results suggest that the slow and large depolarizations observed in the slices of KA rats were originated from the sprouting of the mossy fibers and it contributes to the hyperexcitability of granule cells which may be a cause of hippocampal seizure.

819.3

BLOCKADE OF MOSSY FIBER SPROUTING DO NOT AFFECT THE OCCURRENCE OF SPONTANEOUS RECURRENT SEIZURES IN THE PILOCARPINE MODEL. B.M. Longo* and L.E.A.M. Mello, Depto. Fisiologia, UNIFESP-EPM, 04023-900, São Paulo, Brazil.

Neuronal death and aberrant synaptic reorganization and dendritic patterns are important features of the pilocarpine model of epilepsy. Here we evaluated whether the blockade of protein synthesis can prevent the supragranular mossy fiber sprouting (MFS) promoted by pilocarpine-induced status epilepticus (SE) and the associated spontaneous recurrent seizures. Adult, male Wistar EPM-1 rats were injected with a protein synthesis inhibitor, cycloheximide (CHX) (1mg/kg, s.c.), 1 h before the induction of SE with pilocarpine (320mg/kg, i.p.). Controls were injected with pilocarpine only. After SE, animals were behaviorally observed for approximately 60 days, 5 h/day, 5 days/week, for the occurrence of generalized spontaneous recurrent seizures (SRS). The animals were then processed with the Neo-Timm staining to visualize granule cell mossy fibers. Cell counts in the 40μm thick Nissl-stained sections were performed in the hippocampal complex. Our results showed that a single injection of CHX was enough to dramatically decrease MFS and neuronal death, but not the frequency of SRS. These data suggest that the MFS might be an epiphenomenon, i.e., the new circuitry being neither excitatory nor inhibitory in nature. Alternatively, SRS seizures in the pilocarpine model might be multifocal and not primarily rely in the MFS. In any case, our data clearly indicates a mean through which is possible to block MFS and assess its involvement in different models of epilepsy.

PLASTICITY OF THE GRANULE CELL-MOSSY FIBER SYSTEM FOLLOWING KAINIC ACID INDUCED SEIZURES. Q. Yang*, S. Wang, A. Hamberger and K.G. Haglid. Dept. Anatomy Cell Biology, University of Göteborg, 413 90 Göteborg, Sweden.

Kindling and kainic acid (KA) induce a structural reorganisation of mossy fibers and spontaneous recurrent seizures. Alterations of granule cell properties may be possible mechanisms. We have investigated dynamic alterations of calbindin, a calcium binding protein proposed to be an intracellular buffering system, and neurofilaments, major cytoskeletal components of neurons, in the rat hippocampus after the KA administration. The immunoreactivity for phosphorylated heavy weight neurofilament (pNFH) and non-phosphorylated heavy weight neurofilament (npNFH) decreased in the CA1 field and inner molecular layer of the dentate gyrus 3 and 10 days after the KA administration. The calbindin immunoreactivity decreased slightly in the CA1/CA2 during 1 and 3 days, and was almost lost in the pyramidal layer at day 10. After 10 days, npNFH immunoreactivity appeared in the mossy fibers, in which it is normally absent. From day 21, the immunoreactivity of pNFH and npNFH was normalised or above normal in the CA1 stratum lacunosum-moleculare, mossy fibers, hilus and inner molecular layer of the dentate gyrus. In the meantime, the calbindin immunoreactivity decreased in dendrites and soma of the granule cells and mossy fibers. These alterations in the later phase remained at least to day 90. The reappearance and increase of the neurofilament immunoreactivity in the inner molecular layer of the dentate gyrus probably reflects a collateral extension of the granule cell axons known as mossy fiber sprouting. The delayed decrease of calbindin has a time course similar to that of spontaneous recurrent seizures, suggesting a correlation in the two events. SPROUTED MOSSY FIBERS OF DENTATE GRANULE CELLS FUNCTION DURING SELF-SUSTAINED SEIZURE IN KINDLED RAT. H. Ohata[1], Y. Otsu[1], E. Maru[1] and Y. Kawakami[2]*. [1]Dept. of Physiol., Nippon Medical School, Tokyo 113, Japan [2]Dept. of Physiol., Tokyo Women's Medical College, Tokyo, 162, Japan

Aberrant mossy fiber sprouting into the supragranular layer in epileptic animals has been suggested to provide a recurrent excitatory circuit which may lead to hyperexcitability in dentate granule cells. To address the functional consequences of sprouting on granule cell excitability, current source density analysis was used to investigate the spatial and temporal patterns of membrane currents evoked in dentate gyrus by perforant path stimulation and during self-sustained seizure activity in kindled rats under pentobarbital-anesthesia. Stimulation of perforant path fibers evoked a monosynaptic population excitatory postsynaptic current (EPSC) in the middle molecular layer (200µm from the soma of the granule cells) and then evoked a population spike (PS) current in the somatic layer. In kindled rats, following the monosynaptic EPSC and PS current, a late population EPSC (late EPSC) appeared in the supragranular layer (50µm from the soma of the granule cells). The late EPSC was not observed in control rats. An appearance of the late EPSC depended on the granule cell discharge and had a general correlation with the degree of mossy fiber sprouting shown by Timm staining. The latency between the onset of PS current and that of late EPSC was from 0.5 to 1.1 ms. The late EPSC, therefore, appeared to be induced through a recurrent excitatory circuit formed by mossy fiber sprouting. Although the late EPSC evoked no further firing in dentate granule cells, e.g. repetitive PS firing before seizure occurrence, during seizures a population EPSC resembling the late EPSC appeared spontaneously and repetitively in the supragranular layer and initiated repetitive PS firing. These results support the hypothesis that mossy fiber sprouting induces hyperexcitability in dentate granule cells and potentiates seizure activities.

THE ROLE OF THE CHOLINERGIC SYSTEM IN KINDLING-INDUCED MOSSY FIBER SPROUTING **B. Adams[1]*, P. Osehobo[2], M. Sazgar[2], M. Fahnestock[2] and R.J. Racine[1]** [1]Department of Psychology, McMaster University, Hamilton, Ont., Canada, L8S 3K1, [2]Department of Biomedical Sciences, McMaster University, Hamilton, Ont., Canada, L8S 3Z5

We recently demonstrated that intraventricular (ICV) infusion of antibodies to NGF retards kindling rates, inhibits mossy fiber sprouting, and decreases the ChAT immunostaining density of cholinergic neurons in the medial septum and the vertical diagonal band of Broca by 33% (Van der Zee et al., 1995). To date, it is not clear how anti-NGF mediates these effects. One possibility is that anti-NGF acts indirectly via the cholinergic system. Although there is ample evidence showing that the cholinergic system is involved in kindling (for review see Cain, 1989), there is no experimental data showing that the cholinergic system is involved in kindling-induced mossy fiber sprouting. Given that ICV-infused anti-NGF decreases the synthesis of acetylcholine (Ach) in the basal forebrain cholinergic neurons, it is possible that this decrease in basal forebrain Ach levels may retard the rate of kindling and may also inhibit kindling-induced mossy fiber sprouting. The purpose of this study is to determine whether the cholinergic system mediates kindling and kindling-induced sprouting effects. Rats were kindled twice a day for 11 days and were injected with either a cholinergic agonist (pilocarpine; 10 mg/kg), distilled water (control group), or a cholinergic antagonist (scopalomine; 15 mg/kg) 30 minutes prior to each kindling stimulation. Rats injected with pilocarpine kindled significantly faster than control rats ($p<0.001$), whereas rats injected with scopalomine kindled significantly slower than the controls ($p<0.001$). Mossy fiber sprouting data from both kindled and non-kindled rats treated with either pilocarpine, scopalomine, or water will be reported. (Supported by grants from the Medical Research Council of Canada and the NCE Neuroscience Network to M.F. and R.J.R. 819.7

GLIAL CELL HYPERTROPHY AND KINDLING-INDUCED INCREASES IN HILAR AREA **M. Sazgar[1]*, B. Adams[2], P. Osehobo[1], L.White[2], M. Fahnestock[1] and R.J. Racine[2]** [1]Department of Biomedical Sciences, McMaster University, Hamilton, Ont., Canada, L8S 3Z5, [2]Department of Psychology, McMaster University, Hamilton, Ont., Canada, L8S 3K1

We recently found that amygdala kindling twice a day for 11 days significantly decreases neuronal density by approximately 15% in adult male Long-Evans rats compared to non-kindled, implanted controls. In addition, hilar area was significantly increased by approximately 15% in these kindled rats compared to non-kindled controls. These results suggest that kindling-induced decreases in neuronal density may be explained by kindling-induced area changes rather than changes in neuronal number. To date, the mechanisms underlying this effect are not known. One possibility is that kindling-induced increases in hilar area are due to an expansion of glial processes (Bertram & Lothman, 1993). Evidence supporting this hypothesis is provided by previous findings that: 1) kindling increases glial fibrillary acidic protein (GFAP) levels, not only in the kindled site, but also in areas synaptically activated by the resultant seizures and 2) kindling of the amygdala results in astrocyte hypertrophy in a number of brain regions, including the hilar region of the hippocampus (Khurgel et al., 1990). The purpose of this study is to determine whether kindling-induced increases in hilar area are related to kindling-induced changes in glial cell size and/or number. Results from GFAP immunostaining and hilar area measurements will be reported for both kindled and non-kindled animals.

MANIPULATIONS OF ASTROCYTES LEAD TO CHANGES IN SEIZURE THRESHOLD. M. Khurgel*, S.C.Barsoum, N.W. Milgram and G.O. Ivy. Depts. Anatomy & Cell Biology and Psychology, University of Toronto, Scarborough, M1C 1A4, Canada.

Astrogliosis is invariably observed in clinical and experimental epileptic foci. The hypothesis that gliosis contributes to epileptogenesis was tested by inducing gliosis prior to kindling, or by eliminating astrocytes prior to or following kindling.

Adult rats were implanted with a cannula + 2 electrodes assembly aimed at the piriform cortex. The threshold for afterdischarges (ADT) was determined before and after a single, 5 µl injection of one of the following: 1) saline, 2) basic fibroblast growth factor (bFGF, 50 µl/µl, in saline), or 3) L-alpha-aminoadipate (aAA, 20 µg/µl, in saline). Subsequently, the animals were kindled at the post-injection ADT intensity. Following the establishment of kindling, the animals were injected with either saline or aAA, and tested for changes in ADT.

Injections of bFGF resulted in a widespread "gliosis", characterized by an apparent hypertrophy of astrocytes, as well as an **increase** in ADT. Ablation of astrocytes with aAA prior to kindling resulted in a **decrease** in ADT. Injections of saline also lowered ADT. There was no difference in the progression of kindling between the groups. Injections of aAA following the establishment of kindling resulted in a large **increase** in ADT as compared to post-kindling injections of saline.

The results suggest that the initial hypertrophy of astrocytes, which has been shown to occur in response to seizures, is not epileptogenic. The results also suggest that an increase in the levels of bFGF, demonstrated in several models of epilepsy, is an adaptive response.

EXAMINATION OF THE ROLE OF THE SUPERIOR COLLICULUS IN GENERALIZED TONIC-CLONIC SEIZURES AND BRAINSTEM EVOKED FOREBRAIN SEIZURES. M.A. Merrill[1]*, R.W. Clough[1], P.C. Jobe[2] and R.A. Browning[1]. [1]Southern Illinois Univ. Sch. Med., Carbondale, IL 62901 and [2]Univ. Illinois Coll. Med., Peoria, IL 61656.

Generalized tonic-clonic (GTC) seizures in Genetically Epilepsy-Prone Rats (GEPRs) are of brainstem origin. Recent data suggest that the superior colliculus (SC) is part of the GTC seizure propagating pathway in GEPRs. For example, knife cuts interrupting connections between the inferior and superior colliculi reduced sound-induced GTC seizure severity in GEPR-9s (Ribak et al. 1994). Further, infusions into the SC of drugs which increase extracellular norepinephrine attenuated GTC seizures (Jobe et al. 1994). Therefore, it was of interest to determine if lesions of the SC alter audiogenic seizure (AGS) behavior in GEPR-9s. In the present study male GEPR-9s (350 - 480g) received bilateral electrolytic lesions of the SC and their response to an audiogenic stimulus (110db) was evaluated 1 - 2 weeks later. Animals were grouped according to lesion location and size. Rats with lesions damaging 80% of the SC including deep layers displayed a marked reduction in seizure severity (median response score = 1) compared with sham-operated controls (median response score = 9) ($P < 0.05$). Repetition of brainstem seizures result in a progressive propagation of epileptic discharge to the forebrain. Inasmuch as the SC appears to be part of the propagation pathway for brainstem seizures, it was of interest to determine if the SC is involved in the propagation of seizures from brainstem to forebrain following repeated AGS (referred to as audiogenic kindling). Unexpectedly, 83% of the SC lesioned GEPR-9s displayed facial and forelimb clonus (FFC; a forebrain seizure marker) by the 9th AGS, while none of the sham-operated controls displayed FFC at this time. Furthermore, only 33% of the controls showed FFC by the 24th AGS. The present findings show that while lesions of the SC attenuate the expression of brainstem seizures, they appear to facilitate the transfer of seizure activity from brainstem to forebrain. PERIAQUEDUCTAL GRAY NEURONS EXHIBIT INCREASED RESPONSIVENESS ASSOCIATED WITH AUDIOGENIC SEIZURES IN THE GENETICALLY EPILEPSY-PRONE RAT. **P. N'Gouemo* and C.L. Faingold.** **Department of Pharmacology Southern Illinois University School of Medicine Springfield, IL 62794-1222.**

Neuronal Fos expression and microinjection studies indicate that the ventrolateral periaqueductal gray (PAG) is a component in audiogenic seizure (AGS) network in the genetically epilepsy-prone rat (GEPR-9), which exhibits tonic seizures. The present study examined changes in PAG neuronal responses in the awake and behaving GEPR-9 and normal Sprague-Dawley rats. Acoustic stimulation consisted of 12 kHz tone bursts (100 ms duration, 5 ms rise-fall, at 1/2s and 1/s), which was effective in evoking AGS at high intensities. Neuronal responses were analyzed using poststimulus time histograms. Recordings involved 27 PAG neurons in the GEPR-9 and 20 neurons in normal rats. Most PAG neurons in both GEPR-9 (84%) and normals rats (70%) responded at long latencies (>10 ms). The mean PAG acoustic response threshold of these neurons in the GEPR-9 (94.00±1.3) was significantly ($p<0.01$) elevated as compared to normals (87.9±1.4). The mean PAG firing rate was also significantly elevated in the GEPR-9, particularly at the highest acoustic intensity, as compared to normals. Repetition-induced attenuation (habituation) at 1/s vs. 1/2s was observed in PAG neurons. During AGS in the GEPR-9, PAG neurons overcame this habituation and exhibited a tonic firing pattern just prior to the onset of tonus. Phenytoin (10 mg/kg, i.p.) and tiagabine (11 mg/kg, i.p.) reduced PAG neuronal firing and concurrently suppressed AGS susceptibility. Thus, PAG neurons were activated prior to tonus, which was blocked by anticonvulsant drugs. These data suggest the critical involvement of PAG neurons in the AGS network for tonic seizures in the GEPR-9. **(Support NIH NINDS NS 21281).**

820.3

SEIZURE PREDISPOSITION AND NORADRENERGIC (NA) TERMINAL FIELDS IN THE SUPERIOR COLLICULUS (SC) OF GEPR-9s *P.K. Mishra*, N.P. Bhosale, N.J. Shah, J.W. Dailey and P.C. Jobe*, Department of Biomedical and Therapeutic Sciences, University of Illinois College of Medicine, Peoria, IL 61656.

The level of NA transmission in the brain is reciprocally linked to the magnitude of seizure predisposition in genetically epilepsy-prone rats (GEPR-3s and GEPR-9s). Neuroanatomical studies show that in GEPR-3s NA seizure regulation occurs in the SC and ventrally adjacent areas. Desipramine infusion with microdialysis probes elevates extracellular NE levels in the SC and abolishes sound-induced generalized clonus but not running episodes in GEPR-3s. This observation is compatible with the concept that amplification of an auditory impulse into a seizure occurs in the SC or in a region regulated by the SC. In the present study, desipramine (30-200 mM in artificial cerebrospinal fluid) was infused into the central portion of the SC of twelve GEPR-9s. Continuous 5 minute microdialysis samples before and after infusion of desipramine were analyzed using an on-line microbore HPLC-EC system. When norepinephrine elevation was at its peak, animals were acoustically stimulated and seizure severity was determined. No significant alterations were observed in seizure intensity in these GEPR-9s which suggests that structures outside those exposed to the dialysate in the SC underlie the tonic elements of a GEPR seizure. Also, current data support the hypothesis that, compared to GEPR-3s, the GEPR-9s have greater level of seizure predisposition because they have an absence of NA seizure regulation in the central portion of the SC. Since experimentally induced global increments in NA transmission produce anticonvulsant effects in GEPR-9s, NA terminals outside the SC appear to play seizure determinant roles. Other data suggest that these terminals reside in the pons/medulla and/or in the ventrolateral edge of the SC.

820.4

PROTECTION AGAINST ABSENCE-LIKE AND GENERALIZED SEIZURES INDUCED BY THE ORGANOPHOSPHATE TRIMETHYLOLPROPANE PHOSPHATE (TMPP). G.D. Ritchie*[1], J. Rossi III, A. Nordholm, C.Y. Ademujohn[1], C. Onyika, J. Smith and A. Walsh. Naval Medical Research Institute-Detachment (Toxicology) and [1]Geo-Centers, Inc., Wright-Patterson AFB, OH 45433-7903.

Trimethylolpropane phosphate (TMPP), a potent neuroconvulsant produced through partial pyrolysis of certain synthetic turbine lubricants, has been shown to induce absence-like as well as clinical seizures through interference with the $GABA_A$ receptor. Spontaneously epileptic Fischer-344 or non-epileptic Sprague-Dawley rats were implanted with EEG electrodes, then protected with one of eight common anticonvulsant drugs (ethosuximide, sodium valproate, diazepam or clonazepam, MK-801, phenytoin, CGP 35348, vigabatrin, or phenobarbital) before single or repeated ip injection with TMPP (0.1-0.4 mg/kg) PTZ (20-50 mg/kg), GHB (25-50 mg/kg) or baclofen (1-5 mg/kg). The relative ability of each drug to protect against or reduce absence-like SWDs, sub-clinical seizures and clinical convulsions was evaluated. Animals were subsequently evaluated, as long as 30 days post-treatment, for the presence or absence of long-term sensitization effects as measured by EEG paroxysms or increased susceptibility to audiogenic seizures.

LONG-TERM BEHAVIORAL SENSITIZATION INDUCED BY A BRIDGED ORGANOPHOSPHATE J. Rossi III*, M.Y. Bekkedal, B. Knutson, G. D. Ritchie, and J. Panksepp. Tri-Service Toxicology Consortium, Wright-Patterson AFB, OH and Psychology Department, Bowling Green State University, Bowling Green, OH.

Trimethylolpropane phosphate (TMPP) is a bridged organophosphate that can be produced by the partial pyrolysis of certain synthetic lubricants. Last year, we reported data demonstrating that doses of TMPP that yield no convulsive behaviors or other indication of altered neural activity, induced long-term behavioral sensitization to an amphetamine challenge. This year, we extended these findings by demonstrating that sub-convulsive doses of TMPP are capable of inducing long-term sensitization in acquisition of schedule-induced polydipsia (SIP) as well as in appetitive reinforcer approach (ARA) duration. Male Long-Evans rats were used. They were injected (ip) with either 0.20 mg/kg of TMPP or vehicle on seven consecutive days. Thirty days following the last injection, the animals were evaluated for SIP using an SIP procedure in which 45 mg food pellets were unconditionally delivered at a frequency of 1 pellet/min for a 1-hour session. TMPP reliably reduced the number of SIP sessions necessary to induce asymptotic drinking levels. For ARA testing, rats were injected (ip) with TMPP (0.10 or 0.20 mg/kg) or vehicle equivalent on several different schedules. Fourteen to thirty days following the last injection, rats were placed in a modified open-field chamber that contained 'fenced off' raw hamburger meat in two adjacent corners of the chamber. TMPP reliably increased the sniffing duration for the hamburger reinforcer. These results suggest that TMPP produces physiological changes that persist much longer than the pharmacological effect of the compound.

820.6

TMPP MICROPERFUSIONS INTO THE NUCLEUS ACCUMBENS OF THE RAT: NEUROBEHAVIORAL AND NEUROCHEMICAL EFFECTS J.W. Lindsey*[1], S.L. Prues[2], C. Alva[1], G.D. Ritchie[2], and J. Rossi III[1]. [1]Naval Medical Research Institute-Detachment (Toxicology) and [2]Geo-Centers, Inc., Wright-Patterson AFB, OH 45433-7903.

Trimethylolpropane phosphate (TMPP) induces sub-clinical behavioral seizures, such as forequarter-jerking and twitches that are correlated with EEG paroxysms in Sprague-Dawley rats. EEG paroxysms, neurobehavioral activity, and changes in neurotransmitter levels were investigated in association with TMPP microperfusions into a nucleus believed to be associated with seizure induction or recruitment. Rats were implanted with cortical EEG electrodes. The tip of microdialysis probes were implanted within the nucleus accumbens of the rat. Microperfusions of TMPP directly into the nucleus accumbens via the microdialysis probe resulted in an increase in hyperlocomotor activity, forequarter-jerking, and stereotypic behaviors, such as defensive burrowing and activated sniffing in rats. A video editing system was used in the recording and analyses of behavioral seizure activity. A neurobehavioral activity profile was developed and correlated with specific neurochemical changes. Microdialysis samples were collected and analyzed via HPLC with electrochemical detection for changes in the catecholamines, norepinephrine (NE) and dopamine (DA). Changes in these catecholamines were temporally correlated with the neurobehavioral activity profile. Repeated microperfusions of the neurotoxicant resulted in sensitization of EEG paroxysms and stereotypic behavior (activated sniffing) in Sprague-Dawley rats. Spontaneous spike-and-wave discharges were observed in the cortical EEG of rats treated with TMPP. Overall behavioral seizure activity decreased following repeated microperfusion of the nucleus accumbens with TMPP. In some cases, *in vivo* electrochemistry was used to increase the temporal resolution in correlating behavioral seizure activity with changes in neurotransmitters.

820.7

REPEATED EXPOSURE OF TRIMETHYLOLPROPANE PHOSPHATE (TMPP) INDUCES MESOLIMBIC DOPAMINE SYSTEM SENSITIZATION IN MALE RATS. J. Lin*, J. Cassell[1] and J. Rossi III[1] ManTech Environmental Technology Inc., P.O. Box 31009, Dayton, OH 45437-0009 and [1]Naval Medical Research Institute, Detachment-Toxicology, Wright-Patterson AFB, OH 45433-7903.

The actions of a potent organophosphate convulsant trimethylolpropane phosphate (TMPP) were tested on the mesolimbic dopamine pathway of freely moving rats using *in vivo* stimulating-recording electrophysiological techniques. The effects of known convulsants pentylenetetrazol (PTZ) and N-Methyl-β-carboline-3-carboxamide (FG-7142) were also tested and compared with that of TMPP. Stimulating/recording electrodes were implanted in the nucleus accumbens (NAc) and ventral tegmental area (VTA) of male Sprague-Dawley rats. TMPP (0.275 mg/kg), PTZ (20 mg/kg), FG-7142 (7.5 mg/kg) or vehicle (0.5 ml/kg) were administered i.p. to rats 3 times/week for 10 weeks (n=5 per group) and local electroencephalogram (EEG) were recorded from both NAc and VTA, 20 min and 24 hr following the drug administration. TMPP, PTZ and FG-7142 induced spontaneous myoclonic jerks or clonic seizures and epileptiform discharges in both NAc and VTA 20 min following each drug administration, after three, seven and eight weeks of drug treatment, respectively. However, 24 hr following drug administration, spontaneous behavioral and local EEG change were not observed. Electrical stimulation (0.1 Hz, 0.1 ms duration, 6-12 V) of VTA, evoked both behavioral jerking and NAc electrographic seizures (after discharge) in 100% of TMPP (0.275 mg/kg, after 16th dose), 80% of PTZ (20 mg/kg, after 21st dose) and 20% of FG-7142 (7.5 mg/kg, 21st dose) treated rats. The animals treated with vehicle solution shown neither immediate nor delayed behavioral and NAc EEG responses to vehicle injection and electrical stimulation of VTA. The present study indicates that long term exposure of rats to low doses of TMPP, PTZ and FG-7142 induces sensitization of mesolimbic dopaminergic pathway. BRAINSTEM-FOREBRAIN INTERACTIONS DURING AUDIOGENIC KINDLING. AN INTEGRATED VIDEO-EEG, NEUROETHOLOGY AND FOS PROTEIN EXPRESSION STUDY. N.Garcia-Cairasco*, M.F.D.Moraes, O.Y. Galvis-Alonso, and [1]E.A.Del Bel. Physiology Department. School of Medicine. [1]Physiology Department. School of Dentistry. University of São Paulo, CEP 14049-900. Ribeirão Preto, SP, Brazil.

Repeated audiogenic seizures (AS) or audiogenic kindling (AK) evoke limbic seizures in AS susceptible (S) rats. This phenomenon does not occur in AS resistant (R) rats. We evaluated behavioral sequences, EEG, and Fos expression, to study brainstem-forebrain interactions during AK development in 16 S and 13 R animals, acoustically (120 dB) stimulated 3 times daily (Video-EEG group; 21 stimuli) and 2 times daily (Fos group; 60 stimuli). Video analysis was done using specific programs (Ethomatic). EEG analysis was done by spikes and bursts detection, with monopolar electrodes in basolateral amygdala (AMY), deep layers of superior colliculus (SC) and parietal cortex. Fos (Cambridge) expression studies were done, 2 hours after a new AS, done after a 2 months interval. Typical AS were correlated with epileptogenic activity mainly in SC. Animals displaying limbic seizures only, presented epileptogenic activity in amygdala and cortex and animals with concomitant brainstem and limbic seizures displayed SC, cortical and AMY activity, which could switch from one "driver" to the other, concomitantly with behavioral changes. Fos expression was very similar in both S and R animals up to the level of inferior colliculus. Medial geniculate nucleus, amygdala, hippocampus, piriform and endopiriform nuclei, among others, were strongly labeled only in S animals. Thus, limbic recruitment occurred after AK and some of these changes (Fos) seemed permanent because they were present after a 2 months interval.

EPILEPSY: BASIC MECHANISMS—TRANSMITTERS AND SECOND MESSENGERS

821.1

LAMOTRIGINE DECREASES THE *IN SITU* ACTIVITY OF TYROSINE HYDROXYLASE IN CAUDATE NUCLEUS OF NORMAL AND SEIZURE-PRONE BALB/C MICE. J.P. Vriend*. Department of Anatomy, University of Manitoba, Winnipeg, Canada R3E 0W3.

Lamotrigine (LTG) is an anticonvulsive agent which blocks sodium channels and inhibits glutamate release. A report of its use in Parkinson's disease (Zipp et al., 1993) led us to examine the effects of LTG on dopamine (DA) metabolism in the striatum. We previously reported that a single IP dose of LTG (in the anticonvulsive range) resulted in substantial reductions in striatal tissue content of the DA metabolies, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) in both normal audiogenic seizure-resistant BALB/c mice (ER) and in audiogenic seizure-prone (EP) BALB/C mice. In the present study we examine the effects of LTG on the *in situ* activity of tyrosine hydroxylase (TH), the rate limiting enzyme in DA synthesis. LTG (20 mg/kg ip) was administered 45 minutes prior to sacrifice. This dose was chosen for its effectiveness in inhibiting audiogenic seizures in the seizure-prone line of BALB/C mice. The *in situ* activity of TH was determined by measuring the accumulation of L-DOPA following the administration of an aromatic L-amino acid decarboxylase inhibitor (m-hydroxybenzylhydrazine, 100 mg/kg). Concentrations of L-DOPA in extracts of striatal tissue punches were determined by HPLC with electrochemical detection. Significant reductions in TH activity were observed in striatum of both ER and EP mice treated with LTG. In the ER line LTG administration was associated with a reduction of TH activity to 75% of saline-injected controls ($p < .05$); in EP mice a reduction to 72% was observed ($p < .001$). These data show that LTG administration inhibits DA synthesis in striatum of mice. A reduction in DA synthesis could account for the previously observed decrease in striatal tissue content of DA metabolites observed in BALB/C mice treated with LTG. Supported by St. Boniface Hospital Research Foundation.

821.2

NIGRAL LESIONS BY DOPAMINE AND 6-HYDROXYDOPAMINE: FOS EXPRESSION AND LIMBIC SEIZURES X. D. Fan, X. Zhang, P.H. Yu, X.-M. Li and A.V. Juorio* Neuropsychiatry Research Unit, Dept. of Psychiatry, University of Saskatchewan, Saskatoon, SK, S7N 5E4, Canada.

The substantia nigra pars reticulata (SNpr) has been proposed to play an important role in controlling the propagation and/or the generation of limbic seizures. Earlier work has shown that SN lesions have differential effects on seizure activity, suggesting that at least two discrete topographical regions mediate anticonvulsant or proconvulsant effects. The present investigation showed that exogenous dopamine (DA: 1.5-2.0 µmole) and 6-hydroxydopamine (6-OH-DA: 0.075-0.1µmole) unilaterally injected into the SNpr induced seizure attacks (wet dog shakes) and Fos oncoprotein expression in the limbic system. These effects were observed in 90% of the rats with anterior SNpr DA injection and in 30% of the rats with anterior SNpr 6-OH-DA injection. Rats with posterior SNpr injection did not show seizure behavior nor Fos expression. These results show for the first time that unilateral DA or 6-OH-DA lesion of the anterior portion of SNpr elicits Fos expression and limbic seizures, while 6-OH-DA does not seem to be so effective as DA in the induction of seizure behavior and Fos expression. In addition, the results suggest that lesion of the anterior and posterior regions of SNpr appear to exert different influences in the generation of limbic seizures. The time course of seizure behavior and Fos expression was also studied. Supported by Saskatchewan Health and Ciba Geigy Canada.

821.3

NITRIC OXIDE DIRECTLY DETERMINED BY ELECTRON SPIN RESONANCE SPECTROSCOPY IS INCREASED IN THE BRAIN CORTEX OF RATS WITH EPILEPTIFORM SEIZURES. *K.S. Rayevsky[1]*, V.G. Bashkatova[1], V.B. Narkevich[1], G.U. Vitskova[1], V.D. Mikoyan[2], A.F. Yanin[2], Inst. Pharmacology RAMS[1], Institute of Chemical Physics RAS[2], Moscow, 125315 Russia.*

Nitric oxide (NO), a highly reactive, short-living radical species, is believed to be a transsynaptic messenger in the brain. It is suggested that an abnormal formation of NO could play a role in the pathophysiology of epilepsy. The aim of the present study was to investigate whether experimental convulsions of different origin are accompanied by increasing NO concentration and lipid peroxidation in the rat brain. Several convulsive models were used: Maximal Electroshock Seizure (MES), Thiosemicarbazide-, Pentilentetrazole-, and NMDA-induced convulsions in rats. NO was trapped in vivo as a paramagnetic mononitrosyl-iron diethyl (DETC) complex, the concentration of which was determined ex vivo by cryogenic electron spin resonance (ESR) spectroscopy. Male Wistar rats (200-250 g) were injected with NO scavenger DETC, 500 mg/kg i.p. simultaneously with the mixture of $FeSO_4$, 37.5 and sodium citrate, 165 mg/kg s.c., 30 min prior decapitation of animals. The ESR -spectra were recorded at 77 K on a Brucker ESR 300 spectrometer at a frequency of 9.33 Ghz, hf-modulation frequency 100 kHz, hf-modulation 0.5 mT, microwave power 20 mW and time constant 0.05 s. The concentration of NO trapped was calculated from the intensity of the third hyper-fine splitting line of resonance at g perpendicular = 2.035 of the NO-iron-DETC complex. Basal NO formation was detected in the brain of control rats. Thiobarbituric acid reactive substances (TBA RS) were measured as index of lipid peroxidation. In all the above-noted models, seizures were followed by nearly 5-fold increase in NO content in the brain. TBA RS content were shown to be increased at the peak of tonic extension phase of the MES in comparison to control. NO signal failed to be detected when N-nitro-L-arginine, an inhibitor of NO synthase, was injected prior to MES application. It is concluded that observed increase in NO formation was due to NOS activation. Whether the endothelial, neuronal, or glial NOS is involved in seizure-triggered NO increase remains to be identified The results are consistent with the hypothesis on a trigger role of NO in pathophysiology of convulsive seizures.

OPIOID PEPTIDE CHANGES INDUCED BY A SINGLE NON-CONVULSANT AMOUNT OF PENTYLENETETRAZOL. A. Cano-Martínez[1], R. Villalobos[2], N. Maidment[3], C. Evans[3] and L. Rocha[1]*. [1]Instituto Mexicano de Psiquiatría and [2]CINVESTAV, México; [3]University of California Los Angeles, USA.

Opioid peptide changes in the brain of rats receiving a single non-convulsive administration of pentylenetetrazol (PTZ) (30 mg/kg i.p.) were investigated. Microdialysis combined with a universal opioid peptide radioimmunoassay (RIA) revealed that extracellular opioid peptide levels in amygdala were elevated (250%) within the first 90 min after PTZ injection, returning to basal conditions 120 min following the administration. Immunoreactive material recovered after PTZ coeluted with Met- and Leu-enkephalin on HPLC/RIA analysis. *In vitro* autoradiography experiments showed that, 24 h after PTZ administration, there is decreased mu receptor binding in parietal (38%), piriform (32%), and entorhinal (27%) cortices; basolateral (33%) and cortical (32%) amygdaloid nuclei and medial thalamic nuclei (25%). Binding assays performed with amygdala samples indicated that reduced mu receptor levels resulted from decrease in the binding capacity (36%). It is suggested that the enhanced opioid peptide release following non-convulsant amounts of PTZ may result in decreased mu receptor binding. (Supported by CONACyT grant 3918-N9402).

KAPPA OPIOIDS DECREASE THE SEVERITY OF PILOCARPINE-INDUCED SEIZURES IN THE RAT S.B. Bausch*, T.M. Esteb, G.W. Terman and C. Chavkin Depts. of Pharmacology and Anesthesiology, University of Washington, Seattle, WA 98195

The pilocarpine model of temporal lobe epilepsy was used to investigate the effects of kappa opioids on both behavioral motor seizures and on the pathology associated with temporal lobe epilepsy. Rats pretreated with 20 mg/kg, i.p. of the kappa opioid receptor agonist, U50,488 (U50), prior to injection with 325-375 mg/kg pilocarpine exhibited a 65% decrease in the length of the longest motor seizure and a 92% increase in the latency to first seizure when compared to rats pretreated with saline. These behavioral effects of U50 were blocked by pretreatment with 10 mg/kg, i.p. of the kappa$_1$ opioid receptor antagonist, norbinaltorphimine (norBNI). Histological analysis showed that pilocarpine alone caused a significant increase in mossy fiber sprouting and an approximately 40% decrease in the number of hilar neurons. Pretreatment with U50 prior to pilocarpine significantly decreased mossy fiber sprouting and increased hilar neuron survival by approximately 60%.

To investigate the ability of endogenous kappa opioids to decrease the severity of pilocarpine-induced seizures, rats were pretreated with 10 mg/kg norBNI prior to a lower dose (275 mg/kg) of pilocarpine. Pretreatment with norBNI increased the incidence of rats exhibiting seizures by 34%. Histological analysis showed that the lower dose of pilocarpine did not significantly increase mossy fiber sprouting or significantly decrease the number of hilar neurons. Treatment with norBNI prior to pilocarpine however, did cause a significant increase in mossy fiber sprouting and a 38% decrease in the number of hilar neurons in the middle hippocampus. Injection of U50 or norBNI alone (in the absence of pilocarpine) had no effect on either the behavioral or histological measures; although, U50 did cause mild sedation. These data show that kappa opioids can decrease the severity of pilocarpine-induced seizures. Supported by NS33898.

TIME COURSE AND DISTRIBUTION OF THE ABERRANT EXPRESSION OF NEUROPEPTIDE-Y (NPY) FOLLOWING SYSTEMIC ADMINISTRATION OF KAINIC ACID IN THE RAT. J. N. Armstrong,* R. W. Currie and H. A. Robertson,. Laboratory of Molecular Neurobiology, Departments of Pharmacology Anatomy and Neurobiology, Faculty of Medicine, Dalhousie University, Halifax, Nova Scotia B3H 4H7, Canada.

Systemic administration of kainic acid (KA) in the rat produces many of the clinical features of human temporal lobe epilepsy including the induction of motor convulsions and degeneration of neurons in the hippocampus and piriform cortex. Using immunohistochemistry we examined the rat brain for the expression of NPY at 3, 6, 12 and 24 hours after systemic administration of KA. We report here that aberrant NPY-like immunoreactivity was detected in the cytoplasm of dentate granule cells as early as 6 hours after KA-induced seizures. At 12 and 24 hours, aberrant NPY-like immunoreactivity was apparent in mossy fibers termination zones throughout both the dentate hilus and CA3. NPY-like immunoreactive neurons were abundant in the dentate hilus of control animals and animals examined 3, 6 and 12 hours after KA injection. Very few NPY-like immunoreactive neurons were apparent in the dentate hilus of animals examined 24 hours after KA injection. Furthermore, using fluorescence microscopy for NPY and parvalbumin (PARV), we have been able to demonstrate that the aberrant expression of NPY in the dentate gyrus is limited to the granule cells because PARV-immunoreactive basket cells displayed no aberrant expression of NPY. Contrary to previous reports, the present study demonstrates that the novel expression of NPY in the dentate granule cells precedes the seizure-induced loss of dentate hilar neurons and suggests that the *de novo* synthesis of NPY occurs in response to seizure-dependent activity of dentate granule cells rather than the loss of inhibition that occurs 24 hours after systemic administration of KA.

FUNCTIONAL ACTIVATION OF SOMATOSTATIN (SRIF)- AND NEUROPEPTIDE Y (NPY)-CONTAINING NEURONS IN THE ENTORHINAL CORTEX (EC) OF EPILEPTIC RATS. M. Rizzi, D. Cavaleri, M. Gariboldi, R. Samanin and A. Vezzani*. Lab. of Neuropharmacology, Mario Negri Institute for Pharmacological Research, Milano, Italy 20157.

The *in vitro* release of SRIF and NPY, their tissue concentration and immunocytochemical pattern were examined in the EC of chronically epileptic rats. Rats were made chronically epileptic by a subcutaneous administration of 12 mg/kg kainic acid (KA) inducing status epilepticus (SE) for at least 3 hours after the injection. Two days after SE, the release of both peptides from EC slices induced by high KCl was significantly reduced under depolarizing conditions by 15% on average. At 60 days, the spontaneous and 30 mM KCl-induced release of SRIF were significantly enhanced by 30% on average while that induced by 100 mM KCl was increased by 70%. The spontaneous, 30- and 100 mM KCl-induced release of NPY were increased respectively by 120%, 76% and 36%. Sixty days after KA, NPY but not SRIF tissue concentration were increased in the EC. This was confirmed by immunocytochemical evidence showing that NPY-, but not SRIF-immunoreactive neurons were increased in the lateral EC of KA-treated rats. Injection of 12 nmol SMS 201-995, a SRIF analog resistant to endogenous peptidases, in the lateral EC significantly reduced the electroencephalographic seizures induced by intrahippocampal infusion of 0.2 nmol KA.

These results indicate that peptides-mediated neurotransmission is enhanced in the EC of chronically epileptic rats and may play a role in limbic epileptogenesis.

TRANSPLANTATION OF FETAL CHOLINERGIC NEURONS INTO THE 192 IgG-SAPORIN LESIONED HIPPOCAMPUS-EFFECT ON HIPPOCAMPAL KINDLING.

I. Ferencz, M. Kokaia, M. Keep, E. Elmér, Z. Kokaia and O. Lindvall*, Section of Restorative Neurology, Department of Clinical Neuroscience, Wallenberg Neuroscience Center, S-221 85 Lund, Sweden.

The role of the basal forebrain cholinergic system in kindling has been poorly understood. 192 IgG-saporin is an efficient and selective neurotoxin for cholinergic neurons, and intraventricular injection of this toxin leads to extensive cholinergic denervation in cortical and hippocampal areas. Our previous studies have shown that intraventricular injection of 192 IgG-saporin facilitates the development of traditional hippocampal kindling (stimulation once daily) and enhances the responsiveness to rapid kindling stimulations (40 suprathreshold stimulations during 3.3 hours). In order to explore the possibility that cholinergic reinnervation of the hippocampus can reverse the increased kindling rate in denervated rats, we have grafted fetal cholinergic neurons into the hippocampus of 192 IgG-saporin lesioned animals (lateral ventricle; 4 µg bilaterally). The cell suspension grafts (2 µl) were stereotaxically injected at three sites bilaterally in the hippocampal formation. 192 IgG-saporin-lesioned, sham transplanted animals (cortical cell suspension or saline injection) were used as controls. Three months after transplantation, the animals were subjected to daily electrical stimulations according to the traditional hippocampal kindling paradigm. Our preliminary data show that kindling development was slower in animals grafted with fetal cholinergic neurons (n=8) as compared to sham grafted rats (n=7). The rats with cholinergic grafts needed significantly more stimulations to exhibit three generalized seizures as compared to the controls (28±2.8 and 18±2.9, respectively; $p<0.05$, Student´s t-test). The results of this study indicate that the cholinergic neuronal transplants, which had reinnervated the hippocampus, were able to dampen the accelerated kindling epileptogenesis caused by the lesion of the basal forebrain cholinergic system. *Supported by grants from the Swedesh MRC and Medical Faculty, University of Lund*

CENTRAL NICOTINIC RECEPTORS MEDIATE NICOTINE-INDUCED SEIZURES IN RATS. M. Gasior*, S.R. Goldberg and M. Shoaib. Preclinical Pharmacology Laboratory, National Institute on Drug Abuse, D.I.R., N.I.H., Baltimore MD 21224, USA.

In common with other drugs, large doses of nicotine (NIC) can lead to toxic effects, which are manifested behaviorally as convulsions. Despite behavioral-genetic approaches revealing a role for α-bungarotoxin binding sites in mediating these seizures, the pharmacology of NIC-induced seizures, especially CNS mechanisms remain unexamined. The present study describes experiments using a variety of NIC receptor antagonists to protect against NIC-induced seizures. Male Sprague Dawley rats implanted with intravenous jugular catheters, displayed dose-dependent clonic seizures (ED50 = 0.22 mg/kg [0.18 - 0.26]) following intravenous infusions of nicotine. Pretreatment with mecamylamine (0.25-1.0 mg/kg SC; 20 min pt), a NIC receptor antagonist, dose-dependently diminished seizures produced by 0.6 mg/kg of NIC, revealing a protective ED50 value of 0.27 mg/kg [0.17 - 0.41]; the dose-response curve for NIC was shifted to the right and down, indicative of a non-competitive antagonism. In contrast, systemic pretreatment of chlorisondamine (0.1-10.0 mg/kg SC; 20 min pt), a NIC receptor antagonist which fails to penetrate into the CNS, did not block NIC-induced seizures. However, when chlorisondamine was administered ICV (5µg, 30 min pt), it completely antagonized the NIC-induced seizures, a block that lasted for over 9 days after the single ICV administration. Intracerebroventricular administration of methyllycaconitine, a neuronal α-bungarotoxin receptor antagonist, in the dose range of 3.0 - 30.0 µg (2µl volume, 5 min pt) failed to modify the seizure potency of NIC. These preliminary observations suggest that seizures induced by IV infusion of NIC are mediated via central nicotinic receptors. Further, the nicotinic receptors associated with α-bungarotoxin sites appear to have little function in NIC-induced behavioral toxicity. *Supported by N.I.D.A./D.I.R.*

IMMUNOLESIONING WITH 192 IgG SAPORIN: THE ROLE OF BASAL FOREBRAIN CHOLINERGIC NEURONS IN PILOCARPINE-INDUCED SEIZURES. C.G. Massant, A.C. Pomarico and L.E.A.M. Mello*, Depto. Fisiologia, UNIFESP-EPM, 04023-900 São Paulo, Brazil.

In the study of the central nervous system, structural and functional effects of lesions are the basis for several studies. Recently, a new approach was introduced to destroy specifically and selectively the cholinergic neurons of the basal forebrain. It consists in a monoclonal antibody to the NGF receptor (192 IgG) linked to a ribosome inactivating citotoxic protein (saporin). Using this drug, the function of this specific group of neurons was studied in the pilocarpine (a cholinergic agonist) model of seizures. Male Wistar EPM-1 rats (250-300g) were submitted to i.c.v. stereotaxic injection of 5µl of buffered saline or 5µl of 192 IgG saporin (4µg) under chloral hydrate anesthesia (400 mg/Kg, i.p.). Two weeks after surgery, animals received pilocarpine i.p. (350 mg/kg) and were observed for the development of *status epilepticus* (SE). IgG-injected animals had a 83% incidence of pilocarpine-induced SE as compared to a 48% incidence for controls. Histological analysis with AChE histochemistry revealed an important and selective destruction of specific groups of basal forebrain cholinergic neurons. Our data suggests that, contrary to previous assumption, the basal forebrain cholinergic projection to the hippocampus (the one most lesioned by IgG 192-saporin) tends to antagonize rather than induce pilocarpine-induced seizures.

NON-HOMOGENEOUS DENTATE GRANULE CELL POPULATIONS: EVIDENCE FROM ACUTE AND CHRONIC PILOCARPINE-EPILEPTIC RATS. L. Covolan*, C. Hamani, R. Mendez-Otero and L.E.A.M.Mello, Depto. Fisiologia, UNIFESP, 04023-900 São Paulo and Instituto de Biofísica Carlos Chagas Filho, UFRJ, 21941-590 Rio de Janeiro, Brazil

The dentate gyrus granule cell (GC) layer has been usually regarded as a uniform symmetric layer relatively resistant to prolonged seizures. Yet, recently (J. Comp.Neurol., 366 (1996) 516-533) it has been reported an asymmetric pattern of GC loss in animals submitted to continuous perforant path stimulation, demonstrating that cellular degeneration was more exuberant in the inferior blade of the GC layer. Here, we report further asymmetries in the GC layer, which were revealed with the pilocarpine (PILO) model of epilepsy. Status epilepticus (SE) was induced in male, Wistar EPM-1 animals through systemic injections of pilocarpine (320 mg/Kg, i.p.). Serial, coronal brain sections were processed according to a silver staining method specific for degenerating cells (J. Neurosci. Meth., 50 (1993) 159-164). Animals were sacrificed 1 h. after SE or 2-12 months after SE induction 0.5-6 h. after behaviorally detected spontaneous recurrent seizures. One h. after SE animals exhibited a specific spatial distribution pattern of cell degeneration in which the inferior blade portion of the GC layer was predominantly affected (rostral more than caudal levels). In chronic epileptic animals, cell degeneration could be observed in both superior and inferior blades of the GC layer, although a clear predominance of the later could be seen. Use of combined staining techniques (Neo-Timm, NADPHd and Nissl) revealed a particular GC sub region in the superior blade, near its tip, which was often found to be selectively destroyed. The non-uniform patterns of degeneration in the GC layer reported above might be relevant for the understanding of seizure genesis and spread within the hippocampal formation.

IDENTIFICATION OF A DISTINCT NEURONAL POPULATION IN THE DORSAL PONTINE TEGMENTUM EXPRESSING FOS-LIKE IMMUNOREACTIVITY INDUCED BY BRAINSTEM-EVOKED SEIZURE. J.B. Eells*, R.A. Browning and R.W. Clough. Depts. of Anat. and Physl., Sch. of Med., Southern Illinois Univ., Carbondale, IL 62901.

Several studies have utilized induction of c-fos protein or mRNA as a marker for neuronal activation during seizures. Our previous studies revealed a dense, circumscribed, but previously unidentified cluster of neurons in the pons that exhibit a dramatic increase in Fos-like immunoreactivity (FLI) following tonic seizures induced by electrical (MES), chemical (PTZ) or audiogenic stimulation. The present study was designed to identify this unknown nucleus which appears activated during seizure. This cluster of FLI neurons is triangular in shape with its dorsal border along the ventral aspect of the posterior cuneiform nucleus, lateral border along the dorsal nucleus of the lateral lemniscus and medial-ventral border adjacent to the lateral parabrachial nucleus and superior cerebellar peduncle. Possible identities of these FLI neurons included 1) the pedunculopontine tegmentum-pars compacta (PPTg-pc) or 2) the superior lateral subnucleus of lateral parabrachial (slPB) area. The precise anatomy of this cluster of FLI neurons was studied using comparative NADPH diaphorase histochemistry (a marker for cholinergic neurons of the PPTg) and retrograde transport of WGA-HRP injected into the ventromedial hypothalamus (VMH-an area that receives strong projections from slPB). These sections were compared to FLI distribution following MES. Our results show that this cluster of FLI neurons is closely associated, but not overlapping, with the PPTg-pc cholinergic neurons' lateral and most caudal aspect. Alternatively, following WGA-HRP retrograde transport from the VMH, a dense, triangular shaped collection of neurons labeled with WGA-HRP corresponds well with this cluster of FLI neurons. These results demonstrate that the seizure-induced FLI neurons do not overlap with the cholinergic neurons of the PPTg-pc, but appear to represent the neurons of the slPB. This is the first report of seizure-induced Fos expression specifically attributed to the superior lateral subnucleus of lateral parabrachial area. (Supported by an SIUSM)

EFFECT OF CENTRAL NOREPINEPHRINE DEPLETION ON THE DOWN REGULATION OF β-ADRENERGIC RECEPTOR INDUCED BY ELECTROCONVULSIVE SHOCK IN RATS. **D.O. Seo[1], C.Y. Shin[1], P.C. Jobe[2], J.W. Dailey[2], J.H. Lee[1], M.J. Song[1] and K.H. Ko[1]. [1]Department of Pharmacology, College of Pharmacy, Seoul National University, Seoul 151-742, Korea. [2]Department of Biomedical and Therapeutic Sciences, University of Illinois College of Medicine, Peoria, Illinois 61656, U.S.A.**

The purpose of the present study was to demonstrate the relationship between the down regulation of β-adrenergic receptor induced by electroconvulsive shock (ECS) and the changes of norepinephrine (NE) content at the synapse induced by seizure. Sprague-Dawley rats were employed in this experiment. Four groups of animals were prepared; Group 1: ECS (70 mA, 0.5 sec, 60 Hz) or sham shock (no current) was given daily for twelve days. Group 2: Reserpine (5 mg/kg, i.p.) was given every third day (total four times). ECS or sham shock treatment started from the next day after the first injection of reserpine. Group 3: 6-OHDA (250 μg in 20 μl Ringer solution containing ascorbic acid, i.c.v.) was given daily for two days. ECS or sham shock treatment started from the third day after the last injection of 6-OHDA. Group 4: Reserpine (1 mg/kg, i.p.) was given daily for ten days followed by ECS or sham shock treatment daily for twelve days. ECS was delivered through ear-clips to induce tonic extension seizures. The densities of β-adrenergic receptor were measured using [^{3}H]dihydroalprenolol (DHA) as a radioligand and the contents of NE were measured by HPLC-ECD. In the ECS treated group, the densities of β-adrenergic receptor were decreased significantly by approximately 30 % while the NE contents were increased significantly by approximately 30 % compared with those of the control group in the frontal cortex and the hippocampus. Both in the reserpine and 6-OHDA treated groups, the NE contents were decreased significantly by approximately 90 % while the β-adrenergic receptor densities were increased compared with the sham-control group. ECS treatment caused no change in the densities of β-adrenergic receptor and NE contents in these conditions where β-adrenergic receptor density were elevated and NE contents were decreased by reserpine or 6-OHDA. Whereas, in Group 4 NE contents were restored up to approximately 80 % and the receptor density up to approximately 90 % of the control level at the twelfth day after the last treatment of reserpine. In this condition ECS caused the density of β-adrenergic receptor to decrease only by 16 %. These results suggest that the down regulation of β-adrenergic receptor induced by ECS may be mediated through the change of NE contents at the synapse induced by seizure.

INCREASED SEIZURE SUSCEPTIBILITY IN ADULT RATS FOLLOWING HIPPOCAMPAL DAMAGE DURING DEVELOPMENT. E.F. Sperber * and J. Velíšková. Dept of Neurology, Albert Einstein Coll. of Med., NYC, NY 10461

Temporal lobe epilepsy (TLE) is the most common form of idiopathic epilepsy in adults. In recent years, there has been much debate regarding the relationship between convulsions early in life and TLE in adulthood. Is hippocampal sclerosis a consequence of convulsions early in life or is the sclerosis a result of some antecedent injury that becomes epileptogenic and increases the likelihood of seizures in adulthood?

In the present study, we examined the effects of lesion induced hippocampal damage early in life and examined its affect on seizure susceptibility in adulthood. Rats at 15 days of age had hippocampal lesions (by radio frequency lesions). As adults, they were unilaterally implanted with bipolar electrodes in the amygdala. Following a week recovery period, the animals were kindled using a 20 min interstimulus paradigm. While neither group of adult rats kindled after 20 stimulations, adult rats that were lesioned during development reached a higher kindling stage.

Results of the present study suggest there is an increase in susceptibility to seizures in the presence of brain damage. These data support clinical studies that report that the likelihood of seizures is greater in an already compromised brain.

NEONATAL DEPLETION OF TESTOSTERONE ACCELERATES THE FUNCTIONAL MATURATION OF THE SUBSTANTIA NIGRA. J. Velíšková*. Dept. Neurology, A. Einstein Coll. Med., Bronx, NY 10461.

Steroid hormonal regulation is critical for normal brain development and may play an important role in human seizure disorders. the substantia nigra pars reticulata (SNR) is one of the structures controlling the spread of seizure activity via its GABAergic neurotransmission especially through GABAA receptors. In naive 25 day old male rats, infusions of muscimol (a GABAA agonist) in the anterior SNR have no effects on flurothyl seizure threshold, while infusions in the posterior region of the SNR have proconvulsant effects. However, in 25 day old neonatally castrated male rats, anterior infusions of muscimol mediate anticonvulsant effects and infusions in the posterior SNR mediate proconvulsant effects. In contrast, in 25 day old females there is only anticonvulsant effect of muscimol infusions in the SNR without any sit-specificity. the data suggest that the presence of testosterone may be responsible for the functional segregation of the SNR.

SUBTHALAMIC NUCLEUS MEDIATES ANTICONVULSANT EFFECTS OF MUSCIMOL. L. Velíšek*, J. Velíšková, and S.L. Moshé. Depts. Neurology and Neurosci, A. Einstein Coll. Med., Bronx, NY 10461.

There are several sites in the brain that can modify seizures, such as area tempestas, superior colliculus and substantia nigra pars reticulata (SNR). The anterior part of the SNR (which mediates the anticonvulsant effects of muscimol) has significant reciprocal connections with the subthalamic nucleus (STN) indicating that the STN may also participate in the regulation of seizure susceptibility. Therefore, we determined the effects of bilateral and unilateral STN muscimol infusions (100 ng in 0.25 ul of saline per site) on clonic flurothyl-induced clonic seizures in adult rats. Both unilateral and bilateral infusions of muscimol into the STN significantly increased the threshold for flurothyl-induced clonic seizures, i.e., muscimol infusions into the STN were anticonvulsant. The output connections of the STN include the SNR (anterior part), superior colliculus, striatum and the entopeduncular nucleus. All theses sites modify seizures susceptibility in various models. Our data demonstrate that the STN GABA sensitive output system is a part of this seizure controlling network.

ROLE OF GABA RECEPTORS IN THE ANTICONVULSANT ACTIVITY MEDIATED BY THE NUCLEUS RETICULARIS PONTIS ORALIS. S.L.Peterson*. College of Pharmacy, University of New Mexico, Albuquerque, NM, 87131.

Previous studies in this laboratory have begun to establish the specific neurotransmitter receptors in n. Reticularis Pontis Oralis (RPO) that act to inhibit the tonic hindlimb extension (THE) component of maximal electroshock seizures (MES). The purpose of the present study was to evaluate the role of RPO GABA receptors in inhibiting THE.

Bilateral RPO microinfusion of bicuculline, muscimol, baclofen or 2-hydroxysaclofen failed to inhibit THE in any of the rats tested. However, the 200 and 400 nmol doses of bicuculline induced wild running similar to that observed in genetically epilepsy-prone rats.

The present data contribute to the identification of receptors in the RPO that modulate THE. The induction of wild running convulsions by bicuculline suggests the presence of GABAergic systems but the failure of muscimol to antagonize THE suggests no direct role in the anticonvulsant activity mediated by the RPO. (Supported by NIH grant 32626)

LONG LASTING DECREASED MUSCIMOL BINDING IN AN *IN VIVO* MODEL OF LIMBIC EPILEPSY. A.C. Rice*, S.B. Churn, M.D. Shumate, and R.J. DeLorenzo. Department of Neurology, Medical College of Virginia, Richmond, VA 23298.

Alterations in the γ-amino butyric acid (GABA) inhibitory neurotransmitter system have been identified in human epilepsy and in animal models of epilepsy. Data from our laboratory have demonstrated that induction of behavioural seizures in the pilocarpine model of limbic epilepsy (LE) is associated with a long lasting decrease in α2 and α5 $GABA_A$ receptor subunit gene expression in the CA1-CA3 region of the hippocampus (Rice et al, *PNAS*, in press). In this report we have examined the functional result of the changes in $GABA_AR$ subunit mRNA expression by studying the binding of the $GABA_A$ agonist muscimol in the pilocarpine model of LE. A ^{3}H-muscimol concentration binding curve to synaptic membrane enriched fractions from the hippocampus was decreased in the pilocarpine treated rats compared to control animals. A Scatchard analysis indicated the decrease was due to a change in Bmax and not in Kd. Thus, we conclude that functional decreases in $GABA_AR$ correspond to observed subunit expression changes, which could represent an underlying cause for the hyperexcitability observed in this model of LE.

ANISOMYCIN BLOCKS THE INDUCTION OF A RAT MODEL OF FOCAL EPILEPTOGENESIS, THE GABA-WITHDRAWAL SYNDROME (GWS). **S. Brailowsky* and T. Montiel. Institute of Cellular Physiology, Dept. of Neurosciences, UNAM, Mexico D.F. 04510, Mexico.**

Upon withdrawal from a GABA or $GABA_A$-receptor specific agonist infusion in one of different cortical areas, a focal epileptogenesis -or GWS- can be recorded for over 7 days, in baboons and rats. Considering that the exposure to GABA is brief (120 min) and that the generated abnormal electrographic trace lasts several days, GWS can be considered a long-lasting phenomenon. Evidence from behavioral and electrophysiological preparations has indicated a role for protein synthesis in long-lasting processes. We present evidence of a similar involvement of protein synthesis in the induction of GWS.

Rats prepared for chronic EEG recording were unilaterally infused into the somatomotor cortex either with anisomycin, a ribosomal peptidyl transferase inhibitor, alone (75 μM), 60 min before a GABA infusion (0.5 M) for 120 min, or together with GABA for 120 min (3 μl/hr). Only animals pre-treated with the antibiotic fail to show a GWS. A typical GWS was observed in rats following infusion of GABA alone or in combination with anisomycin.

We conclude that the induction of GWS is dependent on protein synthesis. Further experiments will identify the specific protein(s) involved.

DECREASED GABA SYNTHESIS IN THE DENTATE HILUS IN THE PERFORANT PATH STIMULATION MODEL OF EPILEPSY. A.M.Mazarati*, C.W.Wasterlain and R.A.Baldwin VA Medical Center, Sepulveda, CA 91343, Dept. of Neurology and Brain Research Institute, UCLA School of Medicine.

Intermittent electrical stimulation of the perforant path (PfPS) is an animal model of status epilepticus, which is characterized by loss of dentate inhibition, hippocampal neuronal damage, and delayed spontaneous seizures. We examined GABA metabolism in the rat hippocampus after PfPS.

Male adult Wistar rats were stimulated for 24 hrs through a bipolar electrode placed into the perforant path under urethane anesthesia using 10 s 20 Hz 20 V 0.1 ms square wave monophasic stimuli, delivered every minute. GABA metabolism was studied by HPLC in punch biopsies from the hilus by the gamma-vinyl -GABA method.

In the stimulated rats GABA concentration was 14.6±3.5 pmol/ug protein in the lesioned hilus, and 27.4±1.3 in the contralateral hilus ($P<0.01$). In the controls GABA concentration was 19.5±5.4 in the implanted side, and 26.4±3.5 at the contralateral side ($p>0.05$). Lesioned animals showed a significantly lower rate of GABA synthesis (14.65±3.71 pmol/ug protein/hr) than sham- stimulated rats (24.83±2.03 pmol/ug protein/hr, $p<0.02$). GABA turnover time was 39.9±5.3 min after PfPS and 59.62±8.7 in the controls ($p>0.05$).

These results show that the rate of GABA synthesis is decreased in PfPS- lesioned hippocampi, probably due to either the loss of GABA-ergic neurons in the hilus, or to the loss of positive drive for GABAergic neurons.

PRESYNAPTIC γ-HYDROXYBUTYRIC ACID- AND $GABA_B$-MEDIATED SECOND MESSENGER MECHANISMS IN GENERALIZED ABSENCE SEIZURES. O. Carter Snead III, Div. Neurol., Hosp. for Sick Children, Dept. Ped., Fac. of Med., Univ. Toronto, Toronto, Ontario, Canada M5G 1X8

γ-Hydroxybutyric acid (GHB) is a naturally occurring compound which has the ability to induce experimental generalized absence seizures which are exacerbated by $GABA_B$ agonists and blocked by both GHB and $GABA_B$ receptor antagonists. GHB does not appear to induce absence seizures by a simple postsynaptic $GABA_B$-mediated mechanism. However, it is not known what effector is involved in this property of GHB. These experiments test the hypothesis that the effector is adenylyl cyclase.

The effect of GHB on adenylyl cyclase activity in rat brain cortical slices was determined and the pharmacology of the observed response characterized. GHB decreased basal adenylyl cyclase activity, had no effect on isoproterenol-stimulated cAMP, and inhibited forskolin-stimulated cAMP. These effects were blocked by GTPγS indicating that they were linked to a G protein. The effects of GHB and (-) baclofen on forskolin-stimulated cyclic AMP appeared to be additive. The effect of GHB on basal adenylyl cyclase activity and forskolin-stimulated cAMP was blocked by a specific GHB antagonist, NCS 382, and the presynaptic $GABA_B$ receptor antagonist, phaclofen and 2-hydroxy saclofen, but not CGP 35348. This pharmacologic profile of GHB in these experiments is similar to that demonstrated for the effect of GHB on basal GABA release in thalamus (Banerjee & Snead, J. Pharm. Exp. Ther. 273:1534, 1995) and supports the hypothesis that presynaptic, second messenger mediated mechanisms involving cAMP may play a role in GHB-induced absence seizures. Also, the data suggest that the GHB site active in this regard may be an isoform of the presynaptic $GABA_B$ receptor. Supported by NIH grant no. NS17117.

LOWER DENSITY OA A1 ADENOSINE RECEPTORS IN NUCLEUS RETICULARIS THALAMI OF THE GENETIC ABSENCE EPILEPSY RATS FROM STRASBOURG (GAERS): AN AUTORADIOGRAPHIC STUDY. A.Ekonomou[a], F.Angelatou[a], M.Vergnes[b], A.Batistatou*[a] and G.Kostopoulos[a]. [a]Dept.of Physiology, School of Medicine, Univ.of Patras, Greece. [b]Lab.de Neurophysiologie, CNRS, Centre de Neurochimie, Strasbourg, France.

In this model we studied the density of A1 Adenosine receptors, because adenosine is an endogenous neuromodulator implicated in mechanisms underlying sleep-wake cycle as well as absence seizures (caffeine blocks absences in mice). By using in vitro quantitative autoradiography and the specific A1 agonist ^{3}H-cyclohexyladenosine, we determined a significant decrease of about 15% in A1 receptors in Reticular (RT) and Anterior Ventral (AV) thalamic nuclei in GAERS compared to non epileptic rats. Thalamocortical circuits and especially the oscillatory properties of neurons in the RT play a crucial role in the rythmogenicity, evident in the studied type of epilepsy. The possible importance of our findings on the mechanisms underlying absence epilepsy are highlighted by the fact that A1 receptors are primarily located presynaptically on glutamatergic terminals and are thus able to restrain the inputs on RT from both thalamocortical and corticothalamic neurons. It is of interest that in an animal model of convulsive generalized epilepsy, induced by Pentylentetrazol, A1 receptor density in RT is higher than normal.

Supported by an HCM Grant to G.K.

DISINHIBITION OF THE GLOBUS PALLIDUS SUPPRESSES ABSENCE SEIZURES IN THE RAT CONCOMITANTLY WITH A REDUCTION OF NIGRAL EXTRACELLULAR GLUTAMATE.
C. Deransart[1], B.-T. Lê[1], J. De Barry[2], C. Marescaux[1] and A. Depaulis*[1]. [1]INSERM U. 398, Faculté de Médecine, 11, rue Humann, 67085 Strasbourg cedex, France; [2]CNRS UPR 9009, Centre de Neurochimie, 5, rue B. Pascal, 67084 Strasbourg cedex, France.

In different animal models of epilepsy in the rat, activation of the *direct* GABAergic striatal input of the substantia nigra *pars reticulata* (SNpr) leads to a suppression of seizures. The SNpr also receives a glutamatergic excitatory input from the subthalamic nucleus which is part of an *indirect* striatonigral pathway. Inhibition of this input has been shown to suppress absence seizures. The globus pallidus (GP) sends GABAergic inhibitory projections to the subthalamic nucleus and may also be involved in the control of seizures. The aim of the present study was to investigate the effects of GP disinhibition on seizure occurrence and nigral extracellular glutamate levels, as measured by microdialysis coupled to HPLC analysis. In a genetic model of absence epilepsy in the rat, antiepileptic effects were obtained by disinhibition of GP neurons induced by bilateral local applications of a GABAergic antagonist (picrotoxine, 20 and 40 pmoles/side). Concomitant with seizure suppression, disinhibition of the GP led to a transient decrease in extracellular glutamate levels in the SNpr. These results suggest that the observed suppression of seizures is due to a de-activation of SNpr neurons and strengthen the hypothesis of an involvement of the *indirect* striatonigral pathway in the control of absence seizures.

SELECTIVE INCREASE OF PROTEIN KINASE C EPSILON IN THE DENTATE GRANULE CELLS AFTER KAINIC ACID-INDUCED SEIZURES IN RATS.
F. Guglielmetti, S. Baldessari, E. Butelli, A. Manfridi*, M.Rattray and C.Bendotti. Istituto di Ricerche Farmacologiche "Mario Negri", Milan, Italy

A systemic administration of kainic acid (KA, 12 mg/kg s.c.) induces limbic seizures in adult rats and cell loss in the CA3/CA4 areas of the hippocampus which is associated with sprouting of mossy axon collaterals from granule cells. It has been suggested that protein kinase C (PKC) may function as a key enzyme in the neurite outgrowth and regenerating sprouting. The PKC enzyme is constitute by a family of 12 subtypes with the $\alpha,\beta,\gamma,\delta$ and ε subtypes being the most represented in the central nervous system. Using specific radiolabeled oligonucleotides probes in this study we examined, by in situ hybridization technique, the distribution and the expression of the mRNA of these isoenzymes in the hippocampus of rats treated with KA in respect to controls. A significant increase of PKC ε mRNA was observed in the granular cells 48 h after KA treatment . This effect was followed by an increase of PKC ε immunoreactivity in the mossy fibers which was maximal 7 days after the KA but still remain higher than controls one month after the treatment. No significant changes were observed in the mRNA expression of the other PKC isoenzymes in the hippocampus except for a decrease in PKCγ mRNA in the CA1 region. These data suggest that PKC ε may have an important role in the axonal sprouting and functional activity of granule cells in KA induced seizures.This study was supported by CNR, Convenzione Psicofarmacologia, Rome, Italy.

ALTERED REGULATION OF NMDA RECEPTORS AND PROTEIN KINASE C IN LONG-TERM AMYGDALA-KINDLED RATS.
J.C. McEachern, L.E. Kalynchuk, T. Burgmann, J.P.J. Pinel*, & C.A. Shaw. Depts. of Psychology, Physiology and Neuroscience, U.B.C., Vancouver, B.C., V6T 1Z3.

We have investigated the effect of long-term kindling on the regulation of various neurotransmitter receptor systems. Previous studies revealed changes in binding to AMPA, muscarinic ACh, $GABA_A$ and benzodiazepine receptor populations, 36h following the last of 99 kindling stimulations. These receptor changes were site-specific, and occurred in opposite directions for excitatory and inhibitory populations (Kalynchuk et al., 1995; McEachern et al., 1995). Here, we extend these observations with a report of kindling-associated alterations in the regulation of NMDA receptors and protein kinase C (PKC), the major enzyme responsible for NMDA receptor sensitization. Bipolar electrodes were implanted in the basolateral amygdala of 15 male Long-Evans rats. The rats were sacrificed 36h after 99 kindling (n=10) or sham (n=5) stimulations. Autoradiograms of ^{3}H-MK801 binding to NMDA receptors and ^{3}H-phorbol ester (PE) binding to PKC were quantified by measuring optical density in the following regions: hippocampal CA1 and CA3, dentate gyrus, perirhinal cortex and pyriform cortex. Compared to controls, MK-801 binding in kindled rats was significantly decreased only in perirhinal cortex, whereas PE binding was significantly decreased in CA3 and dentate gyrus. Such changes in receptors and the enzymes that regulate their action may be related to the abnormal excitability of the kindled brain. ALDOSTERONE PREVENTS KAINATE-INDUCED DECREASES IN FUNCTIONAL HIPPOCAMPAL NA,K-ATPASE AND SEIZURES.
M. L. Brines*, G. Sehgal, and M. S. Guoth. Neuroendocrine Program, Yale School of Medicine, 333 Cedar Street, New Haven, CT 06520-2080

We have previously shown the critical importance of adequate sodium pump (Na-pump) function for ameliorating both hyperexcitability and potential neuronal damage using rodent in vitro (Brain Res. 591:94; 1992) and in vivo models (Neurosci. Lett. 191:145; 1995). Specifically, a reduction in functional Na-pump capacity is associated with a supersensitivity to glutamate. Whether increased Na-pump capacity is neuroprotective, as we would predict, is unknown. The mineralocorticoid aldosterone potently up-regulates Na-pump expression in kidney and vascular smooth muscle as well as the rat hippocampus. If so, we expected that aldosterone would protect against moderate dosages of kainate. Isoform specific Na-pump activity in crude regional homogenates of brain was estimated using graded ouabain inhibition. Moderate (9mg/kg IP) dosages of kainate reliably caused seizures in young adult male rats (9/9 animals). Pretreatment with aldosterone (12.5ugm/kg SQ 1 hr prior to kainate) potently blocked seizures (2/9 animals seized; $p < 0.001$ by unpaired t-test). In contrast, aldosterone given only at the appearance of wet dogs shakes did not prevent seizures (5/5 animals). Equimolar dosages of the pure glucocorticoid dexamethasone did not reliably antagonize kainate (4/5 animals seized). Analysis of hippocampal Na-pump enzymatic activity showed a ~ 4-fold reduction of activity at 2.5 hrs in kainate-treated animals compared to controls (7 vs 28 nmolesPi/μgProt/hr), whereas the aldosterone-kainate treated animals were typified by a two-fold increase over control, mostly of the high affinity isoforms (52 nmoles/μg/hr). These data support the concept that enhanced Na-pump activity is neuroprotective, as blockade of seizures is associated with large increase in functional Na,K-ATPase. The results further suggest that a rapidly recruitable Na-pump enzyme pool exists which is translocated to the cell membrane, similar to the action of aldosterone in the kidney. To the extent increases in Na-pump occur in the brain, this would constitute a mechanism for providing additional reserves during intense electrical activity. EPILEPSY: BASIC MECHANISMS—PHYSIOLOGICAL STUDIES I

822.1

ROLES FOR METABOTROPIC GLUTAMATE RECEPTORS IN PATTERNING SYNCHRONIZED OSCILLATIONS AMONG HIPPOCAMPAL CA3 NEURONS.
G. W. TAYLOR* and R.K.S. WONG. Department of Pharmacological Sciences, State University of New York, Health Science Center at Brooklyn, Brooklyn, NY 11203.

Blockade of $GABA_A$ergic inhibition produces synchronized bursts. These isolated bursts have been extensively studied and are suggested to be the cellular correlate of the "interictal" spike, a clinical sign of epilepsy. In contrast, the metabotropic glutamate receptor (mGluR) agonists 1S,3R-ACPD; 20 uM to 300 μM) or L-CCG-1 (4 uM to 1 mM) can promote a stereotypical pattern of synchronized discharge among CA3 cells of rat hippocampal slices (22 to 40 d.o.). These oscillations consist of rhythmically recurring trains (0.4 Hz). Each train was composed of a sequence of synchronized depolarizations (up to 38 Hz) with overriding action potentials.

Additionally, agonists of mGluRs accelerated spontaneously recurring interictal spikes that were initially elicited by blocking $GABA_A$ receptor mediated inhibition. While a slight acceleration at low concentrations of mGluR agonists has been suggested to depend on mGluRs 2/3, higher concentrations of mGluR agonists produce a dramatic acceleration which can reach 2-3 Hz (17 times faster than baseline in some instances). At high concentrations of mGluR agonists, the accelerated interictal bursts are suppressed, while rhythmically recurring trains of synchronized depolarizations predominate. At intermediate concentrations of agonist (20 to 70 μM ACPD), activity alternates between accelerated bursting and recurring trains. We used several methods to examine differences between these two modes of synchronized discharge.

822.2

ACTIVATION OF GROUP I mGluRs PROLONGS EPILEPTIFORM BURST DURATION *IN VITRO*.
Lisa R. Merlin* and Robert K.S. Wong.
Departments of Neurology and Pharmacology, SUNY Health Science Center, Brooklyn, NY 11203

To study the role of Group I metabotropic glutamate receptor (mGluR) activation in the patterning of epileptiform discharges, we examined the effects of agents active at these mGluRs on epileptiform activity in the disinhibited guinea pig hippocampus *in vitro*. Picrotoxin (50 μM) induced rhythmic 200-500 ms duration epileptiform bursts in transverse hippocampal slices, recorded with intracellular and extracellular electrodes in the CA3 region.

S-3-hydroxyphenylglycine (S-3HPG; 250-1000 μM), an agonist at Group I mGluRs, elicited a marked increase in the number of afterdischarges per burst, ultimately prolonging the epileptiform burst duration to 2-8 sec. This modification, while rapid in onset, was slowly progressive over time, requiring up to an hour to reach full effect. Washout was a much slower process, and complete reversal of effect was never achieved (up to 4 hours after washout). Both (+)-α-methyl-4-carboxyphenylglycine (MCPG; 1 mM) and S-4-carboxy-phenylglycine (S-4CPG; 1 mM) suppressed but did not abolish the modifications.

Our earlier studies have shown that ACPD at elevated concentrations can elicit spontaneous synchronized activity resembling trains of afterdischarges (Taylor et al. 1995 *J. Neurosci.*). S-3HPG alone elicited similar events here, confirming the hypothesis that these events are mediated by Group I activation.

We previously demonstrated that Group II mGluR activation increases epileptiform burst frequency without altering burst duration (Merlin et al. 1995 *J. Neurophysiol.*). The current results suggest that activation of Group I mGluRs may be in part responsible for allowing the interictal-ictal transition to occur. Persistence after washout suggests a possible role in epileptogenesis as well.

822.3

HIPPOCAMPUS-ENTORHINAL CORTEX INTERACTIONS AND SEIZURE GENERATION IN VITRO, M. Barbarosie, C. Zona* and M. Avoli, Montreal Neurological Institute and Dept. of Neurology & Neurosurgery, McGill University, Montreal, QC, Canada H3A 2B4.

We employed extracellular field potential recordings to study the propagation of spontaneous epileptiform discharges induced by 4-aminopyridine (4AP, 50 μM) in combined entorhinal cortex (EC)-hippocampus slices from adult mouse. Three types of events were recorded simultaneously in CA1, CA3 and EC areas: (i) spontaneous ictal-like discharges lasting 20-155s, that originated in the EC and propagated to the hippocampus following the trisynaptic loop as revealed by sectioning experiments and delay analysis; (ii) brief interictal-like epileptiform discharges (<80 ms; rate=0.5-1 Hz) of CA3 origin that traveled to CA1 and EC as revealed by lesions of the subiculum and by delay measurements (delay CA1-EC=48-60 ms); and (iii) GABA-mediated potentials with no specific site of origin, that lasted 0.5-2s, occurred at 0.03-0.1Hz and were resistant to ionotropic excitatory amino acid antagonists. We also investigated the integrity of the hippocampus-EC connection by stimulating at 0.5-10Hz specific regions of the slice to induce ictal discharges. We found that EC stimulation induced ictal events that spread through the trisynaptic hippocampal pathway. Stimulating one of the hippocampal areas also induced ictal discharges that traveled to the EC. Finally, we established the role of hippocampal inputs to the EC by interrupting the connections between EC and the hippocampal formation; this procedure reduced the duration of the EC ictal discharge by up to 41.5% of control. Our results indicate a preserved, EC-hippocampus-EC loop in this limbic, in vitro slice preparation. As demonstrated in vivo or in the whole brain preparation, our findings suggest that re-entry of neuronal activity to the EC plays a role in sustaining limbic seizures. ANTIDROMICALLY-EVOKED SYNAPTIC CURRENTS IN DENTATE GRANULE CELLS OF PILOCARPINE-TREATED RATS. M.M. Okazaki* and J.V. Nadler. Depts. Pharmacology and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

In complex partial epilepsy and in several animal models of epilepsy, hippocampal mossy fibers develop recurrent collaterals, at least some of which form synapses on dentate granule cells. We used the pilocarpine model of epilepsy to study the function of mossy fiber-granule cell synapses and of feedback inhibitory circuitry. Synaptic currents were recorded from dentate granule cells during low-frequency antidromic stimulation of the mossy fibers. In hippocampal slices from rats that had developed pilocarpine-induced status epilepticus and exhibited robust recurrent mossy fiber growth, antidromic mossy fiber stimulation evoked a glutamate-mediated EPSC in 15 of 16 granule cells. Peak amplitudes ranged from 20 to 145 pA. No such EPSC could be evoked before mossy fiber growth became detectable. Thus mossy fiber growth creates a novel recurrent excitatory circuit. In the same experiments, we found no evidence that mossy fiber growth altered feedback inhibition. The cumulative response distributions of polysynaptic $GABA_A$ receptor-mediated feedback IPSCs were very similar in animals that did or did not develop status epilepticus. This was true whether animals were studied 4-6 days or 3+ months after pilocarpine administration. Finally, antidromic mossy fiber stimulation evoked a small glutamate-mediated EPSC in about half the slices from the older control rats. The occurrence of these excitatory responses was age-related, but did not appear to involve mossy fiber growth. Thus the effects of mossy fiber growth on granule cell physiology are superimposed upon an age-related development of another glutamate innervation whose origin is presently unclear. (Supported by NIH grant NS 17771.)

EPILEPTIC ACTIVITY PREVENTS SYNAPSE FORMATION OF HIPPOCAMPAL MOSSY FIBERS VIA L-TYPE CALCIUM CHANNEL ACTIVATION IN VITRO. Y. Ikegaya*, H. Saito and N. Nishiyama. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Bunkyo-ku, Tokyo 113, Japan.

Although childhood epilepsy often results in a broad spectrum of cognitive deficits, characteristic changes in structure or function of central nervous system of epileptic patients, which may underlie such cognitive deficits, remain unclear. Therefore, hippocampal slice from early post-natal rat was used to elucidate the influence of epileptic activity elicited by picrotoxin on synapse formation of mossy fibers, which are generated mainly in post-natal 1-2 weeks. Neurite re-elongation and synaptogenesis of mossy fibers transected at 8 days in vitro were confirmed by staining with DiI, a fluorescent membrane dye utilized as a neuronal tracer, and by recording field excitatory postsynaptic potentials (fEPSP) in the CA3 region evoked by stimulation of the dentate gyrus. Picrotoxin (50 μM) which evoked spontaneous epileptiform firing in the CA3 region that was occluded by tetrodotoxin (1 μM) hindered development of fEPSP amplitude after a lesion of mossy fibers. Furthermore, observations using a Timm method, a histochemical technique that selectively labels synaptic terminals of mossy fibers, revealed that picrotoxin prevented synaptogenesis in the CA3 region. This inhibitory effect of picrotoxin was completely abolished by tetrodotoxin or nicardipine (10 μM), a L-type calcium channel blocker, but not by 2-amino-5-phosphonopentanoic acid (50 μM), a N-methyl-D-aspartate receptor antagonist, indicating that influx of calcium ion via L-type calcium channels during epileptic bursts mediated the disturbance of appropriate synapse formation of mossy fibers. These results suggest that epilepsy disturbs maturation of the hippocampus, that is known to be involved in memory and cognition. Therefore, our results may account, in part, for cognitive deficits elicited by childhood epilepsy.

822.6

SPONTANEOUS INTERICTAL EPILEPTIFORM POTENTIALS IN THE PIRIFORM CORTEX OF THE ISOLATED GUINEA PIG BRAIN. M. de Curtis *, M. Forti and C. Radici - Dept. Neurophysiology, Ist. Nazionale Neurologico, via Celoria 11, 20133 Milan, Italy.

Spontaneous interictal spikes (*sIS*) are commonly observed in human partial epilepsy and can be reproduced experimentally. The cellular mechanisms that promote initiation and recurrence of *sIC* are still not completely understood. We performed an electrophysiological extra-intracellular study of *sIS* in an acute model of focal epileptogenesis developed on the *in vitro* the isolated guinea pig brain preparation (de Curtis et al., *J. Neurophysiol.* 71: 2463, 1994). A single local ejection of bicuculline in the anterior piriform cortex (150-200 nmoles) induced *sIS* that persisted after the bicuculline washout. The *sIS*s recurred periodically at 0.08 (± 0.02) Hz just after bicuculline injection; the frequency increased gradually to stabilize around 0.14 (± 0.08) Hz within 10 minutes. Ictal-like events were never observed in the piriform cortex. Bicuculline also induced small amplitude potentials subthreshold for *sIS*, which showed a cortical depth reversal at 350-400 μm. The *sIS*s were always preceeded by a subthreshold potential. Simultaneous extracellular recordings from different piriform lobe regions (posterior piriform and periamygdaloid cortices, endopiriform nucleus, olfactory tubercle and bulb) demonstrated that the *sIS*s originate from the primary bicuculline focus in the anterior piriform cortex. Intracellular recordings from layer II and III neurons at the site of bicuculline injection showed that the *sIS*s are associated to a primary, probably intrinsic burst followed by an associative synaptic afterdepolarizing plateau, which was reduced in duration and amplitude by APV (150 μM). The burst/afterdepolarization was followed by an AHP of 615±184 ms with a reversal potential of -81.2±6.7 mV (n=10). A long lasting potential (7.3±2.4 s), activated at membrane potential values negative to -47.1±14.3 mV (n=9) was observed after the AHP. Both the AHP and the late slow potential were associated to an increase in membrane conductance and a decrease in the occurrence of subthreshold potentials.

SPATIOTEMPORAL COMPLEXITY OF HIGH POTASSIUM-INDUCED BURSTS IN HIPPOCAMPAL CA3 REGION. P.G. Aitken*, D.K. Williams, D.J. Gauthier, H.S. Greenside, Depts of Cell Biology, Physics, and Computer Science, Duke University, Durham NC 27710.

Unraveling the mysteries of brain function will require a detailed understanding of both the temporal and the spatial patterns of neural activity. In the spatial domain almost all research has dealt with either the microscopic (single cell) or macroscopic (EEG) levels. It seems likely, however, that much of the neural activity that is mean-ingful in a behavioral, physiological, or pathological sense occurs at an intermediate spatial scale that involves ensembles of dozens, hundreds, thousands of neurons. As an initial step in understanding the level of spatiotemporal heterogeneity present in the activity of populations of neurons, we have investigated the high-K^+ model of bursts in the hippocampal slice, a relatively simple and stereotyped example of neural activity. Hippocampal tissue slices were prepared and maintained using standard techniques. Two or three extracellular recording electrodes were positioned 0.1-1.0 mm apart in or near st. pyramidale of the CA3 region of a slice. Repetitive spontaneous bursts were provoked by bathing the slice in medium containing 8.5mM K^+. The recorded signals were digitized at 10 KHz / channel for several 5-10 minute periods for each of 5 slices. Qualitative and quantitative comparisons were performed between waveforms recorded simultaneously at different loci to determine the extent to which the spatial pattern of activity varied from one burst to the next. We found that the degree of synchrony between two loci varied significantly not only between but also within bursts, and that there is no single "focus" where all bursts originate. These findings indicate that there is a significant degree of spatiotemporal complexity in this preparation. If, as seems likely, a similar degree of complexity is present in other brain regions it may mean that traditional electrophysiological recording techniques are inadequate for addressing certain mechanisms of brain function. INTERICTAL SPIKING AND RECOVERY FROM LOSS OF INHIBITION FOLLOWING STATUS EPILEPTICUS. N.W. Milgram[1]*, E. Head[1], C. Ikeda-Douglas[1], L. Tremblay[1], D. Holsinger[1], and R.J. Racine[2]. [1]University of Toronto, Scarborough College, 1265 Military Trail, Scarborough, Ontario, Canada, M1C 1A4 and [2]McMaster University, Hamilton, Ontario, Canada.

A loss of inhibition and an increase in inhibition in the dentate gyrus have both been reported to follow an interval of status epilepticus (SE). These apparently contradictory findings may reflect differences in the time course of processes triggered by the SE. For example, SE is often followed by spontaneously occurring ictal activity, and these interictal events may transiently impair inhibitory transmission.

To investigate the role of spontaneous interictal activity, we administered kainic acid to rats. The subsequent SE was terminated after either 2, 3 or 5 hours by sodium pentobarbital. Recurrent collateral inhibition in the dentate gyrus was monitored both prior to and following the induction of SE. A marked increase in inhibition following SE was observed in every subject. However, this increase was often preceded by a phase of inhibitory loss, which was variable in duration, persisting for up to two weeks. The length of the period of the transient loss of inhibition was positively related to both severity of SE and the recurrence of interictal spikes. These findings suggest a functional relationship between spontaneous ictal activity and a transient loss of inhibitory transmission.

EARLY-LIFE SEIZURES: CAN SYNAPTIC PLASTICITY PRODUCE NEUROPATHOLGY?

John Swann,* MingHui Jiang, Karen Smith, Chong Lee. The Cain Foundation Laboratories, Department of Pediatrics, and Division of Neuroscience, Baylor College of Medicine, Houston, Texas 77030.

Intrahippocampal injections of tetanus toxin in infant rats (day 10) produces a chronic epileptic condition. Recordings from in vitro slices in adult rats show that area $CA3_C$ appears to be a site of focal epileptiform discharging. Studies were undertaken to investigate morphological substrates for these epileptiform events. Single $CA3_C$ pyramidal cells were injected with biocytin and reconstructed with a computer. Dendrites showed marked local abnormalities. Some dendritic branches were devoid of spines while others had a decrease in spine density. These effects appeared most marked in basilar dendrites where a 20% loss in dendritic branches was also observed

These results appear paradoxical: epileptiform discharging in area CA3 is mediated by recurrent excitatory synapses, yet a loss of spines suggest a major loss of projections onto these cells. We hypothesize that these morphological changes were at least in part produced by synaptic selection early in life. Ongoing epileptiform activity might lead to a consolidation of recurrent excitatory synapses and a withdrawal of synapses projecting from other sites. Synapse consolidation has been suggested to be produced by LTP while withdrawal LTD. Thus, we undertook experiments to determine if seizure activity in in vitro slices from immature hippocampus could produce LTD in afferents not participating in epileptiform discharges. Indeed, results consistently show that 20 minutes of epileptiform discharges in area CA3 leads to LTD of afferents projecting to the subfield. At the same time, epileptiform discharges persist within the recurrent excitatory networks.

Supported by NIH Grants NS18309 and NS11535

822.10

CHANGES IN EPSCs AND IPSCs OF HIPPOCAMPAL CA1 INTERNEURONS AND PYRAMIDAL CELLS IN THE KAINATE MODEL OF EPILEPSY.

F. Morin*, C. Beaulieu and J.-C. Lacaille. Center for Research in Neurological Sciences & Depts. of Physiology and Pathology, Univ. of Montréal, Montréal, Canada, H3C 3J7.

The epileptiform activity of hippocampal CA1 pyramidal cells in the kainic acid (KA) model of epilepsy may arise from changes in excitatory and/or inhibitory synaptic transmission. The aim of this study was to examine, using whole cell recordings, EPSCs and IPSCs evoked in visually identified pyramidal cells and interneurons located (1) in stratum oriens (O/A) and (2) near the stratum radiatum and lacunosum-moleculare border (LM), after KA treatment. Hippocampal slices were obtained from Sprague-Dawley rats 2 weeks post-KA injections (0.55μg/μl i.c.v.). Voltage clamp recordings were made using patch electrodes (7-10 MΩ) filled with (in mM) 120 Cs-CH_3SO_4, 20 QX-314, 8 NaCl, 1 $MgCl_2$, 10 HEPES, 1 EGTA, 2 ATP-tris, 0.4 GTP-tris, and 0.1% biocytin. Synaptic currents were evoked by electrical stimulation of nearby afferents. EPSCs, composed of non-NMDA and NMDA components, were isolated in the presence of bicuculline. In KA animals, non-NMDA and NMDA EPSC slope conductances were unchanged in O/A and pyramidal cells, but diminished in LM cells (47% and 63% of control, respectively). The rise time and decay time constant of EPSCs at -80 mV were unchanged in KA animals, except for a 3.4-fold faster decay time constant in O/A interneurons. $GABA_A$ IPSCs were isolated in AP5 and CNQX. In KA animals, no change in IPSC slope conductance was observed for any cell type. Kinetics of IPSCs were also similar in all cell types in KA animals, except for a 1.4 fold faster rise time and decay time constant in pyramidal cells. Thus after KA treatment, excitatory drive may preferentially be reduced on LM interneurons, to result in a decrease of feedforward polysynaptic inhibition of pyramidal cells. Monosynaptic inhibitory responses in pyramidal cells may not be reduced after KA, but their kinetics may be faster. Such changes may contribute to the hyperexcitability of the CA1 region after kainate treatment. (Supported by MRC, FRSQ, FCAR and Savoy Foundation)

PATCH CLAMP RECORDINGS OF HIPPOCAMPAL ALVEAR/ORIENS INHIBITORY INTERNEURON ACTIVITY DURING ELECTROGRAPHIC SEIZURES.

D. E. Gryder* and D. A. Coulter. Department of Neurology, Medical College of Virginia, Richmond, VA 23298-0599.

Tetanic stimulation of the Schaeffer collaterals triggers epileptiform afterdischarges in CA1 pyramidal neurons. However, effects of this stimulation on GABAergic interneurons and their role in epileptogenesis remains uncertain. In this study, visualized slice patch recording techniques were employed using an upright fixed stage microscope with a water immersion objective. This allows alvear/oriens (A/O) interneurons to be visualized outside the CA1 pyramidal cell layer and identified by their location and shape. Whole-cell patch clamp techniques were used for current-clamp recording in hippocampal slices recorded at 20-22 ^{O} C. Interneurons could also be distinguished physiologically by their short duration action potentials, large afterhyperpolarizations following action potentials and by their spontaneuos activity. Tetanic stimulation (2 s/60 Hz) of the Schaeffer collaterals produced four distinct types of responses in A/O interneurons. The first group exhibited robust afterdischarges (23/55 cells). A second group exhibited sustained inhibition following stimulation (18/55 cells). In some of these cells, there was some rebound excitation following the initial inhibitory response. A third group of interneurons produced variable responses (7/55 cells). A fourth group displayed only minimal excitation following stimulation (7/55 cells). These results demonstrate that A/O interneurons display complex responses during epileptiform activity, and that this heteregenous activity may serve differing roles in the normal and pathological function of the limbic system.

ENHANCED EPILEPTOGENESIS IN TRAUMATIC BRAIN INJURED RATS: ANATOMICAL AND ELECTROPHYSIOLOGICAL MECHANISMS.

M.D. Shumate*[1], A. Rafiq[2], Q-Z Gong[3], B.G. Lyeth[3], and D.A. Coulter[1,2]. Depts. of Physiology[1], Neurology[2], and Neurosurgery[3], Medical College of Virginia., Richmond, VA 23298.

A major cause of remote symptomatic epilepsy in young adults is traumatic brain injury (TBI). Mechanisms underlying this increased susceptibility are unknown. To model a closed head TBI, adult rats were subjected to a moderate (2.0 atm) lateral fluid percussion injury and studied 7-180 days post-injury. In physiological studies, hippocampal entorhinal cortical (HEC) slices were prepared from TBI and sham-operated control animals and results compared to an animal model of temporal lobe epilepsy, pilocarpine-treated rats (PILO). Ipsilateral HEC slices prepared from TBI animals 1 week post-injury displayed stimulus-evoked afterdischarges which, after ≥5 trains, developed into continuous epileptiform activity lasting > 30 min in > 50% slices. HEC slices prepared 1, 2, and 6 months post-TBI showed greater excitability than control, but much less than the 1 week post-TBI slices. Activity in contralateral TBI slices was similar to controls. PILO slices exhibited similar hyperexcitablity to that seen in 1 week post-TBI slices. In anatomical studies, brains were prepared for cresyl violet or Timm's stain. Both two month post-TBI and PILO animals showed similar 20-30% cell loss in hippocampal CA3 and CA1 areas. However, in hilus, TBI animals showed 35-40% while PILO animals showed 70-75% cell loss. Only PILO animals exhibited mossy fiber sprouting into the inner molecular layer. This data suggests that TBI animals have a window of increased susceptibility to epileptic activity which decreases over time.

TETANUS TOXIN INJECTION CAUSES COMPLETE FUNCTIONAL DEAFFERENTATION OF A SUBPOPULATION OF NEOCORTICAL NEURONS

I.A. Fleidervish*, B.L. Amdour, E.L. White and M.J. Gutnick, Zlotowski Center for Neuroscience and Faculty of Health Sciences, Ben-Gurion University of the Negev, Beersheva, Israel.

Tetanus toxin (TT) prevents synaptic transmission by interfering with presynaptic proteins responsible for exocytosis. Intracortical injection of TT produces an epileptic focus; this has been attributed to disinhibition due to a predilection of TT for GABAergic terminals. We used patch-in-slice recording and EM to explore excitatory and inhibitory synaptic release near a neocortical TT injection site.

Whole cell recordings from cortical slices were made 12-48 hours after TT injection (250 MLD in 0.5 µl). Unexpectedly, most neurons near the injection site showed spontaneous EPSCs and IPSCs at frequencies that were not different from normal, and epileptiform events reflected large increases in inhibitory and excitatory conductance. However, about 30% of the neurons in each slice from TT-injected cortex were abnormal: they showed no spontaneous synaptic activity whatsoever, and they did not participate in paroxysmal discharge, although they could generate spikes. In EM experiments on slices from TT-injected and control cortex, incubation in 30 mM K caused a significant decrease in the numbers of presynaptic vesicles in symmetrical and asymmetrical synapses. Terminals in slices from TT-injected cortex showed a significantly high incidence of "Omega" forms, suggesting that vesicles were caught between docking and release.

The data suggest that intracortically injected TT is taken up by a minority of neurons, and that it then enters presynaptic terminals by retrograde trans-synaptic transport. This would explain 1) the complete blockade of synaptic activity onto selected neurons whose neighbors were unaffected, and 2) the apparent lack of an effect on synaptic vesicle accumulation in randomly sampled presynaptic terminals.

Supported by grants from DFG and US-Israel Binational Science Foundation.

822.14

CONTRIBUTION OF A SLOW MEMBRANE HYPERPOLARIZATION TO THE PREVENTION OF EPILEPTIC ACTIVITY IN THE LATERAL AMYGDALA.

L. Danober* and H. C. Pape. Institut für Physiologie, Otto-von-Guericke Universität, D-39120 Magdeburg, Germany.

While the importance of GABAergic disinhibition to the induction of epilepsy is well-known, other mechanisms may also contribute. In the present study, we used intracellular recording techniques in partially disinhibited slices of the guinea pig lateral amygdala. During reduced $GABA_{A/B}$ receptor influence (bicuculline, CGP), single or repetitive stimulation of the external capsule failed to evoke epileptic discharges. Rather, an initial high-frequent burst of spikes was effectively terminated by a slow membrane hyperpolarization of 2 s duration and 10 mV amplitude (when evoked from rest), which reversed close to -75 mV. This event was due to an interaction between intrinsic and synaptic mechanisms. Intracellular injection of the Ca^{2+} chelator BAPTA blocked the slow hyperpolarization, suggesting mediation through a Ca^{2+}-activated K^+ current. In support of this, *(i)* BAPTA also blocked the slow afterhyperpolarization (sAHP) following spike activity upon current injection, *(ii)* the sAHP-current reversed close to E_K, and *(iii)* application of receptor agonists known to modulate I_{sAHP} similarly modulated the synaptically evoked slow hyperpolarization. During blockade of the sAHP, robust epileptic activity occurred spontaneously or upon synaptic activation. Intracellular injection of QX314 under these conditions blocked spike activity and unmasked fast EPSPs riding on a slow depolarization. The slow depolarization reversed close to 0 mV, was mimicked by local application of NMDA and blocked by AP5. By comparison, CNQX abolished the initial component of the epileptic discharge. In conclusion, an intrinsic sAHP and an NMDA-receptor mediated event appear to interact in lateral amygdaloid neurons to produce a slow hyperpolarization with a mixed reversal potential close to E_{Cl}, which in turn may represent an important mechanism to prevent epileptic activity in the partially disinhibited amygdala. Supp: by DFG and LSA.

DIFFERENTIAL MODULATION OF $GABA_A$ AND $GABA_B$ INTERNEURON ACTIVITY IN THE HIPPOCAMPUS. M. Forti, R. Bianchi and H.B. Michelson*. Dept. of Pharmacology, SUNY Brooklyn, Brooklyn, NY 11203.

GABAergic neurons in guinea pig hippocampus fire synchronously in the presence of 4-aminopyridine (4-AP, 100uM) and fast glutamate receptor blockers (CPP and CNQX, both 20 uM), producing large amplitude, triphasic inhibitory responses in pyramidal cells. The triphasic events consist of a hyperpolarizing $GABA_A$-mediated event, followed by a depolarizing $GABA_A$ and a hyperpolarizing $GABA_B$ response. Some interneurons continue to fire synchronously following $GABA_A$ receptor blockade, eliciting large amplitude $GABA_B$ inhibitory responses. We studied the effects of metabotropic glutamate receptor blockers and enkephalin on these subgroups of interneurons.

With 4-AP, CPP and CNQX present, the non-competitive metabotropic glutamate receptor blocker L-AP3 (1mM) decreased the amplitude of the $GABA_A$-mediated components of the synchronized response with little change in the frequency of occurrence of the response. The effects of (+)MCPG (0.5-1mM), a competitive metabotropic glutamate receptor blocker, were variable; however, in several experiments, the amplitude of the hyperpolarizing $GABA_A$ response was reduced, and the amplitude of the depolarizing $GABA_A$ response increased. MCPG had no effect on the isolated $GABA_B$ response.

In contrast, met-enkephalin (10 uM), produced a selective diminution of the $GABA_B$ component of the synchronized response in 50% of the experiments. In other experiments, the isolated synchronized $GABA_B$ response became fragmented, decreased in amplitude and increased in frequency.

These results are consistent with the hypothesis that there are distinct subsets of interneurons mediating $GABA_A$ and $GABA_B$ events in hippocampal pyramidal cells. (Supported by NS 33628 and a grant from the AES)

PRESYNAPTIC $GABA_B$ MEDIATED INHIBITION IN VENTROBASAL (VB) NEURONS IN THE LH/LH MOUSE MODEL OF GENERALIZED ABSENCE EPILEPSY.

S. J. Caddick* and D. A. Hosford. Neurology Res.,Duke & Durham VA Med.Centers,VAMC Bldg 16, Durham NC 27705.

Absence seizures represent the synchronized burst firing (spike wave discharges) of populations of cortical and thalamic neurons in an oscillatory fashion. Previous work in this laboratory has shown an increase in $GABA_B$ receptor binding in lethargic(*lh/lh*) mice, a genetic model of absence seizures[1]. Studies of locally evoked postsynaptic $GABA_B$ responses & $GABA_B$ activated gK^+ were compared between *lh/lh* & non-epileptogenic littermates (+/+) and found to be similar[2]. Following on from this we have looked at and compared the function of the presynaptic $GABA_B$ autoreceptors in VB. Local stimuli were used to evoke $GABA_A$ IPSC's isolated by application of DNQX(20μM) / DL-APV(20μM). The postsynaptic $GABA_B$ component was blocked throughout the experiment (Cs^+/QX-314). The effects of (-) baclofen (30μM) or paired stimuli given 100msec apart, were observed and compared between the two groups. No significant difference was observed for either measurement between the groups (% reduction by baclofen: *lh/lh*=55±4, n=3; +/+=48±7, n=4 and by paired stimuli, % reduction: *lh/lh*=31±8, n=3; +/+=43±18, n=4).We conclude from this that the observed increase in binding does not reflect a difference in presynaptic autoreceptor function in VB and are currently investigating the $GABA_B$ auto/heteroreceptors at other synapses within the thalamocortical loop.

Supported by grants from the NINDS and VA.

EXCITATORY AND INHIBITORY SYNAPTIC ACTIVITY DURING CA3 SYNCHRONIZATION: OSCILLATION VS. INTEGRATION K.J. Staley* and M. Longacher Neurology and Pediatrics, University of Colorado, Denver, CO 80262.

Intrinsically synchronized discharges of the CA3 network occur in vivo, and can be induced in the in vitro slice preparation by 8.5 mM extracellular (EC) K^+. The salient CA3 network characteristics, positive feedback via associational projections and negative feedback via interneurons, suggest that CA3 burst duration and intraburst spike firing may reflect oscillations between these feedback mechanisms.

CA3 bursts consisted of Pyramidal (Py) cell depolarizations synchronous with population potentials recorded in stratum pyramidale. Py cell depolarizations triggered 20-100 Hz spiking with pronounced spike frequency accommodation; EC bursts included nonaccommodating potentials (EC spikes) at 100-250Hz. Voltage clamp experiments revealed minimal membrane current oscillations. EC and Py cell bursts had a very high temporal correlation. Within a burst, EC and Py cell spikes showed a high initial correlation that decreased rapidly with burst duration: late in the burst, 1) spikes were much more likely to be out of phase (EC-Py phase drift) 2) EC spikes were likely to be unaccompanied by Py cell spikes (Py spike drop-out). EC-Py phase drift was not affected by agents that decreased burst duration, including NMDA antagonists and inhibitors of $GABA_A$ receptor-mediated membrane depolarization, nor by agents that increased burst duration ($GABA_B$ antagonists). Py spike dropout was highly correlated with burst duration.

Burst duration was modulated by synaptic conductances that are too slow to synchronize Py cell action potentials, intraburst membrane current oscillation was minimal, and the rate rather than synchrony of Py cell action potentials correlated with burst duration, suggesting that CA3 burst duration and intraburst Py cell firing are regulated not by inhibitory / excitatory oscillations, but by the time integral of synaptic activity. CORTICOTROPIN RELEASING HORMONE (CRH) INDUCES ACUTE ELEVATIONS IN THE INTRACELLULAR CA^{2+} CONCENTRATION ($[Ca^{2+}]i$) IN SUBSETS OF HIPPOCAMPAL NEURONS. J.H. Weiss*, H.Z.Yin, and T.Z. Baram. Depts. of Neurology, Pediatrics, and Anatomy and Neurobiology, U.C. Irvine, Irvine CA 92717.

Picomolar amounts of CRH produce limbic seizures in the immature rat (Baram et al., 1992). CA3 pyramidal neurons express high levels of CRH receptors (Avishai-Eliner et al, 1996), and selectively degenerate after CRH induced seizures (Baram & Ribak, 1995). CRH has been found to induce increases in $[Ca^{2+}]i$ in astrocytes and skin cells (Kiang, 1993). We set out to determine whether CRH induces direct rises in $[Ca^{2+}]i$ in subsets of hippocampal pyramidal neurons.

Embryonic murine hippocampal neurons were dissociated and plated on astrocyte monolayers on glass coverslips (Weiss et al., 1995), and used 8-12 d after plating (corresponding to postnatal days 3-8). After imaging baseline $[Ca^{2+}]i$ values (using Fura 2 fluorescent imaging techniques), either buffer alone or buffer with CRH (final conc. 300 nM - 2 μM) was added. CRH induced an increase in $[Ca^{2+}]i$ in a subset (about 20-30 %) of neurons imaged (> 200 neurons, >20 expts). The increase was generally to 1.5 - 3x baseline $[Ca^{2+}]i$ values, and responding neurons were generally large (>20 μm), often displaying pyramidal morphology. Buffer alone rarely caused any $[Ca^{2+}]i$ response, and kainate (as positive control) caused large, abrupt $[Ca^{2+}]i$ responses in virtually all neurons. In preliminary studies, pre-administration of an excess of a CRH antagonist (α-helical CRH) prevented CRH-induced $[Ca^{2+}]i$ responses. Ongoing studies are examining the mechanism of the $[Ca^{2+}]i$ response, and the relationship between $[Ca^{2+}]i$ responses and expression of CRH receptors. Induction, by CRH, of an acute $[Ca^{2+}]i$ rise in a certain hippocampal neurons could underlie the known ability of the peptide to trigger seizures and selective cell injury in immature animals. *Supported by NIH grants NS 30884 (JHW) and NS 28912 (TZB).*

CORTICAL AND THALAMIC PARTICIPATION IN THE GENERATION OF SEIZURES AFTER BLOCKAGE OF INHIBITION. D. Contreras*, A. Destexhe and M. Steriade. Lab. of Neurophysiol., Sch. Medicine, Laval University, Québec, CANADA G1K 7P4.

We explored the relative contributions of cortical and thalamic networks in the generation of seizures induced by decreased GABAergic inhibition. Seizures were induced by local injections of bicuculline (30 mM) in cortex or thalamus of barbiturate-anesthetized cats. Seizures were recorded as field potentials by means of an array of 8 tungsten electrodes (interelectrode distance of 1 mm) placed over the suprasylvian gyrus or in the thalamus spanning from the rostral pole of the reticular nucleus to the lateral geniculate nucleus. (1) Injection of bicuculline in the cortex induced the appeareance of epileptic-like single spikes in the cortex occurring during spontaneous spindle sequences, that developed into full-blown seizures characterized by highly synchronized spike-and-wave (SW) complexes at 3 Hz, combined with runs of 10-20 Hz spikes. During cortical-induced seizures, the thalamus could reflect the cortical activity, but in other epochs it was still able to generate spindle sequences. Complete decortication abolished the SW seizure, leaving intact spindles in the thalamus. (2) Injection of bicuculline in the thalamus decreased spindling frequency in a dose-dependent manner and increased the synchrony of spike-burts from thalamocortical and thalamic reticular cells. No SW patterns appeared in the cortex during the thalamic injection of bicuculline. Decortication did not modify the effect of bicuculline in the thalamus. (3) Injections of bicuculline in the cortex of athalamic cats showed similar components as those with intact thalamus. (4) Computational models of thalamocortical circuits showed 3-Hz SW-like patterns following the decrease of intracortical $GABA_A$-mediated inhibition, but not by alteration of intrathalamic inhibition alone. Taken together, these results suggest that the cortex is capable of generating 3-Hz SW patterns as well as 10-20 Hz runs of spikes that may be dissociated from thalamic spindles.

CORTICAL PROJECTIONS TO THE THALAMIC RETICULAR NUCLEUS MAY CONTROL THE SPATIOTEMPORAL COHERENCE OF SPINDLE AND EPILEPTIC OSCILLATIONS. A. Destexhe*, D. Contreras, T.J. Sejnowski‡ and M. Steriade. Department of Physiology, Laval University, Québec, CANADA G1K 7P4; ‡ Computational Neurobiology Laboratory, The Salk Institute, PO Box 85800, San Diego, CA 92186, USA.

Recent experiments revealed a powerful effect of the cortex in synchronizing thalamic oscillations into very coherent spatiotemporal patterns. We investigated possible network mechanisms underlying the control of thalamic and cortical oscillations using computer models. The intrinsic properties of thalamic and cortical cells were modeled using voltage-dependent currents described by Hodgkin-Huxley type of kinetics, and synaptic currents were modeled by kinetic models for AMPA, $GABA_A$ and $GABA_B$ receptors. We successfully modeled the following electrophysiological observations *in vivo* and *in vitro*: (a) without cortex, thalamic networks displayed spindle sequences with few simultaneity and propagating properties; (b) in the presence of the cortex, spindle oscillations were nearly simultaneous due to extended thalamo-cortical and cortico-thalamic projections; (c) if cortical discharges were tuned down by increased intracortical inhibition, the spatiotemporal coherence of spindle waves was decreased; (d) decreased cortical inhibition led to stronger cortical discharges that could force the intact thalamic circuitry into ~3 Hz oscillations due to the particular properties of $GABA_B$ receptors; in this case, all cells displayed prolonged discharges similar to some type of epileptic patterns. The model suggests that cortical cells have a powerful influence on recruiting thalamic-generated oscillations primarily via their projections to the reticular nucleus. Through this mechanism, cortical discharges have a decisive impact in controlling the type and spatiotemporal pattern of oscillations generated in the thalamus. LOW-Ca^{2+}-INDUCED EPILEPTIFORM ACTIVITY IS BLOCKED BY THE L-TYPE CALCIUM CHANNEL BLOCKER VERAPAMIL R. Köhling*, G. Weining, H. Straub, A. Lücke, E.-J. Speckmann Institut für Physiologie, Universität, 48149 Münster, Germany

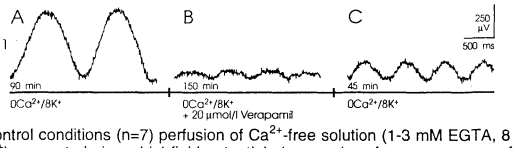
Organic calcium channel blockers (verapamil, nifedipine, nimodipine) have been shown to suppress epileptiform activity in a variety of epilepsy models. In these models synaptic transmission was intact. The question is whether synaptic transmission is a prerequisite for the antiepileptic calcium antagonism. Therefore, the antiepileptic efficacy of the phenylalkylamine-type calcium antagonist verapamil was tested in the absence of synaptic transmission, i.e. in the so called 0-Ca^{2+} model (cf. Jeffereys JGR and Haas HL, *Nature* 300, 448-450, 1982).

The experiments were performed on guinea pig hippocampal slices (n=25) in an interface-type chamber. Field potentials were recorded from stratum pyramidale in the CA1 subfield.

Fig. 1



In control conditions (n=7) perfusion of Ca^{2+}-free solution (1-3 mM EGTA, 8 mM K^+) generated sinusoidal field potential changes in a frequency range of 0.5 to 2.0 Hz which remained stable for 300-360 min (Fig. 1A). The application of verapamil in concentrations of 40, 20 and 10 µM suppressed field potential activity within 60-180 min, respectively (n=10, n=8 and n=6, Fig. 1B). This effect was reversible, at least in part (Fig. 1C).

The experiments indicate that the antiepileptic effect of organic calcium antagonists can be independent of synaptic transmission.

EFFECTS OF MAXIMUM CONDUCTANCE OF LOW THRESHOLD CALCIUM CHANNELS ON OSCILLATORY BEHAVIOR. E. Thomas* and T. Grisar. Department of Neurochemistry, University of Liège, 4000 Liege, Belgium.

The effect of the maximum conductance of the low threshold calcium current ($\bar{g}I_t$) on a model thalamic network were studied. An isolated increase in the $\bar{g}I_t$ of the genetic absence epilepsy rat from Strasbourg (GAERS) is thought to be partially responsible for low frequency (7-11Hz), synchronized neuronal activity during wake. The investigations on GAERS reveal that compared to the normal rat there is an increase in the low threshold calcium current (I_t) of the nucleus reticularis (RT) neurons, but not in the thalamocortical (TC) neurons. A model of two RT neurons and one TC neuron was constructed using the Hodgkin Huxley formalism. The ability of the network to produce oscillations were tested over the RT neuron $\bar{g}I_t$ range of 0.15 to 0.60 mS/cm^2 at a resting membrane potential (rmp) of approximately -55mV. As $\bar{g}I_t$ was incremented the network went from a quiescent state following an initial pulse, to one of maintained oscillations at 0.35 mS/cm^2. Values of $\bar{g}I_t$ unable to produce oscillations at the rmp of -55mV still did so at the rmp of -80mV. Rhythmic oscillations in the network at the rmp of -55mV occurred at 7-9Hz. The oscillations started out at a frequency of 9Hz ($\bar{g}I_t$ 0.30mS/cm^2) and gradually decreased to 7Hz ($\bar{g}I_t$ 0.60mS/cm^2). At $\bar{g}I_t$ values too low for network oscillations, the low threshold spike of the RT neurons did not reach threshold (0mV) for the release of neurotransmitter. The results of the model support the hypothesis that an isolated augmentation of $\bar{g}I_t$ in the RE neurons could lead to low frequency oscillations at elevated membrane potentials. (This work was partially funded by the FNRS of Belgium).

TRH MODULATION OF HIPPOCAMPAL NEURON EXCITABILITY AND HYPERSYNCHRONY IN AN IN VITRO MODEL OF SEIZURE.

Bradley Van Sickle and David Lee Quinn*, Department of Biology, Muskingum College, New Concord, OH 43762.

Over many years of study, researchers have discovered that no single mechanism underlies epileptiform activity (Schwartzkroin, 1993), yet rat in vitro hippocampal slice preparation provides an excellent model for studying physiological and pharmacological mechanisms that cannot be isolated in vivo. Stimulus-evoked afterdischarge (SEAD) model uses electrical stimulus trains to initiate seizure-like activity in the hippocampal slice. (Stasheff et al., 1985). Ujihara et al. (1991) suggested that antiepileptic effect of TRH was mediated by central dopaminergic system. We examined TRH modulation of SEADS and population field spikes in area CA1 of the rat hippocampal slice. Extracellular recordings were taken in the CA1 pyramidal cell body layer while artificial cerebrospinal fluid (ACSF), 20 µM TRH, or 20 mM TRH was pushed into bathing medium. Polygraph recordings of SEAD lengths showed a significant (p<.05) increase, 181%+/-91, in the 20 mM TRH application. Rapid increase in SEAD length decreased over time, and two slices abruptly seized-out and failed to discharge further suggesting an increase in neuronal hypersynchrony. Facilitation of field spikes by stimulus trains resulted in an increased spike height, which was further increased by subsequent application of 20 mM TRH, 76.6%+/-2.8 (p<.05). The increase occurred within 15 minutes with spike height decreasing after reaching peak height. However, field spikes still remained significantly increased throughout post-push period. Also, spike latency recordings significantly increased (p<.05) by 12.4%+/-2.9 in 20 mM TRH. This increase developed 20 minutes after drug perfusion and remained throughout the recording period. Our experiments suggest that 20 mM TRH increases the hypersynchronous activity and neuron excitability in hippocampal neurons and supports the concept of indirect action of TRH on inhibition of seizure activity. THE EFFECT OF ACUTE AND CHRONIC FLUNARIZINE ON HYPERBARIC OXYGEN-INDUCED SEIZURES. C.R. Auker*, D.O. Keyser, and S.T. Ahlers. Naval Medical Research Institute, Bethesda, MD 20889-5607.

Flunarizine, the difluoro derivative of cinnarizine, has been shown to have anti-epileptic properties in certain experimental models of epilepsy due to the block of calcium entry through T-type calcium channels. Previous research has shown that acute administration of flunarizine is ineffective against seizures induced by exposure to 100% O_2 under hyperbaric conditions (Eur J Pharm 228:241, 1993). Recent studies suggest that blockade at T-type calcium channels with flunarizine may become more effective with repeated administrations. Accordingly, rats were injected with either 5 mg/kg or 10 mg/kg flunarizine acutely (i.p. injection 1 hour pre-dive) or chronically (i.p. injection 1 per day over 4 days) and exposed to 100% hyperbaric O_2 (6 ATA). There was a marked decrease in latency to onset of seizure activity in all flunarizine-treated groups relative to vehicle-injected controls (see figure). These data suggest that T-type calcium channel activity may be involved in modulating seizure threshold under hyperbaric oxygen conditions and is consistent with previous data reported from this laboratory using other calcium channel antagonists. *(Supported by NMRDC Work Unit 62233N MM33P30.005-1519)*

EXPOSURE TO 100% NORMOBARIC OXYGEN CAUSES DEPOLARIZATION AND AMINO ACID RELEASE IN MICROCULTURES OF NEURONAL CELLS. N.S. Nadi*, Q.T. Hoang, and I.M. Elayan. Naval Medical Research Institute, Bethesda, MD 20889-5607.

The use of pure oxygen in diving operations reduces the risk of decompression sickness and allows an increase in the duration of dives. However the induction of seizures by hyperbaric oxygen restricts its beneficial use. The molecular mechanisms of hyperbaric-oxygen-induced seizures are not clearly understood. In order to investigate this subject, we have set up microcultures of hippocampal cells dissociated from the fetal rat brain. Whole cell recording techniques have demonstrated that the microcultures establish glutamatergic as well as GABAergic synapses. In addition, whole-cell recordings from our laboratory have confirmed that the microcultures develop seizure-like electrical activity in response to exposure to, and withdrawal from, glutamate antagonists. Using the membrane permeant lipophilic cation, tetraphenylphosphonium, we have shown that the hippocampal microcultures depolarize in response to normobaric hyperoxic conditions from a resting membrane potential of -69±5 mV (n=6) to -15±4 mV (n=6). Sister cultures depolarized to -8±2 mV in the presence of 60 mM K^+. The measurement of endogenous amino acid release from the microcultures showed that glutamate, aspartate, and GABA are released from the cells under hyperoxic conditions in a calcium-dependent manner. The pattern of the hyperoxia-induced release is similar to that observed for 60 mM K^+. Attempts to measure free radical formation in the presence of salicylate have not been successful to date. This question is being further investigated. The hyperoxic depolarization observed in the cells suggests that seizure-like activity may also occur in this model. Whole cell recording studies are currently underway to test this possibility. This preparation may be a useful model for the study of the mechanisms of hyperoxic seizures. (Supported by NMRDC Work Unit No. 61153NMR04101.001-1601).

823.1

SUPPRESSION OF EPILEPTIFORM ACTIVITY BY NIFEDIPINE IN HIPPOCAMPAL AND NEOCORTICAL SLICES (GUINEA PIGS) E.-J. Speckmann*, H. Straub, R. Köhling, A. Frieler and M. Grigat. Institut für Physiologie, Universität, 48129 Münster, Germany

The aim of the present investigation was to compare the antiepileptic efficacy of nifedipine in hippocampal and neocortical preparations.

Experiments were performed on brain slices (500 µm) of guinea pigs. Epileptic field potentials (EFP) were induced by Mg^{2+}-free solution. Nifedipine (40, 20 µmol/l) was added in 4 mmol/l (4 K^+) and 8 mmol/l (8 K^+) K^+ concentration. Criteria for nifedipine effects were repetition rate and area integral of EFP in hippocampal and neocortical slices, respectively.

Hippocampus: EFP occurred with repetition rates of 9/min (4 K^+; n = 25) and 31/min (8 K^+; n = 16). With 40 µmol/l nifedipine (n = 15) latencies of 90% depression ($t_{0.9}$) were 287 min (4 K^+; n = 5; $t_{0.9}$ not reached within 5 hours, n = 2) and 74 min (8 K^+; n = 8); with 20 µmol/l nifedipine (n = 14), $t_{0.9}$ was not reached within 5 hours (4 K^+; n = 6), and $t_{0.9}$ was 136 min (8 K^+; n = 8). During nifedipine application, the repetition rate transiently increased in 26 out of 29 experiments up to 2 fold (8 K^+) and 7 fold (4 K^+) the value before nifedipine application. With washout of nifedipine EFP reappeared.

Neocortex: EFP occurred with repetition rates of 5/min (4 K^+; n = 27) and 10/min (8 K^+; n = 14). With 40 µmol/l nifedipine (n = 20), $t_{0.9}$ were 167 min (4 K^+; n = 11; $t_{0.9}$ not reached within 5 hours, n = 4) and 186 min (8 K^+; n = 5); with 20 µmol/l nifedipine (n = 17) $t_{0.9}$ were 269 min (4 K^+; n = 5; $t_{0.9}$ not reached within 5 hours, n = 4) and 212 min (8 K^+; n = 7; $t_{0.9}$ not reached within 7 hours, n = 1). During nifedipine application the repetition rate transiently increased in all and the area integral in 11 out of 22 experiments up to 3 fold the initial level. With washout the nifedipine effects were not reversible.

The antiepileptic efficacy of nifedipine differs in both preparations, especially concerning the dependency on extracellular K^+-concentration.

A NOVEL NON-SELECTIVE CATION CHANNEL WHICH BEHAVES AS A CALCIUM SENSING RECEPTOR (CaSR) IN HIPPOCAMPAL NEURONS. Zhigang Xiong, J.F. MacDonald*. Department of Physiology, University of Toronto, Toronto, Canada, M5S, 1A8.

Extracellular calcium concentration $[Ca^{2+}]_e$ in the pyramidal cell layer of the hippocampus falls dramatically during high frequency stimulation or during seizure-like activity (Krnjevic, et al 1982; Heinemann, et al 1977). In order to understand how such changes might be detected by the postsynaptic membrane we studied the responses of cultured and acutely isolated mouse hippocampal neurons to rapid changes in $[Ca^{2+}]_e$. In current clamp recordings reductions in $[Ca^{2+}]_e$ from 1.5 to 0.5 mM strongly depolarized and excited cultured neurons. Reductions in $[Ca^{2+}]_e$ evoked graded inward currents from whole-cell voltage-clamped cultured or acutely isolated neurons. This current was generated by a calcium-sensitive (IC_{50}, 0.15 mM) non-specific cation channel possessing a single channel conductance of about 36 pS. Decreasing $[Ca^{2+}]_e$ increased the open probability of this channel without affecting the single channel conductance. The current was also blocked by Mg^{2+}, Ba^{2+}, and Cd^{2+} (IC_{50}: 0.35, 0.30, and 0.42 mM, respectively). This rank order of sensitivity suggested that Ca^{2+} might bind to and shield negative surface charges involved in regulating the channel gating. To further explore the role of membrane surface charge we decreased ionic strength to 1/4 of its normal value. This enhanced the sensitivity of the current to Ca^{2+} by about 3 to 4 fold. Furthermore, the channel was also highly sensitive to Gd^{3+} (IC_{50}, 1.4 µM) which is known to be much more effective at shielding surface charge than calcium. Our results demonstrate the presence of a novel non-specific cation channel in hippocampal neurons that can also serve as a Calcium Sensing Receptor (CaSR) analogous to those of the parathyroid. Calcium depresses the gating of this channel likely by binding to a highly negative region of surface charge on or near the channel. Supported by the Medical Research Council of Canada.

823.3

CALCIUM DYNAMICS IN HIPPOCAMPAL NEURONS DURING CONTINUOUS SEIZURE DISCHARGES AND DURING CHRONIC SPONTANEOUS SEIZURE ACTIVITY S. Pal, J.W. Bigbee[1]*, and R.J. Delorenzo. Dept. of Neurology, Dept. of Anatomy[1], Medical College of Virginia, Richmond, Virginia 23298.

Calcium and calcium-dependent mechanisms have been implicated in multiple aspects of the pathophysiology of epilepsy. Utilizing the hippocampal neuronal culture (HNC) model of "epilepsy" (Sombati et al., J. Neurophysiology, 73 (4):1706-1711), we have shown that cells which demonstrate epileptiform activity display a synchronous pattern of increases in intracellular Ca^{2+} ($[Ca^{2+}]_i$) levels during seizure activity. In this study, using confocal microscopy, we have shown that low Mg treatment and resulting sustained epileptiform discharges produce chronic elevations in $[Ca^{2+}]_i$ to about 300-500 nM. This increase in $[Ca^{2+}]_i$ could be partially blocked by NMDA receptor antagonists APV and MK-801, CNQX (kainate/AMPA receptor antagonist), NBQX (AMPA receptor antagonist) or a combination of nifedipine and w-conatoxin (voltage-gated channel antagonists). Moreover, the increase in $[Ca^{2+}]_i$ was also blocked when the extracellular medium was depleted of Ca^{2+} ions. The $[Ca^{2+}]_i$ levels returned to almost control levels after the 3h low Mg treatment. This 3h treatment has been previously shown in our laboratory to induce recurrent spontaneous seizure activity in the HNC model which was blocked by NMDA receptor antagonists. These results demonstrate the dynamic changes in intracellular Ca^{2+} during continuous and intermittent seizure activity.

ELECTROPHYSIOLOGICAL EFFECTS OF AMINO-OXYACETIC ACID (AOAA) IN THE RAT MEDIAL ENTORHINAL CORTEX: RELATIONSHIP TO SUBSEQUENT NEURODEGENERATION, R. Schwarcz*[1] and H.E. Scharfman[2]. [1]Maryland Psychiatric Research Ctr., Baltimore, MD 21228, and [2]Neurology Research Ctr., Helen Hayes Hosp., NY State Dept. of Health, W. Haverstraw, NY 10993, and Depts. Pharmacol. & Neurol., Columbia Univ., NY, NY 10032.

Injection of AOAA into the rat entorhinal cortex (EC) produces seizures and cell loss, particularly in layer III of the medial EC. To understand its effects, AOAA was applied focally to layer III (by leak from a pipette containing 100mM or by pressure ejection) or bath-applied (50-500µM). Extracellular and intracellular recordings were made in horizontal slices. Stimulation of the angular bundle was used to monitor synaptic responses. In control conditions, the typical response to stimulation in layer III cells was a small EPSP and IPSP. AOAA application led to a progressive decrease in amplitude of the IPSP and appearance of a slow EPSP that evoked discharges. The EPSP was largest at membrane potentials depolarized to -60 mV, and decreased with hyperpolarization. The effect did not reverse even 2 hours after removal of drug from the perfusing buffer or AOAA-containing micropipette from the slice. Repetitive stimulation after AOAA application led to increases in the slow EPSP and depolarization of the cell, and could lead to spontaneous repetitive discharges that were synchronized with slow extracellular negative field potentials. The N-methyl-D-aspartate (NMDA) receptor antagonist D-amino-5-phosphonovaleric acid (APV) blocked all of the effects of AOAA reversibly. APV that was applied focally to layer III (50-100µM) was as effective as bath-application (25µM). Focal application of vehicle had no effect. These data suggest that AOAA has a long-lasting effect when applied to medial EC that involves an enhancement of NMDA receptor-mediated activity. The persistence of this action may lead to depolarization and eventual neurodegeneration and could explain the preferential cell loss observed in layer III following AOAA injection in the EC in vivo. Supported by NINDS grant 16102.

OUABAIN- AND DIHYDROOUABAIN-INDUCED INTERICTAL-LIKE BURSTING IN RAT HIPPOCAMPUS. S.E. Mason and B.E. Alger*. Dept. Physiol., Univ. Maryland, Sch. Med., Baltimore, MD 21201.

Epileptiform burst potentials (interictal spikes) can be induced by raising extracellular potassium ($[K^+]_o$) and lowering firing threshold in the rat hippocampal slice. Dihydrooubain (DHO), an analog of the specific Na^+,K^+-ATPase inhibitor ouabain, also produces interictal-like bursting in CA1, which is accompanied by a decrease in IPSPs but insignificant changes in resting potential and local $[K^+]_o$ (Cuttle and Alger, Soc. Neurosci. Abstr., Vol. 20, p. 398, 1994). To investigate the possible mechanism for this effect and to confirm that the DHO effect is indeed mediated by block of Na^+, K^+-ATPase, we examined the dose-response relationship between ouabain or DHO (1 µM-50 µM) and bursting intensity using CA1 population spikes as an assay.

When bath applied at 1 µM-3 µM for 15 minutes, neither ouabain nor DHO induced additional population spikes but caused a slight depression in initial spike amplitude. At 5 µM-7.5 µM, ouabain and DHO both produced a small second spike. Thirty µM DHO and 10 µM ouabain were maximally effective in inducing multiple spikes 10-15 minutes after drug application began. Higher doses produced submaximal bursting. Thus, ouabain is only slightly more efficacious than DHO in our assay. A difference between ouabain and DHO, however, is that the DHO effect is readily reversed, whereas the ouabain effect is irreversible with up to 1 hour of washing. Nevertheless, the similarity in the effects of ouabain and DHO implies that DHO acts specifically to inhibit the Na^+, K^+-ATPase. As previously noted, doses of DHO sufficient to induce bursting cause only minor changes in resting potential and $[K^+]_o$. It will be interesting to determine the cellular mechanisms underlying DHO-induced bursting. Supported by NS22010 to B.E.A.

EXTRACELLULAR ZINC MEDIATES SELECTIVE NEURONAL DEATH IN HIPPOCAMPUS AND AMYGDALA FOLLOWING KAINATE-INDUCED SEIZURE. S. W. Suh*[1], J.Y. Koh[2] and D.W. Choi[1]. [1]Center for the Study of Nervous System Injury and Dept. of Neurology, Washington Univ. Sch. of Med., St. Louis, MO 63110. [2]Dept. of Neurology, Ulsan Univ. Sch. of Med., 388-1 Seoul, Korea

Excessive entry of extracellular Zn^{2+} is toxic to central neurons. We have recently reported evidence that endogenous Zn^{2+} is a key mediator of selective neuronal death in several brain regions following transient global ischemia in rats (J.Y. Koh et al., *Science*, in press). Specifically, chelation of extracellular Zn^{2+} by intraventricularly injected CaEDTA attenuated both Zn^{2+} translocation into the cell bodies of selectively vulnerable neurons, and their degeneration. In the present study, we examined the possibility that Zn^{2+} toxicity might contribute in similar fashion to the selective death of hippocampus and amygdala neurons associated with prolonged seizures, another paradigm where Zn^{2+} translocation has been described (Sloviter, Frederickson).

Adult rats were injected subcutaneously with kainate (8 mg/kg) followed 3 hr later with diazepam (10 mg/kg, to limit seizures and mortality). All the rats developed wet dog shakes followed by sustained generalized convulsions. 3 hr after kainate injection, staining of brain sections with the zinc specific fluorescent dye, TSQ, revealed loss of presynaptic Zn^{2+} in mossy and other terminals, together with the new appearance of Zn^{2+} in certain neurons in hippocampus and amygdala. 72 hr after kainate injection, acid-fuchsin staining revealed a near one-to-one correlation between dense TSQ fluorescence in neuronal cell bodies, and degenerative changes. As an interesting point of comparison, 10-12 d pups, which have less Zn^{2+} in brain, did not exhibit neuronal death in these areas 72 hr after kainate injection (2 mg/kg s.c.), despite also sustaining severe tonic-clonic seizures. Injection of CaEDTA (100mM/5ul) into the ventricles of adult rats 10 min before the kainate injection markedly reduced both zinc translocation and subsequent selective neuronal death in hippocampus and amygdala. Present results support a key role of Zn^{2+} in mediating selective neuronal death occurring after sustained seizures. Supported by NIH NINDS grant 30337 (DWC).

BLOCKADE OF $GABA_A$-MEDIATED INHIBITION REVEALS EXCITATORY CHOLINERGIC EFFECTS IN IMMATURE RAT HIPPOCAMPUS. C. Psarropoulou* and F. Dallaire Dept of Physiology and Biophysics, Faculty of Medicine, University of Sherbrooke, Sherbrooke, QC, Canada J1H 5N4.

We used the hippocampal slice preparation to investigate the effects of cholinergic receptor activation in the immature CA3 area (postnatal days 10-20, Sprague-Dawley rat pups), following blockade of $GABA_A$-receptor mediated potentials by bicuculline (BMI). BMI (10-40μM, n=40 slices) enhanced the amplitude and duration of evoked synaptic responses recorded intra and extracellularly; in addition it induced infrequent spontaneous synchronous discharges (0.011-0.023Hz) in some of the slices. The cholinomimetic carbachol (Cch 25μM, n=22) added in the presence of BMI i) depressed the evoked responses and ii) induced spontaneous synchronous epileptiform discharges (0.1-0.2Hz). Both effects (i and ii) were mimicked by Ach (100μM, in eserine 10μM) and were reversed by the addition of atropine (1μM, n=5) or the M1-muscarinic receptor antagonist pirenzepine (5-10μM, n=3). The spontaneous Cch-induced activity was synaptic in origin since i) it was reversibly blocked by CNQX (10μM, n=3) and ii) cell hyperpolarization changed its amplitude but not its frequency. High Ca^{2+} (7mM) ACSF which inhibits the activation of polysynaptic circuits, blocked reversibly the Cch-induced synchronous activity (n=5). In normal ACSF, Cch (25μM) depressed the evoked responses (reversed by atropine 1μM, n=2), but did not provoke any synchronous spontaneous activity (n=9). Cch depolarized 9/11 cells by 10 $\pm$ 2mV and blocked the AHP reversibly in 5/5 cells.

In conclusion, activation of M1-muscarinic receptors during blockade of $GABA_A$-mediated potentials, exacerbates spontaneous epileptiform activity in CA3 area of immature hippocampus, probably through the recruitment of additional recurrent excitatory connections. Thus, in the absence of GABAergic inhibition, the cholinergic excitatory effects on intrinsic membrane properties appear to play a major role compared to the cholinergic inhibition of transmitter release.

INHIBITORY CURRENTS IN A DEVELOPMENTAL MODEL OF EPILEPSY. K.M. Jacobs*, J.R. Huguenard, and D.A. Prince. Dept. Neurology & Neurological Sciences, Stanford Univ. Medical Center, Stanford, CA 94305.

Human polymicrogyria associated with epilepsy can be modeled in rats with a transcortical freeze lesion at P0 or P1, which produces a microgyrus and an adjacent epileptogenic region of neocortex (Jacobs, et al. Cereb. Cortex 6: 514, 1996). We tested the hypothesis that disinhibition contributes to epileptogenesis in this model, by analyzing spontaneous and evoked postsynaptic inhibitory currents (sIPSCs and eIPSCs) in layer V neurons in cortical slices from control and lesioned (P13-16) rats, using whole cell patch clamp techniques. Of 30 cells recorded 0.5 to 1.25 mm from the microsulcus, 47% showed late, variable-latency, all-or-none evoked outward currents, suggestive of epileptiform activity (epi cells). The mean peak amplitude of sIPSCs was significantly greater for epi cells (69.3±7.1 pA, SEM) than for controls (51.3±2.2 pA; t-test, $p<0.05$). This difference was due to a larger maximum amplitude (1170 pA in epi cells versus 279 in control) and to a greater percentage of large sIPSCs in epi cells: 40.3% of sIPSCs in epi cells and only 19.7% of those in control neurons had an amplitude of >66 pA. These differences were not maintained when DNQX and AP5 were included in the bathing medium. sIPSC frequency was not significantly different for the two groups in normal medium, however during DNQX and AP5 perfusion there was a significantly greater decrease in sIPSC frequency in epi cells (-46.2±10.4%) than in controls (-18.7±6.5%; t-test, $p<0.05$).

Short latency eIPSCs were elicited by stimulation within 300 µm of the recorded cell in control solution. The mean peak amplitude of eIPSCs evoked at stimulation threshold was significantly greater in epi cells (150.3±104.3) than in controls (46.6± 28.0; t-test, $p<0.05$), while there was no difference in peak amplitude for eIPSCs evoked at 4X threshold. This suggests that there is less inhibitory recruitment available with stimulation increases in slices containing a microgyrus.

Increased excitatory input onto inhibitory neurons may account for these differences. Results thus far do not support the hypothesis that epileptogenesis in this model is due to decreased GABAergic inhibition, but rather suggest that both pyramidal neurons and GABAergic interneurons are hyperinnervated in the region adjacent to the microgyrus. Supported by NIH grants NS09806 and NS12151.

REDUCTION OF RECURRENT INHIBITION IN THE RAT HIPPOCAMPUS AFTER ENTORHINAL CORTEX KINDLING. H. Solís, J. Bravo, E. López, L. Parra, B. Barrera-Mera* and A. Ortíz. Dept. of Anatomy. Lab. of Neurophysiology. Fac. of Medicine. National University of México. UNAM.

Recent observations have indicated that recurrent inhibition in the hippocampus, as measured with paired-pulse technique, is reduced following seizures. We have evaluated recurrent inhibition in brain slices of rats that have been kindled beyond the typical stage five criterion. One group of animals served as controls and received no kindling stimulations. Another group was kindled to stage 5 seizures. Coronal sections of 400 µm thick were prepared using a vibrating tissue slicer. Intracellular recordings where done in cells of CA1 region. The recurrent inhibition was assessed by calculating the ratio (PS(T)/PS(C): IMI=index of maximal inhibition) of the amplitude of the second (test) population spike to that of the first (conditioning) population spike. We observed a significant difference between the control (mean=-70 mv) and the kindled (mean=-65 mv) group about the membrane resting potential. The amplitude of the inhibitory postsynaptic potentials was less in the kindling group than the control. Also a significant reduce in the recurrent inhibition was observed. The results suggest that in the enhancement of excitability could be involved a disinhibition phenomenon.

Identification of sources of the interictal transients generation in hippocampus during kindling.

Bragin A.*§‡ ,Chrobak J.,‡ and Csicsvari J.,‡ CMBN, Rutgers University, Newark, NJ,‡ Department of Neurology, UCLA, Los Angeles, CA.§

Development of interictal transients (ITs) in dentate gyrus, CA1- CA3 areas of hippocampus, entorhinal cortex (EC), piriform cortex (Pi) and amygdala (Am) was studied in freely moving rats after seizures evoked by electrical stimulation of perforant path or/and commissural pathways. 16-site recording silicone probes (100 µm vertical spacings) allowed us to record the local field potentials and unit activity along soma-dendritic axis and convert potentials to current-source density maps. ITs emerged after 3-9 seizures in all investigated areas and virtually any region could initiate them. With further seizures, the ITs became hypersynchronous and events occurred within 3-15 msec in the different recording areas.

Three types of ITs were observed in hippocampus. Type 1 and 2 had negative or positive polarities in the stratum radiatum of CA1 or the dentate molecular layer, respectively. Types 1 and 2 IT are expected to be triggered from CA3a, CA3c and EC. Type 3 IT were large population spikes in the CA1 pyramidal layer without obvious dendritic depolarization. The origin of type 3 ITs is unclear. They may reflect enhanced excitation of the somata or may be triggerred antidromically from the CA3 or entorhinal regions. Two types of ITs were observed in the entorhinal and piriform corties, but only one type was found in amygdala. Current source density analysis of local field potentials recorded in CA1 - DG axis showed that ITs with similar shape could be triggered from different afferents. Most interneurons showed a high correlation with ITs and their increased activity typically preceded the ITs. Our results suggest that multiple foci can generate ITs during the kindling procedure. QX-314 EFFECTS ON BICUCULLINE- AND NMDA-INDUCED EPILEPTIFORM BURSTS. S. Birnstiel*, E. Wülfert and S.G. Beck. Dept. Pharmacol., Loyola Univ. Med. Ctr., Maywood, IL 60153.

Epileptiform bursts are complex phenomena which likely result from the activation of numerous ion channels. Selective removal of ionic conductances by toxins may be useful in studying the mechanism of action of antiepileptic drugs on burst firing. We therefore started to investigate the effects of the local anesthetic drug QX-314 on spontaneous epileptiform activity evoked by N-Methyl-D-Aspartate (NMDA) and synaptically evoked bursts in the presence of bicuculline. Intracellular recordings were obtained from the CA3 pyramidal cell layer of transversal slices of rat hippocampus. Synaptic potentials were evoked by stimulation of the septal pathway. When control electrodes (2 M KCH_3SO_4/10 mM KCl) were used, both NMDA- and bicuculline- induced bursts had either the appearance of a big EPSP carrying several action potentials, or the first spikes were followed by a depolarized plateau. All bursts were followed by prolonged afterhyperpolarizations which were not altered by QX-314. In experiments in which the microelectrode contained 100 mM QX-314, NMDA-induced bursts consisted either of a big EPSP carrying one or more calcium spikes or of a calcium spike followed by a depolarized plateau. The area under the burst did not appear to be altered in the presence of QX-314. However, the area under synaptically evoked bursts in the presence of bicuculline was increased in the presence of QX-314. This indicates that bursts induced by NMDA or bicuculline may consist of different components. It is under current investigation if this finding is related to the enhancement of calcium binding to the ryanodine receptor by QX-314. Supported by UCB Pharma.

INVOLVEMENT OF THE NUCLEUS ACCUMBENS-VENTRAL PALLIDAL PATHWAY IN POSTICTAL BEHAVIOR INDUCED BY A HIPPOCAMPAL AFTERDISCHARGE IN RATS. J. MA, S.M. BRUDZYNSKI & L.S. LEUNG* Dept. of Physiology and Clinical Neurosci, Univ.of Western Ont. London, Canada N6A 5A5

The hypothesis that postictal motor behaviors induced by a hippocampal afterdischarge (AD) are mediated by a pathway through the nucleus accumbens (NAC) and ventral pallidum (VP) was evaluated in freely moving rats. Tetanic stimulation of the hippocampal CA1 evoked an AD of 15-30 s and an increase in number of wet dog shakes, face washes, rearings and locomotor activity. Bilateral injection of haloperidol (5 µg/side) or the selective dopamine D_2 receptor antagonist, (+)-sulpiride (200 ng/side) before the hippocampal AD, into the NAC selectively reduced rearings and locomotor activity, but not the number of wet dog shakes and face washes. Injection of R(+)-SCH-23390 (1 µg/side), a D_1 receptor antagonist, or rimcazole (0.4 mg/side), a sigma opioid receptor antagonist, into the NAC did not significantly alter postictal behaviors. Bilateral injection of muscimol (1 ng/side), a γ-aminobutyric acid ($GABA_A$) receptor agonist, into the VP before the AD significantly blocked all postictal behaviors. It is concluded that postictal locomotor activity induced by a hippocampal AD is mediated by activation of dopamine D_2 receptors in the NAC and a pathway through the VP (supported by NSERC and NS 25383).

ENHANCEMENT OF HIPPOCAMPAL EXCITATION BY CA3 STIMULATION IN KAINATE-SEIZED RATS: A CURRENT SOURCE DENSITY STUDY. K.Wu* and L.S. Leung Dept. Physiology and Clin. Neurol. Sci., Univ. Western Ontario, London, N6A 5A5, Canada

Seizures were induced by kainic acid (KA, 0.5μg/1μL, i.c.v) in hooded rats and the effects on the hippocampus were studied 2-4 months later under urethane anesthesia. Extracellular potential was mapped through dorsal hippocampus following ipsilateral CA3b and perforant path stimulation and current-source-density (CSD) analysis was used to reveal the locations and time courses of action or synaptic currents. An current sink of 3.32 ± 0.22ms (n=12) onset in the inner molecular layer (IML) of the dentate gyrus (DG) was observed in KA seized but not control rats. This sink was surrounded by sources at the granule cell (GC) layer and the middle-outer molecular layer of the DG. Mossy fiber (MF) sprouting, assessed by Timm's stain, was found in many but not all rats with an IML sink. It is suggested that the IML sink in KA seized rats could result from an enhanced excitation of the DG by CA3b stimulation and was not solely caused by MF sprouting; Excitation of the MF, as indicated by an antidromic population spike (popspike) in the DG, did not precede the IML sink in some rats. In 8 of 14 KA seized rats, a popspike in the DG starting at 21.28 ± 1.13ms (N=8) was observed during the late reverberant DG excitation after CA3b stimulation; this late DG popspike was not observed in 11 control rats. Similarly, CA3b stimulation resulted in a late popspike (20.63 ± 0.65ms onset) in CA1 in 6 of 14 KA rats and 0 of 11 control rats. The late CA1 popspike appeared to have a sink at the distal dendrites and a source at the CA1 cell layer. These late popspikes suggest an increased excitation of the reverberant hippocampal-entorhinal loop in KA seized rats. In conclusion, functional neural plasticities were found in KA seized rats. These physiological plasticities are additional to those induced by MF sprouting and may provide a better understanding of temporal lobe epilepsy. (Supported by NS 25383)

SUPPRESSION OF PAIRED-PULSE DEPRESSION OF MONOSYNAPTIC INHIBITORY POSTSYNAPTIC CURRENTS (IPSCs) IN CA1 NEURONS BY PARTIAL HIPPOCAMPAL KINDLING. C. Wu* and L.S. Leung. Dept. Clinical Neurological Sciences and Physiology, University of Western Ontario, London, ON, Canada.

Fifteen high-frequency (100 Hz for 1 sec) trains that evoked afterdischarges or 15 control stimulations (100 pulses at 0.16 Hz) were given to the hippocampal CA1 of male Long-Evans rats over 3 days. In vitro hippocampal slices were prepared 1-2 days after kindling/control stimulus, and perfused with a medium containing CNQX (20μM) and D-APV (20μM) to block glutamatergic excitation. IPSCs in CA1 neurons were recorded at 32°C by single-electrode voltage clamp. Paired-pulse stimulations (0.1 Hz) were given to stratum radiatum at 2 x threshold (threshold ~25 μA) with 100 ms interpulse interval. At -50mV holding potential, paired-pulse ratio of IPSCs (IC2/IC1) was 0.92±0.03 (N=13) in kindled rats, which was significantly increased as compared to control rats (0.69±0.05, N=13, P<0.001, Wilcoxon). The ratio of half peak amplitude durations of the IPSCs (D2/D1) was 0.93±0.04 in kindled rats, which was larger (P<0.05) than that in control rats (0.79±0.04). The reversal potential of the IPSC, estimated by linear regression analysis, was not significantly different between cells from kindled and control rats, or between IPSC1 and IPSC2 in each group. Interestingly, CGP35348 (1 mM), a $GABA_B$ receptor antagonist, increased the ratio of IC2/IC1 (0.89±0.04, N=17) and D2/D1(1.00±0.26) in control rats as compared with the non-CGP control group (p<0.01). This confirms the role of presynaptic $GABA_B$ receptors in paired IPSCs suppression. In CGP35348 medium, the IC2/IC1 ratio in kindled rats was 0.96±0.02 (N=21), which was not significantly different from the CGP control and non-CGP kindled groups, suggesting that $GABA_B$ presynaptic inhibition was not detectable in kindled rats. However, the D2/D1 ratio was still significantly greater in kindled rats than control rats. Supported by NS25383.

DUAL ORIGIN OF SLOW REGENERATIVE POTENTIALS IN THE ENDOPIRIFORM NUCLEUS. M.E.Domroese* and L.B.Haberly, Neurosci. Training Prog., MD-PhD Prog., and Dept. of Anatomy, U. of Wisc., Madison, WI 53706.

The endopiriform nucleus (En) is the site of origin of epileptiform activity in slices of piriform cortex from kindled rats (Hoffman and Haberly, J Neurophys, in press) and in slices of piriform cortex that have been subjected to a brief period of intense bursting while in vitro (Hoffman and Haberly, J Neurosci 11:2021). This study examines the origin of a slow regenerative potential in the En that may contribute to its susceptibility to seizure activity.

Experiments were performed in current clamp mode with microelectrodes on slices from adult rats at 30°C. Regenerative potentials were also observed with whole-cell patch pipettes. When cells in En were held at -55 to -60 mV, inward current pulses could elicit a depolarizing potential that slowly increased and evoked action potentials at long delays following pulse offset as previously reported (Tseng and Haberly, J Neurophys 62:386). This apparent regenerative potential was blocked by 1 μM TTX, but not by reduction of Ca^{2+} to 0.2mM or 200 μM Cd^{2+} and 100 μM Ni^{2+}, suggesting that it is mediated by a Na^+ current ("persistent" or "window") and is not dependent on either HVA or LVA Ca^{2+} channels. One hypothesis that could explain the requirement for a depolarizing holding potential is that it inactivates a K^+ current such as I_A that opposes the regenerative potential. The demonstration that large, very brief pulses could evoke the regenerative potential from rest when a small inward current was injected immediately following the pulse suggests that this requirement is unrelated to inactivation.

When 2 mM Ba^{2+} was added to an ACSF with 1.4 mM Ca^{2+}, a TTX-resistent regenerative potential similar to the TTX-sensitive potential in normal ACSF could be elicited by brief inward current pulses, although a depolarized holding potential was not required. This potential was blocked by 300 μM Cd^{2+}, but not by sustained depolarization that was sufficient to inactivate LVA Ca^{2+} channels, indicating that it was generated by Ba^{2+} current through HVA channels.

In summary, the slow regenerative potential in normal ACSF is generated by Na^+ current, and in ACSF containing Ba^{2+} and TTX, by current through a HVA channel. Alterations in channels related to the induction or expression of seizure activity could enhance either current and, perhaps, eliminate the need for Ba^{2+} for slow potential generation by HVA channels. Supported by NS19865 from NINDS.

ELECTRICAL INTERACTIONS BETWEEN NEURONES AFTER TETANIC STIMULATION-INDUCED EPILEPTIFORM ACTIVITY IN RAT HIPPOCAMPAL-PARAHIPPOCAMPAL SLICE. Dan Han, Jose L. Perez-Velazquez, Liang Zhang and Peter L. Carlen*. Playfair Neuroscience Unit, Toronto Hospital Research Institute, Bloorview Epilepsy Program, Depts of Physiology and Medicine (Neurology), University of Toronto, Toronto, Canada

Our previous observations indicated that electrotonic potentials (spikelets) could be observed in whole-cell recordings in the calcium-free model of epilepsy in vitro, and whose appearance was correlated positively with the occurrence of dye coupling between pyramidal neurones. To study the possible relation between electrical coupling and epileptiform discharges with normal synaptic transmission, we performed simultaneous whole-cell (CA1) and extracellular recordings. Tetanic stimulation of the Schaffer collaterals (60Hz, 2s) was delivered every 10-15 min and produced primary afterdischarge and spontaneous interictal discharges. Spikelets were observed in the whole-cell recordings during afterdischarge and were independent of membrane potential. Application of sodium propionate (20 mM), to acidify neuronal cytoplasm, simultaneously blocked electrotonic potentials and extracellular afterdischarges, but single action potentials recorded in whole cell configuration were still observed. Similar treatment with sodium propionate did not block non-bursting synaptic potentials evoked with single shocks. These results suggest that abolition of epileptiform discharges by intracellular acidification might be attributable to blockade of gap junctions between CA1 neurones, which would reduce direct electrical coupling. This work was supported by the Medical Research Council of Canada.

PROPAGATION OF SPONTANEOUS EXCITATORY ACTIVITY IN THE GUINEA PIG HIPPOCAMPAL INTERNEURON NETWORK. S.R. Sinha* and P. Saggau. Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

Two unique mechanisms have been demonstrated for the excitatory recruitment of interneurons independent of principal neurons (pyramidal and granule cells) in the hippocampal slice: (1) depolarizing $GABA_A$ receptor responses at recurrent connections between interneurons and (2) electrotonic coupling between interneurons (Michelson and Wong, 1991 and 1994). Networks of interneurons can be synchronized by these mechanisms. We are investigating the propagation of such activity using optical recording techniques specially designed to allow recording of relatively infrequent spontaneous events with high spatio-temporal resolution.

Transverse hippocampal slices (400 μm) were stained with the voltage-sensitive dye RH-414; evoked and 4-aminopyridine-induced spontaneous activity in the dentate gyrus and areas CA1 and CA3 were recorded using a 10X10 element photodiode array. For comparison, activity was recorded in the absence and presence of excitatory amino acid (EAA) receptor blockers (10 μM CNQX and 25 μM D-APV) from the same slice.

In contrast to epileptiform activity observed in the absence of EAA receptor blockers, which generally originates in CA2/CA3 and propagates into CA1 and the dentate gyrus (Colom and Saggau, 1994), the synchronized excitation of interneurons usually propagates as a wave from the subicular end of CA1 towards the dentate gyrus. The pattern of spread of the synchronized interneuron activity suggests that interneurons in the hilus and *stratum radiatum* and *lacunosum-moleculare* of CA1, CA2 and CA3 are interconnected as a single mesh. This feature distinguishes the interneuron network from the network of principal neurons which are mutually connected only in area CA3. The spread of spontaneous activity in these two networks in the hippocampal subfields and the dentate gyrus will be presented.

$GABA_B$ ACTIVITY WITHIN THE HIPPOCAMPUS ATTENUATES THE PROPAGATION OF LIMBIC SEIZURES, R. G. Vaurio, M. R. Proctor*, and K Gale Departments of Pharmacology and Neurosurgery, Interdisciplinary Program in Neuroscience Georgetown Univ. Med. Ctr., Wash., DC 20007.

We have previously reported that the **blockade of $GABA_A$ receptors**, within the hippocampus impairs the generation of propagated seizures in limbic circuits. In the present study we tested the hypothesis that **activation of $GABA_B$ receptors,** by acting presynaptically to decrease GABA release, may attenuate propagated limbic seizures. Baclofen, a $GABA_B$ receptor agonist, was microinjected bilaterally into the dorsal hippocampus of awake, behaving rats. At 5-15 min following the infusion of baclofen into hippocampus, seizures were evoked by the unilateral application of bicuculline methiodide into area tempestas (AT), an epileptogenic site within the deep anterior piriform cortex. Intrahippocampal application of baclofen (470 pmol) induced focal seizures and "wet rat shakes." These manifestations were remarkably similar to those evoked by the $GABA_A$ antagonist, bicuculline, in the hippocampus. Furthermore, in the rats receiving intrahippocampal baclofen, limbic motor seizures evoked from AT were significantly attenuated, in comparison to controls receiving intrahippocampal saline. When retested after 48 hr, all rats exhibited bicuculline-evoked limbic motor seizures comparable to control animals. These findings indicate that $GABA_B$ receptor activation results in increased local excitatory activity within the hippocampus, possibly through presynaptic inhibition of GABA transmission. This is the first *in vivo* demonstration of a modulatory influence of hippocampal $GABA_B$ receptors on limbic motor seizures and further supports the theory that focal excitatory activity within the hippocampus may interfere with the development of limbic seizures evoked from extra-hippocampal sites.

SYNAPTIC REORGANIZATION OF EXPLANTED CULTURES OF THE RAT HIPPOCAMPUS. R. Gutiérrez* and U. Heinemann. *Instituto Mexicano de Psiquiatría, Calzada México-Xochimilco 101, 14370 México and Institut für Physiologie der Charité, Humboldt Universität zu Berlin, Tucholskystr. 2, 10117 Berlin*

Formation of recurrent excitatory connections in the dentate gyrus (DG) has been associated to temporal lobe epilepsy. A similar reorganization may occur in organotypic hippocampal slice cultures due to loss of innervation. Using extra- and intracellular recordings, we studied the synaptic organization of organotypic hippocampal slice cultures. Hilar stimulation evoked typical population spikes in areas CA3 and CA1 and an antidromic population spike followed by a population postsynaptic potential (PSP) in the DG that could be reduced by the GABA antagonist bicuculline and blocked by glutamate receptor antagonists. Stimulation of CA1 induced a population PSP in the DG that disappeared after its mechanical separation from CA1. Intracellularly, EPSP/IPSP sequences or an antidromic spike with a broad shoulder in its repolarization phase was evoked in granule cells by hilar stimulation and EPSP/IPSPs by CA1 stimulation. During bicuculline perfusion, hilar stimulation caused EPSPs and repetitive firing in the DG. Spontaneous depolarization shifts were also observed even after its isolation from areas CA3 and CA1. Glutamate receptor antagonists blocked the postsynaptic potentials evoked by hilar stimulation. Collateral excitatory synaptic coupling between granule cells was confirmed by paired recordings. Our results show that in this preparation the trisynaptic pathway is preserved. However, presumably due to mossy fiber collateral sprouting and formation of pathways between areas CA1 and DG, new aberrant synaptic contacts are also formed. The generation of seizure like events in a DG expressing recurrent excitatory coupling supports an important role for such reorganization also in ictogenesis in patients with temporal lobe epilepsy.

THE RATIO OF POTASSIUM TO CALCIUM CONCENTRATION DETERMINES THE GENERATION OF BURST FIRING IN RAT HIPPOCAMPAL SLICE CA1 PYRAMIDAL NEURONS. T. Wang*, J.E. Cottrell and I.S. Kass. Depts. of Anesthesiology and Pharmacology, SUNY Health Science Center at Brooklyn, Brooklyn, NY 11203.

Bursting activity plays an important role in both pathological and physiological functions in the central nervous system. The bursting activity can be modified by many factors. Among them, high potassium or low calcium concentrations have been shown to generate bursting activity in rat hippocampal slices. In this study, the interactive effects of potassium and calcium on bursting activity were examined using rat hippocampal slices. The basal solution used in this study consisted of (in mM) NaCl 124, KCl 2, KH_2PO_4 1.25, $NaHCO_3$ 26, glucose 10, $MgCl_2$ 2, $CaCl_2$ 2. The effect of potassium concentration was tested in a range between 3.25 to 13.25 mM with 2 mM increment per step. It was found that 2 out of 7 CA1 pyramidal neurons showed bursting activity when the potassium concentration in the basal buffer was increased to 7.25 mM. The rest of the cells started generating bursts at 9.25 mM potassium. The number of bursts induced by potassium was dose dependent. A burst consists of 2 to 7 spikes and always rode on a transient depolarizing wave. Lowering calcium concentration from 2 mM to 1 mM increased the sensitivity of the cells to potassium for burst generation. Raising the calcium to 3 mM, on the other hand, lowered the sensitivity. By constructing a regression line of the potassium concentration against the number of bursts, the threshold concentration of potassium to induce bursts was calculated to be 3.4 mM at 1mM calcium, 7.2 mM at 2 mM calcium and 8.5 mM at 3 mM calcium. From the results above, the ratio of potassium to calcium for the induction of bursts is approximately 3:1. It appears that the ratio of potassium to calcium, rather than the potassium or calcium concentration alone is critical in determining bursting activity. Supported by funding: NIGMS GM38866.

SPREAD OF EXCITATION IN KAINATE-LESIONED HIPPOCAMPUS DETERMINED BY LASER SCANNING MICROSCOPY. A. Chesi, F. Rucker, Y. Tretter, G. ten Bruggencate and C. Alzheimer*. Dept of Physiology, Univ. of Munich, D-80336 Munich, Germany.

Laser scanning microscopy in conjunction with voltage-sensitive dyes is a valuable tool to study the spread of excitation in the hippocampal slice (Saggau et al. *Soc Neurosci. Abstr.* 1990, 448.9). Here, we used this method to determine the sequelae of kainate-induced lesion of area CA3/CA4 on the spatiotemporal profile of excitatory transmission in hippocampus.

Hippocampal slices 400 μm thick were prepared from the brain of C57BL mice 3 months after intracerebroventricular injection of kainate (0.25 μl, 1μg/μl) into the lateral ventricle. Slices were incubated with the voltage sensitive fluorescent dye N-(3-(triethylammonium)propyl)-4-(4-(p-diethylamino-phenyl)butadienyl)pyridinium dibromide (RH414) for 1 hour. Fluorescence was then elicited with a Nd:YAG laser at a wavelength of 532 nm and measured with a single photodiode at 80 points within the slice (scanning frequency 1.7 kHz, area 1.6 mm^2), resulting in a map of voltage changes occurring over a 300 ms period. The signals evoked by mossy fiber stimulation were also recorded by means of an extracellular recording electrode placed in stratum pyramidale. After recording the control response, slices were superfused with bicuculline 10 μM or magnesium-free ACSF to induce epileptiform bursts.

We show that the generation of burst discharges in area CA3 and their propagation to CA1 can be displayed as sequential decreases in ΔF (the decrease in fluorescence corresponding to a depolarization of the membrane). Preliminary experiments employing this *in vitro* epilepsy model suggest that epileptiform activity arising after disinhibition of NMDA receptors (low-magnesium solution) can bypass the lesioned CA3 subfield, whereas the spread of bicuculline-induced bursts to the CA1 region appeared to be impaired or even prevented by the kainate-induced lesion.

Activity-dependent enhancement of inhibitory postsynaptic potentials (IPSPs) by the GABA-uptake inhibitor tiagabine in hippocampal slices. M.F. Jackson, B. Esplin and R. Čapek* Dept. of Pharmacology, McGill, Montreal, Que. H3G 1Y6.

Our laboratory has previously demonstrated (Epilepsy Res. 16 (1993) 123-130) the activity-dependent enhancement of GABA-mediated inhibition by the potent lipophilic blockers of GABA uptake, SKF 89976A and SKF 100330A. It was suggested that this property would allow these compounds to preferentially inhibit seizures while minimizing the occurrence of side effects. In this study, we examined the effects of the novel antiepileptic drug tiagabine, a potent inhibitor of the GABA transporter, on monosynaptic IPSPs recorded from hippocampal CA1 pyramidal cells using the whole-cell recording technique. With excitatory amino acid receptors blocked by CNQX (20 μM) and CPP (5 μM), direct stimulation of interneurons by a single stimulus (SS) elicited IPSPs consisting of both a fast (FH) and slow-hyperpolarizing (SH) components. As we reported previously (Soc.Neurosci.Abstr., 1995, 21, 983, Abstr.# 388.15), high-frequency stimulation (HFS) (100 Hz, 200ms), intended to mimic the activation of interneurons during an epileptiform discharge, caused a prominent increase in the amplitude and duration of IPSPs. HFS also elicited a GABA-mediated depolarizing response (DR), interposed between the FH and SH components. Bath application of tiagabine (20 μM) caused a twofold increase in the duration of IPSPs elicited by HFS while having little or no effect on those evoked by a SS when using low stimulus intensities (SI) (30-65 μA). With higher SI (150-350 μA), tiagabine caused a slight increase in the amplitude and duration of IPSPs evoked by a SS but, in contrast, a very large increase in the amplitude of the HFS-evoked DR which dominated the synaptic response and caused the firing of a burst of action potentials. These results indicate that the effects of tiagabine on GABAergic transmission are activity-dependent. The significance of the large increase in GABA-mediated DRs remains to be determined. (Supported by the MRC of Canada and FCAR).

ATTENUATION OF KINDLING-INDUCED INCREASES IN mRNA EXPRESSION FOR TRH AND α_4 $GABA_A$ RECEPTOR SUBUNIT WITH CONTINGENT TOLERANCE TO DIAZEPAM. R-Q. Wan*, M. Clark, J.B. Rosen, M. Sitcoske, E.C. Noguera, S.R.B. Weiss and R.M. Post. Biological Psychiatry Branch, NIMH, Bethesda, Md. 20892

Contingent tolerance to the anticonvulsant effects of diazepam (DZP) occurs when the drug is repeatedly administered **prior to**, but not **after** kindling stimulation (Pinel and Mana, 1986). Amygdala kindled seizures induce increases in TRH and $GABA_A$ receptors, which are lost with contingent tolerance to carbamazepine (Weiss et al, 1995). In the present study, we evaluated whether similar effects would be observed with contingent tolerance to DZP, which has different mechanisms of action and does not show cross-tolerance to carbamazepine. Five groups of rats were studied: kindled rats receiving vehicle or DZP before (tolerant group) or after (non-tolerant group) electrical stimulation; and sham kindled rats receiving vehicle or DZP. Kindled groups were matched for numbers of seizures prior to sacrifice. *In situ* hybridization was performed to examine regional changes in mRNA expression for TRH and for subunits of the $GABA_A$ receptor system. The kindled controls (vehicle or DZP **after** seizures) demonstrated increases in TRH mRNA in the dentate gyrus (DG), entorhinal, perirhinal, and piriform cortices relative to sham kindled controls. The tolerant rats (DZP-**before**) did not show seizure-induced increases in TRH mRNA in these regions; they resembled the sham-kindled controls. For the α_4 subunit of the $GABA_A$ receptor system, a significant increase was observed in the DG in kindled controls but not in the tolerant rats. These results suggest that: 1) kindling induces relatively long-lasting molecular alterations in TRH and $GABA_A$ systems, and 2) contingent tolerance to both carbamazepine and diazepam could be related to a loss of seizure-induced endogenous anticonvulsant adaptations.

ACTIVITY-DEPENDENT DEPOLARIZATION OF NEONATAL RAT OPTIC NERVE IS INCREASED BY GABAPENTIN. S. Agulian, D. Donnelly* and J. D. Kocsis. Yale Univ. Med. Sch., New Haven, CT. 06510, and Neuroscience Res. Ctr., VAMC West Haven, CT. 06516.

It has been suggested that the antiepileptic drug gabapentin (GP) enhances cellular GABA levels, and during periods of intense impulse activity cellular GABA is released by reverse operation of its transporter (Kocsis and Honmou, Neurosci. Lett. 169:181-184,1994). To further test this hypothesis we studied the effects of GP and analogue enantiomers of iso-butyl GABA, on activity-dependent depolarizations in the neonatal optic nerve recorded in a sucrose gap chamber. The optic nerve has a reservoir of astrocytic GABA, and its release can be promoted by nipecotic acid (NPA) resulting in a bicuculline-sensitive depolarization of the axons. The NPA-induced depolarization is increased by GP and by both enantiomers of iso-butyl GABA (+ and -). The GABA transporter can also be induced to operate in reverse by depolarization and cellular Na^+ accumulation. A 20 Hz-5 sec stimulus train induced a depolarization which resulted from extracellular potassium accumulation and activation of $GABA_A$ receptors. The bicuculline-sensitive component of the stimulus-induced depolarization was increased by 1 hr pretreatment of the nerves with GP (100μM). This enhancement of the stimulus-induced depolarization was blocked by the GABA transporter inhibitor NO-711 HCl (10 μM). These results suggest that GP treatment increases impulse-induced release of GABA mediated by reverse operation of the GABA transporter, and support the hypothesis that its anticonvulsant action is mediated by elevation of free GABA levels and enhanced release during periods of intense impulse activity. Supported by NIH and the VA.

EFFECTS OF FELBAMATE AND GABAPENTIN ON EXCITABILITY IN THE DENTATE GYRUS AND ON HIPPOCAMPAL SEIZURES IN VIVO. Z.Q. Xiong and J.L. Stringer*. Dept. of Pharmacology, Baylor College of Medicine, Houston, TX 77030.

Recently, several new antiepileptic drugs have been introduced, two of which are felbamate (FBM) and gabapentin (GBP). Both drugs have anticonvulsant activity in a variety of animal seizure models and are effective for treatment of partial seizures and some types of generalized seizures, but their mechanisms of action are not yet understood. Here, we studied the effects of FBM and GBP on a model of partial complex seizures in the anesthetized rats, termed maximal dentate activation. Repeated elicitation of maximal dentate activation produces lengthening of the duration and a decrease in the time to onset. GBP (30 and 50 mg/kg) caused a reversible reduction in the duration of maximal dentate activation and had no effect on the time to onset. FBM, at doses of 300 and 450 mg/kg, prevented the lengthening of maximal dentate activation and had no effect on the time to onset. At a dose of 600 mg/kg, FBM reduced the duration of maximal dentate activation and lengthened the time to onset. Excitability, inhibition and long-term potentiation (LTP) were measured in the dentate gyrus. The effects of GBP and FBM on excitability were inconsistent. GBP (50 mg/kg) caused a significant decrease in paired-pulse inhibition, while FBM (600 mg/kg) had no effect. Neither drug blocked LTP. These data demonstrate that FBM and GBP are both effective in this model of partial complex seizures, but that they appear to act through different mechanisms. [supported by NS28871 and NS01784]

824.5

ANTICONVULSANT PROFILE OF SOME NEUROACTIVE STEROIDS. J.M. Witkin*, M. Gasior, S.R. Goldberg, and R.B. Carter. Preclin. Pharmacol. Lab, National Inst. Health, NIDA Addiction Res. Ctr., Baltimore, MD 21224 and Dept. Pharmacol., CoCensys Inc., Irvine, CA 92718.

Neuroactive steroids (NAS) modulate the function of $GABA_A$ receptors. We have determined the efficacy of several NAS as anticonvulsants against seizures induced by pentylenetetrazole (PTZ), N-methyl-D-aspartate (NMDA) and cocaine in male, Swiss-Webster mice. Diazepam (DZP), phenobarbital (PB) and the NAS 3α,5α-pregnenolone, 3α,5β-pregnenolone, Co 2-1068 and Co 1-1042 (ganaxolone) dose-dependently protected against PTZ-induced convulsions; dizocilpine (MK) did not. In contrast, MK protected against NMDA-induced convulsions, while the other compounds were less potent and efficacious. Nonetheless, they generally protected against the lethal consequences of NMDA-induced seizures. MK also completely blocked cocaine convulsions whereas DZP and PB were less effective. The NAS blocked cocaine seizures at doses that were effective against NMDA-induced lethality. The NAS demonstrated a comparable or improved motor-effect profile in relation to anticonvulsant effects. Ineffective doses of the NAS were able to potentiate the anticonvulsant effects of DZP without augmenting its motor side-effects. NAS may be an important new class of anticonvulsants that could also be used as an adjunct therapy with currently existing compounds.

824.6

CHARACTERIZATION OF THE ANTICONVULSANT PROPERTIES OF Co 2-1068, A NOVEL NEUROACTIVE STEROID MODULATOR OF THE $GABA_A$ RECEPTOR. R.B. Carter*[1], K.C. Yang[2], S. Robledo[1], M. Suruki[1], H.S. White[3], and R.B. Upasani[2]. Depts. of [1]Pharmacology and [2]Medicinal Chemistry, CoCensys, Irvine, CA 92718 and Anticonvulsant Screening Program, [3]Dept. of Pharmacology, Univ. Utah, Salt Lake City, UT 84108.

Neuroactive steroids are allosteric modulators of the $GABA_A$ receptor that act at a novel recognition site on the receptor complex. Co 2-1068 is a long-acting, water-soluble, orally-bioavailable neuroactive steroid prodrug, the parent of which has been demonstrated by binding and electrophysiology to be a potent modulator of the $GABA_A$ receptor. The anticonvulsant properties of Co 2-1068 were defined using an array of animal seizure models. Co 2-1068 was effective in nontoxic doses against clonic convulsions induced by s.c. pentylenetetrazol (PTZ) administration in mice and rats (ED_{50}s - 3.0 and 15.4 mg/kg, p.o., respectively). Co 2-1068 administered at subataxic doses also effectively blocked tonic seizures induced by maximal electroshock (MES) in mice and rats (ED_{50}s - 4.5 and 12.6 mg/kg, p.o., respectively). The duration of Co 2-1068 anticonvulsant activity against PTZ- and MES-induced seizures in mice and rats was compared to that of ganaxolone, valproate, and ethosuximide. Co 2-1068 exhibited a markedly longer duration of action than any of the reference agents. Moreover, Co 2-1068 exhibited potent anticonvulsant activity against fully-kindled Stage-5 seizures induced by corneal kindling in the rat (ED_{50} - 3.1 mg/kg, p.o.), producing these effects at doses well below those that resulted in rotorod ataxia (TD_{50} - 22.2 mg/kg, p.o.). Seizure threshold, as determined by an increase in the dose of intravenously-infused PTZ required to induce clonus, was also significantly elevated by nonataxic doses of Co 2-1068 in the mouse. Thus, Co 2-1068 exhibits potent anticonvulsant activity across a range of animal procedures. These data suggest that Co 2-1068 may possess therapeutic utility in the treatment of generalized tonic-clonic as well as simple and complex partial seizure disorders in humans.

NEUROACTIVE STEROID PREGNENOLONE SULFATE INDUCES SEIZURES AFTER INTRACEREBROVENTRICULAR ADMINISTRATION IN MICE. T.G. Kokate*, R.D. Kirkby and M.A. Rogawski. Neuronal Excitability Section, Epilepsy Research Branch, NINDS, NIH, Bethesda, MD 20892.

Neuroactive steroids are endogenous metabolites of certain steroid hormones that rapidly alter the excitability of neurons by direct actions on membrane ion channels. Several of these steroids are known to potentiate GABA-evoked inhibitory responses *in vitro* and to have potent anticonvulsant activity *in vivo*. Recently, however, the endogenous steroid metabolite pregnenolone sulfate (PS) has been shown to selectively potentiate NMDA receptor responses *in vitro* and increase the convulsant potency of NMDA *in vivo*. In the present study, we investigated in detail the effects of PS after intracerebroventricular administration in mice. Coapplication of PS (10 & 30 nmol) and a subconvulsant dose of NMDA (0.2 nmol) caused severe clonic-tonic seizures in 50% and 100% of animals respectively. Moderate doses of PS (30–150 nmol) alone produced seizure activity that eventually progressed into status epilepticus and subsequent lethality. High doses of PS (150–200 nmol) produced severe clonic-tonic seizures and death without status epilepticus. The CD_{50} value (dose producing convulsions in 50% of animals) obtained from this data was 60 nmol. PS-induced seizures and subsequent lethality were completely blocked by systemic administration of the NMDA receptor antagonist MK-801 (1 mg/kg, i.p.), suggesting the involvement of NMDA receptors in the seizures induced by PS. (Supported by NINDS, NIH)

IDENTIFICATION OF A ^{3}H-DESGLYCINYL REMACEMIDE BINDING SITE IN RAT BRAIN MEMBRANES. M. S. Ahmed, A. Mather[1] and S.J. Enna*. Dept. Pharmacol., Toxicol. and Therap., Univ. Kansas Med. Sch., Kansas City, Ks 66160 and [1]Dept. Chem., Astra Charnwood, Leics, England.

Remacemide (±)(-2-amino-N-{1-methyl-1,2-diphenylethyl}-acetamide) and its des-glycine metabolite (DGR) display anticonvulsant activity in animal models, with the parent compound undergoing clinical trials as a novel antiepileptic. Previous work suggested that both inhibit the NMDA subtype of the excitatory amino acid receptors system, with DGR being more potent than remacemide. Electrophysiological studies indicate the NMDA receptor channel is the primary target for these compounds. The present experiments were undertaken to identify more precisely the site of action of DGR using a radioligand binding assay.

For the study, desglycinyl remacemide (17 Ci/mmole) was tritiated using a standard procedure. Equilibrium binding experiments, with thoroughly washed rat P2 brain membrane fractions, revealed a saturable binding site with a Kd of 300 nM. The density, but not affinity, of the sites varied with brain region from 0.6 to 1.6 pmole/mg protein. Specific binding was destroyed by trypsin, but was unaffected by N-ethylmaleamide. The IC_{50} for remacemide displacment of ^{3}H-DGR binding was 9.8 μM. In contrast, neither MK-801, an NMDA channel blocker, nor NPC 17742, a competitive antagonist for this receptor, inhibited ^{3}H-DGR binding in concentrations as high as 100 μM. The results suggest the existence of a selective and saturable binding site for remacemide and its desglycinyl metabolite in rat brain membranes. While this binding component may be associated with the NMDA receptor, it appears to be distinct from the MK-801 channel site and the receptor recognition site. Studies are continuing to characterize further ^{3}H- DGR binding to define the site and mechanism of action of this agent.

The effects of anticonvulsant drugs-phenobarbital, phenytoin and valproic acid on NMDA-EPSP, AMPA-EPSP and GABA-IPSP in the rat hippocampus. L. M. Brown-Croyts*, G. Y.-P. Ko+ and T. J. Teyler+. Depts. Neurobiology+ and Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272-0095, USA

Epilepsy is a neuronal disorder caused by abnormal synchronous and excessive discharges of large group of neurons (McNamara, 1992). Different pharmacological actions of anticonvulsant drugs in experimental situations suggest multiple mechanisms of epilepsy (McNamara, 1994). Understanding the actions of anticonvulsant drugs will help understand the mechanisms underlying epilepsy and will help develop better anticonvulsant therapies. The effects of phenobarbital, phenytoin, and valproic acid on pharmacologically isolated NMDA-EPSP, AMPA-EPSP, and GABA-IPSP were examed. Phenobarbital (0.05 mg/ml) has no effect on NMDA-EPSP, but it decreases AMPA-EPSP slope by 13.4% and facilitates GABA-IPSP slope by 77.12%. Phenytoin (0.1 mg/ml) has no effects on NMDA-EPSP, AMPA-EPSP, or GABA-IPSP. Valproic acid (0.1 mg/ml) decreases NMDA-EPSP slope by 14.3%, and it increases GABA-IPSP slope by 54.34% and has no effect on AMPA-EPSP. These data suggest that the anticonvulsant effects of these drugs may be via different neurotransmitter systems or ion channels.

THE NEW ANTICONVULSANT D-23129 POTENTLY BLOCKS EPILEPTIFORM DISCHARGES IN TWO HIPPOCAMPAL SLICE PREPARATIONS

C. Rundfeldt* and R. Dost. Department of Pharmacology, Corporate R&D, ASTA Medica Group, Arzneimittelwerk Dresden, Meißner Str. 35, 01445 Radebeul, FRG.

D-23129 (N-(2-amino-4-(4-fluorobenzylamino)-phenyl) carbamic acid ethyl ester) is a broadly acting anticonvulsant currently undergoing phase I clinical trials. An opening effect on potassium channels, a potentiation of GABA induced currents and a block of GYKI 52466 insensitive kainate induced currents was found using patch clamp techniques in cortical neurons. The goal of this study was to investigate, if D-23129 is capable to block epileptiform discharges in the low Ca^{2+} and low Mg^{2+} model in hippocampal slice preparations.

In the low Ca^{2+} model, synaptic transmission is blocked and discharges evolve from ephaptically coupled neurons. Compounds capable of stabilizing membranes like sodium channel blockers suppress the discharges, while compounds interfering with synaptic transmission like NMDA antagonists are not active. D-23129 was capable of suppressing the discharges in a dose dependent manner. A significant reduction in frequency was observed after 60 min bath application of 1 μM, a full block of all discharges after 25 μM. This effect could be correlated with the potent potassium channel opening effect of D-23129.

In the low Mg^{2+} model, excitatory neurotransmission is augmented by reducing the Mg^{2+} block of NMDA channels. While carbamazepine and phenytoine are not active in this model, valproate and ethosuximide are active at very high concentrations; glutamate and calcium antagonists also block the discharges. The activity was significantly reduced after application 10 μM and was fully bocked after of 50 μM D-23129. It is possible, that this effect can be related to the kainate antagonistic effects of D-23129. The results indicate, that D-23129 is a potent anticonvulsant with a novel mode of action.

The work was funded by AWD GmbH.

PRESYNAPTIC INHIBITION OF EXCITATORY TRANSMISSION BY LAMOTRIGINE IN THE RAT AMYGDALA.

P.W.Gean*, S.J.Wang,C.C.Huang, K.S.Hsu and J.J.Tsai. Dept.of Pharmacol.and Neurol. Natl.Cheng-Kung Univ.Tainan, Taiwan, R.O.C.

Lamotrigine (LAG) is a new antiepileptic drug which is licensed as an adjunctive therapy for partial and secondary generalized seizures. In the present study, the mechanisms responsible for it's antiepileptic effect were studied in rat amygdaloid slices using intracellular recording and whole-cell patch clamp techniques. Bath application of LAG (50 μM) reversibly suppressed the EPSPs and EPSCs. Synaptic response mediated by the NMDA receptor ($EPSP_{NMDA}$) was isolated by application of a solution containing CNQX(10 μM) and bicuculline (20 μM). LAG produced a parallel inhibition of $EPSP_{NMDA}$. Postsynaptic depolarization induced by AMPA was not altered by LAG. In addition, LAG increased the ratio of the second pulse response to the first pulse response (P_2/P_1), which is consistent with a presynaptic mode of action.

Nifedipine (20 μM) had no effect on LAG-induced presynaptic inhibition. However, the depressant effect of LAG was markedly reduced in slices pretreated with N-type Ca^{++} channel blocker ω-conotoxin-GVIA (1 μM) or a broad spectrum Ca^{++} channel blocker ω-conotoxin-MVIIC (1 μM). It is concluded that a reduction in ω-CgTX-GVIA-sensitive Ca^{++} currents largely contributes to LAG-induced presynaptic inhibition.

SDZ 224-208, AN ORALLY ACTIVE AMPA RECEPTOR ANTAGONIST. C. L. Meier*, M. Koller, K. McAllister, H. Neijt, S. Urwyler, K.-H. Wiederhold. Sandoz Research Institute Berne, Switzerland.

A series of quinazoline-2,4-dione derivatives are described as a novel class of systemically active AMPA receptor antagonists. The best characterized compound, SDZ 224-208, inhibited AMPA and kainate-induced depolarizations in the rat cortical wedge with pA_2 values of 5.6 and 5.7, respectively. Receptor binding experiments revealed some affinity of the compound to the strychnine-insensitive glycine site of the NMDA receptor complex (pK_i = 4.9), but none to the NMDA recognition site itself. SDZ 224-208 inhibited spontaneous population spike discharges in hippocampal slices with an IC_{50} of 0.5 μM. The compound reduced Schaffer stimulation-induced field EPSPs in hippocampal area CA1 in vitro with an IC_{50} of 6 μM and inhibited the same neuronal system in halothane-anesthetized rats in vivo with an ID_{50} of 30 mg/kg (i.p.). SDZ 224-208 protected against maximal electroshock (MES)-induced convulsions in rats and mice (ID_{50} 10-17 mg/kg, i.p.). Given orally, SDZ 224-208 protected against MES with ID_{50}s of 10-17 mg/kg in rats and 32-56 mg/kg in mice. In rats, SDZ 224-208 dose-dependently blocked kainate-induced seizures and the expression of *c-fos* mRNA in cortical and limbic areas. Behavioral side effects included sedation and motor disturbances. This class of orally available compounds may open up new possibilities for the treatment of epilepsy and other neurodegenerative and psychiatric diseases.

EPILEPSY: ANTI-CONVULSANT DRUGS—OTHER

825.1

CONTINGENT TOLERANCE AND ACUTE ANTICONVULSANT EFFICACY OF CARBAMAZEPINE ON AMYGDALA-KINDLED SEIZURES ARE NOT AFFECTED BY LESIONS OF THE DENTATE GYRUS.

S.R.B. Weiss,* T. Baptista , M. Sitcoske, E. Araujo de Baptista, J.B. Rosen and R.M.Post Biological Psychiatry Branch NIMH, Bethesda, Md. 20892 and Department of Physiology, P.O. Box 109, Merida, 5101-A, VENEZUELA

Contingent tolerance (CT) to the anticonvulsant effects of carbamazepine (CBZ) is the progressive loss of efficacy of the drug when it is administered **before**, but not **after** kindling stimulation. The mechanisms of CT may be relevant to the understanding of kindling itself and to drug tolerance observed in the evolution of affective disorders. Based on biochemical data obtained from previous studies (Weiss et al, 1995), we hypothesized that the hippocampus (HIP) may play a critical role in CT. We explored CT in male rats with kindled seizures induced by electrical stimulation of the amygdala, and colchicine-induced (COL) lesions of the dentate gyrus of the hippocampus. Three control groups were used: rats injected with saline in the HIP; rats with cannulae in the temporal cortex above the hippocampus; and rats with only an electrode. After stage 5 seizures (Racine, 1972) were observed COL or saline was injected bilaterally into the hippocampus while other control groups received no injections. Electrode, cannulae location, and dentate lesions (~ 65% of the dorsal HIP, 94% of the ventral HIP) were verified by standard histology. CBZ (40 mg/kg) was administered daily before electrical stimulation (@ 400 μA) until tolerance was observed (3 out of 4 consecutive days of seizures ≥ stage 3) or for 10 days. The acute response to CBZ and the time required for tolerance to develop (5.14 ± 0.8 days in the lesioned animals compared to 5.0 ± 0.6; 4.75 ± 0.4; and 4.86 ± 0.5 days in the control groups) did not differ between the COL and control groups, suggesting that the integrity of the HIP is not necessary for the acute anticonvulsant effects of CBZ or the development of CT in electrically-induced kindling in rats.

ANTICONVULSANT PROPERTIES OF POLYUNSATURATED FATTY ACIDS.

M. Vreugdenhil[1], W.J. Wadman[1], G.C. Faas[1],* R.A. Voskuyl[2] and A. Leaf[3]. 1: Inst. of Neurobiology, Univ. of Amsterdam, Kruislaan 320, 1098 SM, Amsterdam, the Netherlands.
2: Dep. of Physiology, Univ. of Leiden, Leiden the Netherlands.
3: Dep. of Medicine, Harvard Medical School, Boston MA, USA.

Polyunsaturated fatty acids derived from fish-oil, docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) can reduce cellular excitability as shown in cardiomyocytes. The effect of EPA and DHA on neuronal sodium currents was determined in CA1 neurons acutely isolated from the rat hippocampus. Using the whole-cell voltage-clamp technique we analyzed the voltage dependence and kinetics of sodium current activation and inactivation. Solution was changed from fatty acid free condition (1mg/ml albumin) to 1, 1.3, 2, 4, 8, 16 or 32 μM EPA or DHA. DHA shifted the voltage dependence of inactivation in hyperpolarizing direction by maximally -13 mV with an EC50 of ~2 μM and a Hill coefficient of ~2. As a consequence DHA increased the rate of inactivation and decreased the rate of recovery from inactivation. EPA had basically the same effect but its EC50 was at least five times higher and the maximal shift was two times higher. EPA and DHA did not affect activation, although high concentrations reduced sodium conductance. The plant-oil oleic acid was used as a control and showed only minor effects on inactivation. The pharmacological profile of DHA closely resembles that of the anticonvulsant drug carbamazepine (EC50 ~55 μM). The therapeutical relevance of polyunsaturated fatty acids in focal epilepsies will depend on the actual brain levels of free fatty acids.

INCORPORATION OF VALPROIC ACID INTO PHOSPHOLIPIDS IN GT1-7 HYPOTHALAMIC NEURONS. A. Siafaka-Kapadai, X. Chang, C.L. Bowden*, M. Patiris, and M.A. Javors. Departments of Psychiatry and Pharmacology, University of Texas HSC, San Antonio, Texas 78284.

Valproic acid (VA) has been used as an antiepileptic drug for many years and recently its value in manic depressive disorder has been demonstrated. The exact mechanism of action for either of these uses is still unknown. VA is known to affect GABA and NE metabolism through the inhibition of GABA transaminase and aldehyde reductase, respectively. VA also inhibits the synthesis of major phospholipids and decreases the fluidity of brain mitochondrial membranes. The purpose of this study was to measure the incorporation of [^{3}H]-VA, an 8 carbon, branched chain fatty acid, into lipids of GT1-7 neurons, an immortalized hypothalamic cell line. GT1-7 neurons were grown to confluence in 10 cm culture dishes, then incubated with 10 ug/ml of [^{3}H]-VA (1 μCi/ml) for various times up to 5 hours. The medium was removed, the cells washed with buffer, and the incorporation quenched by the addition of methanol. Total lipids were extracted and phospholipids were separated from neutral lipids using thin layer chromatography (TLC) with a chloroform:acetone (9:5) solvent system. Our results indicate that [^{3}H]-VA was incorporated into phospholipids of GT1-7 neurons in a time dependent manner: 5% of incorporated radioactivity at 10 min, 7% at 30 min, 23% at 90 min, and 39% at 300 min. Subsequent TLC of the phospholipid fraction using a chloroform:methanol:water (65:35:7) solvent system indicated that the radioactivity was mainly incorporated into a phospholipid which migrated just below authentic phosphatidylcholine (Rf value similar to sphingomyelin). Similar experiments with human and rabbit platelets resulted in the incorporation of [^{3}H]-VA in the lipids of these cells also. The incorporation of valproic acid into phospholipids may influence the structure and functional properties of cellular membranes which may account for some of the pharmacological actions of this drug. (Supported by local funds.)

THE POSSIBLE ROLE OF THE BLOOD_BRAIN BARRIER IN THE ANTIEPILEPTIC ACTIONS OF FUROSEMIDE. D. Janigro, K.A. Stanness , L. Lando* and McKhann, G.M.

Furosemide (FUR), a blocker of the $Na^+/K^+/2Cl^-$ cotransporter, has recently been shown to prevent synchronization of neuronal activity in both *in vivo* and *in vitro* models of epilepsy. The anti-seizure properties of this compound *in vitro* can be fully accounted for by FUR's action on the glial cotransporter and its counterbalancing effects on extracellular space shrinkage that accompanies potassium accumulation following prolonged neuronal activity. However, since systemically administered FUR has restricted access to the central nervous system, the mechanism of FUR's anti-epileptic properties *in vivo* are less clear. Furosemide-sensitive, endothelium-mediated K^+ transport to the brain has been demonstrated both *in vivo* and *in vitro*. We have studied the effects of FUR on transendothelial potassium transport in a recently developed model of the BBB *in vitro* (DIV-BBB). Bovine aortic cells (BAEC) were cultured with C6 glioma cells under pulsatile flow conditions, resulting in the induction of BBB properties in BAEC (*Neurotoxicology*, 1996). The permeability to potassium of the BBB was determined under conditions of either high extraluminal ("brain interstitial", $[K]_{ext}$) or high intraluminal ("blood", $[K]_{int}$) potassium. Following application of high $[K]_{ext}$, FUR increased the rate of K^+ efflux ($[K]_{ext}$ to $[K]_{int}$) across the BBB. When K^+ was increased intraluminally, FUR had no effect on K^+ permeability through a complete glia/BAEC barrier, but decreased K^+ movement ($[K]_{int}$ to $[K]_{ext}$) when the barrier was grown with BAEC alone, *i.e.*, in the absence of endothelial tight junctions. These data indicate that 1) FUR acts on the BBB by inhibiting endothelial K^+ uptake 2) FUR facilitates clearance of high $[K]_{ext}$. The BBB may thus contribute to the antiepileptic effects of furosemide by increasing K^+ clearance and/or secondarily impacting on intracerebral ecs size. Supported by NIH NHLB 51624 and NS 07144.

EFFECTS OF VALPROIC ACID ON CALCIUM CURRENTS IN NEURONS FROM EPILEPTIC PATIENTS. C. Bruehl[1], M. Vreugdenhil[1], C.W. van Veelen[2] and W.J. Wadman[1]*. Inst. of Neurobiology, Univ. of Amsterdam, Kruislaan 320, 1098 SM Amsterdam[1] & Dept. of Neurosurgery, Academic Hospital Utrecht, Heidelberglaan 100, 3584 CX Utrecht[2],The Netherlands

The effects of 2 mM valproic acid (VPA) were determined on whole cell calcium currents of acutely dissociated neocortical neurons predominantly of pyramidal shape (n=41). The tissue was obtained from temporal lobe biopsies of human patients (n=12), that suffered from pharmacoresistant epilepsies and subsequently underwent surgery. Depolarizing voltage steps from –50 mV evoked typical inward currents (HVA currents) with a half maximal activation potential (V_a) of –7.5 ±0.8 mV a peak amplitude of 1.34 ±0.09 nA and a time constant of inactivation of 95 ±9 ms. The potential of half maximal inactivation (V_i) was –28.6 ±1.6 mV. Adding VPA to the bath perfusate shifts the V_i by –4.7 ±0.6 mV ($p<0.001$). VPA induced a small shift of the V_a (–1.2 ±0.05mV; $p<0.01$) but did not affect the time constant of inactivation 89 ±9 ms. The peak current amplitude was reduced to –1.09 ±0.09 nA ($p<0.001$). In 9 cells low-voltage-activated currents (LVA) were large enough to be evaluated by potential steps from –120 mV to –30 mV (V_i: –85.8 ±2.9 mV). The mean peak amplitude of this current evoked at –30 mV was –0.08 ±0.01 nA. This LVA current was not changed by VPA.
The results show that VPA shifts the voltage-dependent-inactivation of HVA currents in human neocortical neurons 5 mV in negative direction and reduces their conductance by 19%. The neocortical cells from these patients do have the expected response to the high level of VPA. Therefore, it seems unlikely that the pharmacoresistance of these patients includes a lack of VPA response.

Evidence Supporting a Role for Programmed Cell Death in Soman-Induced Seizure-Related Brain Damage

G. P. H. Ballough* [2], J. P. Makowski[2], N. C. Sordoni[1], M. A. O'Connor[2] and M. G. Filbert[1]. [1]Neurotoxicology Branch, U.S. Army Medical Research Institute of Chemical Defense, Edgewood Area-Aberdeen Proving Ground, MD 21010-5425, U.S.A. [2]Department of Biology, La Salle University, Philadelphia, PA, 19141-1199, U.S.A.

It is well documented that seizure-related brain damage (SRBD), due to soman (pinacolylmethylphosphonofloridate) exposure, may be classified as excitotoxic. While soman-induced seizures are initiated by elevated acetylcholine concentration in the CNS, due to irreversible inhibition of acetylcholinesterase (AChE), they are maintained by excess glutaminergic synaptic transmission. Recent evidence points to an involvement of programmed cell death (PCD) in glutamate excitotoxicity. The present investigation was undertaken to assess the possibility that PCD contributes to soman-induced SRBD. Male Sprague-Dawley rats received intracerebroventricularly (i.c.v.) infusions of either GM1 ganglioside (5 mg/kg/day, for 5.0 ± 0.5 days) or saline; an additional group was sham-operated. Rats from each of these groups received either soman (1.25 x LD50, i.m.) or saline injections 4.0 ± 0.5 days following initiation of infusions. ECoG recordings were monitored via indwelling cortical electrodes. Twenty-seven hours following soman/saline administration, rats were placed under deep pentobarbital anesthesia and euthanized. Brains sections were processed for H&E and cresyl violet histochemistry or p53 immunoreactivity following soman-induced seizures. Piriform-cortical p53 immunoreactivity was assessed using calibrated optical densitometry. The present results show a marked increase in piriform-cortical p53 immunoreactivity following soman-induced seizures in the non-GM1 infused groups only. Soman administration produced status epilepticus but little or no SRBD in the GM1-infused group. Thus, increased p53 immunostaining was highly correlated to the presence of SRBD, but not to the seizures themselves. These findings support the conclusion that PCD contributes to SRBD resulting from soman administration.

SEROTONIN RELEASE BY CARBAMAZEPINE IS NOT BLOCKED BY TETRODOTOXIN. J. W. Dailey*, M. E.A. Reith, Q-S. Yan, M-Y Li, J. F. Graumlich and P. C. Jobe. Dept. of Biomedical & Therapeutic Sci., Univ. of Illinois Col. of Med., Peoria, Illinois 61605.

Serotonin is anticonvulsant in most seizure models. Carbamazepine causes dramatic increases in extracellular serotonin which are tightly linked to anticonvulsant effects in genetically epilepsy-prone rats (GEPRs) (JPET 261: 652, 1992). The increases in extracellular serotonin appear to be related to the anticonvulsant mechanism of action of this drug in GEPRs. Because GEPRs are epileptic as a result of neurological and neurochemical abnormalities (Life Sci. 50: 319, 1992), there is some possibility the effect of carbamazepine on serotonin may be unique to GEPRs' epileptic condition. To determine the generality of this finding, we administered anticonvulsant carbamazepine doses to Sprague-Dawley rats and observed extracellular serotonin from hippocampi by way of microdialysis. We found that carbamazepine administration resulted in significant and dose-related increases in extracellular serotonin. Tetrodotoxin (1 or 10 μM) administration through the dialysis probe decreased basal serotonin release in a dose related fashion. Tetrodotoxin through the probe did not decrease the effect of systemic carbamazepine on extracellular serotonin. These findings suggest that the serotonin releasing effect of systemic carbamazepine administration does not require action potentials in the brain area in which the release takes place. Further they suggest that the effect is mediated by an action of carbamazepine directly on serotonergic nerve terminals. Supported by NS32628. L:\COMMON\JWD\ABSTRACT\NEUROS96.DOC

ANTIEPILEPTIC EFFECT OF β-EUDESMOL. L.C. Chiou*[a,b], C.C. Chang[a] and L.-Y.M. Huang[b]. Department of Pharmacology, College of Medicine, National Taiwan University, Taipei, Taiwan[a], Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77555-1069.[b]

β-Eudesmol, a sesquiterpenol constituent of Chinese herbs with antidotal activity against organophosphate intoxication, was studied for its possible antiepileptic action. β-Eudesmol (300 mg/kg; i.p.) prevented the convulsions and lethality induced by maximal electroshock in mice but not those by pentylenetetrazol or picrotoxin. The effects of β-eudesmol and phenytoin were additive. Intracellular recordings from CA1 pyramidal neurons of rat hippocampal slices showed that β-eudesmol (20-100μ M) had no effect on resting membrane potential and input resistance. The excitatory postsynaptic potentials (e.p.s.ps) evoked by stimulating Schaffer collateral/commisual pathway and monosynaptic inhibitory postsynaptic potentials evoked orthodromically were also unaffected. N-Methyl-D-Asparate-mediated e.p.s.ps and epileptiform activity recorded in the presence of CNQX and bicuculline were also unaffected by β-eudesmol. β-eudesmol curtailed the sustained repetitive firing induced by long (800 ms) depolarizing current without changing the shape of initial action potential and spontaneous bursting. It is suggested that the anticonvulsant activity of β-eudesmol is not due to a modulation of GABA or glutamate synaptic transmission but probably to an use dependent block of sodium channels. COMPUTERIZED TESTS OF HUMAN WORKING MEMORY WITH APPLICATIONS TO ASSESSMENT OF ANTICONVULSANT THERAPY IN EPILEPSY. B. Kisačanin, G. Agarwal*, J. Taber, and A. Bendre. Depts. of Electr. Eng. and Comp. Sci. and Neurology, University of Illinois at Chicago, Chicago, IL 60607.

Neuropsychological tasks have been used to study human working memory for almost a century. Recently, an increasing number of these tasks have been computerized, allowing for the processing of huge amounts of data. Computerized tracking tasks, in which a subject attempts to follow a randomly moving object on a video display terminal, give a measure of motor speed and reaction time. As shown by Baddeley and his colleagues, tracking tasks administered with simultaneous tests of reaction time (RT) also give information of central executive capacity to distribute and coordinate processing resources.

In this study, we investigate the effects of antiepileptic drugs (AEDs) on motor and cognitive function using tracking tasks, with or without simultaneous RT testing. These computerized tests are compared to standard neuropsychological measures (the Grooved Pegboard and the Symbol-Digit Modalities tests), and performance is correlated to blood levels of AEDs.

Tracking and RT tasks are easily administered and rapidly performed. We believe these tasks can be used as clinical measures of the effect of medications, and possibly aging and dementia on working memory.

The data obtained in these tests are also used in development of new techniques to model human performance on tracking and the dual task tests as non-causal stochastic systems.

INHIBITION OF KINDLING DEVELOPMENT BY ARCAINE, A POLYAMINE ANTAGONIST. D.L. Yourick*, W.B. Rittase and J.L. Meyerhoff. Division of Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

Post-traumatic epilepsy, seizures resulting from penetrating and sometimes closed head injuries, occurred in 53% of soldiers suffering such injuries in the Vietnam conflict. The N-methyl-D-aspartate (NMDA) ionophore is thought to be altered in kindling, an animal model for post-traumatic epilepsy. This ionophore has several recognition sites as part of its functional structure, including glutamate, glycine and polyamine receptors with activation resulting in enhanced excitatory neurotransmission. To evaluate the importance of the polyamine site in the epileptogenic phenomenon, arcaine was administered intracerebroventricularly (i.c.v.) during the kindling process. Male Sprague-Dawley rats implanted with basolateral amygdalar electrodes and i.c.v. cannula were administered 0, 32 and 100 μg of arcaine in 10 μl of sterile water 10 min before a daily kindling stimulus. The stimulus parameters were a 1.0 sec train of 1.0 msec biphasic pulses, 60 Hz, 200 μAmp base-to-peak. The number of stimulations required to obtain the first clonic seizure (stage 3), the first generalized clonic seizure (stage 5) and the fifth stage 5 seizure as well as afterdischarge duration were determined. Arcaine increased the number of trials (inhibition of kindling) required to reach the first and fifth Stage 5 seizure at the high dose, 100 μg, when compared to vehicle controls. We have also shown that ifenprodil, another polyamine antagonist, slows kindling development. Compounds which have the ability to interfere with the function of the NMDA receptor complex may be useful in the prevention of post-traumatic epilepsy. (Intramural research funded by U.S. Army Medical Research and Materiel Command.)

IDENTIFICATION AND MEASUREMENT IN THE MAMMALIAN BRAIN OF 2-INDOLINON, A TRYPTOPHAN METABOLITE PROVIDED WITH NEURODEPRESSANT PROPERTIES. R. Carpenedo, V. Carlà, A. Chiarugi, G. Mannaioni, A. Galli, G. Moneti, F. Moroni*. Dept. of Pharmacology, Univ. of Florence, Viale Morgagni, 65, 50134 Firenze, Italy.

The administration of 2-indolinon to mammals may cause sedation, myo-relaxation and anesthesia (*Arch. Int. Pharmacodyn.* **152**; 121,1964). Systematically studying the behavioral effects of tryptophan metabolites, we confirmed that 2-indolinon (1-100 mg/kg) has profound neurodepressant actions and is able to antagonize chemical convulsions in mice. Interestingly, similar doses of its isomers, 4-indolol or 5-indolol, have convulsant properties. In view of these potent effects, we then attempted to: 1) identify 2-indolinon in the mammalian brain and other organs; 2) evaluate its synthesis and its disposition; 3) understand the mechanism of its actions. Utilizing both HPLC and GC/MS, we showed that 2-indolinon is present in the brain and other organs of rats and mice. In the rat brain, its concentration is 48±3.4 picomol/g, in the liver 110±8, in the kidney 490±90 and in blood 96± 4.2. When tryptophan metabolism leading to 5-OH-tryptamine was inhibited (by administration of para-chlorophenylalanine, 300 mg/kg), the concentration of 2-indolinon increased by 250% in the brain, but did not increase in the liver. Tryptophan (300 mg/kg) also increased the brain concentration of 2-indolinon, but only in approximately 50% of the animals. Similarly indole (3-30 mg/kg) increased brain and liver concentration of 2-indolinon, suggesting that it originate from indole oxidation. To understand the mechanism of its action, we studied whether 2-indolinon could displace the binding of ^{3}H-GABA to both $GABA_A$ or $GABA_B$ receptors, obtaining negative results. We also ruled out the interaction of 2-indolinon with ionotropic glutamate receptors both in binding studies and in functional tests. In conclusion, we have demonstrated the presence in the mammalian brain of an endogenous tryptophan metabolite possessing profound neurodepressant actions whose mechanism of action remains to be clarified. *Supported by C.N.R. and by the Univ. of Florence, Italy.*

ANTICONVULSANT EFFECT OF L-DEPRENYL AGAINST DIFFERENT SEIZURE TYPES IN MICE AND RATS. H. Lehmann and W. Löscher (SPON: European Neuroscience Association). Dept. of Pharmacology, Toxicology, and Pharmacy, School of Veterinary Medicine, D-30559 Hannover, Germany

The monoamine oxidase type B inhibitor L-deprenyl exerts not only anti-Parkinsonian, but also cognition-enhancing and neuroprotective effects. Progressive decrease in cognitive function as well as neurodegeneration like hippocampus- or amygdala-sclerosis are common findings in epileptic patients. The idea of an anticonvulsant drug profile comprising effects against cognitive disturbances and neurodegeneration prompted us to investigate whether L-deprenyl shows efficacy in acute and chronic seizure models.

In the kindling-model of complex-partial epilepsy L-deprenyl exerted significant anticonvulsant and antiepileptogenic properties. At a dose of 10 mg/kg i.p. administered 1 h before stimulation seizure threshold was increased up to 250 %, while seizure severity and duration were reduced. During kindling acquisition, 5 and 10 mg/kg i.p. administered 1 h before each stimulation delayed the kindling development (i.e. seizure severity and duration) significantly. In a second approach we tested L-deprenyl in male NMRI-mice in acute models of generalized seizures induced by electroshock and pentylenetetrazole (PTZ) and in behaviour tests to estimate adverse effects. In the electroshock seizure threshold test L-deprenyl at doses of 1-40 mg/kg i.p. significantly increased the threshold up to 50 % above control in a dose-dependent manner. In the PTZ test doses of 2.5-20 mg/kg i.p. increased the threshold for myoclonic and clonic threshold up to 42 % above control. D-deprenyl, which we included in this study in order to assess the stereoselectivity of deprenyl's effects was ineffective or exhibited lower anticonvulsant potency at doses that were associated with major behavioural alterations. The data indicate that L-deprenyl exerts anticonvulsant activity against different seizure types. This anticonvulsant activity and the previously reported neuroprotective and cognition-enhancing action of L-deprenyl offer a unique drug profile which might be of clinical benefit in patients with epilepsy. We are currently testing L-deprenyl's anticonvulsant efficacy in mouse models of epilepsy during chronic administration.

CHRONIC TREATMENT WITH PHENYTOIN RETARDS THE PERFORMANCE OF ADULT RATS IN A RADIAL ARM MAZE. D.A. Coomes[1], M. Sullivan[1], C.L. Wellman[1], J.E. Steinmetz[1,2*], and P.E. Garraghty[1,2], [1]Dept. Psych., [2]Prog. Neural Sci., Indiana Univ., Bloomington, IN 47405.

We have previously reported on the deleterious "cognitive" side-effects of phenytoin and CPP (a highly-specific NMDA receptor blocker) in rats and rabbits performing relatively complex instrumental and Pavlovian tasks, respectively. Based on those observations, we hypothesized that the effects of those compounds were due to their actions in the hippocampus. Here, we have extended our test of this hypothesis by examining the performance of phenytoin-treated rats in an 8-arm radial maze, a task that is thought to be hippocampally-mediated. We ran 16 rats (8 receiving phenytoin via gavage and 8 gavaged with water) for 20 days in the radial arm maze. Relative to controls, we found that the phenytoin-treated rats had significantly higher error rates over the last 5 days of training. Thus, they were less efficient in their choices. We also found that the drug-treated rats took substantially longer to complete trials on the training days when they achieved criterion performance (8 novel arms out of 9 total choices). Other experiments have shown that phenytoin does not slow cued responses, suggesting that the drug does not significantly affect sensorimotor behavior. Thus, the longer latencies to criterion performance in the maze is likely due to the fact that the phenytoin-treated rats find the task more challenging. These results demonstrate that chronic maintenance on phenytoin impairs the performance of rats in a radial arm maze. Given the comparability of the effects of phenytoin and CPP on other behavioral tasks, these data strongly suggest that phenytoin disrupts the function of NMDA receptors in the hippocampus, resulting in the retardation of cognitive and spatial performance.

825.14

A COMPARISON OF THE EFFECTS OF CARBAMAZEPINE AND PHENYTOIN ON TRANSFER FROM APPETITIVE TO AVOIDANCE CONTEXTS IN ADULT RATS. M.K. Banks[1,2*], J. Besheer[2], J.R. Szypczak[2], L.L. Goodpaster[2], and P.E. Garraghty[1,2]. [1]Prog. Neural Sci., [2]Dept. Psychology, Indiana University, Bloomington, Indiana, 47405.

We previously reported that phenytoin (DPH) severely impairs the ability of rats to acquire a tone-signaled avoidance response following training in an appetitive context. Here, we have evaluated the effects of carbamazepine (CBZ) in the same behavioral paradigm. We first trained rats to obtain food reinforcement with a barpress in the presence of a tone for 21 sessions of 100 trials each. Drug treatment with CBZ was then initiated, and the effects of CBZ on behavior in the appetitive context were assessed for 10 days. As in the DPH-treated rats, CBZ had no apparent effect on performance of the appetitive task. The rats were then transferred to the avoidance task for 25 days with 300 tone-signaled trials per session. In comparison to control rats, the CBZ-treated animals were somewhat retarded in the acquisition of avoidance responding, and their terminal avoidance rates were, on average, lower. When compared to DPH-treated rats, the CBZ-treated rats showed far more individual variability (apparently uncorrelated with differing serum levels), with some failing to acquire the avoidance response completely while others performed as well as the control animals. Furthermore, the average avoidance rate of the CBZ-treated rats far exceeded that of DPH-treated rats. Thus, CBZ can produce pronounced "cognitive" deficits, though not as severe, on average, as DPH, and this behavioral paradigm is sufficiently sensitive to detect differences between various compounds.
(Supported in part by RO3 MH55548-01).

825.15

A COMPARISON OF THE EFFECTS OF CPP AND PHENYTOIN ON A DISCRIMINATION REVERSAL EYEBLINK TASK IN RABBITS. J.D. Churchill*[1,2], M.N. Upton[2], S.E. Voss[2], J.E. Steinmetz[1,2], and P.E. Garraghty[1,2]. [1]Prog. Neur. Sci., [2]Dept. Psych., Indiana University, Bloomington, IN, 47405.

We have previously reported that phenytoin maintenance blocks a discrimination reversal task in rabbits. Here, we have investigated the effects of CPP, a highly specific, competitive NMDA receptor antagonist, in rabbits required to learn a stimulus discrimination reversal in a classical eyeblink conditioning paradigm. Discrimination training consisted of two tones, one paired with an air puff to the cornea (CS+), and an unpaired tone (CS-). Discrimination criterion was established at ≥75% conditioned responses (CRs) to the CS+ and ≤25% CRs to the CS-. After rabbits successfully discriminated between the initial tone pairings, bilateral injections of CPP into the lateral ventricles were administered prior to daily training sessions of the same tone pairings. Once CPP-treated rabbits achieved criteria again, the tone pairings were reversed (i.e., the initial CS+ became the CS- and vice versa) and the animals were tested for fifteen days thereafter.

Berger & Orr (1983) have reported that high response rates to the new CS+ emerge within the first 4-6 days of reversal training in normal rabbits, followed by suppression of responsiveness to the new CS- shortly thereafter. In CPP-treated rabbits, response acquisition of the new CS+ is somewhat delayed, but is achieved by day 10. However, responsiveness to the new CS- fails to diminish over the entire 15 days of drug treatment. This pattern is similar to that displayed by both phenytoin-treated rabbits and hippocampal ablated rabbits (Berger & Orr, 1983). These results suggest that the learning deficits associated with phenytoin maintenance are also found in rabbits treated with CPP, and thus may be due to actions upon the NMDA receptor system in the hippocampus. (Supported by NIH grant #MH51178 to JES).

825.16

ANTICONVULSANT PROFILE OF FCE 26743A, A NOVEL 2-AMINOPROPIONAMIDE DERIVATIVE P. Salvati*, C. Algate[1], D. Beard[1], A. Bonsignori, M.A. Cervini, R.A. McArthur, R. Maj, P. Pevarello, M. Varasi, R. Fariello, and C. Post. Pharmacia & Upjohn, CNS Research, Nerviano (Mi), Italy and Huntingdon Research Centre Ltd,[1] Huntingdon, UK.

FCE 26743A [(S)-(+)-2-(4-(3-fluorobenzyloxy)benzylamino)propionamide, methanesulfonate] is a Na^+ and Ca^{2+} channel blocker with glutamate release inhibiting properties showing anticonvulsant activity in screening procedures. The purpose of this study was to profile this activity in standard seizure models in rats, mice and primates. FCE 26743A prevented maximal electroshock seizures (MES: ED_{50}'s = 8.2 mg/kg, *po* in mice and 12.8 mg/kg, *po* in rats). High doses of FCE 26743A are required before rotarod ataxia in mice is noted (Toxic $Dose_{50}$ = 625 mg/kg, *po*). In chemically-induced models of grand mal seizures in mice (bicuculline, picrotoxin, 3-mercaptopropionic acid and strychnine) oral ED_{50}'s of 29.9, 60.6, 21.5 and 104.1 mg/kg respectively were obtained. FCE 26743A prevented generalised clonus with loss of righting reflex by subcutaneous pentylenetetrazole in mice (ED_{50} = 26.7 mg/kg, *ip*). Cynomolgus monkeys were implanted with stimulating electrodes in the amygdala and electrically-evoked afterdischarges, as well as behavioural changes consequent to stimulation were examined. FCE 26743A reduced both electrically-evoked afterdischarges and abnormal behaviours at doses between 25 and 75 mg/kg, *po*. Passive avoidance responding in the rat was not affected with doses up to 400 mg/k, *po* of FCE 26743A. Repeated treatment with 20.0 mg/kg, *po* of FCE 26743A in mice did not induce signs of tolerance. These results indicate that FCE 26743A is a broad spectrum anticonvulsant with low behavioural toxicity, lack of cognitive-impairing activity and tolerance potential in animal models.

825.17

TEMPORAL PATTERN OF SEIZURE OCCURRENCE WITH OR WITHOUT ANTIEPILEPTIC DRUGS, IN PILOCARPINE MODEL OF EPILEPSY. C.Hamani*, E.M.Bastos, M.S.França and L.E.A.M.Mello. Depto. Fisiologia, UNIFESP-EPM, 04023-900 São Paulo, Brazil.

The analysis and potential prediction of distinct patterns of spontaneous seizure occurrence in epileptic patients have been considered to be of extreme value for a more elaborated treatment planning. In this sense, several studies have been performed and contributed by providing valuable data related to specific patterns of temporal seizure distribution as well as the influences of antiepileptic drugs (AEDs) administration on such patterns. Yet, the isolation of singular causative factors as well as the analysis of specific therapeutic approaches is not feasible in various clinical circumstances due to ethical reasons, and the multifactorial aspects of the human epilepsies. Therefore, we decided to analyze the temporal pattern of spontaneous epileptic seizures (SRS) in an experimental model of epilepsy, with or without AEDs. Adult, Wistar male and female EPM-1 rats were injected with pilocarpine (320-350 mg/Kg, i.p.) and behaviorally observed 3 to 8 hours/day, 5 days/week for more then 10 weeks for the occurrence of SRS. Another group of animals received an i.p. injection of oxcarbazepine (a potent AED) either 30 min. before pilocarpine or for 7 days after pilocarpine-induced status epilepticus (respectively 60 mg/Kg or 20 mg/Kg/day). Mean latency for the behavioral observation of the first SRS was 20 days for the pilocarpine group and 43 days for the oxcarbazepine. The incidence of SRS over time was compared to a random distribution (Poisson). Animals injected with pilocarpine only, were found to follow a random distribution of SRS. Oxcarbazepine injection, even a single injection, was found to alter SRS distribution to a non-random pattern. Most human studies indicate the predominant presence of a non random temporal pattern of seizures. The present study suggests that the human data might be strongly influenced by the AEDs taken by the subjects in such studies.

SINGLE IMPLANTATION OF POLYMERIC-TRH MICRODISKS SUPPRESS KINDLED EPILEPTOGENISIS IN THE RAT. M. J. Kubek*[1,2,3] D. Liang[1], Y. Nie[1], A. J. Domb[4] and K. E. Byrd[1], Departments of Anatomy[1], Psychiatry[2] and [3]Program in Medical Neurobiology, Indiana University School of Medicine[1] Indianapolis, IN 46202 and [4]School of Pharmacy, Hebrew University, Jerusalem, Israel

Exogenous Thyrotropin-releasing hormone (TRH) and TRH analogs demonstrate antiepileptic and anticonvulsant properties in animals and humans. Nonetheless, their pharmacological application is limited by diverse physiological barriers to site-specific bioavailability. To address this problem, TRH was attached to a biodegradable polyanhydride (FAD), as a sustained-release delivery system and tested in the kindling model of temporal lobe epilepsy. Prior to kindling, Polymeric-TRH or control microdisks were implanted unilaterally in the basolateral amygdala immediately dorsal to the bipolar stimulating/recording electrode. Kindling (1 sec biphasic square waves @200 μA) was initiated 5 days after implantation. Animals with TRH implants required significantly more daily stimulations (2-fold) to reach each of the five behavioral kindling stages, and twice the number of daily stimulations (8.63 ± 0.924 vs 16.67 ± 1.369, Mean ± SEM; P<0.0001) to become fully kindled. Additionally, TRH implants significantly shortened the afterdischarge (AD) duration (sec.) in both the ipsilateral (89.0 ± 5.36 vs 51.8 ± 15.65; P<0.0001) (electrode side) and contralateral (94.4 ± 7.05 vs 48.67 ± 15.80; P<0.0001) amygdala, respectively. A 60% reduction in clonus duration (P<0.0001) was also observed in the TRH-implanted group. The TRH-FAD polymer had no demonstrable effect on afterdischarge threshold prior to kindling. We suggest that TRH in situ microdisk pharmacotherapy (TRH-ISMP) is useful in suppressing both the development and severity of kindled seizures. Moreover, these results demonstrate potential use of TRH-ISMP in this and other neurological disorders. Supp. by RVA to MJK & NIDR to KEB.

DEGENERATIVE DISEASE: ALZHEIMER'S-BETA-AMYLOID—MEMBRANE INTERACTIONS

826.1

MEMBRANE DISRUPTION BY ALZHEIMER B-AMYLOID PEPTIDES MEDIATED THROUGH SPECIFIC BINDING TO EITHER PHOSPHOLIPIDS OR GANGLIOSIDES: IMPLICATIONS FOR NEUROTOXICITY. J. MCLAURIN, W. JACOBSON*, A. CHAKRABARTTY.

Increasing evidence implicates Aβ peptides as neurotoxic agents in Alzheimer's disease. We investigated one possible mechanism of neurotoxicity, namely, Aβ-membrane lipid interactions. We find that fibrillar-Aβ disrupts membranes containing acidic phospholipids. This disruption is greater at slightly acidic pH (characteristic of endosomes) than at neutral pH (characteristic of the extracellular space). This pH dependence suggests that fibrillar-Aβ has the capacity to disrupt endosomal and plasma membranes, and this disruption could account, at least in part, for the observed neurotoxic effects of the peptide. We also find that gangliosides induce Aβ to adopt a novel α/β conformation at neutral pH, and we suggest that gangliosides can prevent fibril formation by sequestering Aβ in this novel conformation.

CHANGES IN ASTROCYTE MORPHOLOGY AND ION CHANNEL ACTIVITIES INDUCED BY ß-AP(1-40) AND (25-35). T.O. Jalonen*, D.B. Wielt, C.J. Charniga and A.J. Popp. Division of Neurosurgery A-60, Albany Medical College, Albany, N.Y. 12208.

Excess amounts of ß-amyloid peptides (ß-APs) have been suggested to cause neuronal degeneration in Alzheimer's disease. Other important brain cells, such as glia, survive, but change their behaviour. Fibrous (reactive) astrocytes are found around senile plaques, but the early effects of gradually increasing amounts of ß-APs on these cells are not yet known. We found that in cultured rat astrocytes already small (10-200 nM) concentrations of ß-AP(1-40) and (25-35) induce process outgrowth starting within 1 h of ß-AP addition, as well as a dense net of processes and hypertrophy when cells were treated overnight. Contradictory to the reported effects on some neurons, in astrocytes neither ß-AP(1-40) nor (25-35) caused any consistent change in intracellular Ca^{2+} levels. However, increased K^+ and Cl^- channel activities were seen with 10-100 nM ß-APs, and larger concentrations (20 μM) of ß-APs induced giant nonselective currents, similar to those induced in lipid bilayers. Therefore, it seems that even small increases in ß-AP levels in brain during the advancement of Alzheimer's disease cause multiple functional and morphological changes in astrocytes, and these early changes may eventually play a role in the observed neuronal degeneration. DISTURBANCE OF ELECTROPHYSIOLOGICAL NEURONAL FUNCTION BY CONTINUOUS INFUSION OF ß-AMYLOID PROTEIN IN RATS. A. Itoh, A. Nitta, R. Iida, T. Akaike#, M. Sokabe#, T. Kameyama$,*, T. Hasegawa and T. Nabeshima, Dept. of Neuropsychopharmacol. and Hospital Pharm., #Dept of Physiol., Nagoya Univ. Sch. of Med., Nagoya 466, $Dept. of Chem. Pharmacol. Meijo Univ. Facul. of Pharmac. Sci., Nagoya 468, Japan

Many reports showing neurotoxic effects of ß-amyloid protein (Aß), a main component of senile plaques in patients with Alzheimer's disease (AD), suggest important roles of Aß on pathogenesis of AD. Our previous study shows continuous infusion of Aß into the cerebral ventricle of rats impairs learning and memory with concomitant decrease of choline acetyltransferase activity and of K^+-stimulated dopamine release and nicotine-stimulated acetylcholine and dopamine release in *in vivo* brain microdialysis. We report here neuronal dysfunction in rats induced by continuous infusion of Aß by means of electrophysiological techniques.

Male Wistar rats were infused Aß (1-40, 300 pmol/day) into the cerebral ventricle by using osmotic minipump. Ten or eleven days after starting infusion, rats were sacrificed and the hippocampal slices were cut to record the field potentials in the hippocampal CA1 pyramidal cells induced by stimulating Schaffer collateral. Nicotine perfusion reduced the amplitude of population spikes in the control rats, however, the Aß-infused rats showed less response consistent with brain microdialysis study. Moreover, tetanic stimulation induced long-term potentiation (LTP) in the hippocampal CA1 pyramidal cells in the control rats but not in the Aß-infused rats.

These results suggest that Aß infusion may impair the signal transduction *via* nicotinic receptors. Further, this dysfunction may be responsible for impairment of the formation of LTP and leads to the impairment of learning and memory.

EFFECTS OF PEPTIDE FRAGMENTS OF β-AMYLOID PRECURSOR PROTEIN ON PARALLEL FIBER-PURKINJE CELL SYNAPTIC TRANSMISSION IN RAT CEREBELLUM. YOO-HUN SUH[1]*, KWANG WOO LEE[2] AND NICK A. HARTELL[3]
[1]Department of Pharmacology, and [2]Department of Neurology Seoul National University, College of Medicine, 28 Yongon-Dong, Chongno Gu, Seoul 110-799, Korea. [3]Laboratory for Synaptic Frontier Research Program, RIKEN, Hirosawa 2-1, Wako-shi, Saitama, 351-01, Japan.

The effects of various protein fragments of βAPP were examined on the parallel fiber-Purkinje cell synapse in the rat cerebellum. Of 4 proteins examined, βAPP, CT_{105}, $A\beta_{25-35}$, and $A\beta_{1-16}$, localised applications of only CT_{105} to discrete dendritic regions of Purkinje cells consistently induced large, transient inward currents that were associated with calcium influx. All four proteins, however, induced depression of PF-Purkinje cell synaptic transmission at site of application through a combination of pre- and postsynaptic effects. Recovery was not observed with either CT_{105} and $A\beta_{25-35}$ and in the former case, the depression spread to distant sites and was consistently followed by cell death within 30-40 minutes of application. These data indicate that C-terminal fragments of the βAPP can both block synaptic transmission and have neurotoxic effects and as such may be considered alternative candidates for some of the neurotoxic effects of Alzheimer's disease.

STEREOTAXIC INJECTIONS OF β-AMYLOID CAUSE EARLY METABOLIC AND MEMBRANE CHANGES IN THE RAT BRAIN. M.T. Caserta[1]*, F.S. Yao[3], A.M. Wyrwicz[2]. [1]Dept. Psych., Northwestern Univ. Med. Sch., Chicago, IL 60611 and [2]Ctr. for M.R. Rsrch., Evanston Hosp., and [3]Northwestern Univ. Inst. for Neuroscience, Evanston, IL 60201

Injections of β-amyloid peptide (βA4) into rat hippocampus result in neuronal cell death (Yankner, B.A., et al; 1989). The mechanism by which this degeneration occus, however, remains unsolved. Alterations in membrane phospholipids have been suggested to play some part since studies of AD patients show decreased amounts of key membrane components. To determine what early changes may occur in phospholipid and metabolite levels, we use a rat model of βA4 deposition. Adult female Sprague-Dawley rats were stereotaxically injected with approximately 4 nmol βA4 (1-42), dissolved in a sterile vehicle solution of 35% acetonitrile and 0.1% trifluoroacetic acid in distilled water, in the left hippocampus and with vehicle in the right. Previous confirmation of peptide deposition was achieved using immunocytochemistry. After 24 hours, animals were decapitated and their heads frozen in liquid nitrogen. Brain tissue was extracted with a 2:1 chloroform-methanol solution. The phases were separated and washed so that the organic phase, consisting of various phospholipid membrane components, was prepared for analysis using ^{31}P NMR spectroscopy on a Bruker 400 MHz spectrometer. The aqueous phase, consisting of various metabolites, was prepared for analysis using ^{1}H spectroscopy on a GE 500 MHz spectrometer. Phosphorus NMR spectroscopic results show a trend towards decreased levels of major phospholipid membrane components Proton NMR spectroscopic results demonstrate a trend towards decreased levels of lactate and choline on the βA4-injected side compared to the right hemisphere. NAA and acetate levels are elevated on the βA4-injected side, whereas taurine and aspartate levels are unchanged. Since membrane damage and changes in the phosphoinositol second-messenger cascade have been implicated in AD, our phosphorus NMR findings are consistent with these hypotheses and also suggest these changes may occur very early in the disease process. C-TERMINAL FRAGMENT OF THE ß-AMYLOID PRECURSOR PROTEIN FORMS CATION SELECTIVE CHANNELS IN PLANAR LIPID BILAYER. H.J. Kim[1], Y.H. Suh[3], M.H. Lee[2], P.D. Ryu[1]* [1]Dept. of Pharmacol., [2]Biochem., Coll. of Veterinary Med. Seoul Nat'l U., Suwon 441-744, [3]Dept. of Pharmacol., Coll. of Med. Seoul Nat'l U., Seoul 110-799, Korea.

C-terminal fragment of ß-amyloid precursor protein (ßAPP) has been found in the patient with Alzheimer Disease and known to be toxic to neurons. Recently it was shown that a 105-amino-acid C-terminal fragment (CT105) of βAPP induces membrane current in *oocyte* (Fraser et al., J Neurochem, 1996). In this work we further studied the electrical properties of ion channels formed by CT105 in planar lipid bilayer composed of palmitoyl-oleoyl-phosphatidylethanolamine and palmitoyl-oleoyl-phosphatidylcholine (80:20, 25 mg/ml in decane).

Channel activity was readily seen at 200/0 mM (*cis/trans*) NaCl in 1-5 min after adding CT105 (100-500 nM) to the media. The channels showed 2-7 conductance levels of 3-100 pA and unitary conductance at 200/0 mM NaCl or KCl was about 3 pA. The amplitudes of various conductance levels were multiples of unitary conductance in the majority of the channels. More conductance levels were observed at larger voltage gradient (> 40 mV). Current-voltage curve was linear at -80 - +80 mV and slope conductances ranged 100-200 pS in 200/40 mM NaCl and 150-750 pS in symmetrical 200 mM NaCl. The reversal potentials estimated in 200/40 mM NaCl or KCl were close to those expected by Nernst Equation, indicating high selectivity for cations. The permeability sequence of 3 cations, estimated from the reversal potential under bi-ionic conditions, was $P_{Cs} > P_{Na} > P_K$.

Our data indicate that CT105 form cation selective ion channels on the cell membrane which could be responsible for the neurotoxicity caused by this fragment. (Supported by Korea Research Foundation).

CHANGES IN INTRACELLULAR $[Ca^{2+}]$ AND pH IN SINGLE HIPPOCAMPAL NEURONS TREATED WITH β-AMYLOID PEPTIDE.
H.S. Mogensen[1,2], O.S. Jorgensen[2*], S.J. Morris[1]. [1)]Div. Mol. Biol. & Biochem., UMKC, Kansas City, MO 64112, and [2)] Lab. Neuropsych., Dep. Pharmacology, Univ. Copenhagen, Denmark.

Insoluble aggregates of the β-amyloid peptide (βAP) is a major constituent of senile plaques found in brains from Alzheimer Disease patients. The βAP deposits are believed to contribute directly to the neuronal impairment progressing with the disease. βAP is toxic to CNS neurons but the mechanism of toxicity is still unknown. The toxic effects of βAP seem, however, to be associated with a destabilized intracellular Ca^{2+} homeostasis. Changes in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) has been shown to be closely coupled to changes in intracellular pH (pH_i). In this study, we examined the effects of βAP(25-35) on both $[Ca^{2+}]_i$ and pH_i in single hippocampal neurons maintained in defined-medium primary cultures. The simultaneous measurement of $[Ca^{2+}]_i$ and pH_i was achieved by real-time fluorescence imaging at four different wavelengths. This allowed the dual imaging of Ca^{2+}- and pH-specific ratio dyes, Indo-1 and SNARF-1, respectively. The experimental set-up enabled the correction of the pH-dependent K_d of indo-1, which results in more accurate estimates of the $[Ca^{2+}]_i$. We found that the resting $[Ca^{2+}]$ increased and pH_i decreased with time in culture. We also found that long exposure (9 days) to 0.3 and 3 μM βAP increased the resting $[Ca^{2+}]_i$ and decreased the resting pH_i. We conclude that, as well as destabilizing the intracellular Ca^{2+}-homeostasis, long time exposure to βAP also decreases pH_i. Such acidification of neurons might disrupt pH-dependent cellular processes and contribute to neuronal impairment. BETA-AMYLOID TREATMENT INDUCTION OF NEURONAL DEATH AND NEURONAL / CELLULAR DISFUNCTION IN NGF-TREATED PC12 CELLS: BLOCKADE BY COMPOUNDS WHICH ALSO BLOCK AGGREGATION. F. Wirtz-Brugger, P. Sander, and A. Giovanni*. Hoechst Marion Roussel, Neuroscience Therapeutic Domain, Somerville, N.J 08876.

Amyloid-β-peptide is found in Alzheimer's Disease (AD) brain and has been shown to induce neurodegeneration in vitro. In these studies we have used Aβ 1-40 and 1-42 exposure of NGF-treated PC12 cells to model the neurodegenerative process(es) that occur in AD and to probe for potential points for therapeutic intervention in this debilitating disease. Our initial studies focus on defining the effects of the peptide on biochemical markers for neuronal/cellular function and viability with respect to dose and time course. Thus, we have examined markers for cell death including LDH release and ethidium homodimer binding, as well as markers for cellular function including MTS and MTT. We are also assessing specific neuronal functions including neurotransmitter uptake and release. It appears clear that amyloid has effects on both cellular viability and neuronal/cellular function and that agents which can interfere with amyloid aggregation can also block these effects. The process of β-amyloid induced neuronal death resembles apoptosis in that DNA fragmentation occurs. Furthermore, the morphology of the neurons appears altered such that neurites become convoluted and fragmented. Amyloid's effects appear to be both concentration and time dependent. These effects are reliable and reproducible and provide useful end-points with which to study β-amyloid-induced neurodegeneration *in vitro*.

INHIBITION OF Na^+/K^+ ATPase BY AMYLOID β-PEPTIDE ($A\beta_{1-40}$): IMPLICATIONS FOR ALZHEIMER'S DISEASE. G. M. Bores*, A. Giovanni and C. P. Smith. Hoechst Marion Roussel, Neuroscience Therapeutic Domain, Bridgewater, New Jersey 08807.

Mark et al (1995) reported the selective inhibition of Na^+/K^+ ATPase activity in primary rat hippocampal cell cultures after 2-6 days of exposure to 20 μM $A\beta_{1-40}$. We have expanded these studies using rat hippocampal slices (hippocampal tissue cross-chopped at 0.4 mm thickness) and rat primary cortical cultures. Hippocampal slices were incubated in the presence or absence of $A\beta_{1-40}$ for one hour. The slices were then homogenized in 0.32 M sucrose, pH 7.1. The assay was performed in membranes derived from a synaptosomal-enriched pellet (P_2) and the reaction was started by the addition of 3 mM ATP. After a one-hour incubation at 37°C, control total activity in these membranes was approximately 20 nmol Pi/mg prot/min and 2 mM ouabain-insensitive activity was approximately 10 nmol Pi/mg prot/min.

We have found that one hour incubations with 1 - 30 nM $A\beta_{1-40}$ with hippocampal slices caused a 40-60% reduction in membrane Na^+/K^+ ATPase activity, defined by 2 mM ouabain. The ouabain-insensitive activity was not consistently affected. The reduction in Na^+/K^+ ATPase activity was consistently observed only when the slices were incubated with the various concentrations of $A\beta_{1-40}$. In agreement with other investigators, similar incubations of $A\beta_{1-40}$ with hippocampal membranes were without effect. The requirement for intact neuronal preparations implies an indirect effect of $A\beta_{1-40}$ on membrane Na^+/K^+ ATPase. Furthermore, the range of nanomolar concentrations of $A\beta_{1-40}$ which inhibit this enzyme rat brain tissue is in the same range shown to enhance the in vitro $[Ca^{2+}]_i$ response to minimal depolarization with 10 mM KCl (Li et al, next abstract). The relationship between these two effects of $A\beta_{1-40}$ will be discussed. Research funded by HMR, Inc.

826.10

FURTHER CHARACTERIZATION OF $A\beta_{1-40}$ EFFECTS ON INTRASYNAPTOSOMAL CALCIUM ($[Ca^{2+}]_i$) IN RAT CORTEX : EFFECTS OF SODIUM CHANNEL BLOCKERS. M. Li*, L. Tang, S. Kongsamut and C. P. Smith. Hoechst Marion Roussel., Neuroscience Therapeutic Domain, Bridgewater, New Jersey 08807.

We have recently shown in purified rat cortical synaptosomes that 3 nM $A\beta_{1-40}$ increases the in vitro $[Ca^{2+}]_i$ response to minimal depolarization with 10 mM KCl by 77% (Li and Smith, 1996). We now show that 0.3 and 3.0 picomolar $A\beta_{1-40}$ also increase $[Ca^{2+}]_i$ response to 10 mM KCl by 50-60%. Mark et al (1995) have suggested that Aβ-induced increases in $[Ca^{2+}]_i$ and neurotoxicity in rat hippocampal cells may be causally linked with Na^+ influx and anticonvulsant drugs such as carbamazepine block this. We investigated carbamazepine (at 1 and 10 μM) in purified rat cortical synaptosomes and found it completely antagonized the 3 nM $A\beta_{1-40}$ enhanced $[Ca^{2+}]_i$ response to minimal depolarization with 10 mM KCl. These concentrations of carbamazepine alone had no effect on control $[Ca^{2+}]_i$ responses to 10 mM KCl. Carbamazepine and other anticonvulsants are known inhibitors of $[^3H]$BTX, which binds to the modulatory site (site II) of the voltage dependent sodium channel. We have found that HP 184,[N-(n-propyl)-N-(3-fluoro-4-pyridinyl)-1H-3-methylindol-1-amine], blocks sodium channels in rat brain ($[^3H]$BTX IC_{50} = 31 μM and blockade of 25 μM veratridine-stimulated increases of $[Ca^{2+}]_i$; IC_{50} = 58.2 μM), We investigated this compound and P11467, a combined AChEI and α_2 adrenoceptor antagonist (Vargas et al, 1996), and found they can also prevent the 3 nM $A\beta_{1-40}$ - induced increase in $[Ca^{2+}]_i$ due to 10 mM KCl. We will discuss the relationship between binding affinity for $[^3H]$BTX and the increased $[Ca^{2+}]_i$ response after 3 nM $A\beta_{1-40}$ exposure. Research funded by HMR, Inc.

FORMATION OF CATION-SELECTIVE ION CHANNELS BY AMYLOID ß-PROTEIN ACROSS MEMBRANES OF HYPOTHALAMIC NEURONAL CELLS

M. KAWAHARA*[1], Y. KURODA[1], N. ARISPE[2], and E. ROJAS[2,3]
[1]Department of Molecular & Cellular Neurobiology, Tokyo Metropolitan Institute for Neuroscience, 2-6 Musashidai, Fuchu, Tokyo 183, Japan, [2]Laboratory of Cell Biology and Genetics, NIDDK, NIH, Bethesda, MD 20892, U.S.A., [3]Department of Physiology and Biophysics, Faculty of Medicine, University of Chile, Santiago, Chile.

Alzheimer's amyloid ß-protein (AßP) incorporates into phospholipid bilayer membranes and forms cation-selective ion channels that conduct Ca^{2+} and other cations (Arispe-N, *et al.*, PNAS, 90, 10573, (1993)). To investigate the formations of ion channels by AßP on neuronal membranes, we exposed excised membrane patches from hypothalamic GnRH neurons (GT1-7 cells) to AßP [1-40] solutions. Within 3-40 minutes of the application of 5 μM of AßP [1-40], AßP-specific channel currents were appeared in a symmetrical CsCl solution system. The AßP [1-40] channels exhibited spontaneous conductance changes over a wide range (50-500 pS). The channel activity was effectively blocked by addition of 50-500 μM of Zn^{2+} and was recovered by the Zn^{2+}-chelator, *o*-phenanthroline. These properties of the AßP [1-40] channels formed across GnRH neuronal membrane patches are similar to those observed in the bilayer (Arispe-N, *et al.*, PNAS, 93, 1710, (1996)). GT1-7 cells showed neurotoxicity by WST-1 assay. Deposition of AßP on cell surfaces were also identified by immunohistochemistry and western blotting. These results support the idea that AßP-channel and abnormal calcium-influx are be based on the neurotoxic effects of AßP. The preventive role of Zn^{2+} in the etiology of Alzheimer's disease is also suggested. (Supported by Japan Health Science Foundation, FONDECYT 1950774, and Fundación Andes, Chile).

ELECTROPHYSIOLOGICAL CHARACTERIZATION OF A CHOLINERGIC SEPTAL CELL LINE. L.V. Colom[1]*, A. Neely[2], and D.R. Mosier[1]. [1]Department of Neurology, Baylor College of Medicine, Houston, TX 77030; [2]Department of Physiology, Texas Tech University, Health Science Center, Lubbock, TX 79430.

Septal cholinergic neurons, which strongly influence the firing of neurons in the hippocampus (a key structure in memory processing), are selectively affected in Alzheimer's disease (AD). To develop a model for selective vulnerability of cholinergic neurons in AD, we characterized ionic currents in the SN56 cell line (a N18TG2 neuroblastoma/PND 21 mouse brain septal neuron hybrid expressing high levels of choline acetyltranferase activity after cAMP differentiation (Lee *et al.*, Dev. Brain Res., 52: 219, 1990; Blusztajn *et al.*, J. Neurosci., 12: 793-799, 1992). Whole-cell and cell-attached patch recordings were made using SN56 cells differentiated for 7-14 days. All SN56 cells showed large Na^+ currents, which were TTX-resistant (50% block at 100 nM) and Zn^{2+}-sensitive (80% blockade at 100 μM Zn^{2+}). These cells also expressed a TEA-sensitive outward current (>50% block at 5 mM), resembling a delayed rectifier K^+ current. In addition to a 12 pS channel consistent with a delayed rectifier, single-channel recording also demonstrated a 130 pS channel consistent with a Ca^{2+} activated "maxi-K" channel. A rapidly inactivating Ca^{2+} current was also recorded, which activated near -60 mV in 10 mM Ba^{2+}, was blocked by 10 μM Ni^{2+} (>75%) and high concentrations of nifedipine (50 μM), and was insensitive to ω-agatoxin IVa, ω-conotoxin GVIA, and ω-conotoxin MVIIC (all 1 μM). These Ca^{2+} currents appeared to be poorly coupled to the maxi-K channel since an "N-shape" was not observed in I-V plots. Since recent evidence suggests a possible role for Zn^{2+} in AD pathogenesis, observation of a Zn^{2+}-sensitive Na^+ current in SN56 cells enhances the value of this cell line as a model for AD-related pathophysiology. Moreover, the lack of tight coupling between a Ca^{2+} channel and an expressed maxi-K channel may be functionally relevant in these cells, and will require further investigation. Supported by Methodist Hospital Foundation and Curtis Hankamer Foundation grants to L.V. Colom.

IN VITRO CHOLINERGIC CELLS ARE SELECTIVELY VULNERABLE TO AMYLOID β PROTEIN. M.E. Diaz*, L.V. Colom, M.E. Alexianu, and S.H. Appel. Department of Neurology, Baylor College of Medicine, Houston, TX 77030.

Septal cholinergic neurons critically influence the firing patterns of hippocampal neurons, play a relevant role in memory processes, and are clearly affected in Alzheimer's disease (AD). The major protein found in senile plaques, the neuropathologic hallmark of AD, is a 39-42 residue peptide termed amyloid β protein (Aβ). To understand the selective vulnerability of cholinergic cells in AD two cell lines derived from the septal region were selected as our experimental model. The SN56 and SN48 cell lines were developed in Bruce Wainer's laboratory by somatic fusion of N18TG2 neuroblastoma cells with postnatal day 21 mouse brain septal neurons. When differentiated in dibutyryl-cAMP, SN56 cells show high levels of choline acetyltranferase activity (ChAT), whereas SN48 cells lack significant ChAT activity (Lee *et al.*, Dev. Brain Res., 52: 219, 1990; Blusztajn *et al.*, J. Neurosci., 12: 793-799, 1992). Here we present evidence that SN56 cholinergic cells are susceptible to Aβ toxicity, while SN48 non-cholinergic cells are resistant to Aβ toxicity. To evaluate Aβ cytotoxicity, images of cells in culture were acquired and processed using an inverted microscope and a confocal unit. The Aβ peptide 1-40 was added directly to culture wells to reach final concentrations of 10 μM. Cells survival was assayed by serial quantification of bright-phase cell profiles retained on dish substrata in fields defined at day 0. Cytotoxicity was calculated as a percentage of cell survival in untreated cultures. While SN56 cell survival was reduced by 24% (±7) and 43% (±7) following 48 and 96 hours of treatment with 10 μM Aβ, respectively; SN48 cells survival was not affected by Aβ (111% and 107% survival at 48 and 96 hours, respectively). These results show that cholinergic cells are selectively vulnerable to Aβ toxicity. We are currently studying specific channel/receptor systems in both cell lines to explain the selective vulnerability of SN56 cells. Supported by Methodist and C. Hankamer Foundations to L.V. Colom.

β-PEPTIDES ENHANCE THE MAGNITUDE AND PROBABILITY OF LONG-TERM POTENTIATION. P.E. Schulz*, Dept. Neurol. & Div. Neurosci., Baylor College of Medicine, Houston, Tx 77030.

Memory loss is an early and prominent symptom of Alzheimer's disease (AD). Understanding this loss may provide an important clue to the pathophysiologic processes underlying AD. One explanation for this memory loss is that the β-peptides deposited in AD *inhibit* the mechanisms of memory storage, which may include long-term potentiation (LTP), an increase in synaptic efficacy induced by high-frequency stimulation (HFS). Alternately, these peptides could induce excitotoxic cell death through a mechanism such as increasing intracellular calcium, which might also *increase* LTP. To distinguish between these possibilities, we have tested the effect of two β-peptides on LTP in the acute rat hippocampal slice preparation using standard extracellular recording techniques.

The effects of β1-42 on LTP were compared to those of β1-28 on a second input in the same slice. An LTP induction paradigm was chosen that induced little LTP in control slices. The probability of LTP was greater in the β1-42 input (82%; 14/17) vs. the β1-28 input (40%; 6/15 slices). LTP magnitude amongst all slices was also greater at 26.6±5.2% (mean±SEM, n=17) vs. 5.7±4.7% (n=15, p=0.009 by t-test). This result was preliminarily repeated using β1-40 vs. vehicle, in agreement with Rowan et al (1995). Three mechanisms by which β1-42 could enhance LTP were investigated. The results are that: β1-42 increased NMDA currents in 2 of 7 slices, which would not account for the increases in LTP that occurred almost every time; β1-42 did not increase synaptic activity during HFS, which would indirectly increase NMDA currents; and, β1-42 did not affect AMPA currents, either pre- or postsynaptically. Thus, the mechanism(s) by which β1-42 enhances LTP remains elusive.

We conclude that β-peptides increase LTP, and we are investigating the effect of this on subsequent cell health (supported by NIH).

ALZHEIMER DISEASE AMYLOID β PEPTIDE (25-35) INTERCALATES INTO THE MEMBRANE BILAYER AND INHIBITS LIPID PEROXIDATION AT NANOMOLAR CONCENTRATIONS.

M.F. Walter*, P.E. Mason and R.P. Mason. Neurosciences Research Center, Medical College of Pennsylvania & Hahnemann University, Allegheny Campus, Pittsburgh, PA 15212.

Alzheimer disease neuropathology is characterized by neuritic plaques composed primarily of amyloid β (Aβ) peptide. The Aβ molecule has been shown to have neurotrophic activity in cultured neurons, an effect which may be related to decreased membrane susceptibility to lipid peroxidation. In this study, the membrane interactions of Aβ(25-35) were probed using small-angle x-ray diffraction, and correlated with its lipid antioxidant activity.

X-ray diffraction data demonstrated that Aβ(25-35) partitions deep into the lecithin membrane hydrocarbon core, 0-12Å from the bilayer center. The membrane intrabilayer headgroup separation and unit cell periodicity were 40Å and 54Å, respectively. The effect of Aβ(25-35) on lipid peroxidation at 37°C was tested in dilinoleoyl phosphatidylcholine multilamellar vesicles, a system composed of polyunsaturated fatty acids. At 10 nM, Aβ(25-35) inhibited lipid peroxide formation by 90%. These results show that Aβ(25-35) partitions to a discrete location in the membrane and inhibits lipid peroxide formation at nanomolar concentrations. The strong physico-chemical membrane interactions and potent antioxidant activity of Aβ(25-35) may contribute to its neuroprotective properties.

MEMBRANE INTERACTIONS OF ALZHEIMER DISEASE AMYLOID β PEPTIDE IS MODULATED BY CHOLESTEROL CONTENT: X-RAY DIFFRACTION ANALYSIS.

P.E. Mason*, M.F. Walter, C.M. DeRosia and R.P. Mason. Neurosciences Research Center, Medical College of Pennsylvania & Hahnemann University, Allegheny Campus, Pittsburgh, PA 15212.

Amyloid β peptide (Aβ) is a primary constituent of neuritic plaques, a hallmark neuropathological lesion in Alzheimer disease. It has been proposed that Aβ perturbs calcium homeostasis in neuronal cell cultures as a result of physico-chemical interactions with the plasma membrane. In this study, small-angle x-ray diffraction was used to directly examine the interactions of Aβ(1-42) with lecithin membrane bilayers prepared in the absence and presence of cholesterol. In membranes without cholesterol, Aβ(1-42) intercalated into the phosphate headgroup/glycerol backbone region, 11-28Å from the center of the bilayer, and increased the molecular volume of the hydrocarbon core, 0-10Å from the center of the membrane. These membrane samples had a hydrocarbon core width of 40Å and unit cell periodicity of 56Å. In contrast, membranes prepared with physiological cholesterol levels (30mol%) showed a broad and concentration-dependent increase in electron density 0-12Å from the bilayer center following the addition of Aβ(1-42). The overall membrane hydrocarbon core width and unit cell periodicity were 42Å and 58Å, respectively. These data indicate that in the presence of cholesterol, Aβ(1-42) partitions to a discrete location deep in the membrane hydrocarbon core. The strong membrane interactions of Aβ may underlie changes in the activity of various membrane proteins, including ion channels, enzymes and signal transduction proteins involved in neuronal calcium homeostasis.

SELECTIVE BINDING OF CHOLESTEROL AND FATTY ACIDS TO AMYLOID β_{1-40} PEPTIDE AGGREGATES : A FLUORESCENT STUDY.

N.A.Avdulov, S.V.Chochina, U.Igbavboa, A.V.Vassiliev, G.J.Maletta* & W.G. Wood. Geriatric Research, Education and Clinical Center, VA Medical Center, and Dept. Pharmacology, Univ. Minnesota School of Medicine, Minneapolis, MN 55417.

Aggregation of amyloid β-peptides (Aβ) is neurotoxic to cells and is thought to be involved in brain dysfunction seen in Alzheimer's disease (AD). However it is not understood how the aggregates are formed and how those aggregates influence the membrane, particularly membrane lipid structure. Platelets of AD patients were reported to be more fluid, than control membranes, and the cholesterol/phospholipid ratio was reduced by 30% in brain membranes of AD patients. Aggregated Aβ may disrupt membrane lipid homeostasis by binding cholesterol and/or other lipids. This hypothesis was tested in the present study using fluorescent labeled lipids and $A\beta_{1-40}$. Our data show that $A\beta_{1-40}$ aggregates of approximately 10 molecules of $A\beta_{1-40}$, as measured by SDS-gel electrophoresis, can bind fluorescent labeled cholesterol and the saturated fatty acids, stearic acid and hexadecanoic acid in nM concentrations. Binding was not observed for unsaturated fatty acids and phosphatidylcholine. These findings illustrate a potential mechanism of neuronal damage in AD. Aβ aggregates may bind cholesterol and saturated fatty acids in neuronal membranes or disrupt lipid transport. Changes in lipid homeostasis induced by aggregated Aβ may result in neuronal dysfunction. Supported by AG 11056 and Dept. of Veterans Affairs.

EFFECTS OF ß-AMYLOID PEPTIDES ON MEMBRANE FLUIDITY IN ALZHEIMER'S DISEASE

W.E. Müller[1*], G.P. Eckert[1], K. Scheuer[1], A. Maras[2], W.F. Gattaz[2], N. Cairns[3] and H. Förstl[1]. Depts. of [1]Psychopharmacology & [2]Psychiatry, Centr. Inst. Mental Health, 68159 Mannheim, Germany and [3]MRC Alzheimer's Disease Bank, Institute of Psychiatry, London, UK.

The primary constituent of senile plaques, the insoluble form of ß-Amyloid protein (ßA4), has been associated with neurodegeneration and cortical atrophy in Alzheimer's disease (AD) brain. There are evidences that the interaction of ßA4 with neuronal membranes contributes to its neurotoxicity. The hypothesis that ßA4 causes alterations of membrane integrity is supported by previous findings from our laboratory indicating that rather low concentrations of biologically active ßA4-fragments significantly decreases the fluidity of neuronal membranes from the mouse and rat brain. Brain samples of parietal and frontal cortex were obtained from patients with neuropathologically confirmed AD and non-demented controls. Samples were incubated with different aggregated ßA4-fragments. Membrane fluidity was measured using the fluorescent dyes DPH and TMA-DPH. The addition of different peptide sequences of ßA4 to human brain membranes enhanced the fluorescence anisotropy of membrane bound fluorescent dye, which is inversely correlated with membrane fluidity, in a concentration depend manner. Fluidity changes were different for the individual peptides and were mostly pronounced for $ßA_{1-42}$ and $ßA_{1-43}$. Incubation of brain membranes from AD patients and non-demented controls with ßA4-fragments showed no difference in the concentration-depend increase of anisotropy. The effects of ßA4-fragments on membrane fluidity, probably caused by disrupting membrane structure, could be responsible for the direct neurotoxic properties of the protein. Our results suggest that during AD neuronal membranes are susceptible to ßA4 as in normal aging.

MECHANISM OF ASSOCIATION OF NON-TRANSMEMBRANE FULL-LENGTH AMYLOID PRECURSOR PROTEIN (APP) WITH CHROMAFFIN GRANULE MEMBRANES.

N.Tezapsidis*, H.-C.Li[1], J.A.Ripellino, S.Efthimiopoulos, D.Vassilacopoulou, K.Sambamurti, V.Y.H.Hook[3], & N.K.Robakis. Departments of Psychiatry & Biochemistry[1], Mt. Sinai School of Medicine, New York, NY 10029 and Medicine[3], UCSD, San Diego, CA 92103.

Recently, we detected a soluble form of full-length APP in the lumen of chromaffin granules (CGs). Furthermore, it was observed that a fraction of the membrane-bound full-length APP is released from the membranes at pH 9.0 by an enzymatic mechanism, sensitive to protease inhibitors [Vassilacopoulou et al., (1995) *J. Neurochem. 64*, 2140-2146]. Previously, we have shown that this population of APP could not be labeled by 3-(trifluoromethyl)-3-(m-^{125}I-iodophenyl) diazirine (^{125}I-TID). In this study we show that this released APP could not be labeled by N-hydroxysuccinimide-S-S-biotin (NHS-SS-biotin) when intact CGs were used, in contrast to transmembrane APP which could readily be labeled by the probe. Both experiments suggested that the solubilized APP did not derive directly from a transmembrane APP. Chemical cross-linking of CG lysates with dithiobis (succinimidylpropionate) (DSP) revealed that APP forms complexes with itself in the membranes..Furthermore, high molecular weight APP-complexes could be detected in CGs under non-reducing conditions and release of full-length APP from CG membranes was facilitated by reducing agents in a dose-dependent manner. Consistent with the data obtained is a model, according to which non-transmembrane APP exists as a complex with transmembrane APP held together with disulfide bridge(s). Therefore the mechanism of release of full-length APP from membranes could involve both an enzymatic activity, sensitive to protease inhibitors and a reduction of disulfide bridges between two APPs, each acting independently or in concert. O-LINKED N-ACETYLGLUCOSAMINE IN THE NERVOUS SYSTEM - AN ALTERNATIVE TO PHOSPHORYLATION? Brigitte Schmitz* and Lee S. Griffith, Dep. of Biochemistry, Inst. of Animal Anatomy and Physiology, Univ. of Bonn, 53115 Bonn, Germany.

It has been suggested that the novel intracellular carbohydrate N-acetylglucosamine O-glycosidically linked to serine or threonine residues (O-GlcNAc) may function in signal transduction analogous to phosphorylation (1). This carbohydrate is often found on proteins in a $S/TX_{(0-2)}P$ motif, which is the same motif recognized by proline directed kinases.

In order to investigate the possibility that O-GlcNAc may be an alternative to phosphorylation, we treated murine cerebellar neurons with a number of pharmacological agents that affect kinase or phosphatase activities. Because of our earlier results showing incorporation of O-GlcNAc into membrane associated Amyloid Precursor Protein (APP) and the increase of O-GlcNAc expression in the cytoskeletal fraction of Alzheimer brain (2,3), we determined the level of incorporation of O-GlcNAc into the total cell homogenate, the detergent soluble and the detergent insoluble cytoskeletal fraction.

We here show that perturbation of protein kinase and phosphatase activities has profound effects upon the levels of O-GlcNAc in the detergent insoluble cytoskeletal fraction indicating a cross talk between O-GlcNAc and the phosphorylation signalling mechanisms. Taken in context with our earlier work on APP and Alzheimer brain our results point to a possible involvement of O-GlcNAc in aberrant signal transduction mechanisms assumed to play a role in the pathology and development of Alzheimer disease.

HIPPOCAMPAL β -AMYLOID INDUCES POST-DELAY ERRORS IN AN EIGHT ARM RADIAL MAZE, W. A. Sweeney*, J. Luedtke, M. McDonald, and J. B. Overmier, University of Minnesota, Minneapolis, MN 55455.

One of the most prominent symptoms of Alzheimer's disease is the gradual and progressive loss of short term memory. Correlated with this memorial degeneration is the accumulation of large amyloid plaques in the hippocampus and other areas involved in memory processing. The primary make-up of the plaque's core is the β-amyloid (β A4) peptide. It has been suggested that βA4 is neurotoxic and plays a causative role in the memory degeneration seen in Alzheimer's patients. The current study was designed to test the effects of bilateral intrahippocampal (IH) injections of βA4 on performance in a radial arm maze task with a delay imposed following the fourth choice. Eight Sprague-Dawley rats were injected (IH) with either βA4 (2 μl) or vehicle (HPLC buffer) immediately prior to testing in the maze. While βA4 did not impair performance on the first four choices, it did significantly increase the number of errors immediately post-delay. These results suggest that contrary to previous findings, βA4 does appear to have acute toxic effects. Thus, based on the results presented here it seems logical to suggest that βA4 plays a significant role in the etiology of the memory deficits seen in Alzheimer's disease.

This research was funded through NIDA training grant 2 T32 DA07097-16A1.

β-AMYLOID PROTEIN INDUCES HUMAN GABAERGIC NEURONAL DAMAGE. S. Hu*, P. K. Peterson and C. C. Chao. Minneapolis Med. Res. Fdn and the Univ. Minn. Med. Sch., Minneapolis, MN 55404

Deposition of β-amyloid plaque in association with neurodegeneration is the histopathological hallmark of Alzheimer's disease (AD). Using highly enriched (>95%) human fetal neuronal cell cultures, we investigated the potential injury by β-amyloid protein to neurons which produce the inhibitory neurotransmitter, γ-amino butyric acid (GABA). Treatment of primary human cerebrocortical neurons with β-amyloid$_{1-40}$ (100 μg/ml) for 3 to 5 days induced marked neuronal injury (642±48 neurons/5 fields and 6.42±1.24 U/L LDH in control cultures vs 214±38 neurons/5 fields and 11.43±2.64 U/L LDH in the β-amyloid-treated group, $P<0.01$). β-amyloid protein-induced neuronal injury was dose-dependent. Treatment of neuronal cultures with the N-methyl-D-aspartate receptor antagonist 2APV reduced β-amyloid protein-induced neuronal injury by only 20%, suggesting minimal involvement of NMDA receptors. Using antibodies specific to GABA, we found that the highly enriched neuronal cell cultures were comprised of approximately 30% GABAergic neurons. Treatment of neuronal cultures with β-amyloid protein induced a significant reduction in the number of GABAergic neurons (143±18 in control cultures vs 62±12 in the β-amyloid-treated group, $P<0.01$) as well as a marked attenuation of neuronal processes. β-amyloid protein also induced apoptosis in a large portion of injured neurons as reflected by TUNEL staining, and the β-amyloid protein-induced loss of GABAergic neurons was largely via an apoptotic pathway. These findings suggest that exposure of human neurons to β-amyloid protein could result in an apoptotic injury to GABAergic neurons and that strategies aimed at rescuing GABAergic neuronal death could provide a new therapeutic approach for AD. EFFECTS OF β-AMYLOID (1-40) DEPOSITION IN THE NUCLEUS BASALIS OF RATS ON CHOLINERGIC AND GABAergic SYSTEMS.
L.Giovannelli, F.Casamenti, C. Prosperi, MA. Colivichi, L.Bianchi and G.Pepeu*. Department of Pharmacology, University of Florence, Viale Morgagni 65, 50134 Florence, Italy.

Deposits of β-amyloid peptides (Aβ) in senile plaques are a molecular hallmark of Alzheimer's disease. *In vivo* injection of aggregated Aβ 1-40 peptide in the rat forebrain induces cholinergic hypofunction and some cognitive deficits. In the present study we have investigated the effects of 10 μg of Aβ 1-40 peptide injection into the right nucleus basalis (NB) of adult rats on cholinergic and GABAergic neurons up to 6 months post surgery. Four months post injection the peptide deposit exhibited Congo Red birefringency, whereas at 6 months the deposit, although still present at the injection site, had lost the fibril organization since almost no trace of birefringency could be detected. Extracellular acetylcholine levels in the cortex and the number of choline acetyltransferase-immunoreactive (ChAT-IR) neurons in the injected NB were reduced up to 4 months post surgery, whereas a complete recovery was observed at 6 months, concomitantly with the loss of fibril conformation. On the contrary, at 3 weeks as well as at 6 months post injection, extracellular GABA levels in the cortex ipsilateral to the injected NB were increased by more than 100 percent, as compared to saline injected rats. Quisqualic acid lesions of the NB induced in the ipsilateral cortex a prominent decrease in ACh levels without affecting GABA levels, indicating that the peptide-induced increase of extracellular GABA levels is not a consequence of cholinergic hypofunction. Our results provide evidence that Aβ cholinotoxicity is related to the fibrillary conformation of the deposit. Whether the increase of extracellular GABA levels in the cortex is due to a direct action on GABAergic forebrain neurons needs to be investigated. (Grant from University of Florence)

NEUROTOXICITY OF A CARBOXYL-TERMINAL FRAGMENT OF THE ALZHEIMER'S AMYLOID PRECURSOR PROTEIN. Seong-Hun Kim[1]*, Jong Inn Woo[2] and Yoo-Hun Suh, Department of Pharmacology and Dept. Physiatry College of Medicine and Department of Molecular Biology, Neuroscience Research Institute, Seoul National University

We have previously shown that a recombinant carboxyl-terminal 105 amino acid fragment(CT105) of the amyloid precursor protein induced strong nonselective inward currents in Xenopus oocytes. Here we investigated the toxic effect of CT105 peptide on the cultured mammalian cells. The CT105 peptide induced a significant LDH release from cultured rat cortical neurons and PC12 cells in a concentration(from 10 mM) and time(from 48 h) dependent manner. The toxic effect of CT105 was more potent than any fragments of amyloid beta protein(Ab). However the CT105 did not affect the viability of U251, human glioblastoma cells. In contrast to CT105, Ab increased LDH release only slightly even at 50mM but significantly inhibited MTT reduction at submicromolar concentration. Among the various neuroprotective drugs tested, only cholesterol which alters the membrane fluidity could attenuate the cytotoxicity of CT105 significantly. The CT105 peptide formed multiple self-aggregates upon solubilization. Endogenous CT peptides were found not only in the cell lysates but also in the conditioned media of PC12 cells. These results imply that CT peptide can directly attack the cell membrane probably by making pores or nonselective ion channels while Ab impairs intracellular metabolic pathway first. Oxidative stress induces dephosphorylation of tau in rat brain primary neuronal cultures. [1]D.R.Davis, [1]B.H.Anderton, [3]J-P.Brion, [2]P.N.Leigh*, [1]C.H.Reynolds and [1]D.P.Hanger, Depts of [1] Neuroscience and [2] Neurology, Institute of Psychiatry, DeCrespigny Park, Denmark Hill, London, SE5 8AF and [3]Universite Libre de Brussels, Faculte de Medicine, 808 Route de Lennik, Bldg C-10. B-1070 Bruxelles, Belgium.

Oxidative stress and free radical damage have been implicated in the neurodegenerative changes characteristic of several neurodegenerative disorders, including Alzheimer's disease. Two pathological hallmarks are evident in Alzheimer brain tissue: the neuritic plaque that displays a β-amyloid core; and neurofibrillary tangles that consist of bundles of paired helical filaments (PHF) of which the microtubule-associated protein tau is a major constituent. There is experimental evidence that β-amyloid exerts its neurotoxic effects via generation of free radicals and since the deposition of β-amyloid precedes the formation of PHF in Alzheimer's disease, we have investigated the effect of subjecting primary neuronal cultures to oxidative stress on the phosphorylation state of tau protein. We show biochemical data in the form of western blot and immunocytochemical analysis that treatment of cortical neurones in primary culture with hydrogen peroxide induces a dephosphorylation of tau contrary to the hyperphosphorylation that is associated with PHF formation. We conclude that oxidative stress is not the direct cause of tau hyperphosphorylation and hence PHF formation in Alzheimer's disease.

INCREASED RELEASE OF NITRIC OXIDE IN SENESCENT CELLS: IMPLICATIONS FOR ALZHEIMER'S DISEASE. C. Ghosh* and D. K. Lahiri. Laboratory of Molecular Neurogenetics, Institute of Psychiatric Research, Dept. of Psychiatry, Indiana Univ. School of Medicine, Indianapolis, IN-46202.

Nitric oxide (NO) is an unstable radical produced during the oxidative deamination catalyzed by NO synthase which converts L-arginine to L-citrulline. In the CNS, NO acts as a neural messenger involved in key physiological events such as neurotransmitter release. Here we investigated the effect of NO release on metabolism of Alzheimer's beta-amyloid precursor protein (ßAPP) in cell lines.

The basal level of nitric oxide as measured by our assay system was undetected in all cell lines tested. When cultured cells of different origin were induced with NO donor such as sodium nitroprusside (SNP), a significant level of NO was detected in a time and dose-dependent manner. As compared to the conditioned medium, level of NO could not be detected in intracellular lysates of different cell types. Two groups of cells were observed: one with high level of NO release (such as astrocytic cells), and the other with low level of NO release (neuronal cells). The latter group of cells were more sensitive to NO-mediated damage. Results from the assay of lactate dehydrogenase release in different samples indicate that increased NO release could damage the integrity of the cell.

When level of NO release was compared between senescent and actively growing neuronal cells, a greater level of NO was released from the senescent cells than from regular neuronal cells. When level of ßAPP was measured in the conditioned medium of SNP-induced cells, normal level of secretion of ßAPP was decreased when there was a significantly high level of NO release. Taken together, these data suggest that a high NO release with a concomitant decrease of secretion of ßAPP in the medium makes cells more vulnerable to injury. Our use of senescent cells (because of greater NO release) may be a relevant model system to study either NO-mediated or free-radical mediated neuronal damage as observed in Alzheimer's disease. This work was supported by the NIH-R01 grant (DKL).

THE INVOLVEMENT OF NITRIC OXIDE IN β-AMYLOID PEPTIDE-INDUCED NEUROTOXICITY. S.-N. Yang*, W.-Y Hsieh, J.-N. Wu., C.-S Tung. Department of Physiology and Biophysics, National Defense Medical Center, Taipei, Taiwan, ROC

β-amyloid peptide (βAP), a 40-42-amino acid peptide, is an important constituent of senile plaques found in the brains of individuals with Alzheimer's disease (AD). βAP can not only destabilize intracellular Ca^{2+} homeostasis and thus enhance excitatory amino acid-induced excitotoxicity, but also can develop neurodegeneration in cultured cortical neurons showing morphological and biochemical features of apoptosis. Furthermore, nitric oxide (NO) produced by the constitutive synthase has been implicated in mediating excitotoxic neuronal death. Due to the dependence between cNOS and Ca^{2+}/calmodulin activity that could be activated by βAP-induced intracellular increase of Ca^{2+}, the major goal of the present study was therefore to determine whether nitric oxide is involved in βAP-induced neurotoxicity. βAP-induced neurotoxicity of mixed cortical cultures of SD rat pups is assessed via morphological analysis using phase-contrast microscopy (neuronal apoptosis), LDH activity of culture medium. NO production was measured of nitrite (Greiss reagent methods). Following a 48-h exposure of 1, 10, 25, and 50 μM of $\beta AP_{25\text{-}35}$, the LDH (n=4) and NO (n=3) activity was 103.2±2.4% and 99.6±18.8%, 125.1±7.7% and 98.9±4.8%, 130.9±4.1% and 176.7±19.0%, and 151.6±7.3% and 243.3±44.5% (compared with the control value of sister wells), respectively. In morphological analysis, neurons exposured to the $\beta AP_{25\text{-}35}$ treatment showed significant dystrophic neurites in both 25 and 50 μM of $\beta AP_{25\text{-}35}$. More importantly, there is a significant correlation (r =0.9) between the LDH activity and NO production following the $\beta AP_{25\text{-}35}$ treatment. Thus, these results suggest that NO may play a role in βAP-induced neurotoxicity. [NSC Grant # 85-2331-B-016-074-M04]

MEDIATORS OF β-AMYLOID INDUCED TOXICITY IN RAT HIPPOCAMPAL PYRAMIDAL NEURONAL CULTURES. M F. Galindo*[1], J Jordán[1], J.M. Leiden[2], and R J. Miller[1]. Departments of [1]Pharmacological and Physiological Sciences, [2]Medicine Univ. of Chicago, Chicago, IL. 60637.

We investigated the impact of possible down-stream modulators of β-amyloid (Aβ) induced death of hippocampal pyramidal neurons in culture. Neuronal death under these conditions proceeds via apoptotic mechanisms. We investigated the potential role of different proteases in the death of hippocampal neurons produced by Aβ (25-35), staurosporine and NMDA. The peptide inhibitor of interleukin converting enzyme (ICE) and related proteases, Ac-YVAD-CMK and MDL28170, an inhibitor of the Ca regulated protease calpain 1, inhibited neuronal death produced by all 3 agents, whereas leupeptin was only effective in preventing NMDA induced death. Aβ(25-35) produced a 30.4% increase in the appearance of the 150 kDa calpain breakdown product of spectrin 7 hours after addition of the peptide. This increase was completely prevented by MDL 28170 but not by AcYVAD-CMK, thereby placing the Ca sensitive step upstream of ICE. Thus, our studies indicate that a Ca activated protease plays a key role in neuronal death in this case. This is consistent with our previous report that Aβ(25-35) induced apoptosis could be blocked by the overexpression of the Ca binding protein calbindin D28K (Prehn et al. *Molec Pharmacol* 1996).

Overexpression of a constitutively active non-phosphorylatable form of the retinoblastoma gene product, using an adenoviral vector, failed to protect the cultures against Aβ(25-35) or staurosporine induced toxicity, although it was effective in blocking irradiation induced death of hippocampal neurons (J.Jordán et al., in this meeting).

ORGANOTYPIC MOUSE HIPPOCAMPAL SLICE CULTURE REVEALS DIFFERENTIAL SENSITIVITY TO Aß PEPTIDES M.P. Lambert[1], C. Zhang[1]*, W.L. Klein[1], G.A. Krafft[1], P. Wals[2], I. Rozovsky[2], T. E. Morgan[2], C. E. Finch[2] [1] Dept. of Neurobiol. & Physiol., Northwestern Univ., Evanston, Il 60208, [2]Andrus Gerontology Ctr., Dept. of Biol. Sci., Univ. of S. Calif., Los Angeles, CA 90089

Amyloid ß proteins in their aggregated state induce disadhesion and death in cultured cells (Lambert, et al. 1994, J. Neurosci. Res. 39:377). To generate a better model for the complex interactions leading to these responses in the brain and to determine if specific neurons respond preferentially to Aß peptides, hippocampal brain slice cultures were established using a method pioneered by Stoppini, et al. (1991, J. Neurosci. Meth. 37:173) which was adapted for mouse slices. The mouse model was used to take advantage of transgenic mice strains in which the selective change in signal transduction associated with protein tyrosine phosphorylation seen previously with Aß peptides (Zhang, et al., J. Bio. Chem. 1994, 269:25247) may be altered. Hippocampal slice cultures from control animals were prepared and incubated with Apo J/Aß toxic supernatant (Oda, et al. 1995, Exp. Neurol. 136:22) for various times. Cell viability was determined *in situ* using the fluorescent Live/Dead assay from Molecular Probes. After 24 hours exposure, extensive cell death was seen in the granule cell layer of the dentate gyrus. Other areas, notably CA3 pyramidal and some hilar neurons, also had regions of dead cells, although not as extensive as in the dentate gyrus. Exposure to Apo J alone did not cause increased cell death. Animals as young as P23 or as old as P69 responded with area-specific cell death. Using this culture model with a fyn (-) mouse (Jackson Labs), preliminary data suggest that the toxic Apo J/Aß supernatant kills dentate gyrus cells via a fyn-dependent pathway. The current model approximates a more physiological system in which complex interactions caused by acute or chronic exposure to Aß can be dissected. ALTERED GENE EXPRESSION DURING NEURONAL DEATH INDUCED BY AMYLOID ß-PROTEIN TREATMENT. S. Estus#*, C. van Rooyen#, H.M. Tucker#, S. Wright§, E.F. Brigham§, and R.E. Rydel§. Dept. of Physiology#, Sanders-Brown Center, University of Kentucky, Lexington, KY 40536, and Athena Neurosciences, Inc.§, South San Francisco, CA 94080.

To gain clarity into the neurotoxic actions of amyloid ß-protein (Aß), we are analyzing Aß effects on gene expression in fetal rat cortical neuron preparations maintained *in vitro*. Neurons dying after Aß-treatment manifest hallmarks of apoptosis. By using quantitative RT-PCR, as well as *in situ* hybridization, we are evaluating temporal changes in the expression of several gene classes. First, the majority of mRNAs, including those encoding neuronal "markers", decline during Aß treatment. Second, immediate early and cell cycle-related genes, e.g., *c-jun*, *c-fos*, and *cyclin D1*, induced in a developmentally-appropriate model of neuronal apoptosis, i.e., NGF-deprived sympathetic neurons, are increased similarly in Aß-treated neurons. Third, *ngfi-b*, increased in models other than the sympathetic neuron model, is induced by Aß-treatment. Fourth, a broad group of genes associated with oxidative stress, some of which encode proteins relevant to Alzheimers disease (AD) neuropathology, e.g., *mcp-1*, or that are induced in AD, e.g., *heme oxygenase-1* and *hsp-27*, are induced by Aß-treatment, suggesting this model is relevant to events in AD. Current work focuses on assessing the cells of origin of the oxidative stress response. In summary, these results contrast changes in gene expression during physiologically appropriate and inappropriate neuronal apoptosis and may be of predictive value in identifying altered gene expression that underlies AD neuropathology. Supported in part by NIA grant T32AG00242 and by a pilot grant from the Alzheimers Association.

VULNERABILITY OF LYMPHOCYTES AGAINST PROGRAMMED CELL DEATH IN ALZHEIMER'S DISEASE. A. Eckert*, C.W. Cotman#, R. Zerfass, M. Hennerici§ and W.E. Müller. Centr. Inst. Mental Health and §Dept. Neurology, Med. Fac. Univ. of Heidelberg, 68159 Mannheim, Germany; #Inst. Brain Aging and Dementia, Univ. of California, Irvine, CA 92717.

Recent evidence indicates that programmed cell death (apoptosis) may contribute to neuronal death in Alzheimer's disease (AD). *In situ* data derived from post mortem brain tissue indicate that DNA fragmentation which represents an important and typical apoptotic feature is markedly increased in brain cells of AD patients compared to controls. Furthermore, *in vitro* studies demonstrate that the peptide β-amyloid (Aß) and its fragments induce apoptosis in neuronal cell cultures. One possible mechanism initiating apoptosis could be free radical generation by the peptide leading to oxidative stress. In a wide range of cell types common morphological and molecular events occur during apoptosis and several genes appear to be involved. Particularly in lymphocytes, apoptosis plays an important physiological role. Recently, we could demonstrate that Aß (Aß1-42) induces apoptosis in mature human lymphocytes. Thereby, Aß1-42 exhibited about a four fold stronger efficacy than Aß25-35 at equal concentrations confirming findings in neuronal cells as well as in cerebrovascular smooth muscle cells. In addition, oxidative stress induced apoptosis in peripheral lymphoctes. The experiments demonstrated that the same agents can initiate programmed cell death in mature human lymphocytes as well as in neurons. Therefore, the lymphocyte provides a powerful model to investigate ongoing mechnisms in apoptosis in man and especially during disease. Susceptibility to apoptosis of lymphocytes from AD patients, from patients with vascular dementia, and from non-demented controls is currently under investigation treating lymphocytes with several agents (Aß, oxidative stress, serum deprivation). Nuclear DNA fragmentation and morphological apoptotic features are detected by quantitative sandwich enzyme immunoassay, *in situ* end labeling, and by fluorescent dyes. 4-HYDROXYNONENAL MEDIATES AMYLOID β-PEPTIDE INDUCED LOSS OF ION HOMEOSTASIS AND NEURONAL DEATH. R. J. Mark*, M. A. Lovell, W. R. Markesbery and M. P. Mattson. Sanders-Brown Center on Aging, Dept. of Anatomy & Neurobiology, and Dept. of Neurology, Univ. of KY, Lexington, KY 40536.

Oxidative injury to neurons in brain regions involved in learning and memory processes, such as the hippocampus, is believed to play a major role in the pathogenesis of Alzheimer's disease (AD). Peroxidation of membrane lipids results in release of the aldehyde 4-hydroxynonenal (HNE). Studies of non-neuronal cells indicated that HNE contributes to membrane damage and cell death induced by a variety of oxidative insults. Since amyloid β-peptide (Aβ) can promote free radical production, we tested the hypothesis that HNE mediates Aβ-induced disruption of neuronal ion homeostasis and cell death. HNE impaired plasma membrane ion-motive ATPase activites, destabilized calcium homeostasis; impaired glucose uptake, and increased vulnerability of neurons to excitotoxicity. Aβ induced large increases of free and protein-bound HNE in hippocampal cells. Antioxidants protected neurons against Aβ toxicity, but were less effective in protecting against HNE toxicity. Glutathione was very effective at attenuating both Aβ and HNE- induced neurotoxicity. Collectively, the data indicate that HNE mediates Aβ-induced oxidative damage to neuronal membrane proteins which, in turn leads to disruption of ion homeostasis and cell degeneration. (supported by the NIH and the Alzheimer's Association).

827.14

AMYLOID β-PEPTIDE AND LPA DISRUPT CALCIUM HOMEOSTASIS, AND INDUCE OXYRADICAL PRODUCTION AND MITOCHONDRIAL DYSFUNCTION IN SYNAPSES. J. Keller*, S. Steiner, and M. P. Mattson. Sanders-Brown Center on Aging, Dept. of Anatomy & Neurobiology, Dept. of Biological Sciences, University of Kentucky, Lexington, KY 40536.

Impairment of synaptic transmission and degeneration of synapses may be early events in the pathogenesis of many neurodegenerative conditions including Alzheimer's disease (AD) and ischemic brain injury. In both of these disorders there is considerable evidence that oxidative stress and disruption of cellular ion homeostasis contribute to cell injury and death. However, the evidence has accrued almost entirely from studies of the neuronal cell body and neurites, and very little is known about reactions of synapses to environmental alterations that occur in Alzheimer's disease and stroke. Here we report on studies of rat neocortical synaptosomes in which we show that the Alzheimer's amyloid β-peptide (Aβ) and lysophosphatidic acid (LPA), a compound released from membranes in cells exposed to ischemic and excitotoxic insults, induce: lipid peroxidation (LP); elevation of cytoplasmic free calcium levels ($[Ca^{2+}]_i$); and impairment of mitochondrial function (decreased MTT reduction). In addition, Aβ and LPA caused a decrease in uptake of radiolabeled glutamate in the synaptosomes. Each of these alterations occurred within 1-4 hr of exposure to Aβ and LPA. p

The effects of Aβ and LPA on $[Ca^{2+}]_i$, LP, MTT reduction, and glutamate uptake appear to be synergistic. We are currently determining the time courses of each alteration, and we are employing a battery of pharmacological agents in order to elucidate the specific mechanisms whereby Aβ and LPA disrupt Ca^{2+} homeostasis, free radical metabolism, and mitochondrial function. ARE REACTIVE OXYGEN SPECIES INVOLVED IN MUTANT AMYLOID PRECURSOR PROTEIN INDUCED APOPTOSIS IN PC12 CELLS B. Zhao(1)*, C. A. Sherman(1), J. Rifkind(2), C. Balagopalkrishna(2), S. S. Sisodia(3), and J. W. Kusiak(1). LBC(1), LCMB(2), GRC/NIA/NIH, Baltimore, MD 21224, Department of Pathology, Johns Hopkins University, Baltimore, MD 21205(3).

We previously reported increased apoptosis in mutant amyloid precursor protein (APP) transfected PC12 cells. The present studies investigated possible molecular and cellular mechanism(s) for this cell death. When antioxidants Vitamin E (100μg), N-acetylcysteine (1mM), butyl-phenylnitrone (50μM) and diphenylene iodonium (0.1μM) were added to mutant cell lines prior to, but not after, the initiation of apoptosis, DNA laddering was inhibited in APPA692G transfected cells. Reactive oxygen species were rapidly produced in NGF/cAMP treated cells when measured by EPR spin trapping technique. Hydroxyl radical was detected predominantly in APPV717F transfected cells. Both hydroxyl and carbon-centered radicals were produced in APPA692G transfected cells, which shares a similar pattern with wild-type APP transfected cells. Preliminary data showed a decrease in total phosphotyrosine proteins in mutant APP transfected cells. These data suggest that expression of mutant APPs may result in an imbalance between the generation of reactive oxygen species and antioxidant defenses. The rapid production of reactive oxygen species may serve as an early signal, rather than toxic agent, possibly through a tyrosine phosphorylation pathway to activate apoptosis in the system, which may contribute to the cell death seen in Alzheimer's disease. (Supported by NIH and Aluminum Association)

TUMOR NECROSIS FACTORα (TNFα) MEDIATES β-AMYLOID INDUCED TOXICITY THROUGH INTERLEUKIN -1β-CONVERTING ENZYME (ICE) PATHWAY.

A. Resink[1]*, V.L. Dawson[1-3], T.M. Dawson[1,2], Department of Neurology[1], Neuroscience[2] and Physiology[3], Johns Hopkins University School of Medicine, Baltimore, MD 21287.

Alzheimer's disease (AD) is characterized by progressive neurodegeneration. A pathological feature of AD brains is the presence of senile plaques containing abnormally metabolized β-amyloid. Activated astrocytes and microglia surround β-amyloid plaques and release pro-inflammatory cytokines including interleukin-1 and -6 and tumor necrosis factor-α (TNFα). Thus, neuro-cytokine interactions may play a role in the pathology of AD. Since TNFα induces cell death in many cell systems through multiple pathways, we investigated the role of TNFα and its downstream targets in β-amyloid induced toxicity in primary mixed cortical cultures.

Our pharmacological studies indicate a clear involvement of TNFα in β-amyloid neurotoxicity. TNFα mediates toxicity through the activation of ICE and/or ICE-like proteases. Furthermore, inhibition of cyclooxygenase prevents β-amyloid neurotoxicity. Inhibition of neuro-cytokine interactions including blockade of TNFα dependent cell death pathways may have therapeutical effects in AD.

NF-κB May Mediate Both Aβ (1-40) Induced Neurotoxicity and Glial Activation. K.R. Bales*[1], R. Dodel[1], G-M. Yan[1,2], E.Hamilton-Byrd[1], X. Wu[1], and S.M. Paul[1,2] [1]Division of CNS Research, Eli Lilly & Co., Indianapolis, IN and [2]Departments of Pharmacology, Toxicology, and Psychiatry, Indiana University School of Medicine, Indianapolis, IN 46285.

The amyloid β peptide (Aβ) is deposited in both diffuse and neuritic plaques which are characteristic of Alzheimer's disease (AD). Prominent neurodegeneration occurs around these plaques leading to the hypothesis that Aβ may play a causative role in disease pathogenesis. The Aβ peptide is also a well known neurotoxin, however neither the cellular nor molecular mechanisms underlying Aβ-induced neurotoxicity are known. We have recently identified the nuclear transcription factor NF-κB as playing a pivotal role in the vulnerability of cultured cerebellar granule neurons to apoptose in response to bilirubin, and surmised that NF-κB may play a similar role in Aβ-induced neurotoxicity. Surprisingly, the constitutively activated NF-κB levels present in rat fetal cortical neurons decrease in a time- and concentration-dependent fashion following exposure to Aβ (25 μM). No corresponding decrease in NF-κB message or protein (p65) occurs, suggesting that the reduced levels of activated NF-κB seen by gel shift analysis may be the result of regulation of the inducible form. Additionally, we found an upregulation of IκB-α, one of the proteins responsible for retaining NF-κB in the cytoplasm, may be responsible for the observed decrease in activated NF-κB in cultured cortical neurons following Aβ exposure. By contrast, in rat primary astroglial cultures exposure to Aβ activates NF-κB in a time- and concentration-dependent fashion. In preliminary experiments, pretreatment of astroglia with DNA decoys to the NF-κB consensus sequence resulted in attenuation of activated NF-κB following Aβ exposure. We postulate that the Aβ-induced decrease in constitutively active NF-κB mediates Aβ-induced neurotoxicity, presumably via a decrease in the transcription of NF-κB target genes. However, in astroglia Aβ exposure activates NF-κB and target genes containing the NF-κB consensus sequence which are associated with the inflammatory response.

CELL SURFACE GLYCOSAMINOGLYCANS MAY MEDIATE Aβ–INDUCED TOXICITY OF CULTURED RAT NEURONS

R. P. Irwin*[1,2], G. M. Yan[1,4], S. Z. Lin[1], Y. Du[4], K. Fuson[4], P. C. May[4] and S. M. Paul[1,3,4] [1]Departments of Pharmacology and Toxicology, [2]Medicine, [3]Psychiatry, Indiana University School of Medicine, Indianapolis, IN 46202; [4]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285

Beta-amyloid peptide (Aβ) has been postulated to induce the neurodegenerative and inflammatory changes seen Alzheimer's disease (AD), and has been shown *in vitro* to be directly toxic to several types of neurons. However, the mechanisms by which Aβ–induces neurotoxicity are not fully understood. We have found that the exogenous glycosaminoglycans (GAGs), heparin and heparan sulfate block Aβ–induced neurotoxicity in primary cultures of rat cerebral cortical and hippocampal neurons. Small molecular weight heparins and chondroitin sulfate were without effect. Pretreatment of these neurons with heparinase, to remove membrane-bound heparin, resulted in a robust protection of Aβ–induced neurotoxicity, but failed to alter the toxicity induced by glutamate. We have confirmed the reduction of membrane–bound heparin by heparinase using the fluorescent heparin stain berberine. Heparinase was also able to block the Aβ–induced rise of intracellular hydrogen peroxide (H_2O_2) in cortical neurons. The rise in H_2O_2 was also blocked in neurons where heparinase was washed out before the addition Aβ. Our data suggests that heparin and heparan sulfate-containing GAGs present on the cell surface of neurons may mediate Aβ toxicity by functioning as Aβ "receptor" or "docking" molecules.

THE ROLE OF LYSOSOMES IN Aß MEDIATED NEUROTOXICITY. A. J. Yang*, D. Chandswangbhuvana, T. Shu and C. G. Glabe. Dept. of Mol. Bio. and Biochem., Univ. of Calif. Irvine, Irvine, Ca 92717

Biochemical studies of Aß indicate that it is organized as an axially amphipathic, detergent-like structure in solution. We have proposed that Aß may act as a lysosomotropic detergent, a class of self-assembling amphipathic molecules that accumulates inside the lysosomes and ultimately results in the dysfunction of lysosomes and cell death. To test this hypothesis, cultured cells were incubated with different length Aß peptides at various concentrations for 6-16 hours. Soluble cell extracts were then prepared and the activity of several lysosomal enzymes were measured. Lysosomal enzyme activities were increased 2-10 fold only in cells that had been treated with Aß1-42. The increase in hydrolase activity is specific for Aß1-42 which is resistant to degradation and accumulates in lysosomes, since the addition of high concentration of non-accumulating Aß1-28 and freshly dissolved Aß1-40 has no effect on the up regulation of lysosomal enzyme activities. To further test whether lysosomal dysfunction may be associated with Aß toxicity, the cells were labeled with the impermeant vital stain, lucifer yellow, which is internalized and concentrated in lysosomes. Preliminary results indicate that under conditions where Aß is not toxic to the cell, the lucifer yellow label is present as punctate, fluorescent staining in a perinuclear distribution with no apparent cytoplasmic fluorescence. However, when a cytotoxic concentration of Aß1-42 is added, one of the earliest morphological effects is a loss of lysosomal membrane impermeability as evidenced by leakage of the fluorescent marker from lysosomes into the cytoplasm resulting in extensive cytosolic fluorescence. These results suggest that a loss of lysosomal membrane permeability may be an early event in Aß cytotoxicity and support the working hypothesis that the intracellular accumulation of Aß peptide and its resistance to degradation is an important component of AD pathogenesis. CO-INJECTION OF LPS AND Aβ1-42 INTO RAT STRIATUM AND HIPPOCAMPUS. L.A. Holcomb* and D.G. Morgan. Dept. of Pharmacology, University of South Florida, Tampa, FL 33612-4799.

Neuronal loss and glial reactivity suggestive of a CNS inflammatory response accompany compacted Alzheimer's disease (AD) amyloid plaques. However, diffuse plaques which are also composed largely of the beta-amyloid (Aβ) peptide have little associated neuronal damage or glial activation. Recently, the longer Aβ1-42 form has been shown to be deposited earliest in AD brain. Aβ1-42 may form a nucleus for plaque formation as well as potentially being neurotoxic. Injections of Aβ1-42 were made into rat brain in order to determine the formation of fibrillar, neurotoxic Aβ1-42 deposits. Collagen, which is also capable of fibril formation, was used as a control substance with or without LPS to ensure that fibrils alone are not neurotoxic.

Young male SD rats were injected with a) LPS; b) collagen; c)collagen+ LPS; d) Aβ1-42 or e) Aβ1-42+LPS (n=4 for each group) in the hippocampus and striatum (3 µl each site). On the contralateral side, control solutions were injected f) collagen vehicle (n=8); g) Aβ1-42 vehicle (n=8) or h) PBS (N=4). In 5 of 8 rats injected with Aβ1-42, congophilic deposits were found 1 week later. In 7 of 8 Aβ1-42+LPS injected rats, congophilic deposits were present. When necrosis was evaluated, the rats with Aβ1-42 or Aβ1-42+LPS had substantially more degeneration than vehicle injected rats. Supported by Pfizer Inc. and Alz. Assn. IIRG 93-083.

FATE OF BETA-AMYLOID IN RAT BRAIN. S.K. Brining*. LNS, NIA, NIH, Bldg. 10/Rm. 6C-103, Bethesda MD 20892-1582.

It is well known that few animals other than primates develop Alzheimer's-like neuropathology, which includes regionally-specific beta-amyloid (βA4)-containing plaques and neurofibrillary tangles . Using various methods, synthetic βA4 has been introduced to rodent brains in largely unsuccessful attempts to replicate plaque pathology [reviewed in K.Kosik and P.D. Coleman, *Neurobiol. Aging* **13**, 1992]. In the present work, the metabolism of βA4 by rat brain homogenate was investigated. A 58 µM concentration of βA4 solution was incubated (37°C) with the post nuclear supernatant (PNS) of Sprague Dawley rat brain for varying times. Similar concentrations of βA4 have been shown to be toxic to PC-12 cells (S.K. Brining et al., *Neurobiol. Aging*, in press 1996]. Western blot analysis of the PNS/βA4 samples revealed a time-dependent decrease in the amount of monomeric βA4. No corresponding increase in any immunoreactive protein was observed. Incubation of βA4 only, or boiling the PNS prior to incubating it with βA4, produced no change in the βA4 monomers over time. Boiled PNS alone resulted in no detectable bands corresponding to monomeric βA4. Future work includes densitometric quantification of the bands and experiments to assess the possibility of proteolytic activity to explain these findings. These results indicate that rat brain PNS is capable of *in vitro* metabolism of toxic βA4. *Supported by intramural NIH/NIA program.*

DEGENERATIVE DISEASE: ALZHEIMER'S-BETA-AMYLOID—APOLIPOPROTEINS

828.1

APOLIPOPROTEIN E INHIBITION OF ZINC INDUCED AGGREGATION OF THE BETA-PEPTIDE OF ALZHEIMER'S DISEASE. R.D. Moir, C.S. Atwood, T.-W. Kim, D.M. Romano, X. Huang, B.T. Hyman, D.K. Strickland, A.I. Bush and R. E. Tanzi* Genetics and Aging Unit, Massachusetts General Hospital, Building 149, 13th St, Boston, MA 02129.

The pathological hallmark of Alzheimer's disease (AD) is the deposition of ß-amyloid deposits. The principal component of amyloid is the Aß peptide. Inheritance of the e4 allele of apoE is a risk factor for AD. One possible mechanism by which apoE may affect AD pathology is by directly affecting the propensity of Aß to polymerize. We have previously reported that zinc induces the precipitation of Aß from simple solutions containing >1 µM of Aß peptide. We have recently developed a novel high sensitivity assay that can detect 2 ng of Aß aggregate. Using this assay we have shown that Aß aggregation also occurs in simple solutions containing concentrations of zinc (5-10 µM) and Aß1-40 (0.5-5 nM) that are within the range of those found in human CSF. Our preliminary findings suggest that the formation of zinc-induced Aß aggregates is inhibited by apolipoprotein E (apoE) under conditions where the concentrations of zinc, Aß1-40 and apoE approach physiological. Both apoE3 and apoE4 were found to inhibit aggregation in the presence of albumin, suggesting the interaction is specific. Consistent with the increase risk associated with the e4 allele of apoE, apoE4 inhibited aggregation with less potency than apoE3. We are presently extending our study to include apoE2 and Aß1-42 and are investigating the effect of other proteins commonly found in biological fluids.

EFFECTS OF APOLIPOPROTEIN E ON Aβ AGGREGATION vs. Aβ DEPOSITION *in vitro*: MECHANISTIC IMPLICATIONS FOR THE ENHANCED AMYLOID BURDEN IN ε4 ALZHEIMER'S DISEASE

JE Maggio*, WP Esler, ER Stimson, JR Ghilardi, HV Vinters, and PW Mantyh
BCMP Dept. Harvard Med. Sch., Boston MA 02115; Molec. Neurobiol. Lab (151), VA Med. Ctr., Mpls, MN 55417; Dept. Pathol. & Lab. Med., UCLA Med. Ctr. LA, CA 90024.

Inheritance of one or more apolipoprotein ε4 (*APO*ε4) alleles is a risk factor for Alzheimer's disease (AD). Since AD patients carrying the ε4 allele have increased amyloid burden relative to ε3 or ε2 AD cases, it has been proposed that apoE isoform specific differences in apoE:β-amyloid peptide (Aβ) interactions may lead to enhanced amyloidogenicity in ε4 patients. Aβ aggregation (initial amyloid template formation) and subsequent Aβ deposition are biochemically distinct; thus enhanced amyloid burden in ε4 patients may occur as a result of effects of apoE on either or both of these processes. To probe the role of apoE in these processes, the effect of apoE isoforms on Aβ aggregation and Aβ deposition was examined using *in vitro* model systems. While the rate of Aβ aggregation was faster in the presence of apoE4 than apoE3, neither apoE isoform had any discernible effect on the rate of Aβ deposition, implying that apoE4 enhances amyloid template formation but has no effect on subsequent plaque growth. These results are consistent with published observations that while AD patients carrying the *APO*ε4 allele have a higher number of amyloid deposits than *APO*ε3 patients, there is no isoform specific difference in plaque size, and that *APO*ε genotype affects age of onset but not rate of decline in AD. Thus compounds which target apoE:Aβ interaction would more likely be useful as prophylactic rather than therapeutic agents. Supported by NIH (AG11852, AG12853, AG10123, AG12435) and VA (Merit Review).

828.3

EFFECT OF NATIVE APOLIPOPROTEIN E ISOFORMS ON β-AMYLOID INDUCED ACTIVATION OF RAT GLIAL CULTURES.
L.J. Van Eldik*, J. Hu, K. Akama, and M.J. LaDu#. Dept Cell and Mol Biol, Northwestern University Med Sch, and #Dept of Pathology, University of Chicago, Chicago, IL.

The amyloid plaques found in Alzheimer's disease (AD) brains are composed of activated astrocytes surrounding a neuritic shell and activated microglia in the β-amyloid (Aβ) core. Apolipoprotein E (apoE) is also found associated with Aβ-containing plaques. Previous in vitro work has shown that Aβ induces neurotoxicity and leads to glial cell activation. Although apoE is known to affect Aβ-induced neurotoxicity, the influence of apoE on glial cell responses to Aβ has not been studied in detail. In neonatal rat glial cultures, we evaluated by morphological measurements the effect of apoE on Aβ-induced glial activation by using a native preparation of apoE from conditioned media of HEK cells stably transfected with human apoE3 or apoE4 cDNA. Four experimental conditions were tested: a) Aβ aged with apoE prior to addition to cultures, b) apoE and aged Aβ added to cultures simultaneously, c) apoE pretreatment of cells before addition of aged Aβ, and d) apoE added to cultures 12 hrs after addition of aged Aβ. We found that apoE attenuated Aβ-induced glial activation, particularly when Aβ was aged with apoE. In addition, apoE pre-treatment of cells prevented Aβ-induced activation, and apoE reversed the Aβ-induced morphological effects within 1 hr of apoE addition. Although both apoE3 and apoE4 inhibited Aβ-induced glial activation, the apoE4 isoform appeared to be more effective. These data suggest a role for apoE in modulating Aβ interactions with glia. (Supported in part by American Health Assistance Foundation (AHAF) grant 95100 and NIH grant 1F32 HL08833-01).

APOE POLYMORPHISM AND DISEASE DURATION DETERMINE ALZHEIMER'S DISEASE NEUROPATHOLOGY IN "SWEDISH" APP DOUBLE MUTATION CARRIERS.
N. Bogdanovic*, E. H. Corder, L. Lannfelt, H. Basun, and B. Winblad. Dept. of Clinical Neuroscience, Geriatric Section, Huddinge Univ. Hosp., S-14186 Huddinge, Sweden. Center for Demographic Studies, Duke University, USA.

We contrasted Alzheimer's disease (AD) pathology in three carriers of the "Swedish" APP double mutation at codons 670/671 of the APP gene. Our aim was to investigate the influence of APOE polymorphism and disease duration on neurofibrillary changes. We quantified neurofibrillary tangles (NFT) and neuritic plaques (NP) in the superficial (I-III) and deep (IV-VI) layers throughout the cortex, and in subcortical regions. Two subjects were brothers who carried the APOE ε2/3 genotype and differed in the duration of clinical AD symptoms from onset until death: 11 years for P1 and 5 years for P2. The third subject P3 was a distant cousin who carried the APOE ε4/4 genotype and had 12 years disease duration, comparable to P1. Formaldehyde fixed and paraffin embedded sections were stained by the modified Bielschowsky method. Number of NFT, NP and the % of NP found/mm^2 were counted using a stereological method. Statistical comparisons were made using Wilcoxon's signed rank and Kruskal-Wallis tests. We found that the ε4/4 genotype (i.e., P3 vs P1) was associated with more NFT, more NP, and higher plaque density. Conversely, shorter duration of disease (i.e., P2 vs P1) was associated with fewer NFT, fewer NP, and lower plaque density. Within the cortex, regional NFT varied more than 4-fold: temporal > parietal > other regions, except for P3 who had elevated NFT in frontal and limbic regions. There was relatively little regional variation in NP count and density. The plaque load, and to some extent the NFT count, indicated more pathology in superficial than deep cortical layers. In contrast to the cortex, the hippocampal distribution of AD pathology was only modesty higher for P3 than for P1. For both subjects, the hippocampus had twice as many NFT and half the plaque load as was found in the cortex. P2 had 30% fewer hippocampal NFT, most notably in CA1 and CA2. In conclusion, APOE polymorphism and disease duration appeared to influence the pattern and extent of pathology, more with the ε4/4 genotype and less with shorter duration, particularly in the cortex.

828.5

APOLIPOPROTEIN E4, BUT NOT E3 OR E2, ENHANCES COMPLEMENT ACTIVATION BY β-AMYLOID PROTEIN (1-40)
P.L. McGeer[1]*, D.G. Walker[1], R.W. Mahley[2], R.E. Pitas[2] and E. McGeer[1], [1]Kinsmen Laboratory of Neurological Research, University of British Columbia, 2255 Wesbrook Mall, Vancouver, B.C., V6T 1Z3, Canada, [2]Gladstone Institute, PO Box 419100, San Francisco, CA 94141-9100, United States

Apolipoprotein E4 (apoE4) is a risk factor for late onset Alzheimer disease (AD). We tested the hypothesis that apoE4 might be responsible for promoting the observed association of complement proteins with senile plaques by measuring its effects on the ability of beta-amyloid protein 1-40 (BAP) to activate complement in vitro. Freshly prepared BAP (200 or 430 ng) was plated in ELISA wells and then exposed for 1 hour to 100 or 200 ng of human apoE4, apoE3, apoE2 or bovine serum albumin (BSA). Human serum was then added as the source of complement proteins, and activation assessed by antibody capture of the C3bi formed. Taking the BSA values as 100%, the relative activation for 430 ng BAP exposed to 200 ng of apoE was 121±4.9% for apoE4, 102±3.1% for apoE3 and 102±5.9% for apoE2. Corresponding figures for exposure of 430 ng BAP to 100 ng of apoE were 120±3.8% for apoE4, 102±2.3% for apoE3 and 96.3±3% for apoE2. Similar data were obtained when 200 ng of BAP was used. The apoE isoforms did not activate complement on their own. This apoE4 effect on complement activation by BAP may contribute to the associated risk of late onset AD. Supported by grants from the Alzheimer Society of B.C. and the Jack Brown and Family A.D. Research Fund

828.6

DISTRIBUTION OF ENDOGENOUS AND EXOGENOUS β-AMYLOID IN PLASMA LIPOPROTEINS FROM APOLIPOPROTEIN E GENOTYPED DONORS.
M.J. LaDu[1], M.F. Falduto[2]*, J.R. Lukens[1], G.S. Getz[1], and C.A. Reardon[1]. [1]Dept. of Pathology, University of Chicago, Chicago, IL 60637 and [2]Immunoscience Discovery, Abbott Laboratories, Abbott Park, IL 60064.

We have previously demonstrated by non-reducing SDS-PAGE that native preparations of apolipoprotein E3 (apoE3), but not apoE4, readily form complex with β-amyloid (Aβ). Although Aβ has been detected in plasma, the existence and nature of apoE:Aβ complexes in physiologic fluid is unknown. This study was undertaken to characterize the distribution of Aβ in plasma lipoproteins and determine whether apoE phenotype affects this pattern. Plasma from individuals homozygous for the ε2, ε3, and ε4 allele was fractionated by size with and without 250μM Aβ(1-40). Fractions were analyzed under non-denaturing conditions by immunoblotting for Aβ. Select fractions were also run on non-reducing SDS-PAGE to identify SDS-resistant Aβ complexes. Endogenous Aβ co-elutes predominantly with high density lipoprotein (HDL) and intermediate density lipoproteins (IDL), regardless of apoE phenotype. In HDL, a portion of the Aβ forms an SDS-resistant complex with apoJ, with apoAIV and with apoAI. Exogenous Aβ co-elutes primarily with the IDL and larger particles, where a portion of it is complexed with apoE in E2/2 and E3/3 plasma but not in E4/4 plasma. While Aβ does associate with several classes of lipoproteins, it does not co-elute with LDL particles, suggesting that Aβ association with lipoproteins is more than a non-specific interaction with the lipid components of lipoprotein particles, and may involve specific protein:protein interactions with apoproteins. Grant support: AHAF 95100, NIH 1F32 HL08833-01.

828.7

ISOFORM-SPECIFIC EFFECT OF APOLIPOPROTEIN E ON β-AMYLOID INDUCED TOXICITY IN RAT HIPPOCAMPAL PYRAMIDAL NEURONAL CULTURES.
R.J. Miller[1]*, M.F. Galindo[1], J. Jordán[1], J.R. Lukens[2], M.J. LaDu[2], and G.S. Getz[2]. Dept. of [1]Phamacological and Physiological Sciences, and [2]Pathology, University of Chicago, Chicago, IL 60637.

While the correlation between the ε4 allele of apolipoprotein E (apoE) and Alzheimer's disease is well established, the role of apoE in the pathogenesis of the disease remains unclear. We have previously observed that β-amyloid (Aβ)(1-40) readily forms an SDS-resistant complex with native apoE3 but not E4. This differential binding may affect Aβ-induced neurotoxicity. To investigate this possibility, we examined the effect of native preparations of apoE3 and E4 on Aβ-induced toxicity in primary cultures of rat hippocampal pyramidal neurons. The source of apoE was conditioned media from HEK-293 cells stably transfected with human apoE3 or E4 cDNA. Cultures were treated on day *in vitro* (DIV)-1 with 10 μg/ml apoE3 or E4, 10μM Aβ was added at DIV-5, and cell viability was analyzed at DIV-10. Only apoE3 pretreatment prevented the toxicity induced by Aβ(1-40) or Aβ(25-35). The effect of apoE appears to be specific to Aβ-induced toxicity as neither apoE isoform was able to protect against the cytotoxicity produced by NMDA or staurosporin. To rule out growth factor-like activity of apoE on immature neurons as the source o apoE effect, mature cultures (DIV-5) were pretreated with apoE for 1 h, prior to the addition of Aβ(25-35) and cell viability was analyzed at DIV-10. Under these conditions, apoE3 again protected against Aβ-induced toxicity while apoE4 did not. This isoform-specific effect may result from sequestration of the peptide by preferential apoE3:Aβ binding. Grant support: PHS DA02121, DA02575, MH40165, AHAF 95100, and NIH 1F32 HL08833-01.

828.8

APOLIPOPROTEIN E UPTAKE AND DEGRADATION IN PRIMARY CULTURES OF NEURONS AND ASTROCYTES.
U. Beffert*, Marie-Pierre Faure, N. Aumont, D. Dea, J. Davignon and J. Poirier, Molecular Neurobiology Lab., Douglas Hospital Research Centre, Depts. of Psychiatry, Neurology and Neurosurgery, McGill University, Montréal, Québec, Canada; Advanced Bioconcept, 1801 McGill College Ave., Suite 720, Montreal, Québec, Canada

Apolipoprotein E (apoE) is a known risk factor for late-onset sporadic and familial Alzheimer's Disease (AD). ApoE binds to beta amyloid (Aß) protein, a peptide isolated from extracellular AD neuritic plaques. Previously, we demonstrated that apoE uptake can be increased by Aß peptides in an apoE isoform specific manner in cultures of primary hippocampal neurons and cortical astrocytes. Since one potential role for apoE in the CNS is to aid in the reinnervation process following lesions, then modulation of apoE uptake by Aß may explain the lack of reinnervation or increased cell death in pathologies such as AD. To further characterize apoE and Aß interactions in the CNS, we investigated the uptake and degradation of the three major apoE isoforms in two different rat cell culture models: primary hippocampal neurons and cortical astrocytes. ApoE2, apoE3 and apoE4 liposomes were prepared using purified human apoE from pre-genotyped individuals. The apoE liposomes were preincubated in the presence of Aß peptides for 2 hours at 37°C. Cultures were then exposed to apoE and/or Aß for 24 hours. Cell homogenates and media were collected for analysis by Western blot for apoE or Aß. Previous work from our lab showed that uptake of apoE3 was consistantly less than apoE2 or apoE4 in these models. Investigation of their respective degradation profiles revealed that apoE3 degradation was significantly higher than apoE4 and apoE2. Differential apoE metabolism which may be accentuated in the presence of Aß may explain the biochemical mechanism underlying AD. *(Supported by the FRSQ and the Alzheimer Society of Canada).*

828.9

ALZHEIMER'S SOLUBLE AMYLOID BETA PROTEIN IS ASSOCIATED WITH HIGH DENSITY LIPOPROTEINS IN NORMAL HUMAN CEREBROSPINAL FLUID AND IS SECRETED BY HEPG2 CELLS AS A PART OF LIPOPROTEIN COMPLEXES A. R. Koudinov*, N. V. Koudinova, A. Kumar, R. C. Beavis and J. Ghiso, New York University Medical Center, TH 427, 560 First Avenue, New York, NY 10016.

The soluble form of amyloid β protein (sAβ) is associated with high density lipoprotein (HDL) in normal human plasma (*Biochem Biophys Res Commun* (1994) **205**, 1164-71). This suggests that sAβ to HDL association is rather a more general phenomenon taking place in other biological fluids and tissues. To ascertain this hypothesis the colocalization of sAβ with lipoproteins (LP) was investigated in cerebrospinal fluid (CSF) and in cell culture supernatant. Normal human CSF LPs were obtained by sequential flotation ultracentrifugation and analyzed for the presence of sAβ via immunoblot, size-exclusion HPLC, immunoelectron microscopy, N-terminal sequence and mass-spectrometry analyses. Soluble Aβ was associated with ~200 kDa CSF-HDL particles of 16.8 ± 3.2 nm in diameter. A ~4.3 kDa component purified by reverse phase HPLC was immunoreactive with anti-Aβ antibodies, exhibited an N-terminal sequence identical to the Aβ peptide and a mass of 4325.1 Da, and therefore indicates that the main sAβ specie associated with CSF-HDL is sAβ1-40. The sAβ secretion by cells in association with LPs was tested in human hepatoma HepG2 cell line. Soluble Aβ in the cell culture supernatant was detected in ~200 kDa molecular mass LP complexes in association with apoJ, apoA-I, phospholipids, triglycerides and free and esterified cholesterol. Our results suggest that the association of sAβ with LP represents a common mechanism for the peptide transport in biological fluids.

APOLIPOPROTEIN E4 ACCUMULATES IN SENILE PLAQUES IN ALZHEIMER'S DISEASE WITH E4 ALLELE , N.Nukina*, G. Wang, K. Ide, I. Kanazawa, F.Oyama and Y.Ihara. Department of Neurology and Neuropathology, University of Tokyo, Tokyo, Japan

Apolipoprotein E4 has been comfirmed as a genetic risk factor for Alzheimer's disease. Although several hypotheses have been advanced to explain how the inheritance of apolipoprotein E isoforms affects the rate of Alzheimer's disease expression, the mechanism whereby apolipoprotein E is involved in the pathogenesis of Alzheimer's disease is still uncertain. To clarify the way in which the apolipoprotein E4 isoform differs from others , we generated monoclonal antibody specifically reactive with ApoE4 isoform as described in BBRC 216:467,1995 and used it to analyse the Alzheimer's brain with ApoE4. Sections from cases whose apoE genotype were identified were stained with this antibody(412-1-12-2) and the antibody reactive with all apoE isoform(E12). Ab E12 stained senile plaques and some neurofibrillary tangles in cases with any apoE genotypes. However Ab 412-1-12-2 stained senile plaques and NFT only in cases with apoE4 genotype. These results suggest that the antibody specific to apoE4 isoform can be used to the histochemical analysis of AD and detected only apoE4 on the section. Moreover the results suggest that apoE4 isoform including the polymorphic site accumulates in senile plaques.

CLUSTERIN (ApoJ) - Aß INTERACTIONS: CONGO-RED BINDING AND MODIFICATION OF TOXICITY. P.A. Wals,T.E. Morgan, I. Rozovsky, S.K.Goldsmith* and C. E. Finch. Andrus Gerontology Center and Department of Biology, University of Southern California, Los Angeles, CA 90089.

In the Alzheimer's disease (AD) brain, senile plaques are composed primarily of amyloid beta (Aß) and other associated proteins including clusterin (ApoJ). Recently we demonstrated that in the presence of clusterin, Aß1-42 forms a slowly sedimenting (16,000 g/10 min) fraction with increased neurotoxicity (Oda et al., Exp. Neurology, 1995). We are examining the Congo Red binding characteristics of this Aß-clusterin fraction. Congo Red generally binds to the ß-sheets but does not bind to soluble non-fibrillar Aß. Binding studies with Congo Red indicate a hyperchromicity and a shift in the absorbance with the slowly sedimenting Aß-clusterin fraction suggesting ß-sheet structure. Moreover, in the presence of Congo Red this Aß+clusterin fraction is sedimentable.

Cultured astrocytes respond to Aß with NF-kB activation and a transient reduction in mitochondrial activities, but no cell loss. Clusterin mRNA in cultured astrocytes was increased after treatment with the Aß+clusterin fraction, while clusterin secretion into conditioned medium was reduced. In contrast, there was no change in GFAP or vimentin mRNAs after Aß exposure. Time course studies demonstrate that reduced clusterin secretion occurs prior to both mitochondrial impairment and NF-kB activation. Thus, changes in clusterin levels may be an initial cellular response induced by Aß. (Supported by AG13499 to CEF and Alz. Assoc. FSA-95-033 to TEM).

Ca^{2+}-DEPENDENT INTERACTION BETWEEN ALZHEIMER'S Aβ PEPTIDES AND SERUM AMYLOID P-COMPONENT. S. Governale, E. Matsubara[1], C. Soto, S. Ferris* B. Frangione and J. Ghiso. Dept of Pathology, New York University, New York, NY 10016 and [1]Dept of Neurology, Gunma University, Gunma, Japan.

Amyloid β (Aβ) is the main fibrillar component of the Alzheimer's amyloid lesions and is also found as a soluble peptide (sAβ) in biological fluids. It has been previously demonstrated that when synthetic Aβ immobilized on a solid matrix is allowed to interact with normal human plasma or cerebrospinal fluid, the main Aβ-binding protein retrieved from the biological fluid is apolipoprotein J (apoJ). However, in the presence of physiologic concentrations of Ca^{2+}, an additional 27 kDa component binds to the matrix and can be eluted by the chelating agent EDTA. Immunoblot and amino acid sequence analysis identified the binding protein as serum amyloid P-component (SAP), a normal plasma glycoprotein composed of 10 non-covalently associated identical subunits of 204 amino acids. SAP is considered to be the circulating source of the amyloid P-component, an integral constituent of vascular basement membranes and an amyloid associated protein found in all amyloid lesions where it constitutes 5 to 10% of the fibrillar deposits.

Ca^{2+}-dependent solid-phase ELISA experiments indicate that the SAP-Aβ interaction is saturable and specific. The affinity of the binding (Kd ≈ 4 nM) is similar to the one calculated for apoJ (Kd= 2 nM). However, SAP binds the aggregated forms of Aβ1-40 and Aβ1-42 with higher affinity than apoJ. These results were corroborated by competitive inhibition experiments in solution showing that SAP has two times higher relative affinity for the aggregated Aβ peptides than apoJ . The data suggest that the interaction apoJ-sAβ primarily occurs in body fluids whereas the interaction between SAP and Aβ is favored in tissue deposits.

DEGENERATIVE DISEASE: ALZHEIMER'S—COGNITIVE FUNCTION III

829.1

COGNITIVE DISTURBANCES DURING COPYING IN DOWN'S SYNDROME.
N.Nakano*,R.Fukatsu ,S.Murakami , S.Hayashi , M.Fujii , K.Utsumi , Y.Hayashi ,N.Sasaki , T.Takakuwa +, and N.Takahata
Dep. of Neuropsychiatry, Sapporo Med. Univ.,Sapporo, Japan 060.
+ Prefectural Training School for Mentally Retarded, Date, Japan 052.

Most studies of Down's syndrome(DS) reveal a age-dependent increase of neuropathology associated with Alzheimer's disease (AD). However ,cognitive disturbances of AD in DS are not well characterized ,partly because of the preexisting mental retardation.On the other hand, characteristic eye movements are observed in AD patients from the early clinical stage.
In this paper, we studied the eye movements of 12 DS(21 trisomy), 10 simple mental retardation (MR) and 12 AD using vision analyzer (TKK939). Eye movements of the subjects were analyzed when drawing and coping geometric figurest o right and left side.Some DS were analyzed when drawing and coping animal pictures.

As a results, 1) eye velocity(EV) of 5 DS (AD type,DA) over 35 years old and 12 AD were widely distribution and no peak velocity was notable. In 7 DS(non-AD type,DN) and 10 MR, there were EV peak below 12 deg/sec., instead of widely distribution pattern. 2) average gazing time and total gazing time/total performing time of DA and AD were significantly lower than DN and MR. 3) gazing points of DA and AD distributed in small areas of the figures when compared to those of DN and MR. There were no significant differences between right and left side copy.

These data indicate that DS after age 35 show visual cognitive disturbances similar to those of AD, which may result from premature aging occurring in DS before the clinical onset of dementia.

POSTMORTEM CORRELATIONS IN ALZHEIMER DISEASE USING THE FUNCTIONAL ASSESSMENT STAGING SCALE (FAST). E.H. Franssen, B. Quinn, & B. Reisberg*, NYU Aging & Dementia Res. Center, New York, NY 10016.

Existing studies have correlated intellectual function in dementia patients, as assessed by standardized tests, with Alzheimer pathologies such as amyloid plaque burden, neurofibrillary tangles, or synapse loss, each of which has been proposed in at least one study as the best correlate of dementia. However, one disadvantage of cognitive testing like the Mini-Mental State Exam is that test scores zero-out in severe-stage Alzheimer's disease (AD). The FAST behavioral scale continues to show meaningful and reliable grading of dementia severity even in the final stages of dementia. We have validated this late-disease FAST staging against volumetric loss in hippocampal subregions (Bobinski, *Dementia* 6:205, 1995). In the present pilot study, we correlated global neuropathologic findings with terminal FAST score (5-7F) in six patients. Sections surveying the brain were stained for Nissl, H&E/myelin, two silver stains (Bielschowsky and Reusche), congo red, and immunostained for GFAP, tau & ubiquitin. A neuropathologist blind to FAST stage, original neuropathologic diagnosis, and clinical history applied the CERAD postmortem criteria as well as qualitative pathologic criteria (mild to severe) for neuronal loss, gliosis, plaque density, neuropil threads, infarct/vascular disease, and other parameters. This neuropathologic screening approach is important to guide the selection of future, more quantitative studies. In this pilot study, all patients met CERAD criteria for "Definite AD"; cortical Lewy body disease was encountered in one case. Amyloid plaque burden in frontal cortex, assessed in blind-rated photos, did not show strong correlation with FAST stage 5-7F, concordant with reports that amyloid plaque burden may asymptote in AD or covary with ApoE status. However, neuropil thread/ neurofibrillary tangle ranking in frontal cortex did correlate closely with FAST rank in this pilot sample. The findings support the potential value of using validated clinical rating scales such as the FAST, which can partition late-stage patients for neuropathologic studies, to avoid the zeroing-out effect of cognitive testing. Further, FAST can be determined by caregiver interview in postmortem cases where recent testing was unavailable. The findings suggest that progressive neuropil thread disease should be assessed against cognitive and FAST staging in a larger series of AD cases which pass the threshold of the CERAD AD criteria. Supported by the NYU Aging & Dementia Research Center.

829.3

THE EFFECTS OF DISEASE SEVERITY AND ENCODING CONDITION ON WORD-STEM COMPLETION PRIMING IN ALZHEIMER'S DISEASE. D.A. Fleischman*, J.D.E. Gabrieli, J.D. Hauser, and K.L. Lange. Rush Medical College and Stanford University. Conflicting findings exist regarding whether word-stem completion priming (WSC) is intact or impaired in Alzheimer's disease (AD). Disease and/or task differences across studies may account for the discrepancy. One disease factor is dementia severity. Most studies have examined patients that are, on average, in the mild stage of the disease, but studies differ to the extent that additional sampling occurs from the very mild or the moderate stages. If priming diminishes with disease progression, any group finding may reflect this sampling difference. One task difference across studies involves encoding manipulations that may invoke different blends of perceptual and semantic processing. Because AD patients perform better on perceptual than semantic tasks, any group finding may reflect the extent of perceptual processing at study. To date, however, there is no compelling evidence that either of these factors alone can account for the mixed findings. In this study, 3 levels of dementia severity were crossed with 3 encoding conditions for patients with AD (75; 19 moderate, 39 mild, 17 very mild) and matched old normal controls (ONC = 43). In the study-phase, participants processed single words under three conditions in mixed lists: words were either read aloud, read and rated for likability, or generated from short definitions. In the test-phase, participants completed three-letter word stems with the first word that came to mind. All four groups primed. Priming was greatest after study-phase reading (17%), intermediate after rating (15%), and least after generating (8%). Relative to ONC priming (18%), AD priming was intact for the very mild group (14%). Priming was impaired for the mild (11%) and moderate (8%) groups, and these deficits varied as a function of encoding condition. The results suggest that processes that may be invoked differentially by certain encoding manipulations and contribute to WSC priming, may diminish at different points in the AD disease course. This would lead to discrepant findings if studies sample patients from different disease stages and measure multiple priming processes that do not change uniformly. IMPROVING DEMENTIA SCREENING TESTS WITH MACHINE LEARNING METHODS. W.R. Shankle*, M. Dillencourt, M. Pazzani UC Irvine Department of Neurology & Computer Science, University of California, Irvine, 92717-4285. We applied Machine Learning (ML) methods to test whether their application on data derived from two simple tests, the Functional Activities Questionnaire (FAQ) and the Six-Item Blessed, Orientation, Memory and Concentration Exam (BOMC), can improve dementia screening. DSM-IV criteria for dementia were used to categorize patients into normal, cognitively impaired-but-not-demented, and demented groups. The sample consisted of the initial visits of 609 normal, cognitively impaired or demented subjects evaluated at the UC Irvine Brain Aging Center (BAC). Using published cutoff criteria for the FAQ (>8=demented) and the BOMC (>10=demented) tests gave classification accuracies of 73% and 64% respectively. Combining the cutoff criteria gave a 60% classification accuracy. On this same sample, we applied four ML algorithms using the FAQ and BOMC test response results. ML methods obtained 86% overall classification accuracy, an increase of 13-24% over conventional cutoff criteria. For the cognitively impaired group, classification accuracy was 24% using cutoff criteria, and 61-64% using ML methods, representing a 37-40% improvement. ML methods extract more information from these simple tests recommended by the Agency for Health Care Policy Research to increase substantially their accuracy in detecting cognitive impairment and dementia combined use in a simple, descriptive way.

THE IMPACT OF SEMANTIC IMPAIRMENT ON IMPLICIT MEMORY FUNCTION IN ALZHEIMER'S DISEASE. H. Chertkow*, M. Beauregard, S. Murtha, H. Bergman, S. Leblanc, J. Benhamou, D. Gold. Dept. of Neuroscience, and Div. of Geriatric Medicine, Jewish General Hospital, McGill University. Centre de Recherche, Centre Hospitalier Cotes-des-Neiges, Montreal, Canada.

The status of implicit memory function (IMF) in patients with Alzheimer's disease (AD) remains controversial. Two-thirds of reported studies in AD using the word stem completion task (WSCT) found impairment in IMF, while the remaining studies did not. We wondered whether these inconsistent findings might reflect the variable degree of semantic impairment within subject groups. Thirteen subjects with mild to moderate AD and thirteen matched Normal Elderly Controls (NECs) were tested on the WSCT using 60 test items. Subjects constructed words from two and three letter stems, half of which had been presented beforehand (15 test items at a time) as the prime list at a study phase. Word completions corresponding to the 60 item list were considered correct. In Experiment 1, each list was presented and simply read silently by the subject. In Experiment 2, a semantic decision was carried out on each list word item, to encourage deeper encoding. At separate sessions, semantic knowledge for each of the 60 test items was assessed using forced choice probe questions. In Experiment 1 (passive viewing of words) the NEC's showed a 13 item priming effect, while the AD subjects showed a 10 item effect, not significantly different. Priming for semantically intact vs. degraded test items was equivalent. In Experiment 2, NEC's again showed a 12 item priming effect, vs. a 7 ms effect for the AD patients. Analysis of the semantic status of the items revealed that for the semantically degraded items, a priming effect of only 3.4 items was found, compared with 10.2 seconds for the semantically intact items($p<.001$). This suggests that under encoding conditions promoting conceptual processing, the presence of semantically "degraded" items in the test lists will significantly decrease the implicit priming produced in the WSCT. At least a portion of the "Implicit Memory Systems" are not encapsulated from deterioration within semantic memory.

LONG-LIVED PICTURE PRIMING IN NORMAL ELDERLY PERSONS AND DEMENTED PATIENTS. W.W. Beatty*, S. English and P. Winn. Departments of Psychiatry and Behavioral Sciences and Family Medicine, Univ. of Oklahoma Health Sci. Center, Oklahoma City, OK 73190.

As part of a longitudinal study of preserved cognitive skills in dementia, normal elderly subjects (N = 9) and demented patients (N = 11) received a battery of neuropsychological (NP) tests at study entry and one year later. The NP battery included measures of implicit memory (Gollin Figures picture priming test, pursuit rotor learning), naming (30-item BNT), letter and category fluency, digit and visual memory span, WISC-R Block Design, Trails A, and letter and symbol cancellation.

At Year 1 testing, all subjects showed priming (improvement in naming fragmented figures on retest 10 min after initial presentation); the magnitude of priming was greater for controls (Mean = 21.3 vs 10.5 items). On Trial 1 of Year 2 testing, controls improved their naming of fragmented figures compared to Trial 1 of the previous year (Mean = 10.4 items), an average "retention" of 54%. By contrast, on Trial 1 patients with dementia showed a decline in naming fragmented figures from Year 1 to Year 2 (Mean = -4.6 items), but they continued to show priming over the 10 min test-retest interval on the Year 2 tests (Mean improvement = 10.9 items).

On all of the other NP tests performance by control subjects did not change significantly over the one year test-retest interval, while performance by patients with dementia declined. The most likely explanation for the long-lived priming displayed by controls is that they acquired a perceptual skill for processing fragmented figures, a form of implicit memory. However, the design of the study does not rule out involvement of explicit memory. A generalized practice effect can be ruled out because performance by controls did not change from Year 1 to Year 2 on the other 11 NP measures.

THE RELIGIOUS STUDY: DESIGN, METHODS AND PRELIMINARY FINDINGS. D.A. Bennett*, E.J. Cochran, R.S. Wilson, L.A. Beckett, E.J. Mufson, J.H. Fox, D.A. Evans. Rush Alzheimer's Disease Center, Chicago, IL.

A large longitudinal clinical-pathologic study was initiated to: 1) obtain *comparable* cases and controls for clinical and neurobiologic studies of Alzheimer's disease (AD) and other common neurologic conditions of older people; 2) relate risk factors to *change in* cognition and *incident* AD; 3) relate *change in* cognition and other neurologic indices with post-mortem findings. The study design includes uniform structured baseline and annual follow-up clinical evaluations, and brain autopsy. Neuropathological data are collected blind to clinical data. Groups of older Catholic Nuns, Priests and Brothers from across the country are participating because they are altruistic, many live communally, and Religious Groups have participated in other similar studies. From Jan 1, 1994 through April 20, 1996, 570 baseline, 383 first-year follow-up, and 90 second-year follow-up evaluations were performed. At entry, the average age was 77; MMSE was 27.9, and 39% were male; 88% did not have dementia. Of 30 deaths, 29 had a brain autopsy. Of the first 24 cases, average age at death was 82, MMSE was 26.2, 50% were male and 17 did not have dementia. Twenty-one cognitive tests were converted to z-scores and averaged to provide a global measure of cognitive function. The global score was highly correlated (Spearman Rank) with the average number of neocortical (frontal, parietal and temporal) neuritic plaques ($r=-0.72$, $p<.001$), and neurofibrillary tangles ($r=-0.47$, $p<.05$), but not diffuse plaques ($p=.24$). Similar correlations were seen with the MMSE. The value of this research lies in the longitudinal design, high rate of clinical follow-up and brain autopsy, and procurement of both cases and controls from a single cohort. Supported by NIA, AG10161.

829.8

ENTORHINAL CORTEX BETA AMYLOID LOAD AND ITS RELATION TO COGNITIVE FUNCTION IN MEMBERS OF THE RELIGIOUS STUDY E-Y. Chen*, E. J. Cochran, D. A. Bennett, L.A. Beckett, R.S. Wilson, S. Jaffar, J.H. Kordower and E.J. Mufson, Rush Alzheimer's Disease Research Ctr, Rush Presbyterian-St. Luke's Medical Ctr, Chicago, IL 60612.

Amyloid is a major component of senile plaques and is thought to be central to the pathology of Alzheimer's disease (AD). However, whether amyloid deposition in senile plaques correlates well with cognitive function in aged humans and those with AD remains unresolved. Nineteen people with an average age of 82 yrs came to autopsy from a cohort of 570 people enrolled in the Religious Study. All individuals were cognitively tested within 12 months of death (average MMSE of 25.6). Twenty-one cognitive tests were converted to z-scores and averaged to provide a global measure of cognitive function. Clinically, 6 subjects had dementia, 5 of whom had probable AD and 13 did not have dementia. A computer based quantitative system evaluated the cross sectional area of the entorhinal cortex occupied by ß-amyloid immunoreactive deposition. Higher ß-amyloid load was significantly correlated with lower global cognitive function at the most recent pre-mortem evaluation (rank correlation = -0.47, $p=0.04$). There was a trend for greater ß-amyloid load to be associated with lower MMSE at most recent clinical evaluation (rank correlation = -0.39, $p=0.095$). ß-amyloid load was not correlated with age at death, post mortem interval, clinical diagnosis of dementia or AD. Eight of the 19 subjects had at least one ApoE e4 allele, which was not significantly related to ß-amyloid load ($p=.13$, Wilcoxon rank sum test). Supported by AG10668, AG10161 and AG09466.

829.9

NEUROFIBRILLARY DEGENERATION IN THE TEMPORAL CORTEX: RELATION TO COGNITIVE FUNCTION IN MEMBERS OF THE RELIGIOUS STUDY E.J.Cochran*, D.A.Bennett, R.Joglekar, L.A.Beckett, R.S.Wilson, M.Nainys, J.H.Kordower, E.J.Mufson Rush Alzheimer's Dis. Ctr., Rush Medical Center, Chicago, IL 60612.

Braak and Braak have developed a staging system of Alzheimer's-related morphological changes based upon patterns of neurofibrillary tangle (NFT) and neuropil thread (NT) changes in the brain at autopsy. Correlation of these changes with cognitive function in Alzheimer's Disease (AD) and elderly non-demented individuals is limited. Nineteen people (mean age of 82 yrs) came to autopsy from a cohort of 570 people enrolled in the Religious Study. All individuals were cognitively tested within 12 months prior to death (mean MMSE of 25.6). Twenty-one cognitive tests were converted to z-scores and averaged to provide a global measure of cognitive function. A semiquantitative analysis of PHF-1 immunostained NFT and NT within the hippocampus, entorhinal cortex, subicular complex, and temporal neocortex was rated according to Braak stages (I-VI: indicating increasing deposition of NFT and NT). Clinically, six subjects had dementia, five of whom had probable AD, and 13 did not have dementia. A higher Braak Stage was significantly correlated with lower global cognitive function at last evaluation prior to death (rank correlation=-0.58, p=0.009). Braak staging showed a significant association with clinical diagnosis of dementia ($p<0.01$) and AD ($p<0.05$), and a borderline significant association with MMSE at most recent clinical evaluation (rank correlation=-0.454, p=0.051). Older age at death was also associated with higher Braak stage (rank correlation=-0.50, p=0.02). Eight of the 19 people had one ApoE e4 allele; Braak stages did not differ significantly from those lacking an ApoE e4 allele. Support: AG10668, AG10161, and AG09466.

DIVIDED ATTENTION DURING MOVEMENT IN DEMENTIA OF THE ALZHEIMER TYPE (DAT). V. Diggles-Buckles*, E. Raub J.C. Morris,. Alzheimer's Disease Research Center, Washington University School of Medicine, MO, 63110.

The costs of movement on attention resources is not known in DAT, and in general is underappreciated, although such costs are directly relevant for tasks with a motor component such as driving. Attention deficits in subjects with DAT have been documented within and between the visual and auditory modalities, reporting attentional costs of dual task processing over single task processing between 28 and 50% depending on the modality and complexity of the secondary task. Similar findings are reported in the elderly controls (17%-50%). The present experiment used dual task methodology to assess the attention demands of movement on a secondary probe reaction time task. Ten healthy controls (no dementia), 8 very mildly demented and 7 mildly demented subjects with DAT performed a primary task of prehension (reaching, grasping, and transporting a cylinder to a target in response to a "go" signal) while monitoring a secondary task of tone detection requiring a verbal response(probe). Subjects were screened for motor or sensory disorders. The probe tones were presented on 16 of the 50 trials of the primary prehension task randomly within an interval following the primary 'go' tone. Reaction times (RTs) to these tones were compared to baseline RTs collected prior to the dual task. Results showed that the attentional costs (probe RT minus baseline RT) of moving were significantly higher in the demented groups than in the controls. The cost was 66% of baseline for controls, 100% for very mildly demented, and 150% for the mildly demented group. Movement places great demands on already limited attentional resources in DAT, suggesting caution in motor tasks with risk, e.g. driving. This research was supported by AG05681.

FAST FOURIER TRANSFORM METHOD AND FRACTAL ANALYSIS OF HORIZONTAL MINIATURE EYE MOVEMENT IN ALZHEIMER'S DISEASE S. Hayashi*, M. Fujii, S. Murakami, N. Nakano, K. Utsumi, Y. Hatakeyama, R. Fukatsu, and N. Takahata.
Dept. of Neuropsychiatry, Sch. of Med., Sapporo Medical Univ., Sapporo, Japan 060

It is well known that visuospatial dysfunctions appear in patients suffering Alzheimer's disease (AD) from an early stage of the disease. We have carried out analysis of eye movement during the constructional performance of AD patients, and reported that the eye movements observed were similar to the abnormal eye movements seen in Bálint's syndrome. These disorganized eye movements may be involved in higher visual information processing abnormalities, visual-inattention, visual-memory and visual-language dysfunction.

On the other hand ,miniature eye movements are assumed to be essential for obtaining visual cognition, and chaotic in nature. We then carried out fractal analysis of the miniature eye movements. These results showed that abnormal findings are characteristic of the patients with AD .

Miniature eye movements were detected by binocular eye movement analyzer (Takei Co.LTD.). And we carried out mathematical analysis including fast fourier transform (FFT) method and correlation function distance dependence, the results of tests carried out on the patients with AD, vascular dementia patients and healthy subjects, by using the analytical software program.

These results show that the patients with AD were different for healthy subjects and vascular dementia patients. and the results of these mathematical analyses did show that vascular dementia patients and elderly healthy subjects were similar. The physiological implications of these phenomena remained unclear, but recent advances in visual cognitive science have gradually shed light on possible roles underlying these chaotic phenomena. Thus,the results of this analysis are thought to be useful in the differential diagnosis of vascular dementia and Alzheimer's disease. It is thought that the difference in the analytical results for these two diseases may also reflect the difference in the nature of the recognition deficit between vascular dementia and Alzheimer's disease.

829.12

VISUAL SPATIAL COGNITION TO DEPTH DIRECTION IN ALZHEIMER'S DISEASE:RECORDING BINOCULAR EYE MOVEMENT. S.Murakami*, M.Fujii, S.Hayashi, K.Uomori[1], R.Fukatsu, N.Nakano, M.Yamada[2], K.Utsumi and N.Takahata Dep. of Neuropsychiatry, Sch. of Medicine, Sapporo Medical Univ., Sapporo 060, Japan, 1) Matsushita Electric Ind. Central Res.Labo. Soraku-gun,Kyoto 619-02,Japan and 2) NHK Science and Technical Research Labo. Setagaya-ku, Tokyo 157,Japan

A patient with Alzheimer's disease(AD) has visual spatial impairment as one of the typical clinical signs. However, visual spatial cognition to depth direction was not revealed in AD and we studied it by recording binocular eye movement and vergence angle using Vision Analyzer(Takei Co.LTD) with nine patients with AD (5 stage I and 4 stage II:Sjogren classification, 52-66years), three multi infarction dementia patients(60-72 years) and thirteen normal subjects(8-75 years). These subjects were requested to gaze the non-moving targets under binocular stimulated condition(BS) which was the binocular gazing the targets located at the near and far positions and lit alternatively in normal visual field, and under monocular stimulated condition(MS) which was the visual stimuli to only one eye for gazing the targets in the hemivisual field divided into right and left by a thin board. And the other task was to gaze the moving target toward depth direction. In results of the AD patients under BS and MS with non-moving targets, the vergence is limited and the change of the convergence angle is small, unstable and the both eyes do not move and do not make a vergence angle. These results are different from other subjects but the results of gazing the moving target is almost same in AD and other subjects. These suggest that the visual spatial cognition to depth direction of AD patient is impair and it is not due to the eye movement disorder but due to the impairment of the neural function to make three dimension space image from binocular visual information .

CLOSING IN PHENOMENON IN ALZHEIMER'S DISEASE -ANALYSIS BY EYE MOVEMENT AND PATHOPHYSIOLOGY-

MITSURU FUJII,SHINJI MURAKAMI,NORIHITO NAKANO,KUMIKO UTSUMI, YUKI MIDORIKAWA,YOSHIHISA HATAKEYAMA,RYO FUKATSU,NAOHIKO TAKAHATA Department of Neuropsychiatry,Sapporo Medical University School of Medicine

Closing in phenomenon is one of the constructional apraxia often observed in the patient with Alzheimer's disease. However,little is known about the nature of the phenomenon and pathophysiology underlying the phenomenon.To know the nature of the phenomenon and pathophysiology,we examined drawing behavior,eye movement of AD(n=10) of an early onset,multi-infarct dementia(MID)(n=5) and age matched healthy ccontrol subjects(n=8). The results were as follows:In AD,contrary to age matched healthy subjects and MID,the patients' drowing behabior was disorganized and the copied figures were incomplete and often fragmented.Their eye movements were characteristic modes in which there were eye movements similar to Balint's syndrom. W reported the mechanism of praxic and gnostic behabior in AD(1995).That crucial point, through eye movement experiments,may exist in failing to make object-centered coordinate axis . This, in other words,suggest that AD fails to connect original figure with copied figure.Other subjects, as we are so,recognize the original and copied figures by collecting the image through various projective transform. But AD looks like putting into forming a connection two figures. Appearence of closing in phenomenon in AD ,at the same time,may imply disorganization of object's independence and singleness named "in sich reflektieren"(Hegel). We reported the importance of naming ability to objects in AD. AD shows constructional disabilities even in early stage,but can construct some figures by verbal instruction.This suggests that verbal dysfunction may play an important roll in" in sich reflektieren "and closing in phenomenon.

829.14

TESTS OF OCCIPITAL LOBE FUNCTION PREFERENTIALLY PREDICT THE DENSITY OF OCCIPITAL LOBE PATHOLOGY IN AD. K. A. Nielson*, W. R. Shankle, and C. W. Cotman. Institute for Brain Aging and Dementia, University of California, Irvine, CA 92717-4540.

Defining the relationship between regional AD neuropathology and cognitive decline could elucidate the pathogenesis of AD, and provide progressive indices of the underlying pathology in the living patient. Since sensory regions show neuropathology only late in the disease, they may be useful for defining structure-function relationships. Therefore, we compared performance on a variety of cognitive tests, including visual tests, with occipital cortex neuropathology.

Sixteen confirmed AD cases who were cognitively assessed shortly before death were studied. Occipital (area 18) and frontal cortices (area 9) were examined by immunocytochemistry and computer-based imaging for early-stage tau pathology (AT8) and ß-amyloid protein (ß42). The cognitive tests included the MMSE, delayed memory, vocabulary, reasoning, naming, verbal fluency, digit span, and three visually mediated tests: figure copying, stereopsis, and color vision. Since the tests were highly intercorrelated, a factor analysis was performed which produced two factors. Factor 1 loaded on all except the three visual tests (65% variance). Factor 2 loaded on just the visual tests (19% variance). Factor 1 was not a significant predictor for any of the pathology measures, though it neared significance for ß42 "load" in frontal cortex ($R = .472$, $R2 = .223$, $p = .065$). Factor 2 was a significant predictor specifically for AT8 "load" in area 18 ($R = .829$, $R2 = .686$, $p < .0001$).

Thus, visually mediated task performance is a good predictor of the underlying neuritic pathology in occipital cortex. Notably, ß-amyloid deposition was already quite extensive in occipital cortex in the majority of cases, and ß-amyloid correlated best with global dementia severity, rather than with performance on specific cognitive tests. Therefore, this study demonstrates clear links between a) occipital cortex integrity and functioning, and b) neuritic pathology and impaired cognitive performance in AD. CONTRAST SENSITIVITY AND FACE DISCRIMINATION IN ALZHEIMER'S DISEASE. A. Brown, T. Dunne, K. Jain, M. Cronin-Golomb, and A. Cronin-Golomb*. Department of Psychology, Boston University, Boston MA 02215 and Electro-Optics Technology Center, Tufts University, Medford MA 02155.

Face discrimination depends on information at low spatial frequencies expressed in cycles/face (cpf). Individuals with Alzheimer's disease (AD) are impaired at the discrimination and recognition of faces. One possible source of this impairment is the decline in contrast sensitivity, expressed in cycles/degree (cpd), seen throughout the spatial frequency range in AD. One way to test this hypothesis is to present face stimuli that have been image-enhanced by computer at low cpf. However, nonlinear crosstalk in the interactions of the various frequencies in the image processing algorithm and in the visual system complicate interpretation of data from such tests. To overcome this problem, we developed a test that uses the natural cpd filter response of the visual system to enhance the perception of faces at specific cpf. Faces from the Benton Facial Recognition Test were presented at various sizes to selectively enhance different cpf. Enlarging *(reducing)* the stimulus brought the high *(low)* cpf to peak cpd response. The visual filter was calibrated using Vistech contrast sensitivity charts. Preliminary data from 13 young adults, 4 elderly adults, and 2 individuals with AD indicated a relatively specific response of the AD patients to selective cpf enhancement. The results suggest that contrast sensitivity abnormalities in AD, which presumably reflect neuropathological changes in visual cortex, may be associated with impairments in face discrimination.

A DOUBLE DISSOCIATION BETWEEN THE EFFECT OF NUMBER OF LEARNING TRIALS ON THE EARLY DETECTION OF ALZHEIMER DEMENTIA IN PATIENTS WITH HIGHER VERSUS LOWER EDUCATIONAL LEVELS. R. F. Zec*, S. Markwell, K. Vost, M. Ward, R. Elble, and D. McManus. Center for Alzheimer Disease and Related Disorders, Southern Illinois Univ. School of Med., Springfield, IL. 62794

A five- versus eight-trial version of the Rey Auditory Verbal Learning Test (RAVLT) was compared in terms of ability to discriminate patients with early Alzheimer dementia (N=44; Folstein MMSE scores >23) from the normal elderly (N=447) as a function of educational level. A double dissociation was found in which the five-trial version was superior in discriminating early AD patients from the normal elderly in subjects with greater than 12 years education, whereas the eight-trial version was superior in discriminating these two groups in subjects with less than or equal to 12 years of education. The overall percentage of correct classifications using the optimal cutting scores on the 5 minute delayed recall following the 5 versus 8 trial versions of the RAVLT were 86% and 92.25% (a difference of 6 percentage points favoring the 8 trial version) for subjects with less than or equal to 12 years of education, whereas the classification rates for subjects with greater than 12 years of education were 96.25 and 84.25 (a difference of 12 percentage points favoring the 5 trial version). There was a difference of 12.2 percentage points favoring the 8th versus 5th learning trial for the less than 12 years education group. There was a difference of 16 percentage points favoring the 5 trial version for the 5-minute delayed recognition memory measure for subjects with greater than 12 years education, but no advantage favoring the 5 trial version for subjects with less than or equal to 12 years of education. This study demonstrates that educational level not only affects what are the optimal cutting scores for differentiating early Alzheimer patients from the normal elderly but it also affects which test measures produce an optimal differentiation.

METRIFONATE IMPROVES SPATIAL NAVIGATION IN YOUNG SCOPOLAMINE-TREATED, MEDIAL SEPTUM-LESIONED AND AGED RATS. P. Riekkinen Jr.[1]*, B. Schmidt[2], and M. Riekkinen[1]. [1]Department of Neurology, University of Kuopio, P.O.Box 1627, FIN-70211 Kuopio, Finland. [2]Institute for Neurobiology, Troponwerke, Köln, Germany.

We investigated the effects of acute per oral (po.) pretraining treatment with an indirect acetylcholinesterase inhibitor, metrifonate, on water maze spatial navigation and passive avoidance behavior. Metrifonate (10-100 mg/kg, po.) did not improve water maze or passive avoidance performance of young intact rats. Contrary, in young rats metrifonate at a broad dose range (10-100 mg/kg, po.) alleviated scopolamine (a muscarinic acetylcholine receptor antagonist; 0.4 and 2.0 mg/kg in water maze and passive avoidance study, respectively) treatment- and medial septal lesion-induced spatial reference and working memory failure and passive avoidance performance defect. In old (23-month-old) rats a defect of water maze and passive avoidance behavior was observed. In old rats metrifonate improved water maze spatial reference memory function and passive avoidance at 10-30 mg/kg, but the lowest (3 mg/kg) dose was ineffective. Very old (27-month-old) rats were more severely impaired in water maze than old rats, and metrifonate 3-30 mg/kg did not improve the spatial navigation performance of very old rats. These results show that metrifonate may at a broad range of doses stimulate cognitive functioning, but during advenced aging neurobiological defects develop that may mask some of the therapeutic effects of metrifonate in rats.

Supported by Troponwerke, Köln, Germany.

A CHOLINESTERASE INHIBITOR, METRIFONATE, DESYNCHRONIZES NEOCORTICAL EEG ACTIVITY IN RATS. P. Jäkälä[1]*, B. Schmidt[2], M. Björklund[1], M. Riekkinen[1], E. Koivisto[1] and P. Riekkinen Jr.[1]. [1]Department of Neurology, University of Kuopio, FIN-70211, Finland. [2]Institute for Neurobiology, Troponwerke, Köln, Germany.

The present study investigated the efficacy of a cholinesterase inhibitor, metrifonate, to desynchronize cortical EEG activity in muscarinic acetylcholine receptor antagonist (scopolamine 0.2 mg/kg, i.p.) treated and nucleus basalis (NB)-lesioned young rats and in aged rats. In young (10, 30 and 60 mg/kg, p.o.) and aged (3, 10, 30 and 60 mg/kg, p.o.) rats metrifonate dose-dependently suppressed spontaneously occurring waking-immobility related high-voltage spindling (HVS) activity occurring during low levels of arousal. Scopolamine increased neocortical slow waves and 1-20 Hz sum amplitude values. Metrifonate (10, 30 and 100 mg/kg, p.o.) fully and THA (3 and 6 mg/kg, i.p.) only partially restored normal EEG activity. Quisqualic acid NB lesions decreased frontal cortical choline acetyltransferase activity by 80 % and increased cortical EEG slow waves. Metrifonate (30 and 100 mg/kg, p.o.) and THA (3 and 6 mg/kg, i.p.) were not able to reverse the NB lesion-induced EEG abnormality. These data suggest that metrifonate may enhance the activity of cholinergic synapses on the afferents from nucleus basalis and hence have therapeutic potential for the treatment of Alzheimer's disease.

Supported by Troponwerke, Köln, Germany.

COMBINED TREATMENT WITH TACRINE AND THE MUSCARINIC AGONIST CI-979 (RU 35 926) REVERSES A SCOPOLAMINE-INDUCED IMPAIRMENT OF SUSTAINED ATTENTION IN RHESUS MONKEYS. M. J. Callahan*. Parke-Davis Pharm. Res., Div. of Warner-Lambert Co., Ann Arbor, MI 48105.

Pharmacologic blockade of postsynaptic muscarinic receptors interferes with cognitive function. The muscarinic receptor antagonist scopolamine impairs various aspects of memory including selective attention. The role of an intrinsic attentional deficit in Alzheimer's disease and the muscarinic cholinergic contribution to this deficit may be important in developing appropriate therapy. In this study, test-experienced rhesus monkeys with established baseline performance were used. Responses on a continuous performance task were measured using a microcomputer-controlled test environment. Animals were rewarded for responding to a target object displayed on the screen of a touch-sensitive color television monitor (CRT). Display of the target object on the CRT was randomized with respect to time and spatial location. Scopolamine (0.003-0.01 mg/kg, IM) produced a dose-dependent decrease in responses which persisted 2 hrs after dosing. Tacrine (0.03-1.0 mg/kg, IM) given 60 min after scopolamine and 30 min before testing, reversed the performance impairment produced by scopolamine in a dose-dependent manner. CI-979 (0.001-0.01 mg/kg, IM) given similarly also improved performance in a dose-dependent manner. Given in combination, tacrine and CI-979 reversed the scopolamine-induced impairment at lower doses and across a broader range of doses than with either drug alone. In addition, the appearance of adverse events was not significantly potentiated by combination treatment. These data suggest that combining low doses of tacrine and CI-979 can reverse the behavioral effects of muscarinic blockade as effectively as higher doses of either compound alone. Supported by Warner-Lambert.

INTRACEREBELLAR INJECTION OF BACTERIAL LIPOPOLYSACCHARIDE INCREASES EXTRACELLULAR cGMP IN RATS THROUGH INOS A.D. Ramirez, J.P. Holland, B.G. Sahagan, R.B. Nelson and L.O. Wilkinson* Pfizer Central Research, Groton, CT 06340

Nitric oxide (NO) is a major messenger molecule used by cells of the immune and nervous systems, and endothelial cells. NO readily diffuses across cell membranes where it activates guanylyl cyclase and increases cGMP levels. The bacterial endotoxin LPS has been shown to activate the inducible form of the enzyme (iNOS) *in vitro*. We examined the effect of LPS infusion on extracellular cGMP and expression of iNOS and nNOS mRNAs in rat cerebellum. LPS produced a marked and sustained increase in extracellular cGMP levels, reaching a maximal effect at 7 hrs post injection (LPS: 1.484 + 0.3 pmol/ml, saline: 0.175 + 0.9 pmol/ml). This effect was markedly attenuated by perfusion of the dialysis probe (500 uM) with the NOS inhibitor nitro-L-arginine and by preadministration of the antiinflammatory steroid dexamethasone (10 mg/kg p.o. 30 min pre-LPS). NOS mRNA levels were measured by the ribonuclease protection assay using iNOS and nNOS specific riboprobes. Compared to saline, LPS resulted in a 6-7 fold increase in cerebellar iNOS mRNA. As expected after dexamethasone pretreatment, the increase in iNOS mRNA was no longer evident. No significant elevation in nNOS mRNA was measured following LPS treatment. LPS is known to generate toxic levels of glutamate which could increase cGMP levels through activation of NMDA receptors, but administration of the NMDA antagonist MK-801 (0.3 mg/kg s.c.) had no effect. These data suggest that the increase in cGMP efflux produced by intracerebellar infusions of LPS reflects NO production through iNOS activation.

WAL 2014 FU: MUSCARINIC RECEPTOR BINDING AND ACTIVATION OF HUMAN MUSCARINIC RECEPTORS EXPRESSED IN CHO CELLS. R. Hammer*, K.D.Mendla, G.Speck and H.A.Ensinger, Dept. Research and Dept Biological Research, Boehringer Ingelheim KG, 55216 Ingelheim, Germany

In Alzheimer's disease there is a deficit in cholinergic neurotransmission which might be overcome by therapy with M1 selective muscarinic agonists.

Muscarinic receptor binding with WAL 2014 FU and reference compounds has been carried out in rat tissue membrane preparations (M1, M2 and M3).WAL 2014 FU shows similar binding affinity for M1 (hippocampus,[^{3}H]Pz) K_i=6.6±1.1µM and for M2 (heart,[^{3}H]NMS) K_i=6.6±1.4µM and a 5fold weaker affinity for M3 (lacrimal gland,[^{3}H]NMS) K_i=29.6±6.6µM. Using homogenates from transfected CHO cells the affinities of WAL 2014 FU have been determined as K_i=25.5±5.4µM(hm1), 7.1± 3.7µM(hm2), 34.0±11.2µM(hm3), 17.0±5.2µM(hm4) and 16.8±8.1µM(hm5), respectively. In comparison data of several muscarinic agonists as reference have been determined.

The functional efficacy in vitro at hm1, hm2 and hm3 receptor subtypes expressed in CHO cells have been investigated in comparison to carbachol and MCN-A-343 by using the cytosensor technology.Thus, the proton outflow after stimulation with the respective agonist has been measured. WAL 2014 FU demonstrates at hm1 subtype a high degree of intrinsic activity with 66.4% as compared to carbachol (100%) and only a very low intrinsic activity at hm3 receptors (18.5%). In hm2 expressing CHO cells no stimulation of the proton outflow could be detected indicating very little if any efficacy in this model. After using forskolin as a stimulator of adenylate cyclase in CHO-hm2 cells no agonistic effect could be registered as well.

Furthermore, WAL 2014 FU stimulated α-secretion of APP (amyloid precursor protein) in hm1 receptor-expressing human astrocytoma cells with about the same efficacy as the full agonist carbachol.

ESTRADIOL PROTECTS AGAINST AMYLOID-INDUCED TOXICITY IN SK-N-SH CELLS. K. E. Gridley*, P. S. Green and J. W. Simpkins. Department of Pharmacodynamics and the Center for Neurobiology of Aging, University of Florida, Gainesville, Fl 32610

Estrogen-replacement therapy has been associated with a reduced incidence of Alzheimer's disease (AD) and improved cognition in several small, open clinical trials. In the present study, we assessed the possibility that estrogens may reduce toxicity of ß-amyloid by testing the effects 17 ß-estradiol on the neurotoxic fragment of ß-amyloid (Aß 25-35) in SK-N-SH neuroblastoma cells *in vitro*. Aß 25-35 caused a dose-dependent death in SK-N-SH cells with a LD_{50} of 28.9 µM. In cultures exposed simultaneously to 20 µM Aß and 17 ß-estradiol (2 nM), Aß-induced toxicity was reduced after 96 hours by 83 and 51 % in two studies. Further studies show that the 0.2 nM 17 ß-estradiol concentration was as effective as the 2 nM concentration, demonstrating neuroprotection at physiologically relevant doses. Time-course evaluations of the neuroprotective effects of 17 ß-estradiol revealed reductions in Aß toxicity by 43%, 87%, 96%, and 71%, at the 24, 48, 72, and 96 h time points, respectively. This reduced Aß toxicity by 17 ß-estradiol was associated with concomitant reductions in Aß-induced formation of thiobarbituric acid reactive products by 50%, 83%, 94%, and 66%, respectively. These data suggest that estrogens reduce Aß-induced lipid peroxidation, thus supporting the hypothesis that estrogens serve to reduce the oxidative toxicity of ß-amyloid and providing a possible explanation for the observed beneficial effects of estrogens in AD. Supported by NIH AG 10485.

PHENOLIC A RING REQUIREMENT FOR THE NEUROPROTECTIVE EFFECTS OF STEROIDS. P. S. Green[1], K. Gordon[2] and J. W. Simpkins[1*]. [1]Center for the Neurobiology of Aging and Department of Pharmacodynamics, College of Pharmacy, University of Florida, Gainesville, FL 32610. [2] Apollo Genetics, Inc., Cambridge, MA 02142.

Estrogens are reported to reduce the incidence of Alzheimer's disease and 3,17ß-estradiol, the potent, naturally occuring estrogen, exerts neuroprotective effects in a variety of *in vivo* and *in vitro* model systems. The present study was conducted to determine the structural requirements of steroids and related compounds for neuroprotectivity. A phenolic A ring and at least 3 rings of the steroid structure are required for their neuroprotectivity in an *in vitro* system. Meeting this requirement are the 18-carbon estratrienes; 3,17ß-estradiol, 3,17α-estradiol, 1,3,5(10)-estratriene-3-ol, 1, 3,5(10) estra-2,3,17ß-triol, estrone, estriol and 17α-ethynyl-3,17ß-estradiol. The phenolic A ring hydroxyl group is particularly important as demonstrated by the inactivity of all 3-O-methyl ether cogeners tested. The diphenolic estrogen mimic, diethylstilbesterol (DES), was as neuroprotective as 17ß-estradiol. Retention of a single hydroxyl function on DES was sufficient to retain most neuroprotective activity, whereas the di-O-methyl ether of DES was inactive. Phenol and tetrahydronaphthol representing the phenolic A and AB ring of the steroid structure, respectively, did not show neuroprotection. The following steroids lack a phenolic A ring and were also inactive: the 19-carbon androgens, testosterone and dihydrotestosterone; the 21-carbon steroids, progesterone, corticosterone, aldosterone, prednisolone and 6 α-methylprednisolone; and the 27-carbon cholesterol. These results suggest that a phenol in the A ring of a steroid nucleus is necessary for the neuroprotective activity of steroids. Supported by NIH AG 10485 and Apollo Genetics, Inc.

THE RAPID NEUROTOXIC EFFECTS OF APOLIPOPROTEIN E (APOE) PEPTIDES DEPEND ON FREE RADICAL FORMATION. Eric Gruenstein* and Xiaoshu Wang, Dept. of Molecular Genetics, Biochemistry & Microbiology and The Neuroscience Graduate Program, University of Cincinnati, Medical School, Cincinnati, OH 45267.

ApoE has been implicated in the pathogenesis of Alzheimer's disease and peptides corresponding to its receptor binding domain cause neurite degeneration in chick ganglion explants as well as cytostatic/cytotoxic effects in lymphocytes. In the work reported here we have used a dimer of one of these peptides ($E_{(141\text{-}149)2}$) to examine neuronal function and viability in dissociated rat cortical neurons. After 10 days in vitro these cells form clusters which display synchronized, synaptically driven calcium oscillations. We found that the apoE peptide suppressed these oscillations in a dose dependent manner. At higher concentrations the inhibition was followed by a sustained calcium rise to which both extracellular and intracellular calcium stores contributed. We also found that the ability of apoE peptide to inhibit calcium oscillations was dependent on exposure of the cells to the 485 nM blue light (BL_{485}) which we used to measure cytoplasmic Ca^{2+} with the dye fluo-3. At low concentrations of apoE, brief exposure to BL_{485} caused a rapid but reversible reduction in both the frequency and amplitude of calcium oscillations, an effect that was not observed with either peptide alone or light alone. At higher concentrations of apoE, BL_{485} illumination led to an irreversible inhibition of oscillations. In parallel with these effects on calcium oscillations, we found that brief BL_{485} illumination at low apoE concentrations led to substantial neurite degeneration while the same illumination at higher concentrations of apoE caused neuronal death. Both neurite degeneration and cell death occurred within 30 minutes of treatment, and neither effect was seen in cultures treated with BL_{485} alone or with apoE alone. Additional studies using the peroxide sensitive dye dichlorofluorescin showed that BL_{485} generates reactive oxygen species (ROS), suggesting a role for ROS in the toxic effects. Furthermore, addition of catalase to the extracellular buffer reduced the neurotoxicity. Taken together, these data suggest that apoE may exert its neurotoxic effects via a pathway involving the generation of ROS along with an associated disruption of calcium homeostasis.

10,10-BIS(4-PYRIDINYLMETHYL)-9(10H)-ANTHRACENONE (XE991) AND 10,10-BIS(2-FLUORO-4-PYRIDINYLMETHYL)-9(10H)-ANTRACENONE (XR543), POTENT NEUROTRANSMITTER RELEASE ENANCERS: COMPARISON TO LINOPIRDINE. R. Zaczek, R.J. Chorvat, M.E. Marynowski*, C. M. Maciag, A.R. Logue, B.N. Fisher, R.A. Earl. The Du Pont Merck Research Laboratories., Wilmington, Delaware.

Linopirdine (3,3-bis (4-pyridinylmethyl)-1-phenylindolin-2-one, DUP 996) is a compound which has been shown to increase the performance of laboratory animals in a number of behavioral paradigms used to assess learning and memory. These effects appear to be mediated through the enhancement of the release of acetylcholine (ACh) as well as several other neurotransmitters. We have recently identified functional analogs of linopirdine based upon an anthracenone backbone. These compounds 10,10-Bis(4-pyridinylmethyl)-9(10H)-anthracenone (XE991) and 10,10-Bis(2-fluoro-4-pyridinylmethyl)-9(10H)-anthracenone (XR543) are superior to linopirdine in *in vitro* potencies. While linopirdine possesses an EC50 of 4.5 µM to enhance the release of ACh, XE991 and XR543 have EC50s of 450nM and 830 nM, respectively. Both compounds are also more potent than linopirdine in enhancing ACh release *in vivo*. While 5 mg/kg linopirdine leads to a marginal and short lasting (20 min) 50 % increase in hippocampal extracellular ACh levels, 5 mg/kg XE991 leads to statistically significant increases (maximal effect > 90% over baseline) that are observed for 60 minutes. XR543, a fluorinated analog of XE991, at 1 mg/kg causes greater than a 100% increase in ACh levels and the effect of the compound lasts over 3 hours. These results suggest that XE991 and XR543 may prove to be superior to linopirdine as AD therapeutics and as tools for preclinical studies on the control of neurotransmitter release.

830.10

EFFECTS OF THE NEUROTRANSMITTER RELEASE ENHANCERS (NTR) LINOPIRDINE (L) AND XR543 (X) AND TACRINE (T) ON A SCOPOLAMINE (S)-INDUCED DEFICIT IN AN FI/FR FOOD REWARD PARADIGM AND M-SEPTAL LESION-INDUCED DEFICIT IN A WATER MAZE IN RATS. W. J. Keim, R. Zaczek*, K. R. Spencer, K. W. Rohrbach. Central Nervous System Diseases Research, The DuPont Merck Pharmaceutical Company, Wilmington DE 19880-0400.

The NTR L has demonstrated activity in a number of behavioral paradigms consistent with enhanced learning and memory and reversal of deficits in learning and memory (Cook et al., 1990; Brioni et al., 1993). The compounds L, X and T were studied in a Fixed Interval 60 sec/Fixed Ratio 30 schedule of food reinforcement in rats both alone and with a S-induced deficit. X and T were also studied in m-septal lesioned rats in a water maze. X decreased rates of responding in the FR portion of the schedule at 0.3 mg/kg po and decreased rates of responding in both the FR and FI portions of the schedule at 1.0 mg/kg po. S, 0.8 mg/kg ip decreased responding in the FR portion of the schedule to approximately 50% of control. S had no effect on the FI portion of the schedule. X, L and T reversed the S-induced deficit at .03, 0.1 and 0.3 mg/kg po respectively. At higher doses, all three compounds further decreased response rates in FR and decreased response rates in FI. In the water maze, X reversed the lesion-induced deficit at .03 and 0.1 mg/kg po. and T reversed the deficit at 0.3, 1.0 and 3.0 mg/kg po. These results show that the bell shaped curve typically seen with drugs that enhance learning and memory is due to non-specific impairments in performance at higher doses and are consistent with the interpretation that the neurotransmitter release enhancers reverse cholinergic deficits in experimental animals.

830.11

GALANIN RECEPTORS IN HUMAN BASAL FOREBRAIN AND NEOCORTEX: DISTRIBUTION AND PHARMACOLOGICAL CHARACTERIZATION. M. Basile*, J.K. Staley[1], D.C. Mash[1], and E.J. Mufson.[2] [1]Dept. Neurology, University of Miami Sch. Med., Miami, FL. [2]Dept. Neurological Sciences, Rush Presbyterian Med. Ctr. Chicago, IL.

Galaninergic fibers which innervate cholinergic-containing basal forebrain neurons (CBF) hypertrophies and hyperinnervates remaining CBF neurons in Alzheimer's Disease (AD). It also been suggested that galanin (GAL) plays a critical role in the modulation of cholinergic neurotransmission. Although many studies have evaluated the localization and regional expression of GAL immunoreactivity, less is known about the GAL receptor in human brain. The present study used *in vitro* receptor autoradiography to visualize the localization of GAL receptors in human basal forebrain and entorhinal cortex. The binding parameters for [^{125}I]GAL binding were determined in the nucleus basalis and entorhinal cortex by saturation binding analysis. High densities of GAL receptors were visualized within the medial septal nucleus (Ch1), the vertical limb nucleus of the diagonal band (Ch2), and throughout the nucleus basalis (Ch4). In addition to the cell body fields, GAL receptors were elevated over the entorhinal cortex. Rosenthal plots were curvilinear in both the nucleus basalis and entorhinal cortex with high and low affinity constants of 0.22 ± 0.05 nM and 18.7 ± 3.6 nM. The Bmax values corresponding to the high and low affinity sites in the entorhinal cortex were 0.58 ± 0.03 and 5.8 ± 2.2 pmol/g respectively and in the basal forebrain were 3.9 ± 0.5 and 5.0 ± 2.6 pmol/g respectively. The biphasic nature of [^{125}I]GAL binding may represent binding to multiple subtypes or affinity states of GAL receptors Studies are underway to evaluate the distribution and status of GAL receptors in Alzheimer's disease. Supported by AG 10668, AG 10161 and AG 09466.

ALZHEIMER'S DISEASE: BIOCHEMISTRY

831.1

MASS SPECTROMETRY AND NMR CHARACTERIZATION OF THE GLYCOLIPID ASSOCIATED WITH ALZHEIMER PAIRED HELICAL FILAMENTS, W. J. Goux, S. Rodriguez, D. R. Sparkman and C. J. Fredrickson*, Depts. of Chem. and Human Dev., Univ. of Texas at Dallas, Richardson, TX 75083

In the present study, gas chromatography/mass spectrometry (GC/MS) assisted carbohydrate linkage-analysis, one and two-dimensional NMR and matrix-assisted laser desorption/ionization time of flight mass spectroscopy (MALDI-MS) have been used to characterize the structure of the glycolipid associated with the paired helical filaments (PHF) isolated from Alzheimer diseased brain. The ^{1}H NMR spectrum of acid hydrolyzed protein resistant core PHF displays resonances which can be assigned to fatty acid and glucose. There are no resonances present which would indicate the presence of protein, amino acids or a sphingosine base. Using two-dimensional homonuclear NMR experiments, resonances in the ^{1}H and ^{13}C NMR spectrum of native PHF were assigned to a nonreducing terminal α-1,6-glycosidically linked glucose, an internal α-1,6-linked glucose and a terminal α-1,2,6-linked glucose. GC/MS linkage analysis confirmed the presence of residues in a molar ratio of 2:1:1. Three components of the PHF associated glycolipid fraction having masses 2416, 2325 and 2237 Da were observed using the MALDI-MS. The heavier, least abundant mass component (2416 Da) was best fit to a structure with a tridecamer of glucose having a single esterified C_{20} fatty acid while the more abundant lower mass components were best fit to noncovalently associated glycolipid dimers, each with a glucose pentamer or hexamer having two C_{14}, C_{16} or C_{18} esterified fatty acids. The ratio of glucose to fatty acid calculated from these best fit structures of the more abundant mass components (5.5:1) is in reasonable agreement with the same ratio calculated from peak integrations in the NMR spectra of acid hydrolyzed prcPHF (6.2±1.6). Structural similarities between PHF associated glycolipid and other glycolipid amphiphiles known to form PHF-like filaments indirectly suggests that this unique glycolipid may be an integral component of the PHF suprastructure.

PRESENCE OF MATRIX METALLOPROTEINASES IN CANINE BRAIN. G.P. Lim[1], M.J. Russell[2], M.J. Cullen[1*], and Z.A. Tökés[1]. [1]USC School of Medicine, Los Angeles, CA, 90033 and [2]University of California, Davis, CA, 95616-8634.

Matrix metalloproteinases (MMPs) are elevated in the Alzheimer (AD) hippocampus and in the CNS of amyotrophic lateral sclerosis (ALS) patients (Backstrom et al., *J of Neurochemistry,* 1992; Lim et al., *J of Neurochemistry,* 1996). Two major proenzymes were identified as MMP-2 (70 kDa) and MMP-9 (100 kDa) in these patients, and the increased amounts of latent enzymes may contribute to the pathogenesis of these diseases. We now report the presence of two major proenzymes (60 and 95 kDa) in the canine brain using zymography where gelatin was copolymerized in a 7.5% acrylamide gel (SDS-PAGE). These proteinases were not inhibited by serine- and thiol-proteinase inhibitors. However, they were inhibited by 1,10-phenanthroline and EDTA, and their activities were reestablished by the addition of Zn^{+2} and Ca^{+2}, suggesting that they are MMPs. Immunodepletion studies using monoclonal antibodies to MMP-9 removed the 95 kDa enzyme, indicating that this proteinase is the canine equivalent of the human MMP-9 (92 kDa gelatinase B). The organomercurial activator of MMPs, *p*-aminophenylmercuric acetate (APMA), reduced the molecular mass of the 95 kDa enzyme in a manner consistent with the removal of the N-terminal propeptide domain from the latent form of the enzyme. In view of the observation that older dogs develop diffuse plaques, the striking similarities between human and dog MMPs suggest that the canine model is useful to study the role of these enzymes in the CNS neurodegeneration. BRAIN S-ADENOSYLMETHIONINE LEVELS ARE SEVERELY DECREASED IN ALZHEIMERS DISEASE. L. D. Morrison*, D. D. Smith and S. J. Kish.The Human Neurochemical Pathology Laboratory, Clarke Institute of Psychiatry, University of Toronto, 250 College Street, Toronto, M5T 1R8.

S-adenosylmethionine (SAM) is an essential ubiquitous metabolite central to many biochemical pathways including transmethylation and polyamine biosynthesis. Reduced CSF SAM levels in Alzheimer's disease have been reported; however, no information is available regarding the status of SAM or SAM-dependent methylation in the brain of patients with this disorder. Concentrations of SAM and its demethylated product, *S*-adenosylhomocysteine (SAH), were measured in postmortem brain of 11 patients with Alzheimer's disease. We found decreased levels of SAM (-67 to -85%, $p < 0.001$, Student's two-tailed t-test) and SAH (-56 to -79%, $p < 0.001$) in all brain areas examined (cerebral cortical subdivisions, hippocampus and putamen) as compared with matched controls (n=14). The reduction in SAM levels could be a consequence of excessive utilisation in polyamine biosynthesis in brain of patients with Alzheimer's disease. These severe reductions in levels of such an essential biochemical substrate would seriously compromise metabolism and brain function in patients with Alzheimer's disease and may provide the basis for the preliminary observations of improved cognition in some Alzheimer's disease patients following SAM therapy. IDENTIFICATION OF AN a1-ANTICHYMOTRYPSIN COMPLEX IN HUMAN BRAIN. X. Liu, E. P. Dixon, E. M. Johnstone and S. P. Little.* Central Nervous System Research Division, Lilly Research Labs., Lilly Corporate Center, Indianapolis, IN 46285

Although links are found between a1-antichymotrypsin (ACT) and Alzheimer's disease (AD) such as the association of ACT with senile plaque amyloids and over expression of ACT in the gray matter of AD brain, the role of ACT in the pathological process in AD as well as the normal biological function of ACT in central nervous system (CNS) is not defined. Several amyloid-precursor-protein (APP) cleavage enzymes were reported to be inhibited by ACT *in vitro*, indicating that ACT may play a role in regulation of APP proteolysis which may lead to the amyloid-ß-protein (Aß) generation or clearance. Our present goal is to investigate the functional role of ACT in human CNS. Proteins were extracted from brain tissues with 0.2% Triton X-100 at a neutral pH. By using a monospecific polyclonal antibody, we identified a protein of approximately 90 kDa in addition to the free ACT on reducing SDS-PAGE/Western blot. The ratio of the 90 kDa protein versus the free ACT varied among samples from different individuals but were additive, suggesting that the protein could be an ACT complex. Both AD and non-AD brains contained ACT and the ACT complex although some samples of non-AD contained only trace amount of the complex. Comparison of the protein complex in cortex and the hippocampus showed similar levels in non-AD whereas AD patients exhibited higher levels of the complex in the cortex. ACT immunoreactivity extracted from rat brains did not contain the 90 kDa protein suggesting that the putative ACT complex could be human specific. The complex was stable under our experimental conditions and partially purified through mono Q column chromatography. The identify and properties of the complex are currently under investigation.

TOTAL PROTEIN PHOSPHORYLATION IN HUMAN BRAIN BIOPSY SAMPLES

J. Song*, C. K. Combs[1], W. H. Pilcher[2], L. Y. Song[1], A. K. Utal[1], P. D. Coleman[1]. [1]Department of Neurobiology and Anatomy, [2]Department of Surgery, University of Rochester Medical Center, Rochester, NY 14642

Phosphorylation of total protein was observed in adult human cortical biopsy tissue. Total protein-bound phosphate immediately after biopsy from patients, age 14 to 59, ranged between 0.2 to 1.5 nmole phosphate/μg protein. During 4 hours in PBS at room temperature following excision, proteins showed two phases of total protein phosphorylation. The first peak of phosphorylation occurred within the first 30 mins, reaching 158% ± 30% of the zero time point level. This was followed by a recovery toward the zero time point level over the next 30 mins. Then the total protein showed another phase of phosphorylation which peaked at 153 % ± 15% by 90 mins following which phosphorylation fell slowly to the zero time point level by 4 hours. These results indicated possible multi-stage protein phosphorylation in post excision neuronal tissue. Immunoassay of neurofilaments (NF) with monoclonal antibody SMI-31 which recognized phosphorylated NF-H and NF-M also demonstrated two-phases of NF phosphorylation, with the first phase at 20-30 mins and the second at 90-120 mins. Our previous observation (1) of tau phosphorylation in adult human brain biopsy corresponds temporally to the first phase of total protein phosphorylation.

REDUCED GROWTH INHIBITORY FACTOR (GIF) EXPRESSION IN ALZHEIMER'S DISEASE

W.H. Yu*, H. Niznik and P.E. Fraser. Centre for Research in Neurodegenerative Diseases, University of Toronto, Toronto, ON M5S 1A8.

Growth Inhibitory Factor (GIF), a 68 amino acid member of the metallothionein family, may play a crucial role in controlling aberrant neuronal sprouting. In Alzheimer's disease (AD), GIF may prove pivotal for neuronal survival. In this study, a novel antibody raised to a unique sequence near the carboxyl terminal was used to determine the level of GIF expression. Quantitative western analysis and immunohistochemistry of Alzheimer's disease tissue indicated a substantial reduction of Growth Inhibitory Factor in the temporal cortex and to a lesser degree in the frontal region. Age-matched normals were used as controls. Immunohistochemical counts of GIF-positive astrocytes were dramatically reduced when compared to regions in control brains. This study illustrates the reduction of GIF in Alzheimer's disease and may provide insight into its biological role as well as the consequence of its downregulation in AD.

This research was funded by the Ontario Mental Health Foundation and the Alzheimer Society of Canada.

A GENETIC ASSOCIATION OF THE DIHYDROLIPOYL SUCCINYL-TRANSFERASE GENE WITH ALZHEIMER'S DISEASE

K.-F. R. Sheu,[1] P. Sarkar,[1] A. Brown,[1] N. Relkin,[2] W. Wasco,[3] R. E. Tanzi[3] and J. P. Blass[1,*] [1]Burke Med Res Inst, Cornell Univ Med Col, White Plains, NY 10605; [2]Dept of Neurology & Neurosci, Cornell Univ Med Col, New York, NY 10021 and [3]Mass General Hospital, Harvard Univ, Boston, MA 02129

A deficit of oxidative metabolism is a prominent feature of Alzheimer's disease (AD), characterized by deficiencies of specific oxidative enzymes. The α-ketoglutarate dehydrogenase complex (KGDHC) mediates a highly regulated and potentially rate-limiting step in the mitochondrial tricarboxylic acid cycle. KGDHC activity is reduced in AD brains and cultured fibroblasts. To ascertain whether there is a genetic basis for the deficit of KGDHC in AD, we have sought to test for an association of the gene for the dihydrolipoyl succinyltransferase (DLST, the E2k component of KGDHC) with the common, late-onset "sporadic" form of AD. The *DLST* gene consists of 15 exons that spans 23 kb. Each of the exons were PCR amplified and analyzed by the single strand conformation polymorphism technique. Five polymorphisms were identified. They are located in introns 3 and 10, and in exons 8, 14 and 15. None of the substitutions cause alterations of the encoded amino acids. Two series of studies are being performed. In the first series with unselected, mostly Caucasian subjects, the polymorphism within exon 14 was found to be significantly more common in AD than in age- and sex-matched controls. This study also suggested that the genetic association may vary among different ethnic groups. The second series, that is in progress, tests whether there is a stronger association of *DLST* with AD in Ashkenazi Jews. The result of an initial screening has been consistent with that hypothesis.

25-HYDROXYCHOLESTEROL MODULATES TEMPERATURE PROFILES IN ALZHEIMER'S FIBROBLASTS.

S.T. Christian*, J.C. Isbell, L.D. Nelson, and P.D. Bell Departments of Medicine, Division of Nephrology, and Psychiatry, University of Alabama at Birmingham, Birmingham, AL 35294.

Previous work has suggested that there are abnormalities in membrane viscosity in peripheral tissues from Alzheimer's disease (AD) patients. The ability of cholesterol or other lipophilic molecules to correct altered membrane viscosity is not clear. Therefore, we elected to determine the thermal profile of control membranes and 25-hydroxycholesterol enriched membranes in young, normal aged, and AD cultured fibroblasts by polarization of fluorescence. The fluorescent membrane probe 1-oleoyl-2-{12-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino] dodecanoyl}-sn-glycero-3-phosphocholine was used as a viscosity indicator for the outer membrane leaflet as temperature was increased from 10 to 35°C. Polarization values at 10°C were 0.366, 0.372, and 0.373 for AD, young, and aged membranes, respectively. As temperature increased polarization declined hyperbolically to values of 0.335, 0.336, and 0.339 for AD, young, and aged membranes, respectively. The trend in viscosity profiles, AD < young < aged, was relatively constant over the 25°C temperature range. 25-hydroxycholesterol enrichment of membranes increased viscosity of aged and AD membranes. Polarization values of 0.374, 0.368, and 0.379 for enriched AD, young, and aged membranes, were observed at 10°C and respective values of 0.338, 0.335, and 0.344 were observed at 35°C. Viscosity profiles were young < AD < aged over this 25°C temperature range. These results demonstrate an increased membrane fluidity in AD fibroblasts. In addition, this viscosity deficit can be reversed by cholesterol supplementation. (Supported by RO1 HL50163).

CHARACTERIZATION OF NERVE GROWTH FACTOR RELEASE BY RS-66252.

C.J. Emmett*, M. Haraguchi, P. A. Baecker, T. Chang, R. M. Eglen and R.M. Johnson. Dept. of Neurobiology, Inst. of Pharmacology, Neurobiology Unit, Roche Bioscience, Palo Alto, CA 94304.

Nerve growth factor (NGF) has been considered as a potential treatment for Alzheimer's disease because of its neurotrophic activity on central cholinergic neurons. As an alternative to intracerebroventricular delivery of NGF, small molecules that enhance its release/synthesis after peripheral administration have been examined. Using human T98G glioblastoma cells and a two-site ELISA for detecting NGF in cell supernatants, RS-66252 (10 μM) consistently demonstrated a 3-5 fold increase in NGF release above vehicle, detectable within 12 h after administration, with maximal release by 24 h. In companion studies, mRNA levels for NGF peaked 6 hours after addition. Dose-response analysis of NGF released 24 hours after stimulation by RS-66252, produced an EC_{50} of 13.7 μM. No evidence of cytotoxicity or dose-dependent release of other neurotrophic proteins such as bFGF or CNTF was noted. Efficacy of RS-66252 was examined in vivo, comparing NGF synthesis in aged versus young rodents and in the fimbria-fornix (FF) transection model of acute cholinergic cell loss. In aged animals (28-32 mos. old), 6 hours after administration of RS-66252 (10 mg/kg, ip), hippocampal levels of mRNA NGF was elevated two-fold above vehicle treatment. In contrast, there was no change in hippocampal mRNA NGF levels in young animals (3 mos. old). Immediately following a unilateral, FF aspirative lesion, RS-66252 was delivered twice a day (ip) for two weeks (1.0 or 10 mg/kg). The numbers of choline acetyltransferase (ChAT)-positive neurons were counted on the lesioned and non-lesioned sides. Unlike the efficacy demonstrated in the aged rodents after acute administration, RS-66252 did not rescue ChAT-positive neurons after transection in young animals at either dose tested. The results suggest that while RS-66252 demonstrated efficacy *in vitro*, its ability to upregulate NGF in animal models of cholinergic dysfunction was equivocal.

AMANTADINE REGULATES AADC, SOD AND LNGFR mRNAs: IMPLICATION FOR PARKINSON'S DISEASE AND ALZHEIMER'S DISEASE.

X.-M. Li*, J. Qi, A. V. Juorio and A. A. Boulton. Neuropsychiatry Research Unit, Department of Psychiatry, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0 Canada

Amantadine is efficacious alone, but it also exhibits a synergistic effect when combined with L-Dopa as a treatment for Parkinson's disease. Its precise mechanism of action, however, remains to be elucidated. In this study, we report on the effect of amantadine on the gene expression of aromatic L-amino acid decarboxylase (AADC), superoxide dismutase (SOD) and the low affinity NGF receptor (LNGFR).

AADC converts exogeneous L-Dopa to dopamine in Parkinson's disease. SOD is an antioxidative enzyme; LNGFR constitutively induces neural cell death in the absence of NGF. The expression of LNGFR determines the dependence of neuronal cells on NGF for survival. The highest level of LNGFR expression in the CNS is in the cholinergic neurons of the nucleus basalis of Meynert, the cells that are most severely affected in Alzheimer's disease. In contrast, cholinergic cells in the brainstem which resemble morphologically those in the nucleus basalis of Meynert, do not express LNGFR, nor do they degenerate in Alzheimer's disease.

Results obtained so far show that amantadine induces AADC and SOD gene expression both in PC12 cells and in the rat substantia nigra and adrenal gland. In PC12 cells, amantadine reduces basal LNGFR mRNA levels as well as NGF-induced LNGFR mRNA levels. This may indicate that the stimulation of AADC and SOD gene expression by amantadine may be relevant to its anti-parkinsonian effects whilst its inhibitory effect on LNGFR may indicate a possible role in Alzheimer's disease.

EVIDENCE FOR DENDRITIC TARGETING OF RC3 mRNA IN HUMAN TEMPORAL CORTEX. J.W. Chang*, E. Schumacher, P.M. Coulter II, and J.B. Watson. Department of Psychiatry and Biobehavioral Sciences, Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

RC3/ neurogranin is a postsynaptic PKC-/ calmodulin-binding substrate implicated in LTP-forms of synaptic plasticity. Our previous Digoxigenin *in situ* hybridization (DIG-ISH) studies detected RC3 mRNA in apical dendrites and cell bodies of a subpopulation of neurons in the rat cerebral cortex and hippocampus (Landry et al., 1994, Mol Brain Res 27: 1-11). This observation suggested that a portion of RC3 mRNA is selectively translocated to dendrites and may be translated locally in response to synaptic potentiation. To test this hypothesis further, we isolated a full-length cDNA clone of the homologous human RC3 mRNA from a human cortex λGT11 library, determined its nucleotide and predicted amino acid sequences, and performed mRNA expression studies in human temporal cortex. The human cDNA clone detects on Northern blots a single 1.3 kB mRNA whose nucleotide sequence is 73% similar to the rat nucleotide sequence and 90% similar to its amino acid sequence. Consistent with previous rodent studies, DIG-ISH detects robust staining of RC3 mRNA in cell bodies of numerous neurons throughout Layers II-VI and in apical dendrites of some presumptive, pyramidal neurons. We conclude that dendritic targeting of RC3 mRNA is conserved in human brain. Future studies will test whether RC3 mRNA targeting is altered in Alzheimer's brain (in progress) when synapses are compromised and in LTP-stimulated slices when synapses are strengthened. Supported by NIH grant NS 32521 and NICHD Training Grant in Mental Retardation 5T32 HD 07032-18.

REGULATION OF MITOCHONDRIAL GENE EXPRESSION IN VULNERABLE BRAIN REGIONS IN ALZHEIMER DISEASE

K.Chandrasekaran*, K. Hatanpää, Li-Ing Liu and S.I. Rapoport, Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892-1582.

Levels of mRNA for mitochondrial DNA (mtDNA)-encoded subunits of oxidative phosphorylation system (OXPHOS) are decreased in Alzheimer disease (AD) brains in the vulnerable regions. Levels of mRNA for cytochrome oxidase (COX) subunits I and III, and NADH dehydrogenase subunit 4 were decreased by 50% relative to levels in control brains. In contrast, levels of mtDNA-encoded 12S rRNA, and of mtDNA were unaffected (Chandrasekaran et al., Mol Brain Research, 24: 336, 1994; Fukuyama et al., Brain Research, in press, 1996). At the cellular level, decreases in COX subunit mRNA were observed in both tangle-free and tangle-bearing neurons in AD (Hatanpää et al., Ann. Neurol, in press,1996). In this study we investigated if mitochondrial transcription factor A (mtTFA) is responsible for the decreases in mtDNA-encoded mRNAs. Northern blot analysis showed no change in mRNA levels of mtTFA between AD and control brains. Gel-shift assay using mtDNA H-strand transcription promoter oligonucleotide with mitochondrial protein extract prepared from control and AD brains showed no qualitative differences in the binding characteristics. Recently developed mitochondrial in vitro transcription system will be used to investigate other regulatory mechanisms that could explain the decreased mitochondrial gene expression in AD brains.

CULTURED CELLS FROM RODENT LEPTOMENINGES EXPRESS NEURONAL PROTEINS IMPLICATED IN ALZHEIMER'S DISEASE. Noel Y. Calingasan[1]*, Hsinhwa L. Lee[1], Hanna Ksiezak-Reding[2], Maryanne Murtaugh[2] and John P. Blass.[1] [1]Cornell University Medical College at the Burke Medical Research Institute, White Plains, New York 10605; [2]Albert Einstein College of Medicine of Yeshiva University, Bronx, New York 10461.

Cultured skin fibroblasts have been widely used to study the cellular and molecular lesions of Alzheimer's disease (AD). However, their utility is limited by the low quantities of proteins that are characteristic of adult neurons. The current study examined the morphological and biochemical properties of fibroblasts cultured from neural sources. Primary cultures from rat and mouse pia-arachnoid were grown in differentiation media containing nerve growth factor and basic fibroblast growth factor. Pleomorphic rat and mouse cultures contained spindle-shaped or flat, polygonal cells, occasionally displaying long processes. As in human leptomeninges, cells from both rat and mouse immunoreacted consistently with antibodies to neurofilaments, neuron-specific enolase and fibronectin. These fibroblast-like cells were also immunoreactive to Alz 50, as well as antibodies to Tau-1, microtubule-associated protein 2 and amyloid precursor protein (APP). Immunoblotting revealed detectable amounts of Tau-1 immunoreactive proteins in mouse cultures. Preliminary studies show that exposure to 20 μM amyloid β-peptide Aβ-(1-40) for 3 days resulted in mouse leptomeningeal cell degeneration. Thus, leptomeningeal cells may provide a convenient cell culture model in which to study the patho-mechanisms of AD including Aβ neurotoxicity and altered processing of tau and APP. *(Supported by the Will Rogers Institute, Overbrook Foundation and NIA grants AG 09014 and AG 03853).*

BIOCHEMICAL CHARACTERIZATION OF AMYLOID PEPTIDES IN AN ALSATIAN PATIENT WITH GERSTMANN-STRÄUSSLER-SCHEINKER DISEASE: A PRNP CODON 117^{VAL} MUTATION. F. Prelli[1], F.Tagliavini[2], F. Perini[1], M. Porro[2], R. C. Beavis[1], C. Tranchant[3], J.-M. Warter[3], E. Katz[1]*, B. Ghetti[4], O.Bugiani[2], B. Frangione[1]. [1]New York University Medical Center, New York, NY, [2]Istituto Nazionale Neurologico C. Besta, Milan, Italy, [3]Hôpitaux Universitaires, Strasbourg, France, Indiana University ,Indianapolis, IN

Gerstmann-Sträussler-Scheinker (GSS) disease is a cerebral amyloidosis linked to mutations of the prion protein gene (PRNP). The aim of this study was to characterize amyloid peptides purified from brain tissue of a 24-year-old patient from the Alsatian family of GSS. The patient carried a mutation at PRNP codon 117 resulting in Ala>Val substitution, and was heterozygous Met/Val at codon 129, the Val129 being in coupling phase with the mutant Val117. The major peptide extracted from amyloid fibrils was a ~7kDa PrP fragment. Amino acid sequence analysis and laser desorption mass spectrometry showed that this fragment had ragged N- and C- termini. Only Val was present at positions 117 and 129, indicating that amyloid protein originated from mutant molecules. It is noteworthy that the ~7kDa amyloid subunit comprises a putative alpha-helical region with high propensity to adopt a β-sheet structure , which is increased by the Ala>Val substitution at codon 117. In addition to the ~7kDa peptides, the amyloid fraction contained N- and C- terminal PrP fragments corresponding to residues 23-41, 191-205 and 217-228. Thus, mutant PrP isoforms associated with GSS disease may be processed extracellularly where they are degraded by proteases to a 7kDa proteolytic resistant core, that is similar in patients with different mutations. Alternatively, a 7kDa PrP peptide may be a soluble amyloid precursor.

ACTIVE MITOTIC KINASE COMPLEX IN NEURONS OF ALZHEIMER'S DISEASE BRAIN, I. Vincent , M. Avellaneda and Dennis Dickson.* Dept. of Pathology, Albert Einstein College of Medicine, Bronx, NY, 10461.

Phospho-epitopes similar to those in eukaryotic M phase accumulate in neurons of Alzheimer's disease brain tissue. These epitopes are recognized by two series of PHF antibodies (TG and MC) and the MPM-2 mitotic marker antibody. In M phase these epitopes are produced by a highly conserved posttranslational mechanism. To determine whether a similar mechanism produces the epitopes in Alzheimer's disease, we have examined the occurrence and distribution of the mitotic kinases cdc2 and cdk2, and the mitotic cyclin B1 in hippocampal sections from human brain. Polyclonal antibodies recognizing C-terminal sequences in the human cdc2 and cdk2 mitotic kinases and specific for each kinase, and a monoclonal antibody to the PSTAIRE motif contained in both mitotic kinases, showed widespread staining of neurons with neurofibrillary tangles (NFT) in AD brain. The antibodies also stained some neurons without obvious neurofibrillary pathology, a few neuritic processes in senile plaques and variable amounts of glial and endothelial cells. Similar staining of non-neuronal cells was observed with the antibodies in normal brain, but in addition, the cdk2 antibody revealed widespread staining of pyramidal neurons. A monoclonal antibody specific for the mitotic cyclin B1 showed extensive staining of neuronal nuclei in AD and normal brain. Double immunofluorescence staining experiments showed that the mitotic kinases and cyclin B1 are found in the same neurons containing mitotic phospho-epitopes recognized by the MPM-2 and TG-3 antibodies. We have also stained brain tissue with a pair of mutually exclusive antibodies which distinguish between the active (Tyr15-dephosphorylated) and inactive (Tyr-15 phosphorylated) forms of the cdc2 and cdk2 kinases. While the 'inactive' kinase antibody stained only glia and endothelial cells in AD tissue, the 'active' kinase antibody reacted intensely with NFT and neurites in AD. No staining with either antibody was observed in normal brain neurons. Our data suggest that active mitotic kinase/cyclin complexes are localized to neurofibrillary structures in AD and may participate in AD pathology.

831.16

EXPRESSION OF FOS, JUN AND KROX FAMILY PROTEINS IN ALZHEIMER'S DISEASE. G.A. MacGibbon*[1], P.A. Lawlor[1], R.L.M. Faull[2] and M. Dragunow[1]. Depts. of [1]Pharmacology and Clinical Pharmacology and [2]Anatomy, The University of Auckland, Private Bag 92019 Auckland, New Zealand.

Apoptosis is an active process of cell death characterized by distinct morphological features, and is often the end result of a genetic program of events, i.e. programmed cell death (PCD). There is growing evidence supporting a role for apoptosis in Alzheimer's disease (AD), in both the morphological features as well as recent findings of increased levels of inducible transcription factors (ITFs) such as c-Jun that are thought to be involved in PCD. We have characterized the expression of a large range of ITFs (c-Fos, Fos B, Fos-related antigens, c-Jun, Jun B, Jun D, Krox20 and Krox24) using multiple antisera in AD hippocampi (post-mortem) and compared this with human control hippocampi as well as Huntington's disease hippocampi and human biopsy tissue. We found no evidence of nuclear expression of any ITF except for c-Jun in the human post-mortem tissue, compared with nuclear staining in biopsy tissue. There was no difference in protein expression of ITFs in neurons between the AD cases and controls. Neurofibrillary tangles stained positive for several protein products investigated, but this was not always consistent with different antisera used. Krox24 mRNA was significantly increased in the CA1 region of Alzheimer's hippocampi compared with controls, which may relate to high levels of Krox24 protein in tangles.

BAX EXPRESSION IN ALZHEIMER'S DISEASE BRAIN. S. O'Barr*, J. Schultz, J. Rogers. Sun Health Research Institute, Sun City, AZ 85372.

The roles of apoptosis related proteins in Alzheimer's disease (AD) are not understood, although studies to identify these proteins in specific disease states continue. To investigate the role of Bcl-2-associated X protein, Bax, in AD, we compared two groups of patients: AD, and nondemented elderly with little or no AD pathology at autopsy (ND). The 21 kD Bax protein is decreased in expression by more than three-fold in AD compared to ND samples, as detected by immunoblots.

Immunohistochemical analyses of superior frontal gyrus reveal Bax staining in both AD and ND tissue but is more prominent in the latter. Bax in AD and ND tissue stains strongly in blood vessels in both white and gray matter. There is also general staining in granular layer cells in both AD and ND tissue. In ND tissue, staining is found in pyramidal neurons with large amounts of lipofuscin, and in white matter glial cells. In AD tissue, Bax immunoreactivity is more sparse, with light staining in white matter glia. Gray matter staining in AD is present but less profound in lipofuscin rich pyramidal neurons. However, there is very strong staining in paired helical filament (PHF) rich dystrophic neurites.

The general decrease of Bax in glia shown in this study (and increase of Bcl-2 in previous studies) may aid in overcoming cell death due to AD insults such as amyloid beta, in these cell types. The large increase in Bax staining of PHF rich dystrophic neurites seen in this study (and a decrease in Bcl-2 staining seen in other studies) may point to a molecular mechanism for apoptotic influences on neuronal cell death in AD.

BAX PROTEIN EXPRESSION IN ALZHEIMER'S BRAIN AND CORRELATION WITH BRAIN PATHOLOGY. J. H. Su*, G. Deng and C. W. Cotman. *Brain Aging and Dementia Institute. University of California, Irvine. Irvine, CA 92697-4540 USA*

Many neurons in Alzheimer's disease (AD) exhibit terminal deoxynucleotidyl transferase (TdT) labeling for DNA strand breaks, and a subset of such neurons exhibits the classical, morphological characteristics of apoptosis (Su 1994). During the past several years the *bcl-2* gene family has been suggested as a common regulator of multiple apoptotic pathways. We have recently shown that up-regulation of Bcl-2 is associated with neurons exhibiting nuclear DNA fragmentation, while down-regulation of Bcl-2 is associated with tangle-bearing neurons in the AD brains (Su 1996). Consequently, we examined whether Bax is associated with brain pathology. Immunoreactivity for Bax was seen in neurons and microglia of hippocampal formation, and was elevated in the majority of AD cases as compared to control cases. Interestingly, one transitional case which had mild senile degeneration changes exhibited relatively high levels of Bax immunoreactivity. Most Bax-positive neurons showed TdT-labeled nuclei, while a subset of neurons with strong TdT-positive nuclei was not Bax-positive. Majority of Bax positive neurons did not colocalize with tangle-bearing neurons, although Bax immunoreactivity was detected within some early tangle-bearing neurons. In regions of relatively few tangles in mild AD brains, many TdT-labeled neurons were immunolabeled with Bax antibody and most of them lacked evidence of neurofibrillary changes. These findings suggest that *bax* may contribute to neuronal cell death in AD, and DNA damage and the up-regulation of Bax precede tangle formation and may represent an alternative pathway of cell death in AD. Supported by NIA AG 13007.

DNA DAMAGE IS INCREASED IN DOWN'S BRAIN IN COMPARISON WITH AGE- AND ARCHIVAL-MATCHED CONTROLS. Aileen J. Anderson*, Anne M. Cataldo and Ralph A. Nixon Labs for Molecular Neuroscience/Harvard Medical School Department of Psychiatry. McLean Hospital. 115 Mill Street. Belmont, MA 02178.

Neuropathological parallels between Alzheimer's disease (AD) and Down's syndrome (DS) have led to the hypothesis that similar disease mechanisms may be at work in these conditions. TUNEL labeling for DNA damage is dramatically increased in AD relative to control brain, and exhibits an apoptotic morphology in at least some cells in AD. If similar disease mechanisms are operating in AD and DS this aspect of AD pathology should also be present in DS brain; we examine this hypothesis in the present study. Tissue from the prefrontal cortex of control and DS cases with postmortem delays of less than 6h was employed as described below. DS tissue had typically been archived in formalin for prolonged periods. We have previously observed little or no TUNEL labeling in control tissue without AD pathology archived 1-2y; therefore, we evaluated the potential effect of archival time on TUNEL labeling by examining a sample of 15 control brains spanning an archival period of 2-12 years. ß-amyloid immunoreactivity was conducted on alternate sections to assess AD pathology in these cases. Data from these brains suggests that archival in 10% neutral buffered formalin can significantly affect TUNEL labeling in postmortem human brain. Control tissue archived 7y or more exhibited a large increase in TUNEL labeling in comparison with tissue archived 4y or less. Intermediate archival periods exhibited greater variability. This observation could be due to the breakdown of DNA over time or a direct action of formaldehyde on the DNA itself. These findings highlight the need for careful selection of cases for the interpretation of TUNEL labeling in postmortem tissue. Accordingly, evaluation of TUNEL labeling in DS was restricted to cases with archival times of 4y or less. These cases exhibited TUNEL labeling similar to that previously observed in AD tissue, and a large increase in TUNEL labeling relative to matched controls. These data provide further evidence of neuropathological parallels between AD and DS. (AG10916 to RAN; 5T32 MH19905 to Harvard MS)

PARKINSON'S DISEASE: ANIMAL MODELS I

832.1

MPTP INDUCED ASYMMETRIC PARKINSONISM IN NONHUMAN PRIMATES 6-8 YEARS AFTER A UNILATERAL INTRACAROTID (ICA) DOSE. M.E. Emborg*, E.F. Domino and K.S.Bankiewicz. Univ. of Michigan, Ann Arbor, MI 48109; Somatix Therapy Corporation, Alameda, CA 94501.

Various degrees of parkinsonism and recovery after MPTP treatment have been described in nonhuman primates (Ueki *et al.*, 1989; Elsworth *et al.*, 1989; Tremblay *et al.*, 1989; Piffl *et al.*, 1992; Schneider *et al.*, 1995). Some of these changes can be related to species, age and the way the neurotoxin was administered. The present report describes the results in five female monkeys (*Macaca nemestrina*), 3.8-6.7 kg, which received only one ica MPTP-HCl infusion (2.3-3.5 mg). The animals were videotaped in their home cages. A trained observer, using a parkinsonian scale, rated the animals before and after MPTP (4 months post-lesion and yearly on the month of lesioning ± 2 months). The features considered were tremor, posture, gait, bradykinesia, balance, gross motor skills, and freezing. Daily monitoring of feeding and monthly weight were recorded. Two to three days after MPTP administration, the animals developed a syndrome characterized by rigidity and flexed posture of the arm contralateral to the infusion side, with episodes of tremor, slow one-side circling ipsilateral to the lesion side, some balance disturbance, and stooped posture. The parkinsonian features did not show statistically significant changes. A slight (nonsignificant) increase in the speed of movements (general bradykinesia) was seen. Observations during the following 6-8 years showed no disturbances in grooming and feeding. The appetite was normal and the weight increased (actual weights between 5.5-9.0 kg). In conclusion, unilateral ica MPTP infusion induced an asymmetric parkinsonian syndrome that remained stable 6-8 years after surgery. 832.2

ROTATIONAL ASYMMETRY IN NONHUMAN PRIMATES 6-8 YEARS AFTER A SINGLE UNILATERAL INTRACAROTID (ICA) MPTP INFUSION. E.F.Domino*, M.E.Emborg,J.D.Belluzzi, D.McAfee, K.S.Bankiewicz Univ. of Michigan, Ann Arbor; MI 48109; Univ. of California, Irvine, CA 92717; Discovery Ther. Inc., Richmond, VA 23230; Somatix Ther. Corp., Alameda, CA 94501.

The rotational response to dopaminergic (DA) agonists has been widely used as a test of an asymmetric DA nigral lesion. Behavioral recovery after MPTP treatment has been described in non human primates. Long term observations of the stability of parkinsonian animal models is essential for studying potential therapies. The present report describes the results in 5 female monkeys (*Macaca nemestrina*), 3.8-6.7 kg, which received one ica MPTP-HCl infusion (2.3-3.5 mg). Rotational activity following control vehicle, L-DOPA methyl ester, and N-0923 was assessed from videotapes by raters blind to the treatments. Each animal showed rigidity and flexed posture in the arm contralateral (contra) to the side of infusion, as well as ipsilateral (ipsi) rotations 24-72 hr after MPTP administration. These signs remained over time. After vehicle, predominantly ipsi rotations were observed in all of the animals. Occasional contra rotations were observed; in 3 monkeys, they significantly increased after 6-8 yr. All of the animals responded to the DA agonists with contra rotations. After L-DOPA (12.5 mg/kg im), 4 monkeys showed a progressive decrease in contra rotations that was significant after 6-8 yr. After 10 and 32 µg/kg im of N-0923, 3 monkeys showed a progressively decreased number of contra rotations after 3-4 yr, with significant decreases after 6-8 yr. Two yr post MPTP, the contra rotations induced by 100 µg/kg im significantly decreased in 1 monkey, remaining stable afterwards. Some ipsi rotation was observed more often after lower doses of DA agonists. In conclusion, MPTP induced asymmetrical motor behavior that remained after 6-8 yr with individual variations. The animals that had an increase in frequency of contra rotations after control vehicle showed a decrease in contra rotations after DA agonists, suggesting neuroplastic changes over the years. [Supported in part by the Psychopharmacology Research Fund 361024.]

LEVODOPA IMPROVES LONG-TERM COGNITIVE IMPAIRMENT IN MPTP-TREATED MONKEYS. J. Fernandez-Ruiz*, D. Doudet and T. Aigner. Laboratory of Neuropsychology, NIMH, NIH. Bethesda, MD 20892-4415.

Administration of MPTP (1-methyl-4-phenyl-1,2,3,6-tetra-hydropiridine) induces a long-lasting Parkinson-like motor syndrome in monkeys. We recently demonstrated (NeuroReport, 7:102-104, 1995) that MPTP monkeys also manifest long-term cognitive deficits. Here we report the cognitive effect of levodopa in monkeys ten years after MPTP administration. Initially, four MPTP-treated and four age-matched control male rhesus monkeys (*Macaca mulatta*) performed a delayed-response spatial task in a Wisconsin General Test Apparatus. Delays from 0 to 60 sec (in intervals of 10) were repeated randomly five times each during a session. The MPTP-treated monkeys were then tested 45 minutes after the oral administration of 100, 250, and 500 mg of levodopa. Each dose was tested until the monkey completed 25 trials with each delay. Once the levodopa was suspended, a final control test without drug was given to the MPTP-treated monkeys. The results showed that without levodopa both groups performed equally well at 0 and 10-sec delays; with longer delays the MPTP monkeys' performance declined, leading to a statistically significant interaction between delay and MPTP. The performance of the MPTP monkeys improved greatly with levodopa. At the 100 and 250-mg doses, the performance of the MPTP-treated monkeys was indistinguishable from that of the untreated controls. At the 500-mg dose, the MPTP-treated group, although different from the control group, still performed better than without levodopa. In the last test without levodopa, the MPTP-treated group again showed increased errors to a level similar to their initial non-levodopa condition. These results suggest that the MPTP-treated monkeys have a delay-sensitive spatial memory impairment that is reversible with levodopa treatment. In this respect, the MPTP-treated primate displays spatial deficits similar to those observed in Parkinson's patients and thus may offer a useful model for evaluating novel therapeutic approaches to this disease. Supported by NIMH-IRP.

LACK OF CALBINDIN-D_{28K} DOES NOT INCREASE THE LOSS OF MIDBRAIN DOPAMINE NEURONS IN MPTP-TREATED OR IN WEAVER MICE. M. S. Airaksinen*, H. Thoenen and M. Meyer. Dept. of Neurochemistry, Max-Planck-Institute for Psychiatry, D-82152 Martinsried, Germany.

Calbindin-D_{28k} (calbindin) is an intracellular calcium-binding protein which is expressed abundantly in many populations of neurons. Previous studies suggest a role for calbindin in rapid intracellular calcium buffering, regulation of calcium signaling and synaptic transmission. Calbindin has been proposed to protect neurons against excitotoxic damage mediated by calcium overload. Consistent with this notion, calbindin is expressed in those midbrain dopamine neurons that are preferentially spared in Parkinson disease and its MPTP and weaver animal models. A general neuroprotective role for calbindin is, however, a highly controversial issue.

To study the possible neuroprotective role of calbindin in vivo, we counted midbrain dopamine neurons from calbindin nullmutant mice treated with the dopamine neurotoxin MPTP and from weaver-calbindin double mutant mice. Calbindin nullmutation itself was without effect. The extent and localization of dopamine neuron loss in MPTP-treated wild type mice and in weaver mutants were as previously described. Surprisingly, neither MPTP-treated calbindin nullmutant nor weaver-calbindin double mutant mice showed more extensive neuronal loss than the respective control mice, treated wild type or weaver mutant. Thus, also in mice lacking calbindin, dopamine neurons in the ventral tegmental area, most of which normally contain calbindin were preferentially spared. It is unlikely that this protection is due to the presence of related calcium-binding protein calretinin because it is colocalized only partial. with calbindin and was not upregulated in these mice. These results indicate that the resistance of calbindin containing dopamine neurons is not causally related to the expression of calbindin and furthermore, they do not support a general neuroprotective role of calbindin.

D2 RECEPTOR IMMUNOREACTIVITY IN THE SUBSTANTIA NIGRA OF THE MUTANT MOUSE WEAVER. **S.G. Xu, C. Prasad[1], and D.E. Smith*. Departments of Anatomy and Medicine[1], LSU Medical Center, New Orleans, LA 70112.**

To test the hypothesis that loss of dopamine (DA) neurons in the substantia nigra (SN) of weavers would cause disturbances in local circuits and D2 immunoreactivity, eight-week-old homozygous weaver mice paired with littermate wildtype controls were perfused transcardially. The brains were removed, blocked and sectioned. SN sections were incubated overnight with polyclonal antibodies against dopamine D2 receptors and tyrosine hydroxylase (TH). Visualization of D2 used the ABC technique; D2/TH double labeling used an immunogold technique. Light microscopy indicated fewer D2-labeled cells in weaver and less intense immunoreactivity. Electron microscopy revealed fewer D2-labeled profiles, fewer synapses contacting labeled dendrites, and signs of neuronal degeneration. Double labeling showed that the majority of the D2 cells also expressed TH. These results suggest a down-regulation of D2 receptors and a function primarily as autoreceptors.

DISTRIBUTION OF GIRK2 IMMUNOREACTIVITY IN THE VENTRAL MESENCEPHALON : EFFECT OF 6-OHDA LESION IN RATS AND OF THE WEAVER MUTATION IN MICE

[1]C. Adelbrecht , [2]I. Lauritzen , [1]G. Murer , [2] F. Lesage [2]M. Lazdunski , [1]Y. Agid , [1]R. Raisman-Vozari*. [1]INSERM U289, Hôpital de la Salpêtrière, 75013 Paris and [2]Inst. of Pharmacol. Mol. and Cell., Sophia Antipolis, France.

GIRK2 is one of the members of a family of inward rectifying K+ channels regulated by neurotransmitters through G proteins. By using a specific GIRK2 antibody we found immunolabeled cells in the substantia nigra (SNC) and the ventral tegmental area (VTA). The presence of GIRK2 protein in dopaminergic cells was confirmed by two different approaches: 1) double immunocytochemical methods showed a colocalization of GIRK2 and TH proteins in the same cells; 2) 6-OHDA lesion of the SNC reduced the number of GIRK2 positive cells. GIRK2 immunolabeling was observed in both the soma and dendrites of DA neurons. Besides the number of positive cells was higher in SNC (70%) than in theVTA (30%). A mutation in GIRK2 gene has been recently identified in the weaver (wv) mouse (Patil et al., 1995) suggesting its role in the loss of dopaminergic cells in the ventral mesencephalon and of granule cells in the cerebellum. Mesencephalic neurons surviving to the effect of the weaver mutation showed a significant decrease of GIRK2 immunostaining. We are currently studying the distribution of GIRK2 protein in the ventral mesencephalon of parkinsonian patients in order to determine its relation with dopaminergic cell degeneration in this illness. SUSTAINED VERSUS TRANSIENT EFFECTS OF MPTP ON RAT NIGRO-STRIATAL DOPAMINERGIC NEURONS. F. Cardozo-Pelaez* and L. Wecker. Dept. Pharmacol., Univ. South Florida Coll. of Med., Tampa, FL 33612

Although rodents are less sensitive than other species to the toxic effects of 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP), injection of this neurotoxin into rat CNS leads to dopamine (DA) depletion and a decreased number of tyrosine hydroxylase immuno-positive (TH+) nigrostriatal neurons. It is unclear, however, whether these effects persist over time. Thus, these studies determined the dose- and time-dependent effects of the unilateral intranigral injection of MPTP on the levels and turnover of DA in striata and the number of TH+ neurons in substantia nigra (sn). MPTP produced a dose-dependent loss of DA and increased DA turnover in striata, and a decreased number of TH+ neurons in sn 1 week after injections with an IC_{50} of 150µg; 500µg produced a maximal effect. The effects of 150µg MPTP were transient with partial recovery by 2 weeks, and full recovery by 4 weeks. In contrast, the injection of 500µg MPTP led to a sustained 85% DA depletion, 85% increased DA turnover, and 90% loss of loss of TH+ neurons throughout the 4 weeks. The transient effects of 150µg MPTP were prevented by pretreating animals with either the MAO_B inhibitor selegiline or the free radical spin trap *N*-tert-butyl-α-phenylnitrone (PBN); these pretreatments did not affect the neurotoxicity of 500µg MPTP. Results indicate that MPTP has both dose- and time-dependent effects on rat nigrostriatal dopaminergic neurons. The effects of doses ≤ the IC_{50} are transient and mediated by oxidation of MPTP via MAO_B and the production of free radicals, whereas effects of higher doses leading to a sustained loss of nigrostriatal neurons may involve other mechanisms. DOPAMINE-LIKE IMMUNOREACTIVE CELLS PROLIFERATE IN THE PARAMEDIAL BRAIN REGION OF THE RAT FOLLOWING THE INJECTION OF S-ADENOSYL METHIONINE IN THE LATERAL VENTRICLE. C. G. Charlton*, R. Nesby, E. Lee, B. Sears and K. Johnson. Florida A&M Univ., Coll. of Pharmacy, Tallahassee, Fl 32307

S-adenosylmethionine (SAM) is a very reactive compound, a limiting factor in methylation and has a narrow physiological/toxicological index, so an increase in SAM will increase methylation and may induce toxicity. The activity of SAM increases in aging and SAM induces Parkinson's disease-like and aging-like changes in animals; by causing functional feebleness (tremor, hypokinesia and rigidity), reduction of dopamine and tyrosine hydroxylase (TH), substantia nigra (SN) degeneration and gliosis. To know more about the gliotic-like changes, 4 daily injections of 0.75 umole of SAM or 5 ul of saline were made in the lateral ventricle of rats. Brain slices were prepared and immunohistochemical double-labeling of dopamine and glial fibrillary acidic protein (GFAP) and single labeling of TH were performed. DA-like and TH-like cells with identical morphology (oval to spindle and small to medium) were identified in the paramedial region of the brain, close to the 3rd ventricle of SAM-injected rats. GFAP labeling occurs throughout the brain, but none was co-localized with the DA and TH immunoreactivity., meaning that the DA and TH cells were not functional glial cells. They seem to be imposing on the architecture of the regular brain cells and probably exhibit different stages of development. SAM may activate or induce a trophic factor that causes the proliferation of these cells. These DA and TH reactive cells may serve to replenish the DA metabolised by SAM and to counteract the dopaminolytic effects of SAM, thus may help to explain the tolerance that develops to the injection of SAM. CHANGE IN NITRIC OXIDE (NO) AND SUPEROXIDE DISMUTASE (SOD) LEVELS IN CULTURED MOUSE ASTROCYTES AFTER 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP) TREATMENT

H.Y. Li and A. Stadlin. Dept. of Anatomy, Chinese University of Hong Kong, Shatin, N.T., Hong Kong. (SPON: The Hong Kong Society of Neurosciences)

Astrocyte-derived NO may play a significant role in Parkinson's disease (PD). NO synthase (NOS) is present in astrocytes and the potential of NO to interact with oxygen free radicals may result in oxidative damage to surrounding neurons. Astrocytes from C57 neonatal black mice were used to establish primary astrocytic cultures from the cortical, striatal & mesencephalic regions. Cells were treated with 500µM MPTP and incubated for 4, 8, 12, 24, 48 and 72 hours. NO production was assessed by the amount of nitrite and nitrate released into the medium as well as by the accumulation of NO-stimulated cGMP levels. MPTP treatment caused an increase in the release of nitrite into the medium from cultured astrocytes. The order of nitrite secretion were mesencephalic > striatal > cortical astrocytes. This change correlated with the elevation of cGMP levels, peaked at 8h in striatal (85% higher than control) as well as mesencephalic (300% higher than control) with no significant change in cortical astrocytes. The increase in nitrite level were completely blocked by L-NAME (NOS inhibitor). An increase in SOD activity was also observed in striatal astrocytes at 8 hr after treatment. Mesencephalic & cortical astrocytes however showed a gradual decrease and no change in SOD activities respectively. The present results showed that MPTP can induce an increase in NO production in striatal and mesencephalic astrocytes but not in cortical astrocytes. There may be a corresponding increase in superoxide production in striatal astrocytes at 8 hour MPTP treatment. However, the decrease in SOD activities in mesencephalic astrocytes may render more peroxynitrite formation resulting in a more conducive environment for oxidative-induced neuronal degeneration.

LESION OF NIGROSTRIATAL TRACT EFFECTS STRIATAL GLUTAMATE SYNAPSES . C.K. Meshul* and C. Allen. V.A. Medical Center and Oregon Health Sciences University, Portland, OR. 97201.

It is known that Parkinson's Disease (PD) is due to a loss of dopamine containing neurons within the substantia nigra pars compacta. A lesion of the nigrostriatal tract should theoretically result in a decrease in activity of the corticostriatal pathway. However, data from several studies suggests otherwise. This same decrease in corticostriatal activity has also been suggested to occur following chronic haloperidol (HAL) treatment. We have shown that there is a HAL-induced increase in the mean percentage of striatal asymmetric synapses containing a perforated postsynaptic density (PSD), which suggests an increase in nerve terminal activity (Meshul et al 1994; Meshul and Tan 1994). Activation of the corticostriatal tract also produces an increase in the density of nerve terminal glutamate immunoreactivity (# gold particles/μm^2) which is similar to that seen following HAL treatment (Meshul et al 1996). One month following a 6-OHDA (8 µg/4 µl) lesion of the nigrostriatal pathway, we find a significant increase in the mean percentage of striatal asymmetric synapses containing a perforated PSD compared to the sham controls (17.8% vs 9.8%). There is also a smaller, but significant, decrease in the density of striatal nerve terminal glutamate immunolabeling compared to the controls (37.1 vs 49.9 gold particles/μm^2). This suggests that following a lesion of the nigrostriatal pathway, depletion of striatal nerve terminal glutamate levels may be due to a sustained increase in glutamatergic neuronal activity, leading to an increase in the mean percentage of asymmetric synapses containing a perforated PSD. This would validate the use of glutamate antagonists in the treatment of PD. Supported by the Dept. of Veterans Affairs.

THE COADMINISTRATION OF SELECTIVE DOPAMINE D1 RECEPTOR ANTAGONISTS WITH L-DOPA FAILED TO DISSOCIATE THE L-DOPA-INDUCED DYSKINESIAS FROM THE RELIEF OF SYMPTOMS IN L-DOPA PRIMED MPTP MONKEYS. V.D. Doan, R. Grondin, L. Grégoire and P.J. Bédard* . Dept. Pharmacol., Fac. Med., Laval Univ. Canada. G1K 7P4

Dyskinesias are a common and poorly understood side-effect of chronic L-dopa therapy in Parkinson's disease. Thus far, clinical and experimental evidences have implicated the potential role of dopamine D_1 receptor stimulation in the genesis of L-Dopa-induced dyskinesias (LDID). In the present study, 4 L-Dopa primed MPTP monkeys were used to test whether or not acute blockade of D_1 receptors might reduce LDID without altering the relief of symptoms. All animals were challenged s.c. with 3 doses (0.03, 0.10 and 0.3 mg/kg) of either the selective D_1 antagonist SCH 23390 (SCH) or NNC 01-112 (NNC) alone (together with an empty capsule) or in combination with oral L-Dopa (100 mg). S.c. injections of saline together with an empty capsule served as control. The antiparkinsonian and the dyskinetic response were assessed using disability and dyskinesias scales and motor activity was monitored using photocell counters. L-Dopa alone significantly increased motor activity and improved disability with severes dyskinesias vs saline. Blockade of D1 receptors with either SCH or NNC alone tended to decrease motor activity and to exacerbate the symptoms vs saline without production of concomittant dyskinesias. The coadministration of L-Dopa with either SCH or NNC reduced the LDID during the first 90 min after treatment vs L-Dopa alone but also caused a return of parkinsonian disability and reduced significantly, in a dose dependent manner, the L-Dopa-induced increase in locomotion. Thereafter, animals treated with SCH displayed locomotor activation which was similar to that seen after L-Dopa alone with significant improvement in disability and the return of severe dyskinesias while such return of response was virtually not observed with NNC. These data argue against the view that locomotion activity is mediated via D_2 receptor stimulation while D_1 receptor stimulation is responsible for dyskinesias induction. Some contribution of both receptor is likely to be involved in these behavioral responses. (MRC and Parkinson foundation of Canada).

832.12

REGULATION OF STRIATAL PREPROENKEPHALIN mRNA LEVELS IN MPTP-TREATED MONKEYS FOLLOWING CHRONIC TREATMENT WITH DOPAMINE D1 OR D2 RECEPTOR AGONISTS. R. Grondin[1]*, M. Goulet[2], M. Morissette[1], P.J. Bédard[1] and T. Di Paolo[2]. [1]Dept. Pharmacol., Fac.Med. : [2]School Pharmacy. Laval Univ., Canada. G1K 7P4

Studies in parkinsonian patients and in MPTP-treated monkeys have shown elevated striatal preproenkephalin (PPE) mRNA levels, unaltered by chronic L-Dopa therapy, known to induce dyskinesias. In the present study, the mRNA levels of PPE were measured by *in situ* hybridization in the striatum of MPTP-treated monkeys after chronic treatment with either the D1 agonist SKF-82958 (SKF) or the D2 agonist U-91356A (U91) both administered s.c. in pulsatile or continuous mode compared to pulsatile L-Dopa therapy. Untreated MPTP as well as normal animals were also studied. Pulsatile treatment (n=3/group) with either L-Dopa, U91 or SKF relieved parkinsonian symptoms and induced dyskinesias whereas either U91 or SKF (n=3/group) given continuously led to behavioral tolerance without dyskinesias.The PPE mRNA levels were elevated in the caudate nucleus and putamen of untreated MPTP monkeys compared to control animals with a more pronounced increase in the lateral compared to the medial part of both structure. In general, elevated PPE mRNA observed in MPTP monkeys were not corrected by chronic oral L-Dopa (100 mg/dose, once daily). On one hand, pulsatile administration of U91 (0.6 mg/kg, twice daily) led to partial correction of PPE mRNA level vs control whereas continuous treatment with U91 (equivalent daily dose) generally restored PPE mRNA to control values. On the other hand, elevated PPE mRNA levels observed in MPTP monkeys were markedly increased by pulsatile administration of SKF (1 mg/kg, thrice daily) in 2/3 monkeys in which dyskinesias developped whereas it remained close to control values in the third one, who did not display dyskinesias. Continuous treatment with SKF (equivalent daily dose) did not altere the elevated PPE mRNA levels caused by denervation. The mode of administration, for a given agonist, was shown to affect differentially the expression of PPE mRNA but most importantly, our data suggest an opposite contribution of both D1 and D2 receptor on PPE mRNA levels. Alterations in PPE expression may be involved in the induction of dyskinesias. (MRC and Parkinson foundation of Canada).

832.13

EFFECT OF ACUTE AND CHRONIC GM-1 GANGLIOSIDE IN MPTP-TREATED MONKEYS. M.R.Luquin*, J.Guillén, C. Oset, R.Insausti, D.Frechilla and J.Del Río. Depts. of Neurology, Anatomy and Pharmacology, School of Medicine, University of Navarra, Pamplona, Spain.

Cynomolgous monkeys (4-6 animals/group) received acute or chronic MPTP treatment. Acute treatment consisted of 2 weekly MPTP injections (0.75 mg/kg iv), the monkeys being sacrificed 4 days after the second injection. Chronically treated animals were given weekly injections of MPTP (0.5-1 mg/kg iv) until a severe parkinsonism was obtained (10-14 months). In acutely intoxicated monkeys, saline or GM-1 was daily given for 18 days (20 mg/kg/day im). Monkeys chronically treated with MPTP received either the same daily dose of GM-1 or saline for 2 months and were sacrificed one day later. Acute MPTP produced a dopamine (DA) depletion in the range of 60-80% in caudate nucleus and putamen without reducing at all 5-HT content in the striatum. Chronic MPTP produced a much more marked DA loss approaching a 99% reduction in the caudate. Interestingly, striatal 5-HT content was decreased by approximately 50% in these animals. In either case, GM-1 did not promote a recovery in striatal DA content, although the density of tyrosine hydroxylase fibers was increased in the s.nigra of acutely intoxicated monkeys. The results suggest that GM-1 may represent a useful treatment in the early stages of Parkinson's disease. (Supported by Botín Fdn., Spain)

832.14

MPP^+ RAPIDLY APPEARS IN NORADRENERGIC AND SEROTONERGIC SOMATA AFTER SYSTEMIC ADMINISTRATION OF ^{3}H-MPTP. S.G. Speciale*, P.K. Sonsalla, L. Manzino and D.C. German, Dept. of Psychiatry, Univ. of Texas Southwestern Med. Cntr., Dallas, TX 75235, and Dept. of Neurology, UMDNJ Robert Wood Johnson Sch. of Med., Piscataway, NJ 08854.

MPTP is a neurotoxin that has been used to create an animal model of Parkinson's disease (PD). In the C57BL/6 mouse, MPTP causes a loss of similar dopaminergic (DA) A8, A9 and A10 neurons that degenerate in PD (German *et al.*, 1996), but unlike the neuropathology of PD, there is no loss of the noradrenergic locus coeruleus (LC) or serotonergic dorsal raphe (DR) neurons. The purpose of the present study was to determine which monoaminergic neurons contain the toxic metabolite of MPTP (MPP^+), the time-course of the accumulation/formation, and relative amounts of MPP^+ in the nuclei. Male, C57BL/6 mice were injected intraperitoneally with 100 µCi ^{3}H-MPTP (10 µg/kg), and sacrificed by cervical dislocation 3, 7, 24 or 48 h later (n=3/group). Brain sections were apposed to Hyperfilm-^{3}H for 6 weeks. Light MPP^+ labeling was apparent in nuclei A8, A9 and A10 only at 3 and 7 h, but never in the striatum. In the LC and DR very heavy labeling was apparent from 3-24 h, with the heaviest labeling at 7 h. These data indicate that low , non-toxic doses of MPTP produce (1) higher amounts of MPP^+ in DR and LC neurons than in midbrain DA neurons, and (2) no evidence of retrograde transport of MPP^+ from the striatum to the midbrain DA neurons. It can be speculated that the monoamine vesicular transporter disproportionately accumulates the toxin within LC and DR cell bodies, as opposed to midbrain DA somata (Vander Borght *et al.*, 1995), and protects them from degeneration. MEASUREMENTS OF DOPAC LEVELS IN THE PARTIALLY DOPAMINERGIC DENERVATED STRIATUM IN THE RAT BRAIN. M. Savasta[1*], M. Le Cavorsin[2], C. Dentresangle[2] and V. Leviel[2]. 1. INSERM-LAPSEN U.318, Pavillon de Neurologie, CHU de Grenoble, BP 217, 38043 Grenoble cedex 9; 2. CNRS UMR 5542, Faculté de Médecine A. Carrel, 69372 Lyon Cedex 02, France.

Partial lesion of the nigrostriatal dopaminergic (DA) pathway in the rat represents an animal model that reproduces the presymptomatic situation of Parkinsonian patients. In this model, only lateral DA neurons of the substantia nigra pars compacta (SNC) are destroyed by unilateral stereotaxic injection of 6-hydroxydopamine. The present study tested the hypothesis that normal concentrations of extracellular dihydroxy-phenyl-acetic acid (DOPAC) can be generated in the partially denervated striatum. This could explain the lack of modification of the striatal levels of DA D1 and D2 receptors, D2 and PPE mRNAs observed in the denervated striatal region comparatively to control values. Four weeks after lesions, striatal levels of DOPAC were measured *in vivo*, under halothane anesthesia, by voltametry technique using carbon-fiber microelectrodes. Voltametric recordings were collected at different points on dorso-ventral and medio-lateral axes in the partially lesioned striatum and contralateral control side. Our results show that there is a clear dorso-ventral gradient of DOPAC levels in the control side whereas no gradient was observed in the medio-lateral axe. On the contrary, in the partially denervated striatum, no gradient was detectable in the dorsoventral axe while a clear gradient was observable medio-laterally which could be divided in three parts: the medial one where DOPAC levels were comparable to control values, the intermediate one where DOPAC values were decreased by 30% comparatively to control levels and the lateral one where DOPAC levels were largely reduced (-68%). These data were correlated *in vitro* with striatal TH contents as revealed by immunoradioautography. These data support the hypothesis that dopamine metabolism is drastically reduced in the denervated region. Question thus rise to know if the maintainance of the functional equilibrium observed must be attributed to dopamine diffusing from undenervated regions. This maintenance could probably play an important role during the preclinical phase of Parkinson's disease particularly to delay the appearance of neurological symptoms.

832.16

NEUROPROTECTIVE EFFECT OF STRYCHNINE-INSENSITIVE GLYCINE SITE ANTAGONISTS IN EXPERIMENTAL MODELS OF PARKINSON'S DISEASE: EVIDENCE FOR EXCITATORY MECHANISMS OF NEURODEGENERATION. A. Kanthasamy[1], D.D. Truong[1], X. Huang[2], C.R. Freed[2] and A.G. Kanthasamy[1*]. [1]Parkinson & Move. Disord. Lab., Dept. of Neurology, Univ. of Calif., Irvine, CA 92717. [2]Univ. of Colorado, Sch. of Med. Denver, CO 80262.

Overstimulation of excitatory amino acid neurotransmission has been suggested in idiopathic Parkinson's disease (PD). Therefore, this study was designed to further investigate the excitatory mechanism of degeneration of dopaminergic neurons and the neuroprotective effects of novel strychnine insensitive glycine site antagonists (SIGA) using both *in vitro* and *in vivo* models. Novel quinoxalinedione derivatives (ACEA-1021, ACEA-1022, ACEA-1328) were compared with the known SIGA (R)-HA-966 in MPTP-treated C57 black mice. Pretreatment with the ACEA compounds or (R)-HA-966 (0-30 mg/kg, i.p.) dose-dependently attenuated MPTP-induced depletion of striatal dopamine and DOPAC, and nigral TH-positive neurons. Post-treatment of the ACEA compounds also had neuroprotective effects in mice. In contrast, (S)-HA-966 neither prevented the neurochemical depletion nor the neuronal injury caused by MPTP. Further, ACEA-1021 and ACEA-1328 at 30 μg/ml significantly promoted the survival of mesencephalic dopaminergic neurons *in vitro*, confirming the neuroprotective effect of SIGAs on dopaminergic neurons per se. Therefore, the results indicate the therapeutic potential of SIGAs for attenuating progressive neurodegeneration and strengthen the view that excitatory mechanisms are involved in the degeneration of dopaminergic neurons in PD.

PARKINSON'S DISEASE: ANIMAL MODELS II

833.1

ANIMAL MODELS OF PARKINSONIAN SYMPTOMS: EFFECTS OF SELECTIVE MUSCARINIC AGENTS ON PILOCARPINE-INDUCED TREMULOUS JAW MOVEMENTS IN RATS. A.J. Mayorga*, M.S. Cousins, G. Gianutsos and J.D. Salamone. Depts. of Psychology and Pharmaceutical Sciences, U. of Connecticut, Storrs, CT 06269-1020.

Although it is known that tremulous jaw movements are induced by muscarinic stimulation, the subtype of muscarinic receptor that produces this effect remains uncertain. In the present study, various muscarinic antagonists were injected intra-ventricularly in order to antagonize the jaw movements induced by 4.0 mg/kg pilocarpine. Scopolamine reduced pilocarpine-induced tremulous jaw movements at doses of 8.0-16.0 ug. The relatively selective muscarinic antagonists methoctramine and pirenzepine also reduced tremulous jaw movements, although higher doses were required (e.g. 50.0-100.0 ug). The rank order of potency was scopolamine >> methoctramine > pirenzepine, which is more consistent with a pattern of m2 or m4 antagonism than with m1 antagonism. Nevertheless, based solely on these pharmacological data it is difficult to identify a particular receptor subtype that is involved in tremulous jaw movements. The muscarinic antagonists currently available are not highly selective, and antagonists with various selectivity profiles all block tremulous jaw movements. Therefore, additional methods (e.g. antisense oligonucleotides, selective muscarinic toxins) may be necessary for identifying the particular muscarinic receptor subtype involved in the generation of tremulous jaw movements. Muscarinic antagonists that are currently used to treat idiopathic and neuroleptic-induced parkinsonism are relatively non-selective. Thus, identification of the muscarinic receptor subtype involved in tremulous movements may lead to the development of more selective antiparkinsonian drugs with fewer side effects.

ANIMAL MODELS OF PARKINSONIAN SYMPTOMS: DIALYSIS STUDIES OF STRIATAL ACETYLCHOLINE AND DOPAMINE DURING TACRINE-INDUCED JAW TREMOR. M.S. Cousins*, M. Finn, D. Carriero and J.D. Salamone. Dept. of Psychology, U. of Connecticut, Storrs, CT 06269-1020.

Several lines of evidence indicate that tremulous jaw movements in rats are induced by dopamine depletions or cholinergic stimulation in the ventrolateral neostriatum (VLS). The VLS is the most effective site for induction of tremulous jaw movements by 6-hydroxydopamine, physostigmine and pilocarpine. Tacrine-induced tremulous jaw movements have been shown to be reduced by microinjection of scopolamine into the VLS. In experiment 1, the acetylcholine (ACh) synthesis inhibitor hemicholinium-3 was injected into the VLS or overlying neocortex in order to determine the most effective site for reducing tacrine-induced jaw movements. The VLS was the most effective site at which microinjections of hemicholinium-3 (10.0 ug/side) could reduce tacrine-induced (5.0 mg/kg) tremulous jaw movements. Thus, in experiment 2 microdialysis probes were implanted in the VLS so that extracellular levels of ACh and dopamine could be monitored during tacrine-induced tremulous jaw movements. Tacrine (1.25-5.0 mg/kg) increased extracellular ACh in the VLS in a dose-related manner, across the same dose range at which tremulous jaw movements are produced. At the higher doses of tacrine, the increases in extracellular ACh were very large (150-400% of baseline). In some animals, extracellular dopamine tended to increase later in the session as tremulous jaw movements and extracellular ACh were decreasing. Taken together, these experiments show that VLS cholinergic mechanisms are important for the generation of tremulous jaw movements. Microdialysis methods could be useful for monitoring extracellular ACh during a variety of conditions that induce tremulous jaw movements (e.g., dopamine depletions or neuroleptic drugs).

833.3

ANIMAL MODELS OF PARKINSONIAN SYMPTOMS: INVOLVEMENT OF PALLIDAL AND NIGRAL GABA IN THE GENERATION OF TACRINE-INDUCED JAW TREMOR IN RATS. M. Finn*, A.J. Mayorga, K. Bittman and J.D. Salamone. Dept. of Psychology, U. of Connecticut, Storrs, CT 06269-1020.

Three experiments were conducted to investigate the role of pallidal and nigral GABA in the generation of tremulous jaw movements in rats. Previous work has shown that the tremulous jaw movements induced by cholinomimetics and dopamine depletions are dependent upon striatal mechanisms. Thus, the present study investigated potential striatal output pathways that could be involved in the generation of tacrine-induced movements (5.0 mg/kg IP). Because there are GABA-ergic projections from neostriatum to entopeduncular nucleus (medial globus pallidus) and substantia nigra pars reticulata, the GABA agonist muscimol was injected directly into these structures to study the effects of GABA stimulation on tacrine-induced jaw movements. Injections of muscimol into the entopeduncular nucleus (25.0-100 ng) failed to have any significant effects on tacrine-induced vacuous jaw movements. However, injections of muscimol (12.5-50 ng) into the substantia nigra pars reticulata completely blocked the jaw movements induced by tacrine. In the third experiment, it was again demonstrated that 25 ng of muscimol injected directly into the substantia nigra pars reticulata blocked the jaw movements induced by tacrine; additionally, it was shown that injections of this dose 2.0 mm dorsal to the substantia nigra pars reticulata failed to affect tacrine-induced tremulous jaw movements. These results indicate that stimulation of GABA A receptors in substantia nigra pars reticulata can block tacrine-induced tremulous jaw movements. This finding is consistent with the notion that striato-nigral GABA projections are involved in the generation of tremulous jaw movements. It is possible that striato-nigral GABA mechanisms are involved in human clinical phenomena such as parkinsonian tremor.

833.4

ANIMAL MODELS OF PARKINSONIAN SYMPTOMS: EFFECTS OF CLOZAPINE, HALOPERIDOL AND THIORIDAZINE ON CHOLINOMIMETIC-INDUCED TREMULOUS JAW MOVEMENTS. J. Trevitt*, M. Lyons and J.D. Salamone. Dept. of Psychology, U. of Connecticut, Storrs, CT 06269-1020.

Evidence indicates that the antipsychotic drug clozapine has therapeutic effects in patients with idiopathic Parkinson's disease. Because tacrine-induced tremulous jaw movements in rats have been suggested as a possible model of parkinsonian tremor, the present work was undertaken to investigate the effects of clozapine on tremulous jaw movements. Clozapine decreased tacrine-induced tremulous jaw movements in a dose-related manner, with substantial effects in the range of 8.0 -16.0 mg/kg. In order to determine the relative potency of this effect compared to other behavioral effects of clozapine, suppression of lever pressing also was studied. Clozapine suppressed lever pressing in the dose range of 4.0-8.0 mg/kg, indicating that clozapine suppressed jaw movements at doses about 2 times higher than those required for suppression of lever pressing. In contrast, the typical antipsychotic drug haloperidol failed to suppress tacrine-induced tremulous jaw movements in doses up to 1.0 mg/kg, which is about 15-fold higher than the ED50 for suppression of lever pressing with that drug. Thioridazine showed a pattern of effects that was intermediate between those of clozapine and haloperidol. It is possible that the suppression of tacrine-induced tremulous jaw movements by clozapine in rats is related to the unique behavioral and motor effects of clozapine. The ratio of potencies of these effects (i.e., suppression of tremulous jaw movements vs. suppression of lever pressing) could be used as a behavioral procedure for assessing clozapine-like activity in novel compounds. Although the biochemical basis of the clozapine-induced reduction in tremulous jaw movements is unknown, it is possible that this effect is related to the cholinergic and serotonergic properties of clozapine.

ANIMAL MODELS OF PARKINSONIAN SYMPTOMS: REVERSAL OF TACRINE-INDUCED TREMULOUS JAW MOVEMENTS WITH ANTIPARKINSONIAN DOPAMINERGIC AND CHOLINERGIC DRUGS. J.D. Salamone*, D. Carriero, M.S. Cousins. Dept. of Psychology, U. of Connecticut, Storrs, CT 06269-1020.

It has been suggested that tremulous jaw movements induced by cholinomimetic drugs could be used as an animal model of parkinsonian tremor. Several antiparkinsonian drugs were assessed for their ability to reverse the jaw movements induced by 2.5 or 5.0 mg/kg of the anticholinesterase tacrine. The non-selective dopamine (DA) agonist apomorphine and the D2 agonist bromocriptine both significantly reduced tacrine-induced jaw movements in a dose-related manner. The D1 agonists SKF 38393 administered in doses up to 30.0 mg/kg failed to reverse the jaw movements induced by tacrine, and in fact enhanced the jaw movements induced by the lower dose of tacrine. These results are particularly interesting in view of the fact that SKF 38393 is a partial agonist that is not effective as a treatment for Parkinson's disease. In contrast, the full D1 agonist APB does significantly reduce tacrine-induced jaw movements. Several additional antiparkinsonian drugs, including L-DOPA, amantadine and benztropine also reduced the jaw movements induced by tacrine. These results demonstrate that several different antiparkinsonian drugs reduce the tremulous jaw movements induced by tacrine. Tremulous jaw movements are characterized by a functional interaction between acetylcholine and DA that also is similar to that shown in human parkinsonism. It is possible that reversal of tacrine-induced tremulous jaw movements could be a useful test for assessing the potential antiparkinsonian effects of novel therapeutic agents.

833.6

ANIMAL MODELS OF PARKINSONIAN SYMPTOMS: TREMULOUS JAW MOVEMENTS AND MOTOR SLOWING INDUCED BY THE ANTICHOLINESTERASE TACRINE. D. Carriero*, G. Outslay, A.J. Mayorga, G. Gianutsos, and J.D. Salamone. Depts. of Psychology and Pharmaceutical Sciences, U. of Connecticut, Storrs, CT 06269-1020.

In the present study, three experiments were conducted to provide a characterization of some of the motor effects of the anticholinesterase tacrine. In the first experiment, the effects of tacrine (1.25 - 5.0 mg/kg) were assessed using operant conditioning procedures. Behavioral output during lever pressing on a fixed ratio 5 schedule was recorded by a computerized system that measured response initiation time (time from offset of one response to onset of the next) and duration for each lever press. Tacrine administration substantially depressed lever pressing response rate. This deficit was largely due to a substantial increase in the average response initiation time. Analysis of the distribution of response initiation times indicated that tacrine-treated rats made relatively few responses with fast initiation times (e.g. 0-125 msec), and also that tacrine led to a dramatic increase in the number of pauses in responding (i.e. response initiation times greater than 2.5 sec). Analysis of response durations indicated that there was an overall increase in average response duration among animals that received the higher doses of tacrine. In the second experiment, it was demonstrated that tacrine produced a dose-related suppression of open-field locomotor activity, with significant effects at the 5.0 mg/kg dose. The third experiment demonstrated that tacrine induced tremulous jaw movements in the dose range of 2.5-5.0 mg/kg. It is possible that studies of the motor effects of tacrine in rats could be useful for understanding the motor side effects of tacrine administration in humans.

833.7

AN AUTOMATED ROTAROD TEST FOR DRUG-FREE EVALUATION OF RAT MODELS OF PARKINSONISM. J.L. Labandeira*, G. Rozas, I. Liste, E. Lopez, H.J. Caruncho and M.J. Guerra. Dept. of Morphological Sci., Univ. of Santiago School of Medicine. 15705-Santiago de Compostela. Galicia. Spain.

We describe a drug-free rotarod test that was used to evaluate the effects of unilateral 6-hydroxydopamine lesions, and nigral grafts or other therapeutic strategies. The rotarod unit was automated and interfaced to a personal computer allowing automatic recording of the time that each rat was able to stay on the rod at different rotational speeds (i.e. progressively increasing the difficulty of the task). A combination of lesion induced deficits resembling those of Parkinson's disease appears to be involved in falling from the rod. The test shows high effectiveness for identifying rats with maximal dopaminergic lesions. Rotarod performance profiles were useful for investigating the effects of intrastriatal nigral grafts, since low rotation speeds revealed differences from lesioned rats (i.e. improvements) while higher speeds revealed differences from normal rats (i.e. remaining deficits and partial lesions). The test was effective regardless of whether rats were trained on the rod before lesion, after lesion, or after grafting. The results indicate that the rotarod test is a useful drug-free procedure for overall evaluation of basic motor abilities in rat models of parkinsonism and treatment-induced changes.

BLOCKAGE OF SNc GLUTAMATERGIC INPUTS, A NEW BASE FOR PRESYMPTOMATIC DIAGNOSIS IN PARKINSON'S DISEASE ? E. Bezard, T. Boraud, B. Bioulac, B. Dufy* and C.E. Gross. CNRS UMR 5543, Université de Bordeaux II, 33076 Bordeaux Cedex France.

Symptoms of Parkinson's disease appear only when a considerable number of the dopaminergic neurons have already been destroyed. Earlier diagnosis could open the way to more effective treatment and to a slower evolution of the disease. The substantia nigra pars compacta (SNc) receives glutamatergic inputs from several structures. We have already shown that these inputs are largely implicated in compensatory effects at the beginning of the symptomatic period. Our present postulate is that these glutamatergic inputs are also implicated in the presymptomatic period. Two monkeys were each given a low daily dose of MPTP (i.v., 0.2 mg/kg) for 6 days. This allowed us to obtain monkeys with SNc damage but without symptoms. Intracranial injections of kynurenic acid (10 µl at 5µl/min ; broad spectrum glutamatergic antagonist) into the SNc were also performed daily during this period. Parkinsonism was assessed by a clinical rating scale. Since these intracranial injections did not provoked motor disturbances in either animal, a seventh dose of MPTP was given to both. In the first monkey, an injection of kynurenic acid was then sufficient to provoke important motor disturbances; in the second monkey, there was still no modification. Two more injections of MPTP were necesary to elicit motor abnormalities after the injection of kynurenic acid. At this stage, after seven doses of MPTP for the first, and nine for the second, both monkeys were still asymptomatic but each injection of kynurenic acid induced motor abnormalities. These results are the first to support the idea that a glutamatergic antagonist could be eventually used for presymptomatic diagnosis of Parkinson's disease.

DECREASE IN GLUTAMATE UPTAKE FOLLOWING TREATMENT OF ASTROCYTES WITH MPTP

A.S. Hazell*, M.D. Norenberg, and Y. Itzhak. Veterans Administration Medical Center and Departments of Pathology and Biochemistry & Molecular Biology, University of Miami School of Medicine, Miami, FL 33101.

Increased glutamatergic stimulation of basal ganglia output nuclei associated with dopaminergic denervation in the striatum is considered to play a role in the development of Parkinson's disease. The basis for the enhanced glutamatergic activity is unclear, but impaired uptake of glutamate represents one possible mechanism. Since astrocytes provide effective spatial buffering of extracellular glutamate concentration and also actively convert 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to the neurotoxin MPP^+ via the action of MAO-B, we examined the effect of MPTP on glutamate uptake in these cells. Cultured astrocytes were treated with 50 µM MPTP for 24 hrs and glutamate uptake was determined using the non-metabolized glutamate analogue [^{3}H]D-aspartate. This resulted in a 52% decline in glutamate uptake compared with untreated controls. No change in cell morphology was noted. Addition of 100 µM deprenyl, an inhibitor of MAO-B, led to a complete reversal of the uptake inhibition suggesting an involvement of MPP^+. These findings indicate a profound effect of MPTP on glutamate transport in astrocytes which may play an important role in the pathogenesis of MPTP neurotoxicity. POSSIBLE ANTIPARKINSONIAN ACTION OF (+)MK801 ON RESERPINE-INDUCED VACUOUS JAW MOVEMENTS AND CATALEPSY. L.D. Mitchem*, E.D. Dallmann, C.K. Kruschel, J.J. Panos, and R.E. Steinpreis. The University of Wisconsin-Milwaukee, Milwaukee Wisconsin, 53211.

(+)MK801 is a non-competative glutamatergic antagonist. The purpose of the present study was to examine the ability of (+)MK-801 to reverse reserpine-induced vacuous jaw movements (VJMs) in rats. Rats received either 10.0 mg/kg reserpine or vehicle. Ninety minutes later the frequency of VJMs and catalepsy measures were recorded. Immediately following this baseline measurement, all rats received (+)MK-801 (either 0.001, 0.01, or 0.1 mg/kg). Sixty minutes after this second injection, a second round of VMJs and catalepsy measures were taken. Two trained observers blind to the drug conditions recorded the behaviors. Reserpine produced elevations in VJMs and catalepsy measures. Furthermore, (+)MK-801 significantly attenuated reserpine-induced VJMs and catalepsy. These results indicate that (+)MK801 may be useful in the treatment Parkinsonian-type symptoms.

833.11

ASSESSING THE APPETITIVE PROPERTIES OF GLUTAMATERGIC COMPOUNDS USING THE CONDITIONED PLACE PREFERENCE PARADIGM. K. Thompson*, J.J. Panos, T.E. Egan, M. Kramer & R.E. Steinpreis. Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI 53211

In the first experiment, male Sprague-Dawley rats were conditioned to a standard two-chambered conditioned place preference (CPP) apparatus. On alternating days, rats received NMDA (1.0, 15.0 or 30.0 mg/kg IP) paired with one chamber and saline paired with the other chamber. On the 6th day rats were allowed free run of the entire apparatus and the time spent in each chamber was recorded by computer. NMDA produced a dose-dependent aversion to the drug chamber. In the second experiment the same procedure was done to investigate the appetitive properties of MK801 (0.05, 0.1, 0.25, 0.50, or 0.75 mg/kg IP). MK801 produced a dose-dependent preference for the drug chamber. In a third experiment, co-administration of NMDA and MK801 resulted in neither preference or aversion. In the fourth experiment, rats were surgically implanted with bilateral cannula in the pre-frontal cortex one week prior to conditioning. Rats received alternating infusions of either 0.1, 0.01 or 0.001 M MK801 or saline and the results indicated that the lowest dose of MK801 was appetitive.

833.12

UPREGULATION OF STRIATAL PERIPHERAL-TYPE BENZODIAZEPINE RECEPTORS FOLLOWING THE ADMINISTRATION OF MPTP TO MICE. R.S. Dombro*, M.D. Norenberg, Y. Itzhak. Departments of Surgery, Pathology and Biochemistry & Molecular Biology, University of Miami School of Medicine, and VA Medical Center, Miami, FL 33101.

In brain, peripheral-type benzodiazepine receptors (PBRs) are present primarily in the mitochondria of glia and are upregulated as part of the gliotic process following CNS injury. The conversion of N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) into the neurotoxin MPP^+ occurs via mitochondrial monoamine oxidase (MAO) in astrocytes. The present study was undertaken to investigate whether the administration of MPTP regulates PBR binding in the striatum. Male Swiss Webster mice were administered either saline or MPTP (20 mg/kg; q 2h x 4, i.p.) and sacrificed 72 hr after the last injection. The striatum was dissected and prepared for ligand receptor binding assays. MPTP neurotoxicity was assessed by [^{3}H]mazindol binding to the dopamine carrier. The total number of [^{3}H]mazindol binding sites in striatal tissue derived from MPTP-treated mice was reduced by 60-65% (control = 520 fmole/mg protein). Labeling of PBRs by [^{3}H]PK 11195 and [^{3}H]Ro5-4864 revealed a 30-40% increase in the Bmax of these ligands. Since the PBR is known to be associated with steroidogenesis, our findings suggest a role for the PBR and neurosteroids in the pathogenesis of MPTP neurotoxicity. (Supported by the Department of Veterans Affairs.)

FIXED-RATIO DISCRIMINATION TRAINING (FRDT) REVERSES FUNCTIONAL APOMORPHINE (APO) HYPERSENSITIVITY IN A RAT MODEL OF PARKINSON'S DISEASE (PD). K.R. Van Keuren, C.J. Stodgell, S.R. Schroeder, and R.E. Tessel*. Dept. of Pharmacology and Toxicology and the Schiefelbusch Institute For Life Span Studies, Lawrence, KS 66045-2505

FRDT reverses neonatal 6-hydroxydopamine (6HD)-induced striatal dopamine (DA) and metabolite depletion in an adult rat Lesch-Nyhan Syndrome (LNS) model (Tessel et al., Pharmacol. Biochem. and Behave. 51: 861, 1995; Stodgell et al., Brain Res. 713: 246, 1996). To determine if similar changes would occur in a rat PD model, 2-month old rats received two injections one week apart of 6HD (200 ug per injection the first injection after 50 mg/kg pargyline; Breese et al., BR. J. Pharmac. 42: 88, 1971) or vehicle (control); route of administration was ICV. Two weeks after PD rats had started eating solid food (approx. 1 mo later), all rats were weight-reduced to 85% of *ad libitum*, which was maintained throughout the experiment. Then, half of each treatment group were exposed to 6.5 months of FRDT; the remainder were left untrained (UT) in their home cages for the same period. Behavioral responsiveness to amphetamine (AMP) was significantly reduced in PD animals prior to training (T), but were sensitized in both T and UT rats when assessed 1 week post-T. One week later, responsiveness to APO was tested. 6HD-treatment abolished APO-induced intense licking. However, T abolished hypersensitivity to APO-induced locomotor activity and rearing in PD rats. Thus, in contrast to LNS rats, in PD rats, T only induces a small non-significant recovery from 6HD-induced striatal DA depletion. Nevertheless, the present data suggest that FRDT would be useful in the treatment of humans with PD. (Supported in part by PHS grant #PO1-HD26927)

833.14

STRIATAL INFUSION OF MALONATE PRODUCES CELL LOSS IN IPSILATERAL SUBSTANTIA NIGRA. L. Manzino*, G.D. Zeevalk, P.K. Sonsalla, C.M. Sinton and D.C. German. Dept. of Neurology, UMDNJ-RWJ Med. Sch., Piscataway, NJ 08854 and Dept. of Psychiatry, UT Southwestern Med. Sch., Dallas, TX 75235.

Studies from several laboratories have demonstrated mitochondrial defects in Parkinson's disease. These findings suggest that impaired energy metabolism might contribute to the neurodegeneration of the nigrostriatal dopamine (DA) neurons. In experimental animals, impaired energy metabolism can produce a loss of neurons. We have previously shown that an intranigral infusion of malonate, a reversible inhibitor of succinate dehydrogenase, produces extensive cell loss in the infused substantia nigra pars compacta and a loss of DA in the ipsilateral striatum. Substantial damage to striatal DA nerve terminals also occurs after an intrastriatal infusion. However, it is not known if there is a loss of nigral DA cells following a striatal infusion of malonate. The purpose of the present study was to evaluate nigral cell morphology one month after a striatal infusion of malonate (4 μmol/1μl) in male Sprague-Dawley rats (4 mos old). DA was reduced by >70% in the infused striatum as compared to contralateral side (12.1 ± 0.9 μg/g, mean ± SD, n = 3). In the substantia nigra pars compacta ipsilateral to the injection, there was a substantial loss of TH-positive cells (47 ± 5 %, n = 3) but no change in the number of Nissl/non-TH containing cells as compared to the contralateral side. These findings suggest that decreased energy metabolism in the striatum is not only damaging to the dopaminergic nerve terminals but also can lead secondarily to the loss of nigral DA cell bodies. This work was supported by a grant from the National Parkinson Foundation.

L-DOPA EXACERBATES AMPHETAMINE-INDUCED DOPAMINE DEPLETION. C.S. Myers*, L. Yu, M. Witten, G.C. Wagner. Psychology Dept., Rutgers Univ., New Brunswick, NJ 08903

The present study addressed the hypothesis that the combination of RO4-4602 plus L-dopa would exacerbate amphetamine-induced neurotoxicity. Mice were pretreated with either saline or RO4-4602 plus L-dopa (25 or 100 mg/kg) prior to receiving SC amphetamine (15 mg/kg) every 2-hr for 4 injections. Amphetamine alone caused significant depletions of striatal dopamine (to 29% of control) and DOPAC (to 48% of control) when mice were assayed one week later. Pretreatment with L-dopa (100 mg/kg) significantly exacerbated the depletion of striatal dopamine (by 15%) and DOPAC (by 20%) induced by the amphetamine. The enhancement of amphetamine-induced dopaminergic toxicity may be consequent to the increase in dopamine turnover following L-dopa, a situation akin to that observed in the compromised dopaminergic neurons of the Parkinsonian patient.

PRE-PUBESCENT OVARIAN HORMONES DETERMINE THE SEXUAL DIFFERENCES IN SENSITIVITY TO METHAMPHETAMINE-INDUCED STRIATAL DOPAMINE DEPLETION IN ADULT MICE. L.Yu*, L.A.Selznick and G.C.Wagner. Dept. of Psychology, Rutgers Univ., New Brunswick, NJ 08903.

The administration of four consecutive doses of methamphetamine (10 mg/kg) causes greater, long-lasting depletions of striatal dopamine in adult male as compared to adult female mice. However, gonadectomy of adult mice and a subsequent reduction of gonadal hormones did not alter the magnitude of methamphetamine-induced dopamine depletion or the differential sensitivity between two sexes. The present study investigated the effect of pre-pubescent gonadectomy in modulating this sex-dependent, differential sensitivity to the neurotoxic effects of methamphetamine. Orchidectomy on day 21 postpartum did not alter the magnitude of the dopamine depletion induced by methamphetamine on day 90 as compared to sham-surgical, control male mice treated with the same dosing regimen; furthermore, both intact and pre-pubescent orchidectomized males treated with methamphetamine had greater dopamine depletions than intact female, methamphetamine-treated mice. However, ovariectomy on day 21 postpartum significantly increased the sensitivity of these mice to the methamphetamine-induced dopamine depletion (again treated on day 90) as compared to the sham-surgical controls. These observations are discussed with respect to the role of ovarian hormones in modulating methamphetamine-induced neuronal damage.

DOSE-DEPENDENT EFFECTS OF AMPHETAMINE AND GINSENG TOTAL SAPONIN ON FIXED-INTERVAL PERFORMANCE IN RATS. G.C. Wagner*, L.Yu, J. Palmer and A.K. Halladay. Psychology Dept., Rutgers Univ., New Brunswick, NJ 08903.

Past studies indicated that ginseng total saponin (GTS) antagonized the neurotoxic effects of amphetamine. Therefore, the interaction of GTS with amphetamine was studied in rats performing on a FI-90 s schedule for water reinforcement. Amphetamine (IP 30 min presession) disrupted performance in a dose dependent manner with an ED-50 of 1.8 mg/kg for quarter life value, 2.0 mg/kg for total responses, and 1.9 mg/kg for reinforced responses. GTS administered alone (IP 30 min presession) did not alter performance on any of the measures except at the high dose of 100 mg/kg. When amphetamine was coadministered with various doses of GTS, the amphetamine dose response function shifted to the right, achieving statistical significance at 50 mg/kg (ED-50=3.0 for quarter life value). Neurochemical analysis revealed no significant differences in striatal dopamine or DOPAC between groups receiving saline, 50 mg/kg GTS or 50 mg/kg GTS + 2 mg/kg amphetamine 30 minutes prior to sacrifice. These observations provide a behavioral verification that GTS antagonizes the effects of amphetamine.

MARKED ALTERATIONS IN APOLIPOPROTEIN E IMMUNOREACTIVITY FOLLOWING ACUTE SUBDURAL HEMATOMA. K. Horsburgh*, M. Fitzpatrick, M. Nilsen, J. A.R. Nicoll^ Wellcome Surgical Institute and Department of Neuropathology^, University of Glasgow, Glasgow G61 1QH, UK.

There is a genetic association between apolipoprotein E (apoE) and human CNS disorders such as Alzheimer's disease and head injury however, the mechanistic association remains unknown. This study examined alterations in apoE in the rat cortex following acute subdural hematoma which in humans is a major complication following head injury.

Acute subdural hematoma was induced in male, adult Sprague-Dawley rats by injection of autologous venous blood into the subdural space. In sham animals (n=10), hematomas were not induced. The brains were perfusion fixed with 4% paraformaldehyde at 30min (n=6) or 4hr (n=6) post-hematoma, cryoprotected and processed for immunohistochemistry. Sections were immunostained to apoE and counterstained with haematoxylin. Extensive areas of ischemic cell damage were observed in the cortex underlying the hematoma with minimal damage observed in shams.

In sham animals, apoE immunoreactivity was minimally altered compared to normal cortex and was confined to astrocytes and their processes. Following the hematoma induction, apoE immunoreactivity was dramatically altered. At 30min post-hematoma, intense apoE staining was observed in clusters of neuronal perikarya and the neuropil throughout the cortical layers underlying the hematoma and this persisted at 4hr post-hematoma. Additionally, at 4hr post-hematoma marked apoE staining of discrete foci within the neuropil was consistently observed in the ipsilateral cortex and this was closely associated with capillaries.

This study demonstrated marked and rapid alterations in the cellular localisation of apoE following acute subdural hematoma which may be pertinent to human pathophysiology.

THE EFFECT OF THE MUTATION FOUND IN HEREDITARY CEREBRAL HEMORRHAGE WITH AMYLOIDOSIS, ICELANDIC TYPE, ON CYSTATIN C STABILITY AND AGGREGATION. E. Levy*. Depts. Pharmacology and Pathology, New York University Med. Center, New York, NY 10016.

The amyloid deposited in the cerebral vasculature of patients with the Icelandic autosomal dominant form of hereditary cerebral hemorrhage with amyloidosis, HCHWA-I, is a variant of cystatin C, a cysteine protease inhibitor. The concentration of cystatin C in the cerebrospinal fluid of HCHWA-I patients is lower compared to normal controls. The amino acid substitution, Leu68Gln, may be the primary defect in this inherited disorder, rendering the protein resistant to normal turnover, enhancing its susceptibility to fibrillogenesis and deposition in cerebral vessel walls. It may affect the processing, secretion and accumulation of cystatin C in vessel walls with a concomitant depletion from the cerebrospinal fluid.

We compared the expression, processing, secretion and aggregation of the variant cystatin C to the wild type protein in human kidney 293 cells stably overexpressing the cystatin C genes. Pulse-chase experiments followed by electrophoretic analysis of immunoprecipitated proteins from cell lysates and cell culture media demonstrated similar levels of normal and mutated cystatin C protein expression and secretion. However, the cystatin C normal protein secreted into the culture media was unchanged for much longer periods of time than the mutated protein suggesting a difference in stability and/or aggregation between the normal and Icelandic variant of cystatin C. Supported by NIH grant AG11481.

CEREBROVASCULAR AMYLOID IN HEREDITARY CYSTATIN C AMYLOIDOSIS AND VASCULAR SMOOTH MUSCLE CELLS. F. R. Thormodsson*, I. H Olafsson, M. G. Hrafnsdottir, and H. Blöndal. Dept. of Anatomy, University of Iceland, Med. Sch., 101 Reykjavik, Iceland.

Hereditary Cystatin C Amyloidosis (HCCA) belongs to a family of conditions (Cerebral Amyloid Angiopathies, CAA), that includes Alzheimer's disease, and all manifest amyloid deposits in blood vessels and other tissues. HCCA, which is confined to Iceland, is characterised by amyloid fibre, constructed from variant of cystatin C, that are deposited in blood vessels of the brain (and other tissues), and causing haemorrhage early in life. Microscopically small arteries and arterioles throughout the CNS are seen infiltrated by hyaline material, that stains positively with anti-cystatin C antibodies. The hyalinisation is found most consistently in the tunica media, among scattered smooth muscle cells in different stages of degeneration. By double immunostaining for smooth muscle α-actin and cystatin C, it is apparent that the smooth muscle cells (SMC) disintegrate and disappear as they get buried in increasing quantity of cystatin C amyloid, whereas the endothelia appears unaffected. Therefore it is possible that SMC might be active participant in its formation, as has been reported for Alzheimer's disease. To investigate if SMC in blood vessels are a major source of cystatin C, we immunostained, isolated SMC from human umbilical cord. An intense staining for cystatin C, showing pattern compatible with protein en route through the golgi apparatus, was found in the SMC. However, cystatin C immunostaining of cultured fibroblasts and endothelial cells was insignificant. [Supported by The Icelandic Research Council]

NUCLEOTIDE EXCISION DNA REPAIR IN THE DEVELOPING AND ADULT RAT BRAIN P.J. Brooks,* Section on Molecular Neurobiology, Laboratory of Neurogenetics, Nat'l Inst. on Alcohol Abuse and Alcoholism, Rockville. MD 20852

DNA repair is essential for maintaining the integrity of genomic DNA over time. In view of recent increases in understanding specific types of DNA repair, there is a need for studies of distinct DNA repair processes in brain cells. Previous work from this lab described short patch DNA mismatch repair in extracts from adult brain (J Neurosci 16:939). In studies presented here I have focused on nucleotide excision repair (NER) in the adult and developing rat brain. The neurological degeneration seen in human patients with Xeroderma Pigmentosum (XP), who lack the capacity to carry out NER due to genetic defects, indicates that nucleotide excision repair is critically important in brain cells.. To examine NER in brain cells, I used a 140 base duplex DNA containing a cholesterol "lesion", which has been shown to be an excellent substrate for the human NER machinery (JBC 270:20862). Extracts from adult and embryonic (E16) brain could remove an approx. 28 base long oligonucleotide containing the damaged base, in an ATP dependent reaction, characteristic of NER. No such excision activity was detected using a control substrate. Levels of this excision activity in extracts for adult cerebellum (CB) were comparable to those seen in replicating CHO cells. NER synthesis of DNA containing platinum adducts was also detected in extracts from adult CB and E16 brain. Ongoing experiments include the detailed analysis of the excision and repair synthesis steps in brain extracts, and the regulation of these activities during brain development. Such work may help to better understand the neurological deficits in XP patients and to address DNA repair deficits in other neurological diseases.

CREATINE KINASE ISOENZYMES IN NEOCORTEX OF PATIENTS WITH NEURODEGENERATIVE DISORDERS. M.V.Aksenova*, M.Y.Aksenov, J.Q.Trojanowski^ and J.M.Carney. Dept. of Pharmacology, Univ. of KY, Lexington, KY, 40536. ^Dept. of Pathology , Univ.of PA School of Medicine, Philadelphia, PA.

Creatine kinases (CKs) are a family of enzymes catalyzing the reversible transfer of a phosphoryl group between ATP and creatine. CKs play a key role in energy transfer in cells with high energy requirements. In brain two of the four isotypes of CK are expressed: cytoplasmic BCK and mitochondrial ubiquitous uMtCK. Because of the central role of the CK system in regulation of brain ATP, alterations in CK have been proposed in CNS diseases with altered energy metabolism. It was shown previously that total CK activity decreased dramatically in the brain in Alzheimer's disease (AD). In present study we compare total CK activity in brains of patients with AD, Pick's disease (PD), Parkinson disease (PkD) and diffuse Lewy body disease (DLBD). We demonstrate that with the lowest level of total CK activity in the brain of AD patients (about 10% of normal controls), CK activity was declined in DLBD (50% of control), PD (30% of control) and did not significantly change in PkD. To estimate the contribution of BCK and uMtCK isoforms in total CK activity, CK isoenzymes were separated by non-denaturing electrophoresis following by the activity staining . The content of immunoreactive CK isoforms was assessed by Western blotting. The results demonstrate that the decrease of total CK activity in AD, PD and DLBD is exclusively due to the decline of BCK isoenzyme activity and content, while in PkD BCK activity and content were similar to control. In contrast to the other disease brains in PkD uMtCK activity was not detectable, while the level of immunoreactive protein varied from very low to normal. The inactivation of mitochondrial isoform (uMtCK) in PkD did not significantly affect the total CK activity numbers due to the high prevalence of cytosolic isoenzyme (BCK). This study shows that patients with major neurodegenerative disorders have marked damage to brain CK.

α-SPECTRIN BREAKDOWN BY CALPAIN AND ICE-LIKE PROTEASE(S) IN NEURONAL APOPTOSIS. Rathna Nath*, Kadee J. Raser, Daniel Stafford, Iradj Hajimohammadreza, Avigail Posner, Hamish Allen†, Robert V. Talanian†, Po-wai Yuen and Kevin K.W. Wang, Department of Neuroscience Therapeutics and Neuroscience Chemistry#, Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, Ann Arbor, Michigan 48105, USA; BASF Bioresearch Corporation†, Worcester, Massachusetts 01605, USA.

In necrotic neuronal cells (e.g., maitotoxin-treated human neuroblastoma SH-SY5Y cells and rat cerebellar granule neurons), cytoskeletal protein α-spectrin was degraded by cellular calpains, producing breakdown products (SBDPs) of 150 kD and 145 kD. In contrast, in neuronal cells undergoing apoptosis (granule neurons subjected to low potassium and SH-SY5Y cells treated with staurosporine), an additional SBDP of 120 kD was observed. The formation of the 120 kD SBDP was insensitive to calpain inhibitors (calpain inhibitor I and PD150606) but was completely blocked by an interleukin-1beta converting enzyme (ICE)-like protease inhibitor, Z-Asp-$CH_2OC(O)$-2,6-dichlorobenzene. Autolytic activation of both calpain and ICE-homolog CPP32 was also observed in apoptotic cells. Furthermore, α-spectrin can be cleaved *in vitro* by purified calpains to produce the SBDP doublet of 150/145 kD and by ICE homolog CPP32 to produce SBDPs of 150 kD and 120 kD. Inhibition of either ICE-like protease(s) or calpain protects both granule neurons and SH-SY5Y cells against apoptosis.

CADMIUM TOXICITY IN A MOUSE NEURONAL CELL LINE LEADS TO THE ACCUMULATION OF UBIQUITINATED PROTEINS AND HSP70, AS WELL AS TO CHANGES IN GLUTATHIONE, GLUTATHIONE DISULFIDE AND PROTEIN MIXED-DISULFIDES." Maria E. Figueiredo-Pereira*, Svetlana Yakushin and Gerald Cohen, *Depts. of Pharmacology and of Neurology, Mount Sinai School of Medicine of CUNY, N.Y., N.Y. 10029*

Ubiquitin protein conjugates are commonly detected in neuronal brain inclusions of patients with neurodegenerative disorders. The failure to eliminate the ubiquitin-protein deposits in the degenerating neurons may result from changes in the activity of the ubiquitin/ATP-dependent proteinase also known as the 26S proteasome. This proteolytic pathway plays a major role in the degradation of short lived, abnormal and denatured proteins. Cadmium is a potent cell poison and is known to affect the ubiquitin pathway and to cause oxidative stress. To investigate the relationship between the ubiquitin pathway and cellular glutathione (GSH), we treated HT4 cells (a mouse neuronal cell line) with different concentrations of the metal ion. Four hour incubations with 10 μM Cd^{++} induced the accumulation of ubiquitinated proteins as well as of the heat shock protein HSP70. Detection was by Western blotting of total cell extracts probed with antibodies that recognize ubiquitin-protein conjugates and HSP70, respectively. Increases in glutathione disulfide (GSSG) and protein mixed-disulfides (PrSSG) are often used as markers of oxidative stress. We observed marked increases in GSSG and PrSSG, as well as GSH, after four hours of exposure to 50 μM Cd^{++}. These higher Cd^{++} concentrations led to a change in cell morphology and to cell death. These results suggest that the ubiquitin-pathway is closely involved in the cell response to oxidative stress. (Supported by NIH grants NS29936, NS34018 and NS23017).

HIPPOCAMPAL NEURODEGENERATION INDUCED BY QUINOLINIC ACID: HISTOLOGICAL AND BEHAVIORAL PROTECTION BY NICOTINE. A.B. O'Neill[1], S.J. Morgan[2], T. Sykora[2], S. Postl[2] and J.D. Brioni*[1]. [1]Neuroscience Discovery (D-47W) and [2]Pathology Department (D-469), Abbott Laboratories, Abbott Park, IL 60064.

The neurotoxic effect of quinolinic acid injections in the hippocampus was investigated in Long Evans rats. Quinolinic acid (60, 180 and 600 nmoles/0.5 μl) was injected in the dorsal hippocampus of anesthetized rats under stereotaxic control, and the rats were sacrificed 1 or 3 days later. Histological evaluations (H&E stain) at Day 1 post injection revealed a complete neuronal loss in the 180 and 600 nmoles groups. At this time point, rats that received 60 nmoles exhibited a substantial neuronal loss, but with retention of a portion of the dorsal dentate. By day 3 a complete neuronal loss was evident in the hippocampus.

To determine the potential neuroprotective effect of (-)-nicotine, rats were subcutaneously implanted with Alza minipumps that delivered saline, 19 and 62 μmol/kg/day of (-)-nicotine. Two weeks later, the rats received bilateral injections of quinolinic acid (60 nmoles), and after a recovery period of one week they were trained in the Morris water maze. Quinolinic-injected rats were significantly impaired to find the platform in comparison to control rats; this cognitive impairment was not affected by the lower nicotine dose, but a significant improvement was observed in those rats receiving 62 μmol/kg/day of (-)-nicotine. Histological analysis confirmed that (-)-nicotine provided a significant neuroprotection in the hippocampus at the 62 μmol/kg/day dose.

These data indicate that a subacute treatment with (-)-nicotine protects against quinolinic acid induced neurodegeneration at the histological and behavioral levels. The use of novel nicotinic ligands with reduced side effect liabilities in comparison to (-)-nicotine could be of benefit for the treatment of some neurodegenerative disorders. *[Supported by Abbott Laboratories]*

U-95666E: A POTENTIAL NEUROPROTECTIVE DRUG. V.H.Sethy* and H.Wu, Pharmacia & Upjohn, Inc., Kalamazoo, MI 49001

Dopamine agonists (DAA) have been shown to be neuroprotective in animal models of neuronal insults. U-95666E (U) is a dopamine agonist and it has been investigated for neuroprotective effects in a 3-acetylpyridine (3-AP) model of neurotoxicity using Wistar rats. Cerebellar cGMP and ATP and motor coordination were measured to assess the neuroprotective effects of U, and the results were compared with those obtained with bromocriptine (BR). 3-AP (500 μmol/kg i.p.) significantly ($p<0.01$) decreased cGMP and ATP and impaired motor coordination. Oral treatment with U or BR dose-dependently attenuated 3-AP-induced reduction in cGMP and ATP when administered before and after the injection of 3-AP. U and BR had similar potency and efficacy. 3-AP-induced impaired motor coordination was also significantly attenuated by U and BR. In addition, a significant ($p<0.01$) neuroprotection was observed when U (60 μmol/kg) or BR (10 μmol/kg) were given 3 hr after 3-AP. U and BR had no significant effect on body temperature. Pretreatment with raclopride (3 μmol/kg i.p.) did not block U-induced neuroprotection. The results indicate that neither hypothermia nor dopamine receptors are involved in the neuroprotective activity of U.

IDENTIFICATION OF POLYGLUCOSAN BODIES IN DIABETIC RAT BRAIN N.A. Sherren[1], S.A.L. Bennett[1,2], and D.C.S. Roberts*[1]. [1]Institute of Neuroscience, Carleton University, Ottawa, Ont, Canada, K1S5B6; [2]W. Alton Jones Cell Science Center, Lake Placid, NY, USA, 12946.

Diabetes mellitus is a general term used to classify a number of distinct conditions characterized by aberrant carbohydrate metabolism resulting in hyperglycemia and glycosuria. Alterations in the carbohydrate components of the extracellular matrix and *de novo* deposition of polyglucosan bodies in diabetic tissue have been associated with nephropathy and peripheral neuropathy under both clinical and experimental conditions. The existence of central nervous system (CNS) lesions in diabetic brain has been less-well documented. In the present study, we demonstrate that polyglucosan bodies are present in the CNS of diabetic animals. Diabetic male and female animals of various ages were obtained from the spontaneous diabetic Wistar breeding colony at Health and Welfare Canada. Animals received daily injections of insulin from the onset of glycosuria to control systemic hyperglycemia. Diabetic animals, non-diabetic litter mates, and age-matched control Wistar rats were euthanized and brains examined by histochemistry and SDS-PAGE using the periodic acid-Schiff-dimedone (PAS-D) reaction. The carbohydrate composition of these polyglucosan bodies was determined by enzymatic digestion of SDS-PAGE separated glycoproteins and glycosaminoglycans and localized *in situ* by digestion of tissue sections prior to PAS-D analysis. Data indicate that diabetic rats demonstrated both extracellular and intracellular PAS-D-positive lesions as early as 7 months after onset of glycosuria while control subjects failed to demonstrate CNS polyglucosan bodies. Furthermore, in diabetic tissue, lesions became progressively more extensive with age. [Supported by an MRC grant to DCSR and an Alzheimer Society of Canada fellowship to SALB.]

ENDOGENOUS MONO-ADP-RIBOSYLATION IN RETINA AND PERIPHERAL NERVOUS SYSTEM. EFFECTS OF DIABETES. A. Gorio*, M.L. Donadoni, C. Finco and A.M. Di Giulio. Lab. for Research on Pharmacology of Neurodegenerative Disorders, Dept. Medical Pharmacol, University of Milano, Via Vanvitelli 32, 20129 Milano, Italy

The extranuclear endogenous mono-AD-ribosylation of proteins was monitored in cellular preparations of retina, superior cervical ganglion, dorsal root ganglia and peripheral nerve. At least 6 protein fraction are ADP-ribosylated in the crude extract, membrane and cytosolic fractions from control preparations, while in diabetic rats the number of labelled proteins and the extent of labelling are highly reduced. In the superior cervical ganglion and in the dorsal root ganglia labelling occurred in 10 and 7 proteins respectively, while in diabetic rats it was largely decreased. Treatment of diabetic rats with silybin, a flavonoid mono-ADP-ribosyltransferase inhibitor, did not affect hyperglycemia, but prevented the alteration of extent of protein ADP-ribosylation. These data suggest that retina and peripheral ganglia proteins are excessively *ADP-ribosylated *in vivo*. The effect of silybin was associated with the prevention of substance P-like immunoreactivity axonal transport, typical of diabetic neuropathy. In the membrane fraction of sciatic nerve Schwann cells, at least 9 proteins were ADP-ribosylated, diabetes caused a marked increase of labeling. A comparable increase involving the same proteins is triggered by chronic nerve injury and by corticosteroid treatment. Silybin treatment of diabetic rats prevented such an increase. We propose that the inhibition of excessive protein mono-ADP-ribosylation by silybin prevented the onset of diabetic neuropathy. While the effects on Schwann cells is likely indirect and secondary to the improvement of diabetic axonopathy.

EFFECTS OF EXPERIMENTALLY-INDUCED DIABETES ON LUMBAR DORSAL ROOT GANGLION CYTOSKELETAL GENE EXPRESSION. F.J. Liuzzi*, S. M. Bufton and A.I. Vinik. Dept. of Anatomy and Neurobiology and the Molecular Neurobiology Lab., the Diabetes Institutes, Dept. of Internal Medicine, Eastern Virginia Med. Sch., Norfolk, VA 23501.

Diabetic neuropathy is characterized by sensory neuronal changes that include disturbances in nociception, vibratory sense and conduction velocity. Additionally, sciatic nerve regeneration in diabetic rats is impaired. The present study examined neurofilament (NF68kD) and βIII tubulin gene expression in lumbar dorsal root ganglion (DRG) neurons in adult female diabetic and non-diabetic rats using *in situ* hybridization.

Rats were made diabetic by a single I.P. injection of streptozotocin (55mg/kg). Blood glucose levels were maintained within 200-400mg/dl by daily injections of insulin (Humulin). After 8 weeks, the rats were killed by lethal injection and perfused intracardially with PBS saline followed by buffered formalin. The L4 and L5 DRGs were harvested and placed in fresh fixative before paraffin embedding. Sections were hybridized with P^{33}-labelled cRNA probes to the 68kD NF gene and the βIII tubulin gene. Control slides were hybridized with sense probes.

Quantification of the results with an Image 1 Morphometric System (Universal Systems) suggest that diabetic DRG neurons behave similarly to axotomized DRG neurons. NF mRNA levels are decreased, while βIII tubulin mRNA levels are increased relative to those in non-diabetic DRG neurons. A number of factors including hyperglycemia and insulinopenia, may underlie these changes in cytoskeletal gene expression in diabetic DRG neurons. However, the similarity of these changes in cytoskeletal gene expression suggest that decreased growth factor availability may be a major cause of the diabetic axotomy-like response. *Supported by the Diabetes Institutes Foundation, Norfolk, VA.*

NEUROPATHOLOGY, ELECTROPHYSIOLOGY AND VASCULAR PERFUSION OF CHRONIC EXPERIMENTAL DIABETIC NEUROPATHY. J. D. Schmelzer*, P. J. Zollman, H. Sasaki and P. A. Low. Department of Neurology, Mayo Foundation, Rochester, MN 55905.

Vascular perfusion, nerve conduction and neuropathologic evaluation of peripheral nerve, superior cervical ganglia (SCG), lumbar spinal roots and dorsal root ganglia (DRG) were studied in longstanding (duration 12-18 months) streptozotocin-induced diabetic rats and age- and sex-matched control rats. Vascular perfusion was studied using ^{14}C-iodoantipyrine autoradiography. The values for different levels of peripheral nerve were not statistically different for sciatic or tibial nerves ($p > 0.05$, ANOVA). The DRG was about three times as high as nerve ($p < 0.01$), and superior cervical ganglion was significantly higher (about 5-6 fold; $p < 0.001$) than all peripheral nerve segments. Nerve conduction studies showed the markedly reduced conduction velocities in the distal nerve segments and prolonged F wave latency and proximal conduction time despite the shorter conduction pathway in diabetic rats. Neuropathic alterations, studied with light and electronmicroscopy, were those of a radicular myelinopathy and a sensory root vacuolar ganglionopathy. DRG neurons showed vacuoles of all sizes with cristae-like residue, suggestive of mitochondria. These findings suggest that diabetes mellitus has a dual effect; it accelerates the normal age-related degenerative changes in the spinal roots and DRG, and it also has a selective effect on the sensory neuron. We suggest that the combination of hyperglycemia and ischemia results in oxidative stress and a predominantly sensory neuropathy.

835.5

ELECTROGENIC Na,K PUMPING IN DIABETIC NEUROPATHY. T. Hashiguchi, A. Tanaka, J. Cristall, D. Maysinger, A.L. Padjen*. Department of Physiology, Tokyo Medical College, Tokyo, Japan, Department of Pharmacology & Therapeutics, McGill University, Montreal, QC, Canada

Diabetic neuropathy (DN) is associated with a decrease in conduction velocity of peripheral nerves presumably as a result of metabolic dysfunction that affect Na,K-ATPase activity and Na^+ channels.

We have studied Na,K pumping in peripheral nerves of streptozotocin-induced diabetic rats (STZ rats) using electrophysiological techniques (sucrose gap and intra-axonal recording). Post-tetanic hyperpolarization (PTH), elicited by supramaximal stimulation (trains of 50 - 120 s, 50 - 300 Hz), was considered to be mediated by Na,K pumping because of its sensitivity to metabolic inhibitors (blocked by 2,4-dinitrophenol, Na-azide), ouabain (partially blocked), blockade by low $[K^+]_o$ and by $[Li^+]_o$ replacement of $[Na^+]_o$.

In STZ rats the rate constant of decay of PTH (a measure of Na^+ extrusion) was significantly decreased (from $4.38 \pm 1.2\ 10^{-3}$ /s to 3.63 ± 10^{-3} /s, n = 30), as well as the area of PTH. The slope of relationship between the frequency of stimulation *vs.* area of PTH (another measure of Na,K pump activity) was decreased in diabetic rats presumably because of more pronounced defect in pumping at higher frequencies (i.e., at higher $[Na^+]_i$).

These results demonstrate a functional defect in Na,K pumping in DN, in agreement with previously established defect in Na,K ATPase.

835.6

DIFFERENTIAL EXPRESSION OF IMMEDIATE-EARLY GENES IN THE THIAMINE DEFICIENT RAT BRAIN

L. McGahan*[1,2], A.S. Hazell [2], Y. Nakabeppu [3], G.S. Robertson[1] and A.M. Hakim[2]. Dept. of Pharmacology[1], and Neuroscience Research Institute[2], University of Ottawa, Ottawa, ONT, CANADA, K1H 8M5, and Dept. of Biochemistry[3], Medical Institute of Bioregulation, Kuyshu University 69, Fukuoka 812, Japan.

Pyrithiamine-induced thiamine deficiency (PTD) in the rat is associated with selective neuronal loss in the thalamus and inferior colliculus. Although the basis for this pattern of histological damage is unclear, programmed cell death (PCD) represents one possible mechanism. Given that immediate-early genes (IEGs) encode transcriptional regulating factors which mediate PCD, the present study examined the expression of four IEG proteins (Fos, Jun, FosB, and NGFI-A) in PTD animals utilizing immunohistochemistry. Male Sprague Dawley rats (275 g) were fed a thiamine deficient diet and administered pyrithiamine (0.5 mg/kg/day, i.p.). Pair-fed control animals received a thiamine-containing diet limited in quantity to that of their PTD counterparts and saline injections. Animals were perfused transcardially at the acute symptomatic stage (day 16 - 17) of the deficiency. Immunohistochemical analysis revealed increased immunoreactivity for all genes examined in the thalamus at the acute symptomatic stage. In contrast, while elevated Fos- and Jun-like immunoreactivity were detected in the inferior colliculus, NGFI-A-like immunoreactivity declined below basal levels, suggestive of a translational block. These results indicate that differential alterations in IEG expression occur in the thalamus and inferior colliculus in response to PTD, and that PCD may contribute to the pathogenesis of PTD encephalopathy. (Supported by the Medical Research Council of Canada.)

835.7

RAT BRAIN GLUTATHIONE IS SELECTIVELY DEPLETED IN DIETARY SULFUR AMINO ACID DEFICIENCY. Tor-Agbidye J., Palmer, V., Blythe L., Craig A.M., Spencer, P.S. and Sabri M.I.* Center for Research on Occupational and Environmental Toxicology, Oregon Health Sciences University, Portland OR 97201, and *College of Veterinary Medicine, Oregon State University, Corvallis OR 97331.

Glutathione (GSH), the most abundant non-protein tissue thiol, plays an important role in the detoxification of xenobiotics. Brain GSH depletion is implicated in oxidative stress and neurodegeneration. As a cysteine-containing tripeptide, GSH levels may be impacted by dietary intake of sulfur amino acids. Brain and liver GSH levels were determined in tissue homogenates from female Sprague Dawley rats (275-300 g) maintained on a balanced diet (group A), (b) the same diet minus L-cystine and L-methionine (group B), or (c) standard rat chow (group C). Animals were housed in metabolic cages and the concentration of urinary inorganic sulfate $[SO_4]_u$ (the bulk of sulfur therein) determined daily. Group C [SO4]u baseline excretion was 30.7 ± 4.3 mmol/24h/kg. $[SO_4]_u$ was reduced to 0.6 ± 0.5 mmol/24h/kg in rats fed the sulfur-"free" diet for 5 days, as compared to 35.7 ± 2.9 mmol/24h/kg in group A. Brain GSH of group B (13.2 ± 0.4 nmol/mg protein) was 30% and 40% lower than in group A (18.7 ± 0.7) and group C (21.7 ± 1.5), respectively. Liver GSH was not reduced in rats on the sulfur-"free" diet. In conclusion, dietary sulfur amino acid intake selectively modulates brain GSH levels in rats, an observation of potential importance for brain function in individuals subsisting on low-protein diets. [Supported in part by NIH grant NS 19611].

RECOMBINANT TRANTHYRETIN VARIANTS AND TTR AMYLOIDOSIS. M. Tsiper[1], A.L. Schwarzman[1], M.P. Vitek[2], M. H. Wente[1], A. Wang[1], R. Bhasin[1]*, D. Goldgaber.[1] [1]Dept. of Psychiatry, SUNY, Stony Brook, NY 11794; [2]Dept. of Neurology, Duke Univ., NC 27710.

The key pathological features of familial amyloidotic polyneuropathy are periferal and cerebral amyloid depositions of transthyretin (TTR). In order to understand the mechanism of TTR amyloidosis we produced 47 known recombinant TTR variants in *E. coli*. All recombinant proteins were purified and analyzed for thyroxine binding and fibril formation. Several TTR variants with altered affinity to thyroxine were identified. The level of amyloidogenicity of TTR variants was compared at different pH. Only M30, G42, I50, P55 variants exhibited a high level of aggregation at pH 6.2 and 6.8. Aggregates of G42 and P55 variants at pH 6.8 formed typical amyloid fibrils. A synthetic peptide including residues 30-60 of the "hot spot region" and its mutant prototypes containing G42 or P55 did not form fibrils. These results demonstrate that structural determinants for amyloid formation should be established using the whole TTR molecule. Supported by Alzheimer's Association.

CHRONIC INTOXICATION OF KHAT (miraa) IN HUMANS

N. B. Patel , R. N. Kalaria and S. Gatere (SPON: Society of Neuroscientists of Africa) Department of Medical Physiology, University of Nairobi and Avenue Nursing Home, Nairobi, Kenya; Department of Neurology, Case Western Reserve University, Cleveland, OH 44106.

It has long been known that leaves and stems of the khat shrub (*Catha edulis Forsk*) exhibit psychostimulatory actions. An estimated 5 million people in the countries of the Arab Peninsula and Eastern Africa chew and swallow the exudate from khat for stimulatory purposes. The active ingredient of khat, cathinone, which degrades within days, has structural and pharmacological activity similar to amphetamine. The fact that relatively young Somalis exhibit a dementing disorder prompted us to investigate the possibility that their condition may be linked to habitual use of khat which causes neurotoxicity. Subjects were selected on the basis that they 1) had used khat almost daily for a minimum of five years, 2) were between 24 and 48 years of age, and 3) had not used any other drug or alcohol. Brain CT scans showed variable frontal lobe atrophy in a group of patients who had admitted use of khat for 9-22 years. Clinical features were characterized by loss of memory with profound forgetfulness, fear, apprehension, disinhibited behavior in self grooming and speech, and fitful sleep patterns. The analyses were consistent with a diagnosis of dementia involving the frontal lobes. Our observations suggest that chronic use of khat results in disturbed memory and behavior. γδ T CELLS CONTRIBUTE TO THE PATHOGENESIS OF EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS IN THE SJL MOUSE.

A. J. Rajan, Y-L. Gao, C. S. Raine* and C. F. Brosnan. Dept of Pathology, Albert Einstein College of Medicine, Bronx, NY 10461.

Experimental allergic encephalomyelitis (EAE) is an inflammatory demyelinating disease of the central nervous system (CNS) that is considered to be an animal model for the human disease multiple sclerosis (MS). In the SJL mouse a relapsing-remitting form of EAE can be induced by the adoptive transfer of myelin basic protein sensitized lymphocytes. In this model it is known that disease induction is dependent on $CD4^+$Th1-type T cells. However, γδ T cells are known to be present in EAE lesions but their role in the disease process remains obscure. In the present study, we assessed γδ T cell dynamics and distribution in spleen and CNS from mice with relapsing-remitting EAE, and studied the effect of depleting these cells on clinical and pathologic expression of disease using the mAb GL3. By immunohistochemistry and FACS analysis striking disease-related changes were observed in the γδ T cell population in the CNS. FACS analysis showed that while γδ T cells remained low in the spleen (~2% total $CD3^+$ T cells) at all stages, in the CNS they increased to ~12% at the height of the acute attack, fell to ~5% during the recovery phase, but rose again to ~12% during the chronic phase. In animals in which γδ T cells were depleted immediately before the onset of acute disease, or during the chronic stage, a striking and significant reduction in the severity of the clinical signs was observed that was associated with a decrease in the percentage of $CD3^+$/ γδ T cells in the CNS. In depleted animals a statistically significant reduction in inflammation and demyelination was noted during the acute stage, but only marginal effects on these disease parameters were found in the chronic phase. Taken together the data support the conclusion that γδ T cells play an important role in the pathogenesis of EAE in mice during both acute and chronic-progressive phases of the disease process. Supported by USPHS grants NS31919 and NS11920.

APOPTOTIC CELLS IN THE CNS DURING THE CHRONIC PHASE OF ACTIVELY-INDUCED EAE: EVIDENCE FOR CONTINUAL IMMUNE CELL MIGRATION.

S.J. Hyduk*, H. Horner# and S.J. Karlik. Dept of Physiology, University of Western Ontario, London, Ontario, Canada N5A 3C1 and Athena Neurosciences#, South San Francisco, CA.

In experimental allergic encephalomyelitis (EAE), cells of the immune system enter the CNS via a VLA-4/VCAM-1-dependant process causing inflammation and demyelination. We have previously shown that anti-VLA-4 reversed the clinical and histological signs of actively-induced EAE. Apoptotic T cells and macrophages have been identified by other investigators during the spontaneous recovery of acute monophasic EAE. Actively induced EAE of the guinea pig does not follow this monophasic course; after the initial acute episode, animals enter a chronic progressive disease with continued clinical deficits. The purpose of this study was to identify the presence of apoptotic cells throughout acute and chronic phases of EAE. Apoptotic cells were identified *in situ* through fluorescent detection of end-labelled genomic DNA in paraffin-embedded sections of spinal cord. Labelled cells were observed several days following the onset of cell infiltration of the CNS. Significant numbers were seen throughout the acute and chronic stages of EAE, despite the fact that animals never recovered from disease and continued to show CNS inflammation. The number of apoptotic cells in anti-VLA-4 treated animals was similar to that seen in control animals at the same time after immunization (d12-15). However, treated animals had fewer non-apoptotic inflammatory cells. This suggests that programmed-cell death of CNS inflammatory cells also occurs in chronic EAE. However, instead of showing the recovery of monophasic disease, continued cellular trafficking maintains the inflammatory reaction. Therefore, disease reversal produced by anti-VLA-4 therapy is likely related to the prevention of entry of additional inflammatory cells, while the existing inflammation undergoes apoptotic clearance. This further supports the efficacy of anti-VLA-4 treatment for autoimmune disorders of the CNS such as multiple sclerosis. (Supported by the Multiple Sclerosis Society of Canada).

GENDER DIFFERENCES IN NITRIC OXIDE PRODUCTION IN MICE WITH EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

M. Ding*, J Wong, G. W. Ellison, R. R. Voskuhl. Multiple Sclerosis Research, Dept. of Neurology, Univ. of California, Los Angeles, CA 90095.

Inducible nitric oxide synthase (iNOS) has been shown to be involved in the pathogenesis of multiple sclerosis (MS) and experimental autoimmune encephalomyelitis (EAE), an animal model for MS. Since EAE is more prevalent in female than in male mice, we hypothesized that the NO and iNOS production in EAE mice may be unevenly distributed in female and male mice. In the present study, myelin specific T lymphocytes derived from either female or male mice were used to induce EAE in female and male mice. The clinical scores of EAE severity were recorded. The iNOS mRNA expression, iNOS enzyme activities, NO and cGMP production were determined by Northern blot analysis, citrulline assay, Griess reaction and radioimmunoassay, respectively. We found that both the sex of the donor cells and the gender of the recipients contributed to the EAE severity as well as NO production. The clinical scores of EAE severity indicated that T cells from female mice induced significant EAE in female but not male recipients. However, T cells from male mice failed to induce severe EAE either in female or male recipients. The levels of NO production in the EAE mouse brains displayed a similar sex distribution as the clinic scores, and were highly correlated to the EAE severity. Furthermore, only T cells from female donors induced significant iNOS mRNA, iNOS enzyme activities, and cGMP production in female but not male recipients. No significant iNOS expression and cGMP production were found in either female or male mice after stimulation by male T cells. These data showed a similar uneven gender distribution of iNOS expression, NO production and EAE severity. In addition to providing more information about the skewed sex distribution of EAE susceptibility, these results indicate a possible role of iNOS-derived NO in the pathogenesis of EAE.

INHIBITION OF EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS IN MICE BY ANTISENSE KNOCKOUT OF INDUCIBLE NITRIC OXIDE SYNTHASE

M. Zhang*, J.L. Wong, R. R. Voskuhl, G. W. Ellison and M. Ding. Dept. of Neurology, Sch. of Med., Univ. of California at Los Angeles, Los Angeles, CA 90095.

Increasing evidence has shown a correlation between inducible nitric oxide synthase (iNOS) and multiple sclerosis (MS). Specific blockade of iNOS production might be an effective therapy for MS. In the present study, we used antisense oligodeoxynucleotide(OLD) to specifically stop iNOS protein translation and inhibit the induction of experimental autoimmune encephalomyelitis (EAE) in mice, an animal model for MS. A 21 base phosphorothiorate oligodeoxynucleotide (S-OLD) was designed to be complementary to the translation initial site of mouse iNOS mRNA. The specificity and efficacy of the S-OLD in inhibiting iNOS was evaluated both *in vitro* and *in vivo*. The antisense S-OLD significantly inhibited lipopolysaccharide (LPS) and gamma interferon (IFN-γ)-induced iNOS mRNA expression, iNOS protein synthesis, NO induction, and cGMP production in mixed glial cultures derived from adult *SJL* female mouse brains. When myelin specific T lymphocytes were injected into adult *SJL* female mice to induce EAE, the induction of EAE was significantly blocked by intraventracular injection of the S-OLD. The antisense treatment significantly reduced the clinic score of EAE, iNOS activity and NO production in EAE mouse brains . Neither the sense nor the random S-OLD had any significant inhibitory effects in the studies described above. These data suggest that the antisense knockout strategy is specifc and efficient for the inhibition of iNOS and blockade of EAE induction. This strategy might shed some light on a novel therapy for MS.

The above studies were supported by grant from the Nancy Davis Foundation for Multiple Sclerosis.

DIFFERENTIAL TGF-ß ISOTYPE EXPRESSION IN MULTIPLE SCLEROSIS.

NS Peress*, E Perillo. Neuropathology, SUNY SB, Stony Brook, NY 11794-7025 and VAMC Northport, NY, 11768

We utilized isoform specific antibodies to define TGF-ß1, 2 and 3 expression in 14 MS cases representing a spectrum of disease activity. Acute active lesions were characterized by TGF-ß2 immunoreactivity of ramified microglia which encircled the lesion. Astrocytes in these lesions were faintly TGF-ß2 and 3 positive. In chronic active lesions ramified microglia were not notably positive. Reactive astrocytes, within white matter lesions, expressed all three isotypes. In contrast, selective TGF-ß2 isotype expression characterized reactive astrocytes within cortical boundaries of chronic active lesions. This isotype was also selectively expressed by astrocytes in normal white matter. In acute and chronic active lesions, hematogenous leukocytes exhibited reactivity for all three isotypes. In cases with only chronic inactive lesions, astrocyte TGF-ß immunoreactivity, within lesions, was faintly positive for all three isotypes. Younger control brains did not exhibit glial TGF-ß immunoreactivity while some microglia and astrocytes were TGF-ß2 positive in the older controls. The results suggest that TGF-ß cytokines participate in the evolution of MS lesions and that the ß2 isotype maybe of particular importance in determining lesion boundaries.

SEQUENCE ANALYSIS OF A cDNA LIBRARY MADE FROM MULTIPLE SCLEROSIS LESIONS. 1K.G.Becker,1A.M.Gado,1J.Joy*,2D.Mattson, 1W.E.Biddison 1Neuroimmunology Branch,NINDS,NIH,Bethesda, MD 20892; 2Univ. of Rochester Medical Center, Rochester, NY,14642.

mRNA was prepared from autopsy specimins of four lesions from a patient with chronic progressive multiple sclerosis. This mRNA was used to create a normalized cDNA library (2NbHMSP)(Bento Soares, Columbia Univ.). This library was sequenced through the Washington Univ.-MERCK EST sequencing project using the IMAGE consortium protocol. This resulted in the sequencing of 13,698 5' and 3' ends.

A number of sequences coding for autoantigens were isolated including; 69 KD islet cell autoantigen, paraneoplastic cerebellar degeneration-associated autoantigen, SM-D1, SP-100, and KU autoantigen P86. Many sequences were found that code for immunoregulatory molecules including; IL-10,IL-15,MIP1 alpha,RANTES,cystatin A&B, among others. Receptors for immunologically improtant molecules were also isolated including; IL-1R,IL-2R,IL-8R, IFNR alpha and beta, as well as Ig-FC receptors. Evidence of active myelin synthesis was suggested by the isolation of myelin proteolipid protein, periphereral myelin protein 22, oligodendrocyte-myelin glycoprotein precursor, and myelin associated glycoprotein precursor, No viral sequences were found, although a number of human endogenous retroviral sequences were isolated.

A 17 KD GLIOTOXIN ISOLATED FROM MULTIPLE SCLEROSIS CEREBROSPINAL FLUID INDUCES CELL DEATH IN RAT CENTRAL NERVOUS SYSTEM. N. Benjelloun, C. Charriaut Marlangue, Y. Ben-Ari & F. Rieger*. INSERM U. 153, 17 Rue du Fer à Moulin, 75005; INSERM U. 29, 123 Bd du Port Royal 75014 Paris France.

The cerebrospinal fluid (CSF) from multiple sclerosis (MS) patients contains an original toxic glycoprotein behaving with an apparent molecular weight of 17 kD. This protein selectively induces apoptotis of oligodendrocytes and astrocytes in vitro. We have injected 5-10 ng of this protein in rat CSF and investigated whether the 17 kD protein induces specific cell death in rat central nervous system (CNS), 10 days after injection. We used the TUNEL method to identify the degenerative cells and immunohistochemical technique combined to TUNEL method to characterize the type of dying cells. $TUNEL^+$ cells were observed in the choroid plexus, ependymal cells, in the white matter, often in the gray matter of brain and spinal cord, in the cerebral vascular endothelium and in the arachnoid spaces. The predominant type of $TUNEL^+$cells were GFAP immunoreactive astrocytes. They were seen arround damaged endothelial cells and in the ventricular and subpial spaces. $TUNEL^+$ cells were shown as oligodendrocytes (RIP immunostaining). They were associated with multifocal demyelinating areas. We thus demonstrate in this animal model that the 17 kD toxic glycoprotein isolated from MS CSF is a potential demyelinating protein and we suggest that the early alteration of astrocytes, known to maintain the structural and fonctional integrity of the brain, is possibly implicated in a breakdown of the blood brain barrier and in a demyelinating cascade.

CALPAIN'S ROLE IN OPTIC NEURITIS, D.C. Shields, G.E. Deibler, and N.L. Banik, Jackson B. Pickett*. Neurology Dept, Med Univ SC, Charleston, SC 29425.

The mechanism of optic nerve degeneration in optic neuritis is not known. Calcium-mediated degradation of optic nerve proteins and calpain autolysis indicate the presence of activated calpain in optic nerve in vitro. To examine calpain's involvement in optic nerve destruction, we have determined calpain activity and content in Lewis rats after induction of experimental allergic encephalomyelitis (EAE), a model for human optic neuritis. Optic nerve and chiasma were collected from experimental and control animals, analyzed by SDS-PAGE and immunoblotted with 68kD, 200kD neurofilament protein (NFP) and mcalpain antibodies in association with enhanced chemiluminescence. The extent of NFP loss provides a measure of calpain activity. We found extensive degradation of both 68kD and 200kD (40% and 80%, respectively) NFPs compared to controls, indicating increased calpain activity in optic neuritis. To analyze calpain content, we quantitated the immunoreactive calpain band in control and experimental animals. There was a 104% increase in calpain content in the optic nerve of experimental animals compared to adjuvant controls. The elevated calpain content in optic neuritis may be due to increased synthesis of calpain and/or calpain present in the large number of inflammatory and proliferative glial cells in optic neuritis compared to controls. The increased calpain activity (degradation of NFPs) and synthesis found in experimental optic neuritis indicate a pivotal role for calpain in the degeneration of optic nerve in this disease. Supported by NIH-NINDS NS-31622, PVA SCRF-1238 and MUSC MSTP program.

AN INHIBITOR OF MATRIX METALLOPROTEINASE ACTIVITY AND TNFα PROCESSING IS AN EFFECTIVE THERAPY IN EXPERIMENTAL AUTOIMMUNE NEURITIS

[1]KJ Smith*, [1]EJ Redford, [1]M Davies, [1]N Gregson, [2]P Hughes, [2]AJH Gearing, [2]K Miller & [1]RAC Hughes. [1]Dept. Neurology, UMDS - Guy's Campus, London, & [2]Neures Ltd, Abingdon, Oxford, UK.

The extracellular matrix-degrading metalloproteinases (MMPs) and the pro-inflammatory cytokine, tumour necrosis factor-α (TNFα) have been implicated in the pathogenesis of autoimmune demyelinating disease. We have therefore examined the effect of an inhibitor of MMP activity and TNFα processing (BB1101) in experimental autoimmune neuritis (EAN), an animal model of Guillain-Barré syndrome.

EAN was induced in Lewis rats by immunisation with bovine peripheral nerve myelin. Administration of BB1101 by the intraperitoneal (1mg/kg, twice daily) or subcutaneous (10mg/kg, once daily) routes from the time of immunisation, inhibited inflammation and demyelination in peripheral nerves and prevented the development of neurological deficit. Treatment from the onset of symptoms also reduced disease severity. However, BB1101 did not inhibit the development of an immune response, as anti-myelin antibodies could be detected in the sera.

Combined inhibitors of MMP activity and TNFα processing may have potential as novel therapeutic agents in demyelinating diseases of the peripheral nervous system.

PERIPHERAL NERVES OF A MOUSE MODEL FOR THE CHARCOT-MARIE-TOOTH NEUROPATHY TYPE 1B SHOW INFILTRATION OF MACROPHAGES AND CD4- AND CD8-POSITIVE LYMPHOCYTES INTO PERIPHERAL NERVES. C.D. Schmid, L. Schnell#, M. Schachner and R. Martini*. Department of Neurobiology, Swiss Federal Institute of Technology and #Brain Research Institute, University of Zürich, CH-8093 Zürich, Switzerland.

We have previously shown that mice expressing half of the dose of P0 protein ($P0^{+-}$ mice) are a suitable model for the Charcot-Marie-Tooth (CMT) disease type 1B, an inherited peripheral neuropathy caused by mutations in the gene for P0. Peripheral nerves of such mice show normal myelin formation at young ages followed by myelin degeneration and onion bulb formation in mice older than four months. Myelin predominantly degenerates in muscle nerves and ventral roots, whereas cutaneous sensory nerves and dorsal roots show only subtle alterations. To investigate whether the pathological changes seen in muscle nerves and ventral roots may result from an autoimmune response against myelin components confined to these nerves, we investigated peripheral nerves of $P0^{+-}$ mice for the presence of lymphocytes and/or macrophages by electron microscopy and immunocytochemistry. We found that in mice older than four months, muscle nerves and ventral roots, but not cutaneous sensory nerves and dorsal roots were infiltrated by macrophages and CD4- and CD8-positive lymphocytes. These findings point to the possibility that immune-mediated demyelinating mechanisms could aggravate the pathological changes of some forms of hereditary demyelinating neuropathies.

Characterization of *SCA1* Transgenic Mice: A Model of Neurodegeneration Caused by CAG Trinucleotide Expansion. W.S. Yunis, E.N. Burright, H.B. Clark*, B.Hartman, W. Fahssi,C. Wilcox, A. Servadio, H.Y. Zoghbi and H.T. Orr. Baylor Coll. of Med., Houston, TX and Univ. of Minnesota, Minneapolis, MN 55455.

Spinocerebellar ataxia type 1(SCA1) is an autosomal dominant inherited neurological disorder characterized pathologically by loss of Purkinje cells (PC) in the cerebellum and neurodegeneration in the brain stem and spinocerebellar tracts. SCA1 is one of six neurodegenerative disorders, including Huntington's disease, caused by CAG repeat expansion. Striking similarities in the clinical, genetic, and molecular characteristics of these disorders suggest that, they share a common mechanism of pathogenesis. To study the effects of the expanded CAG repeat in the *SCA1* gene, transgenic mice were generated that expressed the human *SCA1* gene with either a normal or an expanded CAG tract with 30 or 82 repeats, respectively. Expression of the transgenes was directed to PC using the cell-specific gene regulatory region of *Pcp-2*. Five of six transgenic lines with the 82 repeat transgene developed ataxia while none of seven lines with the 30-repeat transgene became ataxic. The onset of ataxia was measured by RotaRod performance which preceded the significant PC loss seen later in the disease. The onset of ataxia was correlated with pathological alterations in PC. Cytoplasmic vacuolation was first detected in the third postnatal week and continued to be seen within some PC throughout the course of the disease. Ectopic PC in the molecular layer were seen, particularly later in the disease. There also was dwindling of PC perikarya and their dendrites with shrinkage and gliosis of the molecular layer. Although the dendrites retained a large degree of complexity until after the onset of ataxia, there was an apparent loss of dendritic spines in some PC. These data demonstrate that expression of expanded but not unexpanded CAG repeats in the ataxin-1 gene induces dysfunction and later death of PC. Onset of ataxia preceded the significant loss of PC indicating that it is related to effects of the CAG expansion on PC function.These findings may have significant implications for other neurodegenerative diseases with similar genetic mechanisms.(NIH1 PO1-NS33718)

ALTERNATIVELY SPLICED ISOFORMS OF THE MACHADO-JOSEPH DISEASE (MJD) GENE.

M.Ikeda*[1], A. Kaneko[2], K. Itokawa[2], K. Hamaguchi[2] and M. Nomura[1]
[1]Dept. of Physiology and [2]Dept.of Neurology, Saitama Medical School, Moroyama, Saitama 350-04, Japan

It is reported that Machado-Joseph disease (MJD) gene (MJD1a) contains CAG repeats and three MJD mRNA splice variants (MJD1a, MJD1b, MJD1c) are expressed in the human brain. To elucidate the function of the gene products, we isolated several length of the MJD cDNA from the human leukocytes using reverse transcription-polymerase chain reaction (RT-PCR) and TA cloning system. Sequence analysis of the cDNA clones identified additional two distinct isoforms, one form (MJD1d) has 54 -bp exon in the upstream of the CAG repeats containing exon and no 86-bp exon in the downstream of the first exon, another (MJD1e) has different 86-bp exon in the middle portion of the MJD gene. These two isoforms have a stop codon before the CAG repeats, resulting no glutamine tracts. The MJD1b and MJD1d isoform were identical for the coding sequence, but the two differed at the 3' noncoding region.

CYTOKINE EXPRESSION IN PATIENTS WITH INHERITED CEREBELLAR ATAXIA. P. J. S. Vig,* S. H. Subramony, P. Joshi, D. Desaiah and J. D. Cleary[1] Department of Neurology and [1]Clinical Pharmacy Practice, Univ. Miss. Med. Ctr., Jackson, MS., 39216

Increased production of interleukin-1 (IL-1) and tumor necrosis factor (TNF) has been reported in peripheral macrophages of neurological mutant mice that exhibit cerebellar degeneration. Therefore, the present study was initiated to identify changes in cytokines (CTs) in inherited cerebellar ataxias. CT levels were determined in cerebellar fractions prepared from lurcher mouse (12 day old) model and patients with inherited ataxia. The CT expression was also measured in the plasma samples and mononuclear cell cultures (MNC) prepared from the blood collected from healthy individuals and from patients with inherited ataxia. TNF∝ expression increased significantly in the cerebella of human ataxic patients as compared with the controls. However, there was no significant change in the CT levels in cerebella of lurcher mice, MNC cultures and the plasma samples of ataxic patients. The results of the present study suggest that inherited cerebellar ataxias may be associated with the increased expression of TNF∝ in the cerebellum. However, whether similar changes are observed in other peripheral systems warrant further evaluation.

Supported by National Ataxia Foundation.

CHARACTERIZATION OF THE PHOSPHOLIPID BIOSYNTHESIS PATHWAY OF HUMAN BRAIN. A. Moszczynska , B.M. Ross, L. Dixon,* and S.J. Kish. Human Neurochemical Pathology Laboratory, Clarke Institute of Psychiatry, Toronto, Ontario, Canada. M5T 1R8.

A number of studies have suggested that drugs aimed at increasing the rate of brain membrane synthesis, for example citocholine, may be useful therapies for the treatment of acute and chronic neurodegenerative conditions. However, no information is available regarding the human brain enzymes, including ethanolamine and choline kinases (EK and CK), and phosphocholine and phosphoethanolamine cytidylyltransferases (PCCT and PECT), which these drugs affect. EK and CK were located in the cytosolic compared to particulate fractions of the temporal cortex of human brain obtained at autopsy. Ethanolamine possessed a K_m of approx. 0.5mM for EK, a value significantly below the cellular concentration of ethanolamine. Choline appeared to possess dual K_m values for CK, the first being approx. 10-20μM and the second 1mM. EK was potently competitively inhibited by choline (K_i = 5μM), while both CK and EK were inhibited by phosphocholine (K_i(CK) = 550μM; K_i (EK) = 50μM), suggesting that EK is partially inhibited by choline compounds *in vivo*. Thermal inactivation experiments revealed EK to be less stable than choline kinase. The next enzyme in the pathway, PECT, was located predominantly in the cytosolic fraction, whilst its counterpart, PCCT was mainly particulate. CTP exhibited a K_m of approx. 1mM for both enzymes, well above its cellular concentrations, suggesting that the activities of these enzymes are highly dependent upon the cellular concentration of CTP, whereas the phosphobases possessed lower K_m's in the range 100-300μM. Our results suggest that different enzymes with varying regulatory properties exist for the synthesis of phosphatidylcholine and phosphatidylethanolamine, and provide a better understanding of the action of compounds which stimulate membrane synthesis in the human brain.

BRAIN MEMBRANE PHOSPHOLIPID BIOSYNTHESIS IN OLIVOPONTOCEREBELLAR ATROPHY. S.J. Kish*, A. Moszczynska, and B.M. Ross. Human Neurochemical Pathology Laboratory, Clarke Institute of Psychiatry, Toronto, Ontario, Canada. M5T1R8.

Olivopontocerebellar atrophy (OPCA) is a neurodegenerative disease characterized by a severe loss of purkinje cells in the cerebellum. Previous work has shown elevated levels of phospholipid metabolites in the disorder, suggesting that OPCA is characterized by increased rates of membrane breakdown. This may contribute significantly to cellular loss if accelerated membrane breakdown is not balanced by increased rates of membrane synthesis. We therefore examined the status of the enzymes phosphorethanolamine cytidylyltransferase (PECT) and phosphocholine cytidylyltransferase (PCCT), the rate limiting enzymes of phosphatidylethanolamine and phosphatidylcholine biosynthesis respectively. The activities of both PECT and PCCT were significantly reduced by approx. 50% in the cerebellum of 10 OPCA subjects compared with that in 10 age and sex matched controls. Thus, the capacity of neurons to produce new membrane components is reduced in OPCA, the opposite of what is required to combat increased rates of membrane breakdown. We therefore suggest that therapeutic strategies aimed at increasing the rate of membrane biosynthesis may prove useful in the treatment of OPCA and possibly other neurodegenerative disorders. Supported by NINDS grant 26034.

ALTERED PHYSIOLOGY OF PURKINJE NEURONS IN CEREBELLAR SLICES FROM IL-6 TRANSGENIC MICE. T.E.Nelson*, I.L.Campbell and D.L.Gruol. AIDS Research Center and Dept. of Neuropharmacol., The Scripps Research Institute, La Jolla, CA 92037.

The cytokine interleukin-6 (IL-6) is elevated within the brain in a number of neuropathological conditions including AIDS dementia complex. Recently, a transgenic murine model has been developed that overexpresses IL-6 and mimics many of the histopathologic and behavioral characteristics of this syndrome, including motor incoordination. In addition, IL-6 mice exhibit progressive neurodegeneration within the cerebellum (for a review see: Campbell (1995) *Int.J.Dev.Neurosci.* **13**:275). Using this model we have investigated the chronic effects of this cytokine on the firing patterns of Purkinje neurons.

Single-unit extracellular recordings of spontaneously active Purkinje neurons were taken from cerebellar slices of young IL-6 and control mice (30-74 days of age). Overall, the firing rates of Purkinje neurons in slices from IL-6 mice were significantly reduced (p<0.0001; unpaired t-test) compared to control animals. The mean spontaneous firing rate of IL-6 Purkinje neurons was 36±22/sec (mean±S.D.; n=116) compared to 62±23/sec for controls (n=130). In addition, 13% of IL-6 Purkinje neurons exhibited oscillatory firing patterns compared to only 1.5% of control neurons (p<0.0005; χ^2). In order to determine whether the overexpression of IL-6 alters Purkinje cell activity at a particular age the data were divided into four age groups: 30-34, 40-44, 45-49, and 70-74 days. In each age group transgenic mice exhibited a significantly lower spontaneous firing rate (30-50% reduction) than age-matched controls (in each p<0.005; unpaired t-test). IL-6-induced alterations of Purkinje neuron physiology will ultimately affect the flow of information out of the cerebellum and might thus explain the motor incoordination observed in both AIDS encephalopathy and transgenic IL-6 mice.

MRI MICROSCOPY OF A NON-HUMAN PRIMATE MODEL OF ALZHEIMER'S DISEASE: IRON DEPOSITS IN THE BRAIN OF THE AGED MOUSE LEMUR. E. P. Gilissen*, P. Ghosh, E. T. Ahrens, R. E. Jacobs and J. M. Allman. Beckman Lab. and Beckman Inst., Caltech, Pasadena, CA 91125.

It has been demonstrated that the formation of senile plaques and neurofibrillary tangles in Alzheimer's disease is an iron related event. The protein iron deposits should have a signature in magnetic resonance imaging (MRI) due to the electronic magnetic moments of the iron locally perturbing the static magnetic field. Standard clinical MRI systems utilizing magnetic fields typically of order 1-2 Tesla are not sensitive enough to detect localized iron deposits in the brain of human Alzheimer patients *in vivo*. The aged (more than 8 years old) mouse lemur (*Microcebus murinus*) is a good animal model for the major features of Alzheimer's disease. In order to detect the localization of iron deposits in the aged cerebral cortex, MR microscopic images of a 12-year old formalin fixed mouse lemur brain were made using a 11.7-Tesla MRI system. Images were acquired using T_2^*-weighted 3-D FLASH with TE=9ms, 57 micron cube voxel resolution, and 3hrs 45min imaging time. MRI shows features consistent with iron deposits localized mainly in nuclei of the hypothalamus, subthalamus, zona incerta (fields of Forel) and substantia innominata. They are also found in the ventral globus pallidus, nucleus accumbens, striatal fundus, septum and diagonal band of Broca. MR images of two 3-year old fixed mouse lemur brains did not show any reputed iron deposits. The iron deposits in the aged mouse lemur brain are consistent with the possible role of the hypothalamus in the regulation of life span. We thank Dr. Kenneth Glander, Duke Primate Center, for providing the Microcebus brains. Supported by the Del Webb Foundation and NIH Grant # DA-08944.

FLUPIRTINE PROTECTS NEURONAL CELLS AGAINST INDUCED APOPTOSIS *IN VITRO*: IMPLICATIONS FOR TREATMENT OF ALZHEIMER'S DISEASE, CREUTZFELDT-JAKOB DISEASE AND AIDS PATIENTS. W.E.G. Müller*, H. Ushijima†, G. Pergande‡ and S. Perovic. Institut für Physiologische Chemie, Universität, 55099 Mainz, Germany; †University of Tokyo, Tokyo 108, Japan and ‡ASTA Medica AG - Deutschland, 60314 Frankfurt, Germany.

Apoptosis [programmed cell death] is an active process which is genetically encoded. Induced apoptosis is one major cause of a series of diseases. Neurons are induced to apoptosis in response to physiological mediators, e.g. to glutamate at unphysiological concentrations [basis of neuronal injuries], and to toxins, e.g. to ß-amyloid peptide [Alzheimer's disease (AD)], HIV-1 gp120 [AIDS] and the prion protein in its altered form (PrP^{Sc}) [Creutzfeldt-Jakob disease (CJD)]. We found that flupirtine (Katadolon®), a clinically safe drug, displays an anti-apoptotic effect on neurons *in vitro* against those inducers. Flupirtine was active at concentrations between 1 and 10 µg/ml in assays using primary cortical cells. Mechanistically, flupirtine is shown (i) to interrupt the signaling pathway of induced apoptosis and (ii) to increase the level of glutathione resulting in a lowering of the reactive oxygen species. No effect of flupirtine is seen on spontaneous apoptosis. In conclusion, flupirtine combines a suitable pharmacokinetic profile with a potent neuroprotective effect. Flupirtine may slow down neuronal loss in patients with AD, AIDS and CJD. Therefore, our results provide the biochemical substrate for flupirtine to be evaluated in clinical studies as neuroprotective therapy. Perovic et al. *Europ. J. Pharmacol.* 288, 27 (1994); Ushijima et al. *Europ. J. Neurosci.* 7, 1353 (1995); Perovic et al. *Neurodegen.* 4, 369 (1995). Supported by the German Government - BMBF [01KI94863].

ACTIVATION OF MICROGLIA BY SECRETED FORM OF THE ALZHEIMER'S β-AMYLOID PRECURSOR PROTEIN. S. W. Barger.* Depts. of Internal Medicine and Anatomy, Univ. of Arkansas for Medical Sci., Little Rock AR 72205.

Inflammatory reactions may play a role in the initiation or progression of Alzheimer's disease (AD) pathology. In AD microglia are associated with amyloid plaques and express markers of inflammation, including elevated levels of cytokines and enzymes such as inducible nitric oxide synthase (iNOS). These changes could result in the neuronal pathology and clinical symptoms of AD, an hypothesis supported by reports of positive results with non-steroidal anti-inflammatory drugs. Several studies have been based on the premise that amyloid β-peptide (Aβ) -- a major component of AD amyloid plaques -- may interact with microglia to induce an activated state. However, other AD-related factors may also influence microglia and recruit them to rudimentary plaques. Previous data from this laboratory had demonstrated the ability of a secreted form of the β-amyloid precursor protein (sAPP) to stimulate an activity consistent with that of NF-κB, a transcription factor crucially involved in inflammatory gene expression. Therefore, the possible influence of sAPP on microglial activation was tested in primary cultures of microglia and in the N9 microglial cell line. Within 24 hours, low nanomolar concentrations of sAPP stimulated an increase in interleukin-1β and iNOS as detected by multiple immunological techniques. In addition, total nitrates and nitrites -- stable metabolites of nitric oxide -- were elevated in the culture medium of sAPP-treated microglial cultures. These results suggest that sAPP, elevated by brain injury, could initiate inflammatory reactions in microglia. However, several cytokines have beneficial effects on neuronal health, and even nitric oxide can be neuroprotective under some circumstances. Therefore, the ultimate implications for pathology await further analysis of the influence of sAPP-treated microglia on neuronal viability. Supported by funds from the NIH and the Inglewood Foundation.

"DEMENTIA LACKING DISTINCTIVE HISTOPATHOLOGY" DEMONSTRATES SEVERE HIPPOCAMPAL AS WELL AS FRONTAL DEGENERATION. S.E. Arnold*, L.-Y. Han, M. Grossman, C. Clark, M.L. Schmidt, J.Q. Trojanowski. Depts. of Psychiatry, Neurology, and Pathology & Laboratory Medicine, Univerity of Pennsylvania, Philadelphia, PA 19104.

Dementia lacking distinctive histopathology ("DLDH") is a descriptive entity usually referring to a spectrum of frontotemporal degenerative dementias in which atrophy, but no diagnostic lesions (e.g., neurofibrillary tangles, Pick bodies, Lewy bodies) are identified on neuropathologic examination. Previous reports have indicated that degenerative changes are largely confined to frontal and temporopolar cortices while hippocampal and other cortical and subcortical regions are infrequently, or mildly affected. In this study, 7 markers of neurodegeneration and neural injury were quantified in midfrontal (MFC) and orbitofrontal cortices (OFC), 4 subfields of the hippocampal region, and primary visual cortex. Case material included 8 patients with a clinical presentation of frontal dementia and DLDH on diagnostic neuropathologic examination, 10 age-compatible normal and 10 Alzheimer disease (AD) control cases. Compared to the normal control cases, highly significant reductions in Nissl-stained neuron densities were observed in the DLDH group with mean densities 63% lower in OFC, 35% in MFC, 60% in CA1, 47% in subiculum, 22% in entorhinal cortex, and 15% in CA3. Similar reductions in MFC and OFC neuron density were not seen in AD, and neither DLDH nor AD had reductions in visual cortex. This neuron loss was accompanied by large and statistically significant increases in ubiquitin immunoreactive (-ir) neuron densities, glial fibrillary acidic protein-ir astrocytosis, and CD68-ir microglial proliferation. No significant increases in PHF-1-ir neurofibrillary tangle counts, Aβ-ir amyloid deposits, or any RMO-32-ir Lewy bodies were observed in the DLDH group. These findings further characterize the profile of neurodegenerative changes in DLDH and highlight severe involvement of the hippocampus in addition to frontotemporal neocortices. Supported by NIH Grants MH55199, AG10124.

AMYGDALO-STRIATAL DEGENERATION IS A CENTRAL PATHOLOGICAL FEATURE OF FRONTOTEMPORAL DEMENTIA. Ann C. McKee, Neil W. Kowall, Jeremy Schmahman, Tonya Chen, Donald Siwek* & Marilyn Albert. GRECC, Bedford VAMC, Dept Neurology & Pathology , Boston University School of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA

Frontotemporal dementia is a clinically distinctive disorder associated with striking personality changes, stereotypic behaviors, and often language disturbance. The neuropathological changes that have been described are heterogeneous. Cases have been variously termed Picks disease, Dementia of the Frontal Lobe Type, Frontal Lobe Degeneration of the non-Alzheimer type, and Dementia Lacking Distinctive Histologic Features. Characteristically, the pathological changes in the cerebral cortex are insufficient to explain the patients pronounced behavioral abnormalities. We examined a group of 10 carefully studied patients and found a consistent pattern of neuronal loss and gliosis affecting the amygdala and striatum in every case. Detailed regional neuropathological analysis showed that the amygdala was consistently involved with degeneration most severe in the basal parvicellular nucleus. The nucleus accumbens and medial inferior caudate were also invariably affected. Restricted areas of the medial frontal lobe (especially layer I-II in the anterior cingulate cortex, Brodmann area 24) and a small zone of CA1-subiculum were also affected. The regional pathology is remarkable in that these neuroanatomical structures are all interrelated as areas receiving specific projections from the basal parvicellular nucleus of the amygdala. The parvicellular nucleus projects to the nucleus accumbens and the medial limbic striatum, layers I-II of the anterior cingulate cortex, and a very discrete region of CA1-subiculum. In cases with a greater degree of pathological change, the amygdala involvement spreads to involve the basal magnocellular nucleus and the temporal isocortex may be damaged. The distinctive anatomical relationship of these structures suggests that the Frontotemporal Dementia in these cases is due to a specific limbic system degeneration centered on the amygdala. Supported by grants from NIH and the VA.

BIOCHEMICAL HETEROGENEITY OF FRONTOTEMPORAL DEMENTIAS USING THE IMMUNODETECTION OF PATHOLOGICAL TAU PROTEINS. P. Vermersch*[1], P.N. Cooper[2], R. Ravid[3], D.M.A. Mann[2], A. Wattez[1], A. Delacourte[1]. [1]INSERM U422, 59045 Lille, France, [2]Department of Pathology, Manchester Univ. Med. School, M13 9PT, UK, [3]Netherlands Brain Bank, 1105 Amsterdam, The netherlands.

A number of pathologic processes may lead to the clinical syndrome of frontotemporal dementia (FTD), including atypical presentations of Alzheimer's disease (AD), Pick's disease and non specific frontal lobe degeneration (FLD). Tau proteins are the main cytoskeletal components modified during these neurodegenerative changes.

In the present study, we analyzed alterations of Tau proteins in brain samples from 15 FTD cases, using a western blot method with the monoclonal antibody AD2, which recognizes a phosphorylation-dependent Tau epitope.

Pathological Tau proteins (PTP) were immunodetected in 11 cases. In 2 of them, we found a Tau triplet similar to that encountered in AD (Tau 55, 64, 69 with smears and minor bands). In 3 other cases, we also detected this Tau triplet but without smears and minor bands. In 4 cases, Tau 55 and 64 were strongly immunoreactive, whereas Tau 69 was almost unlabeled, as described by Delacourte et al. (JNEN 1996,55,159-168). In 2 cases, we observed a different Tau doublet with an intense labelling of the two 64-69 bands. We failed to detect PTP in the 4 remaining cases.

This study shows that Tau proteins are involved in most of the FTD cases. The different Tau profiles demonstrate that FTD is biochemically heterogenous and that the biochemical approach may be useful to help for the diagnosis.

Supported by IPSEN. AD2 was developed through a collaboration between CNRS UMR 9921 and INSERM.

PICK'S DISEASE: A SPECIFIC PATTERN OF PATHOLOGICAL TAU (TAU 55 AND 64) IS PRESENT IN MANY CORTICAL AND SUBCORTICAL BRAIN AREAS.

A. Delacourte*[1], Y. Robitaille[2], P.R. Hof[3], P. Vermersch[1], N. Sergeant[1], L. Buée[1], V. Buée-Scherrer[1], D. Gauvreau[2], A. Wattez[1]. *(1) Unité Inserm 422, 59045 Lille cdx France (Fax: 33.03.20.62.20.79); (2) Projet Image; Hôp. Côte des neiges, Montréal, Canada (3) Fishberg Res. Center Neurobiol.,b1065,Mt Sinai Medical School.NY, USA.*

Pick's disease (PiD) is a dementing illness characterized by a pan-laminar frontotemporal cortical atrophy, widespread degeneration of the white matter, chromatolytic neurons and Pick bodies (PB). Microtubule-associated Tau proteins are the main cytoskeletal components modified during these neurodegenerative changes. In the present study, pathological alterations of Tau proteins were mapped in the brains of six PiD cases at both neuropathological and biochemical levels. Monoclonal antibody AD2 which recognizes a phosphorylation-dependent Tau epitope (Ser306P, Ser404P) and strongly labeled PB was used to study Tau proteins resolved on 1D and 2D gel electrophoreses followed by immunoblots.

In all PiD cases, a specific and characteristic 55 and 64 kDa Tau doublet was observed in limbic, frontal and temporal cortices as well as in striatum, locus cœruleus, substantia nigra and tectum. In their regional distribution, a certain degree of heterogeneity existed among the PiD cases, especially for the parietal cortex which was sometimes spared. The occipital cortex was never concerned. By 2D immunoblotting, Tau 55 & 64 were less acidic than the typical Alzheimer Tau triplet (Tau 55, 64, 69) and the characteristic Tau 64 & 69 doublet of corticobasal degeneration (CBD) and Progressive Supranuclear Palsy (PSP).

Tau 55 & 64 are biochemical markers of PiD. They may be very useful to help for the diagnosis of this disorder that shares similarities with CBD and frontal lobe degeneration (FLD). Together, these results show that pathological Tau proteins can differentiate at least 4 types of degenerative processes (Alzheimer / PSP,CBD / PiD / FLD).

PRP_{27-30} IS A NORMAL SOLUBLE PRION PROTEIN FRAGMENT RELEASED BY HUMAN PLATELETS.

F. Perini[1]*, R. Vidal[1], F. Tagliavini[2], V. Toso[3], B. Ghetti[4], B. Frangione[1], and F. Prelli[1]. [1]Dept of Pathology, New York University School of Medicine, New York, [2]Istituto Nazionale Neurologico C. Besta, Milano Italy, [3]S. Bortolo Hospital, Vicenza, Italy, [4]Indiana University, Indianapolis, IN.

Prion diseases are neurodegenerative disorders characterized by the accumulation of abnormal isoforms of prion protein (PrP^{Sc}) in the central nervous system. PrP^{Sc} isoforms differ from their normal homologue (PrP^{C}), in that they possess increased β-sheet conformation, are partially protease resistant and may be associated with amyloid deposition. Amyloid proteins are thought to derive from soluble precursors or fragments thereof, present in biological fluids, which in the disease state undergo conformational change leading to aggregation and deposition in target tissues. We report here that platelets carry PrP mRNA and release PrP^{C}, a sialoglycoprotein bound to the cell surface by a glycosylphosphatidylinositol (GPI) anchor. Soluble PrP^{C} and a N-terminal truncated PrP^{C} isoform starting at position 90 are secreted by resting and agonist-stimulated platelets and are detectable after deglycosylation of releasates. N-terminal sequence analysis of the soluble 27-30 kDa isoform, GQGGGTHSQ(W)NKP, revealed homology to scrapie PrP_{27-30}, the protease resistant core derived from PrP^{Sc}. These findings indicate that in addition to PrP^{C}, platelets process a soluble PrP_{27-30} isoform. Whether this isoform can be converted into scrapie PrP_{27-30} remains to be determined.

A SURFACE LIGAND FOR THE CELLULAR ISOFORM OF THE PRION PROTEIN.

V. Dodelet and N.R. Cashman*. Neuroimmunology Unit, Montreal Neurological Institute, Montreal, Quebec, Canada, H3A 2B4.

The transmissible spongiform encephalopathies, or prion diseases, are characterized by brain accumulation of PrP^{sc}, which copurifies with prion infectivity. The normal cellular isoform of PrP^{sc} is PrP^{c}, a glycosyl phosphatidylinositol-anchored cell membrane protein which is highly conserved in evolution. By establishing a role for PrP^{c} in lymphocyte activation (Cell, 1990), we hypothesized that PrP^{c} is an "orphan receptor" functionally competent in intracellular signaling. Cell surface PrP^{c} likely interacts with ligand(s) which should also be located at the cell surface. We have constructed and expressed a fusion protein comprising mouse prion protein-human alkaline phosphatase (PrP-AP) as a soluble probe for detection and characterization of PrP^{c} ligand(s). The human heat-stable alkaline phosphatase (AP) moiety of the PrP-AP fusion protein was expressed as an experimental control. We find that PrP-AP (but not AP) binds to the surface of selected murine cell lines in a high affinity, competitive, species-specific, and conformation-dependent fashion. PrP-AP surface binding is ablated by prior trypsin treatment of test cells, indicating that the PrP^{c} ligand is a protein. PrP-AP affinity precipitates proteins not detected in AP precipitates, which are candidates for the PrP^{c} ligand. Our data demonstrate that we have constructed and expressed a PrP-AP "affinity reagent" with which to seek distribution, function and molecular identity of the PrP^{c} ligand. Supported by the MRC and NIH.

14-3-3 IMMUNOREACTIVITY IS PRESENT IN CORTICAL LEWY BODIES.

Thomas M. Kilgallen, Karen Smith*, Neil W. Kowall. GRECC, Bedford VA Medical Center, Bedford MA; Dept. Neurology and Pathology, Boston University School of Medicine, Boston MA.

The 14-3-3 family of proteins have a number of functions including activation of tyrosine and tryptophan hydroxylase, inhibition or activation of protein kinase C, and activation of Raf, a critical kinase in the cascade that regulates growth factor-induced DNA transcription. 14-3-3 immunoreactivity has been localized to synaptic membranes in rat brain. We previous reported the localization of 14-3-3 immunoreactivity in neurofibrillary tangles (NFT) and abnormal neurites in frozen sections obtained from AD brain fixed in periodate-lysine-paraformaldehyde. In the present study we examined the distribution of 14-3-3 immunoreactivity in formalin fixed, paraffin embedded archival material using a commercial polyclonal antibody raised against a 12 amino acid peptide shared by the zeta, gamma and eta isoforms of 14-3-3 (Upstate Biotechnology). Tissue was obtained from seven patients with Alzheimer's disease (AD), one with Pick's disease, seven with diffuse Lewy body disease (DLBD) and six elderly controls. In normal cerebral cortex and hippocampus, axonal and synaptic staining was prominent. In contrast to our observations in frozen tissue sections, NFT were not labeled in AD specimens but plaque neurites were readily identified. Pick bodies were not labeled in the Pick's disease specimen. In DLDB, cortical Lewy bodies were clearly immunoreactive in contrast to Lewy bodies in the substantia nigra which were not labeled. The distinctive localization of 14-3-3 immunoreactivity suggests that it may play a role in the formation of cortical Lewy bodies perhaps related to its unique range of cellular functions. Supported by grants from the Department of Veterans Affairs and NIH.

GENETIC EVIDENCE FOR THE INVOLVEMENT OF TAU IN PROGRESSIVE SUPRANUCLEAR PALSY

C. Conrad[1], A. Andreadis[2], J. O. Trojanowski[3], D. W. Dickson[4], D. Kang[1], X. Chen[1], W. Wiederholt[1]*, L. Hansen[1], E. Masliah[1], L. Thal[1], R. Katzman[1], Y. Xia[1], and T. Saitoh[1]. [1]Dept of Neurosci, Schl of Med, UCSD, La Jolla, CA 92093-0624, [2]Dept of Biomed Sci, Eunice Kennedy Shriver Ctr, Waltham, MA 02254, [3]Dept of Path, Univ of Penn Med Ctr, Phila, PA 19104-4283, and [4]Dept of Path, Albert Einstein Coll of Med, Bronx, NY 10461.

A dinucleotide repeat polymorphism in the tau intron between exon 9 and 10 was identified and used in a case-control study to analyze the genetic association of tau with several neurodegenerative diseases with neurofibrillary tangle (NFT) pathology. Subjects with the homozygous tau A0 alleles were excessively represented in the progressive supranuclear palsy (PSP) group as compared to the age-matched healthy control group among Caucasian subjects. Consequently, this allele is more frequently found in PSP than in a group of healthy subjects. This trend was not found in Alzheimer's disease (AD) or parkinsonism-dementia complex of Guam (PDC) both of which are accompanied with major NFT pathology. The result suggests the direct etiological role of tau alteration in PSP. Since the PSP tau is detected as a doublet instead of triplet which is found in AD, the deletion of exon 10 might be genetically determined in PSP. Tau without the exon 10 seuqence might have higher propensity to aggregate into NFT. Supported by NIH grants.

APOLIPOPROTEIN E IN NEUROFIBRILLARY TANGLES OBSERVED IN PARKINSONISM-DEMENTIA COMPLEX OF GUAM.

N.Sasaki[1)], R.Fukatsu[1)], Y.Hayashi[1)], K.Tsuzuki[2)], Y.Takamaru[3)], T.Yoshida[1)], N.Fujii[2)], I.Wakayama[4)], M Watanabe[1)*], R Garruto[5)], R Yanagihara[5)], N.Takahata[1)] Depts of [1)]Neuropsychiatry and [2)]Microbiology, Sapporo Med. Univ., South 1, West 16, Sapporo 060, Japan. [3)]Sapporo City General Hospital. [4)]Kansai College of Oriental Med. [5)]NIH, Bethesda, MD.

The human apolipoprotein (apo) E gene is polymorphic, with three common alleles (ε2, ε3, ε4) encoding for three isoforms (E2, E3, E4). The ε4 allele is an important determinant of risk for the development of Alzheimer's disease (AD). There has been accumulated evidence suggesting that apoE is involved with amyloid fibrillogenesis. Parkinsonism-dementia complex of Guam (PDC) was a highly prevalent neurodegenerative disease among the native Chamorro population of Guam, and is characterized by widespread formation of neurofibrillary tangles (NFTs). In this study, immunohistochemical nature of the NFTs in PDC were studied using commercially available polyclonal antibodies or monoclonal antibodies established in our laboratory, specific to apoE (Chemicon), amyloid β protein (Aβ), tau protein and ubiquitin (DAKO). Brain tissues were obtained from pathologically confirmed cases of PDC (5 cases), AD (5 cases) and age matched control (3 cases). Deparaffinized sections from the cerebral cortex were pretreated by autoclaving, and stained according to modified ABC method (Vector Lab.).

The NFTs in all sections from PDC were stained with anti-apo E, tau protein and ubiquitin antibody, similar to those seen in AD brain. Both intracellular and extracellular NFTs were stained by apo E antibody. In the PDC brain, some NFTs were stained faintly but others were not stained with anti-Aβ antibody. Patients with PDC studied had ε3 allele for apo E genotype. Our observations suggest that apo E may have a role for fibrillogenesis not only in amyloid and NFTs in AD but also in NFTs in PDC.

836.19

THE NEUROTOXIC ROLE OF NITRIC OXIDE IN AIDS DEMENTIA AND STROKE AND THE PREVENTION OF ITS FORMATION BY α-PHENYL-*TERT*-BUTYLNITRONE (PBN). R.A. Floyd*, T. Tabatabaie, K. Hensley, C.A. Stewart, and Q.N. Pye. Oklahoma Medical Research Foundation, Oklahoma City, OK 73104.

PBN is protective in several neurodegenerative models including several stroke models. PBN traps free radicals but the mechanistic basis of its neuroprotective activity is not known. Data presented shows that PBN prevents the induction of inducible nitric oxide synthase (iNOS) thus preventing the formation of large levels of nitric oxide (NO). We have now shown that PBN offers protection in the rat neonatal model of AIDS dementia. HIV-1 glycoprotein 120 (gp120) administered to rat neonates significantly prolongs the time the neonates require to right themselves and the time required for them to turn upward in a negative geotaxis test. Using N-methyl-D-glucamine dithiocarbamate-Fe^{2+} as a trap, we have shown that gp120 administration causes large levels of NO formation in brains of rat neonates. PBN administration prevents the gp120-mediated retardation of neuronal development and prevents the gp120-mediated formation of NO in the brain. We also show that PBN administration prevents iNOS induction brought on by ischemia/reperfusion in the gerbil stroke model. In cultured mixed glial cell culture, PBN, although at high levels, prevents cytokine *plus* gp120 mediated iNOS induction and NO formation. This research is supported in part by NIH AG 09690.

DEGENERATIVE DISEASE: OTHER—ALS

837.1

METHYLAZOXYMETHANOL (MAM), A CANDIDATE ETIOLOGICAL FACTOR FOR GUAM ALS, DAMAGES RAT BRAIN DNA AND MODULATES ITS REPAIR. [1]G.E. Kisby,* [1]J. Milne, [2]J.G. Hugon, [2]M. Lesort, [2]F. Esclaire, [1]P.S. Spencer. [1]Center for Research on Occupational and Environmental Toxicology, Oregon Health Sciences University, Portland, OR 97201, & [2]Cellular Neurobiology Unit, Faculty of Medicine, University of Limoges, 87025 Limoges, France.

The concentration of cycasin (β-D-glucoside of MAM) in cycad flour prepared by Guam Chamorros shows a remarkable correlation with past (1956-85) age-adjusted incidence rates of amyotrophic lateral sclerosis (ALS) in Chamorro males (r=0.97, p=0.00002) and females (r=0.98, p=0.000005) resident on Guam (Zhang *et al.*, 1996). Brains of Guam ALS and of rat pups treated with the genotoxin MAM display evidence of developmental perturbation. Brains of 1-day- (n=3-4) and 30-day-old (n=7-9) pups of timed-pregnant (GD15) rats administered saline or 25 mg/kg MAM (i.p.) were examined for the DNA adduct N^7-methyldeoxyguanosine (N^7-mdG) and the DNA repair protein APE (apurinic/apyrimidinic endonuclease). Cerebral cortical N^7-mdG levels were 2-3x higher in 1-day-old (p<0.05) and 30-day-old (p<0.001) rats relative to saline-treated controls. In contrast, cerebellar N^7-mdG levels were similar in both MAM- and saline-treated 30-day-old animals. MAM significantly reduced cortical APE levels in 1-day-old pups. In comparison, APE levels and activity were significantly reduced (p<0.02) in cerebral cortical tissue of non-Guam ALS subjects (n=5). MAM treatment (10 μM-200 μM for 12h) of rat cortical neuronal cultures produced 24h later a concentration-dependent increase in N^7-mdG and a reduction in APE levels and activity. The genotoxic properties of the cycasin aglycone merit close consideration in the etiology of Guam ALS. [Supported by NINDS grant NS19611 and the Ministaire de L'Enselgnement superière et de la Recherche, France].

MECHANISM OF NEUROFILAMENT HYPERPHOSPHORYLATION IN MOTOR NEURON DISEASES. M.M. Doroudchi* and H.D. Durham, Montreal Neurological Institute, McGill University, Montreal, PQ H3A 2B4.

Aberrant phosphorylation of neurofilaments commonly occurs in sporadic, familial or chemically-induced motor neuron diseases. Hyperphosphorylation of C-terminal domains of neurofilament proteins, persisting over days, was observed in cultured murine or rabbit motor neurons following activation of protein kinase C (PKC) by synthetic diacylglycerol (10μM). This hyperphosphorylation was detected by increased immunoreactivity with SMI34 recognizing NF-M/NF-H when C-terminal KSP repeat domains are phosphorylated. Increased SMI34 labeling was prevented by pretreatment with the specific Ca^{2+}-calmodulin kinase II (CaMKII) inhibitor, KN-62 (5μM) and by the NMDA receptor antagonist, APV (1mM), but not by the AMPA/kainate antagonist, CNQX, the metabotropic glutamate receptor antagonist, (+)-α-methyl-4-carboxyphenylglycine or by inhibitors of arachidonic acid pathways. The following mechanism is proposed for neurofilament hyperphosphorylation in motor neuron diseases: Activation of PKC, as a nonspecific response to injury, acts cooperatively with stimulation of NMDA receptors to initiate a cascade of reactions in cells that includes activation of CaMKII. Whether neurofilament proteins are directly phosphorylated by CaMKII or subsequent activation of other kinases is required remains to be determined. (supported by MDAC)

837.3

OXIDATIVE STRESS IN A MOTOR NEURON CELL LINE: A MODEL OF AMYOTROPHIC LATERAL SCLEROSIS P.L. Richey, G. Perry , N.R. Cashman and, M.A. Smith (SPON: Society of Neuroscientists of Africa) Institute of Pathology, Case Western Reserve University, Cleveland, Ohio, USA and Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada

Amyotrophic lateral sclerosis (ALS) is a progressive disorder characterized by the accumulation of neurofilaments and degeneration of motor neurons in the spinal cord, brainstem and cortex. Some genetic cases have been linked to mutations in the antioxidant enzyme Cu/Zn superoxide dismutase (SOD-1), and transgenic mice which overexpress a mutated, but not normal, SOD-1 gene develop many clinical and pathological features of the disease. Taken together these findings indicate a pivotal role for oxidative stress in ALS.

In this study, we assessed the differential effects of oxidative stress on the motor neuron/neuroblastoma hybrid cell line NSC34 and compared this to the parental neuroblastoma cell line. NSC34 cells express many properties of primary motor neurons, in constrast to the parent neuroblastoma. After oxidative stress, NSC34 cells displayed cytoskeletal abnormalities such as loss of processes and inclusion-like accumulations of neurofilaments in the cell body. In addition, following stress, NSC34 cells showed an increase in the antioxidant enzymes Cu/Zn superoxide dismutase and heme oxygenase (HO). The latter, HO, catalyzes the conversion of heme into biliverdin which is further reduced to bilirubin, a potent antioxidant. There are two forms of HO: HO-1 which is inducible under conditions of oxidative stress and HO-2 which is constitutively expressed within cells. Our data shows that HO-2 levels remain constant even after oxidative stress whereas HO-1 levels increase. This is consistent with our findings in motor neurons in transgenic mice which overexpress the mutated SOD-1 gene and also show increased HO-1.

Taken together our findings indicate that the NSC34 motor neuron cell model mimics many features of ALS and of *in vivo* oxidative stress. We are therefore hopeful that this cell culture model will allow for rapid evaluation of potentially therapeutic antioxidants.

Supported by grants from the NIH, AHAF, and AFAR.

NITRATION OF GLUTAMATE TRANSPORTERS IN TRANSGENIC MICE WITH A FAMILIAL ALS-LINKED SOD1 MUTATION. J.D. Rothstein*[1], L. Nagano[1], P.C. Wong[2], M.K. Lee[2] and L.I. Bruijn[3]. Dept. [1]Neurology and [2]Pathology, Johns Hopkins University, Baltimore, MD 21287, [3]Ludwig Inst. for Cancer Res., UCSD, La Jolla, CA 92093.

Mutations of SOD1 are found in about 20% of familial ALS patients. We have recently shown that transgenic mice which overexpress mutant human SOD1 (G37R) develop a denervating, paralytic process that resembles ALS. Disease in the SOD1 mutant-expressing mice arises not from diminution of SOD1 activity but rather from an as yet unidentified adverse property of the mutant subunits. A component of the neural degeneration in the transgenic mice may involve glutamate toxicity, as the neuropathology resembles excitotoxicity and anti-glutamate agents increase survival. It has been proposed that the mutant SOD1 molecule may catalyze increased amounts of peroxynitrite. Consequently, peroxynitrite may damage proteins through nitration of tyrosine residues. We have examined CNS tissues of G37R and G85R transgenic mice for the presence of nitrated glutamate transporters using immunoprecipitation. In aged G37R mice which had developed motor neuron disease, there was a loss of glial glutamate transporter GLT-1, and levels of nitrated GLT-1 were found to be elevated compared with those in younger G37R mice without motor weakness or age-matched non-transgenic littermates. Since an *in vitro* study has shown that peroxynitrite can inhibit glutamate transport, these results suggest that peroxynitrite may play an important role in motor neuron degeneration through inhibition of glutamate transport. (Supported by NIH and MDA).

IS NEURONAL NITRIC OXIDE SYNTHASE INVOLVED IN THE PATHOGENESIS OF A TRANSGENIC MOUSE MODEL OF FAMILIAL AMYOTROPHIC LATERAL SCLEROSIS?

M. Sasaki[1*], F. Facchinetti[1], V. Christov[1], H. Brahmbhatt[1], M.F. Beal[4], D. Reif[5] T.M. Dawson[1,3] M.E. Gurney[6] and V.L. Dawson[1,2,3]. Depts. Of Neurol.[1], Physiol.[2] and Neurosci.[3] Johns Hopkins Sch. Med. Baltimore MD 21287, Dept. Of Neurol.[4] Mass. Gen. Hosp. Boston MA, Astra Arcus[5] Rochester NY, Upjohn Lab[6]. Kalamazoo MI

Transgenic mice (line GH1) which overexpress a human superoxide dismutase type 1 (SOD1) containing a gly[93]-ala mutation develop a motoneuron disease similar to familial amyotrophic lateral sclerosis (FALS). Nitric oxide (NO), through an interaction with the superoxide anion, can form the highly neurotoxic peroxynitrite. Therefore NO could play a role in the pathogenesis of FALS-like disease in the mice expressing mutated SOD1. To examine this hypothesis, we chronically treated GH1 mice with several inhibitors of NO production. These inhibitors were L-nitro-arginine-methylester (L-NAME), a non-selective inhibitor for NO synthase (NOS) isoforms, 7-nitroindazole (7-NI) and ARL 17,477, two novel and selective neuronal NOS inhibitors, and FK-506, a calcineurin inhibitor. None of these compounds show a significant effect on survival of the GH1 mice except for ARL 17,477. To investigate the involvement of nNOS more selectively, we cross-bred GH1 mice with transgenic mice lacking the nNOS gene to obtain mice expressing mutated human SOD1 and lacking the nNOS gene. These mice show no remarkable difference in survival when compared to GH1 mice. We cannot exclude the possibility that nNOS plays a role in FALS, since nNOS null mice contain catalytically active truncated nNOS mutants. ARL 17,477 may protect against the FALS mutation through inhibition of nNOS. Thus, nNOS may play a small but important role in the pathogenesis of FALS. Funded by MDA, NIH

837.6

DAMAGE TO THE NIGROSTRIATAL DOPAMINERGIC PATHWAY IN FALS-TRANSGENIC MICE.

S. Przedborski, V. Kostic, R. Yokoyama, S.A. Sadiq*, and A.B. Naini. Dept. Neurology, Columbia Univ., NY, NY 10032.

Some cases of familial ALS (FALS) are associated with copper/zinc superoxide dismutase (SOD1) mutations. These mutations are implicated in the death of motor neurons. Because SOD1 is present in high amounts in nigrostriatal dopaminergic (DA) neurons, we considered the possibility that FALS-linked mutations may be associated with nigrostriatal DA damage. To examine this question, we assessed the status of the DA system in transgenic mice expressing one of the FALS-linked mutations. We confirmed that these transgenic mice have a point mutation in codon 93 (GGT → GCT) of the human SOD1 gene, resulting in Gly → Ala aminoacid substitution. Nigral DA neuron number was determined by tyrosine hydroxylase (TH) immunostaining with quantitative morphology and the content of striatal DA by HPLC. The number of motor neurons in the anterior horn of the spinal cord was also determined. At the time FALS-transgenic mice were unable to stand in upright position, they were sacrificed. At that time, transgenic mice showed dramatic reduction in motor neuron number compared to their non-transgenic littermates. We also found that FALS-transgenic mice showed ~20% reduction in levels of striatal DA and its metabolites, HVA and DOPAC compared to non-transgenic mice. In addition, the number of nigral TH-positive neurons was significantly reduced in FALS-transgenic mice compared to controls. This study indicates that FALS-linked mutations appear to be neurotoxic not only to motor neurons, but to nigral DA neurons as well. This finding may have major implications for Parkinson's disease.

CARBOXY-BUCKMINSTERFULLERENES: NOVEL ANTIOXIDANTS WITH NEUROPROTECTIVE EFFICACY IN VITRO AND IN A MOUSE MODEL OF ALS.

L.L. Dugan[1*], D.M. Turetsky[1], C. Du[1], T.T. Lin[3], D. Lobner[1], R. Almli[2], M. Wheeler[2], D.W. Choi[1]. [1]Center for the Study of Nervous System Injury and Dept. of Neurology, [2]Dept. of Occupational Therapy, and [3]Dept. of Chemistry, Washington University, St. Louis, MO 63110.

A water-soluble derivative of the buckminsterfullerene molecule ($C_{63}(COOH)_6$, containing 6 carboxyl groups per fullerene molecule, showed strong neuroprotective properties in mouse cortical neuronal cell cultures against excitotoxic necrosis and apoptosis. EPR analysis confirmed that $C_{63}(COOH)_6$, like the parent C_{60} molecule, is a potent free radical scavenger. $C_{63}(COOH)_6$ (0.3 - 1 mM) was not itself toxic, and reduced a majority of the neuronal death produced by 10 min or 24 h exposure to NMDA, 24 h exposure to AMPA, or 50 min exposure to oxygen-glucose deprivation. In addition, neuronal apoptosis induced in near-pure neuronal cultures by serum deprivation was also attenuated by 10 μM $C_{63}(COOH)_6$.

To determine whether this promising compound might be neuroprotective in vivo, we have initiated a therapeutic trial in transgenic mice bearing the SOD1 (G93A) mutation found in certain families with amyotrophic lateral sclerosis (ALS) (Gurney et al., Science, 264:1772 (1994)). These mice develop progressive hindlimb weakness at approximately 3.5 months of age, and are moribund 4 weeks after onset of symptoms. $C_{63}(COOH)_6$ (10 mg/kg/day) was administered i.p. starting at 2.5 months of age; initial results from this ongoing study indicate a 1-2 week delay in onset of symptoms and death. No gross toxicity was observed.

HEME OXYGENASE IN EXPERIMENTAL ALS,

S. Lu, B.E. Dwyer*, and R.N. Nishimura, Molecular Neurobiology Laboratory, VA Medical and Regional Office Center, White River Junction, VT 05009.

Heme oxygenase-1 (HO-1) is a stress protein inducible in some cells by oxidative stress. Heme oxygenase-2 (HO-2) is abundant in normal CNS and appears to be localized to neurons. The status of heme oxygenase was investigated in ALS mice since oxidative mechanisms are postulated in neuronal injury. Three ALS mice [(SOD1-G93A)1Gur] and three controls [(SOD-1)2Gur] were obtained from Jackson Labs. Behavioral differences suggestive of neurodegeneration were first observed 4-5 months after birth. Mice were killed by perfusion at 7-8 months of age when two of three ALS mice demonstrated obvious behavioral deficits; the third mouse appeared less affected. Severity of behavioral deficits correlated with severity of histopathology: tissue vacuolation and cell loss (by cresyl violet staining). Motorneurons in control spinal cord and those remaining in ALS mice stained positive for HO-2 but no immunohistochemical evidence for HO-1 induction was obtained leading to the conclusion that enhanced HO-1 immunoreactivity is not a characteristic of neurons with late stage experimental ALS.

IMMUNOGLOBULINS FROM PATIENTS AFFECTED BY AMYOTROPHIC LATERAL SCLEROSIS INCREASE THE FREQUENCY OF SPONTANEOUS GLUTAMATERGIC CURRENTS IN CULTURED RAT HIPPOCAMPAL NEURONS,

P. R. Andjus, D. J. Spergel* and E. Cherubini, Biophys. Lab., Int. Sch. for Adv. Studies (SISSA), 34013 Trieste, Italy.

Excitotoxicity produced by abnormally high levels of glutamate released from nerve endings has been considered as one of the main factors contributing to the aetiopathogenesis of amyotrophic lateral sclerosis (ALS). We have used the whole cell configuration of the patch clamp technique to study the effects of IgGs from ALS patients on glutamate release in cultured hippocampal neurons. As a control, IgGs from healthy donors were employed. IgGs were applied by pressure through a glass pipette positioned at a distance of 100 μm from the patched cell. IgGs from three ALS patients and three healthy donors were used. In control conditions (using K-gluconate in the pipette solution) at a holding potential of -50 mV, spontaneous synaptic currents were recorded at a frequency ranging from 0.5 to 1.0 Hz. These currents were abolished by CNQX (20 μM) suggesting that they originated from the activation of ionotropic glutamate receptors. Application of ALS IgGs induced a significant increase in frequency of spontaneous currents with concomitant decrease in their amplitude. The mean frequency ratio of ALS IgGs over control was 2.3 ± 0.8 whereas the mean amplitude ratio was 0.7 ± 0.1. IgGs from healthy donors were ineffective. ALS IgGs increased more then twofold (n= 5) the frequency of spontaneous miniature glutamatergic events recorded in the presence of tetrodotoxin (TTX, 1 μM). ALS IgGs were also able to increase the frequency of spontaneous currents recorded in the absence of external calcium (substituted with Mg^{2+}) with a mean frequency ratio of 2.0 ± 0.5 compared to the control. We conclude that IgGs from ALS patients enhance glutamate release through a mechanism at least in part independent of extracellular calcium.

GLUTAMATE TRANSPORTER SUBTYPE EAAT2 MUTATIONS IN ALS: DOWN REGULATION OF TRANSPORTER PROTEIN.

G. Lin*, L. A. Bristol, and J.D. Rothstein. Johns Hopkins University, Dept. of Neurology, Baltimore, MD 21287.

Glutamate transport is believed to be critical in preventing glutamate neurotoxicity, which may be one of several important factors in the pathophysiology of amyotrophic lateral sclerosis (ALS). Some sporadic and familial patients with ALS have been found to have a dramatic loss of the astroglial glutamate transporter EAAT2 (GLT-1) protein in motor cortex and spinal cord. To investigate a molecular genetic correlate to those findings, a familial ALS patient, without SOD1 mutations, was chosen for study. This patient had a very low level of EAAT2 protein (5-50% of control) in all brain regions and peripheral tissue. However, the quantity and size of EAAT2 mRNA was normal. A cDNA library was constructed from motor cortex and an abnormal cDNA clone was consequently identified and sequenced. It revealed a truncated transcript of EAAT2 containing intronic sequence at the 3' end. This abnormal mRNA was found in both CNS and peripheral tissues. Subsequently, similar abnormal EAAT2 mRNA was identified in other non-SOD1 familial ALS and sporadic ALS brain tissue. Importantly, this abnormal cDNA was found to dominantly down-regulate the wild-type EAAT2 cDNA expression when they were co-expressed in COS cells or co-translated *in vitro* in rabbit reticulocyte lysate assays. Thus this abnormal mRNA species may account for the loss of EAAT2 in ALS tissue. We are investigating the mechanisms, e.g., gene mutation, which leads to this abnormal mRNA. EVIDENCE OF GENETIC MITOCHONDRIAL PATHOLOGY IN SPORADIC AMYOTROPHIC LATERAL SCLEROSIS. R.H. Swerdlow, J.K. Parks, S.W. Miller, R.E. Davis*, G. Pattee, and W.D. Parker, Dept. of Neurology, University of Virginia, Charlottesville VA 22908, Lincoln, NE, and MitoKor, San Diego, CA 92121.

Some kindreds with familial amyotrophic lateral sclerosis (ALS) possess a mutation of the Cu/Zn superoxide dismutase (SOD) gene. An excess of cellular reactive oxygen species (ROS) may directly result from this genetic derangement and lead to neurodegeneration. Neuronal death in the common sporadic form of ALS is also presumed to involve ROS-mediated mechanisms, despite the absence of an SOD defect.

We previously demonstrated in other sporadic neurodegenerative diseases that mitochondrial DNA (mtDNA) mutations transform the mitochondrial electron transport chain (ETC) into a genetically-determined ROS generator, and hypothesized that similar pathologic mechanisms could be operant in ALS. To test this hypothesis we transferred mtDNA from ALS patients into SH-SY5Y neuroblastoma cells that had been depleted of endogenous mtDNA by prolonged exposure to ethidium bromide (ρ^0 118/5.0 MitoKor, San Diego, CA). The resulting cytoplasmic hybrid (cybrid) cells were assayed for activities of the ETC enzymes NADH:ubiquinone oxidoreductase (complex I) and cytochrome oxidase (complex IV; COX) because these enzymes have significant mtDNA-encoded components. Mean complex I activity in the ALS cybrid group was decreased by 19% compared to an age-matched control cybrid group (p=0.0003). Mean complex IV activity in the ALS cybrids was decreased 16% but this was not statistically significant. We conclude that in ALS mutations of mtDNA are present in sufficient quantities to cause a measurable derangement of the ETC, and that these mutation(s) may be concentrated in the portion of mtDNA that encodes complex I subunits. These ALS cybrid cell lines will allow us to determine the functional consequences (neuronal viability, toxin susceptibility, and ROS production) of this transferred mtDNA defect.

INCREASED PI 3-KINASE ACTIVITY IN ALS

R. Wagey*, R. Lanius , L. Charlton, R. Launer, C.A. Shaw, S.L. Pelech and C. Krieger, Depts. of Medicine and Ophthalmology, University of British Columbia, Vancouver, B.C. V6T 1Z3, Canada.

We have previously demonstrated that protein kinase C (PKC) phosphotransferase activity and protein levels are increased in ALS spinal cords compared to controls. Other studies have shown that lipid products generated by phosphatidylinositol 3-kinase (PI 3-kinase) may activate specific isoforms of PKC, indicating that PI 3-kinase may be upstream of PKC. To further investigate the regulation of protein kinases in ALS we have measured the activity of PI 3-kinase in ALS and control spinal cords. Our results indicate that PI 3-kinase activity is altered in postmortem tissues from ALS patients compared to control subjects. In vitro immunoprecipitation assays using anti-p85 (regulatory subunit of PI 3-kinase) and anti-4G10 (phosphotyrosine) antibodies, revealed that there was more activity in the membrane fraction of ALS spinal cords compared to controls. PI 3-kinase activity in the ALS membrane fractions was increased by approximately 240% and 190% in comparison to controls using anti-p85 and anti-4G10 antibodies, respectively. No significant differences between ALS and control spinal cords were found in the cytosolic fractions. These data indicate that PI 3-kinase is hyperactivated and there is more phosphotyrosine associated PI 3-kinase in the membrane fraction of ALS spinal cords compared to controls. Changes in the phosphorylation state of various protein kinases may contribute to the pathogenesis of neurodegenerative diseases including ALS. PI 3-kinase is an important regulatory enzyme that plays a role in the regulation of other protein kinases such as PKC, PKB, p70 S6 kinase and MAPK. Abnormal regulation of PI 3-kinase may be a primary event leading to altered phosphorylation of PKC and other "downstream" kinases. This preliminary study points to a potential role for PI 3-kinase in the pathogenesis of ALS.

ISCHEMIA: INFLAMMATION AND COAGULATION

838.1

EFFECTS OF HYPERBARIC OXYGEN ON NEUTROPHIL ACCUMULATION AND INFARCT VOLUME FOLLOWING FOCAL CEREBRAL ISCHEMIA IN RATS. M. Miljkovic-Lolic*, G. Fiskum and R.E.Rosenthal. Depts. of Biochemistry & Emerg. Medicine, George Washington Univ. Sch. of Med., Washington, D.C., 20037

We tested the hypothesis that hyperbaric oxygen (HBO) therapy will prevent polymorphonuclear leucocyte (PML) infiltration into the brain following focal cerebral ischemia, thus limiting the extent of brain infarction and improving neurologic outcome. One hour prior to surgery, adult male rats were randomly assigned to either HBO (100% oxygen for one hour at 3 ATA) or normal air (one hour at 1 ATA) in a small hyperbaric chamber. Permanent occlusion of the right middle cerebral artery and 1 hr occlusion of both common carotid arteries was followed by a 24 h recovery period. At the end of 24 hr, rats were tested for neurologic outcome using a 6 point scale (0=normal, 6=severe damage), perfused with saline and their brains removed. Ischemic areas were analyzed either for PMNL infiltration (using myeloperoxydase{MPO} assay) or for volumes of infarction (using TTC staining). Pretreatment with HBO decreased MPO activity (HBO: 0.12+/-0.04 n=6; controls 0.27+/-0.1 n=6; p=0.006), improved neurologic outcome (HBO:1.5+/- 1 n=13: controls: 3.8+/-1 n=15; p=0.0002) and reduced the infarct volume (HBO: 27.5 %+/- 9.9 n=7; controls: 39.5%+/-11.2 n=9; p=0.04). Our findings suggest that HBO pretreatment is neuroprotective in this model of stroke, presumably through prevention of PMNL infiltration. 838.2

DEFEROXAMINE INHIBITS ASPHYXIA–INDUCED INCREASES IN LEUKOCYTE ADHERENCE AND VASCULAR PERMEABILITY T.S. Park*, J.W. Beetsch, E.R. Gonzales, A.R. Shah, R.G. Maceren, Y.-B. Lee, P.L. Gehlbach, J.M. Gidday. Dept. of Neurosurgery, and St. Louis Children's Hospital, Washington University School of Medicine, St. Louis, MO 63110

Free radicals are important mediators of leukocyte adherence to microvascular endothelium. We have previously documented that reperfusion following cerebral ischemia and asphyxia is associated with significant increases in leukocytes adherent to cerebral venules, and increased vascular permeability (see Gonzales et al., this volume), consistent with recent evidence indicating that inflammatory reactions contribute to vascular and parenchymal injury in cerebral ischemia. In the present study, we tested the hypothesis that inhibition of iron-catalyzed hydroxyradical production by the Fenton reaction, using the intravascular iron chelator hydroxyethyl starch–conjugated deferoxamine (HES-DFO; Biomedical Frontiers, Inc.), would attenuate ischemia–induced increases in leukocyte adherence. Closed cranial windows were placed in anesthetized piglets; venular adherence of rhodamine 6G-labelled leukocytes and leakage of sodium fluorescein 20 min after iv injection were measured by dual-filter epifluorescent videomicroscopy. A progressive, significant increase in adherent leukocytes was observed during the initial 2 hr of reperfusion following asphyxia (n=5), at which time fluorescein permeability increased 103% relative to controls (n=5). However, when animals (n=4) received HES-DFO (100mg/kg iv) 15 min before asphyxia, both leukocyte adherence and fluorescein leakage were completely blocked (p<0.05). These findings indicate that, in the cerebral circulation, intravascular iron is critically involved in promoting ischemia-induced leukocyte-endothelial interactions, and that leukocyte-mediated vascular injury can be prevented by iron chelation. (NINDS 21045)

838.3

DISRUPTION OF BLOOD BRAIN BARRIER TRIGGERED BY REPERFUSION FOLLOWING TRANSIENT FOCAL ISCHEMIA IN RATS. H. Yanamoto*, N Hashimoto, N.F. Kassell, K.S. Lee. Department of Neurosurgery, National Cardiovascular Center, Department of Neurosurgery, University of Virginia Health Sciences Center, Charlottesville, VA 22908.

Entry of plasma proteins into brain tissue after cerebral ischemia could aggravate ischemic injury in the acute phase. The present study examined the timing of leakage and distribution of plasma protein in the brain tissue using complement protein, C3 as a tracer following transient and permanent focal ischemia. The complement system is a self-defense system which can kill cells by forming transmembrane pores and compromise the membrane integrity. Sprague-Dawley rats (n=30) were subjected to focal neocortical ischemia by occluding three vessels permanently, or transiently for three hours. In the permanent ischemia paradigm, animals were sacrificed after 185, 210, 240, or 360 min of ischemia. In the transient ischemia paradigm, animals were sacrificed at corresponding time points, i.e. after 5 min, 30 min, 1 hr, or 3 hr of reflow. After perfusion-fixation, 30 μ brain slices were subjected to immunohistochemical staining using the antibody against rat complement protein, C3. The regional immunoreactivity was further analyzed using computerized densitometry. In the permanent ischemia group, the ischemic lesion gradually showed immunoreactivity of C3 from 4 to 6 hours of ischemia. In contrast, a significant elevation of C3 immunoreactivity was observed in the ischemic area within 5 min of reflow; a biphasic elevation of immunoreactivity was observed at 30 min and 3 hours of reflow. Microscopic analyses demonstrated that neurons were not stained in the acute phase after permanent ischemia. In contrast, C3 immunoreactivity was visible in neurons after 1 hour of reflow. These findings demonstrate that reperfusion enhances the disruption of blood brain barrier function in a biphasic manner leading ultimately to the accumulation of plasma complement protein in the neurons. Reperfusion following ischemia may aggravate and accelerate neuronal injury by increasing the participation of complement-mediated mechanisms.

EARLY UPREGULATION OF COMPLEMENT FACTORS AND ASTROCYTE DYSFUNCTION IN ANIMAL MODELS OF GLOBAL ISCHEMIA AND STROKE. C. Post, P. Salvati, M. K-H Schäfer[1], W. Schaeble[2], M. Cini*, M. Calabresi, F. Vaghi, E.H.F. Wong and E. Weihe[1] Pharmacia & Upjohn, CNS Research, Nerviano (Mi), Italy, University of Marburg[1], Marburg, FRG and University of Leicester, Leicester, UK

The complement (C) system has been suggested to play an important pathogenic role in some neurodegenerative diseases, such as Alzheimer's Disease, but little is known of its contribution to neurodegeneration in cerebral ischemia. Astrocyte function has also been shown to be modified in these pathologies. The aim of this work was therefore to evaluate: 1) cerebral expression of different components of the classical C pathway, after global or focal cerebral ischemia, using in situ hybridization and immunohistochemistry; 2) astrocyte function, measuring GFAP immunoreactivity and NGF mRNA expression. Results: C1q mRNA upregulation was detected in rats subjected to a 15 min 4-vessel occlusion (n=39), as early as 4 hrs after reperfusion (further increase after 24 and 72 hrs), mainly in the hippocampus, but also in other brain areas. Cells expressing C1q were predominantly microglial cells. C3 expression followed a similar pattern. NGF mRNA expression showed topospecific biphasic changes (early decrease and late increase in CA1). In the mouse MCAO model (n=40), C1q immunoreactivity was detected in the ischemic area 1 hr after MCA occlusion, with a progressive increase at 4, 24 and 72 hrs. GFAP immunoreactivity decreased in parallel in the core area; astrocytosis was evident in the penumbra, at 72 hrs particularly.

Conclusions: these data suggest that both focal and global ischemia are characterized by: 1) early onset of C protein upregulation in brain resident cells; 2) early astrocyte dysfunction associated with neuronal loss. This is followed by astrocytosis, which might reflect activation of neuroprotective mechanisms in the penumbra. The either direct, or indirect (through C cascade activation), pathogenic role of C1q in these models still remains to be clarified. [supported by DFG]

PROPENTOFYLLINE BLOCKS THE IN VITRO NEUROTOXICITY OF SECRETED MACROPHAGE PRODUCTS. M.P. Flavin* and L.T. Ho, Department of Pediatrics, Queen's University, Kingston, Ontario K7L 2V7 Canada.

Macrophages and microglia may contribute to delayed neuronal death after insult. Macrophage conditioned medium (MCM) is neurotoxic. We reported that increased apoptosis is the major finding in cultured neurons exposed to MCM based on chromatin aggregation, DNA laddering and 3'-OH end labelling. We wished to determine which manipulations of cultured neurons would protect them against MCM effects. We focussed on several factors including propentofylline (ppf) (McRae et al., NeuroReport 5:1193-1196, 1994) which could be protective in ischemia. MCM was developed from peritoneal macrophages between 36 and 60 hours in culture. Hippocampal neurons were cultured form E19-20 fetal rat. Early exposure to cytosine arabinoside 10^{-6}M, serum deprivation in low glutamate medium, supplemented with basic FGF 5 ng/ml provided virtually pure neurons. The culture was exposed to MCM at 5-8 days in vitro. After 24 hours MCM application viability and apoptosis was quantified by counting acridine orange and ethidium bromide-labelled cells. Chromatin aggregation and margination and ethidium bromide admission/exclusion was assessed. A score was also applied to quantify the proportion of process-bearing cells.

Ppf 10^{-6}-10^{-4}M did not alter baseline neuronal status. MCM significantly increased the number of apoptotic and non-viable cells. Co-application of MCM and ppf attenuated this effect in a dose-dependent manner with complete protection at 10^{-4}M. Adenosine and phenylisopropyladenosine were not protective. Pretreatment of macrophages with ppf did not block subsequent MCM toxicity. The NMDA receptor blocker APV was protective even when excess amino acid was removed from MCM by dialysis. Pre-heating of the neurons to 42°C for 20 minutes blocked MCM effects. Co-application of MCM with dexamethasone 10^{-8}-10^{-6}M, indomethacin 10^{-6}M, TGFβ 40 ng/ml, IL-6 100 ng/ml, BDNF 50 ng/ml, FGF 50 ng/ml or NGF 50 ng/ml did attenuate toxicity. Agents such as ppf may impede macrophage-mediated death by direct effects on neurons.

SALICYLATE OR DICLOFENAC BUT NEITHER DEXAMETHASONE NOR DIPYRONE PROTECTS THE RAT BRAIN FROM CHRONIC NEURODEGENERATION FOLLOWING ISCHEMIA C.G. Coimbra*, R. Sinigaglia, and E.A. Cavalheiro, Laboratory for Experimental Neurology, UNIFESP - Escola Paulista de Medicina, R. Botucatu, 862, 04023-900 São Paulo, SP-Brazil.

We have previously reported on evidences of a neurodegenerative process that may be sustained for months after forebrain ischemia in rats (Coimbra et al., Stroke, 1996). Accordingly, reactive microglia (macrophages) was observed throughout the rat forebrain at 2-month survival from the ischemic insult (Coimbra et al., Soc. Neurosci. Abst., 21:220, 1995), suggesting that an inflammatory process could mediate such chronic neuronal death. This study investigates the effect of different anti-inflammatory drugs on neuronal survival.

Male Wistar rats were treated for 7 days from 2 hrs after 10 min ischemia (2-VO associated with hypotension to 50mmHg). Diclofenac sodium (DCP, $2.25 mg.kg^{-1}.day^{-1}$, SC, 3 daily doses), dexamethasone sodium phosphate (DXM, $15x10^{-3} mg.kg^{-1}.day^{-1}$, SC, single dose), acetylsalicylic acid (ASA, $50 mg.kg^{-1}.day^{-1}$, SC, 3 daily doses), sodium dipyrone (DIP, $45 mg.kg^{-1}.day^{-1}$, SC, 3 daily doses) or NaCl (0.9% solution) was administered to of 6-8 rats that were allowed to survive for 7 days or 2 months (total = 10 groups). DCP, ASA and DIP reduced neuronal damage in CA1 region by 48%, 68% and 48% respectively, at 7-day survival compared with NaCl treatment; DCP and ASA reduced neuronal damage by 34% and 32% respectively, at 60-day recovery compared with saline treatment ($p < 0.05$, Mann-Whitney U-test).

These findings provide further evidence of an inflammatory process inducing neuronal demise long after brain ischemia, and shows that it may be differentially affected by anti-inflammatory agents.

Macrophages Contain Neurotrophic Factors Following Embolic Stroke in the Rat by Double Labeling Immunohistochemistry

Fang-Jie Chen, Nancy Futrell, Qi-Hui Zhai*
Cerebrovascular Disease Laboratory, Medical College of Ohio, Toledo, Ohio

Macrophages play an important role in wound healing in many systems, including skin and peripheral nerve. Knowledge of the role of macrophages in stroke is still limited. This work is designed to study the infiltration dynamics, distributions and the possible function of macrophages following embolic stroke.

Photochemically induced embolic stroke was produced in 18 male Fisher rats, 2 months of age. Rats were sacrificed 1 day(n=4), 2 days (n=4), 4 days(n=5) and 7 days (n=5) following stroke by transcardiac perfusion with 10% neutral buffered formalin. Paraffin embedded sections, 7um in thickness, were cut coronally using the microtome. Double labeled immunohistochemistry was performed using streptavidin alkaline phosphatase and ABC techniques. Antibodies used were ED_1 for macrophages, anti-NGF (nerve growth factor) and anti-bFGF (basic fibroblastic growth factor). Chromogens were fast red and diaminobenzadine (DAB). Cell counts were done with an MCID image analysis system.

Occasional macrophages were seen at day 1. They were either in endothelial cells or in the immediate perivascular area. By day 2 macrophages increased and were distributed generally within infarcted tissue, with numbers peaking at 4 days. By day 7 macrophages started to decrease. Approximately half of the macrophages were positive NGF and bFGF.

Our data shows that macrophages enter infarcted tissue at a time corresponding with clinical recovery. NGF and bFGF, which are neuroprotective substances, were found in the macrophages. As macrophages produce NGF and bFGF in tissue culture, macrophages may play a neuroprotective role following cerebral infarction. The direct evidence of macrophages' role in stroke evolution is being studied using specific inhibition of macrophage infiltration and function.

The study is supported by PHS-RO1-AG11759

EFFECT OF HIBERNATING SQUIRREL PLASMA ON MONOCYTE-CEREBRAL VASCULAR ENDOTHELIAL CELL INTERACTIONS

Y. Yasuma, R. M. McCarron, M. Spatz and J. M. Hallenbeck*. Stroke Branch, NINDS, National Institutes of Health, Bethesda, MD, 20892-4128 USA

Adhesion and subsequent penetration of leukocytes into CNS ischemic tissue proceeds via a coordinated inflammation-mediated mechanism involving adhesion molecules at the blood-endothelium interface. The active involvement of endothelium is underscored by the transformation of the endothelial facade to a proinflammatory surface which includes the expression of adhesion molecules. Mammalian hibernation is a state of natural tolerance to severely reduced blood flow (*i.e.*, ischemia). Hibernating thirteen-lined ground squirrels were investigated in attempts to ascertain if adhesive interactions play a role in regulating this tolerance. Since hibernation is associated with a 90% decrease in circulating leukocytes, the role of leukocyte adhesion to endothelium was examined. ICAM-1 expression by EC cultured alone or with plasma from hibernating (H) or non-hibernating (NH) squirrels was quantitated by ELISA using mAb to rat ICAM-1. Adhesion assays utilized purified (>90% ED-1+) populations of peripheral blood monocytes (Mo) freshly isolated from WKY rats, labeled with ^{51}Cr and added to syngeneic EC monolayers (30 min, 37° C). ICAM-1 expression on EC was dose-dependently increased by H plasma and, to a lesser extent, NH plasma. Treatment of EC with H plasma concomitantly induced significantly greater increases in Mo adhesion to EC (35.9% vs 13.4% with NH plasma). Alternatively, treatment of Mo with H or NH plasma significantly inhibited adhesion (58.5% and 40.1%, respectively). Comparison of H and NH plasma effects on Mo adhesion to EC may identify mechanisms responsible for ischemic tolerance in hibernators. Understanding regulation of hibernation could guide development of novel approaches for stroke treatment.

838.9

IMPROVED PERFUSION WITH THROMBOLYSIS IN A MODEL OF EMBOLIC STROKE. M. Yenari*, L. Lee, C. Beaulieu, D. Kunis, G. H. Sun, J. Palmer, G. Albers, M. Moseley and G. Steinberg. Depts. of Neurology, Neurosurgery, Radiology and Stanford Stroke Center, Stanford Medical Center, Stanford , CA 94305

Reteplase (rPA, Boehringer Mannheim)) is a novel, *E. coli* produced thrombolytic which may be superior to tissue plasminogen activator (tPA) because of enhanced fibrin specificity and longer serum half life. We conducted a study using sequential diffusion (DWI) and perfusion MRI (PMRI) to evaluate the efficacy of thrombolysis in an embolic stroke model with tPA compared to rPA. Right internal carotid arteries of 28 rabbits were embolized using aged heterologous thrombi. Baseline DWI and PMRI scans were obtained to confirm successful embolization. I.V. treatment with tPA (6 mg/kg over 1 hr.), rPA (1 mg/kg bolus) or placebo began 1 hour after stroke induction. These doses reduced serum fibrinogen levels by 80%. MRIs were performed at 45, 120 and 240 minutes following treatment and scored in a blinded fashion. Gross brain sections were examined for hemorrhage. Animals treated with either tPA or rPA showed reduction in lesion size and improved cerebral perfusion compared to controls. 50% of animals given tPA and 38% of animals given rPA showed reduction in DWI lesion size compared to 10% of control animals. PMRI scans showed improvement in cerebral perfusion in 88% of animals given tPA, 57% of animal given rPA, and none of the control animals. ($p<0.02$, tPA and rPA compared to controls) There were no differences in cerebral hemorrhage rates although animals given tPA or rPA had a higher incidence of wound site bleeding. ($p<0.05$) 50% of tPA treated animals and 38% of rPA animals compared to 10% of control animals significant had wound site bleeding. 2 animals (1 tPA and 1 rPA treated) suffered fatal wound site hemorrhage. Thrombolytic therapy with tPA or rPA appear equally promising without causing excess cerebral hemorrhage. Systemic hemorrhage, however, was higher with exogenous thrombolytics.

A NEW RAT MODEL OF THROMBOTIC FOCAL CEREBRAL ISCHEMIA. ZG Zhang[1], RL Zhang[1], M Chopp[1,2*], Q Jiang[1], SBK Raman[3], L Cantwell[3]. Henry Ford Health Science Center, Departments of Neurology[1] and Hematology[3], Detroit, MI 48202, Oakland University, Department of Physics[2], Rochester, MI 48309.

We developed a fibrin rich thrombotic focal cerebral ischemia model in rats with reproducible and predictable infarct volume. In male Wistar rats (n=77), a thrombus was induced at the origin of the right middle cerebral artery (MCA) by injection of thrombin via an intraluminal catheter placed into the intracranial segment of the internal carotid artery. Thrombus induction and consequent ischemic cell damage were examined by histopathological analysis, neurological deficit scoring and by measuring changes in cerebral blood flow (laser Doppler flowmetery and magnetic resonance imaging) as well as by diffusion weighted imaging. Regional cerebral blood flow in the right parietal cortex was reduced by 34% to 58% of preinjection levels after injection of thrombin (n=10). Magnetic resonance imaging (MRI) measurements showed a reduction in cerebral blood flow and a hyperintensity diffusion weighted image encompassing the territory supplied by the right MCA. Confocal microscopy revealed that fluorescent material was only present in the lumina of the ipsilateral cerebral microvasculature within the territory of the MCA. Animals (n=15) exhibited neurological deficit. Rats (n=30) exhibited a percent hemispheric infarct volume of $30.1 \pm 4.8\%$ to $34.5 \pm 6.7\%$. Light and electron microscopic examination and phosphotungstic acid hematoxylin staining revealed a high fibrin content of the thrombus. In addition, thrombotic rats (n=3) treated with recombinant tissue plasminogen activator 2 h after thrombosis showed that cerebral blood flow rapidly returned towards preischemic values as measured by MRI perfusion weighted imaging. This model of thrombotic ischemia is relevant to thromboembolic stroke in humans and may be useful in documenting the safety and efficacy of thrombolytic intervention as well as for investigating therapies complementary to antithrombotic therapy. ENDOVASCULAR (EV) INJURY IN SUTURE MCAO STROKE MODELS

YY He[1], HY Li[2], SX Zhang[2], G Dong[2], R Shi[2], L. Wei[2], GS Fan[1*], XM Xu[2], CY Hsu[1] [1]Dept Neurology, Washington Univ Sch Med, St. Louis, MO 63110 and [2]Dept Anat. & Neurobiol, St. Louis Univ Sch Med, St. Louis, MO 63104.

EV occlusion of the MCA by a suture advanced into the intracranial internal carotid artery (ICA) has become a widely used MCAO stroke model in rodents. To our knowledge, the EV integrity has not been examined in this model. In the present study, we compare the effects of nylon suture (NS) and gut suture (GS) and a polyimide tubing (PT) on the infarct sizes and EV injury in the intracranial portion of ICA. 3-0 NS, 4-0 GS or PT was used to occlude the MCA. The external diameter (ED) was 0.30 mm. A Superglue coat was necessary for 3-0 NS and PT to achieve the required ED. Adult Long Evans male rats (BW: 275 + 25 g) received an intraluminal insertion of a NS, GS or PT through the external CA under anesthesia (chloral hydrate, 400 mg/kg). The tip was advanced 22 mm from the carotid bifurcation. The infarct volume based on TTC staining 24 hr after 90 min ischemia were comparable among the 3 groups. To study EV injury, the animals were perfused with 4% paraformaldehyde in PBS (pH 7.4) containing 2% glutaraldehyde 4 hr after reperfusion following 60-90 min ischemia. By scanning electron microscopy (EM), EV injury in intracranial ICA was noted in all groups and was characterized by deposition of red and white blood cells and especially platelets. The findings were comparable among the 3 groups except that GS caused deposition of a greater number of blood cells. Appearance of bundles of collagen-like fibrils was also confined to the GS group. Transmission EM showed endothelial denudation. The elastica interna and underlying smooth muscle layer was intact. These findings indicate EV injury in the suture MCAO model. The impact of endothelial injury on ischemic brain damage remains to be defined. (supported by NIH grants NS25545 and NS28995)

ISCHEMIA: BEHAVIORAL, CLINICAL, AND IMAGING STUDIES

839.1

NEUROPROTECTIVE EFFECTS OF POST-RESUSCITATION TREATMENT WITH THE LAZAROID U74389G AFTER CHEST-COMPRESSION GLOBAL ISCHEMIA IN RATS.

K. Reid*, A. Dhooper, P. Keelen, S. Chan, M. Tseng, C. Young and V. Iyer, Departments of Anatomical Sciences and Neurobiology and of Neurology, University of Louisville, Louisville KY 40292.

After global ischemia and resuscitation, rats develop behavioral changes indicative of anxiety (Dhooper et al., FASEB J. 9:A380, 1995). The elevated plus maze was used to evaluate rat anxiety and activity during recovery from a 7 minute episode of global ischemia induced by chest compression under ketamine anesthesia. Both anxiety (open arm ratio) and activity (total arm entries) decreased significantly over days 1-5 post-ischemia, with the largest change occurring between days 1 and 2. If the lazaroid U74389G (Upjohn) was given i.p. 5 minutes after the end of the ischemic episode, there was a significant recovery of activity on day 6 for a dose of 18 mg/kg but not for a dose of 8 mg/kg. The open arm ratio was not significantly improved by either dose. Histological evaluation of the CA1 region of the hippocampus showed a significant protective effect at *both* 8 mg/kg and 18 mg/kg. We conclude that plus maze behavior is reliably altered by global ischemia, and that the two measures are differentially affected by the neuroprotective agent U74389G. Since the 8 mg/kg dose protected CA1 the behavioral effects were probably due to damage outside this region. Supported by a grant from Jewish Hospital, Louisville KY.

MORRIS WATER MAZE (MWM) IMPAIRMENTS IN ISCHAEMIC RATS: IS RETINAL DAMAGE THE CAUSE?

B.A. Pappas*, C.M. Davidson, T. Fortin and J.C. de la Torre. Institute of Neuroscience, Carleton University, Ottawa, Ont. K1S 5B6.

Impaired MWM acquisition occurs with both transient global and chronic partial ischaemia. The impairment correlates poorly with hippocampal CA1 damage. Retinal blood flow is reduced in global ischemia. Does this damage the retina and impair performance of the visually-guided MWM? Glial fibrillary acid protein and degeneration-related silver staining in the optic tract are both elevated by chronic ligation of the common carotid arteries (2-VO). These predict but do not completely account for MWM impairment. As well, presurgical MWM training eliminates the early but not the later-emerging MWM deficits. Hence, visual dysfunction cannot account for the early- but could explain the later-emerging deficit. Since 2-VO significantly elevates stress-induced corticosterone release, exacerbated stress-susceptibility may underlie the early MWM impairment. Retinal damage and/or stress may also underlie MWM impairments in other ischaemia paradigms. (Supported by Ontario Heart and Stroke Fndn.)

839.3

HYPERTENSIVE RELATED CHANGES IN A NON-HUMAN PRIMATE MODEL OF CEREBROVASCULAR DISEASE: EARLY STAGE ATTENTIONAL DYSFUNCTION.

R. J. Killiany*, M. B. Moss, B. Duryea, D. L. Rosene, S. Prusty and W. Hollander. Depts. of Anatomy and Neurobiology, Medicine and Neurology, Boston University School of Medicine, Boston, MA 02118

Attentional function represents a cognitive domain that is vital to performing activities of daily living. Hypertension is an age associated risk factor for cerebrovascular disease which, even in its mild stages, has been associated with cognitive impairment. However, most human studies cannot control for complicating atherosclerosis or other risk factors. We assessed the behavioral consequences of hypertension in a non-human primate model of cerebrovascular disease using behavioral tasks that closely resemble those used in the clinical assessment of patients. The performance of eight young adult rhesus monkeys (M. mulatta) that had been made hypertensive by coarctation of the thoracic aorta six months earlier was compared to the performance of ten normotensive surgical control monkeys. The task was administered in an automated touch-screen testing apparatus. We assessed three aspects of attentional function; simple attention, cued attention and vigilance. No significant differences were found on measures of simple attention or vigilance. However, the hypertensive monkeys were significantly ($p's<0.05$) impaired on measures of cued attention. Earlier pilot work demonstrated that by six months following coarctation, hypertensive monkeys evidence uniformly sized microinfarcts scattered in both white and the gray matter of the forebrain and brainstem with no apparent topographic specificity. However, it is unclear if microinfarction alone can account for the behavioral changes observed. (Supported by NIH grant PO1NS31649)

839.4

FLUPIRTINE REDUCES FUNCTIONAL DEFICITS AND NEURONAL DAMAGE AFTER GLOBAL ISCHEMIA IN RATS.

M. Schwarz, F. Block, G. Pergande, J. Noth*. Department of Neurology, Medical School, Technical University, Aachen, FRG

Global cerebral ischemia which leads to selective neuronal damage in the C1-sector of the hippocampus and in the dorso-lateral striatum, results in deficits of spatial learning and memory. Flupirtine is a non-opioid centrally acting analgesic which has been shown to be neuroprotective against NMDA-mediated toxicity *in vitro*. The present study investigates the potential protective effect of flupirtine *in* vivo with both behavioral and histological measure of global cerebral ischemia. Global ischemia was induced by 4-vessel occlusion (4VO) for 20 minutes in rats. Flupirtine was administered at a dose of 5 mg/kg i.p. either 20 min. before and 50 min. after (pre-treatment) or directly and 70 minutes after occlusion (post-treatment). One week after surgery spatial learning and memory was tested in the Morris water-maze. Pre-treatment with flupirtine reduced the increase in escape latency and swim distance induced by 4VO. It also diminished deficits in spatial memory as revealed by probe trial. Post-treatment with flupirtine has no effect on deficits in spatial memory and learning induced by 4VO. Neuronal damage in the C1-sector of the hippocampus and in the striatum produced by 4VO was significantly attenuated by pre-treatment with flupirtine, whereas post-treatment did not affect this neuronal damage. The present data demonstrate that pre-treatment with flupirtine reduces functional deficits and neuronal damage after global ischemia in rats.

839.5

NESTING BEHAVIOR AS AN INDICATOR OF HIPPOCAMPAL ISCHEMIC DAMAGE. P. Wu*, F.J. Antonawich, C.S. Melton and J.N. Davis. Dept. of Neurology, SUNY at Stony Brook, Stony Brook, NY 11794.

The behavioral effects of transient global ischemia begin with a short (2-3 hr.) period of hypoactivity, followed by a well characterized increase in motor activity. Other studies, of this hyperactive period, have characterized a broad range of activities including increased rearing, locomotion, sniffing and drinking. While the specific CA1 damage incurred, following global ischemia, increases the aforementioned behaviors, other patterns of behavior become attenuated. The gerbil exhibits a stereotypical nest-building behavior, characterized by a species specific shredding of the nest material. Nest building is dramatically reduced following ischemic damage.

Male Mongolian gerbils were subjected to either 5 or 10 min. of bilateral carotid artery occlusion. Brain and body temperature were monitored and maintained between 37.0 and 38.0°C. One hr. following ischemic surgery, each animal was exposed to paper towel nesting material. Nesting behavior was recorded every 24 hr. for the duration of the experiment, based on the following parameters: 1= the animal merely pulled the nesting material over to a corner, 2= both pulled the material to a corner and piled it for a nest, 3= pulled the material to a corner, piled it and shred the material. 5 min. of ischemia significantly reduced nesting behavior at both 24 ($p<0.01$) and 48 ($p<0.05$) hr. as compared to sham occluded control animals, however there was no difference in nesting behavior by 72 post-ischemic hr.; while 10 min. of ischemia resulted in 6 days of reduced nesting behavior. This disruption in nesting behavior directly correlates to the amount of ischemic morphological damage and thus may serve as a behavioral indicator of tissue damage. Furthermore, categorizing the pattern of behavioral effects following transient ischemia as a period of hyperactivity, may no longer be appropriate since there are both increases and decreases in motor activities. (Supported by NS 30559, NIH and the VA)

839.6

TRANSIENT ISCHEMIA OF EYE DUE TO INNOMINATE ARTERY STENOSIS

S.R. Brenner* and S. Abbas. Departments of Neurology and Radiology, Cochran Veterans Administration Medical Center, 915 N. Grand Blvd., St. Louis, Mo. 63106 and St. Louis University Medical Center.

A middle aged patient with recurrent amaurosis fujax or temporary blindness of his right eye and unrevealing carotid ultrasound in the past underwent angiography which revealed a tight, ulcerated calcific plaque at the ostia of the innominate artery with 75 to 80 % stenosis. Slow filling of the innominate, subclavian, axillary and vertebral artery distributions was demonstrated. The patient underwent vascular reconstruction. A review of the medical literature did not reveal prior cases of transient eye ischemia due to innominate artery stenosis. Ordinarily it is thought transient monocular blindness is usually due to carotid or ophthalmic artery disease and can be a warning sign of impending stroke.

This case indicates not all cases of transient monocular blindness are due to carotid artery stenosis and investigations of innominate arteries are advisable if carotid ultrasound is unrevealing, in order to reduce the likelihood of impending stroke.

Supported by clinical activities of the Veterans Administration hospital.

VALIDATION OF ADDTC and NINDS-AIREN DIAGNOSTIC CRITERIA FOR POSSIBLE VASCULAR DEMENTIA: A CLINICOPATHOLOGIC STUDY.

G. Gold, P.Giannakopoulos*, G.C. Montes-Paixao, F.R. Herrmann, J-P. Michel, C. Bouras. Division of Neuropsychiatry and Department of Geriatrics, HUG, Belle-Idée, 1225 Geneva, Switzerland.

Accurate diagnosis of vascular dementia (VD) is of crucial importance for both clinical and research purposes. Recently, two groups, the ADDTC and NINDS-AIREN, developed diagnostic criteria for this entity. To examine their performance, we made a clinicopathological evaluation of 113 demented cases. Neuropathologically, there were 40 patients with VD (mean age: 81.0 ± 2.4 years), 32 patients with Alzheimer's disease (AD; mean age: 85.0 ± 3.0) and 41 patients with mixed dementia (MD=vascular and AD type; mean age: 88.0 ± 2.8). The ADDTC and NINDS-AIREN criteria for possible VD and the Hachinski ischemic score (HIS; cut-off point of 7) were applied retrospectively by two independent raters with high inter-rater reliability. Sensitivity and specificity were assessed by comparing the clinical to the neuropathological diagnosis in a double blind design. Receiver Operator Characteristic (ROC) analysis was used to examine the utility of each set of criteria and their combination. The sensitivity was 0.68 for ADDTC, 0.58 for NINDS-AIREN and 0.28 for the HIS while the specificity was 0.66, 0.80 and 0.97 respectively. Patients with MD satisfied the ADDTC in 53.7% of cases, the NINDS-AIREN in 29.3%, and the HIS in only 5.1%. All diagnostic criteria excluded the vast majority of AD cases. The difference between VD and AD was highly significant (Pearson Chi^2; $p < 0.01$-0.001), but ADDTC failed to distinguish VD from MD. ROC analysis showed that the three sets of criteria performed at significantly better than chance levels. The combination of both NINDS-AIREN criteria and HIS was the most valuable to detect VD. These results show that low sensitivity is the main weakness of the above clinical diagnostic criteria for possible VD. Furtermore, they suggest that the combination of NINDS-AIREN and Hachinski criteria provides the most efficient method for clinical diagnosis of VD.

839.8

INDIVIDUAL PATTERNS OF PET ACTIVATION IN PATIENTS WITH SUBCORTICAL STROKES PERFORMING MOVEMENTS OF THE RECOVERED HAND.

J.Chmielowska, E.M.Wassermann, R.A.Weeks, N.Patronas, N.Sadato and M. Hallett*. HMCS, NINDS, NIH, Bethesda, MD

The goal of this study was to compare the individual patterns of cerebral activation in 5 well recovered patients with unilateral subcortical infarcts of different size and shape, involving the putamen, globus pallidus, nucleus caudatus, thalamus and internal capsule with a group of 10 age matched healthy controls.Six ^{15} O PET scans were acquired; 2 at rest; 2 during sequential finger movement of the recovered hand and 2 during sequential finger movement of the unaffected hand. Differences in activation between individual patients and the controls were studied using subtraction analysis (SPM95; ANCOVA) with thresholds of $p< 0.001$ and Bonferoni corrections. The results indicate that each stroke patient exibited a different pattern of cerebral activation due to the movement task of the recovered hand in comparison to the normals. 2 patients showed similar patterns of cortical reorganisation with greater increases of rCBF than controls in the primary motor cortex (area 4), premotor cortex (lateral area 6), prefrontal cortex and thalamus (intact in those patients) of the lesioned hemishere. One of them has also shown a significant decrease of rCBF in the primary motor cortex and in inferior parietal cortex in the ipsilateral, intact hemisphere in comparison to the normals. The remaining patients have shown increased activation during movement in the insula, cingulate cortex and parietal cortex (lateral area 40) in the ipsilateral, intact hemisphere. In conclusion the recovery from subcortical stroke is associated with very different patterns of cortical reorganisation although we have identified a tendency for some patients to exhibit increased activity in motor cortical areas in the affected hemisphere.

IMAGING IN HIPPOCAMPAL SLICES REVEALS SELECTIVE REGIONAL VULNERABILITY TO ANOXIC DEPOLARIZATION AND SWELLING.

N.R. Kreisman*, J.E. Torres, and D. Gozal Departments of Physiology and Pediatrics, Tulane University School of Medicine, New Orleans, LA 70112.

Transmitted light was imaged from hippocampal slices to map onset and spread of swelling associated with anoxic depolarization. Anoxia triggered spreading depolarization (SD) and swelling initially in CA1 oriens, which propagated across stratum oriens and stratum radiatum. SD failed to enter CA3 but slowly spread across the hippocampal fissure into the upper blade of the dentate gyrus. In contrast, the lower blade of the dentate was resistant to anoxia-induced SD. Exposure to combined aglycemia and anoxia triggered SD in CA1 and dentate gyrus with a shorter latency than with anoxia alone but still failed to elicit SD in CA3 and dentate lower blade at 1 hr. The CA3 region did not appear to be damaged by slicing because orthodromic population spikes could be evoked during normoxia and SD could be triggered by local application of a thread soaked in KCL solution. Imaging of mini-slices from CA1 and dentate gyrus showed that initiation of anoxic SD in the upper blade of the dentate gyrus was independent of SD from CA1. The resistance of both the lower blade of the dentate gyrus and CA3 to anoxic SD and associated swelling *in vitro* is consistent with their resistance to ischemic damage *in vivo*. Supported by NIH HD01072.

DELAYED EVOLUTION OF INFARCTION IN HUMAN STROKE.

S Warach*, A Benfield, RR Edelman., G. Schlaug. Depts. of Neurology and Radiology, Beth Israel Hospital, Harvard Medical School, Boston, MA 02215.

Delayed neuronal death has been observed in animal models of cerebral ischemia. It is unknown whether this phenomenon occurs in human stroke. MRI diffusion weighted imaging (DWI) is the most sensitive *in vivo* imaging measure of ischemic cellular injury, evidenced by a reduction in the apparent diffusion coefficient of brain water by approximately 45% and hyperintensity in DWI, within minutes after onset of ischemia. From our series of over 130 acute stroke patients studied with DWI:

(1) One third to one-half of the patients initially studied beyond 6, 12 or 24 hours had further growth of their lesions by greater than 20%.
(2) Lesions continued to grow even after reperfusion of the lesion has been documented.
(3) In a small pilot study, patients treated with citicoline 8-24 hours after stroke onset, showed a trend toward lesion reduction relative to placebo-treated patients.

These observations indicate that prolonged evolution of ischemic infarction is common in human stroke and may occur even after early reperfusion. In clinical trials, emphasis has focused on therapeutic windows of 6 hours or less. Our results suggest that neuroprotective therapies beyond the conventional therapeutic time window may potentially be effective.

Supported by NINDS and the American Heart Association.

839.11

PATHOGENESIS OF VASCULAR LEUKOENCEPHALOPATHY STUDIED BY 3D PET-MRI REGISTRATION TECHNIQUE.

K. Ishii*[1], M. Senda[1], H. Toyama[1], K. Oda[1], S. Ishii[1], K. Ishiwata[1], T. Sasaki[1], H. Nagura[2] and H. Yamanouchi[2]. [1]Tokyo Metropolitan Institute of Gerontology and [2]Tokyo Metropolitan Geriatric Hospital, Tokyo 173, Japan.

The purpose of this study is to investigate the pathophysiological mechanism of vascular leukoencephalopathy. Five patients having diffuse periventricular hyperintensity (PVH) on MRI without manifest neurologic deficit were studied and compared with five normal subjects. The regional cerebral blood flow (CBF), cerebral metabolic rate of oxygen ($CMRO_2$), oxygen extraction fraction (OEF), and cerebral blood volume (CBV) were measured with the inhalation of O-15 labeled gases and PET. The PET images were three dimensionally registered to each subject's T1 and T2 weighted MR images. Regions of interest were placed on the center of PVH, on the edge of PVH, and on the normal intensity white matter.

The OEF was heterogeneously elevated around the edge of PVH. In the center of PVH, both CBF and $CMRO_2$ were declined, and the OEF was not elevated. These results suggest that ischemia in the white matter may play a role in the initial stage of PVH. But other factors may be involved in its development to organic damage resulting in neurologic symptoms.

839.12

Magnetic Resonance Imaging of neuronal damage resulting from hippocampal Fe2+ microinjections.

D.T. Rogers*, R.W. Landrum, M. Zhang, J.M. Carney, C. Avison, R.A. Floyd[1]. Dept. of Pharmacol. and Magnetic Resonance Imaging Center, Univ of Ky. Coll. of Med. Lexington Ky. 40536;[1] Oklahoma Med. Res. Found. Okla. City, Okla 73104.

A role for iron has been ascribed in stroke and head trauma pathologies. Iron is hypothesized to produce neuronal damage by catalysis of oxygen free radical formation. This study examines the viability of subcortical microinjection of $FeSO_4$ in anesthetized rats as a model of Fe^{2+}-induced oxidative damage. Stereotaxic microinjections of $FeSO_4$ (0.1-10uM) were aimed at the right hippocampal formation. Resulting neuronal damage was then visualized 1-24 hr later by Magnetic Resonance Imaging. The presence of $OH^{\cdot}$ radicals in brain sections was confirmed by salicylate ion spin- trapping. This study provides support for the development of Fe2' microinjection in the hippocampus as an *In vivo* model for oxidative damage (Supported by a development grant from Centaur Pharmaceuticals, Inc.).

839.13

EVALUATION OF CEREBRAL CIRCULATION OF THE PATIENTS WITH CEREBRAL VASOSPASM BY THE DYNAMIC ANALYSIS OF THE DIGITAL SUBTRACTION ANGIOGRAPHY

Y.Kinoshita, T.Terada, E.Nakai, K. Nakai*, T.Itakura. Department of Neurological Surg., Wakayama Med. Col., Wakayama, 640 Japan

The purpose of this study is to investigate how we can evaluate the cerebral blood flow by the image data obtained from the digital subtraction angiography (DSA) using digital video recorder and personal computer. Recorded DSA images were transfered to Macintosh computer at a rate one frame per second. The optical density of the region of interest were measured from ten serial dynamic images. The time-density curve was fitted to gamma variate curve by the least square method. We measured mean transit time (mTT) of the curve to represent cerebral circulation time. The mTT of the territories supplied by the anterior cerebral artery (ACA) and the midle cerebral artery (MCA) was calculated. Twelve patients with cerebral vasospasm as well as normal thirteen volunteers were investigated. In order to know reproducibility of this method, mTT was re-evaluated by the repeated angiography in two normal volunteers. In normal thirteen volunteers, mTT of ACA and MCA were 3.4-6.2 sec. (4.4 ±0.7) and 3.7-6.5 sec (4.6± 0.6), respectively. In one patient with ACA vasospasm treated by intra-arterial papaverine hydrochloride, mTT of ACA was improved by 0.8 sec. In another case with vasopasm of MCA treated by the balloon angioplasty, mTT of MCA territory was shortened by 1.2 sec. The difference in mTT between the two series of repeated angiography in two normal volunteers was within 0.5sec. In conclusion, our simple custom-made analyzing softeware for the dynamic DSA is a useful tool to know the cerebral circulation time of the various pathological condition caused by cerebrovascular insults.

ISCHEMIA: MODELS

840.1

EFFECTS OF CEREBRAL ISCHEMIA ON METABOLIC VASODILATION IN PIGLETS.

T. Louis*[3], F. Bari,[1,2] R.Errico,[1] and D. Busija.[1] [1] Bowman Gray Sch. of Med., Winston-Salem, NC 27157, [2]Albert Szent-Györgyi Med. Univ., Szeged, Hungary H-6720, and [3]East Carolina Univ. Sch. of Med., Greenville, NC 27858

Effects of ischemia on factors that link brain metabolism and blood flow in the neonate are unclear. The purpose of this study was to examine effects of ischemia on cerebral arteriolar responses to hypoxia, hypercapnia, and adenosine. Baseline arteriolar diameters in piglets were ~100 μm, and responses were determined prior to, and 1, 2, and 4 hours after 10 minutes of total, global ischemia. Ischemia was induced by increasing intracranial pressure. Inhalation of 5 and 10% CO_2 in air dilated arterioles by 18±2% and 28±3%, respectively, and ischemia abolished dilation (<2%) at 1 hour (n=6). However, arteriolar dilation returned to normal over 2-4 hours. Inhalation of 8.5% and 7.5% O_2 in N_2 dilated arterioles by 19±2% and 30±4%, respectively (n=5), and topical adenosine dilated arterioles by 13±2% at 10^{-5}M and 20±2% at 10^{-4}M (n=8). In contrast to hypercapnia, ischemia did not affect arteriolar dilation to hypoxia or adenosine. We conclude that ischemia selectively attenuates responses to metabolic stimuli. Supported by NIH grants HL-30260, HL-46558, aand HL-50587.

840.2

EARLY PHISIOLOGICAL AND MORPHOLOGICAL CHANGES IN RAT CA1 PYRAMIDAL NEURONS BY TRANSIENT ISCHEMIA IN VITRO.

HORI, N.[1]*, IEIRI, Y.[1], SASAMOTO, K.[1], KOSAKA, T.[2], CAPENTER, D. O.[3]* [1]Faculty of Dentistry & [2]Medicine, Kyushu University, Fukuoka, 812, JAPAN and [3]Wadworth Labs, NYS Department of Health, Albany, New York 12201 U.S.A.).

Brief transient ischemia causes cell death of pyramidal neurons in the CA1 area of hippocampus after several days. It is possible that this cell death is programmed at the early stage just after the ischemic insult. We have studied the time course of physiological and morphological changes in CA1 pyramidal cells in the rat hippocampus slices exposed to in vitro ischemia. Before ischemic insults some of the cells were injected with Lucifer yellow through the intracellular electrodes. After stabilized responses were recorded, the slices were perfused with Ringer solution lacking glucose and oxygen. The population spike induced by Schaffer collateral stimulation was suppressed within 6-7 min after onset of ischemic insult, although there were a transient rebound seen just before disappearance of the evoked response, followed later by a large spreading depression-like potential. After spreading depression, the neuron injected by Lucifer yellow showed extensive beadings on both of apical and basal dendrite trees. The time-dependance of beading formation with ischemia on a single pyramidal neuron injected by Lucifer yellow was observed in a fluorescence microscope. These beadings were blocked by the NMDA receptor antagonists or low Ca (0.1mM) and high Mg (5.3mM) Krebs-Ringer. These results suggest that the transient rebound excitation and spreading depression may result from the beading formation which increases chemosensitivity of the neuron exposed to ischemic insults. The mechanism responsible for generation of the beading may be related to the change of cytoplasmic osmosis and the degradation of cytoskeletal protein. These changes may trigger the neuronal cell death.

840.3

ANOXIA AND REPERFUSION MODEL USING HIPPOCAMPAL BRAIN SLICES: HISTOLOGY, ADENYLATES AND HYDROXYL FREE RADICALS. **Y.Liu, F.E.Hospod, H.Qi, S.Trowbridge*, G.C.Newman Dept. of Neurology, SUNY, Stony Brook, NY and VAMC at Northport, NY.**

Reperfusion after severe focal ischemia yields disappointing recovery of neurological function after even relatively brief periods. In order to better understand the neurochemistry of reperfusion we have developed an *in vitro* model of severe ischemia and reperfusion based on histology of rat hippocampal brain slices exposed to anoxia and reoxygenation and studied this model with adenylates and hydroxyl radicals.

Brain slices were prepared as usual, incubated at 37°C in K-R with 3.1% dextran for 75 min, exposed to anoxia for up to 15 min, reoxygenated and incubated for 2.5 hr. Slices for hydroxyl radical studies were incubated with 10μg/l or 100μg/l salicylate during and after anoxia. Slices were fixed for histology or frozen in liquid N_2 for perchloric acid extraction immediately after anoxia or after the 2.5 hr. Extracts were analyzed for adenylates or dihydrobenzoic acids by HPLC.

Histology scores immediately after anoxia of any duration were the same as for Controls despite severe depletion of high energy adenylates by 7.5 min. All slices reperfused for 2.5 hr showed greater histologic injury than Controls. After 4' of anoxia, injury was mild and limited to CA1. After 5' there was also mild injury in CA2. Slices with 6 or 7 min of anoxia appeared more variable but tended to have moderate injury in all regions. Slices made anoxic for 10 min or more were severely injured. Adenylates recovered incompletely in slices exposed to anoxia for more than 5 min. Hydroxyl radicals were detected within 15 min of reoxygenation following 15 min of anoxia and returned to baseline by 2 hr post-anoxia. **Support: VA Merit Review and NIH #NS28429.**

POSTISCHEMIC VENTILATORY O_2 INFLUENCES NEUROLOGICAL, HISTOLOGICAL AND NEUROCHEMICAL OUTCOME FOLLOWING CANINE CARDIAC ARREST Y. E. Bogaert*, A. Levesque, P. Hof, Y. Haywood, R.E. Rosenthal and G. Fiskum Depts. of Biochemistry and Molecular Biology and Emergency Medicine, George Washington Univ. Sch. Med., Wash. D.C., 20037 and Dept. of Neurobiology, Mt. Sinai Sch. Med., NY, NY, 10029

A canine model of cardiac arrest was used to test the hypothesis that immediate, postischemic hyperoxygenation exacerbates neurological injury whereas administration of 100% O_2 at 2.7 ATA 1-3 hr post-resuscitation improves neurological outcome. The results of neurological exams and histological measures of cortical and hippocampal neuronal injury at 24 hr post-resuscitation indicated significant neuroprotection by treatment with delayed hyperbaric O_2. These tests also indicated significant neuroprotection when animals were initially resuscitated with either 15% or 21% inspired O_2 versus 100% O_2. Impairment of respiration-dependent Ca^{2+} accumulation by isolated cortex mitochondria was also evident in animals resuscitated on 100% O_2. Furthermore, whereas postischemic cortical lactic acidosis at 2 hr reperfusion was not alleviated by hyperoxygenation, HPLC measurements of frontal cortex lipids indicated increasing oxidative stress as the ventilatory O_2 was varied from 15% to 21% to 100%. Early postischemic cerebral hyperoxygenation is not beneficial possibly due to an impaired ability of mitochondria to utilize O_2, and is detrimental due to potentiation of oxidative stress; however, treatment with hyperbaric O_2 is neuroprotective when administered during the period when the ability of the brain to utilize O_2 has recovered and when cerebral blood flow is abnormally low. Supported by NS34152 and the Emergency Med. Foundation..

840.5

GLOBAL CEREBRAL ISCHEMIA IN RATS. A CRITICAL EVALUATION OF HIPPOCAMPAL CELL LOSS. M.J. Herguido, F. Carceller, J.M. Roda* and C. Avendaño. Depts. Neurosurgery and Morphology, Autónoma Univ., Sch. of Medicine, 28029 Madrid, Spain.

The histological assessment of brain damage after transient global cerebral ischemia has been focussed mostly on neuronal damage in the hippocampus. Although not always acknowledged, two important problems hinder the effectiveness and general acceptance of this model as a tool to achieve sound quantitative evaluations of post-ischemia brain damage. One is the high mortality associated to 4-vessel occlussion in spontaneously breathing animals; the other is the difficulties in counting neurons. We have subjected 61 young adult Wistar rats to 20' (n=38, Group 1) or 10' (n=14, Group 2 and n=9, Group 3) ischemia by 4-vessel occlussion; Group 3 was protected with low -anticonvulsant- doses of phenytoin; 6 further animals were sham-operated (Group 4). Peri- and postoperative mortality was 34% and 50% for Group 1, 29% and 29% for Group 2, 22% and 0% for Group 3, and 0% and 0% for Group 4, respectively. Standard physiological parameters and EEG were monitored during the procedure. Animals were perfusion-fixed after 72 hours, their brains were extracted, embedded in celloidin, serially sectioned at 40 μm, and stained with cresyl violet. The "optical fractionator" (*West et al., Anat. Rec. 231:482, 1991*) was applied to obtain unbiased estimations of the number of surviving pyramidal cells in field CA1 of the hippocampus. The procedure was aided by using an interactive computer system running the GRID® Stereological Software Package (Olympus Denmark). Absolute bilateral cell counts were 468±196 (x 1000, mean±SD), 523±166, 352±194 and 762±45 for Groups 1, 2 ,3 and 4, respectively. Differences were significant between Group 4 and each of the ischemic groups. Also, there was a negative correlation between the number of surviving cells and a preferential cell loss on the left hippocampus. Moreover, Groups 1 and 2 tended to exhibit less hippocampal cell loss than Group 3, suggesting that surviving animals in high-mortality groups represented a biased sample. In sum, low mortality rates and unbiased cell counts are mandatory to quantitatively assess brain damage after global ischemia.

INDUCTION OF PHYSIOLOGICAL AND MORPHOLOGICAL CHANGES INDUCED BY CARDIAC ARREST IN RAT HIPPOCAMPUS. K. Suzuki[1], K. Sasamoto[2], K. Migita[3], Y. Kondo[1]*, D.O. Carpenter[4] and N. Hori[2]. [1]Dept. Physiol., Nippon Med. School, Tokyo, Japan, [2]Fac. Dent., Kyushu Univ., Fukuoka, Japan, [3]Fac. Pharmaceut. Sci., Fukuoka Univ. Japan and [4]WCL&R NYS Dept., Health, Albany, NY 12201.

Damage to the central nervous systems produced by cardiac arrest (CAR) as the model of neuronal cell death is little studies. Thus we performed to characterize the functional and morphological changes in hippocampus induced by CAR and to compared with damages by typical occlusion of vertebral arteries (VAO). Under halothane anesthesia, Wistar male rats (about 250g) were fastened to warmed table and blood pressure was monitored from femoral artery. A bent metal wire was inserted under the bundle of cardiac blood vessels and lifted to squeeze those bundle and thus caused CAR. After confirming CAR or zero blood pressure for more than 5 min, resuscitation was started with artificial ventilation and tapping the chest. Then one and three days after CAR treatment, hippocampal slices were cut using conventional method and intra- and extracellular recordings were performed from CA1 and CA3 areas. In CA1 pyramial cell layers in both of CAR and VAO rats, the recorded field potentials evoked by schaffer collateral stimulation were smaller than those of control but were no differences between in both of treatments. One day after CAR treatment, CA3 pyramidal neurons almost did not response to mossy fiber stimulation and sensitivities of neurons to bicuculline (10^{-5}M) were very low compared with control rats. In three days after CAR, neuronal activities of CA3 in CAR rats gradually recovered. One day and three days after ischemic insults, morphological change were not observed in CA1 and CA3 pyramidal neurons injected with Lucifer yellow. These results suggested that in CAR treated rats, neuronal activity of CA3 showed significantly difference compared with that of VAO treated rats.

REPERFUSION-INDUCED CHANGES IN A NINE-VESSEL OCCLUSION MODEL OF ISCHEMIA. T.Lenzi and J.A.Rafols*. Department of Anatomy/Cell Biology, School of Medicine, Wayne State University, Detroit, MI. 48201

A nine-vessel occlusion rat model was utilized in order to induce transient forebrain ischemia without the protective effects of anesthesia. The sensorimotor area of the cerebral cortex was analyzed by electron microscopy at 0-7days reperfusion times to assess the subcellular organelle changes in neuron cell bodies and endothelia. Another phase of the study focused on the changes in glutamate localization, using immunocytochemical and morphometric methods.

Qualitative findings included the presence of dilated Golgi and stringy rough endoplasmic reticulum in neurons at 30,60 and 90 min as well as 6,12,24 and 48 hr reperfusion times. These changes correlate with reported inhibition of protein synthesis and the microvessicle transport system. The sham-operated controls did not exhibit these changes. Many neurons exhibited eccentric nucleoli attached to a condensed body of chromatin on the inner nuclear envelope at reperfusion times of 15 minutes and beyond. These changes may correlate with alterations of transcription initiation factors known to occur during reperfusion. Although eccentric nucleoli were visible in shams, they did not exhibit the same condensed chromatin pattern. Electron dense degenerating neurons were apparent at 24 and 48hr reperfusion times. Changes in cerebral microvessels included a thin-walled endothelium with few microvilli in the absence of perivascular edema in the 15min reperfusion specimens. However, from 60min to 48hr reperfusion times, swelling of astrocytic foot processes was prominent. At 24hrs the microvessels exhibited dark endothelia, and constricted lumina, corresponding to the period of delayed hypoperfusion. The endothelial tight junctions remained intact throughout all time periods. Thus, the subcellular and excitatory transmitter changes occur concurrently during reperfusion-induced cell injury. *Research funded by NIH Grant NS33196.*

VACUOLIZATION IN CEREBELLAR STRUCTURES AS A CONSEQUENCE OF GLOBAL BRAIN ISCHEMIA IN THE RAT. **I. Vanicky, [2]T. Balchen, [3] M. B. Weinger*, [2]N. H. Diemer**, [1]Institute of Neurobiology, Slovak Academy of Sciences, Kosice, Slovakia, [2]Neuropathology Institute, Frederik V's vej 11/6, Copenhagen, Denmark, [3]Dept. of Anesthesiology, University of California, San Diego.

Histopathological consequences of brain ischemia were studied with the high pressure neck tourniquet/hypotension model in the rat. By laser Doppler flowmetry we have demonstrated that the tourniquet model produces complete cessation of blood flow in both parietal cortex and cerebellar vermis. The histological analysis was focused on subtentorial structures as these are usually not made ischemic in the commonly used models of forebrain ischemia. After 12.5 min of ischemia up to 50% of Purkinje cells underwent selective necrosis, in accordance with previous reports. In addition, we observed expressive vacuolization in deep cerebellar nuclei. The vacuoles started to evolve 6 hours postischemia and became fully expanded after 24 hours. At this time, similar but smaller vacuoles appeared in the granular layer, as well. However, the swelling was mostly transient, as with longer survival times the vacuoles disappeared, and no apparent cell loss was observed in this region. Similar changes were reported to occur in vitro after NMDA application to incubated cerebellar slices (Garthwaite and Garthwaite, 1986). We therefore speculate that this readily observable phenomenon might correlate with the time course of postischemic disturbances in excitatory transmission.

VISUALIZATION OF HYPOXIC CELLS WITH EF5 FOLLOWING HYPOXIA-ISCHEMIA IN NEWBORN RAT BRAIN. M. Bergeron[1]*, F.R. Sharp[1], S.M. Evans[3], C.J. Koch[4], E.M. Lord[5] and D.M. Ferriero[1,2]. Depts of Neurology[1] and Pediatrics[2], UCSF and VAMC, San Francisco, CA; School Vet. Med.[3] and Rad. Oncology.[4], U. Penn., Philadelphia; U. Rochester Cancer Ctr[5], NY.

The hypoxia-dependant bioreductive activation of nitroheterocyclic drugs by cellular nitroreductases leads to the formation of adducts between the drugs and cellular macromolecules. This covalent binding is maximal with absence of oxygen, thus detection of bound adducts could provide an assay for estimating the degree of hypoxia in a tissue (Evans et al., 1995). Based on these observations, we have developed a technique of in situ binding using a pentafluorinated derivative of etanidazole called EF5. To study the effect of perinatal hypoxic-ischemic encephalopathy on the distribution of EF5 adducts, 7-day-old rats received an i.p. injection of EF5 solution 30 min prior to left carotid coagulation and subsequent exposure to $8\%O_2/92\%N_2$ for 2.5 h. Brains were frozen at the end of hypoxia exposure. Using a fluorochrome (Cy3) conjugated monoclonal mouse antibody raised against adducts of EF5 (Lord et al., 1993), the distribution of hypoxic cells within brain regions was determined by fluorescence immunocytochemistry. Results showed intense cellular staining in ipsilateral hemisphere with a pattern similar to that previously reported for histological damage. Hypoxia exposure alone (without ligation), which does not result in cellular damage, produced patchy areas of low intensity staining scattered throughout the brain. Controls and vehicle-injected animals showed no staining. In addition, studies on the brains of chronically hypoxic rats bearing congenital cardiac defects (WKY/NCr) showed no staining. This study provides a new sensitive method to evaluate the level and distribution of cellular brain hypoxia in a rat model of perinatal asphyxia and suggests that in vivo formation of macromolecular adducts of EF5 in neonatal rat brain depends on the degree of oxygen depletion in the tissue (Supported by NIH grants and MRC Canada).

A NEW MODEL OF PURE FOCAL ISCHEMIC INJURY IN NEONATAL RAT BRAIN. J.D.E. Barks, B.L. Eun and X.-H. Liu*. Depts. of Pediatrics, Univ. of Michigan, Ann Arbor, MI 48109 and Korea University, Seoul, Korea.

A postnatal day 7 (P7) rat model of neonatal hypoxic-ischemic brain injury (unilateral carotid ligation followed by timed exposure to 8% O_2) has been well characterized. Yet, there has been no P7 rat model of focal cerebral ischemia without systemic hypoxemia, and its associated adverse cardiovascular effects. Size constraints have restricted intraluminal suture-occlusion and other focal ischemia models to rats older than P12-14. We report a new model of focal cerebral ischemia in P7 rats, produced by direct intracerebral injection of endothelin-1 (ET-1) adjacent to the right middle cerebral artery (MCA). ET-1 is a potent vasoconstrictor peptide; injection of ET-1 in adult rats adjacent to the MCA results in striatal and cortical infarction (J Neurosci Methods 60:125). Methoxyflurane anesthetized P7 rats (n=26) received a 2 µl stereotaxic injection of ET-1 (RBI, Natick MA) 60 pmol (n=13, 2 died), or 600 pmol, (n=13) at coordinates AP 0, ML 3.5 (mm, rel. to Bregma), V 5 (rel. to skull surface). Injury was assessed on P12, in coronal sections processed for cresyl violet staining, cytochrome oxidase histochemistry, and GFAP immunocytochemistry. The commonest outcome, in 12/24, was patchy-columnar right cortical neuronal necrosis and striatal atrophy. The most severe outcome, in 7/24, included extensive right cortical infarction, both rostral and caudal to the level of the injection track, and right striatal infarction and atrophy. Evidence of infarction included loss of cresyl violet and cytochrome oxidase staining, with increased GFAP immunostaining. 5 rats had only limited neuronal loss along the injection track, which either did not reach the depth of the entorhinal cortex adjacent to the MCA, or terminated lateral to the MCA. Overall 19/24 (79%) had evidence of striatal and cortical ischemic damage in the right MCA distribution. These results demonstrate the feasibility of inducing focal cerebral ischemic damage in P7 rats using stereotaxic intracerebral injection of ET-1 adjacent to the right MCA. Our data also suggest that ET-1 may play a role in the pathophysiology of cerebral ischemic injury in the immature brain. (Supported by United Cerebral Palsy grant R-608-94)

A HYPOXIC-ISCHEMIC MODEL OF STROKE IN THE ADULT MOUSE. S. L. O'Donnell*, S. J. Vannucci, S. W. Levison, T. L. Wood., Depts. of Neuroscience & Anatomy and Pediatrics, PSU College of Medicine, Hershey, PA 17033.

In order to study genes involved in the brain response to stroke we have developed a model of unilateral cerebral hypoxia-ischemia in the conscious adult mouse. Male C67Bl6/J mice, aged 8-10 weeks were anesthetized with halothane and their right common carotid artery was exposed and ligated. Following 2 hours recovery, the animals were placed in a 37°C, thermostable hypoxic chamber and exposed to 8% O_2/balance N_2 for 15 minutes. At 4 days of recovery mice were perfused transcardially with 2% paraformaldehyde, and the brains were removed and frozen. Cryosections were taken coronally at the level of the anterior hippocampus. Sections were analyzed for GFAP and clusterin mRNAs by *in situ* hybridization. Expression of both genes are known to be elevated following injury and we observed increased levels of GFAP and clusterin mRNAs surrounding necrotic regions located in cortex, striatum, hippocampus and thalamus. Brains from control animals subjected to either hypoxia or ischemia alone did not show increased levels of GFAP mRNA. Adjacent sections immunostained for neuronal or microglia/macrophage specific proteins confirmed significant neuronal loss within infarcted regions and increased numbers of activated microglia/macrophages when compared to the contralateral hemisphere. This hypoxic-ischemic insult in the adult mouse produces consistant damage similar to that seen in other adult rodent stroke models. The simplicity of this model has clear applications for use in transgenic and gene targeted mice. Supported in part by NSF IBN#94-08860 to T.L. Wood.

ASSESSMENT OF NEUROLOGICAL DEFICITS IN MODELS OF FOCAL ISCHEMIA IN THE RAT. M.A. Vinegra, T.L. Miller, J.W. Heyburn, K. Ghosh and M.M. Zaleska* CNS Disorders, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

Evaluation of efficacy of therapeutic agents in animal models of ischemia is usually based on their ability to decrease the volume of infarcted brain tissue. However, a relationship between infarct size and reliable functional outcome measurements is rarely analyzed. In the current studies, these relationships were tested in two focal ischemia models. Fisher-344 rats were subjected to permanent middle cerebral artery occlusion (MCAO) by cauterization and behavioral observations were made at 24, 48, 72, 96, or 168 hours post occlusion to assess the degree of neurological impairment. SHR rats were subjected to transient MCAO by intraluminal suture for 5-180 minutes and evaluated following a 24 hour reperfusion period. Ischemic brain damage was determined histologically using image analysis. A scoring system was used to quantify the degree of neurological impairment. The series of neurological tests (balance beam, prehensile traction, vertical screen, forelimb flexion and hindlimb deficit) revealed a profile of deficits including contralateral forepaw hemipareisis, disruption of hindlimb sensory motor control and decreased performance in complex motor behaviors. In the permanent MCAO model, a correlation between cumulative deficit score and infarct volume was seen at 48 hrs. post occlusion. In transient MCAO, the outcome for all behavioral tests except prehensile traction was proportional to infarct size. Functional behavioral assessment represents a valid experimental model to study efficacy of agents targeted for therapy of acute ischemic stroke.

ASSESSMENT OF BRAIN DAMAGE FOLLOWING VARIABLE DURATION OF ISCHEMIA ON RATS. T.L. Miller, J.W. Heyburn, M. Vinegra, C. Gonzales, J.A. Moyer*, M.M. Zaleska. CNS Disorders, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

While animal models of cerebral ischemia have been used to predict efficacy of neuroprotective agents for the treatment of stroke, their relevance to the clinical situation has been questioned. This criticism is in part due the lack of models that assess ischemia of varying duration such as that seen in human stroke victims. In the present study, male SHR rats weighing 270-290 grams were subjected to middle cerebral artery occlusion (MCAO) by insertion of an intraluminal suture. Following periods of occlusion ranging from 5 to 180 minutes, the MCA was reperfused. Occasional animals were subjected to permanent MCAO. Brains were harvested 24 hours after reperfusion, frozen, sectioned and stained with cresyl violet for histological assessment. Four parameters of brain damage were determined: (i) an absolute infarct volume was calculated by image analysis throughout the infarcted region, (ii) a hemispheric infarct size was expressed as percent of hemisphere relative to the normal contralateral hemisphere, (iii) an indirect edema (hemispheric swelling) measurement was calculated as percent increase in volume of the ipsilateral versus contralateral hemisphere, and (iv) an infarct volume corrected for swelling was calculated. For each of these parameters, an "injury dose-response curve" was generated using a logistic function analysis. This method allows for the calculation of ET50 (duration of occlusion to produce half-maximal response) and Vmax (maximal response) values. In control animals, the calculated ET50 range was 48-68 min and the Vmax of the infarct was 460-530 mm^3. The latter was equivalent to 75% of the total hemisphere volume. The maximal edema was estimated at 25%. These values can be used for comparison to values generated in drug-treated animals to accurately determine drug effects on damage onset and volume of maximal damage. Effects of neuroprotective agents on the parameters associated with the injury curve will be discussed.

TEMPORAL CHANGES IN BLOOD BRAIN BARRIER PERMEABILITY TO DYE TRACERS DURING THE REPERFUSION PERIOD AFTER TEMPORARY OCCLUSION OF THE MIDDLE CEREBRAL ARTERY IN RATS. T. Hanada*, Y. Arakawa, M. Ueno and Y. Nishizawa. Eisai Tsukuba Res. Labs., Tsukuba, Ibaraki, 300-26 Japan

It is well known that blood brain barrier (BBB) dysfunction occurs after ischemic stroke. Functional and pathological changes in the BBB have been suggested by assessing the changes in permeability to tracers of different molecular size. The extravasation of low molecular weight substances seems to occur via a different pathway from that of large molecules. The aim of this study was to clarify the integrity of the BBB to different molecular weight tracers during reperfusion after brain ischemia. We used a 2 h temporary middle cerebral artery occlusion (MCAo) rat model. The integrity of the BBB was evaluated with Evan's blue (EB) and sodium fluorescein (NaFl), injected simultaneously as high- and low-molecular weight tracers. Significant increases in the extravasation of EB and NaFl were observed at 12 h and 24 h, respectively. Both extravasated dyes peaked at 48 h after MCAo and had declined by day 7. A large increase in permeability to NaFl was observed during 48 hours after MCAo, while the change in permeability to EB was small. The ratio was very high in the ischemic brain compared to the concentration ratio of dyes (NaFl/EB) in plasma. The extravasated dye ratio had increased over 72 h and declined by day 7 after MCAo. These results suggest that diverse BBB dysfunction occurs during reperfusion after ischemia. The difference in the permeability change to EB and NaFl may be due to multiple pathways of extravasation, which are modulated by ischemia.

THE EFFECT OF AGING ON FOCAL BRAIN ISCHEMIA IN RATS. S. Shapira*, M. Sapir, E. Grauer and T. Kadar. Dept Pharmacology Israel Inst. Biol. Res., Ness-Ziona, Israel 74100.

Stroke in humans is associated with old age, which is also an important prognostic factor for stroke patients. However, most of the studies dealing with stroke use young animals. The aim of the present study was to investigate the effects of aging on the outcome of brain ischemia. Focal brain ischemia was induced in halothane-anesthetized Wistar rats by injecting a of 50 µm microspheres into the left internal carotid artery. Three age-groups were investigated: Three months (young) rats, 14-16 months (middle age) rats and 23 months (old) rats. The animals were observed for 30 days during which follow-up studies (body weights and a series of neurological assessments) were carried out. Thereafter, behavioral functions were tested (Open Field or Morris water maze), followed by histological evaluation. Although the initial post operative evaluation was much worse in the old compared to the young rats, mortality (24-48 hr post op) rate was much lower in the old (1 of 7, 14%) compared to the young group (6 of 16, 38%). The overall magnitude of the neurological deficits was similar in all three age-groups. Performance at the Morris water maze was equally affected in both, young and middle age rats. Histological damage was found in surviving rats of all the experimental groups. The intensity of the injury was variable, but in all affected rats it was unilateral, multifocal and involved gliosis. Spatial dispersion of focal injury was in the territory of the mid cerebral artery, and included cortex, striatum, hippocampus (mainly CA3), thalamus and hypothalamus. Histological evaluation indicated a damage which was much more severe in the young age group, including liquification degeneration and perivascular hemorrhage which were not found in old rats, whose damage was milder and more confined. It is concluded that since the behavioral deficits in both age groups were similar in spite of a much milder histological damage in old rats, this may indicate an age-related adaptive mechanism which was apparent in the young age group.

PHOTOTHROMBOSIS-INDUCED REMOTE CHANGES OF METABOLISM CAUSED BY CORTICAL SPREADING DEPRESSIONS ARE ABOLISHED BY MK-801 M. Kraemer,* I. Buchkremer-Ratzmann, G. Hagemann, K. Schiene, M. Schroeter, G. Stoll, and O.W. Witte. Neurologische Klinik der Heinrich-Heine-Universität, Moorenstr. 5, 40225 Düsseldorf, Germany.

In the photothrombosis cortical infarct model increased expression of immediate early genes, an increased neuronal excitability and an alteration of brain metabolism have been described in remote brain areas. Here we investigated the mechanisms causing remote changes in deoxyglucose metabolism.

Glucose metabolism in adult rat brain was studied after induction of photothrombosis using the Rose Bengal technique. Changes of metabolism were characterized by an immediate and persisting downregulation of metabolism within the illuminated zone. This was surrounded by a border zone with a strong increase of metabolism lasting for up to 14 days. In the ipsilateral hemisphere remote from the lesion within the first 4 hours after lesion induction the glucose metabolism was increased. This turned into a marked decrease after 24 hours and became normal again 5 days after induction of the lesion. Electrocorticography demonstrated that within the first two hours after lesion induction 5 to 7 waves of cortical spreading depression travelled across the ipsilateral hemisphere. To test whether the remote hypometabolism one day after photothrombosis was due to these spreading depressions, rats were infused 0.5 mg/kg body weight of the NMDA antagonist MK-801 30 minutes before lesion induction. This procedure completely blocked the remote hypometabolism, while it left the lesion itself and the surrounding hypermetabolic rim unchanged.

The data show that cortical spreading depression is an important contribution to remote hypometabolism one day after lesion induction in the photothrombosis model.

CHANGES IN RECEPTIVE FIELD SIZE OF A SINGLE VIBRISSA IN THE VICINITY OF A CORTICAL LESION. K. Schiene*, C. Bruehl, O.W. Witte. Neurologische Klinik, Heinrich-Heine-Universität, 40225 Düsseldorf, Germany

In order to investigate wether a focal cortical lesion can induce plastic changes in the surrounding brain tissue, we examined the receptive field size of a single vibrissa in the vicinity of a cortical lesion.

Focal lesions with a diameter of 2 - 3 mm were induced photochemically in the hindlimb area (HL) of the rat which adjoins the primary somatosensory area Par1. One week after lesioning, the receptive field of the B3 vibrissa, which lies around 2 mm lateral to the border of the lesion, was studied using the 14C-deoxyglucose (DG) autoradiography.

Mechanical stimulation of the B3 vibrissa produced a 2 DG-labeled column in SI cortex. The labelling was visible in all cortical layers. In control animals a maximum of DG uptake was visible in layer IV of Par1. The DG uptake within the activated barrel in layer IV was 45.9 ± 7.7 % higher than in the area lateral to this. In lesioned animals the DG uptake in the cortical column was sligtly smaller than in non - lesioned animals. To compare the receptive field properties of the vibrissa representation, the diameter of the metabolically activated areas was analyzed. The diameter of a barrel was defined as the half - height width of the glucose uptake profile across the barrel in layer IV. The averaged diameter of the labeled area in the barrel in controls was 461.8 ± 77.6 µm (n = 6). In animals with a cortical lesion, the labelled area of the stimulated barrel was markedly wider. The profile across the barrel in layer IV shows an increase in the diameter to 785.5 ± 103.6 µm (n = 6; $p < 0.001$, student t-test) in animals with a lesion.

The experiments show that a cortical lesion induces plastic changes in receptive field size in remote and uninjured brain areas.

LONG-TERM CHANGES IN INTRINSIC OPTICAL SIGNALS AFTER LOCAL ISCHEMIA IN RAT BARREL CORTEX. L. Wei*, C. Rovainen, T.A. Woolsey. Departments of Neurology & Neurological Surgery and of Cell Biology & Physiology, Washington University School of Medicine, St. Louis, MO 63110

Our objective is to test functional changes in somatosensory cortex in the same animals acutely and 30 days after ligations of multiple branches of the middle cerebral artery (MCA). Whisker barrel cortex was targeted in Wistar rats anesthetized with ketamine and xylazine by intrinsic optical signals (IOS) through cranial windows. Patterns of arterioles and collaterals were mapped by videomicroscopic angiography of hemoglobin and fluorescein. Decreased blood flow in acute ischemia was measured by arteriovenous transit times (AVTTs) that were significantly prolonged after ligations. Recovery of blood flow after 30 days was apparent from enlarged arteriolar collaterals, flow through them and shortened AVTTs. IOS to whisker stimulation was lost during acute ischemia but returned by 30 days. Changes in the patterns of IOS to whisker stimulation in the same rats were related to the histological body map and often indicated functional reorganization. These results are relevant for long-term neural and vascular changes that could be key factors in recovery from small infarcts.

AN AVIAN MODEL OF ISCHEMIA. S. Watanabe[1], C.V. Borlongan[2], K. M. Radcliffe[3], and T. Shimizu[3]*. Dept. of Psychology, Keio University, Tokyo, Japan[1], Depts. of Surgery[2] & Psychology[3], Univ. of South Florida, FL 33620.

Pigeons (*Columba livia*) were used to examine anatomical and behavioral effects of Common Carotid Artery occlusion (CCAo) in order to establish an avian model of ischemia. Under deep anesthesia, a small incision was made along the neck level. Using sterile glass probes, fascia and muscles were teased away to expose the CCA. Once the CCA was separated from the vagus nerve, a microsurgical clip was used to clamp the CCA for different durations (30, 45 and 60 minutes). Animals received unilateral or bilateral CCAo for anatomical and behavioral examinations, respectively. One week recovery was allowed prior to histological and behavioral examinations. After unilateral CCAo (45 and 60, but not 30 minutes), atrophy was observed in the ipsilateral telencephalon, whereas no obvious changes were seen in the diencephalon and the brainstem, as well as in the contralateral telencephalon. Within the ipsilateral telencephalon, the areas most significantly affected were the area parahippocampalis, area corticoidea dorsolateralis, hyperstriatum ventrale, and intermediate and caudal neostriatum. Other telencephalic structures, such as the hippocampus and paleostriatum (the avian equivalent of the basal ganglia), also appear to be affected to some degree. Two behavioral tasks (differential reinforcement of low rate schedule and delayed alternation) were used to examine retention of cognitive performance after bilateral CCAo. Although preliminary data demonstrated no severe deficits in both tasks, future studies should investigate CCAo effects on acquisition of these tasks. (This study was supported by Japan Society for the Promotion of Science 95-793, and National Aeronautics and Space Administration NAG 2-1000.)

Hypoxia Reduces Na^+ Current in Hippocampal Neurons Via a Kinase Mediated Pathway. J.P. O'Reilly* and G.G. Haddad. Depts. of Biology, Pediatrics, and Cellular and Molecular Physiology. Yale University and School of Medicine, New Haven, CT 06520

Previous reports from our laboratory have demonstrated that metabolic inhibition or hypoxia inhibit whole cell Na^+ current (I_{Na}) in acutely dissociated hippocampal and cortical neurons. The cellular mechanisms responsible for this hypoxic inhibition are unknown. One mechanism known to reduce I_{Na} is kinase activation. Therefore, we hypothesized that kinase activation may be responsible for I_{Na} modulation during hypoxia. Patch clamp techniques were used to record I_{Na} in acutely isolated CA1 hippocampal neurons from rats aged P17-P25. Control experiments (n=12) showed a gradual rundown of I_{Na} to 85.0 ± 4.0% (mean ± SEM) of baseline during the recording period, and a slow negative shift in the steady state inactivation curve of ≈ -1mV/min. When the neurons were exposed to hypoxia for three minutes, I_{Na} was reduced to 30.5 ± 4.9% of baseline (n=12), and the steady state inactivation curve was shifted in the negative direction by -10.0 ± 1.0 mV. This hypoxic inhibition of I_{Na} was mimicked by activation of protein kinase C (PKC) with 50μM OAG (44.9 ± 2.0%, -7.4 ± 1.1 mV; n=5), 100μM DOG (45.0 ± 2.7%, -7.9 ± 0.8 mV; n=5), or 5nM PMA (40.0 ± 3.7%; -7.2 ± 0.4 mV; n=5). The response to 50μM OAG was attenuated by the kinase inhibitor H-7 (20 μM; 74.3 ± 7.0%; -4.9 ± 0.7mV; n=5). Exposure to 8-Br-cAMP (0.5-2.5 mM; n=8) to activate protein kinase A had little effect on I_{Na} (83.2 ± 4.4%) or steady state inactivation (-5.1 ± 0.8 mV). When the neurons were exposed to hypoxia in the presence of H-7 (20 - 200 μM; n=15), the hypoxic inhibition of I_{Na} was greatly reduced (71.3 ± 6.9% vs 30.5 ± 4.9%), as was the shift in steady state inactivation (-5.9 ± 0.6 mV vs -10.0 ± 1.0 mV). We conclude that kinase activation plays a major role in the Na^+ current inhibition during hypoxia, and that PKC may be involved in this response. Supported by HD32573.

PROLONGED HYPOXIA INCREASES Na^+ CHANNEL DENSITY IN CULTURED RAT NEOCORTICAL NEURONS. **Y. Xia[1]*, J. O'Reilly[2] and G.G. Haddad[1,3], Depts. of Pediatrics[1], Biology[2] & Cell. & Mol. Physiol[3], Yale Univ. Sch. Med., New Haven, CT 06520**

We have previously observed that chronic hypoxia in-vivo increases Na^+ channel mRNA and protein in immature rat brain. In addition, exposed neocortical neurons have increased excitability at rest and are more susceptible for anoxia-induced depolarization than naive, non-exposed neurons. Because in-vivo hypoxia causes complex systemic effects and may interfere with inherent neuronal properties and their responses, we developed a culture system in which we can subject cultured neocortical neurons to any desired O_2 concentration. Neocortical neurons from rat embryos (E16-17) were cultured ($1X10^6$ cells/35mm dish) in a neuron-defined medium. Starting from day 2 (or later), neurons were exposed to hypoxia at various O_2 levels for different durations. Na^+ channel density was assayed by saxitoxin (STX, a specific Na^+ channel ligand) binding and Na^+ current was recorded with voltage clamp techniques in the presence of TEA and Cd^{++}. In our culture system, Na^+ channel density was first low and changed little in the first 3-4 days but increased rapidly after day 5. At culture day 8, STX binding density had increased by 7-fold and peak Na^+ current had also increased by 6-fold as compared to those at culture day 2. After exposure to hypoxia, all cultures (n=6) showed an increase in STX binding density of 30% to 190% depending on the hypoxic conditions (severity, duration, starting culture day). The increase appeared after 3-5 days of exposure and peaked at 5-8 days under 3-6% of O_2. We conclude that prolonged hypoxia increases Na^+ channel density in cultured neocortical neurons and this increase depends on the duration and severity of the stimulus. (Supported by UCP grant R-606-94 and NIH grant P01 HD32573, HL 39924 and NS 32578).

841.3

EFFECT OF AMILORIDE AND ITS DERIVATIVES ON THE ELECTRICAL PROPERTIES OF HIPPOCAMPAL CA1 NEURONS AT REST AND DURING ANOXIA. M.-L. Fung* and G.G. Haddad. Department of Pediatrics (Section of Respiratory Medicine), Yale University School of Medicine, New Haven, CT 06520.

We have previously shown that amiloride, which blocks Na channels and Na dependent exchangers, or the removal of extracellular sodium prevents neuronal injury caused by anoxia in hippocampal CA1 and neocortical neurons. To investigate the mechanism by which amiloride prevents neuronal injury, we hypothesized that amiloride improves the maintenance of membrane potential (Vm) in CA1 neurons during anoxia. In hippocampal brain slices from SD rats (>21 days), we recorded intracellularly from CA1 neurons using sharp electrodes (50-100 MΩ, 3M KCl) at 35oC. We monitored Vm and measured input resistance (Rm) with periodic injections of negative current (-0.5 nA). We found that amiloride (1mM) decreased Vm (-68±1.6 to -57±3.0 mV, N=7) and increased Rm (31.2±4.2 to 51.6±8.9 MΩ) during baseline. In anoxia, amiloride decreased the rate of depolarization (ΔVm/dt, 5.7±1.8 to 4.3±1.0 mV/min, N=4) and increased the rate of decline of Rm (ΔRm/dt, -3.1±1.1 to -5.4±2.2 MΩ/min). Similar to amiloride, benzamil and 5-(N-ethyl-N-isopropyl)-2',4'-amiloride (EIPA), two amiloride derivatives, also had a depolarizing effect on neurons. In anoxia, benzamil and EIPA slightly decreased ΔVm/dt and had a similar increase of ΔRm/dt to that of amiloride. We conclude that: (1) the maintenance of Vm appears to be improved by blocking sodium entry into the CA1 neurons and (2) sodium channel and sodium dependent exchangers probably mediate the entry of extracellular sodium into neurons during acute anoxia. The study is supported by NIH grants HL-07778, P01 HD-32573.

OPPPOSITE INTRINSIC OPTICAL CHANGES ASSOCIATED WITH POTASSIUM INDUCED AND HYPOXIA INDUCED SPREADING DEPRESSION. D.A. Turner*, P.G. Aitken and G.G. Somjen, Neurosurgery, Neurobiology, Cell Biology, Duke Univ. Med. Ctr., VAMC, Durham, NC 27710.

Physiological changes in CNS tissue are accompanied by alterations in the tissue's intrinsic optical properties, with changes in cell volume as a likely mechanism underlying these optical changes. Classical spreading depression (SD) and the SD-like phenomenon provoked by hypoxia (hypoxic SD) are both known to be accompanied by increases in neuron volume, and should therefore be associated with similar optical changes. Hippocampal slices (500 μm) were maintained in an interface chamber at 36°. Translucence images were obtained every 2.5-5 sec (0.1 sec) with a cooled CCD camera. Digital image subtractions were performed between control and experimental images (ΔT/T). Evoked field potentials and extracellular DC voltage (V_o) were recorded in CA1 st. radiatum. SD was provoked either by a microinjection of 1.2M KCl from a glass micropipette into CA1 st. radiatum or by hypoxia caused by temporarily replacing the O_2 above the slices with N_2. SD was diagnosed by decreased V_o (> 8 mV) and loss of the evoked potential. K^+-induced SD was visible as a rapidly spreading patch of decreased translucence starting at the injection electrode but remaining largely limited to the st. radiatum in CA1 (ΔT/T = -6.2±3.0%, n=9 slices). Control solutions (0.15M KCl, 1.2M NaCl) resulted in only a small local perturbation (n=5 slices). Hypoxic SD appeared as a punctate pattern of increased translucence (+29.5 ± 3.55%) in st. radiatum of CA1 and then spread to encompass most or all of CA1. In both treatments the optical changes around the recording electrode occurred concurrently with the change in V_o. These results indicate that there is not a simple relationship between neuron swelling and changes in tissue translucence, and suggest the existence of different forms of optical signals depending on induction mechanisms. Supported by NIA (DAT), VAMC (DAT) and NINDS (PGA and GGS).

ACTIVATION OF ATP-DEPENDENT POTASSIUM (K_{ATP}) CHANNELS PROVIDES PROTECTION IN RAT TRANSIENT FOREBRAIN ISCHEMIA (TFI). M.A. Brody, V.L. Baughman, Q.Wang and D.A. Pelligrino*. Dept. of Anesthesiology, Univ. of Illinois-Chicago, Chicago, IL 60612.

Cellular hyperpolarization, elicited by K_{ATP} channel openers, may provide neuroprotection in cerebral ischemia by restricting pre- and postsynaptic Ca^{2+} uptake, thus limiting neurotransmitter (NT) release and the neurotoxic actions associated with NT receptor activation. In severe TFI, selective excitatory amino acid (EAA) receptor (AMPA) antagonists and K_{ATP} openers provide some neuroprotection (*JCBF &M 12:2, 1992; PNAS 90:9431, 1993*). In less severe TFI models, non-EAA NT's appear to contribute to the neuropathology (*Anesthesiol 76:755, 1992*), but the effects of K-channel openers are unknown. In this study, we examined whether the K_{ATP} channel opener, levcromakalim (CR), could provide neuroprotection in moderate TFI. That TFI model involves right common carotid artery occlusion coupled with hemorrhagic hypotension for 30 min. The amount of blood withdrawal was adjusted so as to produce a fixed reduction of the intra-ischemic right-side cortical blood flow (as determined using laser-Doppler flowmetry) to 15% of normal. Male S-D rats were studied under isoflurane/N_2O anesthesia. Five μl of CR (10 nmol, n=10) or vehicle (controls, n=8) was administered into the right lateral cerebral ventricle at 30 min prior to ischemia and then once per day over the next 3 days. The brains were then fixed and prepared for histopathologic examination. Neurologic function was assessed daily (0=normal; 18=neurologic death) and the daily scores added. The CR-treated rats showed significantly better neurologic outcome scores when compared to controls (18±5 vs 43±5). Histopathologic evaluations revealed lesser damage in hippocampus and striatum of the CR-treated rats. These results imply that K_{ATP} channel-elicited hyperpolarization can provide neuroprotection in moderate TFI. The most likely mechanism relates to preventing excessive elevations in intracellular Ca^{2+}, which in turn may involve limiting NT release, probably norepinephrine (*Anesthesiol 76:755, 1992*), because EAA receptor (NMDA, AMPA) antagonists are not protective in this model.

K CHANNELS MODULATE RESPONSES OF RAT OPTIC NERVES TO METABOLIC INHIBITION. P.K. Stys* & D.A.Hubatsch. Loeb Medical Research Institute, Ottawa Civic Hospital, University of Ottawa, Canada.

The central role of Na channels in the pathogenesis of anoxic injury in CNS myelinated axons has been well established. In contrast, the influence of K channels during glycolytic or mitochondrial inhibition in CNS axons is poorly understood. Rat optic nerves were studied *in vitro* using suction electrode recordings of propagated compound action potentials (CAPs). Induction of anoxia with N_2 caused a rapid fall in CAP area to 50% of control after 4.1±1.2 min ("$t^1/_2$"). CAP area recovered to 24±9% of control after 60 min of anoxia/60 min reoxygenation. 4-aminopyridine (100-300μM) significantly reduced $t^1/_2$ to 0.75 min, but did not alter post-anoxic CAP area recovery. Neither TEA (20 mM), nor the KATP blockers tolbutamide (2mM), glibenclamide (300μM), glipizide (100μM) altered $t^1/_2$; only glibenclamide reduced postanoxic recovery to 4±2% vs. 24% ($p<0.0001$), likely a non-specific effect of such a relatively high concentration. The KATP activator diazoxide (500μM) also did not change post-anoxic recovery (30±13%, p=0.27). In contrast Cs (5 mM), a blocker of inward rectifier and other K channels, significantly improved post-anoxic recovery to 59±23%, $p<0.0001$, even though $t^1/_2$ was markedly reduced to 0.9 min.

Blocking glycolysis with iodoacetate (IAA, 1mM) caused an initial 40% increase in CAP area, followed by a rapid irreversible decline to zero after 30 min exposure. Pyruvate (10mM) completely prevented IAA-induced injury. The initial CAP increase was reduced in Ca-free (+EGTA) bath; TEA (20 mM) abolished the increase in 3 of 4 nerves, whereas KATP blockers had no effect.

Conclusions: 1) blocking various K conductances may alter the acute rate of CAP loss, but does not alter the extent of ultimate anoxic injury. 2) Cs was highly protective, probably by reducing Na influx through the inward rectifier, thus reducing Na-Ca exchanger-mediated Ca overload. In addition to Na channels, this may represent a second important route of pathological Na entry. 3) glycolytic block (but not anoxia) induced a transient Ca-dependent, TEA-sensitive rise in CAP magnitude that may reflect activation of KCa channels by exogenous or internal Ca, released under energy-limited conditions. *Supported by MRC of Canada Grant #MT-11595.*

Ca^{2+} CHANNEL SUBTYPES INVOLVED IN NEURONAL INJURY IN O_2/GLUCOSE-DEPRIVED RAT HIPPOCAMPAL SLICES D.L. Small*, R. Monette, A.M. Buchan† & P. Morley †Foothills Hospital, Calgary, Alberta & National Research Council, Ottawa, Canada

The excessive accumulation of Ca^{2+} in neurons and the release of glutamate are thought to be involved in neuropathological processes including hypoxia-ischemia. Although there is general agreement that the presynaptic Ca^{2+} influx necessary for evoked glutamate release occurs via voltage-sensitive calcium channels (VSCCs), there is controversy over the fractional contribution of the specific channel types involved. We have investigated the protective effects of various VSCC blockers on O_2/glucose-deprived rat brain slices.

Male Wistar rat (~200 g) hippocampal slices held 90 min in ACSF with 10 mM glucose and 2 mM $MgSO_4$, bubbled with 95% O_2/5% CO_2 at 36.5°C were deprived of O_2 (95% N_2/5% CO_2) and glucose (4 mM) for 10 min and then returned to ACSF for 4-6 h. Viability of treated (30 min pre and 10 min during insult) and non-treated slices was assayed electrophysiologically by measuring the evoked population spike (PS) amplitude in the stratum pyramidale of the CA1 region and by imaging slices loaded with fluorochrome dyes specific for dead (ethidium homodimer) and live (calcein) cells using confocal microscopy.

PS amplitudes were significantly ($p<0.01$) depressed from 4.4±0.2 mV to 0.2±0.1 mV after the deprivation insult. Responses from O_2/glucose-deprived slices pretreated with the Q-type VSCC blockers 100 nM ω-conotoxin MVIIC (4.2 ±0.5 mV) and 200 nM ω-aga-IVA (3.3±0.5 mV) were not significantly different from control non-deprived slice responses. In contrast, O_2/glucose-deprived slices treated with either L-type (0.1 or 1 μM nimodipine), N-type (0.1 or 3 μM ω-conotoxin GIVA) or P-type (20 nM ω-aga-IVA) VSCC blockers showed no protection. The viability of CA1 neurons as revealed by the fluorescence live/dead confocal viability assay was consistent with the electrophysiological measurements. In conclusion, the predominant VSCCs involved in neuronal damage in O_2/glucose-deprived rat hippocampal slices are Q-type and blockade of these channels is fully neuroprotective.

CALCIUM INFLUX, BUT NOT RELEASE FROM INTERNAL STORES, INDUCES MAP2 DEGRADATION DURING ISCHEMIA IN THE RAT HIPPOCAMPUS: COMPARTMENTALIZATION OF CALPAIN ACTIVATION. Y.-L. Zhang, J.K. Harting* and P. Lipton. Department of Physiology, Anatomy and Center for Neuroscience, Univ. Wisconsin, Madison, WI, 53706

This study demonstrates the differential roles of various sources of calcium in the degradation of microtubule-associated proteins (MAP2), a sensitive marker of ischemic damage in the rat hippocampal slice.

Immunoblot experiments showed that 10 min of in vitro ischemia caused about 50% loss of MAP2 staining. Complete degradation occurred during 2 hrs reoxygenation. This damage to MAP2 was prevented by preincubation of slices with the selective calpain inhibitor, MDL 28170 (10μM). The inhibitor was required during the reoxygenation period to exhibit full protection.

10μM MK-801 provided as much protection as MDL if present during ischemia and reperfusion. *This is true despite the fact that most of the rise in $[Ca^{2+}]_i$ during ischemia is from intracellular sources.* Selective access of transmembrane Ca^{2+} to calpain was confirmed by effects of ischemia in 0-Ca^{2+} buffer. Despite a large rise in $[Ca^{2+}]_i$, there was no breakdown of MAP2 even during 20 min ischemia. On reperfusion with normal oxygenated buffer there was significant breakdown, which was blocked by MDL, MK-801 and 100μM D-APV. The breakdown did not occur if the reperfusion was carried out in 0-Ca^{2+} buffer.

Conclusion: Ca^{2+} influx via NMDA receptors, during and after ischemia, activates calpain-mediated proteolysis of MAP2. Ca^{2+} released from intracellular stores does not cause MAP2 breakdown. This strongly indicates selective access of transmembrane Ca^{2+} to calpain. Calpain-mediated MAP2 degradation during re-oxygenation may be due to continued excess entry of Ca^{2+} via NMDA receptors, and/or due to ischemia-induced sensitization of MAP2 or calpain.

THE MECHANISM OF Ca^{2+} INFLUX AND THE PROTECTION OF CGRP IN CULTURED HIPPOCAMPAL NEURONS DURING HYPOXIA. Fu-Zhuang Wang*, Hang Yao, Qin Wan and Zhen-Wei Liu. Dept. of Neurobiology Institute of Basic Medical Sciences, Beijing 100850, China

We have previously shown that the elevation of $[Ca^{2+}]i$ induced by influx of Ca^{2+} play an important role in phasic changes of membrane function in hippocampal neurons and its synaptic transmission during hypoxia. Calcitonin gene-related peptide(CGRP) may have a neuronal protective action against hypoxia. To further examine the possible mechanism of Ca^{2+} influx and the influence of CGRP on hippocampal neurons during hypoxia, we monitored $[Ca^{2+}]i$ in cultured rat CA1 hippocampal neurons using calcium sensitive probe fluo-3 and a confocal microscope. A rapid increase of $[Ca^{2+}]i$ ($\Delta f/f=268\pm68\%$) was observed in neurons exposed to hypoxia. After removing extracellular calcium and adding Co^{2+}, the rise of $[Ca^{2+}]i$ in response to hyoxia was decreased($\Delta f/f=28\pm13\%$). Replacing extracellular sodium with choline chloride or blocking voltage-dependent sodium channel with TTX can reduce the elevation of $[Ca^{2+}]i$ induced by hypoxia ($\Delta f/f=74\pm26\%$ and $99\pm8\%$, respectively). Application of N-type voltage-dependent calcium channel blocker ω-conotoxin attenuated the rise of $[Ca^{2+}]i$ caused by hypoxia while L-type calcium channel blocker had no effect. CGRP and Na^+/Ca^{2+} exchange blocker Benzamil can significantly prevent the increase of $[Ca^{2+}]i$ induced by hypoxia. These results indicate that hypoxia lead to an influx of calcium in CA1 neurons. TTX-sensitive sodium channel and N-type calcium channel were involved in the development of hypoxia-induced Ca^{2+} influx. Reducing Ca^{2+} influx may be one of the protective mechanisms of CGRP against hypoxia.

ROLES OF GLUTAMATE AND GABA IN DIFFERENTIAL LAMINAR VULNERABILITY OF PYRAMIDAL CELLS TO $[Ca^{2+}]_i$ RISES INDUCED BY OXYGEN-GLUCOSE DEPRIVATION IN RAT NEOCORTICAL SLICES. A. Fukuda*, K. Muramatsu, A. Okabe, Y. Shimano, H. Hida, I. Fujimoto and H. Nishino. Dept. Physiol., Nagoya City Univ. Med. Sch., Nagoya 467, Japan.

The neocortex is one of the most vulnerable parts of the brain to ischemia. However, regional differences in vulnerability, such as known in hippocampus, are not thoroughly studied. IPSPs are more fragile than EPSPs in neocortical neurons during hypoxia, while glutamate and GABA both increase in extracellular space. Thus, laminar differences in cell damage could exist due to a differential susceptibility to these transmitters during ischemia. We have recorded $[Ca^{2+}]_i$ transient as an indicant of the neuronal deterioration in somatosensory cortex. Immature (P7-14) neocortical slices were labeled with fura-2, and $[Ca^{2+}]_i$ was monitored in the identified pyramidal cells as a ratio of fluorescence intensity ($R_{F340/F380}$) during oxygen-glucose deprivation (O-G [-]). The $R_{F340/F380}$ increased during O-G (-) in all neocortical layers, among them, the increase in layer II/III was significantly greater than in any other layer. This laminar difference was abolished by AP5 or kynurenate but not by CNQX, indicating that layer II/III cells are most vulnerable to O-G (-)-induced $[Ca^{2+}]_i$ increases via NMDA receptor mediation. In addition, not only antagonists above but also bicuculline suppressed the $[Ca^{2+}]_i$ increases during O-G (-) in any neocortical layer. Since GABA caused AP5-sensitive $[Ca^{2+}]_i$ increases when $[Cl^-]_i$ was raised by furosemide, GABA might act as an aggressor during O-G (-) if E_{cl} shift occurs as reported previously.

INHIBITION OF CALMODULIN ACTIVITY BY DY-9760e, A NOVEL CALMODULIN ANTAGONIST, ATTENUATES NEURONAL DAMAGE. Y. Morishima, M. Sugimura, T. Sato, R. Motohashi, S. Kawajiri*, Y. Shirasaki and K. Fukunaga#. New Product Res. Lab. III, Daiichi Pharmaceutical Co. Ltd., Tokyo 134, Japan; # Kumamoto Univ. Sch. Med., Kumamoto 860, Japan.

Intracellular Ca^{2+} overload into neurons by ischemic insults may overactivate Ca^{2+}/calmodulin (CaM) pathways and lead to irreversible neuronal damage. We report here the pharmacological characterization and neuroprotective effect of DY-9760e, a novel CaM antagonist. DY-9760e inhibited CaM-dependent enzymes, such as phosphodiesterase, calcineurin, nitric oxide synthase (NOS), and CaM kinase II and IV, and degradation of fodrin. However, DY-9760e did not affect CaM-independent enzymes (protein kinase A and C and calpains) at a concentration range which exert anti-CaM effect. In N1E-115 neuroblastoma cells, DY-9760e blocked A23187-induced cell death, concomitant with inhibition of nitrite formation. Moreover, we investigated the efficacy of DY-9760e against transient focal cerebral ischemia in rats subjected to middle cerebral artery (MCA) occlusion (1 hr) and reperfusion. An intravenous infusion of DY-9760e (1 mg/kg/hr) was initiated just before MCA reperfusion and continued for 6 hrs, and infarct size at 24 hrs was assessed by TTC staining. DY-9760e significantly reduced infarction volume by 40-50% ($p<0.05$) without affecting any physiological parameters. These results suggest that CaM-dependent pathways, such as NOS and calcineurin, may play a pivotal role in pathogenesis of neuronal damage and that inhibition of CaM by DY-9760e may be a promising approach for the treatment of stroke.

DANTROLENE SODIUM INHIBITS PERTURBATIONS IN IONIC HOMEOSTASIS AS A RESULT OF OXYGEN AND GLUCOSE DEPRIVATION IN THE RAT HIPPOCAMPUS *IN VITRO*. M.D.R. Croning* and N.R. Newberry. Oxford University-SmithKline Beecham Centre for Applied Neuropsychobiology, University Department of Clinical Pharmacology, Radcliffe Infirmary, Oxford, OX2 6HE, England, U.K.

Cerebral anoxia and ischemia cause a characteristic loss of ionic homeostasis - initially (phase 1) extracellular K^+ concentration ($[K^+]_e$) rises gradually with little change in $[Ca^{2+}]_e$, subsequently, $[K^+]_e$ increases rapidly and $[Ca^{2+}]_e$ falls dramatically (phase 2). Dantrolene sodium (dantrolene) is an inhibitor of intracellular Ca^{2+} release and an experimental neuroprotectant. We have investigated its effect upon these changes.

Submerged rat hippocampal slices were superfused with aCSF at 30 °C. $[K^+]_e$ and $[Ca^{2+}]_e$ were measured in the CA1 stratum pyramidale using double-barrelled ion-selective microelectrodes. Slices were perfused with or without dantrolene for 75 min prior to a single period of oxygen+glucose deprivation.

Dantrolene (20 μM) abolished the synaptically-evoked field potential after ca. 25 min of perfusion. In its presence, the maximum increase in $[K^+]_e$ produced by oxygen+glucose deprivation was ca. 50% smaller and phases 1 and 2 of this response were much less distinct. Dantrolene had no clear effect on the peak fall in $[Ca^{2+}]_e$ but in 3 out of 5 slices the rate of this fall was reduced. Dantrolene significantly reduced the negative extracellular d.c. potential associated with phase 2 by about 85%.

In conclusion, these experiments suggest that intracellular Ca^{2+} release may be involved in the loss of K^+ and Ca^{2+} homeostasis seen in the CA1 pyramidal cell layer as a result of oxygen+glucose deprivation.

EFFECTS OF ANOXIA ON PYRAMIDAL NEURONS IN RAT NEOCORTICAL SLICES: A PATCH CLAMP STUDY. S. Miyahara*, H. Ochiai and S. Wakisaka. Department of Neurosurgery, Miyazaki Medical College, Miyazaki, 889-16 JAPAN

The effect of brief anoxia on synaptic physiology was studied in pyramidal neurons of layers II - III from rat neocortical slices by infrared DIC videomicroscopy and whole cell patch-clamp recording. Synaptic responses were evoked with a stimulating electrode in layer IV. After the onset of anoxia, a slow inward current was observed and within 3-4 minutes after the onset of anoxia, the synaptic response of the pyramidal neurons was largely inhibited. The evoked synaptic response consisted of an EPSC followed by IPSC. The IPSC was more sensitive to inhibition by anoxia than was the EPSC. Before the onset of anoxia, spontaneous transient inward currents were observed. The frequency of these currents was markedly increased after anoxia. The transient inward currents persisted in slices incubated in tetrodotoxin(TTX), but were inhibited in slices incubated with N-methyl-D-aspartate (NMDA) antagonist, D-APV and non NMDA antagonist, CNQX. This identified the spontaneous inward currents that were increased during anoxia as glutamatergic miniature EPSCs. The mean amplitude of the miniature EPSCs was not affected during anoxia. The response of pyramidal cells to pressure ejection of glutamate was not inhibited during anoxia. These indicated that the site of anoxia-induced synaptic depression was at the presynaptic terminal.

CHANGES IN BRAIN ACTIVITY FOLLOWING ISCHEMIA MEASURED AFTER THIOPENTAL EEG SUPPRESSION. N. Zarchin, E. Ornstein, E. Guggenheimer-Furman and A. Mayevsky*. Department of Life Sciences, Bar-Ilan University, Ramat-Gan, 52900, Israel.

Thiopental is commonly used during neurosurgical procedures due to its cerebroprotective effect. However, this often results in burst suppression of the EEG, rendering the EEG useless for detecting cerebral ischemia. The aim of this study was to use an animal model to determine the feasibility of using multiparametric assembly (MPA) for monitoring the brain after EEG burst suppression by thiopental. The carotid arteries were isolated in Mongolian gerbils and an MPA was placed on the surface of the brain for measuring NADH fluorometry, laser Doppler flowmetry (CBF), extracellular K^+, Ca^{2+} and H^+ concentrations and DC potential as well as ECoG. In both control and experimental animals (n=7) 1 or 2 carotid artery occlusion was performed after the animal recovered from surgery. In the experimental group, thiopental was injected IP prior to occlusion until burst suppression of >95% was obtained. In the control animals occlusion resulted in a decrease in CBF, an increase in NADH fluorescence and ECoG depression. After 1-2 min. an ischemic depolarization was observed (Mayevsky, A, Brain Res. 524:1-9, 1990). Thiopental caused a significant decrease in CBF (100 vs 77±3%, $p<0.05$) accompanied by ECoG suppression (before carotid occlusion). In the gerbils that received thiopental the time to the large increase in extracellular K^+ concentration was significantly longer than in the control animals (1.8±0.4 vs 4.0±0.7 min, $p<0.05$). Furthermore, the K^+ concentration was significantly less in these gerbils (9.3±1.3 vs 19.7±4mM, $p<0.05$) and the secondary reflectance increase was less pronounced. This indicates that thiopental does indeed have a cerebroprotective effect and that the MPA is capable of measuring changes occurring in the brain after EEG burst suppression.

ANOXIC TERMINAL NEGATIVE DC-SHIFT IN HUMAN NEOCORTICAL SLICES IN VITRO A. Schmidinger, R. Köhling, S. Hülsmann, S. Vanhatalo, A. Lücke, H. Straub, E.-J. Speckmann, I. Tuxhorn, P. Wolf, R. Lahl, H. Pannek, F. Oppel, C. Greiner, D. Moskopp, H.W. Bothe*, H. Wassmann Institut für Physiologie, Universität, 48149 Münster, Germany.

In animal models, a strong negative shift of the DC potential (anoxic terminal negativity, ATN) is the characteristic reaction to hypoxia. The ATN is thought to be primarily due to a breakdown of the membrane potential of neurons. Such massive depolarizations have not been reported for all human neocortical neurons in vitro even during prolonged hypoxic periods. In view of these findings, the aim of the present investigation was to test whether ATN develop also in human neocortical slices made hypoxic.

The experiments were carried out on temporal neocortical slices (500 µm, n=14) from tissue resected during epilepsy surgery (13 patients). DC potentials were recorded with conventional techniques. Simultaneously, evoked potentials were elicited by stimulation of white or grey matter adjacent to the recording electrode. Hypoxias were induced repetitively by exchanging N_2 for O_2 in the gaseous phase of the interface-type chamber. The recovery periods were 30 min.

ATN could be evoked when human brain slice preparations were subjected to periods of hypoxia (10 to 120 min). ATN were usually monophasic and appeared with a latency of 16 ± 4 min (mean ± SEM, n=14). Separating the ATN according to their slopes of rise, steep (> 10 mv/min) and flat (< 10 mV/min) ATN could be distinguished. Steep ATN showed greater amplitudes and slopes of decay. With repetitive hypoxias, the latency of ATN was reduced for the following hypoxic episodes. During ATN, evoked potentials were suppressed. With the 1st through 4th hypoxia, they recovered fully within 30 min after reoxygenation when hypoxia was terminated at the plateau of ATN; with extension of hypoxia, recovery was only partial. From the 5th hypoxia onwards, recovery usually did not take place or was not complete.

CHANGES IN RECURRENT INHIBITION AFTER CEREBRAL ISCHEMIA IN THE RAT HIPPOCAMPUS. E. López, L. Parra, J. Bravo, A. García, L.Zhang* and H. Solís. Dept. of Anatomy. Lab. of Neurophysiology. Fac. of Medicine. National University of México. UNAM.

Following cerebral ischemia we have observed increase in the frequency of hippocampal neuronal discharge and signs of spontaneous paroxysmal EEG activity. Excitotoxic effect has been hypothesized as the cause of this hyperexcitability and a possible disbalance between the excitation-inhibition may contribute to the hyperactivity. The aim of the present study was evaluated the changes in recurrent inhibition in urethane-anesthetized rat hippocampus after 5 and 20 minutes of cerebral ischemia. Cerebral ischemia was induced by bilateral carotid artery occlusion using an atraumatic clasp around each artery. Paired-pulse technique was used to study inhibition. The recurrent inhibition was assessed by calculating the ratio (PS(T)/PS(C): IMI=index of maximal inhibition) of the amplitude of the second (test) population spike [PS(T)] to that of the first (conditioning) population spike [PS(C)]. Changes in recurrent inhibition were evaluated in a control group (n=10), acute animals and after seven days of recovery period. It was observed a significant reduce in the recurrent inhibition (IMI >1.0)in both groups. The results suggest that the changes in the neuronal excitability observed after the ischemic period could be related to a disinhibition mechanism.

TRAUMA VII

TIME-DEPENDENT, CHRONIC ADMINISTRATION OF D-CYCLOSERINE, AN NMDA PARTIAL AGONIST, IMPROVES COGNITIVE RECOVERY FOLLOWING TRAUMATIC BRAIN INJURY. M.D. Temple* R.J. Hamm, B.R. Pike, D.L. Buck, and B.G. Lyeth. Depts. of Psychology and Neurosurgery, VA Commonwealth Univ./Med. College of VA, Richmond, VA 23298-0693.

Several studies indicate that for a prolonged period after traumatic brain injury (TBI) there is suppression of neuronal function and that chronic enhancement of excitatory neurotransmitter systems is an effective strategy to attenuate TBI-induced cognitive impairment. D-cycloserine (DCS), a positive modulator of the NMDA receptor, has previously been shown to improve cognitive performance. Here we report the results of a series of experiments that examined the effect of DCS when administered at different timepoints after injury. Rats were injured at a moderate (2.8 atm) level of lateral fluid percussion injury. All animals were assessed for cognitive performance using the Morris water maze (MWM) days 11-15 following TBI. Subjects (Ss) were injected with either vehicle or 30 mg/kg-DCS days 1-15 post-injury, 30 minutes prior to cognitive assessment (Experiment 1), or 4 h post-MWM evaluation (Experiment 2). The purpose of experiment 2 was to determine if DCS must be pharmacologically active to have its cognitive-enhancing effect. Ss in Experiment 3 received 30 mg/kg-DCS days 11-15, 30 minutes prior to MWM testing. Results reveal that prolonged administration (days 1-15 post-injury) of the 30 mg/kg dose of DCS is effective in enhancing recovery from cognitive impairment when given 30 minutes prior to MWM assessment but not 4 hours after the task as compared to injured-vehicle subjects ($p<.05$; $p>.05$ respectively). In addition, delayed administration of DCS (days 11-15) was also ineffective ($p>.05$). In conclusion, while DCS is an attractive therapeutic option, timepoint of administration is an important variable to consider. (Supported by NS 12587)

THE INTERACTION OF NEUROEXCITATION AND TARGET DEAFFERENTATION IN THE PATHOBIOLOGY OF TRAUMATIC BRAIN INJURY (TBI): AN ASSESSMENT OF DISORDERED RECOVERY IN THE RAT DENTATE GYRUS. DE Gordon*, LL Philips, and JT Povlishock. Depts. of Anatomy and Neurosurgery, Med. Col. of VA.,VA Commonwealth Univ, Richmond, VA 23298

Our research focuses on the interaction between traumatically induced neuroexcitation and deafferentation triggered by axonal injury in an effort to better understand the pathobiology of human TBI. Animals were subjected to moderate TBI, evoking neuroexcitation without pathology, bilateral entorhinal lesioning (BECX), evoking target deafferentation,and the combination of these injuries (CI). Recently, we reported that the combination of these injuries (CI) results in disordered synaptic rearrangement within the dentate gyrus (Phillips et al.,1994).Currently, we extend these studies to assess the anatomical substrates of this disordered brain rearrangement.The dendritic and somatic domains of the dentate gyrus were assessed using a modified Golgi Cox method interfaced with LM and EM qualitative and quantitative analysis to examine granule cell dendritic length (DL), molecular layer height (MH), granule cell layer height (GH), granule cell counts (GC), and number of primary granule cell dendrites (PD) at 15 days post injury.Significant differences were found between animals subjected to CI in relation to TBI and BECX injuries in isolation.In CI, the DL was significantly shorter than control and TBI but not BECX ($P<0.01$).Further, the MH and GH in CI were also significantly smaller than control and TBI ,but not BECX.The PD were significantly fewer with CI than in control and TBI ($P<0.01$).Also, the GC was significantly smaller in CI in comparison to control ($P<0.01$), but not BECX or TBI.These responses cannot be explained as additive results of these injuries alone.Rather,we suggest that the initial neuroexcitatory surge differentially modulates the effects of the deafferentation, which lead to differing dendritic and cellular rearrangements. (NS20193 and NS12587)

CHRONIC POST-INJURY ADMINISTRATION OF A PARTIAL MUSCARINIC M1 AGONIST IMPROVES COGNITIVE OUTCOME AND REDUCES DECREASES IN SEPTAL CHOLINE ACETYLTRANSFERASE (ChAT) IMMUNOREACTIVITY (IR). B.R. Pike*, R.J. Hamm, J.P. Zhu, L.L. Phillips, M.D. Temple, and D.L. Buck. Depts. of Psychology and Neurosurgery, VA Commonwealth Univ./Med. College of VA, Richmond, VA 23298-0693.

Lu 25-109-T is a partial muscarinic M1 receptor agonist that also acts as an antagonist at presynaptic M2 autoreceptors (thus, increasing ACh release). We previously reported that daily post-injury injections of Lu 25-109-T improved cognitive performance in traumatically brain injured (TBI) rats *(J Neurotrauma,1995,12:991)*. This experiment examined the effects of moderate (2.2 atm) central fluid percussion TBI on basal forebrain ChAT-IR at 15 days post-injury following daily administration (s.c.) with saline or 15 µmol/kg Lu 25-109-T. On days 11-15 after injury, Lu 25-109-T-treated rats showed a significant improvement ($p<0.01$) in cognitive performance in a Morris water maze (MWM) procedure as compared to saline-treated rats. Following the last day of MWM testing, rats were sacrificed, sections were collected through the medial septal area and processed for ChAT-IR. Saline- and Lu 25-109-T-treated rats had significantly ($p<0.01$ and 0.05 respectively) fewer (per µm²) ChAT-IR cells in the vertical limb nucleus of the diagonal band (VDB) compared to sham-injured rats (48% vs. 23% respectively). However, Lu 25-109-T significantly ($p<0.05$) reduced the loss of ChAT-IR neurons in the VDB. Neither injured group had significant decreases in ChAT-IR cells in the medial septal nucleus (MSN) compared to sham-injured rats (13% and 5% respectively). Adjacent cresyl violet stained sections indicated no obvious loss of total cell density in the MSN or VDB. These results support the hypothesis that a decrease in post-traumatic cholinergic neurotransmission contributes to TBI-induced cognitive deficits, and that increasing cholinergic tone during the recovery period following TBI will improve cognitive performance. (Supported by NS 12587)

842.4

LONG-TERM ENHANCEMENT OF IL1 AND IL3 EXPRESSION AFTER COMBINED FLUID PERCUSSION AND BILATERAL ENTORHINAL CORTICAL LESION. L.L.Phillips*, J.Zhu, B.G. Lyeth, T.M. Reeves, and J.T. Povlishock, Div. Neurosurgery and Dept. Anatomy, Medical College of Virginia, Richmond, VA 23298.

We have utilized a model of traumatic brain injury combining f luid percussion (FPTBI) with bilateral entorhinal cortical lesion (BEC) to assess the expression of interleukins 1 and 3 (IL1 and IL3) during periods of synaptic plasticity. Previous studies show that BEC synaptic plasticity is altered by FPTBI. Given that both FPTBI and unilateral EC lesion increase IL1 expression, and that IL3 enhances neuronal outgrowth, we examined whether IL1 and IL3 are altered during reactive synaptogenesis in the combined model. Rats received moderate FPTBI followed at 24 hr by BEC lesion, and were sacrificed 2,7,15 and 30 days postinjury (DPI). Sections of hippocampus were processed for immunohistochemical (IHC) localization of IL1a, IL1b and IL3. Sham control and BEC lesion alone were also subjected to IHC for each IL. Both BEC and the combined insult showed enhanced binding for all three ILs over the denervated dentate molecular layer (DML) and the stratum lacunosum moleculare (SLM) of CA1 as early as 2 DPI. Further increases were observed at 7 DPI which persisted to 30 DPI. ILs were observed in dense puncta throughout the DML and SLM. Interestingly, the SLM showed the greatest expression of ILs after the combined injury. Our results show a long-term spatio-temporal correlation between IL1 and IL3 expression and synaptic plasticity following the combined insult. Supported by NIH 12587.

842.5

ALTERATIONS IN BDNF AND NT-3 mRNAs IN THE HIPPOCAMPUS FOLLOWING TRAUMATIC BRAIN INJURY IN THE RAT, R. R. Hicks*, M.R. Prasad[2], H.S. Dhillon[2], J.M. Dose[2], S. Numan[3] and K. Seroogy[3],. Depts. of [1]Physical Therapy, [2]Surgery, and [3]Anatomy and Neurobiology, Univ. Kentucky, Lexington, KY 40536.

Previous studies have suggested that the neurotrophins brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) are neuroprotective or neurotrophic for certain subpopulations of hippocampal neurons following various brain insults. In the present study, the expression of BDNF and NT-3 mRNAs in the hippocampus was examined following traumatic brain injury. Following a lateral fluid percussion brain injury of moderate severity (2.0 atm) or a sham injury, the hippocampi from adult rats with survival times of 1, 3, 6, 24 and 72 hr were analyzed for the in situ hybridization localization of BDNF and NT-3 mRNAs using ^{35}S-cRNA probes. There was a pronounced increase in BDNF mRNA in the bilateral dentate gyrus (DG) which peaked at 1 hr and remained above control levels for up to 72 hrs. A mild increase in BDNF expression was also observed in the bilateral CA1 and CA3 regions of the hippocampus at 1 hr, but expression approached control levels within 3 hrs. Conversely, NT-3 mRNA was decreased in the DG at 6 and 24 hr survival times. These results demonstrate that lateral fluid percussion brain injury differentially induces expression of BDNF and NT-3 in the hippocampus.

The Response of Microglia and Astrocytes in the Rat Spinal Cord to Sciatic Nerve Damage. S. Saporta* and J. A. Moore. Department of Anatomy, University of South Florida College of Medicine, Tampa, FL 33613.

Sciatic nerve damage has long been known to produce a zone of gliosis within the spinal cord two to three weeks following axotomy. Evidence has recently been presented that there is an activation of microglia within 18 hours and astrocytes within 48 hours of axotomy. Evidence form this laboratory has shown that there is a break down of the blood-spinal cord barrier within 48 hours of axotomy associated with an increase in spinal cord perivascular space and an increase in lipoxygenase activity. We investigated the time course of these changes within the same group of animals to examine possible interrelationships between these events. The sciatic nerve of 240-300 gm rats of either sex was ligated near its course around the head of the femur and sectioned distal to the ligation. Animals were allowed to survive for 12, 18, 24, 36, 48, 96 and 168 hours following surgery, and perfused with 4% paraformaldehyde in 0.1M phosphate buffer. The L3-L6 segments of spinal cord were removed, and 10 µm frozen sections reacted for OX-42 for microglia, glial fibrillary acidic protein (GFAP) for astrocytes. Sections from some animals were also reacted for the presence of rat IgG. Microglia within the spinal cord sciatic nerve territory were activated within 18 hours of surgery. Astrocytes within the same territory were activated within 48 hours. Microglia were reactive prior to the breakdown of the blood-spinal cord barrier, but astrocytes appeared activated approximately at the same time as the breakdown of the blood-spinal cord barrier.

AXOTOMY AFFECTS THE RETROGRADE LABELING OF CERVICAL AND LUMBAR CORD-PROJECTING RUBROSPINAL NEURONS DIFFERENTLY, Y.-J. Wang, G.-F. Tseng, and W.-P. Chen*. Department of Anatomy, College of Medicine., National Taiwan University

The effect of axotomy at cervical and lumbar spinal levels upon the ability of rubrospinal (RS) neurons to retrogradely transport tracer was compared. Unilateral RS tractotomy was performed first at C5 and, after a few days, at C2 vertebral levels. Different retrograde tracers were applied at the lesioned sites right after tractotomy and the animals were processed for examination 5 days after the C5 lesion to allow maximal labeling. Tracer applied at C5 labeled both cervical (C-) and lumbar-cord-projecting (L-RS) neurons. Tracer applied at C2 also labeled both groups of neurons if performed 2 days after that at C5, however, only C-RS neurons were labeled when it was performed 3 or 5 days after that at C5. In the later case, tracer didn't appear in these L-RS neurons when examined 1-4 days after the C5 lesion. This ruled out the possibility of a fast turnover of tracer. In addition, tracer appeared in the cell bodies and proximal dendrites of labeled cells in all animals examined suggesting the lack an apparent relocation of tracer either. In another set of experiment, a T10 tractotomy without tracer application was performed 2 or 5 days prior to the C5-C2 series of tract lesions. When preceded by a T10 lesion 2 days in advance, tracer applied at C5 labeled both C- and L-RS neurons. However, a T10 lesion 5 days in advance resulted in the labeling of only C-RS neurons by the tracer applied at C5. In either cases, tracer applied at C2 consistently labeled only C-RS neurons, irrespective of the intervals, 2, 3, or 5 day, allowed between C5 and C2 lesions. Most neurons labeled from C2 were also double-labeled by the tracer applied at C5. Thus, unlike L-RS counterparts, C-RS neurons retain the ability to uptake and/or transport retrograde tracer following axotomy. This seems to imply that C-RS neurons may be surviving in a different functional status from their L-RS counterparts following axonal injury. (NSC-85-2331-B002-286-M10, Taiwan)

ELECTROPHYSIOLOGICAL PROPERTIES OF NORMAL AND AXOTOMIZED RUBROSPINAL NEURONS, G.-F. Tseng*, and J.-R. Chen. Department of Anatomy, College of Medicine., National Taiwan University

The effect of cervical axotomy on the membrane properties and inhibitory synaptic inputs of rubrospinal neurons (RSN) was studied in the rats 3, 4, 28, 56 days after injury. Retrograde tracer Fast blue or DiI was applied in the lesioned site to retrogradely label axotomized RSNs. Brainstem slices containing the caudal red nucleus were studied since RSNs fill this part of the nucleus. Recorded cells were confirmed as axotomized neurons since the intracellular dye biocytin injected following electrophysiological characterization revealed that they also contain the retrograde tracer. Axotomy caused no change in the resting membrane potentials or the IV relationship. However, the input resistance was initially (3 and 4 days) decreased and later (28 and 56 days) increased, corresponding to an increase and decrease in the soma sizes of the axotomized neurons anatomically. Membrane time constant was decreased 3 and 4 days post-lesion. Unlike corticospinal neurons which also belong to the lateral descending system, RSNs generate very fast spikes with a small fast adaptation. These characters were not altered by the axotomy. However, the F-I slope (Hz/nA) increased 28 and 56 days after lesion suggesting that survival neurons have a higher output/input relationship. In coronal slices, a monosynaptic $GABA_A$ receptor-mediated IPSP could be evoked in every RSNs by stimulating the reticular formation dorsolateral to the nucleus. The amplitude and duration of this IPSP was decreased 4 and 56 days following axotomy. In addition, IPSP could no longer be evoked in every axotomized RSN 56 days post-lesion. These results suggest that spinal axotomy causes a transient decrease in the responsiveness of RSNs to inputs including a weakening of inhibitory synaptic inputs. However, these neurons become more excitable in the long term although inhibitory inputs remain weakened. (NSC-85-2331-B002-286-M10, Taiwan)

SYNAPTIC REPLACEMENT IN REGIO SUPERIOR FOLLOWING A SEVERE CORTICAL CONTUSION. S.A. Baldwin*, D.A. Price, J.K. Hamrick, C. Brown, R.R. Hicks and S.W. Scheff. Sanders-Brown Center on Aging, Univ. Kentucky, Lexington, KY 40536-0230.

Partial loss of neuronal input as a result of trauma, signals undamaged afferents to sprout and replace lost synaptic connections. The hippocampus has been a model system to study such plasticity following injury. A traumatic brain injury model of severe cortical contusion significantly disrupts hippocampal circuitry, destroying the CA3 pyramidal cells and disrupts Schaffer collaterals, which project to CA1 regio superior. The present investigation assessed the temporal sequence of possible compensatory synaptogenesis following this injury.

Adult SD rats were subjected to a severe cortical contusion using the Lighthall model. Animals were killed at 2,10,15,30 and 60 days after injury. The ipsilateral regio superior of the hippocampal formation was examined with transmission EM. Changes in total synaptic numbers were determined with the Disector stereological method. At two days following the injury, there was a significant decline in the number of normal synapses and degenerating synaptic complexes were evident throughout the neuropil. By 30 days after the injury most of the degenerative debris had been removed and reactive synaptogenesis replaced many of the lost synaptic contacts. Since the exact same synaptic connections could not be replaced, the regio superior circuitry was altered. The present results demonstrate that significant brain self-repair can occur following a severe cortical contusion.

ULTRASTRUCTURAL CHARACTERISTICS OF THE SITE OF THE CHRONIC SPINAL CORD LESION IN MONKEYS. Talat Khan[1,2], Arthur LaVelle*[4], Kathryn J. Jones [1,3]. [1]Rehabilitation R&D Center, Hines VA Hospital, Hines, IL 60141, Depts. of [2]Neurology and [3]Cell Biology, Neurobiology & Anatomy, Loyola Univ. Chicago, Maywood, IL 60153 and [4]Dept. of Anatomy & Cell Biology, Univ. of Illinois at Chicago, Chicago, IL 60612.

Trauma to the spinal cord produces complex biochemical and physiological changes. In the initial phase, mechanical disruption of the tissue occurs within minutes after injury. During the secondary stage, which occurs over a period of hours or days, multiple vascular, immunological and biochemical changes occur. In the chronic phase, destruction of neural elements, *i.e.*, cavitation of the spinal cord at the site of the lesion, glial migration into this area, and complete disconnection of nerve fibers, leads to permanent loss of function below the lesion. In this study, six monkeys were paralyzed by contusion injury by dropping a 30 gm weight from a height of 22 cm at the T11 level. Electron microscopic examination of the scar tissue at the site of the lesion revealed different ultrastructural changes at 13 weeks and 30 weeks post-trauma. At 13 weeks post-trauma, the lesion site showed areas of active gliosis and proliferation of astrocyte. Microglia and macrophages were found mainly in the white matter, clearing the membranous debris of degenerating myelinated axons, while many small myelinated axons were still intact. At 30 weeks post-trauma, the lesion site was characterized by the presence of increased numbers of microglia, which were actively phagocytizing the degenerating axons, and fewer astrocytes with increased glycogen located in the cell body and processes. In addition, a number of peripheral lymphocytes were present, in the marginal area of the blood vessels. These observations suggest that the injured spinal cord is in a chronic inflammatory state 30 weeks after the injury.

PROTECTIVE EFFECTS OF BASIC FIBROBLAST GROWTH FACTOR AGAINST TRAUMATIC BRAIN INJURY IN VIVO AND IN VITRO. H. Uramoto, N. Murayama, M. Masumura and T. Ohno* Suntory Institute for Biomedical Research, Osaka, 618, Japan.

Neuroprotective effects of basic fibroblast growth factor (bFGF) were examined in the traumatic injured brains and in primary neurons cultured under different experimental conditions. [METHODS] Male Wistar rats received a surgery of turning the screw into the brain. The water contents of ipsilateral cerebral hemispheres (WC) and the extension of IgG leakage (IL) developing after the traumatic brain injury (TBI) were measured with time until 7 days. bFGF (5, 25 ng/5 μl) and platelet factor-4 (PF-4, 50 ng/5 μl) were administered into the right lateral ventricle immediately before TBI. Primary neurons from the neocortex and hippocampus of rat fetuses (E 18) were cultured in DMEM containing 10% horse serum. The neuronal damages were induced by glutamate (0.1 mM for 12 hr) and β amyloid peptide 25-35 (βAP, 10 μM for 3 days) applied 12 hr after treatment with bFGF (1-25 ng/ml) or vehicle. Traumatic neuronal injury in vitro was produced by tearing in the neuronal and glial cell layer. bFGF was applied 24 hr before the mechanical injury. [RESULTS] A biphasic development of brain edema was observed after TBI; the WC increased with time until day 3, which maintained until day 5, and then increased again to a maximum on day 6 after TBI. In contrast, the extension of IL increased to a maximum on postoperative day 3, which persisted until day 7. bFGF significantly inhibited TBI-induced WC, whereas PF-4 increased the WC 6 days after TBI. bFGF also prevented BBB dysfunction (IL) and hypoambulation observed 3 days after TBI. bFGF protected primary cultured neurons from glutamate- and βAP-induced damages in a concentration-dependent manner, which was blocked by pretreatment with actinomycin D, cycloheximide, or PF-4. However, simultaneous application of bFGF with glutamate did not show any neuroprotective effect. Against traumatic neuronal injury in vitro, bFGF also exerted neuroprotective effects and neurite outgrowth at the edge of the tear. [CONCLUSION] These results taken together indicate that bFGF exerts neuroprotective effects against damages in response to mechanical insult.

SELECTIVE HIPPOCAMPAL DAMAGE TO HYPOXIA AFTER MILD CLOSED HEAD INJURY IN THE RAT. K. Shima*, H. Katoh, H. Nawashiro and H. Chigasaki Dept. of Neurosurgery, National Defense Medical College, Tokorozawa, Saitama 359, Japan

Our previous studies have shown selective cell damage in the CA3 region after mild closed head injury (CHI) combined with hypoxia. In the present studies, we have examined the effects of both excitatory (EAAs) and inhibitory amino acids (IAAs) and their receptors following CHI with hypoxia. Four groups of male Sprague-Dawley rats were set up: sham controls, mild CHI (drop a 450 g weight from 1 m on the vertex), moderate hypoxia (30 min) and CHI followed by hypoxia. Two experiments were performed. (1) We determined the function of NMDA, kainic acid (KA) and $GABA_A$ receptors using quantitative autoradiography. (2) Using in vivo microdialysis technique, we measured the extracellular levels of glutamate (GLU), taurine (TAU), glycine and GABA. The dialysis probe was inserted into the hippocampus. The dialysate samples were collected every 15 min until 4 h following CHI. CHI alone did not produce prominent changes in the measured receptor binding. When hypoxia was combined with CHI, significant increase in [3H]Glu binding to NMDA receptor and significant decrease in [3H]muscimol binding to $GABA_A$ receptor were observed in CA1 and CA3 at 1h and 24h post-insult. With CHI alone, Glu and Tau levels were transiently increased by 15 min posttrauma. In the CHI with hypoxia, increases in GLU and TAU levels were sustained until 60 min after CHI. GABA level was also increased until 75 min posttrauma. The present results demonstrate that selective hippocampal damage to hypoxia after mild CHI may be mediated through an increase in NMDA receptor activation and the furhter release of extracellular GLU. This study also suggests that, when hypoxia is superimposed upon CHI, an exacerbated imbalance between EAAs and IAAs may contribute to increase the selective vulnerability of hippocampus.

SPINAL CORD INJURY ALTERS RATE-MODULATION OF LUMBAR REFLEXES: GABAb TREATMENT REPRODUCES RATE-DEPRESSION BUT NOT PTP CHANGES. F.J. Thompson*[1], R. Parmer[1], P.J. Reier[1,2]. Depts. of Neuroscience[1], Neurosurgery[2], Univ. of Florida Brain Institute, Gainesville, Florida 32610-0244

Recently we reported a decrease in rate-sensitive depression of lumbar monosynaptic reflexes (MSRs) subsequent to midthoracic spinal injury (Thompson et al., 1992; 1993). The reflex magnitudes produced by repetitive sensory inputs were 250% increased over those in normal animals. We confirm these findings and report a new observation regarding a significant decrease in MSR posttetanic potentiation (PTP) subsequent to contusion injury. These changes emphasize basic questions regarding fundamental mechanisms which regulate reflex excitability. To identify a more specific neurosubstrate essential for the expression of rate-depression and PTP, we analyzed tibial MSR excitability before and following pharmacologic blockade of GABAb receptors in ketamine anesthetized normal adult rats. Intrathecal application of a specific GABAb antagonist (CPG-35348, CIBA-Geigy to the L_5 spinal cord resulted in decreased rate-sensitive depression of tibial monosynaptic reflexes (MSRs) such that 10 Hz MSRs were 250% larger than observed in the pretreatment controls. Intraspinal injection using micropipettes to deliver < 5μg CGP-35348 resulted in more robust changes with a faster time course of onset. In contrast, no significant changes were observed on the magnitude of PTP following GABAb blockade in normal animals. These data support the conclusion that rate-depression, but not PTP, modulation of reflex excitability is mediated in part by GABAb receptors. In addition, these preliminary findings indicate that focal application of a specific GABAb antagonist produced changes which mimicked, in part, those observed subsequent to thoracic cord lesions. (Supported by NIH-NINCDS (RO1-NS-33333-01A1) and the Brain and Spinal Cord Injury Rehabilitation Trust Fund).

EFFECTS OF GRADUAL BONE LENGTHENING ON THE RABBIT TIBIAL NERVE. T. Urabe, T. Bleasdale, Q. Zhao*, G. Lundborg, J. M. Kerns and N. Danielsen. Dept. Hand Surg., Malmö University Hospital, Lund University, S-205 02 Malmö, Sweden and Dept. Anatomy, Rush Medical College, Chicago, IL 60612.

Little is known about the effect of gradual bone lengthening on peripheral nerves. In the present study, the morphological effects on rabbit tibial nerve fibers were determined by light and electron microscopy. Under general anesthesia an external fixation device was applied to the rabbit tibia which was then divided. After seven days, the tibia was subjected to 0.7 mm/day callus distraction for periods up to one month. The nerves were harvested for glutaraldehyde fixation, plastic embedding and sectioning in transverse and longitudinal planes. The gap length of the node of Ranvier in myelinated axons from the experimental side (mean 1.72 μm) compared to the control side (mean 1.05 μm) significantly increased by 64% ($p < 0.01$, range 21-160%, $n = 7$). The cross-sectional area of the non-myelinated axons was measured on electron micrographs using the Bioquant image analysis system (100 fibers from each side of 8 animals). The overall means from the experimental (0.64 $\mu m^2 \pm 0.36$; mean ± SD) and control (0.67 $\mu m^2 \pm 0.38$) were not significantly different. We conclude that gradual stretching of the nerve elongates the nerve fibers at least at the region of the nodes, perhaps a point of least resistance. In contrast, the fiber size seems to be held more constant during the lengthening procedure. The functional implications of these changes are at this stage unknown.

842.15

THE 4-AP SENSITIVE POTASSIUM CHANNEL CONTRIBUTES TO POSTTRAUMATIC AXONAL DYSFUNCTION AFTER ACUTE SPINAL CORD INJURY. R. Nashmi* and M.G. Fehlings. *Playfair Neuroscience Unit, The Toronto Hospital Research Institute, University of Toronto, Toronto, Ontario, Canaada M5T 2S8.*

The subpopulation of axons in the subpial rim which survive primary and secondary injury to the cord display dysfunctional conduction properties. After chronic SCI, blockade of "fast" K^+ channels with 4-aminopyridine (4-AP) improves axonal conduction. However, the role of K^+ channels in mediating axonal dysfunction after acute SCI has not been established. In the present investigation we examined the hypothesis that "fast" K^+ channels sensitive to 4-AP are involved in posttraumatic axonal dysfunction after SCI.

Studies were conducted on isolated adult rat dorsal columns *in vitro* (n=62). Compound action potentials (CAPs) were recorded extracellularly with microelectrodes and by the sucrose gap recording technique. Compressive injury was inflicted *in vitro* with a modified aneurysm clip (closing force 2.0 g applied for 15 sec). Changes in the pharmacological sensitivity of dorsal column white matter to a variety of K^+ channel blockers, including 4-AP, α-dendrotoxin (α-DTx), a more selective blocker of the "fast" K^+ channel, TEA, a blocker of the "slow" K^+ channel, and CsCl, a blocker of the inward rectifier (IR), were examined following acute SCI.

Infusion of 4-AP (1 and 5 mM) resulted in a significantly greater increase in P2 amplitude of injured (132.9 ± 12.3% and 114.2 ± 2.4%, respectively) ($p < 0.025$) as compared to noninjured axons for the microelectrode derived field potential recordings. Sucrose gap recordings showed a significant increase in CAP area (205.3 ± 9.9%) and an increase in amplitude (104.4 ± 1.9%) of injured axons with 1mM 4-AP. Furthermore, there was a broadening of the CAP with a delay in repolarization of the resting membrane potential. Administration of α-DTx (500 nM) resulted in a significantly greater increase in the P2 amplitude of injured axons to 112.5 ± 3.5% ($p < 0.025$) as compared to noninjured axons. TEA (0.1 mM and 10 mM), when infused alone and with CsCl (10 mM), produced similar effects on injured and intact axons.

The results of this study suggest that the "fast" K^+ channel sensitive to 4-AP and α-DTx displays abnormal activity following compressive SCI. Furthermore, the increase in area and amplitude of the sucrose gap recordings following 4-AP suggests a possible recruitment of dysfunctional axons. *(Supported by MRC Canada).*

THE EFFECTS OF METHYLPHENIDATE TREATMENT ON FUNCTIONAL RECOVERY FOLLOWING TRAUMATIC BRAIN INJURY. C.E. Dixon* and J. Bao. Brain Trauma Research Center, Department of Neurosurgery, University of Pittsburgh, Pittsburgh, PA 15260.

Evidence has begun to accumulate that methylphenidate, a well-characterized mild CNS stimulant, benefits recovery from traumatic brain injury (TBI) in humans (Plenger, et al., Arch Phys Med, in press). Moreover, laboratory studies have shown that methylphenidate can attenuate locomotor deficits following unilateral sensorimotor cortex abalation (Klinn, et al., Pharm Biochem and Behav 48(3):773-9, 1994). The purpose of this study was to examine the effects of daily methylphenidate treatment on functional recovery following TBI produced by controlled cortical impact injury (6 m/sec, 2.5 mm tissue deformation). Sham animals were surgically prepared, but not injured. Beginning one day after injury, animals were injected daily with either methylphenidate (5 mg/kg, i.p., n=8) or saline (n=8). Rats were pretrained and retested on days 1-5 for motor (beam balance and beam walking) performance. On days 10-14, animals were trained on the Morris water maze task. Methylphenidate treatment did not attenuate motor deficits following TBI, However, animals treated with methylphenidate had significantly less ($p < 0.05$) spatial memory performance deficits than animals treated with saline. In summary, daily administration of methylphenidate reduced spatial memory performance deficits, but not motor deficits following TBI. Supported by CDC R49CCR-312296.

843.2

IMPAIRED EXPRESSION OF LONG-TERM POTENTIATION IN HIPPOCAMPAL SLICES 4 AND 48 HOURS FOLLOWING MILD FLUID-PERCUSSION BRAIN INJURY *IN VIVO*. T.J. Sick*, Zhen-Zhou Feng and M. A. Pérez-Pinzón. Dept. of Neurology, U. of Miami Sch. of Medicine, Miami, Fl. 33101

The effect of fluid percussion brain injury on hippocampal long-term potentiation (LTP) was investigated in hippocampal slices *in vitro*. Mild to moderate (1.7 - 2.1 atm) fluid percussion head injury or sham operation was produced in rats 4 or 48 hr prior to harvesting brain slices from the ipsilateral hippocampus. Field excitatory post synaptic potentials (fEPSPs) were recorded in stratum radiatum of hippocampal subfield CA1 in response to electrical stimulation of the Schaffer collaterals. The initial slope of fEPSPs was used to investigate changes in synaptic strength prior to and following 100 or 200 Hz (1 sec) tetanic stimulation. TBI significantly inhibited expression of LTP in hippocampal slices *in vitro*. Post-tetanus fEPSP slopes increased more than 100% in hippocampal slices from sham-operated animals but less than 50% in slices from rats following TBI. The data suggest that changes in functional synaptic plasticity in the hippocampus may underlie cognitive disorders associated with TBI. The data also indicate that TBI-induced effects on hippocampal LTP are robust and may be investigated in the hippocampal slices preparation *in vitro*. These studies were supported by PHS grant NS 30291 and Grant in Aid from American Heart Association.

843.3

Immediate early gene expression in retina after a controlled crush of the adult rat optic nerve C.K. Vowerk[1]*, T.M. Böckers[2], J. Weise[1], B.A. Sabel[1], M.R. Kreutz[1] [1]Inst. of. Med. Psychology, Otto-von-Guericke University, Magdeburg, Germany [2]Inst. of Anatomy, Westfälische-Wilhelms University, Münster, Germany

The expression of immediate-early genes (IEGs) after lesions of the central nervous system has been studied extensively in recent years. Less is known about consequences of partial axonal trauma on IEG expression. We have studied the expression of c-fos, fos-b, c-jun, jun-b, jun-d, krox 24 and pc4 mRNA after optic nerve crush in the rat retina by in situ hybridization. Antisense oligonucleotides were 3'end labeled with ^{35}S-αdATP and retinal cryostat sections were dipped in photoemulsion after hybridization. To ensure a cellular label sections were thereafter counterstained with hematoxylin and investigated at the light microscope level. None of the used probes gave a signal above backgound in control sections. However, 2 days after crush label on cells in the retinal ganglion cell layer was observed with the c-jun probe. Silver grains in this layer were still prsent after 3 days and 1 week. No hybridization signal for any of the other investigated IEG's was seen at any time point after crush in this study. Injection of an antisense but not a sense oligonucleotide against c-jun resulted in more surviving RGC as evidenced by retrograde labelling with horseradish peroxidase. The astonishing specificity of c-jun expression after ONC lead us to speculate on a role of the jun-protein as a factor for RGC cell death and survival.

EARLY EXPRESSION OF CHEMOKINES FOLLOWING TRAUMATIC BRAIN INJURY. R.M. Klein*, E. Hausmann, G.W. Wood and N.E.J. Berman. *Departments of Anatomy and Cell Biology and Pathology and* Laboratory Medicine, University of Kansas Medical Center, 3901 Rainbow Blvd., Kansas City KS, 66160

Chemokines are proteins expressed by damaged tissue attracting macrophages and other infiltrating and resident cells, which are key participants in the wound healing process. Microglia are recruited to the injury site, where they synthesize and respond to cytokines. To determine whether chemokines play a role in the healing process following brain injury, we studied the temporal expression of MCP-1, MIP-1α, MIP-1β, IP-10, KC and RANTES. Messenger RNA levels were determined by northern analysis following stab wounds made by injecting LPS or PBS into mouse cerebral cortex. LPS (lipopolysaccharide), is a bacterial cell wall constituent which induces macrophage and microglial responses, and was used as a model of traumatic brain injury with infection. Message levels were standardized to GPDH. MCP-1 and MIP-1α were elevated at 2 hr. and peaked at 6 hr. following LPS injection. After PBS injection, MCP-1 expression occurred later, and MIP-1α was not elevated. Following LPS injection, MIP-1β peaked at 6 hr., but declined more rapidly than MCP-1 or MIP-1α. IP-10 peaked at 6 hr., and showed the most rapid decline of the chemokines studied. KC was elevated at 1 hr., and peaked at 6 hr. following LPS injection. RANTES was elevated at 1 hr., plateaued between 6 and 18 hr., then declined. The presence of chemokine message as early as 1 hr. indicates that chemokine expression is an early event in the healing response following traumatic brain injury. The involvement of chemokines such as MCP-1, a monocyte chemoattractant, implies a role for microglia in these early repair events. Supported by MH38399, AA10412 and HD30802.

ACTIVATION OF TRANSCRIPTION FACTOR NF-κB AFTER TRAUMATIC BRAIN INJURY. S.M. Knoblach*, A. G. Yakovlev and A.I. Faden. Georgetown Institute for Cognitive and Computational Sciences, Georgetown Univ. Med. Ctr., Washington DC 20007.

The pathophysiological sequelae of CNS injury include several components which have independently been implicated as activators of the transactivating factor Nuclear Factor κB (NF-κB). These include oxidative stress, stimulation of ionotropic glutamate receptors, and cytokine mediated immune and inflammatory reactions. Therefore, we examined whether NF-κB activation occurs in a clinically relevant model of brain injury.

Transcription of the NF-κB precursor p105 is autoregulated by the active NF-κB complex, thus p105 mRNA levels were assessed via semi-quantitative RT-PCR, as an indirect measure of NF-κB activation. The injured cortex and hippocampus of anesthetized, male Sprague-Dawley rats were examined 1, 4, 12, 24 and 72 hr after sham (0 atm), mild (1.2 atm) or moderate (2.0 atm) lateral fluid-percussion injury. Changes in p105 mRNA levels showed an initial early increase at 1 hr and from 12 to 72 hr after injury.

Companion electrophoretic-mobility-shift assay studies indicated a similar pattern of activation, as well as an increase in DNA-binding associated with the p50 and p65 NF-κB subunits after injury.

These results indicate that NF-κB is involved in the posttraumatic events which occur after brain injury. The time course of the response is in agreement with the temporal sequence of potential NF-κB activating cascades. (Supported by CDC CCR306634 and NCMRR T32HD07459).

CHRONIC SYSTEMIC THEOPHYLLINE INDUCES HEMIDIAPHRAGMATIC RECOVERY IN RATS FOLLOWING CERVICAL SPINAL CORD HEMISECTION. K.D. Nantwi* and H.G. Goshgarian. Department of Anatomy and Cell Biology, Wayne State Univ., Sch. of Med., Detroit, MI 48201

The objective of the present study is to assess how chronic administration of theophylline from 3- 30 days may influence its action on latent respiratory motor pathways in female rats subjected to a left C2 hemisection. Four experimental and two control groups were utilized. Control animals were subjected only to hemisection or in addition were injected with the drug vehicle for 3, 7, 14 or 30 days. In some experiments, the functional status of the paralyzed hemidiaphragm was electrophysiologically assessed immediately after surgery to ensure that the hemisection was complete. Thereafter, animals were injected with theophylline 3 times a day for the times indicated above. Respiratory rates were determined daily in all rats. Finally, the serum levels of theophylline were assessed. To assess function in the phrenic nerve and hemidiaphragm ipsilateral to the hemisection, spontaneously-breathing animals were anesthetized with chloral hydrate (400 mg/kg, i.p.). Bipolar electrodes were inserted into the diaphragm and the desheathed nerve was placed on another set of bipolar electrodes in the neck. In 14 out of 17 animals, long term systemic administration of theophylline induced functional recovery in the paralyzed hemidiaphragm. Furthermore, respiratory rates in the theophylline group were higher than in controls. Functional restitution was not observed in any animal in the control groups. Serum analysis of the drug will be presented. The present data confirm our previous findings that acutely administered (i.v.) theophylline in hemisected animals restores function to the hemidiaphragm paralyzed by C2 hemisection. In addition, the data strongly suggest that the drug can induce and maintain long term hemidiaphragmatic recovery in rats after cervical spinal cord injury. It is concluded that the drug mediates this functional restitution by activating latent respiratory pathways.

DIFFERENTIAL EXPRESSION OF iNOS IN RAT CORTEX FOLLOWING TRAUMA. A.B.Page[1], G.S.Krause[2*], and J.A.Rafols[3]. Departments of Anatomy/Cell Biology[(1,3)] and Emergency Medicine[(2)], School of Medicine, Wayne State University, Detroit, MI, 48201.

Using an acceleration-impact model of traumatic brain injury, we studied the temporal and spatial expression of the inducible isoform of nitric oxide synthase (iNOS) in the cerebral cortex of male Sprague-Dawley rats. Cryoprotected frozen 10μm sections were immunostained using a polyclonal antibody for iNOS, and visualized at the light microscopic level. Variations in staining density were studied in blood vessels (endothelia) and adjacent cells, as well as in neurons. In comparing blood vessels with diameters in the range of 12.5-16μm to larger (between 38 and 50μm) diameter vessels, we found that at 24 hours the microvessels were only very slightly stained, while the larger vessels showed somewhat darker endothelial staining. By contrast, immunoreactivity at 48 hours was restricted to the microvessels and absent from the larger vessels. Staining of cortical pyramdal neurons showed a clear progression from lightly reactive at 24 hours, to significantly more staining at 48 hours in layers II, III, V, and VI cell bodies. Reactive puncta, representing synaptic terminals, surrounded the somata and apical dendrites. By 72 hours, neurons throughout all layers of the cortex were very heavily stained.

In order to further characterize the compartmentalization of iNOS within the endothelium and the perivascular glial sheath, we undertook an electron microscopic study using immunogold techniques.

The results suggest temporal and spatial regulation of neural and endothelial NO expression which may be involved in the mediation of post-traumatic cell death, through effects either on the microcirculation, or on the excitototoxic cascade. *Research funded by the Detroit Neurotrauma Institute at Wayne State University School of Medicine.*

THE EFFECTS OF ACUTE SUBDURAL HAEMATOMA ON THE NEURONAL CYTOSKELETON: AN IMMUNOHISTOCHEMICAL AND ULTRASTRUCTURAL STUDY. W. Maxwell, M.O. Fitzpatrick, D. Dewar, J. McCulloch* and D.I. Graham. Wellcome Surgical Institute and Department of Anatomy, University of Glasgow, U.K.

Ischaemic brain damage is the main pathological abnormality detected in patients who die of acute subdural haematoma. Breakdown of the cytoskeleton may be involved in the evolution of ischaemic brain damage and alterations in microtubule associated proteins may play an important role in this process. This study examined the neuronal cytoskeleton in a rat model of acute subdural haematoma by means of immunohistochemical staining and electron microscopy. All experiments were performed in physiologically monitored, mechanically ventilated, halothane anaesthetised rats. A burr hole was drilled 2mm to the left of the sagittal suture and 1 mm posterior to the coronal suture. The dura was incised and a J shaped needle inserted into the subdural space. Acute subdural haematoma was created by the injection of 0.4ml autologous venous blood. Sham controls had the needle inserted only. After 30 minutes, 2 hours and 4 hours the brains were perfused fixed and processed for β-tubulin, MAP2 and Tau-1 immunohistochemistry. In addition transmission electron microscopy was performed in a group of 4 hour survival animals. In the cortex there was loss of MAP2 immunostaining under the haematoma indicating disruption of dendritic structure. Ultrastructural analysis demonstrated misalignment of the dendritic microtubules with the formation of an abnormal helically orientated pattern rather than the linear arrangement identified in control tissue. In the ipsilateral corpus callosum and white matter tracts there was an abnormal punctate, granular pattern of β-tubulin and Tau-1 immunoreactivity compared to shams. These changes were more pronounced at the longer survival times. Electron microscopy demonstrated dissociation of the myelin sheath and the occurrence of peri-axonal spaces associated with a reduction in axonal transverse diameter. There was loss of microtubules and compaction of neurofilaments in axons of reduced calibre. Abnormalities of the neuronal cytoskeleton may play an important role in the pathobiology of acute subdural haematoma.

LOCAL APPLICATION OF TETRODOTOXIN (TTX) REDUCES LONG-TERM FUNCTIONAL DEFICITS RESULTING FROM EXPERIMENTAL SPINAL CORD INJURY.

Yang Dong Teng* and Jean R. Wrathall. Neurobiology Division, Dept. of Cell Biology, Georgetown Univ., Washington, DC 20007

We have previously reported that loss of white matter is significantly correlated with long-term functional impairment after experimental spinal cord injury (SCI) in a rat weight-drop model (Noble & Wrathall, *Exp. Neurol.* **88**:135, 1985; *ibid* **103**:34, 1989). Recently *in vitro* data from other investigators has indicated that sodium influx may be the initial process leading to white matter damage resulting from anoxic conditions. Therefore, we hypothesized that blockade of the sodium channels would reduce long-term functional deficits after experimental SCI.

To test this hypothesis, a standardized rat model of contusive SCI at T8 was used to examine the effects of TTX, the most potent sodium channel antagonist. TTX (0.15 nmole) or vehicle (n=12, per group) was microinjected to the injury site in a total volume of 0.5 μl over a period of 5 min beginning at 15 min post-injury. In uninjured rats, microinjection of this dose of TTX can paralyze hindlimb function for up to 36 hours. Behavioral evaluations of hindlimb functional deficits after SCI were performed at day 1 and weekly thereafter for 8 weeks. Compared to the controls, the group treated with TTX demonstrated a reduction in long-term functional deficits that was significant from 2 through 8 weeks. Besides the improvement in use of the hindlimbs in locomotion, there was improved performance in tests of a number of hindlimb reflexes. The treated group also had a significantly earlier recovery of reflex bladder. The results are consistent with the hypothesis that sodium influx is involved in the secondary injury after spinal trauma that contributes to long-term functional impairment. USE OF ADENO-ASSOCIATED VIRUS FOR GENE TRANSFER AND EXPRESSION IN INJURED SPINAL CORD. S. Keir, C. Brandoli, J.R. Wrathall*, R.J. Samulski, X. Xiao, J. Li, I. Mocchetti and C. Tornatore. LMMN, NINDS, NIH, Bethesda, MD 20892, Dept. of Cell Biology, Georgetown Univ. Sch. of Med., Washington, DC 20007, UNC, Chapel Hill, NC and Somatix, Alamida CA 94501.

There is increasing experimental evidence to suggest that recovery of function following trauma to the central nervous system may, at least in part, be mediated by the induction of neurotrophic factors following injury. This offers the potential for new therapeutic strategies based upon gene transfer to increase local concentration of neurotrophic factors to promote neuronal survival and/or regeneration. Important to such strategies is the development of means to target and express in high amount the appropriate factor(s) at the site of injury. We have investigated the potential for using Adeno-associated virus (AAV), a non-pathogenic dependant parvovirus, as a vector for gene transfer in a standardized incomplete thoracic (T8) rat contusive spinal cord injury (SCI). A recombinant AAV vector expressing the reporter gene ß-galactosidase was microinjected into the thoracic spinal cord of female rats 15 min after laminectomy or SCI. Animals were sacrificed on days 3 and 7 post inoculation and examined for expression of ß-galactosidase. Efficient expression of the reporter gene was observed in both neuronal and glial cells at these time points. Contrary to herpes simplex and adenovirus virus based vector, the non-injured group showed no obvious evidence of any viral toxicity. This study demonstrates the feasibility of using AAV as a vector for gene delivery to the injured and non-injured spinal cord. Experiments are underway to further characterize the duration of expression and presence of any inflammatory response. Also, the potential for delivering neurotrophic factors as a means of promoting functional recovery following injury to the cord is being examined. [Supported by NIH-NS32671].

GLIAL REACTION IN THE PHRENIC NUCLEUS FOLLOWING COMBINED PERIPHERAL AXOTOMY AND SPINAL CORD HEMISECTION. Douglas J. Gould and Harry G. Goshgarian*. Anatomy and Cell Biology, Wayne State Univ. Sch. Of Med., Detroit, MI 48201

The present study characterizes the microglial and astroglial reaction in the phrenic nucleus following either an ipsilateral C2 spinal cord hemisection, a peripheral phrenicotomy, or a combination of the two injuries in the same adult rat. Immunofluorescence and a confocal laser image analysis system were used to study glial cells and phrenic motoneurons at the light microscopic level. Young adult female rats were divided into one experimental group (combined left phrenicotomy and left C2 spinal hemisection with periods of one to four weeks between injuries, N=12) and three control groups (CG). CG 1 consisted of non-injured animals (N=3), CG 2 consisted of animals that received C2 hemisection only (N=3), and CG 3 was made up of animals with phrenicotomy only (survival periods of two (N=3) and four (N=3) weeks after phrenicotomy). Microglia, astrocytes, and phrenic motoneurons were labeled with Texas red, fluorescein, and fluorogold respectively and were visualized simultaneously. Results indicate that in the superimposed injury model, microglia appear to proliferate, migrate toward the injured motoneurons, elongate and eventually contact the neurons. This reaction is greatest in two week animals. By four weeks, the microglial reaction is not as prevalent as it is earlier after injury. From one to three weeks after injury in the experimental group, astrocytic processes begin to gradually become thicker and develop a beaded appearance compared to the thin, wispy control morphology. Early after injury, astrocytic processes are relatively constant in number until they begin to proliferate, become thinner and are found juxtaposed to the motoneurons between three and four weeks post injury. The results suggest that microglial proliferation and migration as well as astrocytic proliferation and morphological alterations in the superimposed injury model are similar to the phrenicotomy alone response. Thus, phrenicotomy alone causes glial changes not easily reversed by spinal cord hemisection. This study is important in determining the response to injury in multiple injury models and in generating new hypotheses.

POLYMORPHONUCLEAR LEUKOCYTES EXACERBATE STRETCH-INDUCED TRAUMATIC INJURY IN CULTURED CEREBRAL ENDOTHELIAL CELLS. J.W. Beetsch*, A.R. Shah, T.S. Park and J.M. Gidday. Department of Neurosurgery and St. Louis Children's Hospital, Washington University School of Medicine, St. Louis, MO 63110.

Polymorphonuclear leukocytes (PMNs) have been implicated as mediators of vascular and parenchymal injury following ischemia, but little is known regarding their involvement in traumatic injury. In this study, we have developed an *in vitro* trauma model to examine the pathophysiology of PMN interaction with cerebral endothelial cells (CECs) following stretch-induced trauma. Piglet CECs were grown to confluency in 25 mm tissue culture wells with silastic membrane bottoms (Flexcell International) and injury was induced by stretching the membrane with 50 msec pressure pulses of various intensities (Cell Injury Controller, Commonwealth Biotechnology). Injured CECs then were exposed to culture media alone or media containing isolated piglet PMNs (1×10^6 PMNs/well) for various times after which CEC viability was assessed by measuring lactate dehydrogenase (LDH) efflux into the culture medium. CEC injury was corrected for background LDH and LDH from PMNs. Control wells received PMNs without trauma. When CECs were stretched 5.5, 7.5, or 9.5 mm, we observed stretch-dependent increases in CEC injury. Injury after 7.5 or 9.5 mm stretches was significantly above control. The addition of PMNs following trauma exacerbated trauma-induced injury by as much as 6-fold. In addition, increasing the time of PMN exposure to CECs following trauma from 1 to 4 hr elevated CEC injury 23-30%. These results indicate vascular injury induced by trauma is increased by exposure to PMNs following the insult, which may augment blood-brain barrier breakdown and subsequent edema characteristic of traumatic injury. (Supported by NIH NINDS 21045 and 32568).

IN VIVO RESEALING OF TRANSECTED RAT AXON MEMBRANES ASSAYED BY DYE EXCLUSION AND IMAGED WITH CONFOCAL MICROSCOPY. M.J. Howard, G. David, and J.N. Barrett*. Dept. of Physiology and Biophysics, Univ. of Miami School of Medicine, Miami, FL 33136.

We have developed an assay for membrane resealing in large populations of transected axons based on exclusion of a membrane-impermeant fluorescent dye by resealed axons. Transverse sections of transected dorsal spinal nerve roots were imaged using confocal microscopy and examined to determine the percentage of axons that contain dye (i.e. were not resealed when the dye was applied).

Calcium has been shown to enhance membrane resealing in a number of cell types, both *in vivo* and *in vitro*. When dorsal roots were transected in physiological saline containing no added Ca^{2+} (free Ca^{2+} estimated to be about 10uM), the percentage of axons that resealed increased with time from 6.5% when the dye was applied 10 minutes after the transection, to 14.0% when the dye was applied 1 hour after the lesion. In saline containing 2 mM Ca^{2+}, resealing increased from 13.1% at 10 minutes, to 46.3% at 1 hour and reaching 66.0% at 2 hours. At all time points, the percentage of axons that have resealed is greater for axons with diameters <6um than for axons with diameters >6um.

In the presence of 2-3 mM BAPTA, resealing remains below 5% up to 2 hours after the lesion.

Based on these findings, we hypothesize that there is a Ca^{2+}-dependent process(es) that enhance resealing in myelinated rat dorsal spinal root axons *in vivo*.

ESTROGENS ATTENUATE OXIDATIVE AND EXCITOTOXIC NEURONAL INJURY IN CORTICAL CELL CULTURE. R. F. Regan* and Y.P. Guo. Division of Emergency Medicine, Thomas Jefferson University, Philadelphia, PA 19107.

A growing body of evidence supports the hypothesis that estrogens may be beneficial in Alzheimer's disease and other neurodegenerative processes. Less is known of their therapeutic potential in acute CNS insults. In this study, we examined the effect of estrogens on the neurotoxicity of hemoglobin and exogenous excitatory amino acids in mixed murine cortical cultures. Exposure to the pro-oxidant hemoglobin (3 μM) for 24 hours resulted in death of about two-thirds of neurons, without injuring glia. Concomitant treatment with 0.1-10 μM 17β-estradiol decreased neuronal loss in a concentration-dependent fashion, with complete protection at 10 μM. 17β-estradiol inhibited hemoglobin-induced oxidative reactions in these cultures, as determined by malondialdehyde assay; effective concentrations were similar to those required for neuroprotection. Estrone (10 μM) and the synthetic estrogen diethylstilbestrol (3 μM) also attenuated hemoglobin neurotoxicity. Estrogen treatment had a more modest and somewhat variable effect on excitotoxic injury. 17β-estradiol (100 μM) reduced neuronal death due to 24 hour exposure to N-methyl-D-aspartate (20 μM) or kainate (45 μM) by 20-40%; preincubation for 2 hours was required for optimal effect. These results suggest that estrogens may be neuroprotective in acute CNS injuries associated with oxidative and excitotoxic stress. This effect may be due, at least in part, to their ability to directly inhibit lipid peroxidation.

Supported by departmental funding, Thomas Jefferson University.

THE EFFECT OF COMBINED LIPOPOLYSACCHARIDE, INDOMETHACIN AND PREGNENOLONE IN SPINAL CORD INJURY. W. Huang*, C. Roonprapunt and W. Young. Department of Neurosurgery, NYU Medical Center, New York, NY 10016.

The combination therapy of lipopolysaccharide (L), indomethacin (I) and pregnenolone (P) has been reported previously to promote recovery (Guth et al., Proc. Natl. Acad. Sci. USA, 91, 12308 - 12, 1994; Guth et al., Exp. Neurol. 126, 76 - 87, 1994) and regeneration in rats after spinal cord crush. We tested this treatment using the NYU weight drop impactor, studying acute effects of the therapy on spinal cord lesion volumes at 24 hours. In separate experiment, we examined chronic effects on locomotor recovery (21-point open field locomotor scale developed by Ohio State University) in a double-blind, randomized trial. The experiments utilized 115 male and female Long-Evans hooded rats injured by a 10g weight 1.25 or 5.0 cm directly onto the dorsal surface of T10 cord exposed by laminectory.

The results showed that LI (L + I) and LIP (L + I + P) therapy had no effect on 24-hour lesion volumes. LIP treatment did not improve locomotor recovery up to 4 weeks after both mild and severe contusions. We found that both LI ($p<0.0005$) and LIP ($p<0.0005$) treated rats had significantly greater body weight loss compared to the vehicle group in the acute study. LIP treatment significantly reduced body weight ($p<0.05$) from day 2 to week 4 after injury, compared to vehicle-treated rats. Both LI and LIP reduced 24-hour urinary [K] and [Na] + [K] concentrations, suggesting diuresis in these treatment groups, possibly explaining the greater body weight losses. Our results indicate that LI and LIP therapies do not significantly reduce 24-hour lesion volumes or improve locomotor recovery in rats after mild and severe contusion. LI and LIP had systemic effects, including diuresis and body weight loss. (Supported by Acorda Therapeutics).

ABERRANT INDUCTION OF NEUROPEPTIDE Y MRNA IN HIPPOCAMPAL CA3 PYRAMIDAL NEURONS IN SCRAPIE-INFECTED MOUSE. M. Diez*[1], J. Koistinaho[1,2], S.J. DeArmond[3], S.I. Prusiner[3] and T. Hökfelt[1]. [1]Department of Neuroscience, Karolinska Institutet, 171 77 Stockholm, Sweden, [2]A.I. Virtanen Institute, University of Kuopio, Finland, [3]Departments of Neurology, Biochemistry and Biophysics, University of California, San Francisco, CA.

The neurochemical alterations preceding the neurologic dysfunction and neuronal death in prion diseases are not well characterized. Here we examined, using in situ hybridization histochemistry, the expression of neuropeptide Y (NPY), an inducible and abundant neuropeptide in mammalian brain with known neuroregulatory functions, and glial fibrillary acidic protein (GFAP), a marker for astroglial activation, in the hippocampus at different time points following intracerebral prion inoculation in male CD-1 mice. At 110 through 140 days postinoculum, the expression of NPY mRNA was specifically upregulated in the CA3 pyramidal neurons, whereas the peptide expression in hilar NPY-containing neurons remained unaltered. Upregulation of GFAP mRNA was observed in the CA1 stratum radiatum at sixty days, and it spread throughout the hippocampus, cortex and thalamus at 110 through 140 days, suggesting early accumulation of prion protein in these regions. The clinical symptoms were first manifested 120 days postinoculum. The aberrant induction of NPY mRNA in the hippocampal CA3 pyramidal neurons precede the onset of neurologic symptoms, and may be involved in the regulation of glutamate release at the Schaffer collateral-CA1 synapses in the scrapie-infected mice. (Supported by the Swedish MRC 2887 and National Institute of Aging P01 AG 10770.)

NATURAL SELECTION OF MICE LACKING THE PRION (PrP) GENE. H.-P. Lipp*[1], I.I. Poletaeva[2], M.G. Pleskacheva[2], V.S. Pazhetnov[3], N.G. Gurskaya[4], M. Stagliar-Bozicevic[1], D.P. Wolfer[1]. [1]Inst. of Anatomy, Univ. of Zürich, CH-8057 Switzerland; [2]Dept. of Biology, State Univ. Moscow; [3]Biological Station "Chicti Lec", Pozhnia, Russia; [4]Engelhardt Inst. of Molecular Biology, Moscow.

Uncontrolled production of a conformationally altered protein (PrP^{Sc}) is the pathological process leading to spongiform encephalopathy (scrapies or "mad cow disease"). Targeted disruptions of the *Prn-P* gene in the mouse have resulted in animals that were resistant to experimental infections and did not show anomalies in common behavioral tests. Minor consequences include Purkinje cell degeneration in aged PrP knockout mice, subtle alterations of their circadian clock, and altered long-term potentiation.

In order to recognize whether the gene disruption has important biological effects unnoticed in the laboratory, two large outdoor pens in Western Russia were populated with hybrid mice carrying the *Prn-P* deletion, each pen with 61 animals (F1 and F2-hybrids), comprising exactly 50% wildtype and 50% knockout alleles. The distribution of wildtype, heterozygous and mutant phenotypes was 1 : 2 : 1. A control stock of 132 mice was kept in standard animal facilities at Moscow State University.

The mice adapted to the outdoor conditions and survived well one summer and one winter, temperatures during this period ranging from -30°C to +30°C. The analysis of genotype frequencies in outdoor pens and animal houses after one year showed that homozygote mutants were reduced in one pen. In the other pen, the 1:2:1 ratio was unaltered as it was in the animal house.

Pending further analysis, we conclude that Prn-P deficient mice are probably being eliminated slowly by natural selection, most likely due to impaired reproduction and/or problems during early development. Once born, however, homozygous Prn-P mutants can survive under very harsh semi-natural conditions and avian predator pressure, at least as well as other feralized laboratory stocks of mice. Hence, barring the propagation of scrapies by means of targeted gene disruption in cattle remains a theoretically valid option.

CHARACTERIZATION OF NATIVE AND RECOMBINANT PRION PROTEIN ISOFORMS BY DIFFERENTIAL EXPOSURE OF ANTIBODY EPITOPES

C. Korth, B. Oesch*. Brain Research Institute, 8029 Zurich, Switzerland.

The protein-only hypothesis of prion diseases proposes that a disease-specific isoform PrP^{Sc} of a normal, host-derived membrane protein PrP^{C} induces its pathogenic isoform on the latter, thereby replicating its unique conformation. For elucidating this novel concept of infectivity it is essential to characterize these PrP isoforms and the mechanisms of their transition.

We introduce a novel technique able to freeze conformational transitions of the prion protein isoforms. This is done in a modification of the previously described ELIFA technique (Oesch et al. 1994, Biochemistry 33:5926-33). Gradual denaturation by urea or pH was performed for prion protein isoforms from plasma membrane fractions of normal and scrapie-infected hamsters as well as for recombinant hamster PrP. The freezing of the unfolding process upon denaturation made it possible to examine the differential binding of epitope-mapped monoclonal antibodies. The resulting binding curves revealed unique unfolding patterns of the respective epitopes able to distinguish normal from disease-specific PrP as well as recombinant hamster PrP. We propose this technique as a novel tool for studying unfolding of distinct parts of proteins as well as their interaction patterns with other proteins as shown for the prion protein.

NEURAL TARGETTING OF *MYCOBACTERIUM LEPRAE* IS MEDIATED BY LAMININ-2. A. Rambukkana, J. L. Salzer* and E. J. Tuomanen. Lab. of Molecular Infectious Diseases, The Rockefeller University, and Dept. Cell Biology and Neurology, New York University Medical School, New York, N.Y.

Nerve damage in leprosy results from the invasion of Schwann cells (SC) of the peripheral nerves by *Mycobacterium leprae*. In order to invade the SC, *M. leprae* must attach to and cross the basal lamina (BL) which surrounds the SC-axon unit. The major matrix protein of SC-BL is laminin (LN), specifically restricted to LN-2/merosin isoform. We investigated the role of LN in *M. leprae* targeting to SC of peripheral nerves. Using immobilized LN isoforms in a bacterial adherence assay, we identified high affinity dose dependent binding of *M. leprae* to purified merosin (1200±80 bacteria/0.25 mm^2) comprised of $\alpha2\beta1\gamma1$ (LN-2) and $\alpha2\beta2\gamma1$ chains (LN-4), but not to LN-1 with $\alpha1\beta1\gamma1$ chains (150±20 bacteria/0.25 mm^2). Using an in vitro myelinating SC-neuron co-culture system in which LN-2, but not LN-1, is the LN isoform in the BL, we showed that *M. leprae* bound avidly along the SC aligned with nerve axons. Binding was competitively inhibited by merosin (>80%) and also blocked significantly by anti-merosin antibodies (>90%). Further, using an in situ bacterial adherence assay on peripheral nerves from LN-2 deficient *dy/dy* dystrophic mice, we demonstrated lack of *M. leprae* binding to *dy/dy* nerves as compared to controls. These data suggest that LN-2 mediates *M. leprae* binding to SC. Since LN-2 is a tissue restricted BM protein of the SC-axon unit, LN-2 may be responsible for the neural tropism of *M. leprae*.

PRIMING WITH β-ESTRADIOL INCREASES TNFα MEDIATED C3 RELEASE FROM ASTROCYTES. C. T. Moore*, M. P. Leuschen, J. Torchia and T.L. Zach University of Nebraska Medical Center, Omaha, NE. 68198-1205

Glucocorticoids, particularly dexamethasone, were previously shown to upregulate C3 mRNA and protein production in both a human type II lung epithelial line, A549, and the human astrocytoma, D54-MG. The upregulation was significant but quantitatively less than that seen following exposure to TNFα. The response was blocked by the glucocorticoid receptor inhibitor RU486. A short priming (2 hr) with dexamethasone or other glucocorticoids including cortisol and hydrocortisone followed by exposure to TNFα alone for 3d significantly increased C3 release above that measured for a 3 d exposure to either the glucocorticoid or TNFα alone. The mineralocorticoid, aldosterone increased TNFα mediated C3 release in both A549 and D54-MG cells. Varying doses(10^{-5} - 10^{-10} M) of β estradiol added to the human astrocytoma, D54-MG, for 3 d did not show a significant enhancement of C3 release over control levels. However, a short priming dose (2 hr) of β-estradiol (10μg/mL) followed by exposure to 10^{-5} M TNFα alone for 3d significantly increased C3 release over that expected following exposure to TNFα alone. The specific mechanism for this extended synergistic action of the steroid β-estradiol on TNFα mediated C3 release from astrocytes is unknown.

THE EFFECT OF POLYRIBONUCLEOTIDES ON NITRIC OXIDE PRODUCTION IN HAMSTER MICROGLIA AND HUMAN MACROPHAGES. J. Snell, O. Chernyshev*, D. Gilbert, and C. Colton Georgetown University School of Medicine, Washington, DC 20007 and Laboratory of Biophysics, NINDS, NIH, Bethesda, MD 20892

Microglia, the CNS macrophage, are well known to produce reactive oxygen species, including nitric oxide (NO). Microglial NO production in cells isolated from rat or mouse CNS has been well characterized. However, NO production from human microglia is not well understood. We have studied NO production in both cultured neonatal hamster microglia as well as adult human monocyte-derived macrophages and have found that like human microglia, hamster microglia also show a low-output NO production in response to typical stimulating agents. In an effort to understand the mechanism of iNOS induction in both human and hamster microglia, we have studied a wide variety of stimulating agents and have found that the synthetic, double-stranded polyribonucleotide known as Polyinosinic-Polycytidilic acid, (Poly I: Poly C) does induce high-output NO production in both hamster microglia and human macrophages. The effect of Poly I:C was inhibited with both L-NMMA and the cytoskeletal inhibitor colchicine. This effect may indicate that in both hamster and human microglia, iNOS induction requires several independent signals including possibly a signal of receptor-mediated phagocytosis.

TRANSCRIPTIONAL ACTIVATION OF iNOS BY PNEUMOCOCCAL CELL WALL (PCW) COMPONENTS IN CEREBRAL ENDOTHELIAL CELLS. R.Manz, A.Meisel, D.Freyer, G.Schönfelder, U.Bruer, J.Schultze, , H.Hörtnagl[1], M.Paul[2], U.Dirnagl, J.R.Weber. Dept. of Neurol., [1]Inst. of Pharmacol. & Toxicol., Humboldt Univers. Berlin, [2] Inst. of Pharmacol., Free Univers. Berlin, FRG.

Cell wall components of gram-positive Streptococcus pneumoniae are potent stimulators of inflammatory processes in the *in vivo* model of pneumococcal menigitis, similar to LPS of gram-negative bacteria. In contrast to LPS little is known about the mediators and effectors in the PCW-induced transduction cascade. One possible mediator for systemic effects of CNS inflammation is NO and the iNOS as NO-producing enzyme. In the present study we have analysed the activation of iNOS by PCW at the transcriptional level. Endothelial cells were prepared from rat brain, cultivated by standard procedures, and total mRNA purified from primary cultures 3 hours after PCW-stimulation. Semi-quantitative RT-PCR for iNOS mRNA was performed according to the Mimics-Protocol using GAPDH mRNA as an internal standard and deletion mutants of iNOS and GAPDH as external standards. After PCW-stimulation the cells showed a dose-dependent stimulation of iNOS transcription. A 4-fold increase in the PCW dose lead to a doubling of iNOS mRNA, indicating a square root dependence of the iNOS transcription rate from the PCW-stimulus in the studied range. In contrast, NO production measured by the Griess-Reaction 48 hours after PCW stimulation tended to reach a maximum with increasing PCW doses.
These results argue for a strong transcriptional activation of iNOS by PCW. However, there seems to be a posttranscriptional repression of iNOS mRNA translation.

PCW dose (10^5 cfu/ml)	iNOS mRNA (fmol/mg total RNA)	GAPDH mRNA (fmol/mg total RNA)	ratio GAPDH to iNOS	stimulation of iNOS mRNA	NO µM
0	0.001	3.6	3600	-	32.6
31.5	0.012	4.3	356	10.1	68.2
125	0.022	4.2	191	18.8	72.5

A RAT AUDITORY DISCRIMINATION TEST FOR THE EFFECTS OF ARTEMISININ ANTIMALARIAL DRUGS. R. F. Genovese*, J.M. Petras, and T.G. Brewer Divisions of Neurosciences and Experimental Therapeutics, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

Rats were trained on a two-choice, discrete trial, auditory discrimination task where the discriminative stimuli were white noise or a tone + white noise. Correct responses produced food reinforcement and incorrect responses delayed the opportunity for reinforcement. Choice accuracy, response output and choice response time, characterized performance. Once responding was stable, increasing and decreasing tone intensity, increased and decreased choice accuracy, respectively. Manipulating reinforcement density produced systematic changes in response bias. Thus, behavioral control of the model was validated. The effects of daily administration of the artemisinin derivative antimalarial compound, arteether (AE) (25 mg/kg/d X 9-11, IM, n=5), or vehicle (sesame oil, n=5), were then assessed. Initially, AE did not affect performance. Continued administration, however, produced significant decreases in choice accuracy and significant increases in choice response time. Subsequent histopathological analysis revealed that AE produced significant neuronal pathology in the auditory system, *nucleus trapezoideus*, but not the cranial nerve nucleus, *nucleus facialis*. These results suggest that the auditory discrimination test provides an objective behavioral measure of the toxic effects of AE, and thus, may serve as a valuable tool for the development and safety assessment of artemisinin antimalarial compounds. BACTERIAL ADHERENCE AND EXPRESSION OF PROINFLAMMATORY CYTOKINES IN THE BRAIN DURING EXPERIMENTAL MENINGITIS. Y.S. Kim, J.J. Honkaniemi, F.S. Sharp, S.M. Sagar and M.G. Täuber*. San Francisco General Hospital, and Veterans Administration Medical Center. UCSF, San Francisco, CA 94110

Interaction of bacteria with host cells and production of the proinflammatory cytokines tumor necrosis factor-α (TNF) and interleukin-1β (IL-1) are critical early steps in bacterial meningitis, but the sites of these events have not been clearly identified. Using an infant rat model of group B streptococcal (GBS) meningitis, we determined the location and time course of GBS adhesion and of TNF and IL-1 expression in the CNS. 12 day old rats were infected by intracisternal inoculation of FITC-labeled GBS. Two h later, GBS were seen in the ventricular space (V) adhering to the ependyma (E) and choroid plexus epithelium (CP). By 4 h, GBS were also visible in the subarachnoid space (SAS). *In situ* hybridization for TNF and IL-1 mRNA performed at 4, 8 and 12 h after infection showed TNF and IL-1 mRNA present in the SAS and E, and throughout the superficial parenchyma adjacent to SAS and V. Induction was visible at 4 h and became more intense at 12 h. In contrast to TNF, IL-1 mRNA was also present in vessel walls/endothelial cells within the cortex. Saline injected control animals showed no induction of TNF or IL-1.

Thus, the spacial and temporal relationship suggests that the contact of bacteria with host cells initiates the expression of inflammatory cytokines in this model of meningitis. These events are localized primarily to the ventricular E and the SAS, but some cells in the brain parenchyma adjacent to the CSF space also contribute to the cytokine production.

THE SIGNIFICANCE OF MEASLES VIRUS ANTIGEN AND GENOME DISTRIBUTION IN THE CNS IN SSPE FOR MECHANISMS OF VIRAL SPREAD AND DEMYELINATION I.V. Allen*, S. McQuaid and S.L. Cosby. Department of Neuropathology, The Royal Hospitals, Belfast and Medical Biology Centre, Queen's University, Belfast.

The distribution of measles virus (MV) antigen and genomic RNA in the CNS in 10 cases of subacute sclerosing panencephalitis (SSPE) was determined using immunocytochemistry and in situ hybridization techniques. Neurons and oligodendrocytes were found to be the most frequently infected cells. It was confirmed that MV infection in neuronal processes was predominantly dendritic but there was also some evidence of occasional axonal involvement, a finding confirmed by electron microscopy. In addition MV genomic RNA was detected in neuronal processes, in some cases in the absence of demonstrable MV antigen. The relationship between myelin destruction and oligodendrocytic infection suggested that the demyelination may be solely the result of virus infection. A possible correlation between viral distribution and form and the clinical duration of disease was examined. Viral antigen and genome were equally abundant in the cerebral cortex in most short duration cases (< 6 months). However, in two of these cases viral RNA but not antigen was detected in the spinal cord. In long duration cases (>36 months) viral RNA was abundant in all areas of the CNS examined, frequently in the absence of demonstrable antigen. These findings suggest viral spread in a cephalo-caudal direction, probably by trans-neuronal spread. The ability of measles virus to spread transneuronally has been confirmed in a murine model. Furthermore the relationship of infection to the putative measles virus receptor CD46 has been studied in vivo and in vitro in CNS cultures. This study has suggested that CD46 could be important for the initiation of MV infection in the CNS

PROPAGATION OF MEASLES VIRUS ALONG OLFACTORY PATHWAYS IN TAP-1 DEFICIENT MICE. E. Urbanska, B. Chambers, H.-G. Ljunggren, E. Norrby and K. Kristensson.* Dept. Neuroscience and Microbiology and Tumorbiology Center, Karolinska Institute, Doktorsringen 17, S-17177 Stockholm, Sweden, and Dept. Pharmacology, Medical University School, Jaczewskiego 8, 20-090 Lublin, Poland.

Mice with disrupted TAP-1 gene lack specific transporter associated with antigen processing and presentation and therefore are deficient in stable surface MHC I molecules and mature peripheral CD8+ T lymphocytes. Here we report the propagation of measles virus following its inoculation into olfactory bulb of TAP-1 mutant mice. Immunohistochemical analyses were performed on 20 µm coronal brain sections using polyclonal antibody against viral nucleocapsid protein.

At day 14 p.i. immunopositive neurons were present within 3 groups of structures: a) projecting to and receiving afferents from olfactory bulb, such as anterior olfactory nucleus, pyriform and entorhinal cortex, amygdaloid and septal nuclei, b) only receiving inputs from olfactory bulb such as indusium griseum, and c) only projecting to olfactory bulb, such as locus coeruleus. Single measles containing cells were also detected in nucleus raphe. Hippocampal area was not infected even though severe CA1 loss was observed. No inflammatory cells around blood vessels or in meninges were found, in contrary to wild type C57BL/6 mice, which also displayed more restricted viral spread in the brain.

Specific tropism of measles after its instillation in TAP-1 deficient mice olfactory bulbs and more prominent infection in TAP-1 than in immunocompetent C57BL/6 mice, underlie the importance of properly functioning CD8+ Tcells in the virally induced neuropathology.

SELECTIVE VULNERABILITY OF MOUSE CNS TO LATENT VIRAL INFECTION WITH A NEUROATTENUATED HSV-1. S. Kesari[1,2*], V. M.-Y. Lee[2], S.M. Brown[3], J. Q. Trojanowski[2], & N.W. Fraser[1], [1]Wistar Inst. & [2]Univ. of Pennsylvania, Phila., PA. [3]MRC Virology Unit, Glasgow, Scotland.

Herpes Simplex Viruses that lack ICP34.5 are neuroattenuated. Previously, we documented the focal presence of the Latency Associated Transcripts (LATs) in the hippocampi of mice after intracranial (IC) inoculation of an ICP34.5 deficient virus (strain 1716). To further characterize strain 1716 in the CNS of immunocompetent mice, we determined the extent of viral gene expression in the CNS. At post-inoculation times >30 days we found that: 1) infectious virus was not detectable by titration and immunohistochemical studies; 2) neurons harbored virus as demonstrated by the detection of the LATs by *in situ* hybridization (ISH); 3) transcripts expressed during the lytic cycle of infection were not detected by ISH; and 4) subsets of neurons were selectively vulnerable to latent infection. These data have implications for the development of ICP34.5 mutant viruses as efficient vectors for gene therapy in the CNS, and further studies of 1716 in the model system described here will facilitate the elucidation of the mechanisms that règulate the selective vulnerability of CNS cells to latent infection.

QUANTITATION OF HSV-1 DNA IN CEREBROSPINAL FLUID OF PATIENTS WITH HERPES SIMPLEX VIRUS ENCEPHALITIS

B. WILDEMANN*, K. EHRHART, J. HAAS, B. STORCH-HAGENLOCHER, A. FÄTH, H. WAGNER, W. HACKE, U. MEYDING-LAMADÉ, Department of Neurology, University of Heidelberg, 69120 Heidelberg, Germany.

Herpes simplex virus type 1 (HSV-1) causes a serious and potentially fatal encephalitis in humans. It is unclear, whether the severity of disease is related to the virus burden within the central nervous system. To address this question, we used a quantitative PCR assay to determine the number of viral copies in cells of cerebrospinal fluid of 8 patients with herpes simplex virus encephalitis (HSVE). The viral load was monitored in serial CSF samples during the course of disease and correlated to clinical symptoms at presentation, radiological manifestations, effect of antiviral therapy with acyclovir, and overall clinical outcome. Before treatment institution HSV-1 DNA was detected at a median value of $93/10^5$ cells with a range from 6 to $7759/10^5$ cells and a mean value of $1728/10^5$ cells. During acyclovir therapy the cellular viral load decreased gradually to a median value of 2 cells (range: 0 to $33/10^5$ cells, mean: $9/10^5$ cells) within 7 to 18 days. However, the number of HSV-1 copies present in the CSF did not clearly correlate with the severity of clinical symptoms or the degree of cranial imaging findings and the overall clinical outcome. These findings indicate that quantitation of HSV-1 DNA by PCR allows rapid and reliable monitoring of effective antiviral therapy. The absence of a clear clinical-virological correlation provides further evidence for indirect mechanisms of central nervous system pathology in patients with HSVE.

CONGENITAL CYTOMEGALOVIRUS INFECTION AND PROGRESSIVE SENSORINEURAL HEARING LOSS IN GUINEA PIGS.

N.K. Woolf*, D.V. Jaquish, F.J. Koehrn, D.D. Richman and H.C. Isom, Dept. of Surgery, UCSD Med School and V.A. Med Center, La Jolla, CA 92161.

Primary maternal guinea pig cytomegalovirus (GPCMV) infection during pregnancy induces congenital infection, labyrinthitis and sensorineural hearing loss in offspring at birth. This study utilized PCR assays on paraffin sections and auditory brainstem response (ABR) recordings to investigate sites of GPCMV infection and postnatal auditory thresholds, respectively. Following primary maternal infection with $10^{4.5}$ PFU GPCMV in the first trimester of pregnancy, and sacrifice shortly before birth, the PCR assays determined 75% of the mothers had GPCMV infected placentas, 58% of the total placentas were infected, and 15% of the fetuses were congenitally infected in their blood and/or salivary glands. Abnormal ABR threshold elevations were also detected in the offspring of infected mothers at birth (29%) and 120 days after birth (50%). Thus, primary maternal GPCMV infection during pregnancy induced placental infection, congenital infection and progressive postnatal sensorineural hearing loss in offspring.

CAT RETINAE SHOW CHANGES FOLLOWING INFECTION WITH FELINE IMMUNODEFICIENCY VIRUS,

N. Tumosa* and M. Podell. U. of MO, Optometry, St. Louis MO 63121 and Dept. Vet. Clin. Sciences, The Ohio State U., Coll. Vet. Med., Columbus, OH 43210.

Five adult cats were infected via an IV injection with the Maryland isolate of the feline immunodeficiency virus (FIV-MD). Sixteen months later histology and immunocytochemistry were performed on the perfused retinae of these cats and from five age-matched controls.

Several histological stains were used to study the retinal structural integrity. H386F, a microglia-specific antibody, was used to study the microglia in the nerve fiber layer (NFL).

The histological stains revealed no obvious changes in the cells in any retinal layers or in the structure of the basement membranes. H386F-specific staining revealed differences between microglia found in the two groups. Throughout the noninfected retinae and in some regions of the infected retinae the microglia were normal in shape and size. In other areas of the infected retinae the microglia had enlarged cell bodies and crenulated processes. Thus, FIV-MD infection does adversely affect the histology of the cat retina.

KEY WORD INDEX

The *Abstracts* volume 22 Key Word Index is printed on the following pages. This subject index uses a permutation process to create an index entry for every key word in the abstract title. Key words are placed at the beginning of the center column of the index and the program numbers in the right column. Text reading left and right of the key word is retained for understanding in context. A slash (/) shows the end and the beginning of the author's title. Space limitations do not permit the full abstract title to be printed. Words with limited search value are not listed as key words. The BioSciences Information Service Subject Index is used by many scientific organizations and has become the standard in computerized scientific indexes.
